A special situation arises when the intermediate step is detuned so much that no velocity group is in resonance, i. e., $|\Delta_1| \approx |\Delta_2| \gg kv$ for all velocities contributing significantly to the spectrum. Then the second coherent term of (69.63) can be written in the form

$$\tilde{\rho}_{fe} = -\frac{A}{\Delta_1^2}\left(\frac{1}{(\Delta_1 + \Delta_2) + (k_1 + k_2)\,v - \mathrm{i}\gamma_{fg}}\right). \tag{69.70}$$

If the two fields $\mathcal{E}_1$ and $\mathcal{E}_2$ have the same frequency but are counterpropagating, then $k_1 + k_2 = 0$, and no velocity dependence occurs in (69.70) for the two-photon resonance. All atoms in the sample contribute to the strength of the resonance, and then polarization is obtained directly by multiplication with the total atomic density. Equation (69.13) then gives

$$\alpha_2'' = \frac{d_2^2}{\hbar}\left(\frac{d_1\mathcal{E}_1}{2\hbar\Delta_1}\right)^2 \frac{\gamma_{fg}}{(2\omega - \omega_{fg})^2 + \gamma_{fg}^2}. \tag{69.71}$$

This is a sharp *Doppler-free resonance* on the two-photon transition ω_{fg}. The advantage is that all atoms contribute with the sharp line width γ_{fg}, which is not easily affected by phase perturbations because of the two-photon nature of the transition. The disadvantage is the weakness of the transition, which is caused by the large detuning, making $d_1\mathcal{E}_1/|\Delta_1| \ll 1$ in most cases. With tunable lasers, however, this Doppler-free spectroscopy method has been used successfully in many cases.

69.7 Special Effects in Three-Level Systems

We continue our considerations of a three-level system but this time in the V-configuration. Thus, we have a ground state $|g\rangle$ coupled to a doublet of excited states $\{|e\rangle, |f\rangle\}$ through the interaction

$$V = \Omega_1|g\rangle\langle e| + \Omega_2|g\rangle\langle f| + \mathrm{h.c.}, \tag{69.72}$$

where the couplings are due to radiation fields and given by

$$\Omega_i = \frac{d_i\mathcal{E}_i}{2\hbar}. \tag{69.73}$$

We use the rotating wave approximation and set the detunings to

$$\Delta\omega_e = \omega_e - \omega_1 \quad \text{and} \quad \Delta\omega_f = \omega_f - \omega_2, \tag{69.74}$$

where the frequency ω_i derives from the coupling field $\mathcal{E}_i$. The energy $E_g = 0$.

The time-dependent Schrödinger equation for this system is then written as

$$\mathrm{i}\dot{c}_g = \Omega_1 c_e + \Omega_2 c_f, \tag{69.75}$$

$$\mathrm{i}\dot{c}_e = \Delta\omega_e c_e + \Omega_1 c_g, \tag{69.76}$$

$$\mathrm{i}\dot{c}_f = \Delta\omega_f c_f + \Omega_2 c_g. \tag{69.77}$$

We now introduce the two new variables

$$c_{\mathrm{C}} = \bar{\Omega}^{-1}\left(\Omega_1 c_e + \Omega_2 c_f\right) \tag{69.78}$$

$$c_{\mathrm{NC}} = \bar{\Omega}^{-1}\left(\Omega_2 c_e - \Omega_1 c_f\right), \tag{69.79}$$

where

$$\bar{\Omega}^2 = \Omega_2^2 + \Omega_1^2. \tag{69.80}$$

The equations of motion follow:

$$\begin{aligned}\mathrm{i}\dot{c}_{\mathrm{NC}} &= \left(\frac{\Omega_2}{\bar{\Omega}}\Delta\omega_e c_e - \frac{\Omega_1}{\bar{\Omega}}\Delta\omega_f c_f\right) \\ &= \frac{1}{\bar{\Omega}^2}\Big[\Omega_1\Omega_2\left(\Delta\omega_e - \Delta\omega_f\right)c_{\mathrm{C}}. \\ &\quad + \left(\Delta\omega_e\Omega_2^2 + \Delta\omega_f\Omega_1^2\right)c_{\mathrm{NC}}\Big],\end{aligned} \tag{69.81}$$

$$\begin{aligned}\mathrm{i}\dot{c}_{\mathrm{C}} &= \left(\frac{\Omega_1}{\bar{\Omega}}\Delta\omega_e c_e + \frac{\Omega_2}{\bar{\Omega}}\Delta\omega_f c_f\right) + \bar{\Omega}c_g \\ &= \frac{1}{\bar{\Omega}^2}\Big[\left(\Delta\omega_e\Omega_1^2 + \Delta\omega_f\Omega_2^2\right)c_{\mathrm{C}} \\ &\quad + \Omega_1\Omega_2\left(\Delta\omega_e - \Delta\omega_f\right)c_{\mathrm{NC}}\Big] + \bar{\Omega}c_g.\end{aligned} \tag{69.82}$$

We notice that c_{NC} is not coupled to the ground state, but, in general, its coupling to the state c_{C} provides an indirect coupling. This indirect coupling, however, can be made to disappear, if we set $\Delta\omega_e = \Delta\omega_f \equiv \Delta\omega$. Then we find the equations

$$\mathrm{i}\dot{c}_{\mathrm{NC}} = \Delta\omega c_{\mathrm{NC}},$$

$$\mathrm{i}\dot{c}_{\mathrm{C}} = \Delta\omega c_{\mathrm{C}} + \bar{\Omega}c_g,$$

$$\mathrm{i}\dot{c}_g = \bar{\Omega}c_{\mathrm{C}}. \tag{69.83}$$

This describes a pair of coupled quantum levels and a single uncoupled level. Thus, if we start in the ground state, this latter level can never be populated. It remains unpopulated and is called a dark state. This state

corresponds to the superposition

$$|\text{NC}\rangle = \frac{1}{\Omega} \left(\Omega_2 |e\rangle - \Omega_1 |f\rangle \right) . \qquad (69.84)$$

Using the coupling operator (69.72), we find the matrix element

$$\langle g | V | \text{NC} \rangle = 0 . \qquad (69.85)$$

We also notice that the dark state can be found if the states $|e\rangle$ and $|f\rangle$ are the lower ones, i.e., we have the Λ-configuration.

Alternatively, if we start the system off in the dark state, it will never be able to get out of this state. This is also taken to hold true if we let the couplings depend slowly on time. In this case, we may let Ω_1 come on later than Ω_2. Then we may have

$$\lim_{t \to -\infty} \left(\frac{\Omega_1}{\sqrt{\Omega_2^2 + \Omega_1^2}} \right) = 0 ,$$

$$\lim_{t \to -\infty} \left(\frac{\Omega_2}{\sqrt{\Omega_2^2 + \Omega_1^2}} \right) = 1 \qquad (69.86)$$

and

$$\lim_{t \to \infty} \left(\frac{\Omega_1}{\sqrt{\Omega_2^2 + \Omega_1^2}} \right) = 1 ,$$

$$\lim_{t \to \infty} \left(\frac{\Omega_2}{\sqrt{\Omega_2^2 + \Omega_1^2}} \right) = 0 . \qquad (69.87)$$

Both couplings are thus pulses, but they occur with a slight time delay. If we now start the system in the state $|e\rangle$, we find from (69.84) that

$$\lim_{t \to -\infty} |\text{NC}\rangle = |e\rangle , \qquad (69.88)$$

and

$$\lim_{t \to +\infty} |\text{NC}\rangle = -|f\rangle . \qquad (69.89)$$

Thus, by keeping the system in this uncoupled state we can adiabatically transfer its population beteen the states without involving any population of the intermediate state $|g\rangle$. Especially if this is an upper state, which may decay and dephase rapidly, the proposed population transfer may be greatly advantageous. Because it is usually applied in the Λ-configuration, it is termed Stimulated Raman Adiabatic Passage (STIRAP).

The dark state has found a wide range of applications in laser physics. As we may use the method to pass radiation through a medium without any absorption, it has led to the phenomenon of light-induced transparency. It can also be used to affect the index of refraction without having the accompanying absorption. The absorptive part of a resonance normally manifests itself as a quantum noise; utilizing the dark state idea one may reduce the noise in quantum devices. The dressing of the levels due to the special features of the interaction has also made it possible to achieve lasing without an inversion of the bare levels. These topics, however, will not be treated here.

A special application of the method to affect the refractive index deserves a more detailed consideration. We look at the relationship between the electric field vectors in the medium:

$$D(\omega) = \varepsilon_0 E + N\alpha(\omega)E(\omega) = \chi(\omega)\varepsilon_0 E(\omega) , \qquad (69.90)$$

where $\chi(\omega)$ is the susceptibility of the medium. From Maxwell's equations we find the relation (68.24)

$$k^2 = n^2(\omega)\frac{\omega^2}{c^2} = \frac{\omega^2}{c^2} \left[1 + \chi(\omega) \right] . \qquad (69.91)$$

If we take the real parts of the quantities, this describes the propagation of waves in the medium.

Now we may use the relations (69.16) to estimate the function $\alpha(\omega)$ in the case when we have two weak fields exciting the three-level system in the V-configuration. We assume that both couplings have the same frequency, $\omega_1 = \omega_2 = \omega$. We write

$$\chi(\omega) \approx \Lambda \left(\frac{(\omega - \omega_e)}{(\omega - \omega_e)^2 + \gamma^2} + \frac{(\omega - \omega_f)}{(\omega - \omega_f)^2 + \gamma^2} \right) ; \qquad (69.92)$$

in the weak field limit we may assume the two processes to add independently. The parameter

$$\Lambda = \frac{Nd^2}{2\hbar\varepsilon_0} \qquad (69.93)$$

has the dimension of a frequency and indicates the strength of the interaction. It is clear that tuning the frequency between the levels may give rise to a value of zero for the susceptibility. For a large enough γ, we

write, in the neighbourhood of the zero,

$$\chi(\omega) \approx \frac{2\Lambda}{\gamma^2} \left(\omega - \bar{\omega}\right) , \tag{69.94}$$

where $\bar{\omega} = \frac{1}{2}(\omega_e + \omega_f)$.

We now have the relation (69.91) to determine the dispersion relation, and assuming the effect of the medium to be substantial, we may derive an expression for the group velocity in the medium

$$v_g^{-1} = \frac{\partial k}{\partial \omega} . \tag{69.95}$$

We find

$$\frac{2k}{v_g} = \frac{2\omega}{c^2}(1 + \chi) + \frac{\omega^2}{c^2}\left(\frac{2\Lambda}{\gamma^2}\right) . \tag{69.96}$$

Even though $\chi = 0$ near the point $\bar{\omega}$, we still have $\omega \sim ck$, so that

$$v_g = \frac{c}{1 + \frac{\Lambda\omega}{\gamma^2}} \approx c\left(\frac{\gamma^2}{\Lambda\omega}\right) \ll c . \tag{69.97}$$

The last inequality follows from the fact that in all cases $\gamma \ll \omega$.

We have thus found that utilizing the interference of two near quantum levels, the refractive index may acquire a very strong dependence on frequency. This may manifest itself in an exceedingly slow propagation of light pulses. Such slow light has been shown to travel at only a few kilometers per hour, which is a most remarkable result. The drawback is, however, that this can only occur over a very narrow frequency range, as follows from the assumption of a strong dependence on frequency.

69.8 Summary of the Literature

Much of the material needed to formulate the basic theory of interaction between light and matter can be found in the text book [69.2]. A comparison between the harmonic model and the two-level model is given by *Feld* [69.1]. The density matrix formulation is presented in detail in [69.2]. The influence of various line broadening mechanisms on laser spectroscopy is discussed in the book [69.3]. The Voigt profile is related to the error function, which is treated in the compilation [69.5]. The numerical evaluation of the Voigt profile is discussed in [69.4]. Rate equations are commonly used in laser theory and they are derived for optical pumping and laser-induced processes in the lectures [69.6]. The Doppler-free spectroscopy was developed in the 1960s and 1970s by many authors following the initial discovery of the Benett hole by Bill R. Bennett Jr. and the Lamb dip by Willis E. Lamb Jr. Much of the pioneering

work can be found in the book [69.3]. The three-level work has been reviewed by *Chebotaev* [69.8]. Various applications of lasers in spectroscopy are treated by *Levenson* and *Kano* [69.7]. For references to other topics, we refer to the specialized chapters of the present book.

Many features of the quantum dynamics of a few-level system are found in [69.9, 10]. The theoretical methods to treat such systems are presented in detail in [69.11]. The ensuing physical processes are presented in [69.12] with much additional material on quantum optics phenomena. The basic theory of the dark state and many of its applications in spectroscopy and laser physics are found in [69.13]. A rather complete review of adiabatic processes induced by delayed pulses is the article [69.14]. The slowing down and stopping of light is reviewed in [69.15]. A very recent article with earlier references is [69.16].

70. Laser Principles

Despite their great variety and range of power, wavelength, and temporal characteristics, all lasers involve certain basic concepts, such as gain, threshold, and electromagnetic modes of oscillation [70.1–3]. In addition to these universal characteristics are features, such as Gaussian beam modes, that are important to such a wide class of devices that they must be included in any reasonable compendium of important laser concepts and formulas. We have therefore included here both generally applicable results as well as some more specific but widely applicable ones.

70.1 Gain, Threshold, and Matter–Field Coupling

All lasers involve some medium that amplifies an electromagnetic field within some band of frequencies. At the simplest level of description, the amplifying medium changes the intensity I of a field according to the equation

$$\frac{dI}{dz} = gI \, , \tag{70.1}$$

where z is the coordinate along the direction of propagation and g is the gain coefficient, typically expressed in cm^{-1}. Amplification occurs as a consequence of stimulated emission of radiation from the upper state (or band of states) of a transition for which a population inversion exists; i. e., for which an upper state has greater likelihood of occupation than a lower state. Different types of lasers may be classified by the pump mechanisms used to achieve population inversion (Chapt. 71). In the case that the amplifying transition involves two discrete energy levels, E_1 and $E_2 > E_1$, the gain coefficient at the frequency ν is given by

$$g(\nu) = \frac{\lambda^2 A}{8\pi n^2} \left(N_2 - \frac{g_2}{g_1} N_1 \right) S(\nu) \, . \tag{70.2}$$

Here $\lambda = c/\nu$ is the transition wavelength, A $\left(s^{-1}\right)$ is the Einstein A coefficient for spontaneous emission for the transition, and g_2, g_1 are the degeneracies of the upper and lower energy levels. These quantities in nearly every case are fixed characteristics of the medium, independent of the laser intensity or the pump mechanism. N_2 and N_1 are the population densities $\left(cm^{-3}\right)$ of the upper and lower levels, respectively, and $S(\nu)$ is the normalized transition lineshape function (Chapts. 19 and 69). n is the refractive index at frequency ν of the "background" host medium and in general has contributions from all nonlasing transitions. Equation (70.2) describes either amplification or absorption, depending on whether $N_2 - (g_2/g_1)N_1$ is positive (amplification) or negative (absorption).

By far the most common configuration is that in which the gain medium is contained in a cavity bounded on two sides by reflecting surfaces. The mirrors allow feedback; i. e., the redirection of the field back into the gain medium for multipass amplification and sustained laser action. The two mirrors allow the field to build up along the directions parallel to the "optical axis" and to form a pencil-like beam of light. In order to sustain laser action, the gain in intensity due to stimulated emission must equal or exceed the loss due to imperfect mirror reflectivities, scattering, absorption in the host medium, and diffraction.

Typically the imperfect mirror reflectivities dominate the other sources of loss. If the mirror reflectivities are r_1 and r_2, then the intensity I is reduced by the factor $r_1 r_2$ in a round trip pass through the cavity, while

according to (70.1) the gain medium causes the intensity to increase by a factor $\exp(2g\ell)$ in the two passes through the gain cell of length ℓ. Equating of the gain and loss factors leads to the threshold condition for laser oscillation: $g \geq g_t$, where the threshold gain is

$$g_t = -\frac{1}{2\ell} \ln(r_1 r_2) + \alpha \,, \tag{70.3}$$

α being an attenuation coefficient associated with any loss mechanisms that may exist in addition to reflection losses at the mirrors.

Suppose, for example, that a laser has a 50 cm gain cell and mirrors with reflectivities 0.99 and 0.97, and that absorption within the host medium of the gain cell is negligible. Then the threshold gain is $g_t = 4 \times 10^{-4}$ cm^{-1}. If the lasing transition is the 6328 Å Ne transition of the He–Ne laser, we have $A \cong 1.4 \times 10^6$ s^{-1}, $n \cong 1.0$ and, assuming a pure Doppler lineshape,

$$S(\nu) = \left(\frac{4 \ln 2}{\pi}\right)^{1/2} \frac{1}{\delta \nu_D} \tag{70.4}$$

at line center, where $\delta \nu_D$ is the width (FWHM) of the Doppler lineshape (Sect. 69.3). For $T = 400$ K and the Ne atomic weight, $\delta \nu_D \cong 1500$ MHz and $S(\nu) \cong 6.3 \times 10^{-10}$ s. Then the threshold population difference required for laser oscillation is

$$\left(N_2 - \frac{g_2}{g_1} N_1\right)_t = \frac{8\pi n^2 g_t}{\lambda^2 A S(\nu)} \cong 2.8 \times 10^9 \text{ cm}^{-3} \,. \tag{70.5}$$

This is a typical result: the population inversion required for laser oscillation is small compared with the total number of active atoms.

Calculations of population inversions and other properties of the gain medium are based on rate equations, or more generally, the density matrix ρ. In many instances, the medium is fairly well described in terms of two energy eigenstates, other states appearing only indirectly through pumping and decay channels. In this case, ρ is a 2×2 matrix whose elements satisfy [70.3] (68.66) and (68.67)

$$\dot{\rho}_{22} = -(\Gamma_2 + \Gamma)\rho_{22} - \frac{1}{2} i\left(\Omega_1^* \tilde{\rho}_{21} - \Omega_1 \tilde{\rho}_{12}\right),$$

$$\dot{\rho}_{11} = -\Gamma_1 \rho_{11} + \Gamma \rho_{22} + \frac{1}{2} i\left(\Omega_1^* \tilde{\rho}_{21} - \Omega_1 \tilde{\rho}_{12}\right),$$

$$\dot{\tilde{\rho}}_{21} = -(\gamma + i\Delta)\tilde{\rho}_{21} - \frac{1}{2} i\Omega_1(\rho_{22} - \rho_{11}), \tag{70.6}$$

with $\tilde{\rho}_{12} = \tilde{\rho}_{21}^*$. Here, Γ_2 and Γ_1 are, respectively, the rates of decay of the upper and lower states due to

all processes other than the spontaneous decay from state 2 to state 1 described by the rate $\Gamma = A$. γ, which is 2π times the homogeneous linewidth (HWHM) of the transition, is the rate of decay of off-diagonal coherence due to both elastic and inelastic processes; in general, $\gamma \geq (\Gamma_1 + \Gamma_2 + \Gamma)/2$. $\Omega_1 = \mathbf{d}_{21} \cdot \boldsymbol{\mathscr{E}}/\hbar$ is the Rabi frequency (The Rabi frequency is often defined as $2\mathbf{d}_{21} \cdot \boldsymbol{\mathscr{E}}/\hbar$.) (Sect. 68.3.3 and Chapt. 73), with $\boldsymbol{\mathscr{E}}$ the complex amplitude of the electric field; i. e., the electric field is

$$\begin{aligned} \mathbf{E}(\mathbf{r}, t) &= \text{Re}\left[\boldsymbol{\mathscr{E}}(\mathbf{r}, t) e^{i(\mathbf{k} \cdot \mathbf{r} - \omega t)}\right] \\ &\cong \text{Re}\left[\boldsymbol{\epsilon} \mathscr{E}(\mathbf{r}, t) e^{ikz} e^{-i\omega t}\right]. \end{aligned} \tag{70.7}$$

It is assumed that $\mathscr{E}$ is slowly varying in time compared with the oscillations at frequency ω $(= 2\pi\nu)$, and that the wave vector $\mathbf{k}$ is approximately $k\hat{z} = (n\omega/c)\hat{z}$, where $\hat{z}$ is a unit vector pointing in the direction of propagation. Finally, $\Delta = \omega_0 - \omega$ in (70.6) is the detuning of ω from the central transition frequency $\omega_0 = (E_2 - E_1)/\hbar$ of the lasing transition. Rapidly oscillating terms involving $\omega_0 + \omega$ are ignored in the rotating wave approximation that pervades nearly all of laser theory (Sect. 68.3.2).

In most lasers, γ is so large compared with the diagonal decay rates that the off-diagonal elements of ρ may be assumed to relax quickly to the quasisteady values obtained by setting $\dot{\rho}_{12} = 0$ in (70.6). Then the diagonal density matrix elements satisfy the rate equations (69.37)

$$\dot{\rho}_{22} = -(\Gamma_2 + \Gamma)\rho_{22} - \frac{|\Omega_1|^2 \gamma/2}{\Delta^2 + \gamma^2}(\rho_{22} - \rho_{11}),$$

$$\dot{\rho}_{11} = -\Gamma_1 \rho_{11} + \Gamma \rho_{22} + \frac{|\Omega_1|^2 \gamma/2}{\Delta^2 + \gamma^2}(\rho_{22} - \rho_{11}). \tag{70.8}$$

Such rate equations, usually expressed equivalently in terms of population densities N_2, N_1 rather than occupation probabilities ρ_{22}, ρ_{11}, are the basis of most practical computer models of laser oscillation. These equations, or, more generally, the density matrix equations, must also include terms accounting for the pump mechanism. In the simplest model of pumping, one adds a constant pump rate Λ_2 to the right-hand side of the equation for ρ_{22} to obtain (69.45)

$$\dot{\rho}_{22} = \Lambda_2 - (\Gamma_2 + A)\rho_{22} - \frac{|\Omega_1|^2 \gamma/2}{\Delta^2 + \gamma^2}(\rho_{22} - \rho_{11}). \tag{70.9}$$

In the case of an inhomogeneously broadened laser transition (Sect. 69.3), equations of the type (70.6) and (70.8)

apply separately to each detuning Δ arising from the distribution of atomic or molecular transition frequencies. In writing these equations, we have assumed a nondegenerate electric dipole transition. The generalization to magnetic or multiphoton transitions, or to a case where the amplification is due, for instance, to a Raman process, is straightforward but of less general interest.

A more realistic treatment of the electromagnetic field than that based on (70.1) proceeds from the Maxwell equations, which, for a homogeneous and nonmagnetic medium, lead to the equation

$$\frac{1}{2ik}\nabla_T^2 \mathcal{E} + \left(\frac{\partial}{\partial z} + \frac{1}{c}\frac{\partial}{\partial t}\right)\mathcal{E} = \frac{4\pi i\omega}{nc}N\mu^*\rho_{21} .$$
(70.10)

Here N is the density of active atoms, $\mu \equiv (\boldsymbol{d}_{12} \cdot \boldsymbol{\epsilon})^*$, and $\nabla_T^2 \equiv \partial^2/\partial x^2 + \partial^2/\partial y^2$. The result (70.10) assumes the validity of the rotating wave approximation as well as the assumption that $\mathcal{E}$ is slowly varying compared with $\exp(ikz)$ and $\exp(-i\omega t)$. In the plane wave approximation, (70.10) becomes (More generally, the velocity c on the left sides of (70.10) and (70.11) should be replaced by the group velocity v_g associated with nonresonant transitions. If there is substantial group velocity dispersion, it is sometimes necessary to include a term involving the second derivative of $\mathcal{E}$ with respect to t)

$$\left(\frac{\partial}{\partial z} + \frac{1}{c}\frac{\partial}{\partial t}\right)\mathcal{E} = \frac{4\pi i\omega}{nc}N\mu^*\rho_{21} .$$
(70.11)

Equations (70.6) or (70.8) and (70.10) or (70.11) are coupled matter–field equations whose self consistent solutions determine the operating characteristics of the laser. The density matrix or rate equations must be modified to include pumping, as in (70.9), and the field equations must be supplemented by boundary conditions and loss terms. With these modifications, the equations are the basis of semiclassical laser theory, wherein the particles constituting the gain medium are treated quantum mechanically whereas the field is treated according to classical electromagnetic theory [70.4]. Aside from fundamental linewidth considerations and photon statistics (see Sects.70.2 and 70.4), very few aspects of lasers require the quantum theory of radiation.

70.2 Continuous Wave, Single-Mode Operation

In the case of steady state, continuous wave (cw) operation, the appropriate matter–field equations are those obtained by setting all time derivatives equal to zero. Equation (70.11), for instance, becomes

$$\frac{d\mathcal{E}}{dz} = \frac{2\pi\omega N|d|^2}{3n\hbar c}\frac{1}{\gamma + i\Delta}(\rho_{22} - \rho_{11})\mathcal{E} ,$$
(70.12)

or, in terms of the intensity I,

$$\frac{dI}{dz} = \frac{4\pi\omega N|d|^2}{3n\hbar c}\frac{\gamma}{\Delta^2 + \gamma^2}(\rho_{22} - \rho_{11})I$$
$$= \frac{\lambda^2 A}{8\pi n^2}(N_2 - N_1)S(\nu)I = g(\nu)I$$
(70.13)

for the nondegenerate case under consideration. Here, $|d|^2 = 3|\boldsymbol{d}_{12} \cdot \boldsymbol{\epsilon}|^2$, $N_j = N\rho_{jj}$, $S(\nu) = \gamma/(\Delta^2 + \gamma^2)$ is the Lorentzian lineshape function for homogeneous broadening, and $A = 4\omega^3|d|^2n/3\hbar c^3$ is the spontaneous emission rate in the host medium of (real) refractive index n. Local (Lorentz–Lorenz) field corrections will in general modify these results, but such corrections are ignored here [70.5].

The steady state solution of the density matrix or rate equations gives, similarly,

$$g(\nu) = \frac{g_0(\nu)}{1 + I/I_{\text{sat}}} ,$$
(70.14)

where the saturation intensity I_{sat}, like the small signal gain coefficient $g_0(\nu)$, depends on decay rates and other characteristics of the lasing species. Thus, in the plane wave approximation, the growth of intensity in a homogeneously broadened laser medium is typically described by the equation

$$\frac{dI}{dz} = \frac{g_0(\nu)I}{1 + I/I_{\text{sat}}} .$$
(70.15)

This equation, supplemented by boundary conditions at the mirrors, and possibly other terms on the right side to account for any distributed losses within the medium, determines the intensity in cw, single-mode operation.

The simplest model for calculating output intensity assumes that the intensity is uniform throughout the laser cavity. In steady state, the gain exactly compensates for the loss; i. e., $g(\nu) = g_t$, the gain clamping condition for cw lasing. Equation (70.14) then implies that the steady state intracavity intensity is

$$I = I_{\text{sat}}\left[g_0(\nu)/g_t - 1\right] .$$
(70.16)

If I is assumed to be the sum of the intensities of waves propagating in the $+z$ and $-z$ directions, i. e. $I = I_+ + I_-$, then the output intensity from the laser is

$$I_{\text{out}} = t_2 I_+ + t_1 I_- ,$$
(70.17)

where t_2, t_1 are the mirror transmissivities at the right and left mirrors, respectively. The uniform intensity approximation implies that $I_+ = I_- = I/2$ and

$$I_{\text{out}} = \frac{1}{2}(t_2 + t_1)I_{\text{sat}}[g_0(\nu)/g_t - 1]. \qquad (70.18)$$

Suppose one of the mirrors is perfectly transmitting, so that $t_1 = 0$ and $t_2 = t > 0$. Furthermore, if the reflectivity r of the transmitting mirror is close to unity, then $g_t \cong (1/2\ell)(1 - r) = (1/2\ell)(t + s)$, where s is the fraction of the incident beam power that is scattered or absorbed at the output mirror. Then

$$I_{\text{out}} \cong \frac{1}{2}I_{\text{sat}}t\left(\frac{2g_0(\nu)\ell}{t + s} - 1\right), \qquad (70.19)$$

and it follows that the optimal output coupling, i. e., the transmissivity that maximizes the output intensity, is

$$t_{\text{opt}} = \sqrt{2g_0(\nu)\ell s} - s. \qquad (70.20)$$

This output coupling gives the output intensity

$$I_{\text{out}}^{\max} = I_{\text{sat}}\left[\sqrt{g_0(\nu)\ell} - \sqrt{s/2}\right]^2. \qquad (70.21)$$

$g_0(\nu)I_{\text{sat}}$ is the largest possible power per unit volume extractable as output laser radiation at the frequency ν.

More generally, when mirror reflectivities are not necessarily close to unity, $I_+ \neq I_-$ and both I_+ and I_- vary with the axial coordinate z. In this more general case, (70.14) and (70.15) are replaced by

$$g(\nu, z) = \frac{g_0(\nu)}{1 + [I_+(z) + I_-(z)]/I_{\text{sat}}} \qquad (70.22)$$

and

$$\frac{dI_+}{dz} = g(\nu, z)I_+, \qquad \frac{dI_-}{dz} = -g(\nu, z)I_-, \qquad (70.23)$$

where it is assumed that $g_0(\nu)$ is independent of z, and that all cavity loss processes occur at the mirrors. The solution of these equations with the boundary conditions $I_-(L) = r_2 I_+(L)$, $I_+(0) = r_1 I_-(0)$ for mirrors at $z = 0$ and $z = L$ gives, for $I_{\text{out}} = t_1 I_-(0) + t_2 I_+(L)$, the formula [70.3, 6]

$$I_{\text{out}} = I_{\text{sat}}\left(t_2 + \sqrt{\frac{r_2}{r_1}}\, t_1\right)\frac{\sqrt{r_1}}{(\sqrt{r_1} + \sqrt{r_2})(1 - \sqrt{r_1 r_2})}$$
$$\times[g_0(\nu)\ell + \ln\sqrt{r_1 r_2}]. \qquad (70.24)$$

Analysis of this result gives an optimal output coupling that reduces to (70.19) in the limit $t + s \ll 1$. Curves for optimal output coupling and I_{out} as a function of g_0 and s are given by *Rigrod* [70.6]. These results are

based on several assumptions and approximations: the gain medium is assumed to be homogeneously broadened and to saturate according to the formula (70.14); g_0 and I_{sat} are taken to be constant throughout the medium; the field is approximated as a plane wave; field loss processes occur only at the mirrors; and interference between the left- and right-going waves is ignored.

Interference of the counterpropagating waves in a standing wave, single-mode laser modifies the gain saturation formula (70.14) as follows:

$$g(\nu, z) = \frac{g_0(\nu)}{1 + (2I_+/I_{\text{sat}})\sin^2 kz} \qquad (70.25)$$

in the case of small output coupling, where $I_+ \cong I_-$ as assumed in (70.18). (The general case of arbitrary output coupling with spatial interference of counterpropagating waves is somewhat complicated and is not considered here.) The $\sin^2 kz$ term is responsible for spatial hole burning: "holes" are "burned" in the curve of $g(\nu, z)$ versus z at points where $\sin^2 kz$ is largest. This spatially dependent saturation acts to reduce the output intensity, typically by as much as about 30%, compared with the case where interference of counterpropagating waves is absent or ignored. Spatial hole burning tends to be washed out by atomic motion in gas lasers, and is absent entirely in pure traveling wave ring lasers. If complete spatial hole burning based on (70.25) is assumed, the output intensity is

$$I_{\text{out}} = \frac{t}{2}I_{\text{sat}}\left(\frac{g_0(\nu)}{g_t} - \frac{1}{4} - \sqrt{\frac{g_0(\nu)}{2g_t} + \frac{1}{16}}\right) \qquad (70.26)$$

in the case where one mirror is perfectly reflecting.

In inhomogeneously broadened media, the gain coefficient is obtained by integrating the contributions from all possible values of ν_0. The different contributions saturate differently, depending on the detuning of ν_0 from the cavity mode frequency ν. If spatial hole burning and power broadening (see Sect. 69.3) are ignored, then, to a good approximation, the gain saturates as

$$g(\nu) = \frac{g_0(\nu)}{\sqrt{1 + I/I_{\text{sat}}}} \qquad (70.27)$$

in typical inhomogeneously broadened media.

Oscillation on a single longitudinal mode (see Sect. 70.3) may be realized simply by making the cavity length L small enough that the mode spacing $c/2nL$ (70.28) exceeds the spectral width of the gain curve. This is possible in many gas lasers where the spectral

width is small, and in semiconductor lasers, where L is very small. More generally the gain clamping condition $g(\nu) = g_t$ implies that the cavity mode frequency having the largest small-signal gain $g_0(\nu)$ saturates the gain $g(\nu)$ down to the threshold value g_t, while the gain at all other mode frequencies then lies below g_t. In other words, the gain clamping condition implies single-mode oscillation. However, this conclusion assumes homogeneous broadening and also that spatial hole burning is unimportant, so that the gain saturates uniformly throughout the cavity. High pressure gas lasers, where the line broadening is due primarily to collisions and therefore is homogeneous, tend to oscillate on a single mode because spatial hole burning is largely washed out by atomic motion. On the other hand, homogeneously broadened solid state lasers can be multi-mode as a consequence of spatial hole burning.

Single-mode oscillation in inhomogeneously broadened media is generally more difficult to achieve because of spectral hole burning (see Sect. 69.3), which makes the simple gain clamping argument inapplicable. However, single-mode oscillation can be enforced in any case by introducing, in effect, an additional loss mechanism for all mode frequencies except one. This is commonly done with a Fabry–Perot etalon having a free spectral range that is large compared with the spectral width of the gain curve. By choosing the tilt angle appropriately, a particular resonant frequency of the etalon can be brought close to the center of the gain curve while all other resonance frequencies lie outside the gain bandwidth.

Laser oscillation at a fixed polarization can likewise be achieved by discriminating against the orthogonal polarization, as is done when Brewster windows are employed.

Laser oscillation, in general, does not occur precisely at one of the allowed cavity mode frequencies. Associated with the $\sin kz$ dependence of the intracavity field is the condition $kL = N\pi$, or

$$\nu = N\frac{c}{2nL} \quad (N \text{ an integer}) , \tag{70.28}$$

for the cavity mode frequencies in the plane wave approximation. If the gain medium of refractive index n does not fill the entire length L between the mirrors, then (70.28) must be replaced by

$$\nu = \frac{Nc/2}{n\ell + (L - \ell)} , \tag{70.29}$$

or

$$\frac{\ell}{L}[n(\nu) - 1]\nu = \nu_N - \nu , \tag{70.30}$$

where $\ell \ (\leq L)$ is the length of the gain medium and $\nu_N = Nc/2L$ is an empty cavity mode frequency. The laser oscillation frequency will therefore be different, in general, from any of the allowed empty-cavity mode frequencies. If the refractive index $n(\nu)$ is attributable primarily to the lasing transition, as opposed to the host material, or other nonlasing transitions, then the following relation between $n(\nu)$ and $g(\nu)$ may be used in the case of homogeneous broadening [70.3]:

$$n(\nu) - 1 = -\frac{\lambda_0}{4\pi}\frac{\nu_0 - \nu}{\delta\nu_0}g(\nu) , \tag{70.31}$$

where λ_0, ν_0, and $\delta\nu_0$ are the wavelength, frequency, and homogeneous linewidth (HWHM), respectively, of the lasing transition. This implies that

$$\nu = \frac{\nu_0\delta\nu_c + \nu_N\delta\nu_0}{\delta\nu_c + \delta\nu_0} \tag{70.32}$$

for the laser oscillation frequency ν, where

$$\delta\nu_c \equiv \frac{cg(\nu)\ell}{4\pi L} \tag{70.33}$$

is the cavity bandwidth. Thus, the actual lasing frequency is not simply one of the allowed empty-cavity frequencies ν_N, but rather is "pulled" away from ν_N toward the center of the gain profile. This is called frequency pulling.

If spatial hole burning is absent or ignored, then $g(\nu) = g_t$ in steady state oscillation, and the cavity bandwidth $\delta\nu_c = cg_t\ell/4\pi L$ is largest for lossy cavities. Most lasers fall into the "good cavity" category, that is $\delta\nu_c \ll \delta\nu_0$, so that (70.32) may be approximated by

$$\nu \cong \nu_N + (\nu_0 - \nu_N)\delta\nu_c/\delta\nu_0 . \tag{70.34}$$

Similar results apply to inhomogeneously broadened lasers. For a Doppler broadened medium, for instance, the frequency pulling formula is

$$\nu \cong \nu_N + (\nu_0 - \nu_N)(\delta\nu_c/\delta\nu_D)\sqrt{4\ln 2/\pi} \tag{70.35}$$

for good cavities. These results show that frequency pulling is most pronounced in lasers with large peak gain coefficients and narrow gain profiles, as observed experimentally.

Spectral hole burning leads to especially interesting consequences in Doppler broadened gas lasers. Since two traveling waves propagating in opposite ($\pm z$) directions will strongly saturate spectral packets of atoms

with oppositely Doppler shifted frequencies, a standing wave field will burn two holes on opposite sides of the peak of the Doppler profile. When the mode frequency is exactly at the center of the Doppler profile, however, the two holes merge, the field now being able to saturate strongly only those atoms with zero velocity along the z-direction. In this case, since the field "feeds" off a single spectral packet of more strongly saturated atoms, there is a dip in the output power compared with the case when the mode frequency is detuned from line center. This dip in the output power at line center is called the Lamb dip. It can be used to determine whether a gas laser is Doppler broadened, and more importantly, to stabilize the laser frequency to the center of the dip. Lamb dip frequency stabilization employs a feedback circuit to control the bias voltage across a piezoelectric element used to vary the cavity length, and thereby sweep the laser frequency.

The above semiclassical laser theory suggests that cw laser radiation should be perfectly monochromatic, since the amplitude and phase of the field given by (70.7) are time independent. However, when quantum electrodynamical considerations are built into laser theory, it is found that spontaneous emission, which adds to the number of photons put in the lasing mode by stimulated emission, causes a phase diffusion that results in a Lorentzian linewidth (HWHM)

$$\Delta \nu = \frac{N_2}{N_2 - N_1} \frac{8\pi h \nu}{P_{\text{out}}} (\delta \nu_c)^2 , \tag{70.36}$$

where P_{out} is the output laser power. This is the Schawlow–Townes linewidth, which implies a fundamentally quantum mechanical, finite linewidth that persists no matter how small various sources of "technical noise", such as mirror jitter, are made. Although the Schawlow–Townes linewidth has been observed in

highly stabilized gas lasers, it is negligible compared with technical noise in conventional lasers. But in semiconductor lasers, L is very small and consequently $\delta \nu_c$ is large, and quantum noise associated with the Schawlow–Townes formula can be the dominant contribution to the laser linewidth.

However, the $10-100$ MHz linewidths typically observed in semiconductor lasers are too large to be explained by the Schawlow–Townes formula (70.36), and two modifications to this formula are necessary, each of them involving a multiplication of the Schawlow–Townes linewidth $\Delta \nu$ by a certain factor:

$$\Delta \nu \to \Delta \nu' = (1+\alpha^2) K \Delta \nu , \tag{70.37}$$

where α is called the "Henry α parameter" and is associated with a coupling between phase and intensity fluctuations above the laser threshold [70.7]. Values of α between about 4 and 6 are typical in semiconductor injection lasers, and consequently, the correction to the Schawlow-Townes linewidth due to the Henry α parameter is substantial. The K factor [70.8–10] arises as a consequence of the deviation from the spatially uniform intracavity intensity assumed in the derivation of the Schawlow–Townes formula [70.11, 12]. (Intracavity intensities along the optical axis are approximately uniform only in the case of low output couplings.) The fundamental quantum mechanical linewidth under consideration can be associated with vacuum field fluctuations, which, according to general fluctuation–dissipation ideas, will increase as the cavity loss increases. This explains why the "Petermann K factor" deviates increasingly from unity as the output coupling (cavity loss) increases. Values of K between 1 and 2 appear to be typical for lossy, stable resonators [70.13, 14], but much larger values are possible for unstable resonators [70.15] (see also *Siegman* [70.2]).

70.3 Laser Resonators

The assumption that the complex field amplitude $\mathcal{E}(\mathbf{r}, t)$ is slowly varying in z compared with $\exp(\mathrm{i}kz)$ leads to the paraxial wave equation (70.10)

$$\nabla_T^2 \mathcal{E} + 2\mathrm{i}k \frac{\partial \mathcal{E}}{\partial z} = 0 \tag{70.38}$$

for a monochromatic field in vacuum. If $\mathcal{E}(x, y, z)$ satisfies the paraxial wave equation and is specified in the

plane $(x, y, z = 0)$, it follows that

$$\mathcal{E}(x, y, z) = -\frac{\mathrm{i}}{\lambda z} \iint \mathrm{d}x' \, \mathrm{d}y' \mathcal{E}(x', y', 0)$$
$$\times \mathrm{e}^{\mathrm{i}k[(x-x')^2+(y-y')^2]/2z} . \tag{70.39}$$

Thus, in the case of a laser resonator, the field $\mathcal{E}(x, y, L)$ at the mirror at $z = L$ is related to the field $\mathcal{E}(x, y, 0)$ at

the mirror at $z = 0$ by

$$\mathcal{E}(x, y, L) = -\frac{\mathrm{i}}{\lambda L} \iint \mathrm{d}x' \, \mathrm{d}y' \, \mathcal{E}(x', y', 0)$$
$$\times \mathrm{e}^{\mathrm{i}k[(x-x')^2 + (y-y')^2]/2L}$$
$$\equiv \iint \mathrm{d}x' \, \mathrm{d}y' \, K(x, y; x', y') \mathcal{E}(x', y', 0) \,.$$
$$(70.40)$$

Similarly, the field at $z = 0$ after one round trip pass through the resonator is

$$\mathcal{E}(x, y, 0)$$
$$= \iint \mathrm{d}x' \, \mathrm{d}y' \, K(x, y; x', y') \mathcal{E}(x', y', L)$$
$$= \iint \mathrm{d}x' \, \mathrm{d}y' \, K(x, y; x', y') \iint \mathrm{d}x'' \, \mathrm{d}y''$$
$$\times K(x', y'; x'', y'') \mathcal{E}(x'', y'', 0)$$
$$\equiv \iint \mathrm{d}x'' \, \mathrm{d}y'' \, \tilde{K}(x, y; x'', y'') \mathcal{E}(x'', y'', 0) \,.$$
$$(70.41)$$

By definition, a mode of the resonator is a field distribution that does not change on successive round-trip passes through the resonator. More precisely, since an empty cavity is assumed, a mode will be such that the field spatial pattern remains the same except for a constant decrease in amplitude per pass. A longitudinal mode is defined by the value of k in $\exp(\mathrm{i}kz)$, whereas a transverse mode is defined by the corresponding (x, y) dependence and satisfies the integral equation

$$\gamma \mathcal{E}(x, y, z) = \int \mathrm{d}x' \, \mathrm{d}y' \, \tilde{K}(x, y; x', y') \mathcal{E}(x', y', z) \,,$$
$$(70.42)$$

where z defines any plane between the mirrors and $|\gamma| < 1$. Iterative numerical solutions of this equation for laser resonator modes were first discussed by *Fox* and *Li* [70.16].

Laser resonators may be classified as stable or unstable according to whether a paraxial ray traced back and forth through the resonator remains confined in the resonator or escapes. This leads to the condition

$$0 \le g_1 g_2 \le 1 \qquad (70.43)$$

for stability, where the g parameters are defined in terms of the (spherical) mirror curvatures R_i and the mirror separation L by $g_i \equiv 1 - L/R_i$. R_i is defined as positive or negative depending on whether the mirror i is concave or convex, respectively, with respect to the interior of the resonator. Plane–parallel mirrors ($R_i \to \infty$) can be used, but they are difficult to keep aligned and have much larger diffractive losses.

Among stable configurations, the symmetric confocal resonator with $R_1 = R_2 = L$ has the smallest mode spot sizes at the mirrors, while the concentric resonator with $R_1 = R_2$ slightly greater than $L/2$, has the smallest beam waist (Fig. 70.1). The widely used hemispherical resonator ($R_1 = \infty$, R_2 slightly greater than L) is relatively easy to keep aligned and allows the spot size at mirror 2 to be adjusted by slight changes in L.

The fundamental Gaussian beam modes of stable resonators may be constructed from the free space solutions of the paraxial wave equation. The most important (lowest-order) solution for this purpose is

$$\mathcal{E}(x, y, z)$$
$$= \frac{A \, \mathrm{e}^{-\mathrm{i}\phi(z)} \, \mathrm{e}^{\mathrm{i}k(x^2+y^2)/2R(z)} \, \mathrm{e}^{-(x^2+y^2)/w^2(z)}}{\sqrt{1 + z^2/z_0^2}} \,,$$
$$(70.44)$$

where A is a constant, $\phi(z) = \tan^{-1}(z/z_0)$, and $R(z)$, $w(z)$, and z_0 are the radius of curvature of surfaces of constant phase, the spot size, and the Rayleigh range, respectively. The confocal parameter, $2z_0$, is also used to characterize Gaussian beams. Here $z_0 \equiv \pi w_0^2/\lambda$, where w_0 is the spot size at the beam waist at $z = 0$ (Fig. 70.1), and $R(z)$ and $w(z)$ vary with the distance z as follows:

$$R(z) = z + z_0^2/z \,, \quad w(z) = w_0 \sqrt{1 + z^2/z_0^2} \,.$$
$$(70.45)$$

The divergence angle of a Gaussian beam (Fig. 70.1) is given by $\theta = \lambda/\pi w_0$.

The ABCD law for Gaussian beams allows the effects of various optical elements on Gaussian beam propagation to be calculated in a relatively simple fashion [70.1–3]. For instance, a Gaussian beam incident on a lens of focal length f at its waist is focused to a new waist at a distance $d = f/(1 + f^2/z_0^2)$ behind the lens,
Fig. 70.1 Variation of the spot size $w(z)$ of a Gaussian beam with the propagation distance z from the beam waist

and the spot size at the new waist is

$$w_0' = \frac{f\lambda}{\pi w_0} \frac{1}{\sqrt{1 + f^2/z_0^2}} , \tag{70.46}$$

which is approximately $f\lambda/\pi w_0 = f\theta$ for tight focusing. This shows that a Gaussian beam can be focused to a very small spot. On the other hand, beam expanders consisting of two appropriately spaced lenses may be used to increase the spot size by the ratio of the focal lengths.

Gaussian beam modes of laser resonators have radii of curvature that match in magnitude those of the mirrors. The spot sizes at the mirrors and the location of the beam waist with respect to the mirrors may be expressed in terms of λ, L, and $g_1 g_2$. The empty-cavity mode frequencies are given by

$$\nu_N = \frac{c}{2L} \left(N + \frac{1}{\pi} \cos^{-1} \sqrt{g_1 g_2} \right) , \tag{70.47}$$

where N is an integer. For a host medium of refractive index n, $c/2L$ is replaced by $c/2nL$, and (70.47) then generalizes the plane wave result (70.28) to account for both longitudinal and transverse effects in the determination of the cavity mode frequencies.

The assumption of Gaussian modes presupposes that the resonator mirrors are large enough to intercept the entire beam without any "spillover"; i. e., that $a \gg w_1, w_2$, where w_1, w_2 are the spot sizes at the mirrors and a is an effective mirror cross sectional radius. This implies that the Fresnel number $N_F \equiv a^2/\lambda L \gg 1$. Diffraction losses generally increase with decreasing Fresnel numbers.

Higher-order Gaussian modes, where the Gaussian functions of x and y in (70.44) are replaced by higher-order Hermite polynomials, are often more difficult to realize than the fundamental lowest-order mode because their larger spot sizes imply higher diffractive losses, and beyond a certain mode order the spot sizes are too large

to satisfy the no-spillover condition for a pure Gaussian mode.

It is not possible in general to write closed form expressions for laser modes. There are at least two reasons for this, the first being that the gain medium cannot in general be regarded as a simple amplifying element that preserves the basic empty-cavity mode structure. In low power gas lasers, the spatial variations of the gain and refractive index are sufficiently mild that the lasing modes can be accurately described as Gaussians, but more generally, there can be strong gain and index variations that themselves play an important role in determining the modes of the laser, as in "index-guided" and "gain-guided" semiconductor lasers.

Secondly, the resonator structure itself may introduce complications that preclude closed form solutions even for the empty cavity. This is generally true, for instance, of unstable resonators, where iterative numerical solutions of the integral equation (70.42) are necessary for accurate predictions of modes. In such computer simulations, the mode structure must be determined self consistently with the numerical solutions of density matrix or, more commonly, rate equations for the gain medium.

Unstable resonators, though inherently lossy, offer some important advantages for high-gain lasers. Thus, whereas the Gaussian modes of stable resonators typically involve very small beam spot sizes, the distinctly non-Gaussian modes of unstable resonators can have large mode volumes and make more efficient use of the available gain volume. Unstable resonators also tend to yield higher output powers when they oscillate on the lowest loss transverse mode, whereas in stable resonators higher output powers are generally associated with multitransverse mode oscillation. For very high power lasers, the fact that unstable resonators involve all-reflective optics, as opposed to transmissive output coupling, can be important in avoiding optical damage.

70.4 Photon Statistics

Optical fields may be characterized and distinguished by their photon statistical properties (Chapt. 78 and [70.17–21]). In a photon counting experiment, the number of photons registered at a photodetector during a time interval T is measured and used to infer the probability $P_n(T)$ that n photons are counted in a time interval T. If the probability of counting a photon at the time t in the interval dt is denoted $\alpha I(t) \, dt$, where $I(t)$ is the intensity

of the field and α is a factor depending on the microscopic details of the photoelectric process and on the phototube geometry, then it may be shown from largely classical considerations that [70.3, 17–21]

$$P_n(T) = \left\langle \frac{1}{n!} \left[\alpha \int_0^T dt' I(t') \right]^n e^{-\alpha \int_0^T dt' I(t')} \right\rangle , \tag{70.48}$$

where the average $\langle \cdots \rangle$ is over the intensity variations during the counting interval. This is Mandel's formula. In the simplest case of constant intensity, P_n follows the Poisson distribution:

$$P_n = \overline{n}^{\,n}\, \mathrm{e}^{-\overline{n}}/n! \,, \tag{70.49}$$

where $\overline{n} = \alpha I T$. Since a single-mode laser field can be thought of approximately as a "classical stable wave" [70.20, 21], it is not surprising that its photocount distribution is found both theoretically and experimentally to satisfy (70.49), which is characteristic of a coherent state of the field (Chapt. 78). A thermal light source, by contrast, follows the Bose–Einstein distribution,

$$P_n = \overline{n}^n / (1 + \overline{n})^{n+1} \,, \tag{70.50}$$

if the time interval T is short compared with the coherence time of the light; i. e., if $T \Delta \nu \ll 1$, where $\Delta \nu$ is the bandwidth. If $T \Delta \nu \gg 1$, P_n is again Poissonian.

Thus, if a quasi-monochromatic beam of light is made from a natural source by spatial and spectral filtering, it has measurably different photon counting statistics from a single-mode laser beam of exactly the same bandwidth and average intensity. Laser radiation approaches the ideal coherent state that, of all possible quantum mechanical states of the field, most closely resembles the "classical stable wave". These differences are exhibited in other experiments, such as the measurement of intensity correlations of the Brown–Twiss type [70.3, 17–21]. In such experiments, thermal photons have a statistical tendency to arrive in pairs (photon bunching), whereas the photons from a laser arrive independently.

70.5 Multi-Mode and Pulsed Operation

Multi-mode laser theory is generally much more complicated than single-mode theory, particularly in the case of inhomogeneous broadening with both spectral and spatial hole burning. In certain situations, however, considerable simplification is possible. For instance, when the cavity-mode frequency spacing is small compared with the homogeneous linewidth $\delta \nu_0$, the gain tends to saturate homogeneously, and the total output power on all modes is well described by the Rigrod analysis outlined in Sect. 70.2.

Pulsed laser operation adds the further complication of temporal variations to the cw theory outlined in the preceding sections. It is possible, nevertheless, to understand some of the most important types of multi-mode and pulsed operation using relatively simple models.

One method of obtaining short, high power laser pulses is Q-switching. In a very lossy cavity, the gain can be pumped to large values before the threshold condition is met and gain saturation occurs. If the cavity loss is suddenly decreased, there will be a rapid buildup of intensity because the small-signal gain is far above the (now reduced) threshold value. The switching of the cavity loss is called Q-switching, the "quality factor" Q being defined as $\nu/2\delta\nu_c$. This type of Q-switching produces intense pulses of duration typically in the range 10–100 ns, as dictated by the fact that a light pulse must make several passes through the gain cell for amplification. Q-switching requires that the gain medium be capable of retaining a population inversion over a time much larger than the Q-switched pulse dura-

tion, and in particular that the spontaneous emission lifetime be relatively long. The pulse duration can be reduced to approximately a single cavity round trip time by Q-switching from low reflectivity mirrors to 100% reflectivities, and then switching the reflectivity of the outcoupling mirror from 100% to 0% at the peak of the amplified pulse. In addition to this pulsed transmission mode is cavity dumping, where both mirrors have nominally 100% reflectivity and the intracavity power is "dumped" by an acousto-optic or electro-optic intracavity element that deflects the light out of the cavity. The pulse duration achieved in this way is again roughly a round trip time. Cavity dumping can be employed with cw lasers and does not require the long energy storage times necessary for ordinary Q-switching.

Shorter pulses can be realized by mode-locking, where the phases of N longitudinal cavity modes are locked together. In the simplest model, assuming equal amplitudes and phases of the individual modes, the net field amplitude is proportional to

$$X(t) = \sum_{n=-(N-1)/2}^{(N-1)/2} X_0 \sin[(\omega_0 + n\Delta)t + \phi_0]$$
$$= X_0 \sin(\omega_0 t + \phi_0)\frac{\sin(N\Delta t/2)}{\sin(\Delta t/2)} \,. \tag{70.51}$$

The temporal variation described by this function for large N is a train of "spikes" of amplitude NX_0 at times $t_m = 2\pi m/\Delta$, $m = 0, \pm 1, \pm 2, \cdots$, the width of each spike being $2\pi/(N\Delta)$. In the case of a mode-locked laser,

$\Delta = 2\pi(c/2L)$, and the output field consists of a train of pulses separated in time by $T = 2\pi/\Delta = 2L/c$. The peak amplitude of the spikes is proportional to N, and the duration of each spike is approximately $2L/cN$.

The maximum number $N_{\max}$ of modes that can actually be phase-locked is limited by the spectral width $\Delta\nu_g$ of the gain curve:

$$N_{\max} = \frac{\Delta\nu_g}{c/2L} = \frac{2L}{c}\Delta\nu_g \ . \tag{70.52}$$

Similarly, the shortest pulse duration is

$$\tau_{\min} = \frac{2L}{cN_{\max}} = \frac{1}{\Delta\nu_g} \ . \tag{70.53}$$

Mode-locking thus requires a gain bandwidth large compared with the cavity mode spacing, and the shortest and most intense mode-locked pulse trains are obtained in gain media having the largest gain bandwidths. Trains of picosecond pulses are routinely obtained with liquid dye and solid gain media having gain bandwidths $\Delta\nu_g \approx 10^{12}\,\mathrm{s}^{-1}$ or more.

Various techniques, employing acoustic or electrooptic modulation or saturable absorbers, are used to achieve mode-locking [70.1–3]. The different methods all rely basically on the fact that a modulation of the gain or loss at the mode separation frequency $c/2L$ tends to cause the different modes to oscillate in phase. Such a modulation is achieved "passively" when a saturable absorber is placed in the laser cavity: the multi-mode intensity oscillates with a beat frequency that is impressed on the saturated loss coefficient. Dye lasers, with their large gains across a broad range of optical frequencies, are often employed to generate mode-locked picosecond pulses.

Ultrashort pulse generation is possible with additional nonlinear or frequency chirping techniques [70.22]. The colliding-pulse laser [70.23] is a three-mirror ring laser in which two mode-locked pulse trains propagate in opposite senses and overlap in a very thin ($\approx 10\,\mu\mathrm{m}$) saturable absorber placed in the ring in addition to the gain cell. The cavity loss is least when the two pulses synchronize to produce the highest intensity, and therefore the lowest loss coefficient in the saturable absorber. The short length of the absorbing cell forces the pulses to overlap within a very small distance and therefore to produce very short pulses ($10\,\mu\mathrm{m}/c \approx 30\,\mathrm{fs}$ pulse duration with $c/L \approx 100\,\mathrm{MHz}$ repetition rate).

Another method of ultrashort pulse generation relies on frequency chirping; i.e., a time dependent shift of the frequency of an optical pulse [70.24–26]. In a medium (e.g., a glass fiber) with linear and nonlinear refractive index coefficients n_0 and n_2, the refractive index is

$$n = n_0 + n_2 I \ , \tag{70.54}$$

so that there is an instantaneous phase shift $\phi(t)$ that depends on the instantaneous intensity. Therefore, as $I(t)$ increases toward the peak intensity of the pulse, $\phi(t)$ increases (assuming $n_2 > 0$), whereas $\phi(t)$ decreases as $I(t)$ decreases from its peak value. The frequency shift $\dot{\phi}(t)$ is such that the instantaneous frequency of the pulse is smaller at the leading edge and larger at the trailing edge of the pulse (Fig. 70.2), resulting in a stretching of the pulse bandwidth.

Following this spectral broadening by the nonlinear medium, the pulse can be compressed in time by means of a frequency dependent delay line such that the smaller frequencies, say, are delayed more than the higher frequencies. The trailing edge of the pulse can therefore "catch up" to the leading edge, resulting in a shorter pulse whose duration is given by the inverse of the chirp bandwidth. The delay line can be realized with a pair of diffraction gratings (see Fig. 70.2). Using this pulse compression technique, 40 fs amplified pulses from a colliding pulse laser have been compressed to 8 fs, corresponding to about four optical cycles [70.27].

In chirped-pulsed-amplification (CPA) lasers [70.28] a laser pulse is chirped, temporally stretched, and then passed through an amplifier. The lengthening in time of the pulse prior to amplification allows greater energy extraction from the amplifier. After amplification,
Fig. 70.2a,b Nonlinear pulse compression by frequency chirping. In **(a)**, the nonlinear refractive index of a glass fiber results in a time dependent frequency of the transmitted pulse, and in **(b)** a pair of diffraction gratings is used to produce frequency dependent path delays such as to temporally compress the pulse

pulse compression is performed with a grating pair. The Ti:sapphire (Ti : Al_2O_3) amplifier is particularly attractive for femtosecond CPA because of its very large spectral width and high saturation fluence.

The wavelength dependence of the linear refractive index n_0 in (70.54) results in a group velocity

$$v_g = c[n_0 - \lambda \, dn_0/d\lambda]^{-1} \tag{70.55}$$

that, if $dn_0/d\lambda < 0$, is such that higher frequencies propagate more rapidly than lower frequencies. Assuming $n_2 > 0$, on the other hand, the nonlinear part of the index causes a delay of higher frequencies with respect to lower ones, as discussed above. This leads to soliton solutions of the wave equation, such that the opposing effects of the linear and nonlinear dispersion are balanced and the pulse propagates without distortion. Soliton lasers, with pulse durations ranging from picoseconds down to $\approx 100\,\text{fs}$, depending on the fiber length, have been made with solid state lasers and intracavity optical fibers [70.29].

70.6 Instabilities and Chaos

Mode-locked pulses and solitons exemplify an ordered dynamics, as opposed to the erratic and seemingly random intensity fluctuations that are sometimes observed in the output of a laser. In fact, it is possible, under certain circumstances, for laser oscillation to exhibit deterministic chaos; i.e., an effectively random behavior that can nevertheless be described by purely deterministic equations of motion [70.30–34].

Lasers are nonlinear and dissipative systems, and as such exhibit essentially all the modes of behavior characteristic of such systems. It was shown by *Haken* [70.35] that (70.6) and (70.11), with $\Delta = 0$ and with pumping and field loss terms included, can be put into the form of the Lorenz model for chaos. For a single-mode, homogeneously broadened ring laser, the Lorenz model instability requires a "bad cavity" in the sense that the field loss rate is larger than the sum of the homogeneous linewidth of the lasing transition and the population decay rate. It also requires the gain medium to be pumped at least nine times above the threshold gain value, a condition sometimes referred to as a "second laser threshold."

When the single-mode laser equations corresponding to the Lorenz model are generalized to the case of inhomogeneous broadening, an instability occurs at small–signal gain values much less than nine times threshold. In particular, the cw output of the laser gives way to an oscillatory intensity, even though the pumping and loss terms in the equations are assumed to be time independent. As the pumping and loss parameters are varied, this self-pulsing instability can give way to chaotic behavior, and numerical studies of the set of coupled matter–field equations reveal period doubling, two-frequency, and intermittency routes to chaos in different regimes [70.30]. This unstable behavior of single-mode inhomogeneously broadened lasers was first discovered experimentally and analyzed by *Casperson* [70.36–38] for low pressure, $3.51\,\mu\text{m}$ He−Xe lasers. *Arecchi* et al. [70.39] reported the first observation and characterization of chaotic behavior in a laser system; by modulating the cavity loss of a CO_2 laser they observed a period doubling route to chaos as the modulation frequency was varied.

Extensive experimental and theoretical work on unstable and chaotic behavior in a wide variety of other laser systems has been reported [70.30–34, 40], including work aimed at the control of chaotic laser oscillation by the so-called occasional proportional feedback technique [70.41, 42]. Instabilities of single transverse mode dynamics have also been studied, especially in connection with spontaneous spatial pattern formation [70.40].

70.7 Recent Developments

Recent developments in the basic physics of lasers include the application of cavity QED techniques to produce a single-atom laser [70.43] that emits $< 10^5$ photons/s, and a two-photon laser [70.44] that operates on the basis of amplification on a two-photon transition. Recent progress in the development of ultrashort pulses includes the generation of attosecond pulses by high-order harmonic generation [70.45, 46], and the application of such pulses to a measurement of the photoionization time of Auger electrons [70.47].

71. Types of Lasers

The availability of coherent light sources (i. e., lasers) has revolutionized atomic, molecular, and optical science. Since its invention in 1960, the laser has become the basic tool for atomic and molecular spectroscopy and for elucidating fundamental properties of optics and optical interactions with matter. The unique properties of laser light have spawned new types of spectroscopy, as discussed in Chapt. 72 to Chapt. 80.

There are now literally hundreds of different types of lasers. However, only a few of these are commercially available, and lasers tailor made with operational properties optimized for specific applications are often needed. Chapter 70 describes the principles of laser operation leading to specific output characteristics. This chapter summarizes the current status of the development of different types of lasers, emphasizing those that are commercially available. There are several ways to categorize types of lasers; for example, in terms of spectral range, temporal characteristics, pumping mechanism, or lasing media.

For this chapter, the types of lasers are categorized in terms of the lasing media, as shown in Table 71.1.

The variety of different laser types offers a wide range of beam parameters. The spectral output of lasers covers the X-ray to far IR regions as shown in Fig. 71.1. Spectral linewidths can be as narrow as 20 Hz and diffraction limited beam quality with coherence lengths up to 10 m can be obtained. Temporal pulse widths of a few femtoseconds have been generated. Some lasers can produce peak powers of over 10^{13} W and average powers of 10^5 W with pulse energies greater than 10^4 J. The important operational characteristics, such

as frequency range and output power, are given for each of the types of lasers described in the following sections. Extensive tables of laser properties have been published in several different handbooks [71.1–5] and all of these details for every laser are not repeated here due to space limitations. The data that are quoted come from these reference books and from recent proceedings of conferences such as CLEO (Conference on Lasers and Electro-Optics) and ASSL (Advanced Solid State Laser Conference). The reader is referred to these sources for further details of specific laser operation parameters.

71.1 Gas Lasers

Gas lasers can be separated into subclasses based on the lasing media: neutral atoms; ions; and molecules. In addition, molecular lasers contain the special classes of excimer lasers and chemical lasers. Except for chemical lasers, the pumping mechanism is generally an electrical discharge in a gas filled tube. This discharge causes the acceleration of electrons that transfer their kinetic energy to the lasing species through collisions, leaving them in a variety of excited states. These relax back to the ground state with different rates, resulting in the possibility of a population inversion for some transitions. These can be electronic, vibrational, or rotational transitions with wavelengths ranging from the near ultraviolet (UV) through the far infrared (IR) spectral regions. Systems lasing at short wavelengths generally operate only in the pulsed mode because of the short radiative lifetimes of the transitions involved. Because of their low gain, gas lasers usually have relatively long linear cavity designs. Gas lasers generally have narrow spectral emission lines with the possibility of lasing at several different wavelengths. They are broadened both by collisions (homogeneous broadening) and the Doppler effect of the motion of the atoms or molecules (inhomogeneous broadening). To date, 51 elements in the periodic table have shown either ionic or neutral ion gas laser emission.

71.1.1 Neutral Atom Lasers

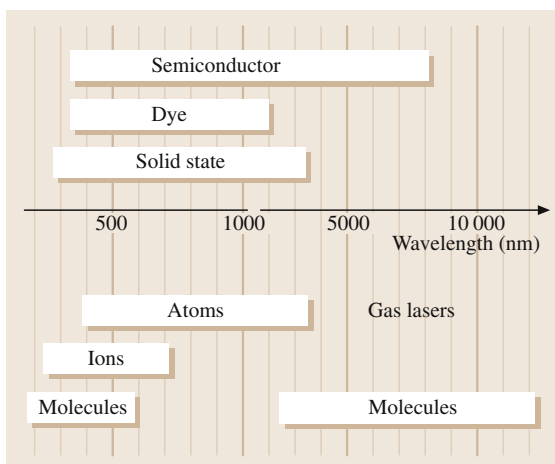
These lasers generally emit in the visible and near IR spectral range. The first and most common laser of this class is the He–Ne laser. Its most prominent emission line is at 632.8 nm. It is usually operated in the continuous wave (cw) configuration with typical power outputs between 0.5 to 50 mW, although powers of over 100 mW have been achieved. Excitation occurs through electrical discharge which pumps both the He and Ne atoms to excited states. The more abundant He atoms transfer their energy to several excited states of Ne atoms. Several radiative transitions of Ne are available for laser transitions. These provide emission at 543.36, 632.8,


Fig. 71.1 Spectral range of laser emission

1152.27, and 3391.32 nm. Final relaxation back to the ground state occurs through collisions with the walls of the gas tube. The desired laser line can be selected by adjusting the reflectivity of the cavity mirrors to discriminate against unwanted transitions. In addition, it is possible to adjust the discharge current, gas ratio, and pressure to optimize a specific emission transition. Using an external magnetic field to produce a Zeeman effect can also be helpful in tuning the laser emission. In addition to the normal red He–Ne lasers, green lasers are now available. Typical He–Ne lasers operate with a coherence length of 0.1–0.3 m, a beam divergence of 0.5–2 mrad, and a stability of 5%/h. The gain at the red line is 0.5 dB/m. This line can be operated as a single mode with a linewidth of 0.0019 nm and a coherence length between 20 and 30 cm.

71.1.2 Ion Lasers

The most important ion lasers are based on noble gas ions such as Ar, Kr, Ne, or Xe in various states of ionization. These operate in either a pulsed or cw mode, and their emission covers the wavelength range from

the near UV through the visible part of the spectrum. In the electrical-discharge excitation process, electrons collide with neutral atoms in their ground states, transferring enough energy to ionize them and leave the ions in several possible excited states. For example, low discharge currents produce Ar^+ giving rise to visible emission lines, while high discharge currents produce Ar^{2+} giving rise to UV emission lines. Radiative emission then occurs to lower excited levels of the ions, followed by subsequent spontaneous emission to the ground state of the ion, and then radiationless relaxation back to the neutral atom ground state. This transition scheme limits the wall plug efficiency to about 0.1% for visible and 0.01% for UV operation. Heat management is accomplished through either water cooling or air cooling.

In the visible region of the spectrum, argon lasers have blue and green emission lines with the strongest ones at 488 and 515 nm, respectively. Krypton lasers have several strong emission lines in the green and red, with the most prominent ones at 521, 568, and 647 nm. Mixed gas lasers can produce all of these lines. In the near UV, argon has a strong laser line at 351 nm as well as several other emission lines down to 275 nm. The same methods for selecting specific laser lines on neutral atom lasers, discussed in Sect. 71.1.1, are used for ion lasers. These lasers can operate at powers of over 20 W of cw emission in the visible and at powers of several watts cw in the UV. The Doppler-limited linewidth of noble gas ion lasers is generally $\approx 5-10$ GHz. By using special techniques for stabilization of the cavity, linewidths of ≈ 500 MHz with drifts of 100 MHz/hr can be obtained. By mode-locking argon or krypton lasers with 10 GHz linewidths, it is possible to produce trains of pulses with pulse lengths of 100 ps and peak powers of 1 kW, at a pulse repetition frequency of 150 MHz. Cavity-dumping produces narrow pulses at pulse repetition frequencies of ≈ 1 MHz with peak powers over 100 times the cw power. Lower power cw lasers of this type typically have beam divergences of 1.5 mrad and a stability of 5%, while high power lasers have beam divergences of ≈ 0.4 mrad with a stability of 0.5%.

71.1.3 Metal Vapor Lasers

These lasers can operate with either neutral atoms or ions. Their excitation process begins with vaporizing a solid or liquid to produce the gas for lasing, followed by normal electrical discharge pumping. Either cw or pulsed operation can be obtained, with laser emission lines in the near UV and visible spectral regions.

One important ion laser of this class is the Helium–Cadmium laser. For the excitation processes, metallic Cd is evaporated and mixed with He. Then a d.c. electric discharge excites the He ions and ionizes the Cd. The excited He atoms transfer their energy to the Cd atoms and the laser transitions take place between electronic levels of the Cd atom. The main emission line of a He–Cd laser is the blue line at 441.6 nm. This typically has a cw output from 130 mW for single-mode operation up to 150 mW for multimode operation. The laser linewidth can be as narrow as 0.003 nm. This system also has an important laser emission at 325.029 nm, which typically has cw powers between 5 and 10 mW single-mode and 100 mW for multimode emission. The wall plug efficiency is between 0.002% and 0.02%.

The most important neutral atom metal vapor laser of this type is the copper vapor laser. This has important emission lines in the green at 510.55 nm and in the yellow at 578.21 nm. These lasers operate in the pulsed mode with temporal pulse widths between 10 and 20 ns at pulse repetition rates of up to 20 000 pps. Typical pulse energies are ≈ 1 mJ, yielding average powers of 20 W. It is possible to increase the repetition rate significantly to achieve average powers of 120 W or even higher. However, this laser is self-terminating since the lower levels of the laser transitions are metastable. This restricts the pulse sequencing of the laser and requires fast discharge risetimes. Copper vapor lasers have high gain (10% to 30%/cm), and very high wall plug efficiency (≈ 1.0%). Gold vapor lasers have similar properties but operate in the red at 624 nm at several watts of power.

71.1.4 Molecular Lasers

There are several types of molecular lasers that can be classified with respect to their spectral emission range, their mode of excitation, or the energy levels involved in the lasing transition. In the far IR, molecular lasers operate on transitions between rotational energy levels. These include water vapor lasers that emit between 17 and 200 μm, cyanide lasers at 337 μm, methyl fluoride lasers emitting between 450 and 550 μm, and ammonia lasers that operate at 81 μm. These are generally excited through optical pumping by a CO_2 laser. They are built with a metal or dielectric wave guide cavity. The former design results in lower thresholds but gives multimode, mixed polarization output, while the latter design results in propagation losses, giving higher thresholds but linearly polarized outputs.

CO_2 lasers are some of the most widely used, with a variety of medical and industrial applications. They

emit in the mid-IR range at 10.6 and 9.6 μm. The CO_2 molecules are excited by electrical discharge, and it is common to mix CO_2 with other gases, such as nitrogen, to enhance the efficiency of the excitation process through energy transfer, or with helium, to keep the average electron energy high and to depopulate the lower levels of the laser transition. Both the initial and final states of the lasing transition are vibrational levels that have many rotational sublevels. This allows discrete tuning of the output within the 9.4 and 10.4 μm bands. Using high pressures of the gas broadens the laser line into a continuum so that the emission can be continuously tuned over several microns near 10 μm. Without any frequency selective element in the cavity, the system oscillates on the transition with highest gain, which is near 10.6 μm. Under pulsed operating conditions, CO_2 lasers can also emit at bands near 4.3 μm and at several bands between 11 and 18 μm.

These laser systems typically operate at a few milliwatts of power to over 100 kW cw. Waveguide and slab cavity designs have been developed for heat removal. In the pulsed or *Q*-switched mode of operation, pulse widths are between a few microseconds and a few milliseconds, with energies as high as 10 000 J/pulse. This leads to peak powers more than 100 times higher than cw powers. It is also possible to mode-lock these systems to get a train of nanosecond pulses. In the transverse-excitation-atmospheric-pressure (TEA) configuration, CO_2 lasers are pumped very rapidly compared with the lifetime of the metastable state, resulting in a large population inversion in the gain medium when the electromagnetic field builds up in the cavity. This results in an intense "gain-switched pulse" of between 100 and 200 ns in duration followed by a lower intensity emission due to continued pumping of the upper state. These systems provide up to 3 J/pulse at pulse repetition frequencies of up to 50 Hz. At much lower pulse repetition frequencies, energies as high as 1000 J/pulse have been obtained. The typical beam divergence of these lasers is less than 3 mrad.

Carbon monoxide lasers operate on the vibrational levels of CO. They can be excited either through electrical discharge or chemical reaction (as discussed in Sect. 71.1.7). CO lasers have a tunable emission between 5 and 7 μm, operating with powers as high as 1 kW cw. In the pulsed mode, the typical energy emission is 10 mJ/pulse with 1 μs pulses at a pulse repetition frequency of 10 Hz. N_2O lasers extend the molecular laser wavelength range to beyond 10 μm.

Nitrogen lasers operate in the near UV at 337.1 nm. These are based on transitions between electronic energy levels of the N_2 molecule excited by electrical discharge. The typical emission from an N_2 laser is a single pulse of 10 ns in duration. The peak pulse power can be as high as 1 MW with 10 mJ/pulse at a pulse repetition frequency of less than 100 Hz. It is also possible to design these systems to obtain picosecond pulses. H_2 operates in a similar way in the 120 to 160 nm region of the UV.

71.1.5 Excimer Lasers

The most important lasers in the near UV to VUV for industrial and medical applications are based on rare-gas halide excimers such as XeF at 351 nm, XeCl at 308 nm, KrF at 248 nm, ArF at 193 nm, and F_2 at 153 nm. The major problem with these systems is the corrosive nature of the gases. They can be pumped by electric discharges, electron or proton beams, or optical excitation. Using electrical discharge excitation, the electrons ionize the noble gas molecules, and these react by pulling an atom off the halide molecule to create an excited state dimer molecule (excimer) that radiates to an unstable lower state where dissociation occurs. The short radiative lifetimes of excimers result in laser pulses of 10 to 50 ns duration. Systems can be configured to have pulse durations ranging from picoseconds to microseconds. These lasers typically operate at high pulse repetition frequencies between 200 and 1000 Hz. The energy per pulse of discharge-pumped excimer lasers ranges from several mJ to 0.1 J, with typical average powers up to 200 W. Single shot, electron-beam-pumped excimer lasers can have as high as 10^4 J/pulse for an average power of almost 1 kW.

Typical emission bands for excimer lasers are approximately $100 \, \text{cm}^{-1}$ wide due to vibrational sublevels. With the use of etalons and gratings, the laser line can be narrowed to $0.3 \, \text{cm}^{-1}$. These frequency-selective elements can be used to tune the emission over several nanometers. Special configurations of excimer lasers have been developed to obtain specific operational parameters. For example, pulses as short as 45 fs have been obtained by mode-locking or by using excimer amplifiers to amplify frequency shifted dye laser pulses [71.3, 4]. Stimulated Brillouin scattering has been used as a phase conjugate mirror to minimize phase-front distortion in excimer lasers. Both master oscillator power amplifiers and injection locked resonator techniques have been used to achieve low spatial divergence with narrow bandwidths [71.3, 4]. Input pulses for the latter system can be from either frequency shifted Nd:YAG or dye lasers.

One interesting recent development has been the demonstration of laser operation of solid state excimer systems [71.6–8]. This is discussed in Sect. 71.2.4.

71.1.6 Nonlinear Mixing

Another way to produce tunable VUV laser transitions is to use nonlinear four-wave sum mixing in atomic vapors and molecular gases. This requires optical pumping with two sources and can be achieved with any of a variety of laser combinations such as excimer lasers with dye lasers, or Nd:YAG lasers with dye lasers. This technique has been used to obtain laser emission in the 57 to 195 nm spectral range with visible to VUV conversion efficiencies as high as 10^{-3}.

71.1.7 Chemical Lasers

It is possible for some chemical reactions between molecules to leave the final molecule in an excited state. This type of "pumping" can result in a population inversion with respect to one of the lower states and laser transitions can occur between vibrational or rotational states of the molecule. Using mixtures of different types of molecules, pumping can be enhanced through energy transfer. Both pulsed and cw laser operation have been obtained with chemical lasers. Typical emission is of the order of a few hundred watts in the IR with a tunable output wavelength. Visible emission from chemical lasers has been demonstrated [71.9–11]. This type of laser provides the possibility of a system with a self contained chemical power supply for use in remote environments. The problems associated with handling hazardous chemicals have restricted the applications of chemical lasers.

The HF chemical laser is associated with an exothermic chain reaction between H_2 and F_2 molecules to yield vibrationally excited HF [71.4]. The fluoride atoms are generated in an electrical discharge tube from the dissociation of SF_6. These are injected into the optical resonator along with the H_2 or D_2 gas which flows perpendicular to the lasing direction. Controlling the gas flow for mixing the reactants is critical to the laser design. The chemical reaction for direct excitation is $F + H_2 \rightarrow HF^* + H$. For this reaction, $\Delta H = -32$ kcal/mole, resulting in laser emission energies of between 100 and 400 kJ/kg, at wavelengths between 2.5 and 3.7 μm. This corresponds to vibrational-rotational transitions in the HF molecule. It is possible to select a single line for the laser output and then tune the laser output wavelength by selecting different lines. Single line output for cw operation can produce up to 100 W of power. If D_2 replaces H_2, the emission shifts to between 3.6 and 4.2 μm, and the single line cw output power drops to about 50 W. The output power for a cw laser of this type, operating in the multiple line mode, can be as high as 2.2 MW, while in the pulsed mode of operation pulse energies of 5 kJ can be obtained with multiple line emission.

An example of energy transfer pumping of chemical lasers is the $DFCO_2$ system. Pumping of vibrational-rotational transitions of DF occurs through multiple chemical reactions of fluorine and deuterium, followed by energy transfer to excited states of the CO_2 molecules. This exhibits laser emission with kilowatts of power at 10.6 μm, as described above. Another important laser system using energy transfer pumping is the chemical-oxygen-iodine laser (COIL). This is based on transitions between electronic levels in which singlet oxygen is excited and transfers its energy to a metastable state of iodine. Emission occurs at 1.3 μm and cw powers of up to 25 kW have been obtained.

One example of chemical laser action in the visible region is excited GeO transferring its energy to atomic Tl, which lases at 535 nm. Only a few systems of this type have been demonstrated, and none are developed to the level of commercial availability [71.9–11].

71.2 Solid State Lasers

Solid state lasers are based on luminescence centers randomly distributed in a crystalline or glass host material. These can be classified in terms of the type of their laser active centers: transition metal ion lasers; rare earth ion lasers; and color center lasers. The use of dye molecules in plastic host media is a new type of solid state laser that is discussed in Sect. 71.4.1. The active ions are substitutionally "doped" into the host during crystal growth or glass melting, whereas the lattice defects that produce color centers are generally produced by post-growth radiation or heat treatments. The excitation mechanism is through optical pumping by either another laser or lamps. The spectral range covered by solid state lasers spans the visible and near IR. The variety of combinations of active centers and hosts provides the ability for both pulsed and cw operation with either narrow band or broad band emission. The latter type can provide frequency tunable output

with the appropriate frequency-selective element in the cavity. Temperature tuning of narrow emission lines is also possible over a limited range. The spectral lines are broadened by internal strains in the host lattice (inhomogeneous broadening) and by radiationless relaxation and scattering processes involving thermal vibrations of the host (homogeneous broadening). Standard Q-switching and mode-locking techniques can be used with most solid state lasers.

71.2.1 Transition Metal Ion Lasers

The laser ions of this type have optically active electrons in unfilled $3d^n$ electron configurations. They include the positively charged ions Cr^{3+}, Cr^{4+}, Co^{2+}, V^{2+}, Ni^{2+}, and Ti^{3+}. The transitions involved in pumping and lasing are associated with the optically active electrons. Because these are outer shell electrons, they are sensitive to their local crystal field environment. Typical host materials are ionic crystals formed from oxides such as sapphire, emerald, chrysoberyl, forsterite, and garnets, or fluorides such as MgF_2, $KMgF_3$, $LiCaAlF_6$, and $LiSrAlF_6$. The host determines the bulk optical, mechanical, and thermal properties of the laser material, and it influences the spectroscopic properties of the active ions.

The most successful transition metal laser ion is Cr^{3+}. It has been made to lase in many different types of host crystals with both strong and weak crystal field environments. The most common strong field host is sapphire, and $Al_2O_3{:}Cr^{3+}$, commonly known as ruby, which was the first laser invented. The typical characteristic of a strong field laser material is a sharp laser line associated with a spin-flip electronic transition between states of the same crystal field configuration. In ruby this occurs at 699.7 nm. Because of its strong, broad absorption bands, ruby can be efficiently pumped by lamps and operates in either a pulsed or cw mode. Typical cw power output is a few watts with an efficiency of $\approx 0.1\%$. Ruby can be Q-switched to produce 10 ns pulses with several joules of energy per pulse, and mode-locked to produce pulses that are 5 ps in duration.

The typical characteristic of a weak field laser material is a broad gain curve associated with vibronic transitions between states of different crystal field configurations. Although chrysoberyl is a host with intermediate crystal field, $BeAl_2O_4{:}Cr^{3+}$, commonly known as *alexandrite*, is sufficiently close to a weak field case to operate as a laser in this regime. Using frequency selective elements in the cavity, alexandrite lasers can be tuned in the 700 to 820 nm range. The gain of alexandrite increases with temperature, with the cross section

at the peak of the gain curve near 10^{-20} cm^2. Typical laser outputs are 4.5 J/pulse at 20 Hz pulse repetition rate and 90 W average power with 2% overall efficiency. In the Q-switched mode, 40 ns pulses with 2 J/pulse are obtained and the pulse width can be stretched to much longer values. Alexandrite lasers can also be mode-locked to obtain 28 ps pulses with 0.5 mJ/pulse.

Fluoride crystals, such as $LiCaAlF_6$ and $LiSrAlF_6$, are also weak field hosts for tunable Cr^{3+} lasers in the near IR. The latter is termed Cr:LiSAF and has a peak stimulated emission cross section of 0.4×10^{-19} cm^2 with a tuning range from 780 to 1020 nm. This system can be either flashlamp pumped or diode laser pumped. Single pulses with energies of 75 J have been generated by these lasers. Kerr lens mode-locking has produced pulses shorter than 100 fs.

One of the most interesting tunable solid state laser systems is Ti-sapphire $(Al_2O_3{:}Ti^{3+})$ because it has the broadest tuning range of any ion, extending from about 660 nm to about 1180 nm. Pumping can be provided by either lasers or flashlamps, resulting in either cw or pulsed operation. This results in a versatile source of excitation in this spectral region and sub-picosecond pulses can be obtained through mode-locking. The single 3d electron of Ti^{3+} gives a simplified energy level scheme which minimizes losses due to excited state absorption, which can be a problem in Cr^{3+} lasers. However, the metastable state lifetime of Ti^{3+} is significantly shorter than that of Cr^{3+}, and therefore Cr^{3+} lasers have much greater energy storage capability. Thus, Ti-sapphire lasers are difficult to pump by flashlamp, and are therefore generally pumped by argon lasers or frequency-doubled Nd-YAG lasers. Ti-sapphire has a very high peak gain cross section of about 4×10^{-19} cm^2. On the other hand, it is difficult to grow Ti-sapphire crystals with high concentrations of Ti^{3+} ions because of valance state stability.

71.2.2 Rare Earth Ion Lasers

All of the trivalent lanthanide ions (Ce^{3+}, Pr^{3+}, Nd^{3+}, Pm^{3+}, Sm^{3+}, Eu^{3+}, Gd^{3+}, Tb^{3+}, Dy^{3+}, Ho^{3+}, Er^{3+}, Tm^{3+}, Yb^{3+}) and the divalent ions Sm^{2+}, Dy^{2+}, Tm^{2+} have been used as active ions in solid state lasers. These ions are characterized by unfilled $4f^n$ electron configurations and the most common source of laser emission comes from electronic transitions among their energy levels. Because the inner shell 4f electrons are shielded by outer shell electrons, the energy levels are not strongly affected by the environment of the local host material. This leads to sharp lines in both absorption and emission.

One exception to this is vibronic emission from Ho^{3+} which can produce tunable laser emission in the near IR. In some cases, transitions between 5d and 4f levels are involved in the laser emission. Since the 5d levels are broadened by the environment, broadly tunable laser emission can be obtained. Examples are Ce^{3+} in the UV and Sm^{2+} in the near IR The only actinide ion that has been made into a laser is U^{3+}.

Both crystals and glasses can be used as host materials for rare earth ion lasers. Common oxide crystal hosts include the garnets such as $Y_3Al_5O_{12}$ (commonly referred to as YAG) and a typical fluoride crystal host is $YLiF_3$. A wide variety of glass hosts has been used, including silicates, phosphates, heavy metal fluorides, and mixtures of these. The major difference between crystal and glass hosts is that crystals provide similar crystal field sites for every dopant ion, leading to a minimum of inhomogeneous broadening, while the disorder associated with glass structure gives many different types of local crystal field sites for the dopant ions and thus significant inhomogeneous broadening.

Because of the abundance of their energy levels, many trivalent rare earth ions have more than one metastable state, and laser emission is possible from several transitions. This results in over 100 possible laser emission lines ranging from the near UV through the visible and near IR. Both pulsed and cw operation can be obtained. The standard configuration for a rare earth solid state laser is a rod of laser material pumped by a lamp. Other configurations are used for special situations, such as a slab of laser material for high power glass lasers where heat management is a problem, and microchip lasers for photonics applications. Glass *fiber lasers* and amplifiers are becoming important configurations for some applications.

A major problem is the inefficiency of coupling the excitation energy of a lamp source with a broad spectral output into the spectrally sharp absorption bands of the trivalent rare earth ions. This can be overcome by using a laser as a pump source. One of the major advances in solid state laser technology has been the development of bars of high power diode laser arrays as pump sources. This has significantly increased the efficiency and decreased the thermal problems in these lasers. Currently available diode laser pump sources cover a limited range of wavelengths and thus can only be used to excite a limited set of metastable states. Several schemes have been adapted to excite other metastable states. One of these is *up-conversion pumping* [71.12–15] in which an

ion is excited to a low-lying metastable state by a photon from the pump source and then re-excited to a higher metastable state either by another photon from the pump source or by energy transfer interaction with a neighboring ion that has also been excited to the low-lying metastable state. *Avalanche pumping* [71.16] relies on thermal fluctuations to populate a low-lying energy level of an ion which can then be re-excited by a pump photon to a high energy metastable state. Another method involves the addition of a second dopant ion to the host. This "sensitizer" ion is one with broad pump bands (such as Cr^{3+}) that can efficiently absorb the energy from the pump lamp. The excited sensitizer then interacts with the "activator" (lasing) ion through a radiationless, resonant energy transfer process. This deactivates the sensitizer and excites the activator ion.

Nd^{3+} has been made to lase in a greater number of host materials than any other active ion. $Y_3Al_5O_{12}:Nd^{3+}$, commonly referred to as Nd-YAG, is one of the most successful commercially available lasers. Although it is possible for Nd-YAG lasers to operate at several different wavelengths around $1\,\mu m$, the standard lasers emit at $1.06\,\mu m$. Continuous wave powers of $250\,W$ are available and pulsed performance of several megawatts at $10\,Hz$ and $1\,J/pulse$ can be obtained. To obtain visible ($532\,nm$) and near UV (354 and $266\,nm$) emission, nonlinear optical crystals are used to modify the near IR output through second, third, and fourth harmonic generation. The optimum concentration of Nd^{3+} in YAG is a few percent, and above this amount, concentration quenching of the emission occurs through energy transfer and cross-relaxation processes. Attempts to co-dope Nd-YAG with Cr^{3+} to enhance pumping through energy transfer have not been successful [71.17, 18]. However, in other garnet crystal hosts such as $Gd_3Sc_2Ga_3O_{12}$ (GSGG), the Cr–Nd energy transfer is strong enough to enhance pumping efficiency. Diode laser pumping of Nd-YAG has significantly increased pumping efficiency.

Other crystal hosts such as the pentaphosphates do not exhibit concentration quenching, so materials with 100% Nd^{3+} can be used as "stoichiometric laser materials". These can be important for some mini-laser applications. In glass hosts, Nd^{3+} ions can produce pulses with energies of $\approx 100\,kJ/pulse$, but these systems must operate at very low pulse repetition rates of one pulse every few minutes to allow for heat dissipation. New athermal glass compositions decrease the problems with thermal lensing for high power laser operation. Nd:YVO lasers have been operated in a microchip configuration pumped by diode lasers.

A major area of recent development involves rare earth doped crystal lasers operating at specific wavelengths in the near IR [71.19–21]. This includes both the "eye safe" region between 1.35 and 2.2 μm for applications involving atmospheric transmission, and the 2 to 3 μm range to match water overtone absorption bands for medical applications. The ions of most interest are Er^{3+}, Tm^{3+}, and Ho^{3+}. Er^{3+} can lase on 13 transitions at wavelengths ranging from 0.56 to 4.8 μm. Both Tm^{3+} and Ho^{3+} exhibit laser transitions near 2 μm, but they are difficult to pump efficiently. One successful laser in this spectral region is triply doped Cr;Tm;Ho:YAG. The flashlamp energy is absorbed by the Cr^{3+} ions and transferred to Tm^{3+} ions. Cross-relaxation between two thulium ions doubles the quantum efficiency by leaving two Tm^{3+} ions in the excited state. Energy transfer among the thulium ions with transfer to Ho^{3+} then occurs and the lasing transition occurs on the holmium ions.

Fiber lasers have been developed that consist of trivalent rare earth ions doped in either oxide or fluoride glass fibers and pumped by other lasers [71.22]. A useful application of active fibers is Er^{3+} and Pr^{3+} optical amplifiers for fiber communication systems. The extended length of the gain media and the nonlinear dispersion effects in fiber transmission allow precise tailoring of laser emission properties. Heavy metal fluoride fibers give improved IR transmission in the 2 to 3 μm spectral region. An important recent development involves writing laser-induced gratings in fibers to produce distributed feedback lasers with stable, single-mode operation [71.23]. Nd-doped fiber lasers pumped by diode lasers have produced 5 W of power. Mode-locked fiber ring lasers have produced solitons. Efficient up-conversion laser operation has been achieved in fibers. In addition, the efficient nonlinear optical properties of fibers has led to fiber Raman lasers.

71.2.3 Color Center Lasers

In color center lasers, the optically active center is a point defect in the lattice. For example, in alkali halide host crystals, such as NaCl, a typical color center consists of an electron trapped at a halide ion vacancy. Similar color centers occur in oxide host crystals such as diamond and sapphire. Color centers can be produced by thermal treatment or exposure to radiation. Many times, these centers are stable only at low temperatures due to ion and electron mobility. In some cases, impurity ions act to stabilize the de-

fect center. A neutral Tl atom at a cation site next to a anion vacancy in KCl is an example of this. A major recent advance in color center lasers involves the development of room temperature stable pulsed laser systems. Systems based on the vibrational transitions of molecular defects such as CN^- have been demonstrated to operate as lasers in the 5 μm spectral region.

Color center absorption generally occurs in the visible, and they are optically pumped by Ar, Kr, or Nd:YAG lasers. Typical color center emission occurs as a broad band in the near IR between 0.8 and 4.0 μm. The emission is based on allowed transitions with high oscillator strengths leading to high gain cross sections.

The homogeneously broadened emission band of color centers allows for efficient, tunable laser emission and single mode operation. Optically pumped cw output powers of ≈ 2 W have been obtained, and mode-locked pulses of less than 100 fs and 1 MW peak power at repetition rates of 100 MHz and hundreds of milliwatts average power have been generated. Laser linewidths of less than 4 kHz have been obtained.

One problem with a high gain medium such as a color center crystal is a tendency for multimode laser operation. In a linear standing wave cavity, a primary oscillating mode reaches gain saturation and burns spatially periodic holes in the population inversion of the gain medium. The high gain allows secondary modes to oscillate with peaks at the nodes of the primary mode. A grating/etalon combination can be used to select and tune the laser output frequency [71.4]. The etalon selects one cavity mode and the grating selects one order of the etalon. This results in single mode tunable output. The single mode power output is 70% of the multimode laser power due to energy loss in the hole burning mode. A ring laser configuration in a traveling wave operation can be used to give uniform saturation of the gain medium, and thus no hole burning. A ring laser cavity needs additional optics such as a Faraday rotator and an optically active plate to force oscillation in only one direction. Active frequency stabilization circuits are necessary to obtain linewidths of less than 4 kHz.

Synchronously pumping a color center laser with a mode-locked Nd:YAG laser gives mode-locked output with pulses typically between 5 and 15 ps. If passive mode-locking is obtained through use of a saturable absorber, pulses of ≈ 200 fs can be obtained. Additive pulse mode-locking consists of two coupled cavities, one with a color center gain medium and the other with a single mode optical fiber. Self phase modulation in the fiber gives a broader frequency spectrum to the pulses

and thus shorter time widths. This scheme has generated pulses of about 75 fs [71.24]. Soliton lasers are also obtained by coupling a color center laser with a fiber laser.

71.2.4 New Types of Solid State Laser Systems

One type of new solid state laser system being studied involves the fourth and fifth row transition metal ions. So far, stimulated emission and gain have been reported for Rh^{3+} [71.25] under strong pumping conditions, but no laser operation has been achieved.

Solid state dye lasers [71.26] consist of organic dye molecules doped in crystal or glass host materials. The first systems of this type used the same class of organic dyes as in liquid lasers (such as rhodamine 6G) and host materials such as sol-gels or polymethylmethacrylate. These systems have traditionally had a problem with photo-degradation of the material after a limited number of shots. However, recent combinations of new dyes and new host materials have produced outputs of tens of millijoules per pulse, over 50% slope efficiency, and a degradation to 60% of the initial output after 30 000 pulses. One example of these new materials is pyrromethene-BF_2 complex dye doped in an acrylic plastic host [71.26]. Another material system that has exhibited good laser performance involves xerogel hosts doped with perylene or pyrromethene dyes [71.27]. The performance of some of these new systems has reached the point that they may be useful for tunable laser applications in the visible spectral region.

Another new type of system can be described as a *solid state excimer laser* [71.6–8]. These materials consist of noble gas solids as host crystals, such as Ar and Ne, doped with excimer molecules, such as XeF. The emission lines occur in the UV and visible, with major lines at 286, 411, and 540 nm. These systems have very high stimulated emission cross sections and large gain coefficients.

71.2.5 Frequency Shifters

Since solid state lasers are commercially available at only a limited number of wavelengths, it is sometimes easier to use nonlinear optical techniques to shift the frequency of an available laser than to develop a new primary laser system. The techniques for this include harmonic frequency generation, frequency mixing, optical parametric oscillators and amplifiers, and Raman shifting. Significant advances have been made recently [71.28] in developing new types of materials for these applications. For frequency mixing, harmonic generation and OPOs in the visible and near UV, important new crystals include $KTiOPO_4$ (KTP), BaB_2O_4 (BBO), and LiB_3O_5 (LBO). In the 3 to $5\,\mu m$ region, new materials for frequency mixing and OPOs include KTA (the arsinate analog of KTP) and $ZnGeP_2$. Gas phase Raman cells have been commercially available for solid state laser systems for many years. Recently, it has been demonstrated that crystals such as $Ba(NO_3)_2$ can be used as efficient solid state Raman shifters. New waveguide configurations with periodic poling for quasiphase matching have greatly enhanced the efficiency of harmonic generation [71.29]. Optical damage threshold is still the limiting parameter for nonlinear optical materials.

71.3 Semiconductor Lasers

The light emission from semiconductor diode lasers is generally associated with the radiative recombination of electrons and holes. This occurs at the junction of an n-type material with excess electrons and a p-type material with excess holes. The excitation is provided by an external electric field applied across the p-n junction that causes the two types of charges to come together. The most common semiconductor laser emission lines occur in the near or mid-IR. These are generally made of III-V compounds such as gallium arsenide in the red and near IR, and lead salts in the mid-IR region. Wide bandgap II-VI materials are currently being explored for use in the green and blue spectral regions. The spectral lines are generally narrow with broadening due to lattice defects (inhomogeneous broadening) and radiationless relaxation and scattering processes associated with the thermal vibration of the host (homogeneous broadening). Temperature tuning can be used to change the output wavelength over a narrow spectral range. Direct modulation of the laser output can be achieved by modulating the external current. This is an important feature of electric current pumped semiconductor lasers, and leads to applications where high frequency modulation is required. Modulation bandwidths in excess of 11 GHz have been obtained.

The ability to design and grow specialized structures one atomic layer at a time using techniques such as molecular beam epitaxy (MBE) has led to the design of

quantum well lasers with enhanced properties, as well as more esoteric designs of quantum wires and quantum boxes [71.30, 31]. Quantum well microlasers can be as small as 100 µm and operate with milliamps of current at a few volts. These are generally based on material systems such as GaAs/GaAlAs or InP/InGaAsP. Heterostructure lasers have layers of aluminum, indium, and phosphorus on the sides of the junction to confine the electronic current to the junction region to minimize the amount of current required, and thus minimize heat dissipation compared with homostructures of the same materials. Special device structures can be fabricated to produce gain-guiding and index-guiding to enhance the operating characteristics of the lasers. Grating structures can be fabricated to give distributed feedback lasers that narrow the laser linewidths to ≈ 1 MHz. External cavity lasers with gratings have achieved linewidths as low as 1 kHz. cw operating powers of up to 10 mW have been achieved from a single p-n junction, while phased arrays have reached combined powers of well over 10 W.

Gallium arsenide (GaAs) was the first compound semiconductor diode laser. It can produce laser emission at wavelengths between 750 and 870 nm. The development of strained-layer technology has allowed the use of mixed compounds of gallium aluminum arsenide ($Ga_{1x}Al_xAs$) to fabricate different types of laser structures, and the concentration of aluminum determines the laser emission wavelength. Wavelengths from 620 nm to 905 nm have been obtained. The most common diode laser structures are simple double-heterostructure lasers, and monolithic arrays of laser stripes can be fabricated for higher power. In a typical GaAlAs laser, the active layer is sandwiched between two layers having larger bandgaps and lower refractive indices. The former characteristic produces electrical confinement and the latter produces optical confinement. This improves the efficiency and allows cw laser operation. In the conventional horizontal-cavity structure, cleaved end facets

of the chip produce the optical feedback required for laser oscillation. Fabricating quantum well structures in the active layer produces improved confinement, and thus higher efficiency operation. For low power lasers, high beam quality is achieved through an index-guiding structure that concentrates the optical beam in the laser stripe. In high power lasers, the current is concentrated in the laser stripe to achieve gain-guiding. Laser arrays can generate cw powers of the order 20 W and in a quasicw mode they can produce peak powers of 100 W. Stacking diode bars in planar arrays can generate kilowatts of power. Another approach to obtaining high powers is a master oscillator power amplifier (MOPA) configuration. This has the advantage of maintaining high beam quality, and gallium arsenide MOPAs have produced single frequency operation at 1 W of power.

Long wavelength IR diode lasers are made of IV–VI compounds such as PbS. These lasers operate at cryogenic temperatures and provide tunable emission from 4 to 32 µm. The tunability is achieved by changing temperature or current.

One of the most important areas of research in semiconducting lasers is the development of new device configurations such as vertical cavity surface emitting lasers (VCSELs) [71.32]. These have lower round trip gain but significantly reduced divergence of the output beam. This configuration allows for the fabrication of two dimensional arrays of independently modulated lasers.

Another major research area is generating new laser wavelengths. Using strained layer technology, a variety of different combinations of direct bandgap materials can be made into semiconductor lasers [71.33]. The range of available bandgaps can conceivably result in lasers with emission wavelengths spanning the visible and near IR spectral regions. There is currently special emphasis on the development of lasers in the blue and green spectral regions using wide bandgap II–VI materials such as ZnSe [71.34].

71.4 Liquid Lasers

There are three classes of liquid lasers. The most widely used are based on organic solvents with organic dye molecules as the active laser species. The other two types are based on rare earth ions for the lasing entity. In one case, the lasing system involves rare earth chelates in organic solvents, while in the other, the rare earth ions are in inorganic solvents. These systems are optically pumped with either flashlamps or other lasers.

71.4.1 Organic Dye Lasers

Dye lasers are generally based on fluorescent dyes in liquid solvents, using optical pumping by either flashlamps or other lasers as the mechanism for excitation. They can operate in either a pulsed or cw mode at wavelengths as short as 310 nm out to about 1.5 µm. Dye lasers provide the versatility of

varying wavelength, bandwidth, and pulse length as desired.

The fluorescence emission of dye molecules appears as broad spectral bands due to coupling of the electronic energy levels with molecular vibrations. This gives a broadband gain curve for lasing, and thus with a dispersive element such as a grating, prism, filter, or etalon in the cavity, dye laser outputs can be tuned over a range of several hundred angstroms (30–60 nm). There are now over 200 organic laser dyes. One of the most successful dyes is rhodamine 6G which covers the spectral range 570–630 nm. Alcohol is a typical solvent. The various types of cavity designs include folded cavities and ring cavities. Flowing dye configurations are useful for heat management. Oscillator/amplifier configurations are used to suppress amplified spontaneous emission. Dispersive elements plus frequency stabilization have been used for spectral line narrowing to single mode cw operation. Frequencies as narrow as 10 GHz or less have been obtained. For cw operation, output powers of a few watts can be obtained, while in the pulsed mode the energy per pulse can be up to 100 mJ in 10 ns pulses. With mode-locking, trains of femtosecond pulses with intervals of 20 ns can be produced.

Mode-locking takes advantage of the broad emission spectrum of the dye molecules to get short pulses. The standard techniques of synchronous pumping, active, and passive mode-locking have been used. In addition, colliding pulse mode-locking has been used in a ring configuration. In this case, pump beams going the opposite direction in the cavity collide in an absorber jet dye to produce interference fringes and saturation. The gain dye is located half way around the ring from the absorber dye. Fiber compression techniques have also been used with dye laser systems. The shortest pulses obtained so far are 6 fs [71.4]. Hybrid mode-locking utilizing synchronous pumping plus a saturable absorber and prism dispersion compensators has been employed to achieve powers of 350 mW and greater tunability than colliding pulse systems [71.4].

Several new technological advances have increased the spectral coverage of dye lasers. These include better pump sources, such as the increased power of argon pump lasers and the availability of UV pump lines, and the use of Ti-sapphire pump lasers. Combining these pump sources with new dyes has provided extended dye laser output in both the blue and near IR [71.4]. Also, improved nonlinear crystals have allowed coverage of the near UV from 260 to 960 nm through harmonic frequency generation and frequency mixing the dye laser output with pump laser wavelengths. Another developing technology is solid state dye lasers. As mentioned in Sect. 71.2.4, significant progress has been made recently in decreasing the photodegradation problems associated with dye molecules doped in solid host materials [71.26, 27].

71.4.2 Rare Earth Chelate Lasers

In these systems, the active lasing center is a rare earth complex with organic molecules in an organic solvent. The chelate ligands are organic phosphates, carboxylate ions, or β-diketonate. The optical pump energy is absorbed by the ligand and efficiently transferred to the rare earth ion. Energy transfer quenching from the rare earth ion to the organic molecule vibrational levels decreases the efficiency of these lasers. This is especially true for Nd^{3+}. The three ions that have been most effective in these systems are Eu^{3+}, Tb^{3+}, and Nd^{3+}.

71.4.3 Inorganic Rare Earth Liquid Lasers

In these systems, the active lasing center is a rare earth ion inorganic complex of heavy metal halides or oxyhalides (the optical pumping is directly into the rare earth ion). Nd^{3+} lasers can produce several hundred joules of energy per pulse in the long pulse mode and peak powers of 180 MW in a Q-switched mode. These lasers have also been mode-locked to obtain 3 ps long pulses having 1 GW of peak power. Self mode-locking and self Q-switching is also observed in these systems.

71.5 Other Types of Lasers

Several more complex laser systems have been developed that have significant interest for scientific studies, but so far have had limited applications outside the laboratory. These include X-ray lasers, particle-beam-pumped lasers, and free electron lasers.

71.5.1 X–Ray and Extreme UV Lasers

These systems are based on highly ionized ions produced by powerful laser sources. Examples are krypton at 93 nm, molybdenum at 13 nm, and carbon at 18 nm.

There is significant interest in developing X-ray lasers for applications in lithography and medical imaging, but so far the lack of reliable X-ray optics for the laser cavities has limited the technology.

71.5.2 Nuclear Pumped Lasers

These are gas lasers excited by high energy charged particles or gamma rays resulting from nuclear reactions. Either nuclear reactors or nuclear explosives are used as pump sources. These can operate in either a pulsed or cw mode and produce emission covering the spectral range from the UV through the IR [71.4]. Typical gases range from Xe_2^* at 170 nm to CO at 5.4 μm. Other gases that have been used include argon and nitrogen. Typical pulsed outputs produce 10 ns pulses with energies from 2×10^{-7} J to 3 J. There are significant problems with radiation damage of the laser components in these systems.

71.5.3 Free Electron Lasers

These lasers are based on a high-energy beam of electrons in a spatially varying magnetic field. The varying field causes the electrons to oscillate, and thus to emit radiation at the oscillation frequency. The stimulated emission produced under these conditions provides the laser output. Since the electrons are making transitions between continuum states instead of discrete states, these systems can give high power output over the entire spectral range from the VUV to the far IR [71.35, 36]. Powers as high as 1 GW and efficiencies as high as 35%

have been obtained. Beam spread is controlled by the use of tapered instead of uniform wigglers. Both cw and picosecond pulsed emission can be obtained.

There are three types of free electron laser configurations [71.35, 36]. The first is a master oscillator power amplifier (MOPA), in which an electron beam is injected into a wiggler in synchronism with the signal to be amplified. The external radiation source to drive the amplifier is a master oscillator such as a conventional laser system. This is a single pass, high gain system. The second configuration is an oscillator. This is designed with reflection at the ends of the wiggler so that the signal makes multiple passes in the cavity. This can operate with low gain. Since it amplifies spontaneous noise, no injected signal is necessary. The third configuration is a super-radiant amplifier. In this configuration, shot noise is amplified over a single pass through the wiggler. These systems require high current accelerators to drive them. Because their operation is based on broad band shot noise, super-radiant amplifier radiation has a broader band than radiation from a master oscillator power amplifier.

Different accelerator configurations can be used to produce the electron beam, storage rings, induction linacs, pulse line accelerators, etc. [71.35, 36]. These give different beam properties such as quality, current, and energy. They also each give a limited range of wavelengths and temporal structure of the output.

Advances have been made recently in designing smaller and less complex free electron lasers [71.35, 36]. As this trend continues, these systems will find important applications in medicine and industry.

71.6 Recent Developments

Over the past eight years, the designs of all types of lasers have continued to evolve, driven by applications requirements for lasers with specific operating parameters. Some of the major advances in this time period are summarized here.

The requirements for laser outputs of several kilowatts with near-diffraction-limited beam quality in the infrared wavelength region has lead to improved designs of CO_2 lasers. This includes a diffusion cooled, annular discharge design with free-space propagation instead of waveguiding [71.37].

The push for solid state lasers in the ultraviolet has led to recent progress in cerium-doped fluoride crystal lasers that provides direct laser emission tunable in the 280 to 330 nm spectral region. Using host crystals such as $LiCaAlF_6$, $LiSrAlF_6$ or $LiLuF_4$ has helped

to overcome the problems with excited state absorption and color center formation that has been a major problem with more common hosts such as YAG and YLF crystals [71.38]. These lasers are pumped by either excimer lasers or frequency-quadrupled Nd:YAG lasers and have produced up to 60 mJ per pulse and 60% slope efficiency. The output can be pulse compressed to 115 fs.

Thin-disk solid state laser configurations using rare earth doped crystals and semiconductor saturable absorber mirrors for passive mode-locking have produced ultrashort (femtosecond) pulse trains with high average powers [71.39]. Yb:YAG thin disks reduce the problem of thermal lensing and have achieved output powers of up to 100 W in cw mode locked operation with near-diffraction-limited beam quality [71.40]. To achieve

shorter pulses, a thin-disk Yb:KYW laser has obtained 22 W with 240 fs pulses [71.41].

Advances continue to be made in the materials for solid state organic dye lasers. The use of polymer materials, organic-inorganic matrices, and nanoparticles has provided advances in this type of laser [71.42–46]. Use of semiconductor excitation and electrical excitation may play important roles in the future of solid state organic dye lasers.

Commercially available solid state Raman lasers have been developed for frequency shifting to a wide variety of wavelengths and for pulse compression to the 0.1–1 ns region [71.47–49]. Both internal and external cavity designs have been demonstrated. New materials, such as $KGd(WO_4)_2$ and $KY(WO_4)_2$, have been used for Raman lasers along with $Ba(NO_3)_2$, which has excellent properties for this application. An external-resonator Raman laser using $Ba(NO_3)_2$ has reached 1.3 W of power [71.50].

The major advancement in fiber lasers has been in cladding geometry to allow for higher powers. Double clad fiber lasers operating in single transverse modes have exceeded 100 W of output for four-level systems and over 1 W for three-level systems [71.51]. These involve a variety of geometric shapes of cladding. A new breakthrough in fiber delivery systems that will impact the future of fiber lasers is the use of holey fibers (photonic crystal fibers) [71.52]. These are glass fibers that have a periodic array of air holes running their entire length. These fibers can be engineered to produce a photonic bandgap and allow for dispersion control and minimized nonlinear effects compared to standard fibers. This is useful for short pulse delivery.

In the field of semiconductor lasers, vertical-cavity surface-emitting lasers (VCSELs) have developed as a competitive alternative to the conventional edge-emitting semiconductor lasers. The most recent advance involves designs that have a horizontal laser cavity but emits from the surface [71.53]. This combines the ease of packaging of VCSELs with the high power and good stability properties of edge-emitting lasers.

Several new designs of high power semiconductor lasers that can be frequency shifted to the blue and green spectral regions have been developed as rugged, efficient sources [71.54, 55]. One of these is a GaAs-based vertical external cavity surface-emitting laser (VECSEL) optically pumped with an 808 nm semiconductor laser. This emits at 976 nm with a cavity that includes a wavelength selector and a doubling crystal. The second configuration uses a semiconductor material as a gain medium in an external cavity with a wavelength selec-

tor. In this case the frequency doubling crystal is outside the cavity. These configurations have reached 20 mW cw operation with high beam quality. One enabling technology is the use of microelectromechanical systems (MEMS) for mirrors to tune VCELs [71.56].

New material configurations offer some advantages. Photonic crystals can be used to produce nanocavity lasers [71.57] while band-structure engineering can be used to design quantum-cascade lasers [71.58]. The latter are multiple-quantum-well heterostructures based on intersub-band transitions. They operate in the infrared to terahertz spectral region.

The broad spectral band available for laser gain is the major distinguishing feature of liquid organic dye lasers. This provides the ability to have tunable output over a broad range of wavelength, the ability to generate ultrashort pulses, narrow linewidth cw operation, and high average power operation. This variety of operating parameters keeps this class of lasers competitive in a variety of applications. They have been especially useful for laser spectroscopy in the visible region of the spectrum and in the area of laser cooling. They have achieved energies of up to 800 J per pulse and average powers greater than 1 kW. The discovery of highly stable water-soluble dyes is an important advancement in this field [71.59].

Free-electron lasers (FELs) can produce coherent emission at a wide range of wavelengths. Output formats include ultrashort pulses and high powers [71.60]. Using a photocathode electron gun in a single pass, self-amplified spontaneous emission mode, FELs can operate at wavelengths where there are no mirrors with high reflectivity. This type of laser emission has been extended to the vacuum ultraviolet and the hard X-ray regions. The technique of using a subharmonic seed laser has been developed to improve the spectral purity of FEL emission. The use of an energy-recovering accelerator produces FELs with high average power (over 1 MW). In the spectral region around 1 mm, FELs have produced over 300 W of picosecond pulses.

Laser systems using various nonlinear optics techniques continue to be developed. There has been significant research on high intensity, ultrashort pulse lasers because of their special characteristics for atmospheric propagation. Using femtosecond pulses above a critical power level produces "light strings" that propagate without dispersion for many kilometers due to the balance between Kerr self-focusing and air ionization [71.61]. Stimulated Brillouin scattering in water has been shown to be effective in pulse compression and the production of nondiffracting laser beams [71.62].

72. Nonlinear Optics

Nonlinear optics is concerned with the propagation of intense beams of light through a material system. The optical properties of the medium can be modified by the intense light beam, leading to new processes that would not occur in a material that responded linearly to an applied optical field. These processes can lead to the modification of the spectral, spatial, or polarization properties of the light beam, or the creation of new frequency components. More complete accounts of nonlinear optics including the origin of optical nonlinearities can be found in references [72.1–4].

Both the Gaussian and MKS system of units are commonly used in nonlinear optics. Thus, we have chosen to express the equations in this chapter in both the Gaussian and MKS systems. Each equation can be interpreted in the MKS system as written or in the Gaussian system by omitting the prefactors (e.g., $1/4\pi\varepsilon_0$) that appear in square brackets at the beginning of the expression on the right-hand-side of the equation.

72.1 Nonlinear Susceptibility

In linear optics it is customary to describe the response of a material in terms of a macroscopic polarization $\tilde{P}$ (i.e., dipole moment per unit volume) which is linearly related to the applied electric field $\tilde{E}$ through the linear susceptibility $\chi^{(1)}$. In order to extend the relationship between $\tilde{P}$ and $\tilde{E}$ into the nonlinear regime, the polarization is expanded in a power series of the electric field strength. We express this relationship mathematically by first decomposing the field and the polarization into their frequency components such that

$$\tilde{E}(r, t) = \sum_l E(r, \omega_l) \, e^{-i\omega_l t} \,, \tag{72.1}$$

$$\tilde{P}(r, t) = \sum_l P(r, \omega_l) \, e^{-i\omega_l t} \,, \tag{72.2}$$

where the summations are performed over both positive and negative frequencies. The reality of $\tilde{E}$ and $\tilde{P}$ is then

assured by requiring that $E(r, \omega_l) = E^*(r, -\omega_l)$ and $P(r, \omega_l) = P^*(r, -\omega_l)$. In this case the general expression for the Cartesian component i of the polarization at frequency ω_σ is given by

$$
\begin{aligned}
P_i(\omega_\sigma) = [\varepsilon_0] \bigg[& \sum_j \chi^{(1)}_{ij}(\omega_\sigma) E_j(\omega_\sigma) \\
& + \sum_{jk} \sum_{(mn)} \chi^{(2)}_{ijk}(\omega_\sigma; \omega_m, \omega_n) \\
& \times E_j(\omega_m) E_k(\omega_n) \\
& + \sum_{jkl} \sum_{(mno)} \chi^{(3)}_{ijkl}(\omega_\sigma; \omega_m, \omega_n, \omega_o) E_j(\omega_m) \\
& \times E_k(\omega_n) E_l(\omega_o) \\
& + \cdots \bigg],
\end{aligned}
\tag{72.3}
$$

where $ijkl$ refer to field components, and the notation (mn), for example, indicates that the summation over n and m should be performed such that $\omega_\sigma = \omega_m + \omega_n$ is held constant. Inspection of (72.3) shows that the $\chi^{(n)}$ can be required to satisfy intrinsic permutation symmetry, i. e., the Cartesian components and the corresponding frequency components [e.g., (j, ω_j) but not (i, ω_σ)] associated with the applied fields may be permuted without changing the value of the susceptibility. For example, for the second-order susceptibility,

$$
\chi^{(2)}_{ijk}(\omega_\sigma; \omega_m, \omega_n) = \chi^{(2)}_{ikj}(\omega_\sigma; \omega_n, \omega_m) .
\tag{72.4}
$$

If the medium is lossless at all the field frequencies taking part in the nonlinear interaction, then the condition of full permutation symmetry is necessarily valid. This condition states that the pair of indices associated with the Cartesian component and the frequency of the nonlinear polarization [i. e., (i, ω_σ)] may be permuted along with the pairs associated with the applied field components. For example, for the second-order susceptibility, this condition implies that

$$
\chi^{(2)}_{ijk}(\omega_\sigma; \omega_m, \omega_n) = \chi^{(2)}_{kji}(-\omega_n; \omega_m, -\omega_\sigma) .
\tag{72.5}
$$

If full permutation symmetry holds, and in addition all the frequencies of interest are well below any of the transition frequencies of the medium, the $\chi^{(n)}$ are invariant upon free permutation of all the Cartesian indices. This condition is known as the Kleinman symmetry condition.

72.1.1 Tensor Properties

The spatial symmetry properties of a material can be used to predict the tensor nature of the nonlinear susceptibility. For example, for a material that possesses inversion symmetry, all the elements of the even-ordered susceptibilities must vanish (i. e., $\chi^{(n)} = 0$ for n even). The number of independent elements of the nonlinear susceptibility for many materials can be substantially fewer than than the total number of elements. For example, in general $\chi^{(3)}$ consists of 81 elements, but for the case of isotropic media such as gases, liquids, and glasses, only 21 elements are nonvanishing and only three of these are independent. The nonvanishing elements consist of the following types: $\chi^{(3)}_{iijj}$, $\chi^{(3)}_{ijij}$, and $\chi^{(3)}_{ijji}$, where $i \neq j$. In addition, it can be shown that

$$
\chi^{(3)}_{iiii} = \chi^{(3)}_{iijj} + \chi^{(3)}_{ijij} + \chi^{(3)}_{ijji} .
\tag{72.6}
$$

72.1.2 Nonlinear Refractive Index

For many materials, the refractive index n is intensity-dependent such that

$$
n = n_0 + n_2 I ,
\tag{72.7}
$$

where n_0 is the linear refractive index, n_2 is the nonlinear refractive index coefficient , and $I = [4\pi\varepsilon_0] n_0 c |E|^2 / 2\pi$ is the intensity of the optical field. For the case of a single, linearly polarized light beam traveling in an isotropic medium or along a crystal axis of a cubic material, n_2 is related to $\chi^{(3)}$ by

$$
n_2 = \left(\frac{1}{16\pi^2 \varepsilon_0} \right) \frac{12\pi^2}{n_0^2 c} \chi^{(3)}_{iiii}(\omega; \omega, \omega, \omega, -\omega) .
\tag{72.8}
$$

For the common situation in which n_2 is measured in units of $\mathrm{cm^2/W}$ and $\chi^{(3)}$ is measured in Gaussian units, the relation becomes

$$
n_2 \left(\frac{\mathrm{cm^2}}{\mathrm{W}} \right) = \frac{12\pi^2 \times 10^7}{n_0^2 c} \chi^{(3)}_{iiii}(\omega; \omega, \omega, \omega, -\omega) .
\tag{72.9}
$$

There are various physical mechanisms that can give rise to a nonlinear refractive index. For the case of induced molecular orientation in CS_2, $n_2 = 3 \times 10^{-14} \, \mathrm{cm^2/W}$. If the contribution to the nonlinear refractive index is electronic in nature (e.g., glass), then $n_2 \approx 2 \times 10^{-16} \, \mathrm{cm^2/W}$.

72.1.3 Quantum Mechanical Expression for $\chi^{(n)}$

The general quantum mechanical perturbation expression for the $\chi^{(n)}$ in the nonresonant limit is (Under conditions of resonant excitation, relaxation phenomena must be included in the treatment, and the density matrix formalism must be used [72.4]. The resulting equation for the nonlinear susceptibility is then more complicated)

$$
\begin{aligned}
&\chi^{(n)}_{i_0\cdots i_n}(\omega_\sigma; \omega_1, \ldots, \omega_n) \\
&= \left[\frac{1}{\varepsilon_0}\right] \frac{N}{\hbar^n} \mathcal{P}_F \sum_{ga_1\cdots a_n} \rho_0(g) \\
&\quad \times \frac{1}{(\omega_{a_1 g} - \omega_1 - \cdots - \omega_n)} \\
&\quad \times \frac{\mu^{i_0}_{ga_1} \mu^{i_1}_{a_1 a_2} \cdots \mu^{i_{n-1}}_{a_{n-1} a_n} \mu^{i_n}_{a_n g}}{(\omega_{a_2 g} - \omega_2 - \cdots - \omega_n) \cdots (\omega_{a_n g} - \omega_n)}
\end{aligned}
\tag{72.10}
$$

where $\omega_\sigma = \omega_1 + \cdots + \omega_n$, N is the density of atoms or molecules that compose the material, $\rho_0(g)$ is the probability that the atomic or molecular population is initially in the state g in thermal equilibrium, $\mu^{i_1}_{a_1 a_2}$ is the i_1th Cartesian component of the $(a_1 a_2)$ dipole matrix element, $\omega_{a_1 g}$ is the transition frequency between the states a_1 and g, and $\mathcal{P}_F$ is the full permutation operator which is defined such that the expression that follows it is to be summed over all permutations of the pairs (i_0, ω_σ), $(i_1, \omega_1) \cdots (i_n, \omega_n)$ and divided by the number of permutations of the input frequencies. Thus the full expression for $\chi^{(2)}$ consists of six terms and that for $\chi^{(3)}$ consists of 24 terms.

In the limit in which the frequencies of all the fields are much smaller than any resonance frequency of the medium, the value of $\chi^{(n)}$ can be estimated to be

$$
\chi^{(n)} \approx \left[\frac{1}{\varepsilon_0}\right] \left(\frac{2\mu}{\hbar\omega_0}\right)^n N\mu,
\tag{72.11}
$$

where μ is a typical value for the dipole moment and ω_0 is a typical value of the transition frequency between the ground state and the lowest-lying excited state. For the case of $\chi^{(3)}$ in Gaussian units, the predicted value is $\chi^{(3)} = 3 \times 10^{-14}$, which is consistent with the measured values of many materials (e.g., glass) in which the nonresonant electronic nonlinearity is the dominant contribution.

72.1.4 The Hyperpolarizability

The nonlinear susceptibility relates the macroscopic polarization P to the electric field strength E. A related microscopic quantity is the hyperpolarizability, which relates the dipole moment p induced in a given atom or molecule to the electric field E^{loc} (the Lorentz local field) that acts on that atom or molecule. The relationship between p and E^{loc} is

$$
\begin{aligned}
&p_i(\omega_\sigma) \\
&= [\varepsilon_0]\Bigg[\sum_j \alpha_{ij}(\omega_\sigma) E^{\text{loc}}_j(\omega_\sigma) \\
&\quad + \sum_{jk} \sum_{(mn)} \beta_{ijk}(\omega_\sigma; \omega_m, \omega_n) E^{\text{loc}}_j(\omega_m) E^{\text{loc}}_k(\omega_n) \\
&\quad + \sum_{jkl} \sum_{(mno)} \gamma_{ijkl}(\omega_\sigma; \omega_m, \omega_n, \omega_o) \\
&\quad \times E^{\text{loc}}_j(\omega_m) E^{\text{loc}}_k(\omega_n) E^{\text{loc}}_l(\omega_o) + \cdots \Bigg],
\end{aligned}
\tag{72.12}
$$

where α_{ij} is the linear polarizability, β_{ijk} is the first hyperpolarizability, and γ_{ijkl} is the second hyperpolarizability. The nonlinear susceptibilities and hyperpolarizabilities are related by the number density of molecules N and by local-field factors, which account for the fact that the field E^{loc} that acts on a typical molecule is not in general equal to the macroscopic field E. Under many circumstances, it is adequate to relate E^{loc} to E through use of the Lorentz approximation

$$
E^{\text{loc}}(\omega) = E(\omega) + \left[\frac{1}{4\pi\varepsilon_0}\right] \frac{4\pi}{3} P(\omega).
\tag{72.13}
$$

To a good approximation, one often needs to include only the linear contribution to $P(\omega)$, and thus the local electric field becomes

$$
E^{\text{loc}}(\omega) = \mathcal{L}(\omega) E(\omega),
\tag{72.14}
$$

where $\mathcal{L}(\omega) = \{[\varepsilon_0^{-1}]\varepsilon(\omega) + 2\}/3$ is the local field correction factor and $\varepsilon(\omega)$ is the linear dielectric constant. Since $P(\omega) = Np(\omega)$, (72.3) and (72.12) through (72.14) relate the $\chi^{(n)}$ to the hyperpolarizabilities through

$$
\chi^{(1)}_{ij}(\omega_\sigma) = \mathcal{L}(\omega_\sigma) N\alpha_{ij}(\omega_\sigma),
\tag{72.15}
$$

$$
\begin{aligned}
\chi^{(2)}_{ijk}(\omega_\sigma; \omega_m, \omega_n) &= \mathcal{L}(\omega_\sigma)\mathcal{L}(\omega_m)\mathcal{L}(\omega_n) \\
&\quad \times N\beta_{ijk}(\omega_\sigma; \omega_m, \omega_n),
\end{aligned}
\tag{72.16}
$$

$$
\begin{aligned}
\chi^{(3)}_{ijk}(\omega_\sigma; \omega_m, \omega_n, \omega_o) &= \mathcal{L}(\omega_\sigma)\mathcal{L}(\omega_m)\mathcal{L}(\omega_n)\mathcal{L}(\omega_o) \\
&\quad \times N\gamma_{ijkl}(\omega_\sigma; \omega_m, \omega_n, \omega_o).
\end{aligned}
\tag{72.17}
$$

For simplicity, the analysis above ignores the vector character of the interacting fields in calculating $\mathcal{L}(\omega)$. A generalization that does include these effects is given in [72.5].

72.2 Wave Equation in Nonlinear Optics

72.2.1 Coupled–Amplitude Equations

The propagation of light waves through a nonlinear medium is described by the wave equation

$$\nabla^2 \tilde{\boldsymbol{E}} - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \tilde{\boldsymbol{E}} = \left[\frac{1}{4\pi\varepsilon_0} \right] \frac{4\pi}{c^2} \frac{\partial^2}{\partial t^2} \tilde{\boldsymbol{P}} . \qquad (72.18)$$

For the case in which $\tilde{\boldsymbol{E}}$ and $\tilde{\boldsymbol{P}}$ are given by (72.1), the field amplitudes associated with each frequency component can be decomposed into their plane wave components such that

$$\boldsymbol{E}(\boldsymbol{r}, \omega_l) = \sum_l \boldsymbol{A}_n(\boldsymbol{r}, \omega_l) \, e^{i\boldsymbol{k}_n \cdot \boldsymbol{r}} ,$$

$$\boldsymbol{P}(\boldsymbol{r}, \omega_l) = \sum_l \boldsymbol{P}_n(\boldsymbol{r}, \omega_l) \, e^{i\boldsymbol{k}_n \cdot \boldsymbol{r}} , \qquad (72.19)$$

where $k_n = n(\omega_l)\omega_l/c$ is the magnitude of the wavevector $\boldsymbol{k}_n$. The amplitudes $\boldsymbol{A}_n$ and $\boldsymbol{P}_n$ are next decomposed into vector components whose linear optical properties are such that the polarization associated with them does not change as the field propagates through the material. For example, for a uniaxial crystal these eigenpolarizations could correspond to the ordinary and extraordinary components. In order to describe the propagation and the nonlinear coupling of these eigenpolarizations, the vector field amplitudes are expressed as

$$\boldsymbol{A}_n(\boldsymbol{r}, \omega_l) = \hat{\boldsymbol{u}}_{ln} A_n(\boldsymbol{r}, \omega_l) ,$$

$$\boldsymbol{P}_n(\boldsymbol{r}, \omega_l) = \hat{\boldsymbol{u}}_{ln} \mathcal{P}_n(\boldsymbol{r}, \omega_l) , \qquad (72.20)$$

where $\hat{\boldsymbol{u}}_{ln}$ is the unit vector associated with the eigenpolarization of the spatial mode n at frequency ω_l. If the fields are assumed to travel along the z-direction, and the slowly-varying amplitude approximation $\partial^2 A_n/\partial z^2 \ll 2k_n \partial A_n/\partial z$ is made, the change in the amplitude of the field as it propagates through the nonlinear medium with no linear absorption is described by the differential equation

$$\frac{\mathrm{d}A_n(\omega_l)}{\mathrm{d}z} = \pm \left[\frac{1}{4\pi\varepsilon_0} \right] \frac{i2\pi\omega_l}{n(\omega_l)c} \mathcal{P}_n^{\mathrm{NL}}(\omega_l) , \qquad (72.21)$$

where $\mathcal{P}_n^{\mathrm{NL}}$ is the nonlinear contribution to the polarization amplitude $\mathcal{P}_n$, $n(\omega_l)$ is the linear refractive index at frequency ω_l, and the plus (minus) sign indicates propagation in the positive (negative) z-direction. Sections 72.3 and 72.4 give expressions for the $\mathcal{P}_n^{\mathrm{NL}}$ for various second- and third-order nonlinear optical

processes. Equation (72.21)) is used to determine the set of coupled-amplitude equations describing a particular nonlinear process. For example, for the case of sum-frequency generation , the two fields of frequency ω_1 and ω_2 are combined through second-order nonlinear interaction to create a third wave at frequency $\omega_3 = \omega_1 + \omega_2$. Assuming full permutation symmetry, the amplitudes of the nonlinear polarization for each of the waves are

$$\mathcal{P}^{\mathrm{NL}}(z, \omega_1) = [\varepsilon_0] 2\chi_{\mathrm{eff}}^{(2)} A(z, \omega_3) A^*(z, \omega_2) \, e^{-i\Delta kz} , \qquad (72.22)$$

$$\mathcal{P}^{\mathrm{NL}}(z, \omega_2) = [\varepsilon_0] 2\chi_{\mathrm{eff}}^{(2)} A(z, \omega_3) A^*(z, \omega_1) \, e^{-i\Delta kz} , \qquad (72.23)$$

$$\mathcal{P}^{\mathrm{NL}}(z, \omega_3) = [\varepsilon_0] 2\chi_{\mathrm{eff}}^{(2)} A(z, \omega_1) A(z, \omega_2) \, e^{i\Delta kz} , \qquad (72.24)$$

where $\Delta k = k_1 + k_2 - k_3$ is the wavevector mismatch (see Sect. 72.2.2) and $\chi_{\mathrm{eff}}^{(2)}$ is given by

$$\chi_{\mathrm{eff}}^{(2)} = \sum_{ijk} \chi_{ijk}^{(2)} (\hat{\boldsymbol{u}}_1^*)_i (\hat{\boldsymbol{u}}_2)_j (\hat{\boldsymbol{u}}_3)_k , \qquad (72.25)$$

where $(\hat{\boldsymbol{u}}_l)_i = \hat{\boldsymbol{u}}_l \cdot \hat{\boldsymbol{\imath}}$. For simplicity, the subscripts on each of the field amplitudes have been dropped, since only one spatial mode at each frequency contributed. The resulting coupled amplitude equations are

$$\frac{\mathrm{d}A(\omega_1)}{\mathrm{d}z} = \left[\frac{1}{4\pi} \right] \frac{i4\pi\omega_1 \chi_{\mathrm{eff}}^{(2)}}{n(\omega_1)c} A(\omega_3) A^*(\omega_2) \, e^{-i\Delta kz} , \qquad (72.26)$$

$$\frac{\mathrm{d}A(\omega_2)}{\mathrm{d}z} = \left[\frac{1}{4\pi} \right] \frac{i4\pi\omega_2 \chi_{\mathrm{eff}}^{(2)}}{n(\omega_2)c} A(\omega_3) A^*(\omega_1) \, e^{-i\Delta kz} , \qquad (72.27)$$

$$\frac{\mathrm{d}A(\omega_3)}{\mathrm{d}z} = \left[\frac{1}{4\pi} \right] \frac{i4\pi\omega_3 \chi_{\mathrm{eff}}^{(2)}}{n(\omega_3)c} A(\omega_1) A(\omega_2) \, e^{i\Delta kz} . \qquad (72.28)$$

72.2.2 Phase Matching

For many nonlinear optical processes (e.g., harmonic generation) it is important to minimize the wave vector mismatch in order to maximize the efficiency. For example, if the field amplitudes $A(\omega_1)$ and $A(\omega_2)$ are constant, the solution to (72.28) yields for the output

intensity

$$I(L, \omega_3) = \left[\frac{1}{64\pi^3 \varepsilon_0} \right]$$
$$\times \frac{32\pi^3 \left[\chi_{\text{eff}}^{(2)} \right]^2 \omega_3^2 I(\omega_1) I(\omega_2) L^2}{n(\omega_1) n(\omega_2) n(\omega_3) c^3}$$
$$\times \text{sinc}^2(\Delta k L/2) , \qquad (72.29)$$

in terms of sinc $x = (\sin x)/x$, where $I(L, \omega_3) = (4\pi\varepsilon_0) n(\omega_3) c |A(L, \omega_3)|^2 / 2\pi$, and $I(\omega_1)$ and $I(\omega_2)$ are the corresponding input intensities. Clearly, the effect of the wavevector mismatch is to reduce the efficiency of the generation of the sum frequency wave. The maximum propagation distance over which efficient nonlinear coupling can occur is given by the coherence length

$$L_c = \frac{2}{\Delta k} . \qquad (72.30)$$

As a result of the dispersion in the linear refractive index that occurs in all materials, achieving phase matching over typical interaction lengths (e.g., 5 mm) is nontrivial. For the case in which the nonlinear material is birefringent, it is sometimes possible to achieve phase matching by insuring that the interacting waves possess some suitable combination of ordinary and extraordinary polarization. Other techniques for achieving phase matching include quasiphase matching [72.5] and the use of the mode dispersion in waveguides [72.6].

However, the phase matching condition is automatically satisfied for certain nonlinear optical processes, such as two-photon absorption (see Sect. 72.4.6) and Stokes amplification in stimulated Raman scattering (see Sect. 72.5.1). One can tell when the phase matching condition is automatically satisfied by examining the frequencies that appear in the expression for the nonlinear susceptibility. For a nonlinear susceptibility of the sort $\chi^{(3)}(\omega_1; \omega_2, \omega_3, \omega_4)$ the wave vector mismatch is given in general by $\Delta k = k_2 + k_3 + k_4 - k_1$. Thus, for the example of Stokes amplification in stimulated Raman scattering, the nonlinear susceptibility is given by $\chi^{(3)}(\omega_1; \omega_1, \omega_0, -\omega_0)$ where $\omega_0(\omega_1)$ is the frequency of the pump (Stokes) wave, and consequently the wave vector mismatch vanishes identically.

72.2.3 Manley–Rowe Relations

Under conditions of full permutation symmetry, there is no flow of power from the electromagnetic fields to the medium, and thus the total power flow of the fields is conserved. The flow of energy among the fields can be described by the Manley–Rowe relations. For example, for the case of sum-frequency generation, one can deduce from (72.26, 27, 28) that

$$\frac{\text{d}}{\text{d}z} \left[\frac{I(\omega_1)}{\omega_1} \right] = \frac{\text{d}}{\text{d}z} \left[\frac{I(\omega_2)}{\omega_2} \right] = -\frac{\text{d}}{\text{d}z} \left[\frac{I(\omega_3)}{\omega_3} \right] . \qquad (72.31)$$

The expressions in square brackets are proportional to the flux of photons per unit area per unit time, and imply that the creation of a photon at ω_3 must be accompanied by the annihilation of photons at both ω_1 and ω_2. Similar relations can be formulated for other nonlinear optical processes that are governed by a nonlinear susceptibility that satisfies full permutation symmetry. Since this behavior occurs at the photon level, nonlinear optical processes can lead to the generation of light fields that have esoteric quantum statistical properties (Chapt. 78 and Chapt. 80).

A nonlinear optical process that satisfies the Manley–Rowe relations is called a parametric process. Conversely, a process for which field energy is not conserved, and thus Manley–Rowe relations cannot be formulated, is said to be nonparametric. Thus, parametric processes are described by purely real $\chi^{(n)}$, whereas nonparametric processes are described by complex $\chi^{(n)}$.

72.2.4 Pulse Propagation

If the optical field consists of ultrashort ($<100\,\text{ps}$) pulses, it is more convenient to work with the temporally varying amplitude, rather than with the individual frequency components. Thus, for a linearly polarized plane wave pulse propagating along the z-axis, the field is decomposed into the product of a slowly varying amplitude $A(z, t)$ and a rapidly varying oscillatory term such that

$$\tilde{E}(\mathbf{r}, t) = A(z, t)\, \text{e}^{\text{i}(k_0 z - \omega_0 t)} + \text{c.c.} , \qquad (72.32)$$

where $k_0 = n_0 \omega_0 / c$. For a pulse propagating in a material with an intensity-dependent refractive index, the propagation can be described by the nonlinear Schrödinger equation

$$\frac{\partial A}{\partial z} + \frac{\text{i}\beta_2}{2} \frac{\partial^2 A}{\partial \tau^2} = \text{i}\gamma |A|^2 A , \qquad (72.33)$$

where $\beta_2 = (\text{d}^2 k / \text{d}\omega^2)|_{\omega=\omega_0}$ is the group velocity dispersion parameter, $\tau = t - z/v_g$ is the local time for the pulse, $v_g = [(\text{d}k/\text{d}\omega)|_{\omega=\omega_0}]^{-1}$ is the group velocity, and $\gamma = [4\pi\varepsilon_0] n_2 n_0 \omega_0 / 2\pi$ is the nonlinear refractive index parameter.

72.3 Second-Order Processes

Second-order nonlinear optical processes occur as a consequence of the second term in expression (72.3), i.e., processes whose strength is described by $\chi^{(2)}(\omega_\sigma; \omega_m, \omega_n)$. These processes entail the generation of a field at frequency $\omega_\sigma = \omega_m + \omega_n$ in response to applied fields at (positive and/or negative) frequencies ω_m and ω_n. Several examples of such processes are described in this Section.

72.3.1 Sum Frequency Generation

Sum frequency generation produces an output field at frequency $\omega_3 = \omega_1 + \omega_2$ for ω_1 and ω_2 both positive. It is useful, for example, for the generation of tunable radiation in the uv if ω_1 and/or ω_2 are obtained from tunable lasers in the visible range. Sum frequency generation is described in detail in Sects. 72.2.1–72.2.3.

72.3.2 Second Harmonic Generation

Second harmonic generation is routinely used to convert the output of a laser to a higher frequency. It is described by $\chi^{(2)}(2\omega; \omega, \omega)$. Let η be the power conversion efficiency from frequency ω to 2ω. Assuming that phase matching is perfect, and the pump wave at frequency ω is undepleted by the interaction, a derivation analogous to that for (72.29) yields

$$\eta = \tanh^2 \left(z/l \right) , \qquad (72.34)$$

where the characteristic conversion length l is given by

$$l = \left[4\pi \right] \frac{c\sqrt{n(\omega)n(2\omega)}}{4\pi\omega\chi^{(2)}|A_1(0)|} . \qquad (72.35)$$

Note that the conversion efficiency asymptotically approaches unity. In practice, conversion efficiencies exceeding 80% can be achieved.

72.3.3 Difference Frequency Generation

Difference frequency generation can be used to create light in the infrared and far infrared by generating the difference frequency $\omega_2 = \omega_3 - \omega_1$ (where ω_3 and ω_1 are positive and $\omega_3 > \omega_1$) of two incident lasers. Consider the case in which a strong (undepleted) pump wave at frequency ω_3 and a weak (signal) wave at ω_1 are incident on a nonlinear medium described by $\chi^{(2)}(\omega_2; \omega_3, -\omega_1) = \chi^{(2)}(\omega_1; \omega_3, -\omega_2)$. The amplitude $A(\omega_3)$ of the strong wave can be taken as a constant,

and thus the interaction can be described by finding simultaneous solutions to (72.26) and (72.27) for $A(\omega_1)$ and $A(\omega_2)$. In the limit of perfect phase matching (i. e., $\Delta k = 0$), the solutions are

$$A(z, \omega_1) = A(0, \omega_1) \cosh \kappa z , \qquad (72.36)$$

$$A(z, \omega_2) = \mathrm{i} \sqrt{\frac{n_1 \omega_2}{n_2 \omega_1}} \frac{A(\omega_3)}{|A(\omega_3)|} A^*(0, \omega_1) \sinh \kappa z , \qquad (72.37)$$

where

$$\kappa^2 = \left[\frac{1}{16\pi^2} \right] \frac{16\pi^2 \left[\chi^{(2)} \right]^2 \omega_1^2 \omega_2^2}{k_1 k_2 c^4} |A(\omega_3)|^2 . \quad (72.38)$$

Equation (72.37) describes the spatial growth of the difference frequency signal.

72.3.4 Parametric Amplification and Oscillation

For the foregoing case of a strong wave at frequency ω_3 and a weak wave with $\omega_1 < \omega_3$ incident on a second-order nonlinear optical material, the lower frequency input wave is amplified by the nonlinear interaction; this process is known as parametric amplification. Difference frequency generation is a consequence of the Manley–Rowe relations, as described above in Sect. 72.2.3. Since $\omega_3 = \omega_1 + \omega_2$, the annihilation of an ω_3 photon must be accompanied by the simultaneous creation of photons ω_1 and ω_2.

An optical parametric oscillator can be constructed by placing the nonlinear optical material inside an optical resonator that provides feedback at ω_1 and/or ω_2. When such a device is excited by a wave at ω_3, it can produce output frequencies ω_1 and ω_2 that satisfy $\omega_1 + \omega_2 = \omega_3$. Optical parametric oscillators are of considerable interest as sources of broadly tunable radiation [72.7].

72.3.5 Focused Beams

For conceptual clarity, much of the discussion so far has assumed that the interacting beams are plane waves. In practice, the incident laser beams are often focused into the nonlinear material to increase the field strength within the interaction region and consequently to increase the nonlinear response. However, it is undesirable to focus too tightly, because doing so leads

to a decrease in the effective length of the interaction region. In particular, if w_0 is the radius of the laser beam at the beam waist, the beam remains focused only over a distance of the order $b = 2\pi w_0^2/\lambda$ where λ is the laser wavelength measured in the non-

linear material. For many types of nonlinear optical processes, the optimal nonlinear response occurs if the degree of focusing is adjusted so that b is several times smaller than the length L of the nonlinear optical material.

72.4 Third-Order Processes

A wide variety of nonlinear optical processes are possible as a result of the nonlinear contributions to the polarization that are third-order in the applied field. These processes are described by $\chi^{(3)}(\omega_\sigma; \omega_m, \omega_n, \omega_o)$ (72.3) and can lead not only to the generation of new field components (e.g., third-harmonic generation) but can also result in a field affecting itself as it propagates (e.g., self-phase modulation). Several examples are described in this section.

72.4.1 Third-Harmonic Generation

Assuming full-permutation symmetry, the nonlinear polarization amplitudes for the fundamental and third-harmonic beams are

$$\mathcal{P}^{NL}(z, \omega) = [\varepsilon_0] 3\chi_{eff}^{(3)} A(z, 3\omega)[A^*(z, \omega)]^2 e^{-i\Delta kz} ,$$
$$\mathcal{P}^{NL}(z, 3\omega) = [\varepsilon_0] \chi_{eff}^{(3)} [A(z, \omega)]^3 e^{i\Delta kz} , \qquad (72.39)$$

where $\Delta k = 3k(\omega) - k(3\omega)$ and $\chi_{eff}^{(3)}$ is the effective third-order susceptibility for third-harmonic generation and is defined in a manner analogous to the $\chi_{eff}^{(2)}$ in (72.25). If the intensity of the fundamental wave is not depleted by the nonlinear interaction, the solution for the output intensity $I(L, 3\omega)$ of the third-harmonic field for a crystal of length L is

$$I(L, 3\omega) = \left[\frac{1}{256\pi^4 \varepsilon_0^2} \right] \frac{48\pi^2 \omega^2 \left[\chi_{eff}^{(3)} \right]^2}{n(3\omega)n(\omega)^3 c^4}$$
$$\times I(\omega)^3 L^2 \sinh^2[\Delta kL/2] , \qquad (72.40)$$

where $I(\omega)$ is the input intensity of the fundamental field. As a result of the typically small value of $\chi_{eff}^{(3)}$ in crystals, it is generally more efficient to generate the third harmonic by using two $\chi^{(2)}$ crystals in which the first crystal produces second harmonic light and the second crystal combines the second harmonic and the fundamental beams via sum-frequency generation. It is also possible to use resonant enhancement of $|\chi^{(3)}|$ in gases to increase the efficiency of third-harmonic generation [72.8].

72.4.2 Self-Phase and Cross-Phase Modulation

The nonlinear refractive index leads to an intensity-dependent change in the phase of the beam as it propagates through the material. If the medium is lossless, the amplitude of a single beam at frequency ω propagating in the positive z-direction can be expressed as

$$A(z, \omega) = A(0, \omega) e^{i\phi^{NL}(z)} , \qquad (72.41)$$

where the nonlinear phase shift $\phi^{NL}(z)$ is given by

$$\phi^{NL}(z) = \frac{\omega}{c} n_2 Iz , \qquad (72.42)$$

and $I = [4\pi\varepsilon_0]n_0 c|A(0, \omega)|^2/2\pi$ is the intensity of the laser beam. If two fields at different frequencies ω_1 and ω_2 are traveling along the z-axis, the two fields can affect each other's phase; this effect is known as cross-phase modulation. The nonlinear phase shift $\phi_{1,2}^{NL}(z)$ for each of the waves is given by

$$\phi_{1,2}^{NL}(z) = \frac{\omega_{1,2}}{c} n_2 (I_{1,2} + 2I_{2,1})z . \qquad (72.43)$$

For the case of a light pulse, the change in the phase of the pulse inside the medium becomes a function of time. In this case the solution to (72.33) for the time-varying amplitude $A(z, \tau)$ shows that in the absence of group-velocity dispersion (GVD) (i.e., $\beta_2 = 0$) that the solution for $A(z, \tau)$ is of the form of (72.41), except that the temporal intensity profile $I(\tau)$ replaces the steady-state intensity I in (72.42). As the pulse propagates through the medium, its frequency becomes time dependent, and the instantaneous frequency shift from the central frequency ω_0 is given by

$$\delta\omega(\tau) = -\frac{\partial\phi^{NL}(\tau)}{\partial\tau} = -\frac{\omega n_2 z}{c} \frac{\partial I}{\partial t} . \qquad (72.44)$$

This time-dependent self-phase modulation leads to a broadening of the pulse spectrum and to a frequency chirp across the pulse.

If the group velocity dispersion parameter β_2 and the nonlinear refractive index coefficient n_2 are of opposite sign, the nonlinear frequency chirp can be compensated by the chirp due to group velocity dispersion, and (72.33) admits soliton solutions . For example, the fundamental soliton solution is

$$A(z, t) = \sqrt{\frac{1}{L_D}} \text{sech}\left(\frac{\tau}{\tau_p}\right) e^{iz/2L_D} , \qquad (72.45)$$

where τ_p is the pulse duration and $L_D = \tau_p^2/|\beta_2|$ is the dispersion length. As a result of their ability to propagate in dispersive media without changing shape, optical solitons show a great deal of promise in applications such as optical communications and optical switching. For further discussion of optical solitons see [72.9].

72.4.3 Four-Wave Mixing

Various types of four-wave mixing processes can occur among different beams. One of the most common geometries is backward four-wave mixing used in nonlinear spectroscopy and optical phase conjugation. In this interaction, two strong counterpropagating pump waves with amplitudes A_1 and A_2 and with equal frequencies $\omega_{1,2} = \omega$ are injected into a nonlinear medium. A weak wave, termed the probe wave, (with frequency ω_3 and amplitude A_3) is also incident on the medium. As a result of the nonlinear interaction among the three waves, a fourth wave with an amplitude A_4 is generated which is counterpropagating with respect to the probe wave and with frequency $\omega_4 = 2\omega - \omega_3$. For this case, the third-order nonlinear susceptibilities for the probe and conjugate waves are given by $\chi^{(3)}(\omega_{3,4}; \omega, \omega, -\omega_{4,3})$. For constant pump wave intensities and full permutation symmetry, the amplitudes of the nonlinear polarization for the probe and conjugate waves are given by

$$\mathcal{P}^{NL}(z, \omega_{3,4}) = \pm[\varepsilon_0]6\chi^{(3)}\left[\left(|A_1|^2 + |A_2|^2\right)A_{3,4}\right.$$
$$\left. + A_1 A_2 A_{4,3}^* e^{i\Delta kz}\right] , \qquad (72.46)$$

where $\Delta k = k_1 + k_2 - k_3 - k_4$ is the phase mismatch, which is nonvanishing when $\omega_3 \neq \omega_4$. For the case of optical phase conjugation by degenerate four-wave mixing (i. e., $\omega_3 = \omega_4 = \omega$ and $A_4(L) = 0$), the phase conjugate reflectivity R_{PC} is

$$R_{PC} = \frac{|A_4(0)|^2}{|A_3(0)|^2} = \tan^2(\kappa L) , \qquad (72.47)$$

where $\kappa = \left[1/16\pi^2\varepsilon_0\right]\left[24\pi^2\omega\chi^{(3)}/(n_0 c)^2\right]\sqrt{I_1 I_2}$ and $I_{1,2}$ are the intensities of the pump waves. Phase-

conjugate reflectivities greater than unity can be routinely achieved by performing four-wave mixing in atomic vapors or photorefractive media.

72.4.4 Self-Focusing and Self-Trapping

Typically a laser beam has a transverse intensity profile that is approximately Gaussian. In a medium with an intensity-dependent refractive index, the index change at the center of the beam is different from the index change at the edges of the beam. The gradient in the refractive index created by the beam can allow it to self-focus for $n_2 > 0$. For this condition to be met, the total input power of the beam must exceed the critical power P_{cr} for self-focusing which is given by

$$P_{cr} = \frac{\pi(0.61\lambda)^2}{8n_0 n_2} , \qquad (72.48)$$

where λ is the vacuum wavelength of the beam. For powers much greater than the critical power, the beam can break up into various filaments, each with a power approximately equal to the critical power. For a more extensive discussion of self-focusing and self-trapping see [72.10, 11].

72.4.5 Saturable Absorption

When the frequency ω of an applied laser field is sufficiently close to a resonance frequency ω_0 of the medium, an appreciable fraction of the atomic population can be placed in the excited state. This loss of population from the ground state leads to an intensity-dependent saturation of the absorption and the refractive index of the medium (see Sect. 69.2 for more detailed discussion) [72.4]. The third-order susceptibility as a result of this saturation is given by

$$\chi^{(3)} = \left[\frac{1}{\varepsilon_0}\right]\frac{|\mu|^2 T_1 T_2 \alpha_0 c}{3\pi\omega_0\hbar^2}\frac{\delta T_2 - i}{\left[1 + (\delta T_2)^2\right]^2} , \qquad (72.49)$$

where μ is the transition dipole moment, T_1 and T_2 are the longitudinal and transverse relaxation times, respectively (see Sect. 68.4.3), α_0 is the line-center weak-field intensity absorption coefficient, and $\delta = \omega - \omega_0$ is the detuning. For the 3s $\leftrightarrow$ 3p transition in atomic sodium vapor at 300 °C, the nonlinear refractive index $n_2 \approx 10^{-7}$ cm^2/W for a detuning $\delta T_2 = 300$.

72.4.6 Two-Photon Absorption

When the frequency ω of a laser field is such that 2ω is close to a transition frequency of the material, it is

possible for two-photon absorption (TPA) to occur. This process leads to a contribution to the imaginary part of $\chi^{(3)}(\omega; \omega, \omega, -\omega)$. In the presence of TPA, the intensity $I(z)$ of a single, linearly polarized beam as a function of propagation distance is

$$I(z) = \frac{I(0)}{1 + \beta I(0)z} , \quad (72.50)$$

where $\beta = \left[1/16\pi^2\varepsilon_0\right]24\pi^2\omega\,\mathrm{Im}\left[\chi^{(3)}\right]/(n_0c)^2$ is the TPA coefficient. For wide-gap semiconductors such as ZnSe at 800 nm, $\beta \approx 10^{-8}$ cm/W.

72.4.7 Nonlinear Ellipse Rotation

The polarization ellipse of an elliptically polarized laser beam rotates but retains its ellipticity as the beam propagates through an isotropic nonlinear medium. Ellipse

rotation occurs as a result of the difference in the nonlinear index changes experienced by the left- and right-circular components of the beam, and the angle θ of rotation is

$$\begin{aligned}
\theta &= \frac{1}{2}\Delta n\omega z/c \\
&= \left[\frac{1}{16\pi^2\varepsilon_0}\right]\frac{12\pi^2}{n_0^2 c}\chi^{(3)}_{xyyx} \\
&\quad \times (\omega; \omega, \omega, -\omega)(I_+ - I_-)z ,
\end{aligned} \quad (72.51)$$

where $I_\pm$ are the intensities of the circularly polarized components of the beam with unit vectors $\hat{\sigma}_\pm = (\hat{x} \pm i\hat{y})/\sqrt{2}$. Nonlinear ellipse rotation is a sensitive technique for determining the nonlinear susceptibility element $\chi^{(3)}_{xyyx}$ for isotropic media and can be used in applications such as optical switching.

72.5 Stimulated Light Scattering

Stimulated light scattering occurs as a result of changes in the optical properties of the material that are induced by the optical field. The resulting nonlinear coupling between different field components is mediated by some excitation (e.g., acoustic phonon) of the material that results in changes in its optical properties. The nonlinearity can be described by a complex susceptibility and a nonlinear polarization that is of third order in the interacting fields. Various types of stimulated scattering can occur. Discussed below are the two processes that are most commonly observed.

72.5.1 Stimulated Raman Scattering

In stimulated Raman scattering (SRS), the light field interacts with a vibrational mode of a molecule. The coupling between the two optical waves can become strong if the frequency difference between them is close to the frequency ω_v of the molecular vibrational mode. If the pump field at ω_0 and another field component at ω_1 are propagating in the same direction along the z-axis, the steady-state nonlinear polarization amplitudes for the two field components are given by

$$\begin{aligned}
\mathcal{P}^{\mathrm{NL}}(z, \omega_{0,1}) &= [\varepsilon_0]6\chi_{\mathrm{R}}(\omega_{0,1}) \\
&\quad \times |A(z, \omega_{1,0})|^2 A(z, \omega_{0,1}) , \quad (72.52)
\end{aligned}$$

where $\chi_{\mathrm{R}}(\omega_{0,1}) \equiv \chi^{(3)}(\omega_{0,1}; \omega_{0,1}, \omega_{1,0}, -\omega_{1,0})$, the Raman susceptibility, actually depends only on the fre-

quency difference $\Omega = \omega_0 - \omega_1$ and is given by

$$\chi_{\mathrm{R}}(\omega_{0,1}) = \left[\frac{1}{\varepsilon_0}\right]\frac{N(\partial\alpha/\partial q)_0^2}{6\mu_M}\frac{1}{\omega_v^2 - \Omega^2 \mp 2i\gamma\Omega} , \quad (72.53)$$

where the minus (plus) sign is taken for the ω_0 (ω_1) susceptibility, μ_M is the reduced nuclear mass, and $(\partial\alpha/\partial q)_0$ is a measure of the change of the polarizability of the molecule with respect to a change in the intermolecular distance q at equilibrium. If the intensity of the pump field is undepleted by the interaction with the ω_1 field and is assumed to be constant, the solution for the intensity of the ω_1 field at $z = L$ is given by

$$I(L, \omega_1) = I(0, \omega_1)\,\mathrm{e}^{G_{\mathrm{R}}} , \quad (72.54)$$

where the SRS gain parameter G_{R} is

$$\begin{aligned}
G_{\mathrm{R}} &= \left[\frac{1}{16\pi^2\varepsilon_0}\right]48\pi^2\frac{\omega_1}{(n_1c)^2}\,\mathrm{Im}[\chi_{\mathrm{R}}(\omega_1)]I_0 L \\
&= g_{\mathrm{R}}I_0 L , \quad (72.55)
\end{aligned}$$

g_{R} is the SRS gain factor, and I_0 is the input intensity of the pump field. For $\omega_1 < \omega_0$ ($\omega_1 > \omega_0$), the ω_1 field is termed the Stokes (anti-Stokes) field, and it experiences exponential amplification (attenuation). For sufficiently large gains (typically $G_{\mathrm{R}} \gtrsim 25$), the Stokes wave can be seeded by spontaneous Raman scattering and can grow to an appreciable fraction of the pump field. For a complete discussion of the sponta-

neous initiation of SRS see [72.12]. For the case of CS_2, $g_R = 0.024\,\text{cm/MW}$.

Four-wave mixing processes that couple a Stokes wave having $\omega_1 < \omega_0$ and an anti-Stokes wave having $\omega_2 > \omega_0$, where $\omega_1 + \omega_2 = 2\omega_0$, can also occur [72.4]. In this case, additional contributions to the nonlinear polarization are present and are characterized by a Raman susceptibility of the form $\chi^{(3)}(\omega_{1,2}; \omega_0, \omega_0, -\omega_{2,1})$. The technique of coherent anti-Stokes Raman spectroscopy is based on this four-wave mixing process [72.13].

72.5.2 Stimulated Brillouin Scattering

In stimulated Brillouin scattering (SBS), the light field induces and interacts with an acoustic wave inside the medium. The resulting interaction can lead to extremely high amplification for certain field components (i. e., Stokes wave). For many optical media, SBS is the dominant nonlinear optical proccess for laser pulses of duration $> 1\,\text{ns}$. The primary applications for SBS are self-pumped phase conjugation and pulse compression of high-energy laser pulses.

If an incident light wave with wave vector $\boldsymbol{k}_0$ and frequency ω_0 is scattered from an acoustic wave with wave vector $\boldsymbol{q}$ and frequency Ω, the wave vector and frequency of the scattered wave are determined by conservation of momentum and energy to be $\boldsymbol{k}_1 = \boldsymbol{k}_0 \pm \boldsymbol{q}$ and $\omega_1 = \omega_0 \pm \Omega$, where the (+) sign applies if $\boldsymbol{k}_0 \cdot \boldsymbol{q} > 0$ and the (−) applies if $\boldsymbol{k}_0 \cdot \boldsymbol{q} < 0$. Here, Ω and $\boldsymbol{q}$ are related by the dispersion relation $\Omega = v|\boldsymbol{q}|$ where v is the velocity of sound in the material. These Bragg scattering conditions lead to the result that the Brillouin frequency shift $\Omega_B = \omega_1 - \omega_0$ is zero for scattering in the forward direction (i. e., in the $\boldsymbol{k}_0$ direction) and reaches its maximum for scattering in the backward direction given by

$$\Omega_B = 2\omega_0 v n_0 / c , \tag{72.56}$$

where n_0 is the refractive index of the material.

The interaction between the incident wave and the scattered wave in the Brillouin-active medium can become nonlinear if the interference between the two optical fields can coherently drive an acoustic wave, either through electrostriction or through local density fluctuations resulting from the absorption of light and consequent temperature changes. The following discussion treats the more common electrostriction mechanism.

Typically, SBS occurs in the backward direction (i. e., $\boldsymbol{k}_0 = k_0\hat{z}$ and $\boldsymbol{k}_1 = -k_1\hat{z}$), since the spatial overlap

between the Stokes beam and the laser beam is maximized under these conditions and, as mentioned above, no SBS occurs in the forward direction. The steady-state nonlinear polarization amplitudes for backward SBS are

$$\mathcal{P}^{\text{NL}}(z, \omega_{0,1}) = [\varepsilon_0] 6\chi_B(\omega_{0,1})$$
$$\times |A(z, \omega_{1,0})|^2 A(z, \omega_{0,1}) , \tag{72.57}$$

where $\chi_B(\omega_{0,1}) \equiv \chi^{(3)}(\omega_{0,1}; \omega_{0,1}, \omega_{1,0}, -\omega_{1,0})$, the Brillouin susceptibility, depends only on $\Omega = \omega_0 - \omega_1$ and is given by

$$\chi_B(\omega_{0,1}) = \left[\frac{1}{\varepsilon_0}\right] \frac{\omega_0^2 \gamma_e^2}{24\pi^2 c^2 \rho_0} \frac{1}{\Omega_B^2 - \Omega^2 \mp i\Gamma_B\Omega} , \tag{72.58}$$

where the minus (plus) sign is taken for the ω_0 (ω_1) susceptibility, γ_e is the electrostrictive constant, ρ_0 is the mean density of the material, and Γ_B is the Brillouin linewidth given by the inverse of the phonon lifetime. If the pump field is undepleted by the interaction with the ω_1 field and is assumed to be constant, the solution for the output intensity of the ω_1 field at $z = 0$ is given by

$$I(0, \omega_1) = I(L, \omega_1)\,e^{G_B} , \tag{72.59}$$

where the Brillouin gain coefficient G_B is given by

$$G_B = \left[\frac{1}{16\pi^2\varepsilon_0}\right] 48\pi^2 \frac{\omega_1}{(n_0 c)^2} \text{Im}[\chi_B(\omega_1)] I_0 L,$$
$$= g_0 \frac{\Omega \Omega_B \Gamma_B^2}{\left[\Omega_B^2 - \Omega^2\right]^2 + (\Omega\Gamma_B)^2} I_0 L$$
$$= g_B I_0 L , \tag{72.60}$$

g_B is the SBS gain factor, I_0 is the input intensity of the pump field, and

$$g_0 = \left[\frac{1}{\varepsilon_0^2}\right] \frac{\omega_0^2 \gamma_e^2}{n_0 c^3 \rho_0 v \Gamma_B} \tag{72.61}$$

is the line-center (i. e., $\Omega = \pm\Omega_B$) SBS gain factor. For $\Omega > 0$ ($\Omega < 0$), the ω_1 field is termed the Stokes (anti-Stokes) field, and it experiences exponential amplification (attenuation). For sufficiently large gains (typically $G_B \gtrsim 25$), the Stokes wave can be seeded by spontaneous Brillouin scattering and can grow to an appreciable fraction of the pump field. For a complete discussion of the spontaneous initiation of SBS see [72.14]. For CS_2, $g_0 = 0.15\,\text{cm/MW}$.

72.6 Other Nonlinear Optical Processes

72.6.1 High–Order Harmonic Generation

If full permutation symmetry applies and the fundamental field ω is not depleted by nonlinear interactions, then the intensity of the qth harmonic is given by

$$
I(z, q\omega) = \left[\frac{1}{4\pi(4\pi\varepsilon_0)^{(q-1)/2}} \right]
$$
$$
\times \frac{2\pi q^2 \omega^2}{n^2(q\omega)c} \left[\frac{2\pi I(\omega)}{n(\omega)c} \right]^q
$$
$$
\times \left| \chi^{(q)}(q\omega; \omega, \dots, \omega) J_q(\Delta k, z_0, z) \right|^2 , \tag{72.62}
$$

where $\Delta k = [n(\omega) - n(q\omega)]\omega/c$,

$$
J_q(\Delta k, z_0, z) = \int_{z_0}^{z} \frac{e^{i\Delta k z'} dz'}{(1 + 2iz'/b)^{q-1}} , \tag{72.63}
$$

$z = z_0$ at the input face of the nonlinear medium, and b is the confocal parameter Sect. 72.3.5 of the fundamental beam. Defining $L = z - z_0$, the integral J_q can be easily evaluated in the limits $L \ll b$ and $L \gg b$. The limit $L \ll b$ corresponds to the plane-wave limit in which case

$$
|J_q(\Delta k, z_0, z)|^2 = L^2 \text{sinc}^2 \left(\frac{\Delta k L}{2} \right) . \tag{72.64}
$$

The limit $L \gg b$ corresponds to the tight-focusing configuration in which case

$$
J_q(\Delta k, z_0, z) = \begin{cases} 0, & \Delta k \le 0 , \\ \frac{\pi b}{(q-2)!} \left(\frac{b\Delta k}{2} \right)^{q-2} e^{-b\Delta k/2}, & \\ & \Delta k > 0 . \end{cases} \tag{72.65}
$$

Note that in this limit, the qth harmonic light is only generated for positive phase mismatch. *Reintjes* et al. [72.15, 16] observed both the fifth and seventh harmonics in helium gas which exhibited a dependence on $I(\omega)$ which is consistent with the $I^q(\omega)$ dependence predicted by (72.62). However, more recent experiments in gas jets have demonstrated the generation of extremely high-order harmonics which do not depend on the intensity in this simple manner (see Chapt. 74 for further discussion of this nonperturbative behavior).

72.6.2 Electro–Optic Effect

The electro-optic effect corresponds to the limit in which the frequency of one of the applied fields approaches zero. The linear electro-optic effect (or Pockels effect) can be described by a second-order susceptibility of the form $\chi^{(2)}(\omega; \omega, 0)$. This effect produces a change in the refractive index for light of certain polarizations which depends linearly on the strength of the applied low-frequency field. More generally, the linear electro-optic effect induces a change in the amount of birefringence present in an optical material. This electrically controllable change in birefringence can be used to construct amplitude modulators, frequency shifters, optical shutters, and other optoelectronic devices. Materials commonly used in such devices include KDP and lithium niobate [72.17]. If the laser beam is propagating along the optic axis (i.e., z-axis) of the material of length L and the low-frequency field E_z is also applied along the optic axis, the nonlinear index change $\Delta n = n_y - n_x$ between the components of the electric field polarized along the principal axes of the crystal is given by

$$
\Delta n = \left[\frac{1}{4\pi} \right] n_0^3 r_{63} E_z \tag{72.66}
$$

where r_{63} is one of the electro-optic coefficients.

The quadratic electro-optic effect produces a change in refractive index that scales quadratically with the applied dc electric field. This effect can be described by a third-order susceptibility of the form $\chi^{(3)}(\omega; \omega, 0, 0)$.

72.6.3 Photorefractive Effect

The photorefractive effect leads to an optically induced change in the refractive index of a material. In certain ways this effect mimics that of the nonlinear refractive index described in Sect. 72.1.2, but it differs from the nonlinear refractive index in that the change in refractive index is independent of the overall intensity of the incident light field, and depends only on the degree of spatial modulation of the light field within the nonlinear material. In addition, the photorefractive effect can occur only in materials that exhibit a linear electro-optic effect, and contain an appreciable density of trapped electrons and/or holes that can be liberated by the application of a light field. Typical photorefractive materials include lithium niobate, barium titanate, and strontium barium niobate.

A typical photorefractive configuration might be as follows: two beams interfere within a photorefractive crystal to produce a spatially modulated intensity distribution. Bound charges are ionized with greater probability at the maxima than at the minima of the distribution and, as a result of the diffusion process, carriers tend to migrate away from regions of large light intensity. The resulting modulation of the charge distribution leads to the creation of a spatially modulated electric field that produces a spatially modulated change in refractive index as a consequence of the linear electro-optic effect. For a more extensive discussion see [72.18].

72.6.4 Ultrafast and Intense–Field Nonlinear Optics

Additional nonlinear optical processes are enabled by the use of ultrashort (< 1 ps) or ultra-intense laser pulses. For reasons of basic laser physics, ultra-intense pulses are necessarily of short duration, and thus these effects normally occur together. Ultrashort laser pulses possess a broad frequency spectrum, and therefore the dispersive properties of the optical medium play a key role in the propagation of such pulses. The three-dimensional nonlinear Schrödinger equation must be modified when treating the propagation of these ultrashort pulses by including contributions that can be ignored under other circumstances [72.19,20]. These additional terms lead to processes such as space-time coupling, self-steepening, and shock wave formation [72.21, 22]. The process of self-focusing is significantly modified under short-pulse (pulse duration shorter than approximately 1 ps) excitation. For example, temporal splitting of a pulse into two components can occur; this pulse splitting lowers the peak intensity, and can lead to the arrest of the usual collapse of a pulse undergoing self-focusing [72.23]. Moreover, optical shock formation, the creation of a discontinuity in the intensity evolution of a propagating pulse, leads to supercontinuum generation, the creation of a light pulse with an extremely broad frequency spectrum [72.24]. Shock effects and the generation of supercontinuum light can also occur in one-dimensional systems, such as a microstructure optical fiber. The relatively high peak power of the ultrashort pulses from a mode-locked laser oscillator and the tight confinement of the optical field in the small ($\approx 2\,\mu$m) core of the fiber yield high intensities and strong self-phase modulation, which results in a spectral bandwidth that spans more than an octave of the central frequency of the pulse [72.25]. Such a coherent octave-spanning spectrum allows for the stabilization of the underlying frequency comb of the mode-locked oscillator, and has led to a revolution in the field of frequency metrology [72.26]. Multiphoton absorption [72.27] constitutes an important loss process that becomes important for intensities in excess of $\approx 10^{13}\,\mathrm{W/cm^2}$. In addition to introducing loss, the electrons released by this process can produce additional nonlinear effects associated with their relativistic motion in the resulting plasma [72.28, 29]. For very large laser intensities (greater than approximately $10^{16}\,\mathrm{W/cm^2}$), the electric field strength of the laser pulse can exceed the strength of the Coulomb field that binds the electron to the atomic core, and nonperturbative effects can occur. A dramatic example is that of high-harmonic generation [72.30–32]. Harmonic orders as large as the 341-st have been observed, and simple conceptual models have been developed to explain this effect [72.33]. Under suitable conditions the harmonic orders can be suitably phased so that attosecond pulses are generated [72.34].

73. Coherent Transients

Coherent optical transients are excited in atomic and molecular systems when a stable phase relation persists between an exciting light field and the system's electronic response. The extreme sensitivity of phase–dependent effects is responsible for the many applications of optical transient techniques in atomic and molecular physics [73.1–7].

The theory of coherent transients distinguishes carefully between two types of relaxation: homogeneous and inhomogeneous. Relaxation occurs whenever the environment of a physical system fluctuates randomly. By random environment one means the combination of all interactions that are too complex to be treated fundamentally, and that can be seen to lead to degradation of the degree of coherence of a particular interaction of main interest. The time scale of environmental fluctuations then provides the division between the two types.

When environmental fluctuations are sufficiently rapid that all dynamical systems in a macroscopic sample experience the whole range of fluctuations in a time short compared with the time of an experiment, the resultant relaxation is called homogeneous. If environmental fluctuations exist randomly over a macroscopic sample, but change relatively slowly in time, then the relaxation is called inhomogeneous. For example, weak distant collisions are experienced constantly by all atoms at thermal equilibrium in a vapor cell, and give rise to homogeneous relaxation. If the vapor is sufficiently dilute, the same atoms may nevertheless retain for long times their own individual velocities. These velocities are relatively fixed in time, but they are random over the Maxwellian distribution of velocities and so give rise to inhomogeneous relaxation. Fundamentally,

the distinction between homogeneous and inhomogeneous relaxation is artificial, depending on a separation of time scales that may not always exist. Nevertheless, when it exists, the distinction provides an extremely useful way to classify coherent transients. It is one of the foundations of the subject.

The presence of quantum entanglement leads to nonintuitive effects in coherent transients.

73.1 Optical Bloch Equations

A very weakly excited dipole transition in an atom responds linearly to an applied time-dependent electric field. This is the basis of classical Lorentzian dielec-

tric theory, but because any transition can be inverted, an atom is more than a classical linear oscillator [73.8]. The three atomic variables that describe the primary co-

herent optical transients in a dipole-allowed transition include the intrinsically quantum mechanical inversion variable, as well as the components of the expectation value of the atomic dipole moment that are in-phase and in-quadrature with the field.

We write the time-dependent atomic dipole moment of a transition excited by light near exact resonance in the form

$$-\langle ex(t)\rangle = -\langle \Psi(t)|ex|\Psi(t)\rangle$$
$$= \mathrm{Re}\left[d(U - iV)\,e^{-i\omega t}\right] , \qquad (73.1)$$

where d is the transition dipole matrix element, ω is the frequency of the impressed optical field, and U and V are the time-dependent amplitudes of the in-phase and in-quadrature dipole components. The impressed field is taken in the quasi-monochromatic form

$$E(t) = \frac{1}{2}\left(\mathcal{E}\,e^{-i\omega t} + \text{c.c.}\right) \qquad (73.2)$$

Both dipole moment and field will be taken to be real scalars because the complications of vector notation add

little to a first discussion of the principles of coherent transients.

Section 68.3.5 shows that U and V are dynamically coupled to each other and to the inversion W through the optical Bloch equations (OBE). When relaxation terms are included, the OBEs are given by (68.55). These are

$$\frac{dU}{dt} = -\Delta V - U/T_2 ,$$
$$\frac{dV}{dt} = \Delta U + \Omega_1 W - V/T_2 ,$$
$$\frac{dW}{dt} = -\Omega_1 V - (W - W_{\mathrm{eq}})/T_1 , \qquad (73.3)$$

the key equations of the theory of optical transients [73.1, 2].

As in Chapt. 68, $\Delta = (E_e - E_g)/\hbar - \omega$ is the detuning and $\Omega_1 = d\mathcal{E}/\hbar$ is the Rabi frequency. It is the dipole interaction energy in frequency units, but has a significance beyond this, as discussed in Sect. 73.3.1.

73.2 Numerical Estimates of Parameters

The nature of the coherent interaction between an atom or molecule and an optical field is controlled by the relative size of a number of frequencies or rates. In the case of single photon transitions they include: Δ and Ω_1, the detuning and Rabi frequency defined above, $1/T_2$ the transverse, and $1/T_1$ the longitudinal damping rates, $1/T^*$ the inhomogenenous linewidth, and $2\pi/\tau_\mathrm{p}$ the transform bandwidth of the optical pulse. All of these frequencies with the exception of the last are defined in Chapt. 68. In the case of multiphoton transitions and simultaneous excitation by a number of resonant laser fields, the appropriately generalized versions of these same parameters apply.

A laser pulse with $\tau_\mathrm{p} \geq 1\,\mathrm{ns}$ and with an intensity less than about $1\,\mathrm{GW/cm^2}$ can be tuned to an isolated atomic resonance and the interaction can be described in terms of a simple two-level theory. Laser pulses as short as a few fs in duration, or with intensities as

high as $10^{22}\,\mathrm{W/cm^2}$, have been produced and such extreme pulses quasi-resonantly excite more than one upper level. A 1 ps pulse has a bandwidth of approximately $20\,\mathrm{cm^{-1}}$, while a 1 fs pulse has a bandwidth of about $20\,000\,\mathrm{cm^{-1}}$. If a 1 ps pulse were tuned so that it resonantly excited the $n = 95$ Rydberg state of an atom, it would simultaneously and coherently excite all the levels from $n = 67$ to the continuum limit, while a 10 fs pulse could excite all the levels from $n = 4$ to the continuum.

Similarly, when laser pulses are intense enough so that the electric field amplitude approaches that of the Coulomb field holding the atom together – in hydrogen this occurs at an intensity of $3.6 \times 10^{16}\,\mathrm{W/cm^2}$ – a Rabi frequency on the order of $200\,000\,\mathrm{cm^{-1}}$ is generated, again much more than enough to excite a coherent superposition of all atomic bound states [73.9].

73.3 Homogeneous Relaxation

Homogeneous relaxation is dominant in well-collimated atomic and molecular beams as well as in high-pressure vapor cells. In the absence of a laser field ($\Omega_1 = 0$) the

solutions of the OBEs are

$$(U - iV) = (U - iV)_0\,e^{-(1/T_2 + i\Delta)t} ,$$

$$W = -1 + (W_0 + 1)\,e^{-t/T_1} \,, \qquad (73.4)$$

where the subscript denotes values at $t = 0$. The roles of T_1 and T_2 as relaxation times are clear. They are homogeneous because they apply to each atom individually.

73.3.1 Rabi Oscillations

The OBEs predict coherent damped oscillations of the inversion with the angular Rabi frequency Ω_1 if Ω_1 is large enough, such that $\Omega_1 T_1 \gg 1$ and $\Omega_1 T_2 \gg 1$. These oscillations were originally called optical nutations following the terminology of nuclear magnetic resonance, however they are now usually called Rabi oscillations. Figure 73.1 shows the behavior of the atomic variables undergoing Rabi oscillations in a representative case.

73.3.2 Bloch Vector and Bloch Sphere

Coherent dynamical behavior is simplest for times much shorter than the relaxation times T_1 and T_2. In this case, the damping terms can be dropped from the OBEs and the resulting equations written in the form (Sect. 68.3.5)

$$\frac{\mathrm{d}\boldsymbol{U}}{\mathrm{d}t} = \boldsymbol{\Omega} \times \boldsymbol{U} \,, \qquad (73.5)$$

where $\boldsymbol{U} = (U, V, W)$ is the Bloch vector, and $\boldsymbol{\Omega} = (-\Omega_1, 0, \Delta)$ acts as a torque vector defining the axis and rate of precession. By conservation of probability, $\boldsymbol{U} \cdot \boldsymbol{U} = 1$.

All possible quantum states of the two-level atom are mapped onto a unit sphere in U–V–W space. Conventionally, W defines the polar axis with the atomic ground state the south pole, and the excited state the north pole. Points on the sphere between the poles are coherent superpositions of the two states. The azimuthal angle ϕ represents the phase between the expectation value of the dipole moment and the optical field. In Fig. 73.2 the solutions to (73.5) are shown for the case of a square pulse applied to an atom in its ground state at $t = 0$. The solutions in this case are

$$U(t, \Delta) = \frac{\Omega_1}{\Omega} \sin \Omega t \,,$$

$$V(t, \Delta) = -\frac{\Delta \Omega_1}{\Omega^2}(1 - \cos \Omega t) \,,$$

$$W(t, \Delta) = -1 + \frac{\Omega_1^2}{\Omega^2}(1 - \cos \Omega t) \,. \qquad (73.6)$$
Fig. 73.1 Damped Rabi oscillations of the atomic variables after sudden turn-on of the field. In this example $T_1 = T_2$, $\Delta T_2 = 1$, and $\Omega_1 T_2 = 15$

For any Δ the solution orbit is a circle on the surface of the sphere with the orbit passing through the south pole. The rate at which the system precesses about the circle is given by the generalized Rabi frequency $\Omega \equiv \sqrt{\Delta^2 + \Omega_1^2}$.

73.3.3 Pi Pulses and Pulse Area

The exactly resonant ($\Delta = 0$) undamped OBEs can be solved analytically even for arbitrarily time dependent laser pulse envelopes. The solutions are

$$U(t, 0) = 0 \,,$$
$$V(t, 0) = -\sin \theta(t) \,,$$
$$W(t, 0) = -\cos \theta(t) \,, \qquad (73.7)$$
Fig. 73.2 Orbits of the Bloch vector on the unit sphere for various ratios of the detuning Δ to the Rabi frequency Ω_1

a rotation of the Bloch vector in the V–W plane. The angle θ is called the *pulse area,* defined by

$$\theta(t) \equiv \int_{-\infty}^{t} dt'\, \Omega_1(t') = \frac{d}{\hbar} \int_{-\infty}^{t} dt'\, \mathcal{E}(t') \,. \qquad (73.8)$$

The area under the envelope of the Rabi frequency is thus the same as the angle through which an exactly-resonant Bloch vector turns due to the pulse. If $\theta = \pi$, the atom is driven from the ground state exactly to the excited state. This is "π-pulse" inversion. A "2π-pulse" takes the atom from the ground state through the excited state and back to the ground state. For $\Delta = 0$, the Bloch vector rotation angle does not depend upon the shape of the field pulse, only on the area of the pulse.

73.3.4 Adiabatic Following

The Bloch vector picture is used for semiquantitative predictions. These are reliable even if Δ and Ω_1 are time-dependent, if the parameters change slowly (adiabatically). For example, if $\boldsymbol{\Omega}$ is moved slowly the Bloch vector follows closely. It is possible to achieve complete inversion smoothly in this way. If the field is initially tuned far below resonance so $\Delta \ll \Omega_1$ then $\boldsymbol{\Omega}$ points approximately toward the south pole of the Bloch sphere.

As shown in Fig. 73.3, the Bloch vector then precesses in a very small circle about the torque vector. If the field frequency is now slowly changed (chirped) so that Δ goes from a large negative value to a large positive value then every atomic Bloch vector will continue to precess rapidly around the torque vector, and follow it as it proceeds from pointing straight down to pointing straight up. In this way the population is transferred between the two levels.
Fig. 73.3 In adiabatic inversion the Bloch vector of each atom precesses in a small cone about the torque vector as the torque vector goes from straight down to straight up

73.4 Inhomogeneous Relaxation

The fact that the various atoms in a sample may have different resonance frequencies produces a number of novel phenomena. Given a distribution $g(\Delta)$ of detunings in a dilute gas of density N, the macroscopic polarization can be written

$$P(t) = -N\langle ex(t) \rangle$$
$$= Nd \int g(\Delta)\, \mathrm{Re}\left[(U - iV)\, e^{-i\omega t} \right] d\Delta \,, \quad (73.9)$$

where $U - iV$ generally depends on both t and Δ.

73.4.1 Free Induction Decay

Free induction refers to evolution of the polarization in the absence of a laser field. For $\Omega_1 = 0$, the Bloch vector of an atom with $\Delta < 0$ precesses counterclockwise in the U–V plane. In a macroscopic sample, there are many values of Δ and about as many are positive as negative. Thus an oriented collection of Bloch vectors, all pointing in the V di-

rection at $t = 0$, will rapidly fan out in the U–V plane due to differing precession rates, and after a short time the net V value will be zero, as will the net U value. This is free induction decay (FID) of polarization.

More precisely, if all atoms are first exposed to a θ_0 pulse, so that at $t = 0$

$$U(0, \Delta) = 0 \,,$$
$$V(0, \Delta) = -\sin\theta_0 \,, \qquad (73.10)$$
$$W(0, \Delta) = -\cos\theta_0 \,,$$

then if $\mathcal{E} = 0$ for $t > 0$, an individual atom with detuning Δ evolves according to (73.4):

$$U - iV = i\sin\theta_0\, e^{-(1/T_2 - i\Delta)t} \,. \qquad (73.11)$$

The macroscopic polarization is found by summing the individual $(U - iV)$ values over the detuning distribution $g(\Delta)$.

For simplicity, in this subsection we will ignore competition from homogeneous decay (take $1/T_2 \approx 0$)

and assume the most common inhomogeneous lineshape (i.e., Doppler-Maxwellian):

$$g(\Delta) = \frac{T^*}{\sqrt{2\pi}}\, e^{-(\Delta - \Delta_0)^2 T^{*2}/2}, \qquad (73.12)$$

where $1/T^*$ is here defined as the width (standard deviation) of the Doppler distribution and Δ_0 is the detuning of the zero-velocity atoms. The collective result is

$$P(t) = Nd \sin\theta_0 \sin\omega t\, e^{i\Delta_0 t} \exp\left(-\frac{t^2}{2T^{*2}}\right). \quad (73.13)$$

The detuning "inhomogeneity" in the sample leads to dephasing of the collective dipole moment, and the inhomogeneous relaxation time is obviously T^*. This is illustrated by the decrease of collective alignment of Bloch vectors in the top row of Fig. 73.4. For a typical room temperature gas a visible transition has a width given by $1/(2\pi T^*) \approx 1.5$ GHz so that $T^* \approx 10^{-10}$ s.

73.4.2 Photon Echoes

A photon echo is generated by pulse-induced recovery of a nonzero $P(t)$ after $P(t) \to 0$ due to free induction decay (FID). This analog of the spin echo effect is possible because each atom retains its own detuning for a relatively long time, usually up to an average collision time T_2.

During FID, the U–V projection of every atom's Bloch vector precesses steadily clockwise or counterclockwise depending on the sign of its Δ. Thus the Bloch vectors could be rephased if they could all be forced at the same moment to reverse their relative sense of precession. The prototypical echo scenario has FID beginning at $t = 0$, with $P(t) \to 0$ for $t \gg T^*$, followed by a π–pulse at the time t', where $t' \gg T^*$. The effect of the π-pulse is to reverse the sign of V and W [recall (73.10)], in effect flipping the equatorial plane of the Bloch sphere upside down. Thus for $t \gg t'$ we have Bloch vectors fanning back together. The macroscopic
Fig. 73.4 The ensemble of dipole moments spreads due to the distribution of resonance frequencies. The distribution of Bloch vectors in the U–V plane is shown at various times after the initial short pulse excitation. By the time t', the dipoles have spread uniformly around the unit circle. A π-pulse then flips the relative orientation of the dipoles so that they subsequently rephase

polarization obeys

$$P(t) = Nd \sin\theta_0 \sin\omega t \exp\left[-\frac{(t - 2t')^2}{2T^{*2}}\right] e^{-t/T_2}, \quad (73.14)$$

where the last factor recovers the effect of homogeneous dipole damping. We require $T_2 \gg t' \gg T^*$ for a strong echo signal in the neighborhood of $t = t'$.

The result is illustrated in Fig. 73.4. An "echo" of the initial excitation at $t = 0$ appears at the time $t = 2t'$. After this, FID occurs again, and this second decay can also be reversed by applying another π–pulse, and so on, until $t \approx T_2$, at which time the inevitable and irreversible homogeneous relaxation cannot be avoided. The scenario of π–pulse reversal is only the most ideal, leading to the most complete echo, and other pulse areas will also lead to echos; a more important factor is that the reversing pulse must be short enough that negligible dephasing takes place during its application.

73.5 Resonant Pulse Propagation

73.5.1 Maxwell–Bloch Equations

Time-dependent atomic dipole moments created by applied fields are themselves a source of fields, another

form of coherent transient. We limit discussion to plane-wave propagation in the z–direction. Note that we use z rather than Z for convenience, although in the dipole approximation the coordinate entering our equations is the

coordinate of the center of mass of the atom rather than the internal electron coordinate. The field is generalized from (73.2) to

$$E(t, z) = \frac{1}{2} \left[\mathcal{E}(t, z) e^{i(Kz - \omega t)} + c.c. \right] , \qquad (73.15)$$

and the macroscopic polarization is the correspondingly generalized form of (73.9):

$$P(t, z) = Nd \int g(\Delta) \operatorname{Re} \left[(U - iV) e^{i(Kz - \omega t)} \right] d\Delta . \tag{73.16}$$

The difference between K and $k = \omega/c$ indicates that the refractive index is nonzero. The traveling-pulse rotating frame is also obtained by replacing ωt by $\omega t - Kz$.

If the field envelope $\mathcal{E}$ is slowly varying, its second derivatives can be dropped when $E(t, z)$ is substituted into Maxwell's wave equation. The resulting dispersive and absorptive reduced wave equations are

$$\left(K^2 - k^2 \right) \mathcal{E} = 4\pi k^2 Nd$$
$$\times \int g(\Delta) U(t, z, \Delta) d\Delta , \tag{73.17}$$

$$\left(K \frac{\partial}{\partial z} + k \frac{\partial}{\partial (ct)} \right) \mathcal{E} = 2\pi k^2 Nd$$
$$\times \int g(\Delta) V(t, z, \Delta) d\Delta .$$

The Bloch equations along with these reduced wave equations form the self-consistent Maxwell–Bloch equations that are used to treat most resonant propagation problems in quantum optics and laser theory [73.1, 2, 5, 8].

73.5.2 Index of Refraction and Beers Law

If a weak pulse of duration τ propagates in a medium of ground-state atoms ($W \approx -1$), the Bloch equations have simple quasisteady-state solutions ($\tau \gg T_2$)

$$U = \frac{\Omega_1 \Delta}{\Delta^2 + 1/T_2^2} ,$$
$$V = \frac{-\Omega_1/T_2}{\Delta^2 + 1/T_2^2} . \tag{73.18}$$

When U and V are substituted back into the reduced wave equations (73.17), the dispersive equation gives the index of refraction $n = K/k$ due to the ground-state atoms:

$$n^2 - 1 = \frac{4\pi Nd^2}{\hbar} \int \frac{\Delta g(\Delta)}{\Delta^2 + 1/T_2^2} d\Delta , \tag{73.19}$$

and the absorptive equation predicts steady state field attenuation during propagation:

$$\frac{\partial}{\partial z} \mathcal{E} = -\frac{1}{2} \alpha_B \mathcal{E} . \tag{73.20}$$

The constant α_B given by

$$\alpha_B = \frac{4\pi Nd^2 \omega}{\hbar c T_2} \int \frac{g(\Delta)}{\Delta^2 + 1/T_2^2} d\Delta \tag{73.21}$$

is called the extinction coefficient, or the reciprocal Beers length.

Since field intensity I is proportional to $\mathcal{E}^2$, the solution to the absorptive equation is

$$I(z, t) = I(0, t) e^{-\alpha_B z} . \tag{73.22}$$

This relation is called Beers Law. Both the dispersive and absorptive results are familiar from classical physics [73.10], with the important distinction that here the $\hbar$-dependent oscillator strength enters naturally rather than as an empirical parameter from Lorentzian dielectric theory [73.8, 10].

73.5.3 The Area Theorem and Self–Induced Transparency

A form of pulse propagation with no classical analog arises in the short-pulse limit ($\tau \ll T_2, T_1$, but $\tau \gg T_2^*$). By integration over the entire pulse, the absorptive Maxwell equation becomes an equation for $\partial \theta / \partial z$, where θ is the pulse area defined in (73.8). In the short-pulse limit, the relaxation terms in the OBEs can be ignored and when substituting from them we obtain the McCall-Hahn Area Theorem [73.1]:

$$\frac{\partial}{\partial z} \theta(z) = -\frac{1}{2} \alpha_B \sin \theta(z) . \tag{73.23}$$

This predicts the same exponential attenuation as (73.20) in the case of a small area pulse, $\theta(z) \ll \pi$, but in the case of larger area pulses the behavior is quite different. In general, the area decreases during propagation for areas in the range $0 < \theta(z) < \pi$, but it increases for areas $\pi < \theta(z) < 2\pi$. As seen from Fig. 73.5, this change of area with propagation causes the pulse area to evolve to one of the stable values $0, 2\pi, 4\pi, \ldots$.

There is one special pulse, a soliton solution with area exactly 2π, which propagates without shape change in the short pulse limit, given by

$$\mathcal{E}(t, z) = \frac{2\hbar}{\tau d} \operatorname{sech} \left(\frac{t - z/v}{\tau} \right) , \tag{73.24}$$

where τ is the pulse duration, which is arbitrary but must satisfy the short-pulse inequality $\tau \ll T_1, T_2$. The soliton's group velocity is determined by the corresponding

Fig. 73.5 McCall-Hahn area theorem for an absorbing medium. On propagation the area of the pulse will follow the arrows toward one of the stable values, $0, 2\pi, 4\pi, \ldots$

soliton solutions to the OBE's and the dispersive

$$v = \frac{c}{1 + \frac{1}{2}\alpha_B c\tau} , \quad (73.25)$$

where α_B is to be taken in the limit $T_2^* \ll T_2$. The group velocity can be slower than the speed of light by orders of magnitude if $\alpha_B c\tau \gg 1$.
73.6 Multi-Level Generalizations

73.6.1 Rydberg Packets and Intrinsic Relaxation

A short laser pulse can populate a band of excited states whose probability amplitudes will exhibit mutual coherence. This single-atom coherence is transient, even without collisions or other external perturbations to disrupt it, and its decay can be called intrinsic relaxation. The decay is basically a dephasing. The dipole moments associated with the excited band interfere due to the wide variety of resonance frequencies of the states in the superposition. Because of the discreteness of the energy levels of any bounded quantum system, this relaxation has its own unique characteristics, including similarities with both homogeneous and inhomogeneous decay.

The wave function for a coherently excited atom can be expressed in the interaction picture in the form [73.9]

$$\Psi(r, t) = a(t)\psi_g(r) + \sum_n b_n(t)\, e^{-i\omega_n t}\psi_n(r) , \quad (73.26)$$

where $\psi_g(r)$ is the ground state wave function, and n labels the states in a band with excitation frequencies $\omega_n \approx \omega$. If $|\omega_n - \omega| \ll \omega_n$, the transition frequency ω_n can be expanded about the principal quantum number $\overline{n}$ of the resonant excited state $E_{\overline{n}} = \hbar\omega$ to obtain

$$\omega_n = \omega_{\overline{n}} + (n - \overline{n})\frac{\partial\omega_n}{\partial n} + \frac{1}{2!}(n - \overline{n})^2\frac{\partial^2\omega_n}{\partial n^2} + \cdots$$

$$= \omega_{\overline{n}} + (n - \overline{n})\frac{2\pi}{T_K} + (n - \overline{n})^2\frac{2\pi}{T_R} + \cdots . \quad (73.27)$$

Thus $2\pi/T_K$ is the mean frequency separating neighboring levels, i.e., $T_K/2\pi = \hbar\rho(E)$, where $\rho(E)$ is the density of excited states, and $2\pi/T_R$ is the mean change in this frequency separation. T_K is the same as the Kepler period a classical orbit, and T_R is the revival time.

Substituting the Bohr frequencies into the definitions for T_K and T_R yields $T_R = \overline{n}T_K/3$.

For times $t \leq T_R$ the expansion can be truncated after the third term. Then the wave function is given approximately by

$$\Psi(r, t) \approx a(t)\psi_g(r) + e^{-i\omega_{\overline{n}} t}\sum_m b_{\overline{n}+m}(t)\, e^{-i2\pi mt/T_K}$$

$$\times e^{-i2\pi m^2 t/T_R}\psi_{\overline{n}+m}(r) , \quad (73.28)$$

where $m = n - \overline{n}$. For high Rydberg states, $\overline{n} \gg 1$, the time scales associated with the two exponentials inside the sum are quite different. For times $t \ll T_K$ the individual levels are not resolved, thus the laser excites what is effectively a continuum with a density of states $\rho(E)$. In that case the ground state population simply decays exponentially at the rate given by first-order perturbation theory, $\Gamma = (2\pi/\hbar)d^2\mathcal{E}^2\rho(E)$. At longer times $t \approx T_K$, the first exponential contributes, but the second does not, giving a simple Fourier series time dependence. In this regime the evolution of the wave function is just periodic motion of a wave packet around a Kepler orbit, as is illustrated in Fig. 73.6a.

The coherent quantum wave packet behaves like a classical particle for many Kepler periods, gradually spreading out as the second exponential in the sum (73.28) begins to contribute. This spreading of the wave packet produces the intrinsic relaxation of the collective dipole moments from the various transitions. However, because the levels are discrete, this decay is not permanent, but is reversed and leads to a spontaneous "revival" of the original wave packet [73.6], without the need for a π-pulse to produce an "echo."

In its evolution toward the revival, the wave packet passes through a number of fractional revivals in which

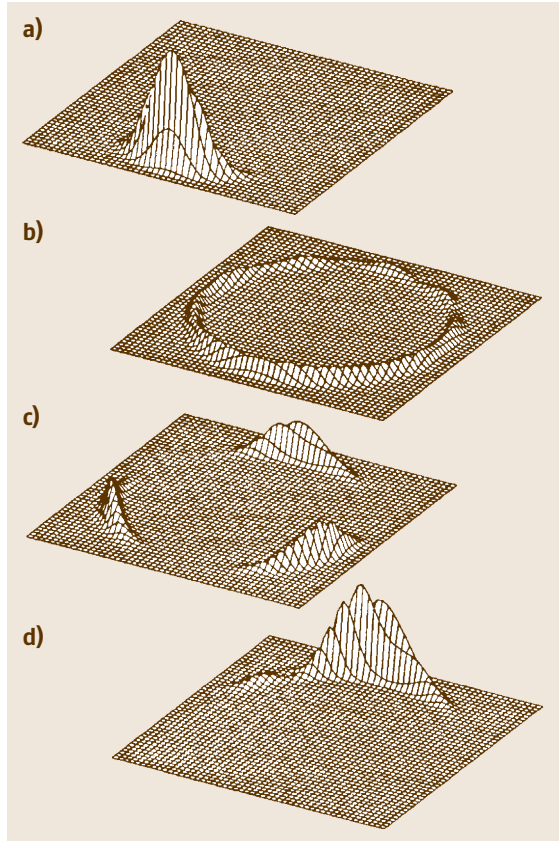
miniature replicas of the original wave packet are equally spaced around the orbit, each traveling at the velocity of a particle traveling in a corresponding classical Kepler orbit. This complex time evolution arises from the spreading of the wave packet all the way around the orbit so that the head and tail of the packet interfere with each other, producing interference fringes. The further evolution of this fringe pattern produces the various revival phenomena shown in Fig. 73.6.


Fig. 73.6a–d The free evolution of a Rydberg wave packet made up of a superposition of circular-orbit states centered about $n = 360$. **(a)** Initially the wave packet is to good approximation a minimum uncertainty wave packet in all three dimensions, but after 12 orbits **(b)** the packet has spread all the way around the orbit so that the head and tail of the wave packet overlap, producing interference fringes. **(c)** After 40 orbits, $t = T_R/3$, the fringes have produced the one-third fractional revival in which three miniature replicas of the original wave packet are equally spaced around the orbit. **(d)** After 120 orbits, $t = T_R$, the complete wave packet revival occurs

73.6.2 Multiphoton Resonance and Two-Photon Bloch Equations

Multiphoton transitions Fig. 73.7a introduce new coherent transient phenomena. If levels $|g\rangle$ and $|e\rangle$ have the same parity, two photons from the same laser field are sufficient to excite level $|e\rangle$. For simplicity we regard $|e\rangle$ as a single state, but any number of intermediate levels $|j\rangle$ of opposite parity may be present.

Substituting the state vector

$$|\Psi(t)\rangle = a_g(t)|g\rangle + \sum_j b_j(t)\, e^{-i\omega t}|j\rangle$$
$$+ a_e(t)\, e^{-i2\omega t}|e\rangle \,, \tag{73.29}$$

into the Schrödinger equation yields

$$i\frac{da_g}{dt} = -\frac{1}{2}\sum_j \Omega_{gj} b_j \,, \tag{73.30}$$

$$i\frac{db_j}{dt} = \Delta_{jg} b_j - \frac{1}{2}\left(\Omega_{jg} a_g + \Omega_{je} a_e\right) \,, \tag{73.31}$$

$$i\frac{da_e}{dt} = \Delta_{eg} a_e - \frac{1}{2}\sum_j \Omega_{ej} b_j \,, \tag{73.32}$$

where the Δs are the detunings and the Ωs are the Rabi frequencies for the dipole-allowed transitions. For example, $\Omega_{gj} = d_{gj}\mathcal{E}/\hbar$, and $\Delta_{jg} = (E_j - E_g)/\hbar - \omega$ and $\Delta_{eg} = (E_e - E_g)/\hbar - 2\omega$.

If the states $|j\rangle$ are not too close to resonance, the b_j oscillate rapidly and to a first approximation average to zero. A better approximation is to retain the small nonzero solution for b_j obtained by setting $db_j/dt = 0$ in (73.31) to obtain

$$b_j = -\frac{\left[\Omega_{jg} a_g + \Omega_{je} a_e\right]}{2\Delta_{jg}} \,, \tag{73.33}$$
Fig. 73.7a,b Model two-photon resonances. Two photons couple the ground state $|g\rangle$ with an excited state $|e\rangle$. Many intermediate nonresonant levels $|j\rangle$ are present. In **(a)** we have the cascade system, and in **(b)** the Λ pump–probe system

which can be used to eliminate b_j from the equations for a_g and a_e. This is called adiabatic elimination of dipole coherence. In this approximation, levels $|g\rangle$ and $|e\rangle$ are directly coupled to each other and two-photon coherence arises. The coupling of levels $|g\rangle$ and $|e\rangle$ is similar to the two-level coupling described in Sect. 73.1 and two-photon Bloch equations analogous to (73.5) are the result:

$$\frac{dU^{(2)}}{dt} = -\Delta^{(2)} V^{(2)} \,,$$
$$\frac{dV^{(2)}}{dt} = \Delta^{(2)} U^{(2)} + \Omega^{(2)} W^{(2)} \,,$$
$$\frac{dW^{(2)}}{dt} = -\Omega^{(2)} V^{(2)} \,, \tag{73.34}$$

Here the superscript (2) indicates that the variables are identified with the two-photon $|g\rangle \rightarrow |e\rangle$ transition.

The various coefficients are similarly generalized [73.11]. For example, the two-photon Rabi frequency is given by

$$\Omega^{(2)} \equiv \frac{1}{2} \sum_j \frac{d_{gj} d_{je}}{\hbar^2 \Delta_{jg}} \mathcal{E}^2 \,. \tag{73.35}$$

and the two-photon detuning $\Delta^{(2)}$ incorporates the laser-induced level shifts

$$\Delta^{(2)} \equiv \Delta_{ej} + \Delta_{jg}$$
$$+ \frac{1}{4} \sum_j \frac{|d_{ej}|^2 \mathcal{E}^2(t)}{\hbar^2 \Delta_{ej}} + \frac{1}{4} \sum_j \frac{|d_{jg}|^2 \mathcal{E}^2(t)}{\hbar^2 \Delta_{jg}} \,. \tag{73.36}$$

The last two terms give the difference in the ac Stark shifts of the upper and lower levels produced by the laser field.

$W^{(2)}$ is the inversion as before, but $U^{(2)}$ and $V^{(2)}$ are somewhat different. They cannot be directly tied to the expectation value of a dipole moment because levels $|g\rangle$ and $|e\rangle$ have the same parity. Thus, while the quantity $U^{(2)} - \mathrm{i} V^{(2)}$ is the two-photon analog of $U - \mathrm{i} V$ in the original OBE's, it cannot serve as a source term in the Maxwell equation.

In the case of cw applied fields, the solutions to the two-photon OBEs are formally identical to those for a two-level atom. In the case of pulsed fields, however, the detuning $\Delta^{(2)}(t)$ is automatically "chirped" in frequency by the Stark shifts. This chirping may significantly modify the dynamics. Multiphoton generalizations of the Bloch equations can be made for other arrangements and numbers of levels. The two-photon

version applies as well to three-level Λ and V configurations as to the cascade system shown in Fig. 73.7a, for which they were derived.

73.6.3 Pump–Probe Resonance and Dark States

Dark states or trapping states occur whenever a field-dependent linear combination of active levels is dynamically disconnected from the other levels. This occurs, e.g., in a pump-probe interaction, which fits the scenario of Fig. 73.7 if two lasers instead of one are used to excite level $|e\rangle$ from the ground level via two-photon resonance. A strong steady laser a is applied for the $|g\rangle \rightarrow |j\rangle$ transitions and a weak tunable "probe" laser b for the $|j\rangle \rightarrow |e\rangle$ transitions. In the simplest format, $\Delta_{eg} = 0$, and all the $|j\rangle$ levels can be combined into a single level labeled $|2\rangle$.

The three-level state vector can be written in terms of field-free states

$$|\Psi(t)\rangle = a_g|g\rangle + b_2|2\rangle + a_e|e\rangle \,, \tag{73.37}$$

or, in terms of field-dependent dressed states

$$|\Psi(t)\rangle = A_{\mathrm{T}}|T\rangle + b_2|2\rangle + A_S|S\rangle \,, \tag{73.38}$$

where $\Omega|T\rangle \equiv \Omega_a|e\rangle - \Omega_b|g\rangle$, $\Omega|S\rangle \equiv \Omega_a|g\rangle + \Omega_b|e\rangle$ and

$$A_S(t) \equiv \Omega^{-1}[\Omega_a a_g + \Omega_b a_e] \,,$$
$$A_{\mathrm{T}}(t) \equiv \Omega^{-1}[\Omega_a a_e - \Omega_b a_g] \,. \tag{73.39}$$

The normalizing factor is $\Omega \equiv \sqrt{\Omega_a^2 + \Omega_b^2}$.

The state $|T\rangle$ is an eigenvector of the three-level RWA Hamiltonian, with eigenvalue zero, and the amplitude $A_{\mathrm{T}}(t)$ is a constant of motion. Thus $|T\rangle$ is termed a trapping state, and population in $|T\rangle$ is inaccessible to the (possibly very strong) laser fields. At two-photon resonance this conclusion is robust, not depending strongly on the idealized conditions assumed here. In fact, A_{T}, the trapping state amplitude, is an adiabatic invariant, remaining constant to first order even under slow changes in Ω_a and Ω_b. In a pump-probe experiment, this trapping state is observed as an abrupt drop in probe absorption as the probe frequency is tuned through two-photon resonance. Since only two-photon resonance is required (both transitions can be equally detuned) this coherent transient effect has no analog in two-level physics.

The ideal method for exciting the trapping state from the ground state uses another coherent transient process called counter-intuitive pulse sequencing in which pulse b is turned on first. The trapping state $|T\rangle$ is essentially

the ground state $|g\rangle$ if $\Omega_a = 0$. Thus if Ω_b is turned on first, and then Ω_a turned on later, the ground state adiabatically becomes the trapping state and all initial probability flows smoothly with it.

An essential point is the ease with which pump-probe adiabaticity is maintained, particularly for strong fields on resonance, in contrast to one-photon adiabaticity, which is never achieved at strong-field resonance. In the pump-probe case one must only satisfy the inequality

$$\left| \frac{d\Omega_a}{dt}\Omega_b - \frac{d\Omega_b}{dt}\Omega_a \right| \ll \left(\Omega_a^2 + \Omega_b^2 \right)^{3/2} , \quad (73.40)$$

which is automatically accomplished by counter-intuitive pulse sequencing. The inequality allows one to tolerate rapid change of Ω_b while $\Omega_a = 0$. Then after Ω_b has reached a high value, Ω_a can also be turned on very rapidly because the right side of (73.40) is already very large. This is "counter-intuitive" excitation because if the population is in level $|g\rangle$ it is "natural" to turn on pulse Ω_a first, not Ω_b. It can be dramatically beneficial to use counter-intuitive excitation when it is important to avoid relaxation associated with level $|2\rangle$.

73.6.4 Three−Level Transparency

The foregoing results for three-level excitation can be extended to resonant pulse propagation in three-level media. The equations governing simultaneous two-pulse evolution in the local-time coordinates $cT \equiv ct - z$ and $\zeta \equiv z$ are

$$\frac{\partial \mathcal{E}_a}{\partial \zeta} = i\frac{\hbar}{d_a}\mu_a a_g^* b_2 ,$$
$$\frac{\partial \mathcal{E}_b}{\partial \zeta} = i\frac{\hbar}{d_b}\mu_b a_e^* b_2 , \quad (73.41)$$

where

$$\mu_a = \frac{4\pi d_a^2 N\omega_a}{\hbar c} , \quad \text{etc.} \quad (73.42)$$

Note that the bilinear combination $2a_g^* b_2$ corresponds to $U - iV$ in (73.16).

Soliton-like pulses can propagate in three-level media. Both pulses must compete for interaction with level $|2\rangle$. They depend only on a single variable $Z \equiv \zeta - uT$ where u is the pulse's constant velocity in the moving frame. Soliton solutions are given (for $\mu_a = \mu_b$) for Λ media by

$$\mathcal{E}_a = \hbar/d_a = A \operatorname{sech} KZ ,$$
$$\mathcal{E}_b = \hbar/d_b = B \tanh KZ , \quad (73.43)$$

and

$$a_g = -\tanh KZ$$
$$b_2 = \frac{-2iKu}{A} \operatorname{sech} KZ , \quad (73.44)$$
$$a_e = \frac{B}{A} \operatorname{sech} KZ ,$$

where the parameters A, B, Ku are nonlinearly related to the pulse length τ:

$$Ku \equiv 1/\tau \quad \text{and} \quad (2/\tau)^2 = A^2 - B^2 . \quad (73.45)$$

The moving frame velocity is given by $1/u = 2\mu/A^2$ and the expression for the lab frame velocity V is $1/V = 1/c + 2\mu/A^2$.

If $B \to 0$, then $\mathcal{E}_a \to \left(2\hbar/\tau d_a\right)\operatorname{sech} KZ$, which is the exact McCall–Hahn formula for the two-level one-pulse soliton amplitude [73.1]. No adiabatic condition was invoked in obtaining the soliton solutions. The physical measure of adiabaticity comes from the pulse duration τ. If τ is short, an appreciable population appears transiently in level $|2\rangle$, but if τ is long (an adiabatic pulse), the population skips level $|2\rangle$ and goes directly from $|g\rangle$ to $|e\rangle$ and back again during the pulse.

Note that the sech and tanh functions are ideally counter-intuitive, with pulse b starting infinitely far ahead of pulse a. In practice, the infinite leading edge of the tanh function plays no role and can be truncated to several times τ without appreciable change in the character of the pulse pair.

73.7 Disentanglement and "Sudden Death" of Coherent Transients

The existence of entanglement (non-separability) of states is the most prominent evidence that quantum mechanics is a truly nonlocal theory. This has consequences for coherent transients, allowing them to exhibit non-intuitive effects unlike any discussed up to this point. We will choose an example that directly illustrates this

point by showing that two entangled atoms whose inversion and coherence decay exponentially can have an entanglement that not only does not decay exponentially but which reaches its steady state long before the atoms reach their final states. In this sense the nonlocal transients of the pair of atoms are not at all

intuitively related to the local transients affecting the atoms separately.

We imagine the situation sketched in Fig. 73.8, two two-level atoms A and B of the type discussed at length already, prepared in a partially excited entangled mixed state and located remotely from each other, without direct or indirect interaction. They each must eventually, because of spontaneous emission, come to their ground states, creating the final joint state $|-_A\rangle \otimes |-_B\rangle$, which is clearly in factored form (disentangled). The question is, what is the manner of evolution by which the quantum entanglement feature evolves toward zero.

The standard Master Equation methods [73.12] for investigating spontaneous emission [73.13] can be applied to each atom separately since they are not interacting with each other. For any initial state $\rho^{AB}(0)$, the density operator at t can be expressed as

$$\rho^{AB}(t) = \sum_{\mu=1}^{4} K_\mu(t) \rho^{AB}(0) K_\mu^\dagger(t), \tag{73.46}$$

where the so-called Kraus operators [73.14] $K_\mu(t)$ are available in closed form in this case [73.15].

For illustration we will choose a partially coherent initial state, expressed by a two-atom density matrix with a single free parameter a:

$$\rho^{AB}(0) = \frac{1}{3} \begin{pmatrix} a & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1-a \end{pmatrix}. \tag{73.47}$$

Here the convention is to label the rows and columns in the order $++$, $+-$, $-+$, $--$. The transient decay of either atom's excitation can be calculated separately from their reduced density matrices $\rho^A \equiv \text{Tr}_B\{\rho^{AB}\}$, etc. For example:

$$\rho^A = \langle +_B | \rho^{AB} | +_B \rangle + \langle -_B | \rho^{AB} | -_B \rangle$$
$$= \frac{1}{3} \begin{pmatrix} 1+a & 0 \\ 0 & 2-a \end{pmatrix}, \tag{73.48}$$

and the upper level excitation of atom A can be found to behave exactly as expected: $\rho_{++}^A(t) = \frac{a+1}{3} e^{-t/\tau_0}$, where τ_0 is the usual spontaneous emission lifetime.

For nonlocal transients we will need a time-dependent measure of entanglement, and there are several options [73.16], all related to the joint entropy of the two-atom system. We will use the concurrence $C(t)$
Fig. 73.8 Illustration of a set-up in which two partially excited atoms A and B are located inside two spatially separated cavities that are possibly very remote from each other. The two atoms are assumed initially entangled, but they have no interaction

of *Wootters* [73.17], which has the convenient normalization $1 \geq C(t) \geq 0$, where $C = 1$ represents completely entangled atoms (such as in a pure Bell state, for example) and $C = 0$ denotes the complete absence of entanglement.

For the specific case $a = 1$ one finds for the state (73.47) the initial concurrence $C(0) = \frac{2}{3}$, indicating a state with partial two-party coherence (incomplete entanglement). At time t one then finds:

$$C^{AB}(t) = \frac{2}{3} \max\left\{0, \, e^{-t/\tau_0} f(t)\right\}, \tag{73.49}$$

where $f(t) = 1 - \sqrt{2\omega^2 + \omega^4}$, and $\omega \equiv 1 - e^{-t/\tau_0}$. The strikingly non-intuitive consequence of this expression is that $C(t) \to 0$ abruptly after a short time (disentanglement suffers a "sudden death") if $2\omega^2 + \omega^4 \geq 1$. In fact, only a minor algebraic rearrangement shows that this strange condition must occur, and the finite sudden
Fig. 73.9 Effect of spontaneous emission on concurrence of two two-level atoms given the initially entangled mixed state (73.47) depending on the single parameter $1 \geq a \geq 0$

death time t_0 is given by

$$\frac{t_0}{\tau_0} \equiv \ln\left(\frac{2+\sqrt{2}}{2}\right) \approx 0.53 \ . \tag{73.50}$$

The non-local coherent transient behavior of entanglement for the entire range of allowed a values [73.15] is shown in Fig. 73.9. This shows that the concurrence undergoes familiar smooth and infinitely long decay only for a values in the limited range $\frac{1}{3} > a \geq 0$. Otherwise

sudden death occurs sooner or later. In our example, non-local coherence becomes zero most abruptly after a finite time for $a = 1$, the case that was calculated in (73.49). Although not yet observed experimentally, it appears that these results are not exceptional. Sudden termination of entanglement has also been predicted for two-party continuum states as well as for qubit pairs experiencing only T_2 decay, in contrast to the combined T_1 and T_2 decay appropriate to spontaneous emission as treated here.

74. Multiphoton and Strong−Field Processes

The excitation of atoms by intense laser pulses can be divided into two broad regimes: the first regime involves relatively weak optical laser fields of long duration, and the second involves strong fields of short duration. In the first case, the intensity is presumed to be high enough for multiphoton transitions to occur. The resulting spectroscopy is not limited by the single−photon selection rules for radiative transitions. However, the intensity is still low enough for a theoretical description based on perturbations of field−free atomic states to be valid, and the time dependence of the field amplitude does not play an essential role. In the second case, the field intensities are too large to be treated by perturbation theory, and the time dependence of the pulse must be taken into account. A discussion on the generation of sub−femtosecond pulses is included.

The excitation of atoms by intense laser pulses can be divided into two broad regimes determined by the characteristics of the laser pulse relative to the atomic response. The first regime involves relatively weak optical laser fields of long duration ($> 1\,\text{ns}$), and the second involves strong fields of short duration ($< 10\,\text{ps}$). These will be referred to as the weak-long (WL) and strong-short (SS) cases respectively.

In the case of atomic excitation by WL pulses, the intensity is presumed to be high enough for multiphoton transitions to occur. The resulting spectroscopy of absorption to excited states is potentially much richer than single-photon excitation because it is not limited by the single-photon selection rules for radiative transitions. However, the intensity is still low enough for a theoretical description based on perturbations of field-free atomic states to be valid, and the time depen-

dence of the field amplitude does not play an essential role.

The SS case is fundamentally different in that the atomic electrons are strongly driven by fields too large to be treated by perturbation theory, and the time dependence of the pulse as it switches on and off must be taken into account. Atoms may absorb hundreds of photons, leading to the emission of one or more electrons, as well as photons of both lower and higher energy. Because the flux of incident photons is high, a classical description of the laser field is adequate, but the time dependent Schrödinger equation (TDSE) must be solved directly to obtain an accurate representation of the atom–field interaction.

For SS pulses of optical wavelength, it is sufficient in most cases to consider only the electric dipole (E1) interaction term defined in Chapt. 68. The atom–field

interaction can then be expressed in either the length gauge or the velocity gauge [74.1] (Chapt. 21). In the length gauge, the TDSE is

$$i\hbar \frac{\partial \Psi(\boldsymbol{r}, t)}{\partial t} = \left[H_0 + e\boldsymbol{r} \cdot \boldsymbol{E}(t) \right] \Psi(\boldsymbol{r}, t) , \tag{74.1}$$

where H_0 is the field-free atomic Hamiltonian, $\boldsymbol{r}$ the collective coordinate of the electrons, and $\boldsymbol{E}(t)$ the electric field of the laser given by

$$\boldsymbol{E}(t) = \mathcal{E}(t) \left[\hat{\boldsymbol{x}} \cos(\omega t + \varphi) + \epsilon \hat{\boldsymbol{y}} \sin(\omega t + \varphi) \right] . \tag{74.2}$$

Here φ is the phase and ϵ defines the polarization: linear if $\epsilon = 0$ and circular if $|\epsilon| = 1$. In the velocity gauge, the TDSE is

$$i\hbar \frac{\partial \psi(\boldsymbol{r}, t)}{\partial t} = \left[H_0 - \frac{ie\hbar}{mc} \boldsymbol{A}(t) \cdot \nabla + \frac{e^2}{2mc^2} A^2(t) \right]$$
$$\times \psi(\boldsymbol{r}, t) . \tag{74.3}$$

Here $\boldsymbol{A}(t) = -c \int^t \boldsymbol{E}(t') \, dt'$ is the vector potential of the laser field. The solutions of (74.1) and (74.3) are related

by the phase transformation

$$\Psi(\boldsymbol{r}, t) = \exp \left[\frac{ie}{\hbar c} \boldsymbol{r} \cdot \boldsymbol{A}(t) \right] \psi(\boldsymbol{r}, t) . \tag{74.4}$$

Since lasers usually must be focussed to reach the strong field regime, measured electron and ion yields include contributions from a distribution of field strengths. The photoemission spectrum, on the other hand, contains a coherent component due to the macroscopic polarization of all the atoms and therefore is sensitive also to the laser phase variations within the focal volume. In this chapter methods for solving (74.1) and (74.3) are discussed along with details of the atomic emission processes.

References [74.1–3] are three recent books which provide excellent introductions to this subject. Further developments are well described in the proceedings of the International Conferences on Multiphoton Physics [74.4–7] and the NATO workshop on Super-Intense Laser-Atom Physics [74.8, 9].

74.1 Weak Field Multiphoton Processes

74.1.1 Perturbation Theory

Since atomic ionization energies are generally $\gtrsim 10\,\text{eV}$, while optical photons have energies of only a few eV, several photons must be absorbed to produce ionization, or even electronic excitation in the case of the noble gases. For WL pulses, the electronic states are only weakly perturbed by the electromagnetic field. The rate of an n-photon transition can then be calculated using nth order perturbation theory for the atom–field interaction. For an incident photon number flux ϕ of frequency ω, the rate is

$$W_{i \to f}^{(n)} = 2\pi \left(\frac{2\pi\alpha\phi\omega}{e^2} \right)^n \left| T_{i \to f}^{(n)} \right|^2 \delta(\omega_i + n\omega - \omega_f) , \tag{74.5}$$

where

$$T_{i \to f}^{(n)} = \langle f | d\, G[\omega_i + (n-1)\omega]$$
$$\times d\, G[\omega_i + (n-2)\omega]$$
$$\cdots d\, G[\omega_i + \omega] \, d | i \rangle , \tag{74.6}$$

$|i\rangle$ is the ith eigenstate of the field-free atomic Hamiltonian, $d = e\hat{\boldsymbol{\epsilon}} \cdot \boldsymbol{r}$, with $\hat{\boldsymbol{\epsilon}}$ the polarization direction and

$$G(\omega) = \sum_j \frac{|j\rangle\langle j|}{(\omega - \omega_j + i\Gamma_j/2)} . \tag{74.7}$$

The sum over j includes an integration over the continuum for all sequences of E1 transitions allowed by angular momentum and parity selection rules. Methods for calculating cross sections and rates in the weak-field regime are described in [74.1, 10] and in Chapt. 24.

74.1.2 Resonant Enhanced Multiphoton Ionization

For multiphoton ionization, ω can be continuously varied because the final state in (74.5) lies in the continuum. If ω is tuned so that $\omega_i + m\omega \simeq \omega_j$ for some contributing intermediate state $|j\rangle$ in (74.7), then that state lies an integer m photons above the initial state, and the corresponding denominator vanishes (to within the level width Γ_j), producing a strongly peaked resonance. Since it takes $k = n - m$ additional photons for ionization, the process is called m, k resonant enhanced multiphoton ionization (REMPI). Measurements of the photoelectron angular distribution are useful in characterizing the resonant intermediate state.

Calculations using the semi-empirical multichannel quantum defect theory to provide the needed matrix elements have been very successful in describing experimental results. This technique is discussed in more detail in Chapt. 24.

The perturbation equation (74.5) indicates that the rate for nonresonant multiphoton ionization scales as ϕ^n for an n-photon process [74.11]. However, this is not the case for REMPI since the resonant transition saturates and (74.5) no longer applies. Then the rate can be controlled either by the m-photon resonant excitation step, or by the number of photons k needed for the ionization step.

74.1.3 Multi–Electron Effects

Multiply excited states can play a role in multiphoton excitation dynamics. These states are particularly important if their energies are below or not too far above the first ionization potential. Configuration expansions including these states have been used successfully in studies, for example, of the alkaline earth atoms, which have many low-lying doubly excited states. The presence of these states also can enhance the direct double ionization of an atom [74.12].

74.1.4 Autoionization

The configuration interaction between a bound state and an adjacent continuum leads to an absorption profile in the single photon ionization spectrum with a Fano lineshape. The actual lineshape reflects the interference between the two pathways to the continuum. Autoionizing states can also be probed via multiphoton excitation [74.13, 14]. Because, in the strong field regime, coupling strengths and phases change with intensity, the lineshapes can be strongly distorted by changing the incident intensity. At particular intensities, the phases of the excited levels can be manipulated to prevent autoionization completely. Then a trapped population with energy above the ionization limit can be created [74.15].

74.1.5 Coherence and Statistics

Real laser fields exhibit various kinds of fluctuations, and so are never perfectly coherent. The effects of such fluctuations on the complex electric field amplitude

$$E(t) = \mathcal{E}(t) \exp\left[-i\omega t + \varphi(t)\right] \tag{74.8}$$

can be modeled by a variety of stochastic processes [74.16], depending on the conditions [74.10, 17–20], as follows.

For cw lasers, a phase diffusion model (PDM) is often used for which $\mathcal{E}(t) = \mathcal{E} = \text{const.}$ and

$$\dot{\varphi}(t) = \sqrt{2b}F(t) , \tag{74.9}$$

where $F(t)$ describes white noise by a real Gaussian function [74.16] characterized by the averaged values $\langle F(t) \rangle = 0$, $\langle F(t)F(t') \rangle = 2b\delta(t - t')$. The stochastic electric field then has an exponential autocorrelation function

$$\langle E(t)E^*(t') \rangle = \mathcal{E}^2 \exp\left[-b|t - t'| - i\omega(t - t')\right] , \tag{74.10}$$

and a Lorentzian spectrum of width b. Far off resonance, such a Lorentzian spectrum often gives unrealistic results, and the model (74.9) is then replaced by an Ornstein–Uhlenbeck process,

$$\ddot{\varphi}(t) = -\beta\dot{\varphi}(t) + \sqrt{2b\beta}F(t) , \tag{74.11}$$

where the parameter β for $\beta \ll b$ plays the role of a cutoff of the Lorentzian spectrum.

A multimode laser with a large number M of independent modes has a field of the form $E(t) = \sum_{j=1}^{M} \mathcal{E}_j \exp[-i\omega_j t + i\varphi_j(t)]$, and according to the central limit theorem [74.16], can be described for large M as a complex Gaussian process defined to be a chaotic field,

$$\dot{E}(t) = -(b + i\omega)E(t) + \sqrt{2b\langle|E(t)|^2\rangle}F(t) , \tag{74.12}$$

where $F(t)$ is now a complex white noise, and ω is the central frequency of the field. The field, (74.12) has an exponential autocorrelation function, and a Lorentzian spectrum of width b.

Various other stochastic models have been discussed in the literature. These include Gaussian fluctuations of the real amplitude of the field $\mathcal{E}(t)$; Gaussian chaotic fields with non-Lorentzian spectra; non-Gaussian, nonlinear diffusion processes (that describe for instance a laser close to threshold [74.16]); multiplicative stochastic processes (that describe a laser with pump fluctuations [74.18]) and jump-like Markov processes [74.21–23]. Statistical properties of laser fields can sometimes be controlled experimentally to a great extent [74.19, 20].

74.1.6 Effects of Field Fluctuations

Since the response of systems undergoing multiphoton processes is in general a nonlinear function of the field intensity (and, in particular, of the field amplitude), it depends in a complex manner on the statistics of the field. The enhancement of the nonresonant multiphoton ionization rate illustrates the point. According to the perturbation equation (74.5), the rate of an n-photon process is proportional to ϕ^n; i. e., to I^n, where I is the field

intensity. For fluctuating fields, the average response is thus

$$W_{i \to f}^{(n)} \propto \left\langle I^n \right\rangle \propto \left\langle \left| E(t) \right|^{2n} \right\rangle . \tag{74.13}$$

Phase fluctuations (as described by PDM) do not affect the average. On the other hand, for complex chaotic fields, the average is

$$\langle I^n \rangle \simeq n! \langle I \rangle^n , \tag{74.14}$$

i. e., significant enhancement of the rate for $n > 1$.

Field fluctuations lead to more complex effects in resonant processes. Two well-studied examples are the enhancement of the ac Stark shift in resonant multiphoton ionization [74.24], and the spectrum of double optical resonance – a process in which the ac Stark splitting of the resonant line is probed by a slightly detuned fluctuating laser field [74.18]. Double optical resonance is very sensitive not only to the bandwidth of the probing field, but also to the shape of its frequency spectrum.

74.1.7 Excitation with Multiple Laser Fields

The simultaneous application of more than one laser field produces interesting and novel effects. If a laser and its second (2ω) or third (3ω) harmonic are combined and the relative phase between the fields controlled, product state distributions and yields can be altered dramatically. The effects include reducing the excitation or ionization rates in the $\omega - 3\omega$ case [74.25] or altering the photoelectron angular distributions and the harmonic emission parity selection rules using $\omega - 2\omega$ [74.26].

A laser field can dress or strongly mix the field-free excited states, including the continuum, of an atom. This can produce a number of effects depending on how the dressed system is probed. By coupling a bound, excited state with the continuum, ionization strengths and dynamics are altered, resulting in new resonance-like structures where none existed before. This effect is called laser-induced continuum structure, or LICS [74.15, 27]. This general idea has been exploited to design schemes for lasers without inversion [74.28] in which the dressed atom can have an inverted population, allowing gain even though in terms of the undressed states the lower level has the largest population. A laser can produce dramatic changes in the index of refraction of an atomic medium [74.29], creating, at specific frequencies, laser-induced transparency for a second, probe laser field. Multistep ionization, where each step is driven by a laser at its resonant frequency, has resulted in two useful applications. These are: efficient atomic isotope separation [74.23]; and the detection of small numbers of atoms in a sample, called single-atom detection. This technique is extremely sensitive because the use of exact resonance for each step yields very large cross sections for ionization, and the efficiency of collecting ions is high [74.30].

74.2 Strong–Field Multiphoton Processes

Recently developed laser systems can produce very short pulses, some as short as a few to tens of femtoseconds, while at the same time maintaining the pulse energy so that the peak power becomes very high. Focused intensities up to 10^{19} W/cm^2 have been achieved. Because the pulses are short, atoms survive to much higher intensities before ionizing, making possible studies of laser-atom interactions in an entirely new regime. A discussion of the status of short pulse laser development is given in Chapt. 71 and in [74.31].

With increasing intensity, higher-order corrections to (74.6) contribute to the transition rate. The next order correction comes from transitions involving two additional photons, one absorbed and one emitted, leading to the same final state. One effect of these terms is to shift the energies of the excited states in response to the oscillating field. This is called the dynamic or ac Stark shift. The ac Stark shift of the ground state tends to be small because of the large detuning from the ex-

cited states for long wavelength photons. On the other hand, in strong fields the shift of the higher states and the continuum can become appreciable. Electrons in highly excited states respond to the oscillating field in the same manner as a free electron. Their energies shift with the continuum by the amount

$$U_{\mathrm{p}} = \frac{(1+\epsilon)e^2 \mathcal{E}^2}{4m\omega^2} , \tag{74.15}$$

where U_{p} is the cycle-averaged kinetic energy of a free electron in the field and ϵ defines the polarization of the field in (74.2). U_{p} is called the ponderomotive or quiver energy of the electron. For strong laser fields, U_{p} can be several eV or more, meaning that during a pulse, many states shift through resonance as their energies change by an amount larger than the incident photon energy. The resulting intensity-induced resonances can dominate the ionization dynamics.

Electrons promoted into the continuum acquire the ponderomotive energy, oscillating in phase with the field. In a linearly polarized field, the amplitude of the quiver motion of a free electron, given by $e\mathcal{E}/4m\omega^2$, can become many times larger than the bound state orbitals. If the initial velocity of an electron is small after ionization, it can be accelerated by the field back into the ion core. The subsequent rescattering changes the photoelectron energy and angular distributions, and allows the emission of high energy photons [74.32, 33]. This simple dynamical picture forms the basis of the current understanding of many strong-field multiphoton processes.

74.2.1 Nonperturbative Multiphoton Ionization

The breakdown of perturbation theory for nth-order multiphoton processes occurs when the higher-order correction terms become comparable to the nth-order term. Assuming that the dipole strength is $\propto ea_0$, where a_0 is the Bohr radius, and the detuning is $\delta \propto \omega$, the ratio of an $(n+2)$-order contribution to the nth-order term from (74.6) is [74.1]

$$R_{n+2,n} \simeq \left(\frac{2\pi\alpha\phi\omega}{e^2}\right)\left(\frac{ea_0}{\omega}\right)^2 = \left(\frac{I}{I_\gamma}\right)\left(\frac{\omega_a}{2\omega}\right)^2 ,$$

(74.16)

where $\hbar\omega_a \simeq 27.2114$ eV is the atomic unit of energy e^2/a_0, and $I_\gamma \simeq 3.50945 \times 10^{16}$ W/cm^2 is the intensity corresponding to an atomic unit of field strength, given by $E_a = \alpha c \left(m/a_0^3\right)^{1/2} \simeq 5.1422 \times 10^9$ V/cm. The atomic unit of intensity itself is defined by

$$I_a = \phi_a \hbar \omega_a = \alpha c E_a^2 ,$$

(74.17)

which is $6.436414(4) \times 10^{15}$ W/cm^2. Thus $I_\gamma = I_a/(8\pi\alpha)$. For photon energies of 1 eV, $R_{n+2,n}$ becomes unity for $I \sim 10^{14}$ W/cm^2. Because of the large number of $(n+2)$-order terms, perturbation theory actually fails for $I > 10^{13}$ W/cm^2. Above this critical intensity, nonresonant n-photon ionization ceases to scale with the ϕ^n dependence predicted by perturbation theory.

74.2.2 Tunneling Ionization

At sufficiently high intensity and low frequency, a tunneling mechanism changes the character of the ionization process. For lasers in the ir or optical range, a strongly bound electron can respond to the instantaneous laser field since the oscillating electric field varies slowly on the time scale of the electron. The Coulomb

attraction of the ion core combines with the laser electric field to form an oscillating barrier through which the electron can escape by tunneling, if the amplitude of the laser field is large enough. The dc rate for this process is $e\mathcal{E}/\sqrt{2mI_P}$, where I_P is the ionization potential of the electron. When this rate is comparable to the laser frequency, tunneling becomes the most probable ionization mechanism [74.34–36]. The ratio of the incident laser frequency to the tunneling rate is called the Keldysh parameter, and is given by

$$\gamma = \sqrt{I_P/2U_P} ,$$

(74.18)

which is less than unity when tunneling dominates and larger than unity when multiphoton ionization dominates.

74.2.3 Multiple Ionization

Excitation and ionization dynamics are dominated by single electron transitions in the strong field regime. Although atoms can lose several electrons during a single pulse, the electrons are released sequentially. There is no convincing evidence of significant collective excitation in atoms in strong fields, even though it has been extensively sought. Once one electron is excited in an atom, the remaining electrons have much higher binding energies. As a result, the laser field is unable to affect them significantly until it reaches much higher intensity. By that time the first electron has been emitted.

Simultaneous ejection of two electrons occurs as a minor channel ($< 1\%$) in strong field multiple ionization. Although it is possible that doubly excited states of atoms could assist in the double ionization, in the helium and neon cases studied, these states are unlikely to be contributors [74.37].

74.2.4 Above Threshold Ionization

In strong optical and ir laser fields, electrons can gain more than the minimum amount of energy required for ionization. Rather than forming a single peak, the emitted electron energy spectrum contains a series of peaks separated by the photon energy. This is called above threshold ionization, or ATI [74.38–40]. The peaks appear at the energies

$$E_s = (n+s)\hbar\omega - I_P ,$$

(74.19)

where n is the minimum number of photons needed to exceed I_P, and $s = 0, 1, \ldots$ is called the number of

excess photons or above threshold photons carried by the electron. Calculations in the perturbative regime for ATI are given for hydrogen in [74.11].

Peak Shifting

As the intensity approaches the nonperturbative regime, the ac Stark shift of the atomic states begins to play a significant role in the structure of the ATI spectrum. The first effect is a shift of the ionization potential, given roughly by the ponderomotive energy U_p. Additional photons may then be required in order to free the electron from the atom; i.e., enough to exceed $I_P + U_p$. If the emitted electron escapes from the focal volume while the laser is still on, it is accelerated by the gradient of the field. The quiver motion is converted into radial motion, increasing the kinetic energy by U_p and exactly canceling the shift of the continuum. The electron energies are still given by (74.19). However, when U_p exceeds the photon energy, the lowest ATI peaks disappear from the spectrum. In this long pulse limit, no electron is observed with energy less than U_p. This is called peak shifting in that the dominant peak in the ATI spectrum moves to higher order as the intensity increases.

ATI Resonance Substructure

If the laser pulse is short enough (< 1 ps for the typical laser focus), the field turns off before the electron can escape from the focal volume. Then the quiver energy is returned to the field and the ATI spectrum becomes much more complicated. The observed electron energy corresponds to the energy

$$E_s(\text{shortpulse}) = (n+s)\hbar\omega - (I_P + U_p) . \quad (74.20)$$

relative to the shifted ionization potential. Electrons from different regions of the focal volume are thus emitted with different ponderomotive shifts, introducing substructure in the spectrum which can be directly associated with ac Stark-shifted resonances [74.38, 39].

ATI in Circular Polarization

The above discussion is appropriate for the case of linear polarization where the excited states of the atom can play a significant role in the excitation. In a circularly polarized field, the orbital angular momentum L must increase one unit with each photon absorbed so that multiphoton ionization is allowed only to states which have high L, and hence a large centrifugal barrier. The lower energy scattering states then cannot penetrate into the vicinity of the initial state. Thus the ATI spectrum in circular polarization peaks at high energy and is very small near threshold.

74.2.5 High Harmonic Generation

High-order harmonic generation (HG) in noble gases is a rapidly developing field of laser physics [74.41, 42]. When an SS pulse interacts with an atomic gas, the atoms respond in a nonlinear way, emitting coherent radiation at frequencies that are integral multiples of the laser frequency. Due to the inversion symmetry of the atom, only odd harmonics of the fundamental are emitted. In the high intensity $\left(> 10^{13} \text{ W/cm}^2 \right)$, low frequency regime, the harmonic strengths fall off for the first few orders, followed by a broad plateau of nearly constant conversion efficiency, and then a rather sharp cut-off [74.41, 42]. The plateaux extend to well beyond the hundredth order of the 800–1000 nm incident wavelengths, using the light noble gases as the active medium. There has also been experimental evidence of HG from ions. Harmonic generation provides a source of very bright, short-pulse, coherent XUV radiation which can have several advantages over the other known sources, such as the synchrotron.

Plateau and Cut-off

A recently developed two-step model [74.32, 33], which combines quantum and classical aspects of laser-atom physics, accounts for many strong field phenomena. In this model, the electron first tunnels [74.43] from the ground state of the atom through the barrier formed by the Coulomb potential and the laser field. Its subsequent motion can be treated classically, and primarily consists of oscillatory motion in phase with the laser field. If the electron returns to the vicinity of the nucleus with kinetic energy $\mathcal{T}$, it may recombine into the ground state with the emission of a photon of energy $(2n+1)\hbar\omega \leq \mathcal{T} + I_P$, where n is an integer. The maximum kinetic energy of the returning electron turns out to be $\mathcal{T} \simeq 3.2 U_p$, resulting in a cut-off in the harmonic spectrum at the harmonic of order

$$N_{\max} \simeq (I_P + 3.2 U_p)/\hbar\omega . \quad (74.21)$$

Theoretical Methods

Calculation of harmonic strengths requires the evaluation of the time-dependent dipole moment of the atom,

$$\boldsymbol{d}(t) = \langle \Psi(t)|e\boldsymbol{r}|\Psi(t)\rangle . \quad (74.22)$$

The strength of harmonics emitted by a single atom are then related to Fourier components of $\boldsymbol{d}(t)$, or more precisely, its second time derivative, $\ddot{\boldsymbol{d}}(t)$.

The induced dipole moment $\boldsymbol{d}(t)$ can be directly evaluated from the numerical [74.44] or *Floquet* [74.26]

solutions of the TDSE. Good agreement with numerical and experimental data is also obtained using a strong field approximation discussed below and a Landau–Dyhne formula. This approach can be considered to be a quantum mechanical implementation of the two-step model [74.45].

Propagation and Phase Matching Effects

A single atom response is not sufficient to determine the macroscopic response of the atomic medium. Because different atoms interact with different parts of the focused laser beam, they feel different peak field intensities and phases (which actually undergo a rapid π shift close to the focus). The total harmonic signal results from coherently adding contributions from single atoms, accounting for propagation and interference effects. The latter effects can wipe out the signal completely a constructive phase matching takes place.

The propagation and phase matching effects in the strong field regime [74.46] can be studied by solving the Maxwell's equations for a given harmonic component of the electric field $\mathcal{E}_M(\boldsymbol{r})$ (68.23),

$$\nabla^2 \mathcal{E}_M(\boldsymbol{r}) + n_M(\boldsymbol{r}) \mathcal{E}_M(\boldsymbol{r}) = -\frac{1}{\epsilon_0}\left(\frac{M\omega}{c}\right)^2 \mathcal{P}_M(\boldsymbol{r}) ,$$

(74.23)

where $n_M(\boldsymbol{r})$ is the refractive index of the medium (which depends on atomic, electronic and ionic dipole polarizabilities), while $\mathcal{P}_M(\boldsymbol{r})$ is the polarization induced by the fundamental field only. It can be expressed as

$$\mathcal{P}_M(\boldsymbol{r}) \propto N(\boldsymbol{r}) d_M M(\boldsymbol{r}) \exp\left[-i M \Delta(\boldsymbol{r})\right] , \quad (74.24)$$

where $N(\boldsymbol{r})$ is the atomic density, $d_M(\boldsymbol{r})$ is the Mth Fourier component of the induced dipole moment, and $\Delta(\boldsymbol{r})$ is a phase shift coming from the phase dependence of the fundamental beam due to focusing. All of these quantities may have a slow time dependence, reflecting the temporal envelope of the laser pulse.

Phase matching is most efficient in the forward direction. In general, the strength and spatial properties of an harmonic depend in a very complex way on the focal parameters, the medium length and the coherence length of a given harmonic. Propagation and phase matching effects can lead to a shift of the location of the cut-off in the harmonic spectrum [74.47].

Harmonic Generation by Elliptically Polarized Fields

The two-step model implies that for harmonic emission it is necessary that the tunneling electrons return to the nucleus and recombine into their initial state. According to classical mechanics, there are many trajectories in a linearly polarized field that involve one or more returns to the origin. However, there are practically no such trajectories in elliptically polarized fields. As a result, the two-step model predicts a strong decrease of the harmonic strengths as a function of the laser ellipticity. This prediction has been confirmed experimentally [74.48].

The Generation of Sub-Femtosecond XUV Pulses

Manipulation of generated harmonics by allowing the temporal beating of superposed high-order harmonics can produce a train of very short intensity spikes, on the order of ~ 100 attoseconds and shorter, where $1\,\text{as} = 10^{-18}\,\text{s}$ [74.49]. The structural characteristics of the generated pulse-trains depend on the relative phases of the harmonics combined. Employing driving pulses that were themselves only a few femtoseconds long, experimental groups in Vienna [74.50] and Paris [74.51] reported the first observations and measurements of such sub-femtosecond UV/XUV light pulse-trains. The scientific importance of breaking the femtosecond barrier is obvious: the time-scale necessary for probing the motion of an electron in a typical bound, valence state is measured in attoseconds (atomic unit of time $\equiv 24\,\text{as}$). Attosecond pulses will allow the study of the time-dependent dynamics of correlated electron systems by freezing the electronic motion, in essence exploring the structure with ultra-fast snapshots. A crucial aspect for all attosecond pulse generation is the control of spectral phases. Measurements of the timing of the attosecond peaks relative to the absolute phase of the ir driving field have been accomplished [74.52]. This provides insight into the recollision, harmonic generation process. Also, the control of the group velocity phase relative to the envelope of the few cycle driving pulses allows the production of reproducible pulse-trains [74.53]. Thus, the highly non-perturbative, nonlinear multiphoton interactions of very short ir or visible light pulses with atoms or molecules is becoming a novel, powerful, and unique source for studies of very rapid quantum-electronic processes.

74.2.6 Stabilization of Atoms in Intense Laser Fields

It has been argued [74.54] that in very intense laser fields of high frequency, atoms undergo dynamical stabilization and do not ionize. The stabilization effect can be explained by gauge transforming the TDSE (74.1)

to the Kramers–Henneberger (K–H) frame; i. e., a non-inertial oscillating frame which follows the motion of the free electron in the laser field. The K–H transformation consists of replacing $r \rightarrow r + \alpha(t)$, where, for the linearly polarized monochromatic laser field, $\alpha(t) = \hat{x}\alpha_0 \cos(\omega t - \varphi)$; $\alpha_0 = e\mathcal{E}/(m\omega^2)$ is the excursion amplitude of a free electron, and $\hat{x}$ is the polarization direction. The TDSE in the K–H frame is

$$i\hbar \frac{\partial \Psi(r, t)}{\partial t} = \left\{ -\frac{\hbar^2 \nabla^2}{2m} + V\left[r + \alpha(t)\right] \right\} \Psi(r, t) , \tag{74.25}$$

i. e., it describes the motion of the electron in an oscillatory potential. In the high frequency limit, this potential may be replaced by its time average

$$V_{\text{K–H}}(r) = \frac{\omega}{2\pi} \int\limits_0^{2\pi/\omega} dt \, V\left[r + \alpha(t)\right] , \tag{74.26}$$

and the remaining Fourier components of $V[r + \alpha(t)]$ treated as a perturbation. When α_0 is large, the effective potential (74.26) has two minima close to $r = \pm\hat{x}\alpha_0$. The corresponding wave functions of the bound states are centered near these minima, thus exhibiting a dichotomy. The ionization rates from the K–H bound states are induced by the higher Fourier components of $V(r + \alpha(t))$. For large enough α_0, the rates decrease if either the laser intensity increases or the frequency decreases.

Numerical solutions of the TDSE [74.55, 56] show that stabilization indeed occurs for laser field strengths and frequencies of the order of one atomic unit. More importantly, stabilization is possible even when the laser excitation is not monochromatic, but rather, is produced by a short laser pulse. Physically, free electrons in a monochromatic laser field cannot absorb photons due to the constraints imposed by energy and momentum conservation. Absorption is possible only in the vicinity of a potential, such as the Coulombic attraction of the nucleus. In the case of strong excitation, i. e., when α_0 is much larger than the Bohr radius, the electron spends most of the time very far from the nucleus, and therefore does not absorb energy from the laser beam. Thus stabilization, as viewed from the K–H frame, has a classical analog. Other mechanisms of stabilization based on the quantum mechanical effects of destructive interference between various ionization paths have also been proposed [74.57].

Due to classical scaling (Sect. 74.2.8) stabilization is predicted to occur for much lower laser frequencies if the atoms are initially prepared in highly excited states. If additionally, the initial state has a large orbital angular momentum corresponding to classical trajectories that do not approach the nucleus, stabilization is even more easily accomplished. The stabilization of a 5g Rydberg state of neon has recently been reported [74.58].

74.2.7 Molecules in Intense Laser Fields

Molecular systems are more complex than atoms because of the additional degrees of freedom resulting from nuclear motion. Even in the presence of a laser field, the electron and nuclear degrees of freedom can be separated by the Born–Oppenheimer approximation, and the dynamics of the system can be described in terms of motions on potential energy surfaces. In strong fields, the Born–Oppenheimer states become dressed, or mixed by the field, creating new molecular potentials. Because of avoided crossings between the dressed molecular states, the field induces new potential wells in which the molecules become trapped. These states, known as laser-induced bound states, are stable against dissociation, but exist only while the laser field is present [74.59]. Their existence affects the spectra of photoelectrons, photons, and the fragmentation dynamics. If the field is strong enough, many electrons can be ejected from a molecule before dissociation, producing highly charged, energetic fragments [74.60]. Such experiments are similar to beam-foil Coulomb explosion studies of molecular structure. However, because of changes from the field-free equilibrium geometries in laser dissociation, the energies of the fragments lie systematically below the corresponding values from Coulomb explosion studies.

74.2.8 Microwave Ionization of Rydberg Atoms

Similar phenomena appear in the ionization of highly excited hydrogen-like (Rydberg) atoms by microwave fields [74.61, 62], but the dynamical range of the parameters involved is different from the case of tightly bound electrons. Recent developments have greatly extended techniques for the preparation and detection of Rydberg states. Since, according to the equivalence principle, highly excited Rydberg states exhibit many classical properties, a classical perspective of ionization yields useful insights (Sect. 74.3.5).

Classical Scaling

The classical equations of motion for an electron in both a Coulomb field and a monochromatic laser field polarized along the z-axis are invariant with respect to the

following scaling transformations:

$$
\begin{aligned}
&\boldsymbol{p} \propto n_0^{-1} \tilde{\boldsymbol{p}}\,, &&\boldsymbol{r} \propto n_0^2 \tilde{\boldsymbol{r}}\,,\\
&t \propto n_0^3 \tilde{t}\,, &&\varphi \propto \tilde{\varphi}\,,\\
&\omega \propto n_0^{-3} \tilde{\omega}\,, &&\mathcal{E} \propto n_0^{-4} \tilde{\mathcal{E}}\,.
\end{aligned}
\tag{74.27}
$$

In the scaled units, the Hamiltonian $\tilde{H} = n_0^{-2} H$ of the system becomes

$$
\tilde{H} = \frac{\tilde{p}^2}{2m} - \frac{1}{\tilde{r}} + \tilde{z} e \tilde{\mathcal{E}} \cos\left(\tilde{\omega}\tilde{t} + \tilde{\varphi}\right)\,,
\tag{74.28}
$$

i. e., it depends only on $\tilde{\omega}$ and $\tilde{\mathcal{E}}$. In experiments, the principal quantum number n_0 of the prepared initial state typically ranges from 1 to 100.

Classical scaling extends to the fields of other polarization and to pulsed excitation, provided that the number of cycles in the rise, top and fall of the pulse is kept fixed. This scaling does not hold for a quantum Hamiltonian, unless one also rescales Planck's constant, $\tilde{\hbar} = \hbar/n_0$. In practice, increasing n_0, keeping $\tilde{\mathcal{E}}$ and $\tilde{\omega}$ constant, corresponds to a decrease in the effective $\hbar$ toward the classical limit. In view of this classical scaling, experimental and theoretical results are usually analyzed in terms of the scaled variables. Since the classical dynamics generated by the Hamiltonian (74.28) exhibits chaotic behavior in some regimes, the dynamics of the corresponding quantum system is frequently referred to as an example of quantum chaos [74.63–65].

Regimes of Response

By varying the initial n_0, several regimes of the scaled parameters can be covered. The experimentally measured response of Rydberg atoms in microwave fields can be divided into six categories:

The Tunneling Regime. For $\tilde{\omega} \le 0.07$, the response of the system is accurately represented as tunneling through the slowly oscillating potential barrier composed of the Coulomb and microwave potentials.

The Low Frequency Regime. For $0.05 \le \tilde{\omega} \le 0.3$, the ionization probability exhibits structure (bumps, steps, changes of slope) as a function of the field strength. The quantum probability curves might be lower or higher than the corresponding classical counterparts calculated with the aid of the phase averaging method (Sect. 74.3.5).

The Semiclassical Regime. For $0.1 \le \tilde{\omega} \le 1.2$, the ionization probabilities agree well for most frequencies with the results obtained from the classical theory. In particular, the onset of ionization and appearance intensities (i. e., the intensities at which a given degree of ionization is achieved) coincide with the onset of chaos in the classical dynamics. Resonances in the ionization probabilities appear that correspond to the classical trapping resonances [74.63–66].

The Transition Region. For $1 \le \tilde{\omega} \le 2$, the differences between the quantum and classical results are visible. Quantum ionization probabilities are frequently lower and appearance intensities higher than their classical counterparts.

The High Frequency Regime. For $\tilde{\omega} \ge 2$, quantum results for ionization probabilities are systematically lower and appearance intensities higher than their classical counterparts. This apparent stability of the quantum system has been attributed to three kinds of effects: quantum localization [74.66], quantum scars [74.67], and perhaps to the stabilization of atoms in intense laser fields (Sect. 74.2.6).

The Photoeffect Regime. When the scaled frequency becomes greater than the single photon ionization threshold, the system undergoes single photon ionization (the photoeffect).

Quantum Localization

The classical dynamics changes as the field increases. Chaotic trajectories start to fill phase space and, as the KAM tori (describing periodic orbits) [74.63–65] break down, the motion becomes stochastic, resembling a random walk. This process, in which the mean energy grows linearly in time, is termed diffusive ionization. In the quantum theory, diffusion corresponds to a random walk over a ladder of suitably chosen quantum levels. However, both diagonal and off-diagonal elements of the evolution operator, which describe quantum mechanical amplitudes for transitions between the levels, depend in a quasiperiodic manner on the quantum numbers of the levels involved. Such quasiperiodic behavior is quite analogous to a random one. Electronic wave packets that initially spread in accordance with the classical laws tend to remain localized for longer times due to destructive quantum interference effects. Quantum localization is an analog of the Anderson localization of electronic wave functions propagating in random media [74.66].

Quantum Scars

Even in the fully chaotic regime, classical phase space contains periodic, though unstable, orbits. Nevertheless, quantum mechanical wave function amplitudes can become localized around these unstable orbits, resulting in what are called quantum scars. The increased stability of the hydrogen atom at $\tilde{\omega} \simeq 1.3$ has been in fact attributed [74.67] to the effects of quantum scars. These effects are very sensitive to fluctuations in the driving laser field. Control of the laser noise therefore provides a powerful spectroscopic tool to study such quantal phenomena [74.68]. Using this tool, it has recently become possible to demonstrate the effects of quantum scars in the intermediate regime of the scaled frequencies (less than but close to 1).

74.3 Strong–Field Calculational Techniques

The SS pulse regime requires a nonperturbative solution of the TDSE. Two approaches have been developed: the explicit numerical solution of the TDSE and the Floquet expansion technique. In addition to these, several approximate methods have been proposed.

74.3.1 Floquet Theory

The excitation and ionization dynamics of an atom in a strong laser field can be determined by turning the problem into a time-independent eigenvalue problem [74.26, 69]. From Floquet's theorem, the eigenfunctions for a perfectly periodic Hamiltonian of the form

$$H = H_0 + \sum_{N \neq 0} H_N e^{-iN\omega t} \tag{74.29}$$

can be expressed in the form

$$\Psi(t) = e^{-iXt/\hbar} \sum_N e^{-iN\omega t} \psi_N . \tag{74.30}$$

Putting this into the time-dependent Schrödinger equation results in an infinite set of coupled Floquet equations for the harmonic components ψ_N. In the velocity gauge, the Floquet equations are

$$(X + N\hbar\omega - H_0)\psi_N = V_+\psi_{N-1} + V_-\psi_{N+1} , \tag{74.31}$$

where, for a vector potential of amplitude $\mathcal{A}$,

$$V_+ = -\frac{e}{2mc}\mathcal{A} \cdot \boldsymbol{p} , \tag{74.32}$$

and $V_- = V_+^\dagger$. The equations (74.31) have been solved, after truncation to a manageable number of terms, using many techniques to provide what are called the quasi-energy states of the laser-atom system. The eigenvalues X of these equations are complex, with $\mathrm{Im}(X)$ giving the decay or ionization rate for the system. The generated rates are found to be very accurate as long as the pulse length of the laser field is not too short, at least hundreds of cycles. The eigenfunctions provide the amplitudes for the photoelectron energy spectra, and the time-dependent dipole of the state can be related to the photo-emission spectrum of the system. Yields for slowly varying pulses can be constructed by combining the results from the individual, fixed-intensity calculations [74.26].

The Floquet method can be applied for any periodic Hamiltonian. In strong enough fields of high frequency, the Floquet equations can be truncated to a very small set in the K–H frame [74.54].

74.3.2 Direct Integration of the TDSE

Methods for the direct solution of the time-dependent Schrödinger equation are described in general in Chapt. 8 and in [74.70, 71] for multiphoton processes. The wave functions are defined on spatial grids or in terms of an expansion in basis functions. The time evolution is obtained by either explicit or implicit time propagators. All these methods are capable of generating numerically exact results for an atom with a single electron in a short pulsed field for a wide range of pulse shapes, wavelengths and intensities. The solutions are time-dependent wave functions for the electrons which can be analyzed to obtain excitation and ionization rates, photoelectron energies, angular distributions, and photoemission yields. The ability to generate an explicit solution of the TDSE allows the study of arbitrary pulse shapes and provides insight into the excitation dynamics.

For multi-electron atoms, one generally has to limit the calculations to that for a single electron in effective potentials which represent, as well as possible, the influences of the remaining atomic electrons. This approach is called the single active electron approximation, and it gives generally accurate results for systems with no low-lying doubly excited states, for example, the noble gases [74.70]. In these cases, the excitation dynamics

are dominated by the sequential promotion of a single electron at a time.

74.3.3 Volkov States

A laser interacting with free a electron superimposes an oscillatory motion on its drift motion in response to the field. The wave function for an electron with drift velocity $v = \hbar k/m$ is given by

$$\Psi_V(\mathbf{r}, t) = \exp\left(-\frac{i}{2m\hbar} \int^t \left[\hbar \mathbf{k} - \frac{e}{c}\mathbf{A}(t')\right]^2 dt'\right)$$

$$\times e^{i[\mathbf{k} - e\mathbf{A}(t)/\hbar c]\cdot\mathbf{r}}, \tag{74.33}$$

where $\mathbf{A}(t) = -c \int^t \mathbf{E}(t') dt'$ is the vector potential of the field. Ψ_V is called a Volkov state. In a linearly polarized field, the electron oscillates along the direction of polarization with an amplitude $\alpha_0 = e\hbar\mathcal{A}/(mc\omega)$. In the strong field regime, this amplitude can greatly exceed the size of a bound state orbital. Volkov states provide a useful tool that can be applied in various strong field approximations discussed in the next Section.

74.3.4 Strong Field Approximations

There have been several attempts to solve the TDSE in the strong field limit using approximate, but analytic methods. Such strong field approximations (SFA) typically neglect all the bound states of the atom except for the initial state. In the tunneling regime ($\gamma < 1$), and a quasistatic limit ($\omega \to 0$), one can use a theory [74.43] in which the ionization occurs due to the tunneling through the Coulomb barrier distorted by the electric field of the laser. The wave function is constructed as a combination of a bare initial wave function of the electron (close to the nucleus) and a wave function describing a motion of the electron in a quasistatic electric field (far from the nucleus). In an second approach [74.34–36], the elements of the scattering matrix $\hat{S}$ are calculated assuming that initially the electronic wave function corresponds to a bare bound state. On the other hand, the final, continuum states of the electron are described by dressed wave functions that account for the free motion of the electron in the laser field. In the simplest case, such dressed states are Volkov states (74.33). Alternatively, the time-reversed $\hat{S}$-Matrix is obtained by dressing the initial state and using field-free scattering states for the final state.

Yet another method consists of expanding the electronic continuum–continuum dipole matrix elements in terms corresponding to matrix elements for free electrons plus corrections due to the potential [74.45]. In the latter version of SFA, the amplitude of the electronic wave function $b(\mathbf{p})$ corresponding to outgoing momentum $\mathbf{p}$ is given by

$$b(\mathbf{p}) = i \int_0^{t_F} dt\, \mathbf{d}[\mathbf{p} - e\mathbf{A}(t)/c] \cdot \mathbf{E}(t)$$

$$\times \exp\left[-iS(t_F, t)/\hbar\right]. \tag{74.34}$$

Here $\mathbf{d}[\mathbf{p} - e\mathbf{A}(t)/c]$ denotes the dipole matrix element for the transition from the initial bound state to the continuum state in which the electron has the kinetic momentum $\mathbf{p} - e\mathbf{A}(t)/c$, t_F is the switch-off time of the laser pulse, and

$$S(t_F, t) = \int_t^{t_F} dt' \left[\frac{[\mathbf{p} - e\mathbf{A}(t')/c]^2}{2m} + I_P\right] \tag{74.35}$$

is a quasiclassical action for an electron which is born in the continuum at t and propagates freely in the laser field. The form of the expression (74.34) is generic to the SFA.

74.3.5 Phase Space Averaging Method

The methods of classical mechanics are particularly useful in describing the microwave excitation of highly excited (Rydberg) atoms [74.61, 62] (Sect. 74.2.8), but have also been applied to describe high harmonic generation, stabilization of atoms in super intense fields and two electron ionization [74.72–74].

The classical phase space averaging method [74.75] solves Newton's equations of motion

$$\dot{\mathbf{r}} = \mathbf{p}/m, \tag{74.36}$$

$$\dot{\mathbf{p}} = -\nabla V(\mathbf{r}) - e\mathbf{E}(t), \tag{74.37}$$

for the electron interacting with the ion core and the laser field. A distribution of initial conditions in phase space is chosen to mimic the initial quantum mechanical state of the system, and a sample of classical trajectories generated. Quantum mechanical averages of physical observables are then identified with ensemble averages of those observables over the initial distribution. Since the dynamics of multiphoton processes is very complex, the neglected phases in this approach generally cause negligible errors and the results can be in quite good agreement with quantum calculations. Additionally, an examination of the trajectories provides details of the excitation dynamics which are often difficult to extract from a complex time-dependent wave function.

75. Cooling and Trapping

Interactions of light with an atomic particle are accompanied by exchange of momentum between the electromagnetic field and the atom. Narrow-band resonance radiation from tunable lasers enhances the ensuing mechanical effects of light to the extent that it is literally possible to stop atoms emanating from a thermal gas, and to trap atoms with light.

References [75.1] and [75.2] are two early sources on laser cooling and trapping of the traditional two-state model atom. A number of articles on cooling and trapping of atoms with the inclusion of angular momentum degeneracy are contained in [75.3]. While the development based on the atom–field dressed states is followed sparingly in the present Chapter, an authoritative survey of this approach is given in [75.4]. Reviews on traps for charged particles include [75.5] and [75.6]. These articles, as well as [75.2], also discuss cooling of trapped particles.

Cooling and trapping of atomic particles are now standard technologies, but development and extension of the methods to new applications continues. The special issues [75.7] and [75.8]

give a current snapshot. Additional references are occasionally listed here to accentuate specific points. These citations are to either particularly representative papers or to the most recent articles on the subject, and are intended as entries to the literature. No assignment of credit or priority is implied.

75.1 Notation

In this Chapter, the lower and upper states of an optical transition are denoted by the respective labels g and e, for "ground" and "excited". The notation $J_g \rightarrow J_e$ stands for a transition in which the lower and upper levels have the angular momentum degeneracies $2J_g + 1$ and $2J_e + 1$. The resonance frequency of the transition is ω_0.

The detuning of the driving monochromatic light of frequency ω from the atomic resonance is $\Delta = \omega_0 - \omega$. Γ is the spontaneous decay rate. Spontaneous emission is taken to be the sole mechanism of line broadening, so that the HWHM linewidth of the transition is $\gamma = \Gamma/2$. The Rabi frequency is $\Omega = \mathcal{D}\mathcal{E}/\hbar$, where $\mathcal{D}$ is the reduced dipole moment matrix element that would apply to a transition with unit Clebsch–Gordan coefficient, and $\mathcal{E}$ is the electric field amplitude of the laser. The

corresponding intensity scale is the saturation intensity

$$I_s = \frac{4\pi^2 \hbar c \Gamma}{3\lambda^3} \, , \tag{75.1}$$

defined in such a way that the light intensity I satisfies

$$\Omega = \Gamma \Rightarrow I = I_s \, . \tag{75.2}$$

If multiple laser beams are explicitly mentioned, laser intensity and Rabi frequency are quoted for each of the equally intense beams.

The momentum of a photon with the wave vector $\boldsymbol{k}$ is $\hbar\boldsymbol{k}$. The recoil velocity

$$v_r = \frac{\hbar k}{m} \tag{75.3}$$

Table 75.1 Laser cooling parameters for the lowest $S_{1/2}-P_{3/2}$ transition of hydrogen and most alkalis (the D_2 line). Also shown are the nuclear spin I and the ground state hyperfine splitting $\Delta \nu_{\text{hfs}}$. Γ is typically known to within a few per cent, so these values of Γ, T_D and I_s may not all be accurate to the full displayed precision

$\Delta \nu_{\text{hfs}}$	1420	228.2	803.5	1772	461.7	1286	3036	6835	9193	2πMHz

equals the change of the velocity of an atom of mass m when it absorbs a photon with wave number $k = 2\pi/\lambda$. The kinetic energy of an atom with velocity v_r and the corresponding frequency,

$$R = \frac{1}{2}mv_r^2, \; \varepsilon_r = \frac{R}{\hbar} \tag{75.4}$$

are referred to as recoil energy and recoil frequency. Two temperatures, the Doppler limit T_D and the recoil limit T_r are often cited in laser cooling. They are

$$T_D = \frac{\hbar\gamma}{k_B}, \quad T_r = \frac{R}{k_B}, \tag{75.5}$$

where k_B is the Boltzmann constant.

Table 75.1 lists numerical values of pertinent parameters for laser cooling and trapping using the D_2 line for most stable and long-lived alkali isotopes and hydrogen.

75.2 Control of Atomic Motion by Light

75.2.1 General Theory

Hamiltonian
The mechanical effects of light may be derived from the Hamiltonian

$$\hat{H} = \hat{H}_A + \hat{H}_{cm} + \hat{H}_F - \hat{\boldsymbol{d}} \cdot \hat{\boldsymbol{E}}(\hat{\boldsymbol{r}}), \tag{75.6}$$

where $\hat{H}_A$, $\hat{H}_{cm}$ and $\hat{H}_F$ are the Hamiltonians for the internal degrees of freedom of the atom, center-of-mass (cm) motion of the atom, and free electromagnetic field. The quantized electric field is $\hat{\boldsymbol{E}}(\hat{\boldsymbol{r}})$, where $\hat{\boldsymbol{r}}$ is the cm position operator. The dipole operator $\hat{\boldsymbol{d}}$ acts on the internal degrees of freedom of the atom. Since the $\hat{\boldsymbol{d}} \cdot \hat{\boldsymbol{E}}(\hat{\boldsymbol{r}})$ term couples all degrees of freedom, the possibility of influencing cm motion by light immediately follows. The inclusion of the quantized cm motion is the essential ingredient not contained in traditional theories of light-matter interactions. For an atom with mass m trapped in a possibly anisotropic harmonic oscillator potential with

frequencies ν_i ($i = x, y, z$), the cm Hamiltonian is

$$H_{cm} = \frac{\hat{\boldsymbol{p}}^2}{2m} + \sum_{i=x,y,z} \frac{m\nu_i^2 \hat{r}_i^2}{2}, \tag{75.7}$$

where $\hat{\boldsymbol{p}}$ is the cm momentum operator. For a free atom, $\nu_i = 0$.

Master Equation
With the aid of Markov and Born approximations, the vacuum modes of the electromagnetic field may be eliminated as described in Sect. 78.7. This gives a master equation for the reduced density operator $\hat{\rho}$ that contains the internal and cm degrees of freedom of the atom. Relaxation terms proportional to Γ and γ are all that is left of the quantized fields.

Consider as an example a two-state atom in a traveling wave of light with the electric field strength

$$E(\boldsymbol{r}, t) = \frac{1}{2}\mathcal{E} \, e^{i(\boldsymbol{k} \cdot \boldsymbol{r} - \omega t)} + \text{c.c.} \tag{75.8}$$

Master equations are conveniently written using *Wigner functions* to represent the cm motion. Given the internal-state labels i and $j = g$ or e, and the three-dimensional variables $\boldsymbol{r}$, $\boldsymbol{p}$, the Wigner functions are defined as

$$\rho_{ij}(\boldsymbol{r}, \boldsymbol{p}) = \frac{1}{(2\pi\hbar)^3} \int \mathrm{d}^3 u \, \mathrm{e}^{\mathrm{i}\boldsymbol{u}\cdot\boldsymbol{p}/\hbar}$$

$$\times \left\langle \boldsymbol{r} - \frac{1}{2}\boldsymbol{u} \middle| \langle i|\hat{\rho}|j\rangle \middle| \boldsymbol{r} + \frac{1}{2}\boldsymbol{u} \right\rangle . \quad (75.9)$$

The Wigner function is one of the quantum mechanical quasiprobability distributions, Sect. 78.5, with the special property that the marginal distribution of $\boldsymbol{r}$ obtained by integrating over $\boldsymbol{p}$ coincides with the correct quantum probability distribution for position, and vice versa with $\boldsymbol{r}$ and $\boldsymbol{p}$ interchanged. In the rotating wave approximation, Sect. 68.3.2, the master equations are

$$\frac{\mathrm{d}}{\mathrm{d}t}\rho_{ee}(\boldsymbol{p}) = -\Gamma\rho_{ee}(\boldsymbol{p}) + \mathrm{i}\frac{\Omega}{2}\left[\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}\hat{\rho}_{ge}\left(\boldsymbol{p} - \frac{1}{2}\hbar\boldsymbol{k}\right)\right.$$

$$\left. - \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}\hat{\rho}_{eg}\left(\boldsymbol{p} - \frac{1}{2}\hbar\boldsymbol{k}\right)\right] , \quad (75.10)$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\rho_{gg}(\boldsymbol{p}) = \Gamma \int \mathrm{d}^2 n \, W(\hat{\boldsymbol{n}})\rho_{ee}(\boldsymbol{p} + \hbar k\hat{\boldsymbol{n}}) - \frac{\mathrm{i}\Omega}{2}$$

$$\times \left[\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}\hat{\rho}_{ge}\left(\boldsymbol{p} + \frac{1}{2}\hbar\boldsymbol{k}\right)\right.$$

$$\left. - \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}\hat{\rho}_{eg}(\boldsymbol{p} + 12\hbar\boldsymbol{k})\right] , \quad (75.11)$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\hat{\rho}_{ge}(\boldsymbol{p}) = -(\gamma - \mathrm{i}\Delta)\hat{\rho}_{ge}(\boldsymbol{p}) - \frac{\mathrm{i}\Omega}{2}$$

$$\times \left[\mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}\rho_{gg}\left(\boldsymbol{p} - \frac{1}{2}\hbar\boldsymbol{k}\right)\right.$$

$$\left. - \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}\rho_{ee}\left(\boldsymbol{p} + \frac{1}{2}\hbar\boldsymbol{k}\right)\right] , \quad (75.12)$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\hat{\rho}_{eg}(\boldsymbol{p}) = -(\gamma + \mathrm{i}\Delta)\rho_{eg}(\boldsymbol{p}) + \frac{\mathrm{i}\Omega}{2}$$

$$\times \left[\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}\rho_{gg}\left(\boldsymbol{p} - \frac{1}{2}\hbar\boldsymbol{k}\right)\right.$$

$$\left. - \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}\rho_{ee}\left(\boldsymbol{p} + \frac{1}{2}\hbar\boldsymbol{k}\right)\right] . \quad (75.13)$$

Here the convective derivative that describes the motion of the atom in the absence of light is

$$\frac{\mathrm{d}}{\mathrm{d}t} = \frac{\partial}{\partial t} + \frac{\boldsymbol{p}}{m}\cdot\frac{\partial}{\partial\boldsymbol{r}} - \sum_i m v_i r_i \frac{\partial}{\partial p_i} ; \quad (75.14)$$

cf. H_{cm} in (75.7). $W(\hat{\boldsymbol{n}})$ is the angular distribution of spontaneous photons, and the integral runs over the unit sphere. Representative expressions for $W(\hat{\boldsymbol{n}})$ are

$$W(\hat{\boldsymbol{n}}) = \frac{1}{4\pi} ,$$

$$\frac{3}{8\pi}\left[1 - (\hat{\boldsymbol{e}}\cdot\hat{\boldsymbol{n}})^2\right] , \quad \frac{3}{16\pi}\left[1 + (\hat{\boldsymbol{e}}\cdot\hat{\boldsymbol{n}})^2\right] . \quad (75.15)$$

These apply, respectively, for isotropic spontaneous emission, for spontaneous emission in a $\Delta m = 0$ transition, and in $\Delta m = \pm 1$ transitions; $\hat{\boldsymbol{e}}$ stands for the unit vector in the direction of the quantization axis for angular momentum. Only the $\boldsymbol{p}$ dependence has been denoted explicitly in the Wigner functions, as the recoil effects displayed on the right-hand sides of (75.10–75.13) take place at a fixed position $\boldsymbol{r}$.

Semiclassical Theory

Suppose that $v_{\mathrm{cm}} \gg v_{\mathrm{r}}$ and $\tau \ll \tau_{\mathrm{cm}}$, where τ and τ_{cm} are the time scales for light-driven changes of the internal state and cm motion of the atom. Then the internal degrees of freedom may be eliminated adiabatically from the master equations in favor of the position-momentum distribution for the cm motion,

$$f(\boldsymbol{r}, \boldsymbol{p}, t) = \sum_i \rho_{ii}(\boldsymbol{r}, \boldsymbol{p}, t) , \quad (75.16)$$

where the sum runs over the internal states of the atom. Technically, the recoil velocity v_{r} is treated as an asymptotically small expansion parameter. The result is the Fokker–Planck equation for the cm motion

$$\frac{\mathrm{d}}{\mathrm{d}t}f = -\frac{\partial}{\partial\boldsymbol{p}}\cdot(\boldsymbol{F}f) + \sum_{i,j}\frac{\partial^2}{\partial p_i \partial p_j}(D_{ij}f) . \quad (75.17)$$

In this semiclassical theory the cm motion of the atom is regarded as classical. The atom moves under the optical force $\boldsymbol{F}(\boldsymbol{r}, \boldsymbol{p}, t)$, which models the coarse-grained flow of momentum between the electromagnetic field and the atom. $D_{ij}(\boldsymbol{r}, \boldsymbol{p}, t)$, with $i, j = x, y, z$, is the diffusion tensor. Diffusion is an attempt to model quantum mechanics with a classical stochastic process, including discreteness of recoil kicks, random directions of spontaneous photons, and random timing of optical absorption and emission processes.

A general prescription exists for calculating the force and the diffusion tensor for an arbitrary atomic level scheme and light field [75.9]. However, the study of diffusion amounts to an involved analysis of photon statistics of the scattered light, and here only the force is considered explicitly. Let $\hat{V}(\boldsymbol{r})$ be the dipole interaction operator coupling the driving field and the internal

state for an atom at position r. By assumption, $\hat{V}(r)$ has been rendered slowly varying in time with the aid of a suitable rotating wave approximation. To compute the force, one takes an atom that travels along a hypothetical trajectory unperturbed by light in such a way that at time t it arrives at the phase space point (r, p), whereupon the density operator of the internal degrees of freedom is $\hat{\varrho}$. The force is then

$$F_i(r, p, t) = -\text{Tr}\left(\hat{\varrho}\,\frac{\partial \hat{V}}{\partial r_i}\right) . \tag{75.18}$$

Quantum Theory

When either $v_{cm} \lesssim v_r$ or $\tau \gtrsim \tau_{cm}$, the full quantum theory of cooling and trapping is needed. Master equations such as (75.10–75.13) must then be solved without the assumption that v_r is small. Most practical calculations have been numerical case studies [75.10–12]. A truncated basis, e.g., of plane waves, is used to expand the cm state. Density matrix equations are solved numerically, either directly, or by resorting to quantum trajectory simulations, Sect. 78.11.

Qualitative Origin of Laser Cooling

Velocity dependent dissipative forces are needed for cooling. They arise because the evolution of the internal state of a moving atom has a finite response time τ. The atom conveys the memory of the field it has sampled over the length $\ell = v\tau$ on its past trajectory. If $\ell \ll \lambda$, a nonequilibrium component proportional to ℓ is present in the density operator of the internal state of the atom. Further interactions with light convert this component into a velocity dependent force of the form

$$F = -m\beta v , \quad \beta \propto I\tau . \tag{75.19}$$

If the damping constant β is positive, (75.19) describes exponential damping of the velocity on the time scale β^{-1}. In the contrary case $\ell \gg \lambda$, when the atom travels many wavelengths during the memory time, linear dependence of force on velocity breaks down. The watershed is the critical velocity or velocity capture range

$$v_c \approx \frac{\lambda}{\tau} . \tag{75.20}$$

One–Dimensional Considerations

Most specific results cited here are one-dimensional. By default, the propagation direction of light and the direction of vector quantities other than light polarization is $\hat{e}_x$. The relevant components of position, velocity and momentum are denoted by x, v, and p.

The general one-dimensional Fokker–Planck equation for a particle trapped in a harmonic oscillator potential with a cm oscillation frequency ν is

$$\left(\frac{\partial}{\partial t} + \frac{p}{m}\frac{\partial}{\partial x} - m\nu^2 x\frac{\partial}{\partial p}\right) f$$
$$= -\frac{\partial}{\partial p}(Ff) + \frac{\partial^2}{\partial p^2}(Df) . \tag{75.21}$$

For the force (75.19) with constant $\beta = \beta_0$ and $D(z, p) = D_0$, the steady state of the Fokker–Planck equation is a thermal distribution of the form

$$f(x, p) = K \exp\left[-\frac{\beta_0 m}{D_0}\left(\frac{p^2}{2m} + \frac{m\nu^2 x^2}{2}\right)\right] , \tag{75.22}$$

where K is a normalization coefficient.

Since Wigner functions give correct quantum mechanical marginal distributions for r and p, expectation values of kinetic and potential energy may be calculated from the distribution function (75.22) as if it were a classical phase space density. For a free atom with $\nu = 0$, the temperature is directly proportional to the kinetic energy,

$$T = \frac{D_0}{\beta_0 m k_B} . \tag{75.23}$$

However, for a trapped particle with $\nu \neq 0$ the Fokker–Planck equation may be valid all the way to the quantum mechanical zero-point energy. Then temperature and energy are no longer directly proportional to one another. For a trapped particle, the safe interpretation of (75.22) is that the total cm energy of the particle is

$$E = \frac{D_0}{\beta_0 m} . \tag{75.24}$$

75.2.2 Two–State Atoms

A two-state or two-level atom, discussed in detail in Sect. 68.3, stands for a closed (recycling) transition with one lower state and one excited state. In practice, a two-state system is often realized by driving a $J \to J + 1$ transition with circularly polarized light. This leads to optical pumping to the states with maximal (or minimal) component of angular momentum along the quantization axis, say, to the transition $m = J \to J + 1$.

Two types of force are generally distinguished: light pressure, or scattering force, or spontaneous force, and dipole, or gradient, or induced force. However, the distinction is neither exclusive, nor exhaustive. Here the two types of force are approached by way of examples.

Traveling Waves

Light Pressure. Consider a cycle of absorption and spontaneous emission. In an absorption, the atom receives a photon recoil kick in the direction of the laser beam, while in spontaneous emission the recoil kick has a random direction and zero average. The atom is on the average left with a velocity change equal to v_r. The corresponding force is along k, and is given by

$$F = F_m \frac{\Omega^2/2}{\gamma^2 + \Delta^2(v) + \Omega^2/2} \ . \tag{75.25}$$

Here the maximum of light pressure force, a convenient scale for optical forces, is

$$F_m = \frac{1}{2} M v_r \Gamma \ , \tag{75.26}$$

and

$$\Delta(v) = \Delta + kv \tag{75.27}$$

is the effective detuning, which includes the Doppler shift experienced by the moving atom.

Diffusion. For a traveling wave, the diffusion coefficient accompanying light pressure is

$$\frac{D}{\hbar^2 k^2 \Gamma} = \frac{(1+\alpha)\Omega^2}{4\left[\Delta^2(v) + \gamma^2 + \Omega^2/2\right]}$$
$$- \frac{\left[\Delta^2(v) - 3\gamma^2\right]\Omega^4}{4\left[\Delta^2(v) + \gamma^2 + \Omega^2/2\right]^3} \ , \tag{75.28}$$

where

$$\alpha = \int d^2 n \, W(\hat{n})(\hat{e}_x \cdot \hat{n})^2 \tag{75.29}$$

depends on $W(\hat{n})$, see (75.15). Representative values are $\alpha = 1/3$ for isotropic spontaneous emission, and $\alpha = 2/5$ ($\alpha = 3/10$) for spontaneous emission with $\Delta m = 0$ ($\Delta m = \pm 1$) with respect to a quantization axis that is perpendicular (parallel) to the direction $\hat{e}_x$.

Spontaneously emitted photons cover all of the 4π solid angle, and so do the directions of photon recoil kicks on the atom. Absorption from a light wave traveling in a particular direction leads to transverse diffusion also in the orthogonal directions, which is not accounted for by the one-dimensional (75.28).

Phenomenology in Multimode Fields

Doppler Cooling in Standing Waves. Next take an atom in two counterpropagating plane waves of light. At low intensity, $\Omega \ll \Gamma$, forces of the form (75.25) for the two

beams may be added when averaged over a wavelength. For velocities well below the critical velocity

$$v_{c,D} = \frac{\Gamma}{k} \ , \tag{75.30}$$

the wavelength-averaged force is of the form of (75.19),

$$F = -m\bar{\beta}v \ , \quad \bar{\beta} = \frac{4\Omega^2 \gamma \Delta}{\left(\Delta^2 + \gamma^2\right)^2} \varepsilon_r \ . \tag{75.31}$$

When light is tuned below the atomic resonance ("red detuning" with $\Delta > 0$), exponential damping of the atomic velocity with the time constant $\bar{\beta}^{-1}$ ensues. No matter which way the atom moves, it is always Doppler tuned toward resonance with the light wave that propagates opposite to its velocity, and away from resonance with the light wave that propagates along its velocity. Net momentum transfer therefore opposes the motion of the atom. This is known as Doppler cooling.

Optical Molasses. For three pairs of counterpropagating waves in three orthogonal directions, (75.31) is valid in all coordinate directions, and hence as a vector equation between the force F and velocity v. For $\Delta > 0$ an atom experiences an isotropic viscous damping force, as if it were moving in a thick liquid. Such a field configuration is dubbed optical molasses. Two counterpropagating beams make a one-dimensional optical molasses.

Limit of Doppler Cooling. Under the conditions of (75.31), the diffusion coefficients for the two counterpropagating beams averaged over a wavelength may be added, and the $v = 0$ form suffices for slow atoms. This yields

$$\frac{\bar{D}(v=0)}{\hbar^2 k^2 \Gamma} = \frac{(1+\alpha)\,\Omega^2}{2\left(\Delta^2 + \gamma^2\right)} \ . \tag{75.32}$$

The random diffusive motion of the atom corresponds to diffusive heating that competes with Doppler cooling. In equilibrium, the temperature is

$$T = \frac{\bar{D}(v=0)}{m\bar{\beta}k_B} = \frac{\hbar\gamma}{4k_B}(1+\alpha)\left(\frac{\Delta}{\gamma} + \frac{\gamma}{\Delta}\right) \ . \tag{75.33}$$

Equation (75.33) also applies to three-dimensional Doppler cooled molasses, provided one uses $\alpha = 1$ corresponding to added transverse diffusion. The minimum temperature is reached at

$$\Delta = \gamma = \frac{\Gamma}{2} \ . \tag{75.34}$$

For three-dimensional molasses, the Doppler limit T_D of (75.5) is obtained.

For $\Omega > \Gamma$, the performance of Doppler cooling deteriorates. Qualitatively, power broadening increases the effective linewidth γ.

Dipole Forces. Dipole forces are the resonant analog of ponderomotive forces discussed in Sect. 74.2. They arise from successions of absorption and induced emission driven by photons with different momenta. Such processes occur only if there is more than one wave vector present in the field, i.e., if there is an intensity gradient. For a zero-velocity two-state atom, the gradient force in a monochromatic field with the local total intensity $I(\boldsymbol{r})$ is

$$F_g(\boldsymbol{r}) = \frac{4\hbar\Delta\gamma^2}{\Delta^2 + \gamma^2[1 + 2I(\boldsymbol{r})/I_s]} \frac{\nabla I(\boldsymbol{r})}{I_s} . \tag{75.35}$$

The dipole force may be derived from the potential energy

$$V_g(\boldsymbol{r}) = -2\hbar\Delta \ln\left(1 + \frac{2\gamma^2 I(\boldsymbol{r})/I_s}{\Delta^2 + \gamma^2}\right) . \tag{75.36}$$

The atoms are strong field seekers for $\Delta > 0$, and weak field seekers when $\Delta < 0$.

Optical Trap and Optical Lattice. Dipole forces are utilized in the optical trap for atoms, and even molecules. A common configuration consists of a focused laser beam tuned below resonance. The focus becomes the trap. The detuning from resonance may be substantial; lasers such as CO_2 and Nd–YAG have been used.

A standing wave of light makes a periodic array of optical traps called an optical lattice. Optical lattices may be set up in 1D, 2D, and 3D configurations.

Induced Diffusion. Random motion of atoms in velocity space owing to absorptions and induced emissions of photons with different momenta leads to induced diffusion. Contrary to diffusion in a traveling wave as in (75.28), induced diffusion does not saturate at high intensity. Instead, the diffusion coefficient continues to grow linearly with I. Induced diffusion is another reason why the lowest Doppler cooling temperatures are generally reached at low ($I < I_s$) light intensities.

Sisyphus Effect. In a standing wave at high intensity and large detuning, another kind of optical force becomes important that cannot be categorized either as light pressure or gradient force.

As explained in Sect. 68.3.4, one may diagonalize the Hamiltonian to obtain the dressed atom-field states. Because the light field depends on position, so do the energies of the dressed states and their decompositions into plain atomic states. In Fig. 75.1 drawn for $\Delta < 0$, the dressed state with a minimum (maximum) at the field nodes coincides with the bare ground state (excited state) at the nodes. At the antinodes the admixtures of ground and excited states are evened out to some extent.

The energy of a dressed state acts as potential energy for the cm motion of an atom residing in that particular state. In fact, the gradient force is the force derived from these potential energies, averaged over the occupation probabilities of the dressed states. The occupation probability is larger for the dressed state with a larger ground state admixture. From Fig. 75.1 one therefore sees that the atom predominantly resides in the dressed state that has a minimum of energy at the nodes. The atom is a weak-field seeker, as it should for $\Delta < 0$.

Spontaneous emission remains to be considered. It gives rise to transitions between the dressed states. These transitions may go both ways between the dressed states, because the states are in general superpositions of the bare ground state and the excited state. The rate of spontaneous transitions from one dressed state to another
Fig. 75.1 Qualitative origin of Sisyphus effect. The *hatched pattern* represents a standing light wave. The energies of the two dressed states are drawn as a function of position, along with a few *filled circles* representing the admixture of the ground state in each dressed state at selected field positions. *Larger circles* correspond to larger ground state admixtures, and hence, larger equilibrium populations of the dressed state. This figure applies for tuning of the laser above the atomic resonance ("blue detuning")

increases (decreases) with the excited (ground) state admixture of the initial state.

In reference to Fig. 75.1, suppose that the atom is coming from the left in the upper dressed state. The probability that the atom makes a transition to the lower dressed state, as marked by the downward vertical arrow, is largest at the node. If this transition takes place, near the next antinode the most probable transition is as shown by the upward vertical arrow. In this manner the atom spends most of its time at an uphill climb against the potential, and is therefore slowed down. In reference to Greek mythology, this is called the Sisyphus effect. In the two-state model atom, cooling takes place when the laser frequency is higher than the atomic resonance frequency.

Exact Results for Standing Waves

Force. The force on a two-state atom in a one-dimensional standing light wave may be expanded analytically to first order in velocity. With the field phase chosen so that the antinode is at $x = 0$, the force is

$$F(x, v) = F_g(x) - m\beta(x)v \, , \tag{75.37}$$

where the gradient force is

$$F_g(x) = -\frac{\hbar k \Delta \, \Omega^2 \sin 2kx}{d} \, , \tag{75.38}$$

and the damping coefficient is

$$\begin{aligned} \beta(x) = {}&8\Delta\Omega^2\varepsilon_r\gamma^{-1}d^{-3}\left(1 - \cos^2 kx\right) \\ &\times\left(\Delta^2\gamma^2 + \gamma^4 - 2\gamma^2\Omega^2\cos^2 kx\right. \\ &\left. - 2\Omega^4\cos^4 kx\right) \, , \end{aligned} \tag{75.39}$$

with $d = \Delta^2 + \gamma^2 + 2\Omega^2\cos^2 kx$.

Diffusion. For a standing wave, the $v = 0$ form of the diffusion coefficient is

$$\begin{aligned} &\frac{D(v = 0)}{\hbar^2 k^2 \Gamma} \\ &= \frac{\Omega^2 \left(\alpha\gamma^2\cos^2 kx + \gamma^2\sin^2 kx + 2\Omega^2\sin^2 kx\cos^2 kx\right)}{2\gamma^2 d} \\ &\quad - \frac{\Delta^2\Omega^4\sin^2 kx\cos^2 kx\left(\Delta^2 + 5\gamma^2 + 4\Omega^2\cos^2 kx\right)}{\gamma^2 d^3} \, . \end{aligned} \tag{75.40}$$

Semiclassical versus Quantum Theory

When $\gamma \gg \varepsilon_r$, the r.m.s. velocity of a cooled two-state atom is always $\gg v_r$, and semiclassical theory is valid.

Under the same condition $\gamma \gg \varepsilon_r$, the Doppler-limit r.m.s. velocity also is less than the critical velocity $v_{c,D}$ from (75.30). Velocity expansions such as in (75.37) and (75.40) are then justified.

In the contrary case, $\gamma \lesssim \varepsilon_r$, the full quantum theory of trapping and cooling must be employed. The cooled velocity distribution is not thermal, and temperature is ill-defined. The lowest expectation value of kinetic energy for a two-state atom in a linearly polarized standing wave occurs at low I for $\Delta = 4.4\varepsilon_r$, and is equal to $0.53\,R$.

75.2.3 Multistate Atoms

Energy levels of atomic systems usually have angular momentum degeneracy. In addition, the polarization of light in general depends on position. A combination of these aspects leads to phenomena beyond the two-state atomic model.

Polarization Gradient Cooling

As explained in connection with (75.19), a finite memory time of the internal atomic state may lead to damping of the cm motion. For a two-state atom, internal equilibration arises from spontaneous emission. The time scale is $\tau_D \sim \Gamma^{-1}$, and Doppler cooling ensues. However, an atom whose ground state has angular momentum degeneracy is also subject to optical pumping. If the polarization of light varies as a function of position, optical pumping is needed to reach local equilibrium. The pumping time scale $\tau_p \propto I^{-1}$ then becomes relevant for a moving atom. The associated cooling is known as polarization gradient cooling. Its hallmark is that, for low I, the damping coefficient $\beta \propto I\tau_p$ is independent of intensity.

Two detailed mechanisms of polarization gradient cooling have been described [75.13], although in three-dimensional light fields they are intertwined. The Sisyphus effect works like the Sisyphus effect for a two-state atom, except that it relies on light shifts and optical pumping within the ground state manifold. Induced orientation cooling is analogous to Doppler cooling. Velocity dependence of optical pumping in counterpropagating waves leads to pumping to a state for which the force due to the wave propagating opposite to the atom exceeds the force due to the wave propagating along with the atom.

Lin ⊥ Lin Molasses. One-dimensional lin ⊥ lin molasses consists of two counterpropagating waves with orthogonal linear polarizations. The net polarization varies

from linear – via elliptical – to circular over a distance of $\lambda/8$. With the phases chosen such that light is linearly polarized at $x = 0$, in the limit of nonsaturating intensity, and at low velocity, the semiclassical force on an atom with a $J = 1/2 \rightarrow 3/2$ transition is

$$F = -\hbar k \Delta \left[\frac{1}{3} s \sin 4kx - \frac{2}{3} qv\gamma^{-1}(1 + \cos 4kx) \right] . \tag{75.41}$$

Here the saturation parameter s is

$$s = \frac{\Omega^2/2}{\Delta^2 + \gamma^2} . \tag{75.42}$$

In this configuration, only the Sisyphus effect contributes to cooling. Cooling takes place for $\Delta > 0$, and the resulting temperature obtained from the position-averaged quantities is

$$T = \frac{135\Delta^2 + 296\gamma^2}{1080(\Delta^2 + \gamma^2)} \left(\frac{2I\Gamma}{I_s|\Delta|} \right) T_D . \tag{75.43}$$

$\sigma^+ - \sigma^-$ *Molasses.* One-dimensional $\sigma^+ - \sigma^-$ molasses consists of two counterpropagating waves with opposite circular polarizations. The net polarization is linear everywhere, but the direction of polarization rotates as the point of observation is displaced along the propagation axis; hence, the alternative name corkscrew molasses. At low intensity and low velocity, the force on an atom with a $J = 1 \rightarrow 2$ transition is

$$F = -\frac{60}{17} \frac{\Delta\gamma}{5\gamma^2 + \Delta^2} \hbar k^2 v . \tag{75.44}$$

In this configuration only induced orientation cooling contributes. Cooling again takes place for $\Delta > 0$, and the resulting temperature is

$$T = \frac{29\Delta^2 + 1045\gamma^2}{300(\Delta^2 + \gamma^2)} \left(\frac{2I\Gamma}{I_s|\Delta|} \right) T_D . \tag{75.45}$$

Lin ∥ Lin Molasses. The designation lin ∥ lin denotes a standing wave with the same linear polarization for both counterpropagating beams. In one dimension there is no polarization gradient, but three lin ∥ lin pairs in orthogonal directions (often with mutually orthogonal polarizations) make a three-dimensional optical molasses with potential polarization gradient cooling.

Experimental Molasses. For $I\Gamma/I_s|\Delta| < 1$ and $|\Delta| > \Gamma$, the temperatures (75.43) and (75.45) both reduce to the form

$$T = C \frac{\hbar\Omega^2}{k_B|\Delta|} = C \frac{2I\Gamma}{I_s|\Delta|} T_D . \tag{75.46}$$

Under these conditions the same scaling is approximately observed also in three-dimensional six-beam optical molasses operating with atoms that have a degenerate ground state. The constant C depends on the degeneracy of the transitions and on the polarizations of the molasses beams. Measured values are mostly in the range $0.25 < C < 0.5$ [75.14].

Limit of Cooling. While the expressions (75.43), (75.45) and (75.46) suggest that T goes all the way to zero as $I \rightarrow 0$ or $\Delta \rightarrow \infty$, there is a lower limit of T reached in polarization gradient cooling. T eventually starts to rise abruptly when $|\Delta|$ is increased or I is decreased. The empirical rule of thumb is that $T \sim 10\, T_r$ is the lowest temperature one can expect.

Semiclassical versus Quantum Theory. According to the semiclassical theory, $T \propto I$, so the r.m.s. velocity of cooled atoms is proportional to $I^{1/2}$. Now, the critical velocity of polarization gradient cooling, estimated roughly as

$$v_{c,p} = \frac{\lambda}{\tau_p} \approx \frac{\lambda\gamma\Omega^2}{\Delta^2 + \gamma^2} , \tag{75.47}$$

is proportional to I. At low enough I, $v_{c,p}$ is therefore smaller than the velocity width of the cooled atoms. Expansions of force and diffusion in velocity are no longer useful, and temperature predictions of the type (75.46) fail. This occurs, at the latest, when the r.m.s. velocity equals a few recoil velocities.

Semiclassical theory does not lead to predictions that grossly violate its key premise that the ensuing velocity distribution is much broader than v_r. However, reliable theoretical limits of temperature for polarization gradient cooling may only be obtained from the full quantum treatment.

Magneto–Optical Trap

Since spontaneous forces may be strong already at modest light intensities $\sim l_{mathrmS}$ use of light pressure to trap neutral atoms appears desirable. However, the optical Earnshaw theorem states that (in the limit of low I) the spontaneous force on a two-state atom is sourceless. While confinement may be possible in some directions, escape routes for atoms remain open in others. Three-dimensional trapping of a two-state atom with light pressure is not possible.

A Magneto-optical trap (MOT) defeats the Earnshaw theorem by relying on angular momentum degeneracy. Consider an atom with a $J = 0 \rightarrow 1$ transition in a magnetic field $\boldsymbol{B}$ that depends linearly on position around the

zero at $x = 0$. Suppose that the gradient of B is chosen in such a way that the $m = 1$ ($m = -1$) magnetic substate of the excited state has the higher (lower) energy for $x > 0$, and that the atom is illuminated by $\sigma^\pm$ polarized beams propagating in the $\pm x$-directions, tuned below resonance. When the atom is displaced from $x = 0$ in either direction, it is closer to resonance with the beam that pushes it back toward $x = 0$. This makes the restoring force responsible for trapping.

A magneto-optical trap can be set up also in three dimensions. A quadrupole magnetic field of the form

$$ B(r) \simeq \left. \frac{\partial B_z}{\partial z} \right|_{r=0} \left(z\hat{e}_z - \frac{1}{2}x\hat{e}_x - \frac{1}{2}y\hat{e}_y \right) \qquad (75.48) $$

is produced by reversing the direction of current in one of the two Helmholtz coils. Three orthogonal pairs of light beams, each in the σ^+–σ^- configuration, complete the trap. The magnetic field is sourceless. To compensate for the ensuing signs of the field gradients, one of the σ^+–σ^- corkscrews has the opposite handedness from the other two.

The mechanism of the magneto-optical trap for the $J = 0 \rightarrow 1$ configuration is the same as the mechanism for Doppler cooling, except that position dependent level shifts of the excited states take the place of velocity dependent Doppler shifts. The restoring force and the damping coefficient of Doppler cooling are closely related. For the coordinate directions $u = x, y, z$ the relation is

$$ F_u = -\kappa_u u, \kappa_u = \beta \frac{m g_e \mu_B}{\hbar k} \left| \frac{\partial B_u}{\partial u} \right| , \qquad (75.49) $$

where g_e is the Landé factor for the excited state.

A magneto-optical trap may similarly be based on the induced orientation mechanism of polarization gradient cooling. In that case, the Landé factor of the ground state, g_g, should probably be used in (75.49). This may be the true mechanism of most magneto-optical traps, but insufficient quantitative understanding precludes firm conclusions.

Atoms in a well-aligned magneto-optical trap reside near the zero of B, so that the magnetic field has little effect on polarization gradient cooling. Trapping and cooling are achieved simultaneously.

75.3 Magnetic Trap for Atoms

The magnitude $B(r)$ of a magnetic field may have a minimum in free space, as in (75.48). A particle with a magnetic dipole moment μ then experiences a trapping potential $U(r) = \mu B(r)$ if μ and B are antiparallel. μ remains locked antiparallel to B if the field seen by the moving dipole satisfies the adiabatic condition

$$ \frac{1}{B} \left| \frac{\mathrm{d}B}{\mathrm{d}t} \right| \ll \frac{\mu B}{\hbar} \qquad (75.50) $$

(Section 73.3.4). However, if $B(r) = 0$ at the minimum, the adiabatic condition is violated and the dipole may flip (Majorana transition). The particle may end up in a repulsive potential, and get expelled from the trap. This becomes a problem at low temperatures, when the

particles accumulate near the minimum of the potential. Trap configurations are therefore designed in which $B(r) \neq 0$ at the minimum.

Evaporative Cooling.
A magnetic trap is often combined with evaporative cooling. The most energetic atoms from the tail of the thermal distribution escape from the trap, whereupon the average energy of the remaining atoms decreases. Successful operation of evaporative cooling requires a high enough rate of elastic collisions so that the atoms thermalize in a time short compared with the lifetime of the sample. In order to sustain the rate of evaporation, the effective depth of the trap is lowered as the atoms cool.

75.4 Trapping and Cooling of Charged Particles

Since the potential $\Phi(r)$ of a static electric field satisfies Laplace's equation, $\Phi(r)$ cannot have an extremum in free space. A static electric field therefore cannot serve as an ion trap (Earnshaw's theorem). Paul and Penning traps circumvent this limitation by making use of an alternating electric field and a magnetic field, respectively. Cooling is often employed to assist trapping.

75.4.1 Paul Trap

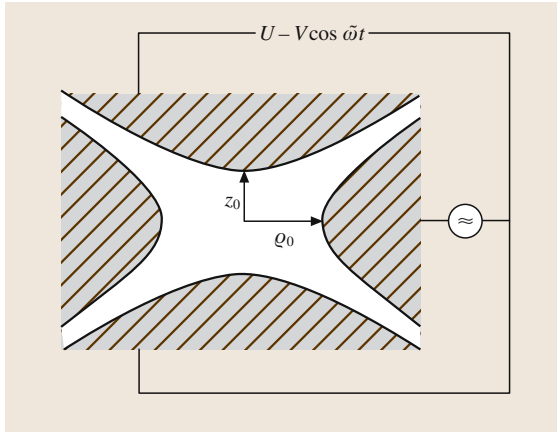
Trapping
Configuration. Consider an ideal trap whose surfaces are hyperboloids of revolution; see Fig. 75.2. The two "endcaps" and the intervening "ring" are equipotential surfaces of the quasistatic electric


Fig. 75.2 Electrode configuration and voltages of an ideal hyperboloid Paul trap

potential

$$\Phi(x, y, z) = \frac{\Phi_0(t) \left(2z^2 - x^2 - y^2\right)}{2\varrho_0^2} , \qquad (75.51)$$

where ϱ_0 is the distance from the center to the ring, $z_0 = \varrho_0/\sqrt{2}$ is the distance to the endcaps, and $\Phi_0(t)$ is a voltage applied between the endcaps and the ring,

$$\Phi_0(t) = U - V \cos \tilde{\omega}t . \qquad (75.52)$$

Motion of an Ion. In the ideal three-dimensional Paul trap, Newton's equations of motion for the coordinates $u = x$, y or z may be recast as Mathieu's equations,

$$\frac{\mathrm{d}^2 u}{\mathrm{d}\tau^2} + (a_u - 2q_u \cos 2\tau)u = 0 , \qquad (75.53)$$

where $\tau = \tilde{\omega}t/2$ is a dimensionless quantity proportional to time, the parameters are

$$a_z = -2a_{x,y} = -\frac{8qU}{m\tilde{\omega}^2\varrho_0^2} , \qquad (75.54)$$

$$q_z = -2q_{x,y} = -\frac{4qV}{m\tilde{\omega}^2\varrho_0^2} , \qquad (75.55)$$

and m and q are the mass and charge of the particle. Stable trapping ensues when a_u and q_u are such that the motion of the ion is stable in all directions. A Paul trap normally operates in the first stability region of (75.53).

Stable motion may be qualitatively divided into forced micromotion at the frequency $\tilde{\omega}$ of the external drive, and into slower secular motion of the center of the micromotion. If $U = 0$, the secular motion takes place in an effective ponderomotive potential U_P, Sect. 74.2,

equal to the cycle-averaged kinetic energy in the micromotion. Explicitly,

$$U_P(\boldsymbol{r}) = \frac{q^2 \mathcal{E}^2(\boldsymbol{r})}{4m\tilde{\omega}^2} = \frac{q^2 V^2 \left(x^2 + y^2 + 4z^2\right)}{4m\tilde{\omega}^2\varrho_0^4} , \qquad (75.56)$$

where $\mathcal{E}(\boldsymbol{r})$ is the ac field amplitude. This is an anisotropic harmonic oscillator potential characterized by the oscillation frequencies

$$\nu_z = 2\nu_{x,y} = \frac{\sqrt{2}qV}{m\tilde{\omega}\varrho_0^2} . \qquad (75.57)$$

Quantization of C.M. Motion. The separation of micromotion and secular motion is excellent, and the trap is stable, when $\nu_{x,y,z} \ll \tilde{\omega}$. Ignoring the micromotion, the cm motion of the ions in the potential $U_P(\boldsymbol{r})$ may be quantized readily. The energy of a state with $n_{x,y,z}$ quanta in the coordinate directions x, y, z is

$$E = \sum_{i=x,y,z} \hbar\nu_i \left(n_i + \frac{1}{2}\right) . \qquad (75.58)$$

Variations of Paul Trap. Little practical advantage usually arises from a realization of the ideal shape. Even a single electrode with an applied ac voltage may work as a Paul trap. A linear trap is basically a two-dimensional Paul trap with an added static longitudinal potential to prevent escape of the ions from the ends of the trap. A closed race track Paul trap is obtained by bending a linear trap into a ring.

Cooling
Laser Cooling in One Dimension. The secular motion of an ion may be cooled using lasers. Consider the motion of the ion in one of the principal-axis directions x, y, z, with ν denoting the corresponding cm frequency. In the common case where $\gamma \gg \nu$, Doppler cooling works basically as with a free atom. In the contrary case, $\nu \gg \gamma$, cooling may be achieved by tuning the laser to $\omega = \omega_0 - \nu$. Resonant photoabsorption starting with n cm quanta decreases the quantum number from n to $n - 1$, and subsequent spontaneous emission on the average leaves the cm energy nearly untouched. The net effect is reduction of the cm energy by $\hbar\nu$ in such a Raman process. Since the oscillating ion sees a frequency-modulated laser with sidebands, this method of ion cooling is called sideband cooling.

For one-dimensional motion of a two-state ion in a traveling light wave at low I, the velocity damping

rate is

$$\beta = \frac{2\Omega^2 \gamma \Delta}{\left[(\Delta + \nu)^2 + \gamma^2\right]\left[(\Delta - \nu)^2 + \gamma^2\right]}\varepsilon_\mathrm{r} \,, \qquad (75.59)$$

and the expectation value of the cm energy is

$$\begin{aligned} E = \frac{\hbar}{4\Delta} \Bigg(& \Delta^2 + \gamma^2 + \nu^2 \\ & + \alpha \frac{\left[(\Delta - \nu)^2 + \gamma^2\right]\left[(\Delta + \nu)^2 + \gamma^2\right]}{\Delta^2 + \gamma^2} \Bigg) \,, \end{aligned}$$
$$(75.60)$$

where α characterizes the angular distribution of spontaneous emission, see (75.29). The result (75.60) is useful when either $\varepsilon_\mathrm{r} \ll \gamma$ or $\varepsilon_\mathrm{r} \ll \nu$. The limit $\nu \ll \gamma$ is for Doppler cooling; the temperature from (75.60) coincides with (75.33) for a free atom. The case with both $\nu \gg \gamma$ and $\varepsilon_\mathrm{r} \ll \nu$ corresponds to sideband cooling in the Lamb–Dicke regime, in which the cooled ion is confined to a region much smaller than λ.

In connection with sideband cooling, it is convenient to cite the expectation number of harmonic oscillator quanta $\langle n \rangle$ instead of energy or temperature; the latter are

$$E = \hbar\nu\left(\langle n \rangle + \frac{1}{2}\right) \,, \quad T = \frac{\hbar\nu}{k_\mathrm{B}}\left[\ln\left(1 + \langle n \rangle^{-1}\right)\right]^{-1} \,. $$
$$(75.61)$$

For optimal sideband cooling, $\nu \gg \gamma$ and $\Delta = \nu$, the result is

$$\langle n \rangle = \frac{1}{4}(1 + 4\alpha)\left(\frac{\gamma}{\nu}\right)^2 + O\left[\left(\frac{\gamma}{\nu}\right)^4\right] \,. \qquad (75.62)$$

In principle, by decreasing the linewidth γ, the ion may be put arbitrarily close to the ground state of the cm harmonic oscillator. Such a decrease is not practical in real two-state systems, but is routinely achieved by using the two-photon resonance in a three-state Λ configuration as an effective two-state system; see Sect. 73.6.2.

Laser Cooling in Three Dimensions. Either by design or chance, no two of the ν_i are precisely degenerate. If the damping rate β and the trap frequencies ν_i satisfy

$$\beta \lesssim |\nu_i - \nu_j|, i \neq j \,, \qquad (75.63)$$

the motion of the ion in each principal axis direction of the trap is cooled independently of the other directions. For $\gamma \gg \nu_{x,y,z}$, a single laser beam propagating approximately in the direction $\left(1/\sqrt{3}\right)(\hat{\boldsymbol{e}}_x + \hat{\boldsymbol{e}}_y + \hat{\boldsymbol{e}}_z)$ suffices to cool all components of the secular motion.

Energy in Micromotion. Possibly with the aid of compensating static electric fields, one cooled ion may be confined near the zero of the trapping ac electric fields. Then the energy in the micromotion is comparable to the energy in the secular motion.

75.4.2 Penning Trap

Trapping

Configuration. In the Penning trap, a dc voltage U is applied between the endcaps and the ring, and a constant magnetic field $\boldsymbol{B}$ in the direction of the trap axis z is added. The magnetic field forces an ion escaping toward the ring to turn back.

Motion of an Ion. The motion of an ion is a superposition of three periodic components. For the same ideal hyperboloid shape that was discussed with the Paul trap, (75.51) and Fig. 75.2, the three components are completely decoupled. Firstly, in the axial direction, the ion executes oscillations at the axial frequency

$$\nu_z = \left(\frac{2qU}{m\varrho_0^2}\right)^{1/2} \,. \qquad (75.64)$$

Secondly, the ion undergoes cyclotron motion in the plane perpendicular to the trap axis. As a result of the electric field, the frequency of the cyclotron motion

$$\nu'_\mathrm{c} = \frac{1}{2}\nu_\mathrm{c} + \left(\frac{1}{4}\nu_\mathrm{c}^2 - \frac{1}{2}\nu_z^2\right)^{1/2} \qquad (75.65)$$

is displaced from the cyclotron frequency $\nu_\mathrm{c} = qB/m$ of a free ion. Thirdly, the guiding center of cyclotron motion rotates about the trap axis at the magnetron frequency

$$\nu_\mathrm{m} = \frac{1}{2}\nu_\mathrm{c} - \left(\frac{1}{4}\nu_\mathrm{c}^2 - \frac{1}{2}\nu_z^2\right)^{1/2} \,. \qquad (75.66)$$

The frequencies typically satisfy

$$\nu_\mathrm{m} \ll \nu_z \ll \nu'_\mathrm{c} \,. \qquad (75.67)$$

Magnetron motion has unusual properties. It takes up the majority of the electrostatic energy in the transverse directions, which in the absence of the magnetic field would lead to expulsion of the ion. Relative to a stationary ion at the trap center, the energy of the magnetron motion is bounded from above by zero. The radius, as well as velocity and kinetic energy of magnetron motion, decreases with increasing total energy. The energy for a state with n_c, n_z and n_m quanta in the cyclotron,

axial and magnetron motions is therefore

$$E = \hbar \nu_c' \left(n_c + \frac{1}{2} \right) + \hbar \nu_z \left(n_z + \frac{1}{2} \right)$$

$$- \hbar \nu_m \left(n_m + \frac{1}{2} \right) . \tag{75.68}$$

Cooling

Laser Cooling. For ions in a practical Penning trap, the frequencies ν_c', ν_z and ν_m are $< \gamma$. If $\boldsymbol{k}$ is not orthogonal to either the cyclotron motion or the axial motion, Doppler cooling proceeds essentially as for a free atom. However, energy should be added to the magnetron motion in order to reduce the magnetron radius and velocity. The solution is to aim a finite-size laser beam off the center of the trap in such a way that an ion experiences a higher (lower) intensity over the part of its magnetron orbit in which it travels in the direction of (opposite to) the laser beam. With a proper choice of the parameters, the ensuing addition of energy overcomes Doppler cooling of the magnetron motion.

Other Cooling Methods. Precision measurements are carried out in Penning traps with objects that do not have an internal level structure suitable for laser cooling; and thus, other cooling methods are used.

For light particles such as electrons, characteristic times of radiative damping of the cyclotron motion are in the subsecond regime, and hence, so are the equilibration times with blackbody radiation. Cooling is accomplished by enclosing the trap in a low-temperature (e.g. liquid helium) environment. For protons and heavier particles, the equilibration times of the cyclotron motion with the environment are impracticably long, and the same applies to the axial and magnetron motions even for electrons.

A workable cooling scheme for the axial motion is based on the charges that the oscillating particle induces on the endcaps. The charges generate currents in an external circuit connecting the endcaps. The endcaps are thus coupled to a cooled resonant circuit tuned to the axial frequency, and axial motion relaxes to thermal equilibrium with the resonant circuit. A variant of this resistive cooling , in which the ring is split into electrically insulated segments, is used to cool the cyclotron motion of protons and heavier ions.

Magnetron motion of an electron or proton is cooled by sideband cooling. An electric field with components in both the z-direction and xy-plane, and tuned to $\omega = \nu_z + \nu_m$, drives transitions which may either increase or decrease the number of quanta in each mode.

However, the matrix elements favor transitions with $\Delta n_z = 1$ and $\Delta n_m = -1$. Pumping of the axial motion is canceled by axial cooling, while an equilibrium with low kinetic energy ensues for the magnetron motion. Ideally, the ratio of kinetic energies becomes

$$\frac{\mathcal{T}_{\mathrm{kin,m}}}{\mathcal{T}_{\mathrm{kin,z}}} = \frac{\nu_m}{\nu_z} . \tag{75.69}$$

75.4.3 Collective Effects in Ion Clouds

As soon as there is more than one ion in the trap, Coulomb interactions between the ions profoundly shape the physics [75.15, 16].

Ion Crystal

In the standard Paul trap radio frequency heating due (presumably) to transfer of energy from micromotion to secular motion limits the number of ions that can be cooled efficiently by a laser. Nevertheless, at a low temperature, the ions settle to equilibrium positions corresponding to a minimum of the joint trapping and Coulomb potentials, and form a "crystal". Depending on the trap parameters, the ions may also execute quasiperiodic or chaotic collective motion, or move nearly independently of one another. Changes between crystalline and liquid forms of the ion cloud resembling phase transitions are observed.

Strongly Coupled Plasma

Cooling of a large number of ions is possible in a Penning trap. However, magnetron motion becomes uniform rotation of the entire cloud, and Coulomb interactions set a lower limit on the attainable radius of the cloud. This leads to a lower limit on the kinetic energy and second-order Doppler shift.

In a co-rotating frame, the ions behave like a one-component plasma on a neutralizing background. The characteristic parameter for a one-component plasma with charge per particle q and density n is

$$\Gamma_P = \left(\frac{4\pi n}{3} \right)^{1/3} \frac{q^2}{4\pi\epsilon_0 k_B T} , \tag{75.70}$$

essentially the ratio of the Coulomb energy between two nearest-neighbor ions divided by the thermal kinetic energy. $\Gamma_P > 1$ indicates a strongly coupled plasma; for $\Gamma_P > 2$ and $\Gamma_P > 170$ solid and liquid phases are expected in an infinite plasma. Experiments with a Penning trap have produced $\Gamma_P \gtrsim 300$. Concentric shells of ions or various more or less crystalline arrangements are seen depending on the experimental conditions.

Sympathetic Cooling

In a trap that holds two or more species of charged particles, cooling of the motion of one species is transferred by Coulomb interactions to the other species. This sympathetic cooling broadens the scope of ion cooling methods.

75.5 Applications of Cooling and Trapping

Trapping and cooling offer increased interaction times between the atoms/ions and the light. This leads to reduced transit time broadening, and indeed to macroscopic (> 1 s) interaction times. Laser cooling in a magneto-optical trap routinely gives temperatures so low that the Doppler width is below the natural linewidth of the cooling transition. A homogeneously broadened atomic sample is thus prepared. Cooling also enables reduction of the second-order Doppler effect.

Various frequency measurements are the prime beneficiary of cooling and trapping. Potential applications range from detection of the change of natural constants in time Chapt. 30 to such feats of technology as the Global Positioning System.

75.5.1 Neutral Atoms

Experimental Considerations

Originally the experiments often started with a longitudinal deceleration and cooling of an atomic beam by a counterpropagating laser beam. To compensate for the change of the Doppler shift of the atoms while they slowed down, the position dependent magnetic field of a tapered solenoid shifted the transition frequency of the atoms to keep them near resonance while they moved down the solenoid. A magneto-optical trap then scooped some atoms, cooled them further, and captured them. Nowadays this Zeeman slower ist mostly supplanted by various schemes in which a MOT directly captures atoms from the low-velocity wing of the thermal distribution. Depths of neutral-atom traps are below 1 K. Storage times are typically of the order of 1 s, limited at high densities by exothermal binary collisions and at low densities by collisions with the atoms in the background gas.

The temperature of cooled atoms may be measured by the time-of-flight method. All cooling and trapping fields are turned off, whereupon the atoms fall freely under gravity. The distribution of arrival times of atoms at a probe laser beam underneath the initial molasses is compared with a numerical model for the disintegration of the molasses. A fit gives the temperature.

The focus is on Li, Rb and Cs, to a large extent because the required laser frequencies can be generated using inexpensive diode lasers. Hyperfine structure of the ground state of the alkalis complicates experiments because the atoms may end up in an inert hyperfine level outside the active cooling/trapping transitions. To counteract this, a second appropriately tuned repump laser is added to return such atoms to circulation. A few experiments use lanthanide atoms or metastable states of rare-gas atoms, some isotopes of which do not have hyperfine structure.

Cold Collisions

In the molecular picture of a collision involving a laser, optical excitation takes place at the interatomic distance for which the difference between the potential curves of the incoming and excited states equals the energy of a laser photon [75.17]. The end products of an inelastic collision (fine or hyperfine structure changing collision, associative ionization, radiative escape, etc.) are normally determined at shorter interatomic distances, when the potential curve of the excited state has an anti-crossing with the potential curve of the product channel. The novel feature of ultracold collisions is the long duration due to the low velocity of the collision partners. Spontaneous emissions and other phenomena irrelevant at room temperature may take place during the collision.

On the scale of typical resonance widths, at very low temperatures the collision partners are in effect in a single continuum state with zero energy. This facilitates photoassociation spectroscopy. Laser-induced transitions from the initial continuum state to bound vibrational states of the molecule are observed.

Collisions are of practical importance in that they limit the achievable atom density in a trap: an inelastic collision may release more kinetic energy than the trap can contain, which results in a loss of an atom (or two atoms) from the trap. Collision rates are actually measured by monitoring the loss rate of atoms as a function of density. Precise energies of the molecular vibrational states from photoassociation spectroscopy are used as input to determine [75.18] s-wave scattering lengths for atoms and to measure molecular parameters to an accuracy that far exceeds the capabilities of ab-initio calculations.

Frequency Standards

An atomic fountain starts with an optical molasses or a magneto-optical trap. The laser beams are then manipulated to give an upward push to the atoms. The atoms fly up against gravity for a few tens of centimeters, then turn back and, because of the initial transverse velocities, fan out to a "fountain". In a fountain clock [75.19], the fountain erupts through a microwave cavity that drives a hyperfine transition in the atoms. The clock is in effect an accurate measurement of the transition frequency. The fountain is beneficial because the interrogation times ≈ 1 s are longer and the atomic velocities ≈ 1 m/s slower than in traditional beam clocks.

Bose–Einstein Condensate

At present, the most prominent basic-physics applications of cooling and trapping of atoms undoubtedly are in studies of Bose–Einstein condensation and quantum degenerate Fermi gases in dilute atomic vapors. This topic is covered in Chapt. 76.

75.5.2 Trapped Particles

Experimental Considerations

Both Paul and Penning traps behave like a conservative potential, and scatter rather than confine a particle coming from the outside. One method to load a trap is to generate the ions in situ, e.g., by letting a beam of atoms and electrons collide inside the trap. Time dependent electric potentials are another loading method. The trapped species is injected thorough a hole in the endcap, and the opposing endcap is raised to an electric potential that makes the entering particles stop. The potential is then lowered before it ejects the particles. A single electron, positron, proton, antiproton or ion may be loaded. Typical depths of ion traps are ≈ 1 eV or $\approx 10^4$ K. With the aid of cooling, the storage time may be made infinite for all practical purposes.

Trap frequencies are measured by observing the resonance excited by added ac fields. For instance, an electric field near the axial cm resonance frequency may be coupled between the ring and one endcap. A resonance circuit coupled between the ring and the other endcap is used to detect the resonance. Alternatively, ejection of the driven ions is monitored.

For an electron in a Penning trap, the cyclotron frequency is in the extreme microwave region. Detection of the resonance is achieved indirectly. The uniform magnetic field is perturbed with a piece of a ferromagnet to make a magnetic bottle. The axial motion and the cyclotron motion are then coupled. A resonant microwave drive adds energy to the cyclotron motion, which detectably alters the axial frequency.

The three trap frequencies satisfy

$$\nu_c^2 = \nu_c'^2 + \nu_m^2 + \nu_z^2 . \tag{75.71}$$

This relation remains valid even if the magnetic field is misaligned with respect to the trap axis, and is also insensitive to small imperfections in the cylindrical symmetry of the electrodes. The bare cyclotron frequency may therefore be deduced accurately.

For an ion with a dipole-allowed resonance transition, fluorescence of a single ion is readily detected. Even absorption of a single ion may be measurable. Various methods of finding the temperature have been devised. At temperatures of 1 K and higher, Doppler broadening of a dipole-allowed optical transition is observable. The size of the single-ion cloud is a measure of temperature. Finally, motional sidebands in the absorption of a narrow transition ($\gamma \ll \nu$), not necessarily the same transition as the one used for cooling, may be measured to find $\langle n \rangle$. In the Lamb–Dicke regime only the carrier absorption at $\Delta = 0$ and sidebands at $\Delta = \pm\nu$ are significant, and the ratios of the peak absorptions are

$$\alpha_- : \alpha_0 : \alpha_+ = \langle n \rangle \frac{\varepsilon_r}{\nu} : 1 : (1 + \langle n \rangle) \frac{\varepsilon_r}{\nu} . \tag{75.72}$$

In an ion crystal, the ions have collective vibration modes akin to phonons, instead of the three vibration modes along the principal axes of the trap of a single ion. Doppler cooling and sideband cooling work for such collective modes much like they work for the vibration modes of a single ion.

Quantum Jumps

Ion traps make it possible to isolate an individual atomic scale particle for studies for a practically indefinite time, which enables clean experiments on various fundamental aspects of quantum mechanics and quantum electrodynamics. Quantum jumps are a case in point. Suppose that, in addition to an optically driven two-level system, a single ion has a third shelving state. The ion infrequently makes a transition to the shelving state, stays there for a long time compared with the time scale of spontaneous emission of the active system, and then returns to the two-level system. When the ion makes a transition to the shelving state, fluorescence from the two-level system suddenly ceases; and the fluorescence reappears, equally abruptly, when the ion returns to the two-level system. The jumps in light scattering are the quantum jumps [75.20]. They are a method to detect

a weak transition with an enormous amplification: a single transition to or from the shelving state may mean the difference between the presence or absence of billions of fluorescence photons.

$g-2$ Measurements

For an electron, the cyclotron frequency ν_c and the spin-flip frequency ν_s are related by

$$\nu_s = \frac{1}{2} g \nu_c . \tag{75.73}$$

Due to quantum electrodynamic corrections $g \neq 2$, and so the anomaly frequency $\nu_a = \nu_c - \nu_s \sim 10^{-3} \nu_c$ is nonzero. A magnetic field at the anomaly frequency causes a simultaneous flip of the spin and a loss or gain of one quantum of energy in the cyclotron motion. In a magnetic bottle, the change in the cyclotron motion causes a change in the axial resonance frequency, which is detected. The anomaly frequency can thus be measured accurately. Together with a measurement of the cyclotron frequency, this yields a measurement of the g-factor of the electron, or positron [75.21].

Measurements of Mass Ratios

As the cyclotron frequency is inversely proportional to the mass of the ion (or electron, positron, proton, antiproton, etc.), an accurate measurement of the cyclotron frequencies of two species in the same Penning trap amounts to an accurate measurement of the ratio of the masses [75.22]. A sufficient resolution to weigh molecular bonds is conceivable.

Quantum System of Motional States

A vibrational mode in a trapped ion and an effective two-state system for the internal degrees of freedom make a realization of the Jaynes–Cummings model (discussed in detail in Sect. 79.5.1). Moreover, sideband cooling enables an experimenter to put this mode cleanly in its lowest quantum state. These observations have inspired quantum-state engineering with the objective of generating an arbitrary state of the vibrational motion of the ion [75.23]. In many-ion crystals the collective vibration modes may be used to couple and entangle the internal degrees of freedom of two or more ions. As discussed in Chapt. 81, prototype quantum gates have been demonstrated in this manner.

More generally, experiments have come to the point when it is possible to address joint quantum states for the internal and cm degrees of freedom almost at will. This facilitates new cooling schemes. Time evolution derived from a Hamiltonian can never lead to cooling; an irreversible mechanism such as spontaneous emission is always needed. The idea of many cooling schemes therefore is to pump atoms optically around the quantum states in such a way there is no pathway out of the target state, so that the atoms eventually accumulate there. Velocity selective coherent population trapping [75.24], Raman sideband cooling of an ion, and Raman cooling of an atom in an optical lattice [75.25] work in this way.

76. Quantum Degenerate Gases

The purpose of this Chapter is to summarize the basic physics of dilute quantum degenerate gases. Given the broad activity in the field, many choices have to be made regarding the topics to include and the style of the discussion. Emphasis is placed on AMO physics, as opposed to condensed matter physics. One related choice is that virtually nothing is said about temperature dependence. Inside AMO physics the approach is in the vein of quantum optics, as opposed to atomic/molecular structure and collisions. For the most part, the coverage is on elementary concepts and basic material. The exception to this is Sect. 76.5, where a few topical issues are addressed.

The review article [76.1] has become the standard reference on the basic properties of a Bose–Einstein condensate (BEC), [76.2] is its contemporary with more of a quantum optics slant, [76.3] concentrates on conceptual issues, [76.4] makes connections between the present theories and traditional condensed matter physics, and [76.5] is particularly explicit about the structure and excitations of a BEC. Here, references are usually not given for topics that are discussed in these reviews, or where a full discussion is easily traced from them. Otherwise,

references are meant to be entries to the literature only. Assignment of credit or priority is never implied.

Bose–Einstein condensation in dilute alkali metal vapors has realized a source of atoms with properties analogous to the properties of laser light, and more recently, ultralow-temperature Fermi gases have come under study. The field of quantum degenerate gases has become a main theme in AMO physics. Dilute-vapor systems are weakly interacting, and subject to a degree of experimental control not seen before in traditional low-temperature condensed matter systems. Ultralow-temperature gases have thereby also given a new lease on life to investigations of superfluid systems in condensed matter physics. The result is a broad interdisciplinary effort that is still expanding at the time of writing.

76.1 Elements of Quantum Field Theory

A Bose–Einstein condensate and a degenerate Fermi gas are both consequences of particle statistics, exchange symmetries of the many-particle wave function. It is possible, in principle, to deal directly with the wave functions, but in practice analyses of many-body systems are usually carried out using the methods of second quantization and field theory. In first quantization, the particles are labeled as if each one had a unique tag

on it, and the wave function for more than one indistinguishable particle must be symmetrized explicitly. In second quantization, the question is how many particles are in a given state without a distinction between identical particles. The exchange symmetries are then taken care of automatically. Here we briefly summarize [76.6] elementary features of quantum field theories for both bosons and fermions.

76.1.1 Bosons

Particles with an integer value of the angular momentum obey the Bose–Einstein statistics. The characteristic property is that a one-particle state can accommodate an arbitrary number of bosons.

State Space for Bosons. Specifically, first consider one particle whose states are completely specified by a set of quantum numbers k. As a notational device for the purposes of the present Chapter, all of the quantum numbers are assumedly mapped in a one-to-one fashion to nonnegative integers, and correspondingly the quantum numbers are written $k = 0, 1, 2, \ldots$. The quantum numbers written here always incorporate a description of the state of the c.m. motion of the particle. We therefore have an orthonormal basis of wave functions to represent any state of a particle, $\{u_k(\boldsymbol{x})\}_k$, where $\boldsymbol{x}$ stands for the c.m. coordinate.

Given the one-particle states, the postulate is that the Fock states $|n_0, n_1, \ldots, n_\infty\rangle$ with $n_k = 0, 1, 2, \ldots$ particles in the states $k = 0, 1, 2, \ldots$ form an orthonormal basis for the many-body system.

Second–Quantized Operators for Bosons. The annihilation operator for the state k, a_k, is defined by

$$
\begin{aligned}
& a_k |n_0, n_1, \ldots, n_k, \ldots, n_\infty\rangle \\
& = \sqrt{n_k}\, |n_0, n_1, \ldots, n_k - 1, \ldots, n_\infty\rangle .
\end{aligned} \tag{76.1}
$$

Its Hermitian conjugate, the creation operator, behaves as

$$
a_k^\dagger |\ldots, n_k, \ldots\rangle = \sqrt{n_k + 1}\, |\ldots, n_k + 1, \ldots\rangle . \tag{76.2}
$$

It follows that

$$
a_k^\dagger a_k |\ldots, n_k, \ldots\rangle = n_k |\ldots, n_k, \ldots\rangle , \tag{76.3}
$$

and so $\hat{n}_k = a_k^\dagger a_k$ is called the number operator for the state k. Correspondingly,

$$
\hat{N} = \sum_k a_k^\dagger a_k \tag{76.4}
$$

is the operator for the total number of particles in the system. The annihilation and the creation operators have the usual boson commutators,

$$
[a_k, a_{k'}] = [a_k^\dagger, a_{k'}^\dagger] = 0, \quad [a_k, a_{k'}^\dagger] = \delta_{kk'} . \tag{76.5}
$$

The boson field operator is defined as

$$
\hat{\psi}(\boldsymbol{x}) = \sum_k u_k(\boldsymbol{x}) a_k . \tag{76.6}
$$

The commutator for the field operator,

$$
[\hat{\psi}(\boldsymbol{x}), \hat{\psi}^\dagger(\boldsymbol{x}')] = \delta(\boldsymbol{x} - \boldsymbol{x}') , \tag{76.7}
$$

follows from boson commutators and the completeness of the wave functions $\{u_k(\boldsymbol{x})\}_k$. The orthogonality of the wave functions gives the expression

$$
\hat{N} = \int \mathrm{d}^3 x\, \hat{\psi}^\dagger(\boldsymbol{x}) \hat{\psi}(\boldsymbol{x}) \tag{76.8}
$$

for the particle number operator. The positive operator

$$
\hat{n}(\boldsymbol{x}) = \hat{\psi}^\dagger(\boldsymbol{x}) \hat{\psi}(\boldsymbol{x}) \tag{76.9}
$$

evidently represents the density of the particles at the position $\boldsymbol{x}$.

The second-quantized operators introduced thus far can be used to express all observables acting on indistinguishable bosons. The most relevant here are the one- and two-particle operators. One-particle operators, such as the kinetic energy, act on one particle at a time, while two-particle operators, such as atom–atom interactions, refer to two particles. In first quantization, these are of the form

$$
O_1 = \sum_n V(\boldsymbol{x}_n), \quad O_2 = \frac{1}{2} \sum_{n, n'} u(\boldsymbol{x}_n, \boldsymbol{x}_{n'}) , \tag{76.10}
$$

where the sums run over the labels of the particles. The corresponding second-quantized operators are

$$
\hat{O}_1 = \int \mathrm{d}^3 x\, \hat{\psi}^\dagger(\boldsymbol{x}) V(\boldsymbol{x}) \hat{\psi}(\boldsymbol{x}), \tag{76.11}
$$

$$
\begin{aligned}
\hat{O}_2 = \frac{1}{2} \int \mathrm{d}^3 x\, \mathrm{d}^3 x'\, & \hat{\psi}^\dagger(\boldsymbol{x}) \hat{\psi}^\dagger(\boldsymbol{x}') \\
& \times u(\boldsymbol{x}, \boldsymbol{x}') \hat{\psi}(\boldsymbol{x}') \hat{\psi}(\boldsymbol{x}) .
\end{aligned} \tag{76.12}
$$

When the particles have internal degrees of freedom in addition to the c.m. motion, such as hyperfine and Zeeman states, it is convenient for the present purposes to regard particles in each internal state as a separate species. Thus, if the quantum number breaks up into

$k \equiv \{p, \alpha\}$, where p stands for quantum numbers of the center of the mass and α for the quantum numbers of the internal state, it is expedient to define a quantum field for each species α as

$$\hat{\psi}_\alpha(\boldsymbol{x}) = \sum_p u_{p\alpha}(\boldsymbol{x}) a_{p\alpha} . \tag{76.13}$$

Mechanisms that cause transitions between the internal states couple the fields $\hat{\psi}_\alpha(\boldsymbol{x})$ for different α.

States of Bosons. To complete the transformation from wave function quantum mechanics to second quantization, the state of the system must be specified in second quantization. For instance, take the Hamiltonian $\hat{H}$ and the particle number operator $\hat{N}$. According to statistical mechanics a system characterized by the temperature T and chemical potential μ is in the state with the density operator $\hat{\rho} = e^{-(\hat{H}-\mu\hat{N})/k_B T}/\mathcal{Z}$, where the grand partition function is $\mathcal{Z} = \mathrm{Tr}\, e^{-(\hat{H}-\mu\hat{N})/k_B T}$.

Bose–Einstein Condensate. The state of a boson system of particular interest here is the BEC. In an ideal gas condensation entails a macroscopic fraction of the particles occupying the ground state of the c.m. motion. Condensation is a phase transition that occurs when either the density of the gas is increased or the temperature is lowered. In a homogeneous ideal Bose gas the governing parameter is the phase space density ζ defined as

$$\zeta = \left(\frac{2\pi\hbar^2}{mk_B T} \right)^{3/2} n , \tag{76.14}$$

where m is the mass of the condensing atoms, T is the temperature, and n is the density of the condensing species. For the purposes of quantum degeneracy, each internal state of an atom behaves as a separate species. Bose–Einstein condensation takes place when the phase space density satisfies $\zeta = 2.612$. Depending on whether density or temperature is regarded as a constant, (76.14) may be regarded as an equation for the critical temperature T_c or the critical density n_c for Bose–Einstein condensation.

76.1.2 Fermions

Particles with a half-integer angular momentum obey the Fermi–Dirac statistics. Each Fock state may then only have the occupation numbers $n_k = 0, 1$. The conventional definition of the annihilation operator contains a phase factor,

$$a_k |n_0, n_1, \ldots, n_k, \ldots, n_\infty\rangle$$
$$= n_k (-1)^{\sum_{p=0}^{k-1} n_p} |n_0, n_1, \ldots, n_k - 1, \ldots, n_\infty\rangle , \tag{76.15}$$

and fermion operators are governed by the anticommutator

$$[A, B]_+ \equiv AB + BA \tag{76.16}$$

rather than the commutator. For instance,

$$[a_k, a_{k'}]_+ = 0, \quad [a_k, a_{k'}^\dagger]_+ = \delta_{kk'} . \tag{76.17}$$

Except for the use of anticommutators in lieu of commutators, all formal expressions for field operators and one- and two-particle operators written down for bosons in Sect. 76.1.1 remain valid as stated.

Degenerate Fermi Gas. A degenerate Fermi gas realized in a dilute atom vapor is the fermion counterpart of a BEC. The basic parameter of a free noninteracting Fermi gas is the Fermi energy, the chemical potential at zero temperature. It is given by

$$\epsilon_F = \frac{\hbar^2 k_F^2}{2m}; \quad k_F = \left(6\pi^2 n\right)^{1/3} , \tag{76.18}$$

where n once more is the density for the relevant fermion species. In the limit of zero temperature the Fermi gas makes a Fermi sea; the states below the Fermi energy are filled with one particle each, the states above the Fermi energy are empty. The gas begins to show substantial deviations from the Maxwell-Boltzmann statistics and may be regarded as degenerate when the temperature is below the Fermi temperature, $T \leq T_F = \epsilon_F/k_B$. Except for a numerical factor, in terms of density and temperature the condition $T \leq T_F$ is the same as the condition for Bose–Einstein condensation.

76.1.3 Bosons versus Fermions

Isotopes of alkali metals with an odd mass number (^{7}Li, ^{23}Na, ^{39}K, ^{85}Rb, ^{87}Rb, ^{133}Cs) make Bose–Einstein gases, while isotopes with an even mass number (^{6}Li, ^{40}K) make Fermi–Dirac gases. Atoms are composite particles consisting of fermions, and how they may act as bosons is a legitimate question. Whether a satisfactory formal answer to this question exists may be debatable, but in practice atoms seem to obey the correct statistics in processes that do not expose their individual constituents.

When two bosonic atoms with integer angular momenta combine into a molecule, the molecule has an integer angular momentum and behaves as a boson. On the other hand, two fermionic atoms also make a bosonic molecule. Models for this latter type of system are basic-

ally ad hoc since, at this point in time, no microscopic theory for such a reorganization of the statistics exists. Nonetheless, empirically, diatomic molecules formed by combining two fermionic atoms indeed appear to be bosons.

76.2 Basic Properties of Degenerate Gases

Atoms Are Trapped. Quantum degenerate alkali vapors are typically prepared in an atom trap. Close to the bottom almost every trap is a three-dimensional harmonic oscillator potential completely characterized by the principal-axis directions and the corresponding trap frequencies ω_i, the (angular) frequencies at which a single atom would oscillate back and forth in the given principal-axis direction. In the principal-axis coordinate system the trapping potential reads

$$V(\boldsymbol{x}) = \frac{1}{2} \sum_{i=1}^{3} m\omega_i^2 x_i^2 \ . \tag{76.19}$$

It is convenient to introduce the characteristic harmonic-oscillator frequency scale and the corresponding harmonic-oscillator length scale as

$$\bar{\omega} = (\omega_1 \omega_2 \omega_3)^{1/3} \ , \quad \ell = \sqrt{\frac{\hbar}{m\bar{\omega}}} \ . \tag{76.20}$$

Atom–Atom Interactions. At low temperatures/energies only s-wave collisions are significant. In the theory of quantum degenerate gases these are frequently represented by a pseudopotential tailored to give the correct s-wave phase shift. For two atoms the atom–atom interaction is

$$u(\boldsymbol{x}_1, \boldsymbol{x}_2) = \frac{4\pi\hbar^2 a}{m} \delta(\boldsymbol{x}_1 - \boldsymbol{x}_2) \ , \tag{76.21}$$

where a is the s-wave scattering length. Qualitatively, the scattering length is positive (negative) if the interaction is repulsive (attractive).

Model Hamiltonian. Quantum field theory for a single-component Bose gas usually starts with the Hamiltonian

$$\hat{H} = \int \mathrm{d}^3 x \ \hat{\mathcal{H}}(\boldsymbol{x}) \ , \tag{76.22}$$

where the Hamiltonian density is

$$\hat{\mathcal{H}}(\boldsymbol{x}) = \hat{\psi}^\dagger(\boldsymbol{x}) \left[-\frac{\hbar^2}{2m} \nabla^2 + V(\boldsymbol{x}) \right] \hat{\psi}(\boldsymbol{x})$$
$$+ \frac{2\pi\hbar^2 a}{m} \hat{\psi}^\dagger(\boldsymbol{x}) \hat{\psi}^\dagger(\boldsymbol{x}) \hat{\psi}(\boldsymbol{x}) \hat{\psi}(\boldsymbol{x}) \ . \tag{76.23}$$

As in Sect. 76.1.1, $\hat{\psi}(\boldsymbol{r})$ is the boson field operator, the kinetic energy $-\hbar^2 \nabla^2 / 2m$ and trapping potential $V(\boldsymbol{x})$ are one-particle operators, and atom–atom interactions are governed by the two-body operator u of (76.21). Analogous models can be written down for multicomponent boson and fermion fields, for coupling between atoms and molecules, and so on.

76.2.1 Bosons

Gross–Pitaevskii Equation
Mean–Field approximation. Conventionally, the next step for bosons is to go over to the corresponding classical field theory. The result is referred to as mean-field theory or semiclassical theory.

Formally, one first writes down explicitly the Heisenberg equation of motion for the boson field $\hat{\psi}$,

$$i\hbar \frac{\partial}{\partial t} \hat{\psi}(\boldsymbol{x}, t) = \left[\hat{\psi}(\boldsymbol{x}, t), \hat{H} \right] \ , \tag{76.24}$$

and then declares that in the equations of motion $\hat{\psi} \to \psi$ is a classical field not a quantum field anymore. We call ψ the macroscopic wave function of the condensate. This approximation is precisely analogous to using the classical instead of the quantum description for the electric and magnetic fields of the light coming out of a laser.

Time–Dependent Gross–Pitaevskii Equation. The time-dependent Gross–Pitaevskii equation (GPE) is

$$i\hbar \frac{\partial}{\partial t} \psi(\boldsymbol{r}, t) = \left[-\frac{\hbar^2}{2m} \nabla^2 + V(\boldsymbol{r}) \right] \psi(\boldsymbol{r}, t)$$
$$+ \frac{4\pi\hbar^2 a}{m} |\psi(\boldsymbol{r}, t)|^2 \psi(\boldsymbol{r}, t) \ . \tag{76.25}$$

This equation is nonlinear, and normalization of the macroscopic wave function ψ is important. Quantum mechanically, the particle number operator is given by (76.8), so that the normalization for a system with N particles naturally reads

$$\int \mathrm{d}^3 x \ |\psi(\boldsymbol{x}, t)|^2 = N \ . \tag{76.26}$$

Time evolution under (76.25) preserves the normalization. Obviously, and in accordance with (76.9),

$$n(\boldsymbol{x}) = |\psi(\boldsymbol{x})|^2 \qquad (76.27)$$

is the local density of the gas.

Time-Independent Gross–Pitaevskii Equation. Solutions to the time-dependent GPE of the form $\psi(\boldsymbol{x}, t) = \phi(\boldsymbol{x})\,\mathrm{e}^{-\mathrm{i}\mu t/\hbar}$ are stationary states with no time evolution in the physics. The analog of the energy of a stationary state is called the chemical potential μ. The corresponding wave function ϕ satisfies the time-independent GPE

$$\mu\phi = \left(-\frac{\hbar^2}{2m}\nabla^2 + V \right)\phi + \frac{4\pi\hbar^2 a}{m}|\phi|^2\phi . \quad (76.28)$$

Both GPEs are nonlinear variants of the Schrödinger equation, and in other contexts they are often referred to as nonlinear Schrödinger equations. The nonlinear term approximates the interaction energy of an atom with the other atoms in an averaged way by relying on the local density of the atoms, hence the term mean-field theory.

Sign of Scattering Length. The qualitative properties of a condensate, as per the GPE, depend on the sign of the scattering length. For repulsive atom–atom interactions or no atom–atom interactions, $a \geq 0$, both the time-dependent and the time-independent forms are mathematically well behaved. Unless otherwise noted, the scattering length is always assumed non-negative.

In the case of a negative scattering length a BEC may, in principle, decrease its energy without a bound by collapsing to a point. Mechanisms such as three-body recombination or molecule formation would eventually set in as the density increases and the collapse would stop, but the condensate must then be presumed lost. In the absence of an external potential, a condensate with a negative scattering length is unconditionally unstable against collapse. For a bounded condensate the increase in the kinetic energy coming with the decreasing size may hold off the collapse, provided the number of atoms in the condensate is sufficiently small. Simple dimensional-analysis arguments give the condition of stability in a harmonic trap as $N|a| \lesssim \ell$.

Behavior attributed to a collapse has been observed in ^{7}Li for trapped states with a negative scattering length. By using a Feshbach resonance it is also possible to adjust the (apparent) scattering length (Sect. 76.5.1) which has led to further demonstrations of collapse-like physics.

Healing Length. Consider the time-independent GPE (76.28) without an external potential, and scale the various quantities as follows:

$$\phi = \sqrt{n}\bar{\phi}, \ \mu = \bar{\mu}\,\frac{4\pi\hbar^2 na}{m},$$

$$\boldsymbol{x} = \xi\bar{\boldsymbol{x}}; \ \xi = \frac{1}{\sqrt{8\pi na}} . \qquad (76.29)$$

Here n is the density scale for the gas, and the length scale is ξ. In terms of these new variables the time-independent GPE reads

$$\bar{\mu}\,\bar{\phi} = -\bar{\nabla}^2\bar{\phi} + \left|\bar{\phi}\right|^2\bar{\phi} . \qquad (76.30)$$

There is a solution in all of space with $\bar{\mu} = 1$, $\bar{\phi} = 1$. If for some reason, such as at an edge of the sample, the condensate wave function must vanish, the length scale over which the wave function grows back to one (in the scaled units) is of the order of unity. In fact, (76.30) has the solution $\bar{\phi}(\bar{\boldsymbol{x}}) = \tanh\left(\bar{z}/\sqrt{2}\right)$ in the half-space $\bar{z} \geq 0$. The quantity ξ is the minimum length scale over which a condensate wave function can build up to the density n. It is called the healing length.

Thomas–Fermi Approximation. Without atom–atom interactions, the ground state of the trapping potential $V(\boldsymbol{x})$ would be the lowest-energy (lowest μ) solution to (76.28). However, experience has shown that even modest repulsive atom–atom interactions ($a > 0$) spread out the macroscopic wave function of the condensate a great deal. With increasing size comes decreasing kinetic energy, according to the Heisenberg uncertainty principle. This suggests the Thomas–Fermi approximation, in which the kinetic energy term in (76.28) is simply ignored. The density of the gas is then easily solved to be

$$n(\boldsymbol{x}) = \begin{cases} \dfrac{m\left[\mu - V(\boldsymbol{x})\right]}{4\pi\hbar^2 a}, & \mu > V(\boldsymbol{x}) \\[2mm] 0, & \text{otherwise,} \end{cases} \qquad (76.31)$$

an inverted image of the trapping potential. The normalization (76.26) can be used to find the relation between chemical potential and particle number, and all of the unknown quantities may, in principle, be found.

For a harmonic potential the Thomas–Fermi approximation can be worked out explicitly with the results

$$\mu = \frac{1}{2}\hbar\bar{\omega}\left(\frac{15Na}{\ell}\right)^{2/5}, \quad R = \ell\left(\frac{15Na}{\ell}\right)^{1/5},$$

$$n(0) = \frac{1}{8\pi\ell^3}\frac{\ell}{a}\left(\frac{15Na}{\ell}\right)^{2/5} . \qquad (76.32)$$

The quantity R represents the size of the condensate. In particular, it equals the radius of the spherical condensate if the trap is isotropic with $\omega_1 = \omega_2 = \omega_3$. Finally, $n(0)$ is the central, maximum, density of the atoms.

The relevant dimensionless parameter is Na/ℓ, which can easily be much larger than unity in the experiments. When the Thomas–Fermi approximation is accurate, the chemical potential exceeds the typical level spacing of the harmonic-oscillator trap, and the condensate is larger than the ground-state wave function of the harmonic oscillator would be. Ordinarily, the condensate is also much larger than the healing length.

Small Excitations in a BEC

Linearizing the GPE. The time-dependent GPE is nonlinear, but may be linearized around a stationary solution. Consider the special case without a trapping potential, $V(\boldsymbol{x}) \equiv 0$. The stationary solutions are plane waves,

$$\phi(\boldsymbol{x}) = \sqrt{n}\, e^{i\boldsymbol{p}\cdot\boldsymbol{x}} . \tag{76.33}$$

This corresponds to a flow of the gas at the velocity $\boldsymbol{v} = \hbar\boldsymbol{p}/m$ and with a momentum $\hbar\boldsymbol{p}$ per atom. The chemical potential of such a mode is

$$\frac{\mu}{\hbar} = \epsilon_p + \frac{1}{2}\epsilon_0 , \tag{76.34}$$

where

$$\epsilon_p = \frac{\hbar p^2}{2m}, \quad \epsilon_0 = \frac{mc^2}{\hbar}, \quad c = \frac{\hbar\sqrt{8\pi na}}{m} = \frac{\hbar}{m\xi} \tag{76.35}$$

are the dispersion relation of free atoms, a peculiar analog of the rest energy, and the speed of sound in the BEC.

The ansatz for small deviations from the stationary solution is written as

$$\psi(\boldsymbol{x}, t) = \sqrt{n}\, e^{i(\boldsymbol{p}\cdot\boldsymbol{x} - \frac{\mu}{\hbar}t)}\big[1 + u\, e^{i(\boldsymbol{q}\cdot\boldsymbol{x} - \nu t)} \\ + v^* e^{-i(\boldsymbol{q}\cdot\boldsymbol{x} - \nu^* t)}\big] , \tag{76.36}$$

where $\hbar\boldsymbol{q}$ and $\hbar\nu$ are the momentum and energy associated with the excitation relative to the momentum and energy of the original flow. The GPE mixes the field ψ and its complex conjugate ψ^*, so that two small amplitudes u and v are needed for the excitations. The ansatz (76.36) is a solution to the time-dependent GPE to the lowest nontrivial order in u and v if these amplitudes and the frequency of the excitation satisfy the

eigenvalue equation

$$\begin{pmatrix} \epsilon_q + \epsilon_0 + \boldsymbol{q}\cdot\boldsymbol{v} & \epsilon_0 \\ \epsilon_0 & \epsilon_q + \epsilon_0 - \boldsymbol{q}\cdot\boldsymbol{v} \end{pmatrix}\begin{pmatrix} u \\ v \end{pmatrix} = \nu\begin{pmatrix} u \\ -v \end{pmatrix}. \tag{76.37}$$

The remaining problem is that the eigenvalue equation has two solutions for each $\boldsymbol{q}$, which gives twice as many small-excitation modes as there are degrees of freedom. The extra modes are the penalty one pays for the linearization of the GPE. The criterion $|u|^2 - |v|^2 > 0$ picks out the correct small-excitation modes. The corresponding dispersion relation for the excitations is

$$\nu(\boldsymbol{q}) = \boldsymbol{q}\cdot\boldsymbol{v} + \sqrt{\epsilon_q(\epsilon_q + 2\epsilon_0)} . \tag{76.38}$$

For a stationary BEC with $\boldsymbol{v} = 0$ and in the limit $q \to 0$, (76.38) gives $\nu \simeq cq$. This confirms the identification of c as the speed of sound.

In the BEC experiments the condensates are trapped, but in principle the same analysis of small-excitation modes may be carried out both numerically and in a myriad of analytical approximations. The generic result is that the trap frequencies lend their frequency scale to small excitations. At low enough temperatures, excitation frequencies calculated in this way agree well with the experiments.

Within the mean-field approximation small excitations may be analyzed similarly in all boson systems, for instance, in a multi-component Bose–Einstein condensate or a joint atom–molecule condensate. The evolution frequencies may be complex, which signals a dynamical instability of the stationary configuration; there are small-excitation modes that grow exponentially. The instability of a free gas with a negative scattering length, which is apparent in (76.38) for $\epsilon_0 < 0$, is a simple example.

Bogoliubov Theory. Bogoliubov theory is the many-body quantum version of the analysis of small excitations. The idea is to treat the condensate mode ψ_0, containing n_0 atoms, separately in the field operator

$$\hat{\psi} = \sqrt{n_0}\,\psi_0 + \delta\hat{\psi} , \tag{76.39}$$

expand the Hamiltonian in the lowest nontrivial (second) order in the remnant quantum field $\delta\hat{\psi}$, and diagonalize. The result is small-excitation modes with the annihilation operators A_k, where k stands for the appropriate quantum numbers. It turns out that the core mathematics of Bogoliubov theory is the same as the mathematics of small excitations, but two features are added.

First, Bogoliubov theory explicitly shows that the co-efficients u and v in the analog of (76.37) need to satisfy $|u|^2 - |v|^2 = 1$ to ensure boson commutators for the operators A_k. Second, with quantum fluctuations, atom–atom interactions force atoms out of the condensate even at zero temperature. In a homogeneous (untrapped) condensate, in the limit $na^3 \ll 1$, at $T = 0$, the fraction of noncondensate atoms is

$$\frac{N - n_0}{N} = \frac{8}{3} \sqrt{\frac{na^3}{\pi}} . \qquad (76.40)$$

When the gas parameter na^3 is much smaller than unity, at low enough temperatures most of the atoms are in the condensate. Mean-field theory and the GPE are expected to apply, and empirically, they do.

Numerical Methods for GPE

Mathematical Properties of the GPE. Let us momentarily assume that by separation of variables, or by some fiat, the problem of solving the time-independent GPE has been rendered one-dimensional. The Schrödinger equation is linear and any constant multiple of a solution is also a solution. One parameter, e.g., the logarithmic derivate of the wave function at a given point in space, determines a stationary state completely. This does not hold for the corresponding GPE, for which the values of the wave function and its derivative can be specified independently at (almost) every fixed point in space. As a result of the added flexibility, and unlike the Schrödinger equation, the GPE has bounded solutions for continuous ranges of the values of the chemical potential μ.

However, the time-independent GPE (76.28) comes with the added normalization condition (76.26). Normalization quantizes the values of μ for the bound states. In practice one might, for instance, find a solution that satisfies the boundary conditions for a given μ with the shooting method, then adjust the value of μ until normalization holds. Techniques used in the first numerical analyses of the time-independent GPE in the context of atom vapor condensates were variations of this theme. Such schemes are not feasible in spatial dimensions greater than one.

In general there is one solution to the time-independent GPE that can be chosen to be positive everywhere, the ground state with the lowest chemical potential. Excited steady states exist, but only a few, such as the flowing states of (76.33) and vortices discussed in Sect. 76.4.1, have obvious physical meanings. As the GPE is nonlinear, excited states are not the same as small excitations.

Split–Step Fourier Method. The superposition principle does not hold for the solutions of the time-dependent GPE, and the excited states are usually not orthogonal to one another in any useful sense. Methods based on eigenstate expansions for solving the time-dependent GPE are cumbersome at best. Instead, one often simply integrates the GPE as a partial differential equation in time. A number of different methods are used, but here we only discuss an elementary split-step Fourier method [76.7]. This is an exceedingly popular algorithm for parabolic equations, easy to implement, and with minor modifications also solves the time-independent GPE in any number of dimensions.

Thus, consider integration of (76.25) forward in time over a step from t to $t + \Delta t$. For this purpose assume first that $|\psi|^2$ in the GPE were a constant equal to its value at time t, then the evolution over the time step Δt would be given by

$$\psi(\boldsymbol{x}, t + \Delta t) = \exp\left[-\mathrm{i}\Delta t \left(-\frac{\hbar \nabla^2}{2m} + U(\boldsymbol{x}) \right) \right]$$
$$\times \psi(\boldsymbol{x}, t) , \qquad (76.41)$$

where $U(\boldsymbol{x})$ is a given function of position. In the algorithm the exponential is first split approximately, for instance, as

$$\exp\left[-\mathrm{i}\,\Delta t \left(-\frac{\hbar \nabla^2}{2m} + U(\boldsymbol{x}) \right) \right]$$
$$\simeq \exp\left(\mathrm{i}\frac{\Delta t}{2}\frac{\hbar \nabla^2}{2m} \right) \exp\left[-\mathrm{i}\,\Delta t\, U(\boldsymbol{x}) \right]$$
$$\times \exp\left(\mathrm{i}\frac{\Delta t}{2}\frac{\hbar \nabla^2}{2m} \right)$$
$$\equiv \tilde{T}\tilde{U}\tilde{T} . \qquad (76.42)$$

The exponential of the kinetic-energy operator is diagonal in the Fourier representation. Consequently, carrying out the Fourier transform $\mathcal{F}$ and its inverse with the aid of the Fast Fourier Transformation gives the split-step algorithm

$$\psi(t + \Delta t) = \mathcal{F}^{-1}\tilde{T}\mathcal{F}\tilde{U}\mathcal{F}^{-1}\tilde{T}\mathcal{F}\,\psi(t) \qquad (76.43)$$

with obvious efficient implementations. The inaccurate constant $|\psi|^2$ may be improved upon in a corrector step in which the average of the initial wave function $\psi(t)$ and the $\psi(t + \Delta t)$ obtained in the first pass is used as $|\psi|^2$, and step (76.43) is taken again. This split-step algorithm preserves the normalization of the macroscopic wave function, and features a high-order approximation to the exponential operator of the kinetic energy.

Integration in Imaginary Time. The split-step algorithm also provides a global method to find the ground state. To this end the time-dependent GPE is integrated in imaginary time, i. e., replacing $\Delta t \to -\mathrm{i}\Delta t$, starting from a more or less random initial wave function and normalizing after every step. If the GPE were linear, this procedure would emphasize the lowest-energy component of the wave function until it is the only one that remains to within a prescribed accuracy. It is not clear that the same should apply to the nonlinear GPE, but often this is the case.

In nonlinear problems, split-operator methods, in spite of their seeming simplicity, often exhibit spurious behavior. Successful applications of these techniques require skill and experience in the art of numerical methods.

Local–Density Approximation

While an experimental BEC is usually trapped, it is often much easier to study the theory for a formally infinite homogeneous condensate. As long as the phenomena under investigation involve length scales much smaller than the size of the condensate and time scales much shorter than the inverse trap frequencies, trapping cannot affect the behavior of the gas locally. Under such conditions one may analyze the gas at each position x as if it were homogeneous, and at the end of the calculations average over the density distribution. The unit-normalized distribution of the density of the gas used in the averaging is

$$P(\varrho) = \frac{\int \delta[\varrho - n(x)]n(x)\,\mathrm{d}^3 x}{\int n(x)\,\mathrm{d}^3 x} \ . \tag{76.44}$$

For instance,

$$P(\varrho) = \frac{15\sqrt{n_0 - \varrho}\,\varrho}{4 n_0^{5/2}} \ H(\varrho)H(n_0 - \varrho) \tag{76.45}$$

holds for the Thomas–Fermi approximation with the maximum density $n_0 \equiv n(0)$. The Heaviside step functions H restrict the density to the correct range $0 \le \varrho \le n_0$. As an example, the average density in the Thomas–Fermi model is

$$\int \varrho P(\varrho)\,\mathrm{d}\varrho = \frac{4}{7}\,n_0 \ . \tag{76.46}$$

76.2.2 Meaning of Macroscopic Wave Function

Here the macroscopic wave function ψ has been introduced by replacing a boson field theory with a classical field theory.

The intuitive interpretation is that, for interacting particles, the atoms condense not to the ground state of the confining potential, but to the one-body state whose wave function is the macroscopic wave function. This notion may be criticized on various grounds, but in practice it makes a useful picture.

A precise formal meaning of the macroscopic wave function, and of Bose–Einstein condensation for interacting systems, is found by considering the one-particle density matrix

$$\rho(x, x') = \left\langle \hat{\psi}^\dagger(x)\hat{\psi}(x') \right\rangle, \tag{76.47}$$

which is sufficient to determine the expectation value of any one-particle operator. This is the position representation of a positive Hermitian operator with the trace equal to particle number (or its expectation value) N. In this way, with an orthonormal set of functions $\{\psi_k(x)\}_k$ and nonnegative eigenvalues n_k, such that

$$\sum_k n_k = N \ , \tag{76.48}$$

an expansion of the form

$$\rho(x, x') = \sum_k n_k\, \psi_k(x)\psi_k(x') \tag{76.49}$$

exists. The system is a BEC if at least one eigenvalue n_k is of the order of the number of particles and does not formally go to zero in the thermodynamic limit (if the limit exists and is sensible). The usual case is that only one eigenstate, call it $k = 0$, has such a large eigenvalue. The macroscopic wave function is the corresponding eigenfunction $\psi \equiv \psi_0$, and n_0 gives the number of condensate atoms. If there is more than one macroscopic eigenvalue, the condensate is called fragmented.

Another interpretation of the macroscopic wave function comes from statistical mechanics. In a continuous (second-order) phase transition typically a symmetry of the system is spontaneously broken. For example, below the Curie temperature a single-domain ferromagnet magnetizes in some specific direction, and the state has a lower symmetry than the rotationally invariant Hamiltonian of an isotropic ferromagnet. Any quantity that appears in a continuous phase transition and characterizes the breaking of the symmetry may be called an order parameter. The macroscopic wave function can be viewed as the order parameter associated with spontaneous breaking of the global phase or "gauge" symmetry of quantum mechanics. Specifically, in quantum mechanics the state of the system is

unchanged if the wave function is multiplied by an arbitrary complex phase factor $e^{i\varphi}$. But to write the wave function as $\psi(\boldsymbol{x})$ already implies a preferred phase, and likewise even if the wave function is adorned with random but, for any given condensate, fixed phase, as in $e^{i\varphi}\psi(\boldsymbol{x})$.

For one condensate the random phase is inconsequential. Suppose, however, that two BECs with the wave functions $e^{i\varphi_1}\psi_1(\boldsymbol{x})$ and $e^{i\varphi_2}\psi_2(\boldsymbol{x})$ are combined. If the macroscopic wave functions behave as wave functions should, the combination of two condensates displays the density $n(\boldsymbol{x}) = |e^{i\varphi_1}\psi_1(\boldsymbol{x}) + e^{i\varphi_2}\psi_2(\boldsymbol{x})|^2$. There should be an interference pattern between the condensates. Two BECs indeed produce an interference pattern when they are combined, although the randomness or the absence thereof of the phases $\varphi_{1,2}$ is difficult to verify experimentally.

From the quantum optics viewpoint, a condensate is a given number of atoms in a given one-particle state, a number state, and cannot possess any phase at all. This seems to contradict the observations of an interference pattern. The resolution is that the process of measurement in itself produces a phase difference between the condensates even if there initially is none.

76.2.3 Fermions

Static Fermi Gas
Thomas–Fermi Approximation. Consider an ideal single-species Fermi gas of trapped atoms. The original Thomas–Fermi approximation (see Chapt. 20) was formulated for fermions, namely, electrons, and in the present case it is modified as follows. For the atom density $n(\boldsymbol{x})$ at position $\boldsymbol{x}$, at a low temperature, the corresponding local internal chemical potential is approximated according to (76.18) as

$$\epsilon_F(\boldsymbol{x}) = \frac{\hbar^2\left[6\pi^2 n(\boldsymbol{x})\right]^{2/3}}{2m} . \tag{76.50}$$

Given the trapping potential $V(\boldsymbol{x})$, the density of the gas adjusts in such a way that the sum of the external potential energy and the local internal chemical potential, the Fermi energy, is a constant across the gas,

$$V(\boldsymbol{x}) + \frac{\hbar^2\left[6\pi^2 n(\boldsymbol{x})\right]^{2/3}}{2m} = \mu, \tag{76.51}$$

the global chemical potential. One may solve the density for a given chemical potential as

$$n(\boldsymbol{x}) = \begin{cases} \dfrac{\sqrt{2}\,m^{\frac{3}{2}}\left[\mu - V(\boldsymbol{x})\right]^{\frac{3}{2}}}{3\,\pi^2\,\hbar^3}, & V(\boldsymbol{x}) < \mu; \\ 0, & \text{otherwise.} \end{cases} \tag{76.52}$$

Finally, the integral of the density over all space should equal the atom number, which gives an equation to determine the chemical potential μ.

For a harmonic trap this program can be carried out in an exact, analytical manner with the result that

$$\mu = 6^{1/3}N^{1/3}\hbar\bar{\omega}, \quad R = 2^{2/3}3^{1/3}N^{1/6}\ell ,$$
$$n(0) = \frac{2\sqrt{N}}{\sqrt{3}\pi^2\ell^3} . \tag{76.53}$$

The quantities $\bar{\omega}$, ℓ, and R have the same meaning as in the BEC case. The Thomas–Fermi approximation for fermions should be applicable whenever $N \gg 1$.

In a one-component Fermi gas at low temperature atom–atom interactions are typically negligible for a multitude of reasons. There is no s-wave scattering, and the presence of the Fermi sea tends to suppress repulsive interactions. However, in the case of attractive interactions between two species, the Fermi sea may be thermodynamically unstable; the energy may be lowered by pairing fermions into Cooper pairs. This is the mechanism behind the BCS theory of superconductivity [76.8].

Excitations in a Fermi Gas
If the interactions do not render a fermion system into a superfluid, see Sect. 76.5.1, the elementary excitations of a degenerate Fermi gas with short-range interactions are basically atom–hole pairs. What happens in the contrary case for trapped and strongly interacting atoms is presently an active area of research.

76.3 Experimental

76.3.1 Preparing a BEC

In a trapped gas the density $n(\boldsymbol{x})$ is self-determined from the atom number N, and the condition for a BEC in an ideal gas is most readily expressed in terms of the total number of atoms as

$$k_B T_c = 0.94\,\hbar\bar{\omega}N^{1/3} . \tag{76.54}$$

In practice, at the bottom of the trap the conditions on temperature and density for a BEC are similar to the conditions for a BEC in a free gas. In the thermodynamic limit, such that $\bar{\omega} \to 0$, $N \to \infty$ with $\bar{\omega} N^{1/3}$ held constant, below the critical temperature T_c the fraction of condensate atoms behaves as a function of temperature T as

$$\frac{n_0}{N} = 1 - \left(\frac{T}{T_c}\right)^3 . \tag{76.55}$$

The experimental realizations of alkali vapor condensates are based on techniques of laser cooling and trapping of atoms. The following discussion relies heavily on material from Chapt. 75.

A BEC in a dilute atomic gas is usually prepared using a two-stage process. First, a magneto-optical trap is used to capture a sample of cold atoms and to cool it to a temperature of the order of a few tens of microkelvin. The atoms are then transferred to a magnetic trap for evaporative cooling that leads to condensation.

A magnetic trap is based on a combination of two ideas. First, if an atom that starts out with its magnetic moment antiparallel to the magnetic field moves slowly enough in a position dependent magnetic field, its magnetic moment remains adiabatically locked antiparallel to the magnetic field. The energy of the atom is then a minimum where the magnetic field is a minimum. Second, the absolute value of the magnetic field may have a minimum in free space. The minimum is then a trap for atoms whose magnetic moments are suitably oriented. The downside is that only atoms in the right magnetic (Zeeman) states are trapped. While the atoms cool down, they accumulate at the center of the trap. The center should not be a zero of the magnetic field, because at zero field an atom would lose the lock between the directions of the magnetic moment and the magnetic field necessary for trapping.

A time orbiting potential (TOP) trap starts with the same kind of magnetic field that is used in a magneto-optical trap. A time-dependent magnetic field is then added in such a way that the zero of the magnetic field orbits around the center of the trap. If the frequency at which the zero orbits is high enough so that the atoms cannot follow, they see an effective potential with a minimum at the center of the trap and do not sample the zero. Alternatively, it is possible to wind a coil in such a way that it makes a magnetic field whose absolute value has a minimum that is not zero. In this type of a Ioffe–Pritchard trap the winding of the wire resembles the seams on a US baseball.

The basic idea of evaporative cooling is that the most energetic atoms escape from the trap, then the remaining atoms thermalize to a lower temperature. Some atoms are lost in the process, but with the decreasing temperature the density at the trap center nonetheless tends to increase and the phase space density increases even more due to the cooling.

The cooling is usually forced by an rf drive. The transition frequency between the Zeeman states depends on the magnetic field, and increases toward the edges of the trap. Atoms are removed where the rf frequency is on resonance and drives transitions to untrapped Zeeman states. Thus, while the atoms cool and concentrate at the center, the radio frequency is swept down in such a way that the "rf knife" removing the atoms slides in from the edge of the trap. At some radio frequency a condensate abruptly emerges. The temperature can be further lowered by continuing evaporative cooling, albeit at the expense of loss of atoms. As a rule of thumb, an atom needs to experience a hundred collisions before condensation occurs, and a typical time needed to prepare a condensate is a few seconds. In a good vacuum a condensate may live for tens of seconds.

It is also possible to condense atoms trapped in a far-off resonant optical trap based on the dipole forces of light, instead of the magnetic trap [76.9]. For tuning below the resonance, atoms are strong-field seekers. A focused laser beam is a three-dimensional trap for atoms, as is an arrangement with two crossed beams focused to the same spot. Furthermore, with extreme off-resonant light from a CO_2 or a Nd-YAG laser, absorption of photons and the associated photon recoil kicks and heating may be negligible.

An optical trap may also be added after a BEC is prepared in a magnetic trap. The advantage is that an optical trap will hold the atoms regardless of their magnetic state, so that multicomponent "spinor" condensates may be studied. Moreover, while an adiabatic change of the strength of a trap cannot change the phase space density, the phase space density may be altered by changing the shape of the trap by adding a tight optical trap to the bottom of a much wider magnetic trap. Reversible condensation inside an added optical subtrap based on such an increase in the phase space density has been demonstrated.

Methods to condense atoms that might be suited for future technological applications are being pursued. For instance, by lithographic techniques it is possible to put conducting wires on a substrate to make an atom chip. With currents flowing, the wires produce magnetic fields that guide the atoms. Condensation

in such a configuration has been reported [76.10]. Two-dimensional condensation in what is known as a gravito-optical surface trap has also been achieved experimentally [76.11].

There is an analogy between a condensate and a beam of light from a laser that we rely on extensively. However, the analogy is only partial. By dropping a condensate under gravity one makes a pulsed atom laser, and by coupling a trapped Zeeman state to an untrapped state by rf excitation it is possible to make a condensate leak slowly out of the trap. Nonetheless, at this time a method to produce a continuous beam of condensate atoms, a continuous-wave atom laser, is yet to be demonstrated.

76.3.2 Preparing a Degenerate Fermi Gas

A single-species, very-low temperature Fermi gas is an uninteresting system, as the Fermi–Dirac statistics forbids s-wave interactions between the atoms and the gas is nearly ideal. In experiments the gas usually has two species, different states of the same atom. The interactions between the species are comparable in strength to the interactions between bosonic atoms.

Evaporative cooling works in a two-species gas, and can be used to prepare a degenerate Fermi gas either in a magnetic trap [76.12] or in an optical trap [76.13]. Second, one can use a gas of bosons, and indeed a BEC, as a refrigerator [76.14]. At this writing the lowest temperatures are of the order of $0.1\,T_F$. Reaching lower temperatures is complicated by various factors, such as the very low heat capacity of a BEC and collisions becoming inefficient at low temperature because the inert Fermi sea reduces the available phase space. Nonetheless, lower temperatures seem to be mainly a matter of advances in technology.

76.3.3 Monitoring Degenerate Gases

Orders of Magnitude. As a rule of thumb, the trapping frequencies in a magnetic trap are $\bar{\omega} \approx 2\pi \times 10\,\text{Hz}$, while the frequencies in an optical trap may reach into the kHz regime. A typical oscillator length is $\ell \approx 1\,\mu\text{m}$. A usual number of atoms is $N \approx 10^6$. Scattering lengths are of the order of $a \approx 10\,\text{nm}$. The size of a degenerate gas is in the neighborhood of $R \approx 0.1\,\text{mm}$, the maximum density is about $n_0 \approx 10^{15}\,\text{cm}^{-3}$, and the BEC transition temperature and the Fermi temperature are of the order of $T_c \approx T_F \approx 1\,\mu\text{K}$. However, much lower temperatures are readily reached in a BEC.

Phase Contrast Imaging. It is possible to monitor condensate features substantially larger than the wavelength of the light used in the measurements nondestructively, in situ, by using phase contrast imaging. In this method the light is detuned far off resonance so that absorptions with the accompanying photon recoil kicks on the atoms are rare, but the phase of the light nonetheless changes upon propagation through the sample. The phase change may be detected by interfering the transmitted light with the original light, with the phase of the latter suitably shifted.

Time–of–Flight Imaging. Usually, though, the observation of a degenerate gas at the end of an experiment is by time-of-flight imaging. The trap is suddenly removed, whereupon the gas expands freely. After the atom cloud has grown to a size large enough compared to the wavelength of the resonant light used to monitor the gas, an absorption image of the cloud is taken. This gives the projection of the density of the gas onto a plane perpendicular to the direction of propagation of the light. Except for the effects of atom–atom interactions, after a sufficiently long time of free flight the density reflects the initial momentum distribution of the atoms. Time-of-flight images bear the signs of both condensation in a Bose gas and quantum degeneracy in a Fermi gas. Nontrivially, other features of interest such as vortex cores are also preserved and can be detected after the free expansion. The downside is that the time-of-flight method is destructive. After each snapshot the sample will have to be prepared again.

76.4 BEC Superfluid

76.4.1 Vortices

Flow Velocity in a Superfluid. By manipulating the Heisenberg equations of motion for a Bose field under the Hamiltonian (76.22) it is easy to derive the equation of continuity for the atoms,

$$\frac{\partial}{\partial t}\hat{n} + \nabla \cdot \hat{\mathbf{J}} = 0\,, \tag{76.56}$$

$$\hat{n} = \hat{\psi}^\dagger\hat{\psi}\,, \quad \hat{\mathbf{J}} = \mathrm{i}\frac{\hbar}{2m}\left(\psi\nabla\psi^\dagger - \psi^\dagger\nabla\psi\right)\,, \tag{76.57}$$

which identifies $\hat{n}$ and $\hat{J}$ as the operators for atom density and atom current density. The corresponding mean-field quantities are obtained when again the boson fields are replaced with the corresponding classical fields. Writing the classical field in terms of the density $n(\boldsymbol{x}, t)$ and phase $\varphi(\boldsymbol{x}, t)$ in the form

$$\psi = \sqrt{n}\, \mathrm{e}^{\mathrm{i}\varphi}\,, \tag{76.58}$$

the local flow velocity $\boldsymbol{v} = \boldsymbol{j}/n$ becomes

$$\boldsymbol{v} = \frac{\hbar}{m}\,\nabla\varphi\,. \tag{76.59}$$

The velocity field is irrotational.

Quantization of Circulation. Integration of the flow velocity around an arbitrary loop gives

$$\oint \mathrm{d}\boldsymbol{l} \cdot \boldsymbol{v} = \frac{\hbar}{m}\,\Delta\varphi = p\,\frac{2\pi\hbar}{m}\,,$$
$$p = 0, \pm 1, \pm 2, \dots\,, \tag{76.60}$$

since the change of the phase $\Delta\varphi$ around a closed loop must be an integer multiple of 2π. Equation (76.60) expresses the quantization of circulation in a superfluid. A medium described by a macroscopic wave function, such as a BEC, cannot sustain arbitrary flow velocities.

Vortices. As an example, in bulk rotation at an angular velocity Ω the line integral around a loop at the distance r from the axis of rotation would be $2\pi r^2 \Omega$, which is not permitted for an arbitrary r. Instead, upon an attempt to make a BEC rotate, the angular velocity will be carried by vortex lines. These are lines through the condensate, entering and exiting at the surface, such that each vortex carries one quantum of circulation. At the core of a vortex the flow velocity should be infinite to sustain a finite circulation, which is physically impossible. Nature solves this problem by making the vortex core normal (not BEC), so that the macroscopic wave function does not apply. The diameter of the vortex core is of the order of the healing length ξ, given by (76.29).

When the trapping potential on the atoms is rotated, it is convenient to study the physics in the co-rotating frame. Given a frame rotating at the angular velocity $\boldsymbol{\Omega}$ and the angular momentum operator $\boldsymbol{L} = \boldsymbol{x} \times \boldsymbol{p}$ per particle, transformation to the rotating frame adds the one-particle term

$$H_{\mathrm{r}} = -\boldsymbol{\Omega} \cdot \boldsymbol{L} \tag{76.61}$$

to the Hamiltonian. Any particular configuration of vortices is a thermodynamically stable equilibrium if it is the minimum of energy in the co-rotating frame. For a trapped condensate, at zero rotation velocity the state without vortices is the energy minimum, and increasing the rotation speed makes states with an increasing number of vortices the stable configuration. However, a vortex configuration may be metastable and live for a long time even if it is not the minimum of energy. Conversely, even the energy-minimum configuration of vortices must first be nucleated. Since the circulation can only have quantized values, it cannot change in a continuous process. It takes a zero condensate density somewhere to create or destroy a vortex.

These alternatives provide a large number of experimental scenarios involving rotation of the trap or stirring of the condensate, condensation of a rotating normal gas by taking it across the transition temperature, and so forth. For instance, when a trap containing a BEC is rotated, vortices are generated at the surface where they start their lives as dynamical instabilities. The vortices then drift in and form a regular vortex array [76.15]. When the rotation is halted, the vortices drift out to the surface and disappear.

76.4.2 Superfluidity

A BEC also has the remarkable property that it may sustain persistent currents that are completely immune to viscosity. The qualitative reason may be seen from the dispersion relation of small excitations (76.38). As long as the flow speed $|\boldsymbol{v}|$ is less than the speed of sound c, all excitation energies are positive, so that the flowing state is the state of lowest energy and is thermodynamically stable. On the other hand, when the flow velocity exceeds the speed of sound, the system has excitations that lower the energy, $\nu(\boldsymbol{q}) < 0$ for some $\boldsymbol{q}$. The flowing state is then not a minimum of energy. The flow is not thermodynamically stable, and it decays when it interacts with an environment by sending off small excitations. The speed of sound gives the Landau critical velocity for superfluidity.

The critical velocity c tends to zero when the atom–atom interactions vanish with $a \to 0$. While the condensate wave function may be written down whether the atoms interact or not, superfluidity and persistent flows rely on the interactions. The same applies to vortices, as in the limit of a noninteracting gas the healing length and the radius of the vortex core tend to infinity.

The conventional picture is that superfluid flow in an inhomogeneous medium is unstable if the local flow velocity exceeds the local (density dependent) speed of sound. In practice, in liquid He experiments and numerical simulations of dilute condensates the current

often dissipates by shedding vortices when it flows too fast past an obstacle. It is not clear if the conventional picture is, or should be expected to be, quantitatively accurate. In fact, at this time there are no experiments with alkali vapor condensates in toroidal geometries that would offer natural conduits for persistent currents.

76.5 Current Active Topics

76.5.1 Atom–Molecule Systems

Diatomic molecules and conversion between atoms and molecules at temperatures low enough to render the system quantum degenerate are at present probably the most active frontier in the studies of ultracold gases. Experimental achievements include a condensate of molecules, and coherent transitions between two chemically different species. More broadly, unforeseen new angles open up into long-standing issues in superfluid systems in condensed matter physics, such as strongly interacting superfluids and BEC-BCS crossover. A snapshot of the field at this time is given in the present section.

Two colliding asymptotically free atoms cannot in general combine into a diatomic molecule, as energy and momentum would not be conserved in the process. However, there are two mathematically equivalent methods to adjust energy conservation, photoassociation and Feshbach resonance [76.16], both of which may lead to molecule formation.

The underlying idea is that two seemingly free atoms may be regarded as a dissociated state of a corresponding diatomic molecule. In photoassociation a laser drives transitions from a dissociated two-atom state to a bounded state of the molecule. Energy conservation is adjusted by tuning the laser. In a Feshbach resonance hyperfine interactions drive transitions from a two-atom state in a particular manifold of electronic states to a molecular state in another manifold of electronic states. The magnetic moments of the two-atom state and the bounded molecular state are different, so that the resonance may be tuned by varying the magnetic field applied on the atom–molecule gas.

Basic Atom–Molecule Model for Bosons. Consider a minimal model for conversion of bosonic atoms (boson field $\hat{\phi}$) into bosonic molecules ($\hat{\psi}$). The Hamiltonian density reads

$$\frac{\hat{\mathcal{H}}}{\hbar} = \hat{\phi}^\dagger \left(-\frac{\hbar}{2m}\nabla^2 \right)\hat{\phi} + \hat{\psi}^\dagger \left(-\frac{\hbar}{4m}\nabla^2 + \delta \right)\hat{\psi} + g(\hat{\psi}^\dagger\hat{\phi}\hat{\phi} + \hat{\psi}\hat{\phi}^\dagger\hat{\phi}^\dagger) \,. \tag{76.62}$$

This model is for free atoms. Atom–molecule coupling is described as a contact interaction characterized by the coupling coefficient g. The detuning δ may be adjusted in photoassociation by tuning the laser, and in a Feshbach resonance by varying the magnetic field.

Effective Scattering Length. Heisenberg equations of motion for the atomic and molecular fields read

$$\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}t}\hat{\phi} = -\frac{\hbar}{2m}\nabla^2\hat{\phi} + 2g\hat{\phi}^\dagger\hat{\psi} \,, \tag{76.63}$$

$$\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}t}\hat{\psi} = \left(-\frac{\hbar}{4m}\nabla^2 + \delta \right)\hat{\psi} + g\hat{\phi}\hat{\phi} \,. \tag{76.64}$$

Suppose now that the detuning from resonance, $|\delta|$, is the largest frequency parameter in the problem, then one may solve the molecular field adiabatically from (76.64) as $\hat{\psi} = -g\hat{\phi}\hat{\phi}/\delta$. Inserting this into (76.63) gives

$$\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}t}\hat{\phi} = -\frac{\hbar}{2m}\nabla^2\hat{\phi} - \frac{2g^2}{\delta}\hat{\phi}^\dagger\hat{\phi}\hat{\phi} \,, \tag{76.65}$$

which is the Heisenberg equation of motion for the atomic field that ensues from an effective Hamiltonian density

$$\hat{\mathcal{H}}_\mathrm{E} = \hat{\phi}^\dagger \left(-\frac{\hbar^2}{2m}\nabla^2 \right)\hat{\phi} + \frac{2\pi\hbar^2 a_\mathrm{E}}{m}\hat{\phi}^\dagger\hat{\phi}^\dagger\hat{\phi}\hat{\phi} \tag{76.66}$$

with the effective scattering length

$$a_\mathrm{E} = -\frac{mg^2}{2\pi\hbar\delta} \,. \tag{76.67}$$

Experimentally, the modification of the scattering length is in addition to a constant "background" scattering length a_0, and the sum of the two scattering lengths

$$a = a_0 + a_\mathrm{E}. \tag{76.68}$$

is usually reported.

As long as one stays sufficiently far away from an atom–molecule resonance, tuning the resonance condition is tantamount to tuning the atom–atom scattering length. When the detuning is negative (positive), the energy of a molecule is lower (higher) than the energy of an on-threshold pair of atoms, the corresponding induced scattering length is positive (negative), and the

induced atom–atom interactions are in effect repulsive (attractive). It should be noted, though, that the scattering length does not simply become very large. Vernacular of this style, and associated attempts to study the theory of an interacting Bose gas in the limit when the gas parameter na_E^3 is not small, are occasionally misguided and misleading. The physics rather is in resonant, energy-conserving conversion between atoms and molecules.

Atom–Molecule Coupling Strength. Given the difference in magnetic moments $\Delta\mu$ between a molecule and two atoms and the position of the Feshbach resonance B_0, the detuning is

$$\delta = \frac{\Delta\mu(B - B_0)}{\hbar} . \tag{76.69}$$

The variation of the scattering length is conventionally parametrized in terms of the magnetic field width of the Feshbach resonance ΔB as

$$a = a_0 \left(1 - \frac{\Delta B}{B - B_0}\right) . \tag{76.70}$$

A combination of (76.67–76.70) gives the relation between the field width and the contact interaction parameter characterizing the Feshbach resonance,

$$g = \sqrt{\frac{2\pi |a_0 \, \Delta\mu \, \Delta B|}{m}} . \tag{76.71}$$

Unfortunately, the difference in magnetic moments $\Delta\mu$ is not always publicized and one may be forced to estimate, say, $\Delta\mu \approx \mu_B$.

Two–Mode Model. Consider next, in the mean-field approximation, the case when only uniform atomic and molecular condensates are present. The condensates are represented by complex amplitudes α and β such that $\hat{\phi} \to \sqrt{n}\,\alpha$ and $\hat{\psi} \to \sqrt{n/2}\,\beta$, where n now is the invariant density equal to atom density plus twice the density of the molecules. It follows from (76.63) and (76.64) that the probability amplitudes for atoms and molecules, normalized as $|\alpha|^2 + |\beta|^2 = 1$, satisfy

$$i\dot{\alpha} = \frac{\Omega}{\sqrt{2}}\,\alpha^*\beta, \quad i\dot{\beta} = \delta\beta + \frac{\Omega}{\sqrt{2}}\,\alpha^2 . \tag{76.72}$$

These are nonlinear variations of the usual two-level equations (see Chapt. 73) of quantum optics, with the quantity $\Omega = \sqrt{n}\,g$ playing the role of the Rabi frequency. This system displays analogs of coherent optical transients (see Chapt. 73), such as Rabi oscillations between atomic and molecular condensates, and adiabatic

following from an atomic condensate to a molecular condensate when the detuning is swept through the resonance [76.17].

The two-mode model is simplistic in that it ignores processes in which molecules dissociate into correlated pairs of noncondensate atoms [76.18, 19]. There are also secondary complications. The molecules created in a Feshbach resonance are highly vibrationally excited, and tend to get quenched in collisions with atoms and other molecules. Typical lifetimes are in the millisecond regime. Usual one-color photoassociation from two atoms to a molecule with the absorption of a photon, on the other hand, creates an electronically excited molecule, which decays spontaneously on a time scale far shorter than the typical photoassociation time scales. To mitigate spontaneous emission, one usually resorts to two-color photoassociation, in which a second laser takes the photoassociated molecules to another more stable level [76.20].

At present, the two-mode system with just an atomic and a molecular condensate has never been realized cleanly in an experiment. Nonetheless, experiments using a Feshbach resonance have demonstrated Ramsey fringes in transitions between atomic and molecular condensates [76.21], and formation of what probably is a (short-lived) molecular condensate from the bosonic isotope ^{23}Na [76.22].

Fermion Systems. Combining two fermionic atoms gives a bosonic molecule, and Feshbach resonance in a Fermi gas is currently a popular topic. The main interest is in the BEC-BCS crossover. Basically, if the magnetic field is tuned so that the detuning is negative, molecules have a lower energy than atoms. Thermal equilibration then leads to molecules that will condense if the temperature is low enough. On the other hand, if the detuning is positive, atom–atom interactions are attractive. The atoms may undergo a phase transition into a fermion superfluid that is analogous to the BCS phase transition in a superconductor. What happens in between has been a question in theory for a while [76.23], and is finally accessible to experiments.

Collisionless adiabatic transfer from atoms to molecules by sweeping the magnetic field across a Feshbach resonance works with fermions much like with bosons [76.24]. Moreover, molecules formed in the 834 G Feshbach resonance in the fermionic isotope ^{6}Li may live for seconds. It is now possible to study thermal equilibrium and long-lived excited states in the neighborhood of the resonance [76.25–27]. In particular, the observation of a vortex lattice over a wide range

of magnetic fields on both sides of the resonance [76.24] indicates that close to the resonance the gas is a strongly interacting superfluid.

76.5.2 Optical Lattice with a BEC

A BEC confined to a periodic potential enjoys a long-standing popularity for reasons that have varied in time. In the early days of BEC the Josephson effect and phase behavior of a BEC were topical. The possibility of a quantum phase transition in an optical-lattice system was the next broad topic to emerge, and nowadays speculations about using condensates in a lattice either as supporting technology or as the active element in quantum information processing abound. The deceptively simple theoretical models of these systems add to their staying power. In this section, a brief discussion of an optical lattice holding a BEC is presented. The quantum information view is not pursued here, as so far no specific experimental progress has appeared in print.

Optical Lattice. Dipole forces of standing-wave fields of light generate a periodic potential, an optical lattice, on the atoms. If the light is detuned far enough from atomic resonances, absorption and spontaneous emission are negligible and the potential is conservative. In one dimension, the potential energy for the motion of the atoms is typically of the form

$$V(x) = V_0 \sin^2 kx , \qquad (76.73)$$

where k is the wave number of the lattice light, and the depth of the lattice V_0 can be inferred from the known parameters of the atoms and the light as explained in Sect. 75.2.2.

Double–Well Potential. One can integrate the GPE numerically for an arbitrary potential, but many more insights have been gained from restricted models. The simplest one is a double-well potential in the two-state approximation, in which only the ground state of the atoms in both wells is taken into account. The Hamiltonian is

$$\frac{\hat{H}}{\hbar} = -\frac{\Delta}{2}\left(a_l^\dagger a_r + a_r^\dagger a_l\right) + 2\kappa\left[\left(a_l^\dagger a_l\right)^2 + \left(a_r^\dagger a_r\right)^2\right] . \qquad (76.74)$$

Here Δ is a parameter characterizing tunneling between the "left" and the "right" potential well, $a_{l,r}$ are the annihilation operators for ground-state bosons in each well, and κ is a measure of atom–atom interactions. The one-particle states in a symmetric double-well potential with weak tunneling come in doublets, one even

state ϕ_+ and one odd state ϕ_-, with respect to the center of the double-well trap. The choices of signs of the wave functions are assumed to work out in such a way that the left and right states are $\phi_{l,r} = \sqrt{1/2}\,(\phi_+ \pm \phi_-)$. Equation (76.74) could be the version of the Hamiltonian (76.22) restricted to the basis of the two states $\phi_{l,r}$.

There are many forms of the Hamiltonian (76.74) that differ by a polynomial of the conserved particle number $\hat{N} = \left(a_l^\dagger a_l + a_r^\dagger a_r\right)$. Inasmuch as particle number is fixed, adding any function of the conserved quantity $\hat{N}$ to the Hamiltonian has no effect on the dynamics, and so such forms are functionally equivalent. Here polynomials of $\hat{N}$ are added to the Hamiltonian without further notice to produce the simplest-looking results.

Semiclassical Approximation. The usual method of going to the classical field theory gives the equations for the semiclassical amplitudes defined by $a_{l,r}/\sqrt{N} \to \alpha_{l,r}$,

$$i\dot\alpha_l = -\frac{1}{2}\Delta\,\alpha_r + \chi|\alpha_l|^2\alpha_l,$$

$$i\dot\alpha_r = -\frac{1}{2}\Delta\,\alpha_l + \chi|\alpha_r|^2\alpha_r , \qquad (76.75)$$

with $\chi = 4\kappa N$. Without atom–atom interactions these are the equations of a resonant two-level system and describe Josephson oscillations of the atoms between the sides of the double-well potential. Interactions temper the oscillations, or stop them completely [76.28].

Phase Diffusion in the Double Well. The model (76.74) is unusual in that one can easily go beyond the semiclassical approximation [76.29]. The entire state space for N atoms is spanned by the vectors $|n_l, n_r\rangle = |n_l, N - n_l\rangle$ with $n_l = 0, \ldots, N$. The Hamiltonian can be diagonalized and the time dependence of the system solved numerically even for large N. Moreover, the common case in which the atom number fluctuations at the sites are at least of the order unity, but small in a relative sense, is amenable to a simple analytical approximation.

The phase difference of the condensates between the two traps, $\hat\varphi$, is a case in point. One can measure it by releasing the atoms from the trap and letting them interfere. Although there are serious in-principle problems with this interpretation, phase difference can be viewed qualitatively as the canonical conjugate of the difference between the number of atoms on the sides of the double well, $\hat{n} \equiv \hat{n}_l - \hat{n}_r$, with $[\hat{n}, \hat\varphi] = -i$. The minimum uncertainty product of phase difference and atom number difference is then $1/2$. On this basis, results for various experiments can be qualitatively and quantitatively predicted.

For instance, suppose the system is prepared in the ground state of the Hamiltonian (76.74). The ground state is an even split of the atoms between the two traps, but atom number fluctuations depend on the ratio between tunneling and atom–atom interactions. For $|\Delta|/\chi \ll 1$, atom–atom interactions dominate, and since moving an atom from one side of the trap to the other costs much interaction energy, the ground state is close to a number state with half of the atoms in each potential well. In the contrary case, the ground state is essentially the many-body state with all N atoms in the symmetric state ϕ_+, which breaks up into a Poissonian distribution of the atoms between the states ϕ_l and ϕ_r. As long as the standard deviation of the atom number difference is at least of the order of unity, it is given by

$$\Delta n = \sqrt{N} \left(\frac{\Delta}{\Delta + 4N\kappa} \right)^{1/4} , \qquad (76.76)$$

and the phase fluctuations are

$$\Delta\varphi = \frac{1}{2\,\Delta n} . \qquad (76.77)$$

As discussed above in Sect. 76.3.2, a measurement of the phase difference will produce a definite result. In the interaction-dominated case the result should in effect be random, while in the tunneling-dominated case the phase difference should come out the same every time, save for fluctuations of the order $1/\sqrt{N}$. Similarly, if one were to start from the ground state in the case when tunneling dominates, and then suddenly turn off tunneling by adjusting the potential well, atom–atom interactions would lead to diffusion (or rather, dispersion) of the phase difference. The result of a phase measurement becomes increasingly random with time according to

$$\Delta\varphi(t) = \frac{1}{2}\sqrt{\frac{1}{N} + 16N\kappa^2 t^2} . \qquad (76.78)$$

Bose–Hubbard Model. The corresponding multi-well problem goes under the rubrics fo the Bose–Hubbard model and tight-binding approximation. The Hamiltonian is

$$\frac{\hat{H}}{\hbar} = \sum_n \left[-\frac{\Delta}{2}\left(a_{n+1}^\dagger a_n + a_{n-1}^\dagger a_n\right) + 2\kappa\left(a_n^\dagger a_n\right)^2 \right] . \qquad (76.79)$$

The sum runs over the sites of the optical lattice, which is taken to be one-dimensional in this example, and Δ and κ again characterize tunneling and atom–atom interactions. At the ends of the lattice there are some boundary conditions, but for a long enough lattice they do not influence the physics.

One-particle eigenstates in a periodic lattice are organized in energy bands, but there is a well-known transformation in condensed matter physics that makes orthonormal Wannier states, more or less localized in the lattice sites, out of the states in each band. The most rigorous interpretation of the Hamiltonian (76.79) is that it is the representation of the Hamiltonian (76.22) in the Wannier states belonging to the lowest energy band of the lattice, ignoring tunneling between non-adjacent sites. Viewed in this way, the model is only valid in the limit when the energy per atom for atom–atom interactions is small compared to the energy spacing between the bands.

Nonetheless, direct integrations of the GPE with atom–atom interactions also show energy bands, and for suitably picked parameters the Hamiltonian (76.79) should be generic for the case when interband transitions are negligible. Now, without atom–atom interactions the width of the energy band from the Bose–Hubbard model would be $\hbar\Delta$. On the other hand, the band structure for the potential energy (76.73) of an optical lattice comes from the Mathieu equation [76.30]. A comparison gives the estimate

$$\Delta = \frac{8}{\sqrt{\pi}} \frac{E_r}{\hbar} \left(\frac{V_0}{E_r} \right)^{3/4} \exp\left(-2\sqrt{\frac{V_0}{E_r}} \right) . \qquad (76.80)$$

This is an asymptotic expression for the limit when the recoil energy $E_r = \hbar^2 k^2/2m$ and the lattice depth V_0 satisfy $V_0 \gg E_r$. Next suppose that one ascribes to each potential well the unit-normalized wave function $\phi(x)$, then an estimate for the atom–atom interaction parameter κ comes from (76.23) in the form

$$\kappa = \frac{\pi\hbar a}{m} \int d^3x \, |\phi(x)|^4 . \qquad (76.81)$$

Phase Diffusion in the Bose–Hubbard Model. The dominant feature of the Bose–Hubbard model again is competition between tunneling and atom–atom interactions. Also, phase and atom number fluctuations may again be studied analytically under the assumptions that atom number fluctuations at each site are at least of the order of unity, but small in a relative sense. For the same numbers of atoms per site, the results are basically the same in the two- and multi-well cases.

In fact, multi-well counterparts [76.31] of the experiments on the phase relations are well ahead of the experiments on two-well systems [76.32]. The multi-well experiments are in satisfactory agreement with the theory.

Superfluid–Mott Insulator Transition. Because the size of the state space tends to grow as L^L with the number of lattice sites L, direct numerical solutions to the multi-well problem are computationally intractable. This is somewhat unfortunate, as a long lattice also presents behaviors with no obvious analogs in the two-well case, and for which analytical approximations have proven hard to come by. When tunneling dominates, the system is in what is referred to as the superfluid phase. Fluctuations of atom number between the states are relatively large. On the other hand, if atom–atom interactions dominate, it becomes costly in energy to put anything but an exact number state of atoms at each lattice site. This is the Mott insulator phase. According to calculations carried out using the so-called Gutzwiller ansatz, the ground state of an optical lattice inserted in an atom trap consists of regions with the same integer number of atoms at the lattice sites within each region [76.33]. When the parameters of the system are varied, in what is known as a quantum phase transition, the system should abruptly switch between these phases.

The superfluid-Mott insulator transition has been observed experimentally [76.34]. Lattice parameters, especially tunneling, can be varied easily by changing the intensity of the lattice light. The observation of the transition is by means of phase coherence. In the superfluid state the system is characterized by a global macroscopic wave function. When the atoms are released from the lattice, atoms originating from different sites are capable of interference, and the interference pattern reflects the lattice structure. On the other hand, in the Mott insulator phase the lattice sites are in number states with little phase coherence between them, and there is no interference pattern.

77. De Broglie Optics

De Broglie optics concerns the propagation of matter waves, their reflection, refraction, diffraction and interference. The main subfields of de Broglie optics are electron optics [77.1], neutron optics [77.2], and atom optics [77.3]. Well-established applications are found in electron diffraction and microscopy [77.4], electron holography [77.5], neutron diffraction and interferometry [77.6]. The subject of atom optics is relatively new, and applications are currently being developed in precision spectroscopy, precision measurement, atom lithography, atom microscopy, and atom interferometry [77.7–9]. This chapter concentrates on the principles of de Broglie optics. Illustrations of these principles will be presented mainly in the framework of atom optics.

A typical de Broglie optical experiment involves a source, a beam of particles produced by that source, an array of optical elements, possibly a probe, other optical elements placed behind the probe, and finally a detector. Optical elements are collimators, apertures, lenses, mirrors, and beam-splitters. A probe could be a crystal, a biological sample, or just another unknown optical element whose properties are to be investigated.

To avoid proliferation of notation, we refer to any object placed in the beam path simply as an "optical element".

77.1 Overview

Any collection of particles of mass M and momentum p has a de Broglie wavelength $\lambda_{\mathrm{dB}} = 2\pi\hbar/p$. Originally meant to explain the orbits of a single Coulomb-bound electron, the ultimate wave character of matter has been confirmed for all fundamental particles, and also for composite particles such as ions, atoms and molecules.

In terms of the Bohr radius a_0, the fine-structure constant α, and the electron mass m_{e}

$$\lambda_{\mathrm{dB}} = \frac{2\pi\alpha a_0}{(v/c)(M/m_{\mathrm{e}})} = 2\pi\left(\frac{E_{\mathrm{h}}}{2\mathcal{T}}\frac{m_{\mathrm{e}}}{M}\right)^{1/2} a_0\,,$$

(77.1)

where $v = p/M$ is the velocity, $\mathcal{T} = \frac{1}{2}Mv^2$ is the kinetic energy, and E_h is the atomic unit of energy (Table 1.4 of Sect. 1.2). For electrons, $\lambda_{dB} \approx 1.226\,426\,\text{nm}/(\mathcal{T}/\text{eV})^{1/2}$. The thermal de Broglie wavelength is defined in (77.80).

Regardless of the particle species, the theory of de Broglie optics divides into two distinct parts: the theory of dispersion and the theory of the optical phenomena. In the theory of dispersion an effective Hamiltonian is derived which describes the interaction of the particles with the optical elements. In the theory of optical phenomena, the ensuing Schrödinger equation is solved and put into the context of geometrical and Fourier optics (e.g., by relating distributions of intensity on the detector screen to properties of a given optical element).

Dispersion of de Broglie Waves

The theory of dispersion is highly particle specific, since it depends on any internal degrees of freedom which may give rise to permanent magnetic moments or to induced electromagnetic moments either in static or in optical light fields. Interaction with the latter fields also may give rise to spontaneous emission. Spontaneous emission has important consequences for the coherence properties of atomic matter waves because of the random recoil associated with it (Chapt. 75).

Dispersion of matter waves differs from that of light waves in a number of regards. First, the dispersion relation of free particles is quadratic in the wavenumber giving rise to spatial spreading of wavepackets even in one-dimensional configurations. Second, particles may be brought to rest, which is impossible for photons. And finally, particles in beams may show self-interaction giving rise to nonlinear optical phenomena even for freely traveling particle waves. Electrons and ions, for example, experience a particle density dependent Coulomb broadening in the focus of a lens (Boersch effect [77.5]).

In atom optics, nonlinear phenomena occur due to atom–atom interactions in the ensemble, the nature of which may be significantly influenced by laser light [77.10]. In the presence of laser light, atom–atom interactions mainly result from photon exchange which, in most cases, leads to a repulsive interaction. Details of the microscopic basis of atom–atom interactions, in particular, those concerning cold collisions, are presented in Sect. 75.5.1. Characteristic effects of nonlinear atom optics like four-wave mixing [77.11] and parametric amplification [77.12] have been observed with the highly dense samples provided by Bose–Einstein degenerate gases (Chapt. 76).

Optics of de Broglie Waves

In contrast to the theory of dispersion, the theory of optical phenomena of matter waves is quite universal and bears strong resemblance to ordinary light optics. This resemblance is closest if the particles can be described by a scalar wave function of a structureless point particle. However, in the presence of resonant laser fields, electronic levels, their Zeeman sublevels and possible hyperfine structure may play an important role, in which case a multicomponent spinor wave function must be used to describe the atom optical phenomena properly.

77.2 Hamiltonian of de Broglie Optics

A large class of phenomena of particle optics is well-described by an effectively one-particle Hamiltonian model in which the particles are not assumed to mutually interact. In such a model the ensemble of particles is described by a wave function $\psi(x, t) = \langle x|\psi(t)\rangle$ whose time evolution is governed by the Schrödinger equation

$$i\hbar \frac{\partial}{\partial t}|\psi(t)\rangle = H(t)|\psi(t)\rangle \tag{77.2}$$

with a one-particle Hamiltonian of the generic form

$$H(t) = \frac{[\hat{p} - \mathcal{A}(\hat{x}, t)]^2}{2M} + \mathcal{U}(\hat{x}, t) . \tag{77.3}$$

Here, $\hat{p}$ and $\hat{x}$ denote the canonically conjugate operators of the center of mass momentum and position, respectively. The cartesian components of $\hat{p}$ and $\hat{x}$ obey the fundamental commutation relation

$$[\hat{x}_i, \hat{p}_j] = i\hbar\delta_{ij} . \tag{77.4}$$

The vector potential $\mathcal{A}(x, t)$ and scalar potential $\mathcal{U}(x, t)$ account for the interaction of the particle with all the optical elements, probes, and samples which are placed between the source and the detector, including the effects of gravitation and rotation.

77.2.1 Gravitation and Rotation

All particles are subject to the influence of gravitation and rotation, which both may be viewed as being special cases of an accelerated frame of reference. Effects of uniform gravitation are described by

$$\mathcal{U}(\boldsymbol{x}) = -M\boldsymbol{g} \cdot \boldsymbol{x} , \quad \mathcal{A}(\boldsymbol{x}) = 0 , \tag{77.5}$$

where $\boldsymbol{g}$ describes the direction and magnitude of gravitational acceleration. Effects of uniform rotation are described by

$$\mathcal{U}(\boldsymbol{x}) = -\frac{M}{2}\left(\boldsymbol{\Omega} \times \boldsymbol{x}\right)^2 , \quad \mathcal{A}(\boldsymbol{x}) = M\left(\boldsymbol{\Omega} \times \boldsymbol{x}\right) , \tag{77.6}$$

where the direction and magnitude of $\boldsymbol{\Omega}$ refer to the orientation of the axis of rotation and the angular velocity, respectively. Here, $\mathcal{U}(\boldsymbol{x})$ is the potential of the centrifugal force while $\mathcal{A}(\boldsymbol{x})$ is the potential of the Coriolis force.

77.2.2 Charged Particles

The interaction of charged particles (electrons, ions) with the electromagnetic field is described by

$$\mathcal{U}(\boldsymbol{x}, t) = q\Phi(\boldsymbol{x}, t) , \quad \mathcal{A}(\boldsymbol{x}, t) = (q/c)\boldsymbol{A}(\boldsymbol{x}, t) , \tag{77.7}$$

where q is the particle charge ($q = -e$ for electrons), and $\boldsymbol{A}$ and Φ denote the gauge potentials of the electromagnetic fields $\boldsymbol{E}$ and $\boldsymbol{B}$, respectively. The fields are given by

$$\boldsymbol{E}(\boldsymbol{x}, t) = -\frac{1}{c}\frac{\partial}{\partial t}\boldsymbol{A}(\boldsymbol{x}, t) - \nabla\Phi(\boldsymbol{x}, t) , \tag{77.8}$$

$$\boldsymbol{B}(\boldsymbol{x}, t) = \nabla \times \boldsymbol{A}(\boldsymbol{x}, t) . \tag{77.9}$$

77.2.3 Neutrons

For neutrons interacting with a spatially homogeneous gas, liquid, or amorphous solid contained in a volume V, a common model is

$$\mathcal{U}(\boldsymbol{x}) = \begin{cases} \mathcal{U}_0 & \text{inside } V , \\ 0 & \text{outside } V , \end{cases} \tag{77.10}$$

where $\mathcal{U}_0 = 2\pi\hbar^2\varrho b/M$, ϱ being the number density of scatterers in the volume, and b the bound coherent scattering length.

For neutrons interacting with perfect crystals, $\mathcal{U}(\boldsymbol{x})$ is a smooth periodic function with the same periodicity

as the lattice and an average value $\mathcal{U}_0$ within a single unit cell (see [77.2] for details).

77.2.4 Spins

The interaction of the spin related magnetic moment $\boldsymbol{\mu}$ with the electromagnetic field is described by

$$\hat{\mathcal{U}}(\boldsymbol{x}, t) = -\hat{\boldsymbol{\mu}} \cdot \boldsymbol{B}(\boldsymbol{x}, t) ,$$
$$\hat{\mathcal{A}}(\boldsymbol{x}, t) = \left[\hat{\boldsymbol{\mu}} \times \boldsymbol{E}(\boldsymbol{x}, t)\right]/c \tag{77.11}$$

Here, the vector potential is due to the motional correction of the magnetic dipole interaction. Usually, it is neglected. However, it does play an important role for the Aharonov–Casher effect (Sect. 77.7).

For fundamental particles with spin $\frac{1}{2}$, one has

$$\hat{\boldsymbol{\mu}} = g\frac{\hbar e}{4Mc}\boldsymbol{\sigma} , \tag{77.12}$$

where $\boldsymbol{\sigma}$ is the vector of Pauli matrices, and g is the g-factor of the particle (Sect. 75.5.2).

Here and in what follows, a hat on $\mathcal{U}$ and $\mathcal{A}$ indicates the matrix character of the hatted quantity, the matrix indices referring to the internal degrees of freedom, like spin. Similarly, $\Psi(\boldsymbol{x}, t)$ denotes a spinor-valued wave function. The wave function of a spin-$\frac{1}{2}$ particle, for example, is displayed in the form

$$\Psi(\boldsymbol{x}, t) = \begin{pmatrix} \psi_\uparrow(\boldsymbol{x}, t) \\ \psi_\downarrow(\boldsymbol{x}, t) \end{pmatrix} , \tag{77.13}$$

where $\psi_\uparrow$ ($\psi_\downarrow$) is the scalar wave function of the $\sigma_3 = +1(-1)$ component of the state $|\Psi(t)\rangle$.

77.2.5 Atoms

Many optical elements in atom optics are based on the mechanical effects of the radiation interaction. In the electric dipole approximation, the interaction of a single atom with the electromagnetic field is described by

$$\hat{\mathcal{U}}(\boldsymbol{x}, t) = -\hat{\boldsymbol{d}} \cdot \boldsymbol{E}(\boldsymbol{x}, t) ,$$
$$\hat{\mathcal{A}}(\boldsymbol{x}, t) = \boldsymbol{B}(\boldsymbol{x}, t) \times \hat{\boldsymbol{d}}/c , \tag{77.14}$$

where $\hat{\boldsymbol{d}}$ is the operator of electric dipole transition. The vector potential $\hat{\mathcal{A}}$ is due to the motional correction of the electric dipole interaction. Usually it is neglected; see however, the paragraph Electric Dipole Phase in Sect. 77.7.

For a monochromatic field of frequency ω

$$\boldsymbol{E}(\boldsymbol{x}, t) = \boldsymbol{E}^{(+)}(\boldsymbol{x})\,e^{-i\omega t} + \text{h.c.} , \tag{77.15}$$

where $\boldsymbol{E}^{(+)}(\boldsymbol{x})$ defines both polarization and spatial characteristics of the field. A standing wave laser field with optical axis in the x-direction and linear polarization $\boldsymbol{\epsilon}$, for example, is described by

$$\boldsymbol{E}^{(+)}(\boldsymbol{x}) = \boldsymbol{\epsilon}\, \mathcal{E}_0\, f(x, y, z) \cos(kx) , \qquad (77.16)$$

where $\mathcal{E}_0$ is the electric field amplitude, $k = \omega/c$ is the wavenumber, and the slowly varying function $f(x, y, z)$ accounts for the transverse profile of the laser field.

The electric dipole operator $\hat{\boldsymbol{d}}$ acts in the Hilbert space of electronic states of the atom. In the particular case that the polarization of the laser field is spatially uniform and that spontaneous emission does not play a role, two states are generally sufficient and the atom may be modeled by a two-level atom with electronic levels $|e\rangle$ and $|g\rangle$ of energy E_e and E_g, respectively ($E_e > E_g$). With the spinor representation

$$|e\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix} , \quad |g\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix} , \qquad (77.17)$$

the electric dipole operator assumes the form

$$\hat{\boldsymbol{d}} = d\, \boldsymbol{\epsilon}_{\mathrm{d}} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} , \qquad (77.18)$$

where d is the matrix element of the dipole transition and $\boldsymbol{\epsilon}_{\mathrm{d}}$ denotes its polarization.

The laser field is assumed to be near resonant with the $e \leftrightarrow g$ transition at $\omega_0 = (E_e - E_g)/\hbar$, and we denote by $\Delta \equiv \omega_0 - \omega$ the atom-laser detuning. Using the rotating wave approximation (Sect. 68.3.2) in an interaction picture with respect to the laser frequency, the Hamiltonian describing the atomic dynamics – both internal and center-of-mass – is given by

$$H = \frac{\hat{\boldsymbol{p}}^2}{2M} - \frac{\hbar}{2} \begin{pmatrix} -\Delta & \Omega_1(\hat{\boldsymbol{x}}) \\ \Omega_1{}^{\dagger}(\hat{\boldsymbol{x}}) & \Delta \end{pmatrix} , \qquad (77.19)$$

where

$$\Omega_1(\boldsymbol{x}) = 2d\, \boldsymbol{\epsilon}_{\mathrm{d}} \cdot \boldsymbol{E}^{(+)}(\boldsymbol{x})/\hbar \qquad (77.20)$$

is the spatially dependent bare Rabi frequency. In the field (77.16), $\Omega_1(\boldsymbol{x})$ is cosinusoidal with peak value $\Omega_0 = 2d\mathcal{E}_0/\hbar$.

Atom Optical Stern–Gerlach Effect
The Hamiltonian (77.19) may be written in the form

$$H = \frac{\hat{\boldsymbol{p}}^2}{2M} + \frac{\hbar}{2}\boldsymbol{\sigma} \cdot \boldsymbol{B}_{\mathrm{eff}}(\hat{\boldsymbol{x}}) , \qquad (77.21)$$

where

$$\boldsymbol{B}_{\mathrm{eff}}(\boldsymbol{x}) = \big(-\mathrm{Re}[\Omega_1(\boldsymbol{x})],\ \mathrm{Im}[\Omega_1(\boldsymbol{x})],\ \Delta \big) . \qquad (77.22)$$

As it stands, the Hamiltonian (77.21) describes the precession and center of mass motion of a fictitious spin in an external "magnetic field" $\boldsymbol{B}_{\mathrm{eff}}(\boldsymbol{x})$. Spatial variations of this field give rise to the Stern–Gerlach effect, i.e., the splitting of the atomic center of mass wave function (see also Sect. 77.5.3).

Adiabatic Approximation
In the position representation, the Hamiltonian (77.19) acts on state vectors of the form of a bispinor

$$\Psi(\boldsymbol{x}, t) = \begin{pmatrix} \psi_e(\boldsymbol{x}, t) \\ \psi_g(\boldsymbol{x}, t) \end{pmatrix} . \qquad (77.23)$$

Alternatively, this state vector may be expanded in terms of the local eigenvectors $\alpha_{\pm}(\boldsymbol{x}), \beta_{\pm}(\boldsymbol{x})$ of the interaction matrix, also called dressed states,

$$\Psi(\boldsymbol{x}, t) = \psi_+(\boldsymbol{x}, t) \begin{pmatrix} \alpha_+(\boldsymbol{x}) \\ \beta_+(\boldsymbol{x}) \end{pmatrix} + \psi_-(\boldsymbol{x}, t) \begin{pmatrix} \alpha_-(\boldsymbol{x}) \\ \beta_-(\boldsymbol{x}) \end{pmatrix} , \qquad (77.24)$$

where

$$\hat{\mathcal{U}}(\boldsymbol{x}) \begin{pmatrix} \alpha_{\pm}(\boldsymbol{x}) \\ \beta_{\pm}(\boldsymbol{x}) \end{pmatrix} = \pm \frac{\hbar\Omega(\boldsymbol{x})}{2} \begin{pmatrix} \alpha_{\pm}(\boldsymbol{x}) \\ \beta_{\pm}(\boldsymbol{x}) \end{pmatrix} , \qquad (77.25)$$

with eigenvalues determined by the dressed Rabi frequency

$$\Omega(\boldsymbol{x}) = \sqrt{|\Omega_1(\boldsymbol{x})|^2 + \Delta^2} , \qquad (77.26)$$

and coefficients (we suppress the $\boldsymbol{x}$-dependence for notational clarity)

$$\begin{pmatrix} \alpha_+ & \alpha_- \\ \beta_+ & \beta_- \end{pmatrix} = \begin{pmatrix} \cos\frac{\vartheta}{2} & -\mathrm{e}^{-\mathrm{i}\varphi}\sin\frac{\vartheta}{2} \\ \mathrm{e}^{\mathrm{i}\varphi}\sin\frac{\vartheta}{2} & \cos\frac{\vartheta}{2} \end{pmatrix} \equiv \hat{S} . \qquad (77.27)$$

Here, the Stückelberg angle $\vartheta \equiv \vartheta(\boldsymbol{x})$ and phase angle $\varphi \equiv \varphi(\boldsymbol{x})$ are defined in terms of the polar representation of the effective magnetic field

$$\boldsymbol{B}_{\mathrm{eff}} = \Omega \left(\cos\varphi \sin\vartheta,\ \sin\varphi \sin\vartheta,\ \cos\vartheta \right) . \qquad (77.28)$$

In the dressed state basis, the transformed Hamiltonian assumes the form

$$\tilde{H} \equiv \hat{S}^{\dagger} \hat{H} \hat{S} = \frac{\left[\hat{\boldsymbol{p}} - \hat{\mathcal{A}}(\hat{\boldsymbol{x}}) \right]^2}{2M} + \frac{\hbar}{2}\Omega(\hat{\boldsymbol{x}})\sigma_3 , \qquad (77.29)$$

with matrix-valued vector potential

$$\hat{\mathcal{A}}(\boldsymbol{x}) = i\hbar S^{\dagger}(\boldsymbol{x}) \left[\nabla S(\boldsymbol{x}) \right] . \tag{77.30}$$

This matrix is not diagonal; its off-diagonal elements describe nonadiabatic transitions between the dressed states. If the detuning is sufficiently large, and the atom moves sufficiently slowly, these nonadiabatic transitions may be neglected in a first approximation. In such an approximation, which is akin to the Born–Oppenheimer approximation in molecular physics, the dynamics of the atom is described by two decoupled Hamiltonians of the generic form (77.3), with scalar potentials $\mathcal{U}$ given by

$$\mathcal{U}(\boldsymbol{x}) = \pm \frac{\hbar}{2} \Omega(\boldsymbol{x}) \tag{77.31}$$

and vector potentials $\mathcal{A}(\boldsymbol{x})$ given by the diagonal elements of (77.30). The vector potential is usually neglected. If included, it describes the Berry phase of the mechanical effects of the radiation interaction of a two-level atom.

The idea behind the adiabatic approximation is that the internal state of the atom, which is described by any of the locally varying dressed states, has enough time to adjust smoothly to the motion of the atom. For the important case of strong detuning $|\Delta| \gg |\Omega_1(\boldsymbol{x})|$, this assumption is usually well justified. In this case, an atom in the dressed ground state experiences a potential which is approximately given by

$$\mathcal{U}(\boldsymbol{x}) = -\frac{\hbar |\Omega_1(\boldsymbol{x})|^2}{4\Delta} . \tag{77.32}$$

For red detuning we have $\Delta > 0$, in which case the atom is attracted towards regions of high intensity (high field seeker). For blue detuning, the atom is repelled from such regions (low field seeker). A potential similar to (77.32) also applies for complex particles like molecules whose transitions are far detuned from the light frequency. The potential is proportional to the dynamic polarizability $\alpha(\omega)$ and the field intensity.

Atom Optical Nonlinearity

In very dense atom ensembles at low temperatures, collisions between particles can be described by a contact interaction whose strength depends, in the simplest case, on a single parameter, the s-wave scattering length a (Sect. 75.5.1). In the mean field approximation, these interactions translate into a density-dependent potential

$$\mathcal{U}(\boldsymbol{x}) = \frac{4\pi \hbar^2 a(N-1)}{M} |\psi(\boldsymbol{x})|^2 , \tag{77.33}$$

where N is the number of particles. This nonlinearity leads to the occurrence of atom solitons [77.13], four-wave mixing [77.11], and parametric amplification [77.12].

77.3 Principles of de Broglie Optics

Since the Schrödinger equation is a linear partial differential equation, de Broglie optics shares most of its principles with principles of other wave phenomena, and in particular with the optical principles of electromagnetic waves.

77.3.1 Light Optics Analogy

The analogy of de Broglie optics and light optics becomes particularly transparent for monoenergetic beams of scalar particles. Such beams are described by a time harmonic wave function $\psi(\boldsymbol{x}, t) = e^{-iEt/\hbar} \psi_{\text{E}}(\boldsymbol{x})$, where $\psi_{\text{E}}(\boldsymbol{x})$ obeys the stationary Schrödinger equation

$$H\psi_{\text{E}} = E\psi_{\text{E}} . \tag{77.34}$$

Setting $\mathcal{A}(\boldsymbol{x}) = 0$ in (77.3) for simplicity, this equation assumes the form

$$\left[\nabla^2 + \tilde{k}_0^2 \left(1 - \frac{\mathcal{U}(\boldsymbol{x})}{E} \right) \right] \psi_{\text{E}}(\boldsymbol{x}) = 0 , \tag{77.35}$$

where the wavenumber $\tilde{k}_0$ is related to the energy E via the dispersion relation

$$E \equiv \frac{\hbar^2 \tilde{k}_0^2}{2M} . \tag{77.36}$$

If $\mathcal{U} = 0$ at the entrance to the interaction region, E is the kinetic energy of the freely traveling de Broglie wave and $\tilde{k}_0$ is the related wavenumber.

Comparing (77.35) with the scalar Helmholtz equation of electromagnetic theory, and identifying

$$\tilde{n}_{\text{E}}(\boldsymbol{x}) \equiv \left[1 - \mathcal{U}(\boldsymbol{x})/E \right]^{1/2} \tag{77.37}$$

as an index of refraction for matter waves, one observes the complete analogy of scalar optics of stationary matter waves and monochromatic light waves. This analogy can be generalized for spinor valued wave functions which would correspond to vector wave optics in anisotropic index media. However, in contrast to light, spinor-valued wave functions do not obey a transversality condition.

In (77.35–77.37), the parameter E describes the kinetic energy of the incoming beam. Thus, E is positive, and therefore $\tilde{n}_E < 1$ for positive values of the potential, while $\tilde{n}_E > 1$ for negative values of the potential. For neutrons, one generally has $\tilde{n}_E < 1$. This contrasts to the index of refraction for light waves which is generally larger than one. For electrons, ions, and atoms both $\tilde{n}_E < 1$ and $\tilde{n}_E > 1$ may be realized.

77.3.2 WKB Approximation

Waves are described by amplitude and phase. Particles are described by position and momentum. The link between these concepts is provided by Hamilton's ray optics. For scalar matter waves, a ray follows a classical trajectory. The optical signature of the ray is the phase associated with it. The quantum mechanical version of Hamilton's ray optics is obtained in the WKB approximation of the stationary Schrödinger equation (77.34).

Any solution of (77.34) may be written in the form

$$\psi_E(\boldsymbol{x}) = A(\boldsymbol{x})\,e^{iW(\boldsymbol{x})} \tag{77.38}$$

with real-valued $A(\boldsymbol{x})$ and $W(\boldsymbol{x})$. In the WKB approximation $A(\boldsymbol{x}) \approx 1$, and

$$W(\boldsymbol{x}) = \tilde{k}_0 \int_{P_i}^{P} \tilde{n}_E(s)\,\mathrm{d}s + \hbar^{-1} \int_{\boldsymbol{x}_i}^{\boldsymbol{x}} \boldsymbol{\mathcal{A}}(\boldsymbol{x}') \cdot \mathrm{d}\boldsymbol{x}' , \tag{77.39}$$

which is called eikonal in Hamilton's ray-optics. In this expression, $\tilde{n}_E(s) \equiv \tilde{n}_E(\boldsymbol{x}(s))$, where $\boldsymbol{x}(s)$ denotes the classical trajectory of energy E connecting the point P_i with the point P, $\boldsymbol{x}_i$ and $\boldsymbol{x}$ are the coordinates of P_i and P, respectively, and $\mathrm{d}s \equiv |\mathrm{d}\boldsymbol{x}|$ is the element of arc length measured along the classical trajectory. Note that the second contribution in (77.39) is generally gauge-dependent. However, for closed loops which are frequently encountered in interferometry, the gauge-dependence disappears by virtue of Stokes theorem which transforms the path integral into an area integral over the rotor of $\boldsymbol{\mathcal{A}}$.

The eikonal (77.39) may also be written in the form of a reduced action

$$W(\boldsymbol{x}) = \frac{1}{\hbar} \int_{\boldsymbol{x}_i}^{\boldsymbol{x}} \boldsymbol{p}(\boldsymbol{x}') \cdot \mathrm{d}\boldsymbol{x}' = \int_{\boldsymbol{x}_i}^{\boldsymbol{x}} \tilde{\boldsymbol{k}}(\boldsymbol{x}') \cdot \mathrm{d}\boldsymbol{x}' , \tag{77.40}$$

where $\boldsymbol{p}(\boldsymbol{x})$ is the local value of the canonical momentum of the particle, $\tilde{\boldsymbol{k}}(\boldsymbol{x}) \equiv \boldsymbol{p}(\boldsymbol{x})/\hbar$ is the corresponding wave vector, and the integral is evaluated along the classical trajectory of the particle. Note that in the presence of a vector potential, $\boldsymbol{p}(\boldsymbol{x})$ and $d\boldsymbol{x}$ are no longer parallel as a result of the difference between canonical momentum $\boldsymbol{p}$ and kinetic momentum $M(\mathrm{d}/\mathrm{d}t)\,\boldsymbol{x} \equiv \boldsymbol{p} - \boldsymbol{\mathcal{A}}$.

The WKB approximation becomes invalid in the vicinity of caustics where neighboring rays intersect. There, connection formulae are used to find the proper phase factors picked up by the ray in traversing the caustics. Depending on the topology of the intersecting rays, different classes of diffraction integrals provide uniform approximations for the wave amplitude near caustics. For further details see [77.14] and [77.15].

77.3.3 Phase and Group Velocity

The velocity of a particle which traverses a region of negative potential increases so that $p(\boldsymbol{x}) > p_0$, and the phase advances: $\delta W = \int [\boldsymbol{p}(\boldsymbol{x}) - \boldsymbol{p}_0] \cdot \mathrm{d}\boldsymbol{x} > 0$. In quantum mechanics, the classical velocity corresponds to the group velocity, while the evolution of the phase is determined by the phase velocity. The phase and group velocities of de Broglie waves are given by

$$v_p(\boldsymbol{x}) \equiv \frac{E}{p(\boldsymbol{x})} = \frac{1}{\tilde{n}_E(\boldsymbol{x})}\sqrt{\frac{E}{2M}} , \tag{77.41}$$

$$v_g(\boldsymbol{x}) \equiv \frac{\partial E}{\partial p(\boldsymbol{x})} = \tilde{n}_E(\boldsymbol{x})\sqrt{\frac{2E}{M}} , \tag{77.42}$$

respectively. Note that the product $v_p v_g = E/M$ is independent of $\tilde{n}_E(\boldsymbol{x})$.

77.3.4 Paraxial Approximation

The paraxial approximation is useful in describing the evolution of wave-like properties and/or distortion of wavefronts in the immediate neighborhood of an optical ray.

Let the z-axis be the central optical axis of symmetry along which the optical elements are aligned. Using the Ansatz $\psi_E(\boldsymbol{x}) = e^{ik_0 z}\phi(x, y; z)$, and dropping $\partial^2\phi/\partial z^2$ in a slowly varying envelope approximation, one obtains

$$i\hbar v_0 \frac{\partial}{\partial z}\phi(x, y; z)$$
$$= \left[-\frac{\hbar^2}{2M}\nabla_\perp^2 + \mathcal{U}(x, y; z) \right]\phi(x, y; z) , \tag{77.43}$$

where $\nabla_\perp^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2$, and $v_0 = \hbar\tilde{k}_0/M$ is the longitudinal velocity of incoming particles. This equation has exactly the form of a time-dependent

Schrödinger equation in two dimensions, with z/v_0 playing the role of a fictitious time t. With this interpretation, the spatial evolution of phase fronts along z can be analyzed in dynamical terms of particles moving in the xy-plane.

77.3.5 Raman–Nath Approximation

In the Raman–Nath approximation (RNA) (also called the short-time, thin-hologram, or thin-lens approximation), the $\nabla_\perp^2$ term in (77.43) is neglected. The potential $\mathcal{U}(x, y; z)$ then acts as a pure phase structure, and the

solution of (77.43) becomes

$$
\phi(x, y; z) = \\
\exp\left[-\frac{i}{\hbar v_0} \int_{z_i}^{z} dz' \mathcal{U}(x, y; z')\right] \phi(x, y; z_i).
$$

(77.44)

In terms of a classical particle moving under the influence of $\mathcal{U}$, the approximation loses validity for $\frac{1}{2}Mv_\perp^2 \gtrsim \mathcal{U}$, which is just a quarter cycle for a harmonic oscillator.

77.4 Refraction and Reflection

Consider a particle beam of energy E incident on a medium with constant index of refraction $\tilde{n}_E$. The boundary plane at $z = 0$ in Fig. 77.1 divides the vacuum from the medium. At the boundary, the beam is partially reflected and partially transmitted, with the angles determined by Snell's law of refraction

$$
\sin \alpha = \tilde{n}_E \sin \beta ,
$$

(77.45)

and the law of reflection

$$
\alpha = \alpha' .
$$

(77.46)

The coefficients of reflectivity $\tilde{R}$, and transmittivity $\tilde{T} = 1 - \tilde{R}$ are given by the Fresnel formula

$$
\tilde{R} = \left|\frac{\cos \alpha - \tilde{n}_E \cos \beta}{\cos \alpha + \tilde{n}_E \cos \beta}\right|^2 .
$$

(77.47)

For $\tilde{n}_E > 1$, the interface is "attractive" and $\tilde{R} \ll 1$, with $\tilde{R} \to 1$ only for glancing incidence $\alpha \to \pi/2$. For $\tilde{n}_E < 1$, the interface is "repulsive" and total reflection

$(\tilde{R} = 1)$ occurs for $\alpha \geq \tilde{\alpha}_c$, where $\tilde{\alpha}_c = \sin^{-1} \tilde{n}_E$ is the critical angle. For $\alpha > \tilde{\alpha}_c$, the de Broglie wave becomes evanescent, with $\psi_E(z > 0) \sim e^{-\tilde{\kappa}z}$ inside the medium $(z > 0)$, where

$$
\tilde{\kappa} = \tilde{k}_0 \left(\sin^2 \alpha - \sin^2 \tilde{\alpha}_c\right)^{1/2} .
$$

(77.48)

For thermal neutrons, $\pi/2 - \tilde{\alpha}_c \sim 3 \times 10^{-3}$ radians.

If $E < \mathcal{U}$, then $\tilde{n}_E$ is imaginary and total reflection occurs for all α. In neutron optics, this total mirror reflection requires ultracold neutrons ($T \approx 0.5$ mK). It has important applications for storage of ultracold neutrons in material cavities, and neutron microscopy using spherical mirrors. For details see [77.2].

77.4.1 Atomic Mirrors

Inelastic processes, such as diffuse scattering and absorption, inhibit coherent reflection of atoms from bare surfaces. The surface must therefore be coated either with material of low adsorptivity (noble gas, see [77.16]) or electromagnetic fields (evanescent light or magnetic fields, see below).

Reflection of Atoms by Evanescent Laser Light
Evanescent light fields are produced by total internal reflection of a light beam at a dielectric–vacuum interface [77.17]. In the vacuum, the field decays exponentially away from the interface on a characteristic length κ^{-1} where

$$
\kappa = k \left(n^2 \sin^2 \theta_i - 1\right)^{1/2} .
$$

(77.49)

Here, n is the light index of refraction of the dielectric, k is the wave number of the light beam in vacuo, and θ_i is its angle of incidence.

Fig. 77.1 Reflection geometry

If the light is blue-detuned from the atomic resonance, an incident beam of ground state atoms experiences the repulsive potential

$$\mathcal{U}(\boldsymbol{x}) = \frac{\hbar}{2}\left[\left(\Omega_0{}^2 e^{-2\kappa|z|} + \Delta^2\right)^{1/2} - |\Delta|\right] .$$

(77.50)

For $\alpha > \tilde{\alpha}_c$, the evanescent field acts as a nearly perfect mirror, the imperfections being due to nonadiabatic transitions into the "wrong" dressed state, and possible spontaneous emission. Reflection of atoms by evanescent laser light was demonstrated by *Balykin* et al. [77.18] at grazing incidence and by *Kasevich* et al. [77.19] at normal incidence.

Reflection of Atoms by Magnetic Near Fields

Magnetic near fields are produced above substrates with a spatially modulated permanent magnetization or close to arrays of stationary currents. In the vacuum above the substrate, the field decays approximately exponentially over a length comparable to the scale of the magnetic modulation. The motion of atoms that cross such inhomogeneous magnetic fields sufficiently slowly is governed by the analog of the adiabatic potential described in Sect. 77.2.5:

$$\mathcal{U}(\boldsymbol{x}) = -\mu\big(m_s/s\big)\big|\boldsymbol{B}(\boldsymbol{x})\big| ,$$

(77.51)

where μ is the magnetic moment and m_s is the (conserved) projection of the atomic spin s onto the local magnetic field direction. A repulsive mirror potential is achieved for spin states with $\mu m_s < 0$; these weak field seekers are repelled from the strong fields close to the substrate.

Experiments have used magnetic recording media like magnetic tapes or hard disks [77.20], arrays of current-carrying wires [77.21], or amorphous magnetic substrates [77.22].

77.4.2 Atomic Cavities

Atomic reflections are used in the two kinds of cavities proposed so far: the trampoline cavity and the Fabry–Perot resonator.

The trampoline cavity, also called the gravito-optical cavity, consists of a single evanescent mirror facing upwards, the second mirror being provided by gravitation. A stable cavity is realized with the evanescent laser field of a parabolically shaped dielectric–vacuum interface, see [77.23] and the experiment by *Aminoff* et al. [77.24]. A cavity with transverse confinement provided by a hol-

low blue-detuned laser beam has been demonstrated by *Hammes* et al. [77.25].

In the atomic Fabry–Perot resonator both mirrors are realized by laser light [77.26].

77.4.3 Atomic Lenses

De Broglie waves may be focused by refraction from a parabolic potential or by diffraction, e.g., by a Fresnel zone plate (Sect. 77.5.2). Consider focusing by the parabolic potential

$$\mathcal{U}(x, y; z) = \left\{\begin{pmatrix}\frac{1}{2}M\omega_f^2(x^2+y^2) & , & -w \le z \le 0 \\ 0 & , & \text{otherwise .}\end{pmatrix}\right.$$

(77.52)

For ground state atoms, such a potential is realized in the vicinity of the node of a blue detuned standing wave laser field of transverse width w. In this case

$$\omega_f = \Omega_0\big(\omega_{\text{rec}}/|\Delta|\big)^{1/2} ,$$

(77.53)

where $\omega_{\text{rec}} = \hbar k^2/2M$ is the recoil frequency.

Comparison with the Raman–Nath approximation (77.44) at $z = 0$, with the phase fronts of a spherical wave converging towards a point $\boldsymbol{x}_f = (0, 0, f)$, shows that $\mathcal{U}$ describes a lens of focal length

$$f = \frac{v_0^2}{w\omega_f^2} .$$

(77.54)

The Raman–Nath approximation is only valid for a thin lens $w \ll f$, and breaks down for $w > w_{\text{RN}} = \pi v_0/2\omega_f$. In the latter case, oscillations of the particles in the harmonic potential become relevant, a phenomenon sometimes called channeling. Channeling may be used to realize thick lenses with focal length $f = w_{\text{RN}}$ corresponding to a quarter oscillation period.

Focusing of a metastable helium beam using the anti-node of a large period standing wave laser field has been demonstrated [77.27]. Such a field is produced by reflecting a laser beam from a mirror under glancing incidence. The standing wave forms normal to the mirror surface. Similar interference patterns provide arrays of thick lenses that have been exploited in atom lithography to focus an atomic beam onto a substrate [77.28].

77.4.4 Atomic Waveguides

Atomic waveguides can be realized with potentials that confine atoms in one or two dimensions [77.29–31]. These devices are key elements for integrated atom

optics, a field that has seen a rapid evolution recently [77.32, 33]. A planar waveguide is provided by the one-dimensional confinement in an optical standing wave [77.34] or an atomic mirror combined with gravity [77.31]. The discrete nature of the waveguide modes in that case could be demonstrated by lowering the amplitude of the confining potential. Linear waveguides can be modeled by the parabolic transverse potential (77.52) that now extends along the waveguide axis (the z-axis). Physical realizations include hollow, blue-detuned laser beams [77.30], hollow fibers whose inner wall is coated with blue-detuned evanescent light [77.35], elongated foci of red-detuned light created by cylindrical lenses [77.36], and magnetic field minima along current-carrying wires, possibly combined with homogeneous bias fields [77.37]. With typical thermal atomic ensembles, these waveguides operate in a multimode regime, and coherent operation has been demonstrated only with Bose–Einstein condensates. A strong transverse confinement that facilitates monomode operation, can be achieved with miniaturized wire networks deposited on a solid substrate [77.38, 39]. This approach may lead to the fabrication of atom chips [77.33]. Even multimode waveguides, however, can yield robust atomic interferometers, as suggested theoretically in [77.40] and [77.41].

77.5 Diffraction

The diffraction of matter waves is described by the solution of the Schrödinger equation (77.34) subject to the boundary conditions imposed by the diffracting object. For a plane screen Σ made of opaque portions and apertures, the solution in the source-free region behind the screen is given by the Rayleigh–Sommerfeld formulation of the Huygens principle

$$\psi_E(\boldsymbol{x}) = \frac{\tilde{k}_0}{i} \int\limits_{\Sigma} \frac{d\xi\, d\eta}{2\pi} \frac{e^{i\tilde{k}_0 R}}{R}$$
$$\times \left(1 + \frac{i}{\tilde{k}_0 R}\right) \frac{\boldsymbol{n}\cdot\boldsymbol{R}}{R} \psi(\xi)\,, \qquad (77.55)$$

where $\xi = (\xi, \eta, \zeta)$ denotes coordinates of points on Σ, $\boldsymbol{n}$ is an inwardly directed normal to Σ at a point $\boldsymbol{\xi}$, and $\boldsymbol{R} = \boldsymbol{x} - \boldsymbol{\xi}$.

A diffraction pattern only becomes manifest in the diffraction limit $r \gg d$, where r is the distance to the observation point, and d is the length scale of the diffracting system. The two diffraction regimes are then the Fraunhofer limit $r \gg d^2/\lambda_{dB}$ and the Fresnel regime $r \approx d^2/\lambda_{dB}$, also called near-field optics.

77.5.1 Fraunhofer Diffraction

In the Fraunhofer limit, the field at position (x, y) on a screen at a distance L downstream from the diffracting object is given by

$$\psi(x, y; L) = \tilde{k}_0 \frac{e^{ik_0 L}}{iL} \int \frac{d\xi\, d\eta}{2\pi}$$
$$\times e^{-i(\tilde{k}_x \xi + \tilde{k}_y \eta)} \psi(\xi, \eta; 0)\,, \qquad (77.56)$$

where $\tilde{k}_x = \tilde{k}_0 x/L$, $\tilde{k}_y = \tilde{k}_0 y/L$. The field at the observation screen is thus given by the Fourier transform of the field in the object plane; i. e. the momentum representation of the diffracted state. Since most diffraction experiments in atom optics are performed in the Fraunhofer limit, most calculations are done in the momentum representation.

Atomic diffractions from microfabricated transmission gratings [77.42] and double slits [77.43] have been observed. Recent experiments have extended de Broglie wave diffraction to heavier, complex particles like fullerence molecules (C_{60}) [77.44].

77.5.2 Fresnel Diffraction

Typical applications of Fresnel diffraction are Fresnel zone plates and the effects of Talbot and Lau. Fresnel zone plates are microfabricated concentric amplitude structures which act like lenses. They are frequently employed in optics of α-particles and neutrons. In atom optics, focusing with a Fresnel zone plate was first demonstrated by *Carnal* et al. [77.45].

The Talbot effect and the related Lau effect refer to the self-imaging of a grating of period d, which appears downstream at distances that are integral multiples of the Talbot length $L = 2d^2/\lambda_{dB}$. For a discrete set of smaller distances than the Talbot length, images of the grating appear with smaller periods d/n, $n = 2, 3 \cdots$. For applications in matter wave interferometry, [77.46]; for applications in atom lithography see [77.47].

77.5.3 Near–Resonant Kapitza–Dirac Effect

The near resonant Kapitza–Dirac effect refers to the diffraction of two-level atoms from a standing wave laser

field with a spatially uniform polarization. The dynamics of the effect is described by the Hamiltonian (77.19) with the mode function of the laser field given by (77.16). Consider atoms traveling predominantly in the z-direction, i.e., orthogonal to the axis of the laser field, with energy $\frac{1}{2}Mv_0^2 \gg \hbar\Omega_0$ (Fig. 77.2). Kapitza–Dirac diffraction is then observed in transmission, which in the theory of diffraction is called Laue geometry. In the paraxial approximation (Sect. 77.3.4) for motion in the z-direction, and assuming that the laser profile is homogeneous in the y-direction, the description reduces to an effectively one-dimensional model for the quantum mechanical motion along the x-axis of the laser field.

Due to the periodicity of the standing wave light field, the transverse momenta of the transmitted atom waves differ by multiples of $\hbar k$ from the transverse momentum of the undiffracted wave. For the important case of strong detuning, and assuming that the incoming atoms are in their electronic ground state moving with transverse momentum $p_x = 0$, the p_x-distribution of the outgoing wave is given in the Raman–Nath approximation (Sect. 77.3.5) by

$$\text{Prob}(p_x = 2n\hbar k) \propto \left| J_n \left(\frac{\Omega_0^2}{8|\Delta|} \tau \right) \right|^2 , \qquad (77.57)$$

where J_n is a Bessel function of order n, $\tau = w/v_0$ is an effective interaction time, w being the width of the laser field, and v_0 the longitudinal velocity of the atoms. The distribution (77.57) was observed by *Gould* et al. [77.48].

For $\tau \gtrsim \tau_{\text{RN}}$, where $\tau_{\text{RN}} = \left(\omega_{\text{rec}}\Omega_0^2/|\Delta|\right)^{-1/2}$, the Raman–Nath approximation becomes invalid. As a result of Doppler related phase-mismatch, the momentum spread saturates and shows a sequence of collapse and revival as a function of τ [77.49].

If the detuning is too small to allow for a scalar description, the two-level character of the atoms must be taken into account. For the particular case of $\Delta = 0$, the ground state evolves into an equal superposition of the two diabatic states $1/\sqrt{2}\left(|e\rangle \pm |g\rangle\right)$ while entering the interaction region. Inside the interaction region, these states experience potentials which differ only by their sign. For atomic beams with a small spatial spread $\delta x \ll 2\pi/k$, the diabatic states experience opposite forces, leading to a splitting of the atomic beam called the atom-optical Stern–Gerlach effect [77.50].

In the general case of arbitrary Δ, the Kapitza–Dirac Hamiltonian (77.21) is most conveniently analyzed using band theoretical methods of solid state theory [77.51].
Fig. 77.2 Geometry of the Kapitza–Dirac effect

77.5.4 Atom Beam Splitters

Beam splitters are optical devices which divide an incoming beam into two outgoing beams traveling in different directions. For thermal neutrons, beam splitters may be realized by diffraction from perfect crystals in Laue geometry. For atoms, they can be realized using diffraction from crystalline surfaces, microfabricated structures (see Sect. 77.5.1), or by using diffraction from an optical standing wave.

The Kapitza–Dirac effect, for example, may be exploited to split an atomic beam coherently using Bragg reflection at the "lattice planes" provided by the periodic intensity variations of a standing wave laser field [77.52]. This process is resonant for an incoming atomic beam traveling with transverse momentum $p_x = \hbar k$ because it is energetically degenerate with the diffracted beam traveling with transverse momentum $\bar{p}_x = -\hbar k$. This level degeneracy is lifted while the atoms enter the interaction region. In the Bragg regime, the lifting happens slowly enough that only the momentum states $|\pm \hbar k\rangle$ participate in the diffraction (two-beam resonance), and their populations show Pendellösung type oscillations as a function of the transit time. The frequency of the oscillations is given by $\delta E/\hbar$, where δE is the energy splitting of the two beams inside the interaction region. For a transit time given by a quarter period of the Pendellösung, a 50% beam splitting is observed [77.52]. In principle, Bragg resonances may also be realized for higher diffraction order $p_x = n\hbar k \leftrightarrow \bar{p}_x = -n\hbar k$. However, in this case, intermediate momentum states become populated (multibeam resonance), which makes the higher-order Bragg resonances less suitable for beam splitting purposes.

More promising for the realization of an atomic beam splitter is the magneto-optical diffraction which refers to the diffraction of three-level atoms from a laser field with a periodic polarization gradient (lin ⊥ lin configuration) (Chapt. 75), and a magnetic field aligned parallel to the optical axis of the laser field. This configuration realizes an interaction potential in the form of a blazed grating, i.e., a phase grating with an approximately triangular variation of phase. In an experiment by *Pfau* et al. [77.53], transverse split-ting of a beam of metastable helium by $42\hbar k$ was observed [77.49].

Diffraction from an evanescent standing wave involves Bragg reflection of atoms under glancing incidence from the periodic grating of a blue detuned evanescent standing wave laser field [77.54–56]. Diffraction at normal incidence has been demonstrated with sufficiently slow atoms and can be described by a generalization of the RNA (Sect. 77.3.5) [77.57, 58].

77.6 Interference

While the overall phase of a wave function ψ is not observable, interferometry makes detectable the relative phases of two components ψ_1, ψ_2 in a superposition $\psi = \psi_1 + \psi_2$. Two types of interferometers are most common: the Young double slit as a paradigm for interferometers based on division of wavefront, and the Mach–Zehnder interferometer as a paradigm for interferometers based on division of amplitude. In de Broglie optics, the latter type is realized in the form of a three-grating interferometer, since division of amplitude is achieved by diffraction at gratings rather than by semitransparent mirrors. Experiments with this geometry have been reported for atoms [77.59] and recently for more massive, complex molecules (fullerenes) [77.60].

77.6.1 Interference Phase Shift

From a fundamental point of view, any interferometer is a ring. At the entrance port of a three-grating interferometer displayed in Fig. 77.3, for example, the wave function is split into two coherent parts which spatially evolve along different paths and subsequently come together at the exit port where they are superimposed to produce two outgoing waves

$$\psi_\pm = \frac{1}{\sqrt{2}} \left(\psi_1 \pm \psi_2 \right) , \tag{77.58}$$

where the components from path 1 and 2 are given by

$$\psi_1 = A_1 \exp \left(iW_1 \right) ,$$
$$\psi_2 = A_2 \exp \left(iW_2 \right) . \tag{77.59}$$

For simplicity, assume $A_1 = A_2 = A_0 / \sqrt{2}$. The relative flux of the outgoing waves is then

$$I_\pm = \frac{1}{2} \left(1 \pm \cos \chi \right) , \tag{77.60}$$

where $\chi = W_1 - W_2$ is the relative phase of the two components. The sinusoidal variations of $I_\pm$ with varying χ are called interference fringes, and $\chi/2\pi$ is called the fringe order number.

In the WKB approximation, the phases W_1 and W_2 are given by

$$W_i = W_0 + \int_i \tilde{\boldsymbol{k}}(\boldsymbol{x}) \cdot \mathrm{d}\boldsymbol{x}, \quad i = 1, 2 , \tag{77.61}$$

where the integrals extend over the classical paths 1 and 2, respectively, and $\mathrm{d}\boldsymbol{x}$ is an element of displacement along the paths. Using (77.61), the relative phase is

$$\chi = \int_C \tilde{\boldsymbol{k}}(\boldsymbol{x}) \cdot \mathrm{d}\boldsymbol{x} , \tag{77.62}$$

where C is the closed interferometer loop. Note, that on path 2, the path element $\mathrm{d}\boldsymbol{x}$ and $\tilde{\boldsymbol{k}}$ are antiparallel.

Usually, the absolute value of χ is not measured, but only variations, called phase shifts, which result from displacements of the diffraction gratings or placement of optical elements into the beam path. Phase shifts
Fig. 77.3 Geometry of the three-grating interferometer

come in two categories: dispersive and geometric. If a phase shift χ depends on v_0, it is called dispersive, otherwise it is called geometric. Geometric phases depend only on the geometry of the interferometer loop. The Sagnac effect (see below), for example, may be geometric. A phase which depends neither on v_0 nor on the geometry of the interferometer loop is called topological. The Aharonov–Bohm effect (see below) is topological.

Using (77.39), χ becomes

$$\chi = \chi_0 + \chi\{\mathcal{U}\} + \chi\{\mathcal{A}\} , \tag{77.63}$$

where for weak potentials $\mathcal{U}$ and $\mathcal{A}$,

$$\chi_0 = \frac{Mv_0}{\hbar} (L_1 - L_2) , \tag{77.64}$$

$$\chi\{\mathcal{U}\} = -\frac{1}{\hbar v_0} \oint \mathcal{U}[\boldsymbol{x}(s)]\,\mathrm{d}s , \tag{77.65}$$

$$\chi\{\mathcal{A}\} = \frac{1}{\hbar} \oint \mathcal{A}(\boldsymbol{x}) \cdot \mathrm{d}\boldsymbol{x} , \tag{77.66}$$

and L_i is the geometric length of the path i. For a constant potential $\mathcal{U}_0$ intersecting the interferometer on a length w, $\chi\{\mathcal{U}\}$ is given by

$$\chi\{\mathcal{U}\} = -\frac{\mathcal{U}_0 w}{\hbar v_0} . \tag{77.67}$$

Using Stokes theorem, $\chi\{\mathcal{A}\}$ may be written in the manifestly gauge-invariant form

$$\chi\{\mathcal{A}\} = \frac{1}{\hbar} \int [\nabla \times \mathcal{A}(\boldsymbol{x})] \cdot \mathrm{d}\boldsymbol{a} , \tag{77.68}$$

where the integral extends over the area enclosed by the interferometer, and $\mathrm{d}\boldsymbol{a}$ is an infinitesimal area element.

Dispersive Phase Shifts. Atom interferometers have been able to measure phase shifts of the form (77.65) due to, for example, the atomic level shift in an electric field (Stark effect) [77.59] or to coherent forward scattering by background gas atoms, see (77.10) and [77.61].

Sagnac Effect. The Sagnac effect refers to $\chi\{\mathcal{A}\}$ in a rotating interferometer. Inserting (77.6) into (77.68), and assuming that the axis of rotation is oriented perpendicular to the plane of the interferometer, the Sagnac phase shift is given by

$$\chi_{\mathrm{Sa}} = 4M\Omega A/\hbar , \tag{77.69}$$

where A is the geometric area enclosed by the interferometer loop. χ_{Sa} may be dispersive or geometric depending on the type of interferometer. In a Young double slit, A is independent of energy and χ_{Sa} is geometric. In a three-grating interferometer, the area is $A \approx \vartheta D^2$, where ϑ is the splitting angle; see Fig. 77.3. In this case, χ_{Sa} is dispersive because of the velocity dependence of $\vartheta \approx 2\hbar k/Mv_0$. The Sagnac effect for de Broglie waves was first observed by *Werner* et al. [77.62] using a neutron interferometer.

Aharonov–Bohm Effect. The Aharonov–Bohm effect refers to the $\chi\{\mathcal{A}\}$ of charged particles encircling a magnetic flux line [77.63]. Inserting $\mathcal{A}$ from (77.7) into (77.68), and assuming particles of charge q encircling a line of flux Φ once, one finds

$$\chi_{\mathrm{AB}} = q\Phi/\hbar . \tag{77.70}$$

A characteristic feature of the Aharonov–Bohm effect is that the particles actually never "see" the magnetic field of the flux line which is confined to some region inaccessible to the particles. χ_{AB} is strictly topological, and only depends on the linking number of the interferometer loop and the flux line. Its appearance is characteristic for all gauge theories. For further details and a summary on its experimental verification see [77.5].

Aharonov–Casher Effect. The Aharonov–Casher effect refers to $\chi\{\mathcal{A}\}$ of a magnetic spin encircling an electric line charge [77.64]. Inserting $\mathcal{A}$ from (77.11) into (77.68), one obtains for proper alignment of $\boldsymbol{\mu}$ and $\boldsymbol{E}$

$$\chi_{\mathrm{AC}} = 2\pi \frac{|\boldsymbol{\mu}|}{\mu_{\mathrm{B}}} \frac{r_0}{\xi} , \tag{77.71}$$

where r_0 is the classical electron radius, μ_{B} is the Bohr magneton, and $\xi = e/\rho_{\mathrm{el}}$, ρ_{el} being the electric line charge density. χ_{AC} is topological only if the spin is aligned parallel to the electric line charge and both are oriented perpendicular to the plane of the interferometer. χ_{AC} for atoms has been observed by *Sangster* et al. [77.65].

Electric Dipole Phase. Electric dipole phase refers to the $\chi\{\mathcal{A}\}$ of an electric dipole moment encircling a magnetic line charge [77.66]. Inserting $\mathcal{A}$ from (77.14) into (77.68), one obtains for proper alignment of $\boldsymbol{d}$ and $\boldsymbol{B}$

$$\chi_{\mathrm{dE}} = 2\pi \frac{|\boldsymbol{d}|}{ea_0} \frac{a_0}{\xi} , \tag{77.72}$$

where a_0 is the Bohr radius, and $\xi = \Phi_0/\varrho_{\mathrm{mg}}$, Φ_0 being the magnetic flux unit, and ϱ_{mg} being the magnetic line charge density. In analogy to the Aharonov–Casher

effect, χ_{dE} is topological, provided that $\boldsymbol{d}$ is aligned parallel to the magnetic line charge, and both are oriented perpendicular to the interferometer plane.

77.6.2 Internal State Interferometry

Manipulation of the internal state of atoms by means of electromagnetic fields makes it possible to realize interferometric setups which involve separation of paths in internal space rather than in real space. Examples of such interferometers are the Optical Ramsey interferometer [77.67], the stimulated Raman interferometer [77.68], and the interferometers using static electric and magnetic fields [77.69, 70].

77.6.3 Manipulation of Cavity Fields by Atom Interferometry

The entanglement of atomic states and quantized field states opens novel possibilities for manipulating and/or measuring nonclassical field states in a cavity. In the adiabatic limit, for example, and assuming sufficient detuning between the atom and the cavity field, the interaction and c.m. motion of an atom traversing a cavity is well described by the potential (77.32)

$$\mathcal{U}(\boldsymbol{x}) = -\hbar \frac{g^2}{\Delta} f(\boldsymbol{x})^2 a^\dagger a , \qquad (77.73)$$

where g is the vacuum Rabi frequency, $f(\boldsymbol{x})$ is a cavity mode function, and a, $a^\dagger$ denote cavity photon annihilation and creation operators, respectively.

Because of the presence of the photon-number operator $a^\dagger a$ in (77.73), the deflection and phase shift of an atom traversing the cavity is quantized, displaying essentially the photon number statistics in the cavity. The quantized deflection is sometimes called the inverse Stern–Gerlach effect.

Due to the entanglement of atom and cavity states, and the position dependence of the interaction strength, the phase shift induced by $\mathcal{U}(\boldsymbol{x})$ in a standing wave cavity may be used to measure either the atomic position via homodyne detection of the cavity field [77.71, 72], or the photon statistics via atom interferometry [77.73, 74]. In a ring cavity, the entanglement of c.m. motion and cavity field may be used to measure the atomic momentum [77.75] via homodyne detection of the cavity field. For further details see [77.76] and Chapt. 78.

77.7 Coherence of Scalar Matter Waves

The general solution of the free Schrödinger equation (77.2) may be written in the form

$$\psi(\boldsymbol{x}, t) = \int d^3\tilde{\boldsymbol{k}} \, a(\tilde{\boldsymbol{k}}) \, e^{i(\tilde{\boldsymbol{k}} \cdot \boldsymbol{x} - \omega(\tilde{\boldsymbol{k}})t)} , \qquad (77.74)$$

where $\omega(\tilde{\boldsymbol{k}}) \equiv E/\hbar = \hbar \tilde{\boldsymbol{k}}^2 / 2M$. If the coefficients $a(\tilde{\boldsymbol{k}})$ are known, the state represented by $\psi(\boldsymbol{x}, t)$ is called a pure state. Otherwise it is called a mixed state, and physical quantities are obtained by an ensemble average over the possible realizations of $a(\tilde{\boldsymbol{k}})$.

The degree of coherence of matter waves is described by the autocorrelation function of $\Psi(\boldsymbol{x}, t)$:

$$\Gamma(\boldsymbol{x}, t; \boldsymbol{x}', t') \equiv \overline{\Psi(\boldsymbol{x}', t')^* \Psi(\boldsymbol{x}, t)} , \qquad (77.75)$$

where the overline $\overline{(\cdots)}$ denotes the ensemble average over the possible realizations of $a(\tilde{\boldsymbol{k}})$. In light optics, $\Gamma(\boldsymbol{x}, t; \boldsymbol{x}', t')$ is called the mutual coherence function. In particular, for equal times, $\Gamma(\boldsymbol{x}, t; \boldsymbol{x}', t)$ describes the spatial coherence, and for equal positions, $\Gamma(\boldsymbol{x}, t; \boldsymbol{x}, t')$ describes the temporal coherence.

For a beam of particles, coherence may be either longitudinal (measured along the beam) or transverse (measured across the beam). In contrast to light optics, there is no simple relation between longitudinal coherence and temporal coherence because the dispersion relation of matter waves is quadratic in the wavenumber.

The spatial coherence function is intimately related to the quantum mechanical density operator of the particles (Chapt. 7)

$$\rho(t) = \overline{|\Psi(t)\rangle\langle\Psi(t)|} . \qquad (77.76)$$

In the position representation, one has

$$\langle\boldsymbol{x}|\rho(t)|\boldsymbol{x}'\rangle \equiv \rho(\boldsymbol{x}, \boldsymbol{x}'; t) = \Gamma(\boldsymbol{x}, t; \boldsymbol{x}', t) . \qquad (77.77)$$

Longitudinal and temporal coherence of a particle beam is determined mainly by the source of the beam. The thermal fission reactors used in neutron optics and the ovens used in atom optics are analogous to blackbody sources in light optics. In contrast, the transverse coherence is mainly determined by the way the particles are extracted from the oven to form a beam.

77.7.1 Atomic Sources

To describe thermal sources, consider a single particle in an oven of temperature T and volume V, assuming

that $a(\tilde{\boldsymbol{k}})$ and $a(\tilde{\boldsymbol{k}}')$ are statistically independent:

$$\overline{a(\tilde{\boldsymbol{k}})^* a(\tilde{\boldsymbol{k}}')} = \rho(\tilde{k})\delta(\tilde{\boldsymbol{k}} - \tilde{\boldsymbol{k}}') \,, \qquad (77.78)$$

where

$$\rho(\tilde{k}) = \frac{\lambda_{th}^3}{V} \exp\left(-\frac{\hbar^2 \tilde{k}^2}{2Mk_B T}\right) \qquad (77.79)$$

accounts for the thermal distribution of wavenumbers, and

$$\lambda_{th} = \left(\frac{2\pi\hbar^2}{Mk_B T}\right)^{1/2} \qquad (77.80)$$

denotes the thermal de Broglie wavelength.

Using (77.78)–(77.80) in (77.75), the mutual coherence function becomes

$$\Gamma(\boldsymbol{x}, t; \boldsymbol{x}', t') =$$
$$\frac{1}{V} \frac{1}{\{1 + [i(t - t')/\tau_{th}]\}^{\frac{3}{2}}}$$
$$\times \exp\left\{-\pi \frac{(\boldsymbol{x} - \boldsymbol{x}')^2}{\lambda_{th}^2 (1 + [i(t - t')/\tau_{th}])}\right\} \,, \qquad (77.81)$$

where

$$\tau_{th} = \frac{\hbar}{k_B T} \,, \qquad (77.82)$$

is the thermal coherence time.

According to (77.81), the spatial coherence of a thermal state falls off in a Gaussian manner on a scale given by λ_{th}. The temporal coherence, in contrast, falls off algebraically on a time scale given by τ_{th}. Expressed in physical units, one has

$$\lambda_{th} = \frac{1.74(5) \times 10^{-9}\,\text{m}}{\sqrt{(M/\text{u})(T/\text{K})}} \,,$$
$$\tau_{th} = \frac{7.63 \times 10^{-12}\,\text{s}}{(T/\text{K})} \,, \qquad (77.83)$$

where u is the atomic mass unit.

Atomic Beams

Effusive Beams. Effusive beams are produced from thermal sources by a suitable set of collimators placed in front of the opening of the oven. This produces a Maxwell–Boltzmann distribution of atomic velocities in the longitudinal direction. The coherence properties in the transverse direction are described by the van Cittert–Zernike theorem [77.77]; for details see any textbook on classical optics.

Supersonic Beams. Supersonic beams are produced by supersonic expansion of a high pressure gas which is forced through an appropriately designed nozzle. The expansion produces a velocity distribution in the longitudinal direction which is approximately Gaussian with a velocity ratio $v/\delta v \approx 10\text{–}20$.

Pulsed Beams. Pulsed beams are produced by chopping any of the beams described above. Important applications for pulsed beams are the resolution of temporal coherence and the mapping of the relative phases of the $a(\tilde{\boldsymbol{k}})$ in matter wave interferometry.

Laser-like Source of Atoms. In these sources, many atoms with integral spin (Bosons) occupy one and the same quantum state of motion [77.78]. Their operational principle is rooted in the quantum statistical effects of indistinguishability. It may be viewed in close analogy to the operational principle of an ordinary laser (Chapt. 70) and the mechanism underlying Bose–Einstein Condensation (Sect. 76.1.1). Laser-like sources have indeed been achieved by letting a small current of atoms leak out of a trapped Bose–Einstein condensate [77.79].

77.7.2 Atom Decoherence

In any interferometer, the contrast of the interference fringes quantitatively measures the coherence of the wave involved. Partially coherent beams show an output flux given by

$$I_\pm = \frac{1}{2}\left[1 \pm \text{Re}\left(C\,\text{e}^{\text{i}\chi}\right)\right] \,, \qquad (77.84)$$

instead of (77.60), with a complex number C. One has $|C| \le 1$, with the maximum achieved for a pure state; the phase of C is measured by scanning the interferometer phase shift χ.

In de Broglie interferometry, coherence can be lost when the interfering matter wave gets entangled with other systems. This happens for atoms, for example, due to the emission or scattering of photons, as soon as the detection of these photons permits, in principle, the resolution of spatially separated paths in the interferometer. In fact, the width of $\Gamma(\boldsymbol{x}, t; \boldsymbol{x}', t)$ as a function of $\boldsymbol{x} - \boldsymbol{x}'$, also called the spatial coherence length, is reduced to the photon wavelength after a single scattering event, see [77.80, 81]. Interference can be restored when the emitted photons are detected and correlated with the atom output [77.82, 83]. Collisions with background gas atoms between the optical elements of a three-grating interferometer also

reduce coherence, as has been shown with fullerene molecules [77.84]. Finally, coherence is lost when atoms interact with random electromagnetic fields. This has become relevant for atom reflection from evanescent light because of the roughness of the dielectric surface used [77.85] (see also [77.86]). The coherent operation of integrated atom optics near metallic surfaces is limited by thermally excited electromagnetic near fields as shown in experiments by *Harber* et al. [77.87] (see also [77.88]).

78. Quantized Field Effects

The electromagnetic field appears almost everywhere in physics. Following the introduction of Maxwell's equations in 1864, Max Planck initiated quantum theory when he discovered $h = 2\pi\hbar$ in the laws of black-body radiation. In 1905 Albert Einstein explained the photoelectric effect on the hypothesis of a corpuscular nature of radiation and in 1917 this paradigm led to a description of the interaction between atoms and electromagnetic radiation.

The study of quantized field effects requires an understanding of the quantization of the field which leads to the concept of a quantum of radiation, the photon. Specific nonclassical features arise when the field is prepared in particular quantum states, such as squeezed states. When the radiation field interacts with an atom, there is an important difference between a classical field and a quantized field. A classical field can have zero amplitude, in which case it does not interact with the atom. On the other hand a quantized field always interacts with the atom, even if all the field modes are in their ground states, due to vacuum fluctuations. These lead to various effects such as spontaneous emission and the Lamb shift.

The interaction of an atom with the many modes of the radiation field can conveniently be described in an approximate manner by a master equation where the radiation field is treated as a reservoir. Such a treatment gives a microscopic and quantum mechanically consistent description of damping.

78.1 Field Quantization

This section provides the basis for the quantized field effects discussed in this Chapter [78.1]. We expand the field in a complete set of normal modes which reduces the problem of field quantization to the quantization of a one dimensional harmonic oscillator corresponding to each normal mode.

The classical free electromagnetic field, i. e., the field in a region without charge and current densities, obeys the Maxwell equations

$$\nabla \cdot \boldsymbol{B} = 0 \, , \tag{78.1}$$

$$\nabla \cdot \boldsymbol{D} = 0 \, , \tag{78.2}$$

$$\nabla \times \boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} = 0 \, , \tag{78.3}$$

$$\nabla \times \boldsymbol{H} - \frac{\partial \boldsymbol{D}}{\partial t} = 0 \, , \tag{78.4}$$

where $\boldsymbol{B} = \mu_0 \boldsymbol{H}$, $\boldsymbol{D} = \epsilon_0 \boldsymbol{E}$. The magnetic permeability μ_0 connects the magnetic induction $\boldsymbol{B}$ with the magnetic field $\boldsymbol{H}$ and the electric permittivity ϵ_0 of free space connects the displacement $\boldsymbol{D}$ with the electric field $\boldsymbol{E}$. In the case of a free field, $\boldsymbol{E}$ and $\boldsymbol{B}$ may be obtained from

$$\boldsymbol{B} = \nabla \times \boldsymbol{A} \, , \tag{78.5}$$

$$\boldsymbol{E} = -\frac{\partial \boldsymbol{A}}{\partial t} \, , \tag{78.6}$$

where the vector potential $\boldsymbol{A}$ obeys the Coulomb gauge condition $\nabla \cdot \boldsymbol{A} = 0$ and satisfies a wave equation. In order to solve this wave equation we expand the vector potential

$$\boldsymbol{A}(\boldsymbol{x}, t) = \sum_{\boldsymbol{k}} \sum_{\sigma=1}^{2} \left(\frac{\hbar}{2\omega_{\boldsymbol{k}} \epsilon_0 V} \right)^{1/2}$$
$$\times \left[\alpha_{\boldsymbol{k}\sigma} \boldsymbol{\epsilon}_{\boldsymbol{k}\sigma} \, \mathrm{e}^{\mathrm{i}(\boldsymbol{k} \cdot \boldsymbol{x} - \omega_{\boldsymbol{k}} t)} + \mathrm{c.c.} \right] \tag{78.7}$$

in a set of normal modes $V^{-1/2} \exp(\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{x}) \boldsymbol{\epsilon}_{\boldsymbol{k}\sigma}$ which are orthonormal in the volume V. Due to the gauge condition $\nabla \cdot \boldsymbol{A} = 0$, we obtain two orthogonal polarization vectors $\boldsymbol{\epsilon}_{\boldsymbol{k}1}$ and $\boldsymbol{\epsilon}_{\boldsymbol{k}2}$ with $\boldsymbol{\epsilon}_{\boldsymbol{k}\sigma} \cdot \boldsymbol{k} = 0$ for each wave vector $\boldsymbol{k}$. The dispersion relation is $\omega_{\boldsymbol{k}} = c|\boldsymbol{k}|$. The Fourier amplitudes $\alpha_{\boldsymbol{k}\sigma}$ are complex numbers in the classical theory.

The field is quantized by replacing the classical amplitude $\alpha_{\boldsymbol{k}\sigma}$ by the mode annihilation operator $a_{\boldsymbol{k}\sigma}$. The complex conjugate $\alpha_{\boldsymbol{k}\sigma}^*$ is replaced by the mode creation operator $a_{\boldsymbol{k}\sigma}^\dagger$. They obey the commutation relation

$$\left[a_{\boldsymbol{k}\sigma}, a_{\boldsymbol{k}'\sigma'}^\dagger \right] = \delta_{\boldsymbol{k}\boldsymbol{k}'} \delta_{\sigma\sigma'} \, . \tag{78.8}$$

The representation of the electric field operator

$$\boldsymbol{E}(\boldsymbol{x}, t) = \mathrm{i} \sum_{\boldsymbol{k},\sigma} \left(\frac{\hbar \omega_{\boldsymbol{k}}}{2\epsilon_0 V} \right)^{1/2}$$
$$\times \left[a_{\boldsymbol{k}\sigma} \boldsymbol{\epsilon}_{\boldsymbol{k}\sigma} \, \mathrm{e}^{\mathrm{i}(\boldsymbol{k} \cdot \boldsymbol{x} - \omega_{\boldsymbol{k}} t)} - \mathrm{h.c.} \right]$$
$$\equiv \boldsymbol{E}^+(\boldsymbol{x}, t) + \boldsymbol{E}^-(\boldsymbol{x}, t) \tag{78.9}$$

in terms of these operators follows from (78.6) and the operator for the vector potential. Note also the often used decomposition of the electric field operator into the positive and negative frequency parts $\boldsymbol{E}^+$ and $\boldsymbol{E}^-$ respectively. A similar relation holds for the operator describing the magnetic induction $\boldsymbol{B}$.

Using the operators for the electric and magnetic field, one can transform the field energy

$$H = \frac{1}{2} \int \mathrm{d}V \left(\epsilon_0 \boldsymbol{E}^2 + \boldsymbol{B}^2/\mu_0 \right) \tag{78.10}$$

into the form

$$H = \sum_{\boldsymbol{k},\sigma} \hbar \omega_{\boldsymbol{k}} \left(a_{\boldsymbol{k}\sigma}^\dagger a_{\boldsymbol{k}\sigma} + 1/2 \right) \, , \tag{78.11}$$

which is a sum of independent harmonic oscillator Hamiltonians corresponding to each mode $(\boldsymbol{k}, \sigma)$. The number operator $N_{\boldsymbol{k}\sigma} = a_{\boldsymbol{k}\sigma}^\dagger a_{\boldsymbol{k}\sigma}$ represents the number of photons in the mode $(\boldsymbol{k}, \sigma)$, while $\hbar \omega_{\boldsymbol{k}}/2$ is the energy of the vacuum fluctuations.

Hence each mode of the electromagnetic field is equivalent to a harmonic oscillator. In the next section we discuss specific states of a single mode. The general quantum state of the electromagnetic field consisting of many modes is given by a superposition of product states that are composed out of these single mode states.

78.2 Field States

This section summarizes the properties of several important states of the electromagnetic field. From the independence of the normal modes, the discussion may be restricted to a single normal mode. With the mode index $(\boldsymbol{k}, \sigma)$ suppressed, a single mode Hamiltonian is

$$H = \hbar \omega \left(a^\dagger a + 1/2 \right) = \frac{\hbar \omega}{2} p^2 + \frac{\hbar \omega}{2} x^2 \, . \tag{78.12}$$

In the second step, the quadrature operators

$$x = \frac{1}{\sqrt{2}} \left(a + a^\dagger \right) , \tag{78.13}$$

$$p = \frac{1}{i\sqrt{2}} \left(a - a^\dagger \right) \tag{78.14}$$

are introduced, which are equivalent to scaled position and momentum operators of a massive particle in a harmonic potential. The quadratures of a quantized field are measurable with the help of homodyne detection as discussed in Sect. 78.4.1

We shall now describe several states of this quantized field mode: number states, coherent states, squeezed states, Schrödinger cats, and phase states. A quantized field in a coherent state shows the most classical behavior. A superposition of two coherent states, which is a Schrödinger cat, already shows nonclassical features. Number states and squeezed states are further typical examples of nonclassical states.

78.2.1 Number States

The eigenstates of the Hamiltonian (78.12) are the eigenstates of the number operator $N = a^\dagger a$,

$$N|n\rangle = n|n\rangle , \tag{78.15}$$

where $n = 0, 1, 2, \ldots$ denotes the excitations or the number of photons in the mode. The vacuum state of the mode $|0\rangle$, is defined by

$$a|0\rangle = 0 . \tag{78.16}$$

The ladder of excitations can be climbed up and down via the application of creation and annihilation operators

$$a^\dagger|n\rangle = \sqrt{n+1}|n+1\rangle , \tag{78.17}$$

$$a|n\rangle = \sqrt{n}|n-1\rangle , \tag{78.18}$$

on a Fock state $|n\rangle$. These number or Fock states form a complete and orthonormal set of states so that

$$\sum_{n=0}^{\infty} |n\rangle\langle n| = 1 , \quad \langle n|k\rangle = \delta_{nk} . \tag{78.19}$$

Their quadrature representations are

$$\langle x|n\rangle = \left(\sqrt{\pi} 2^n n! \right)^{-1/2} H_n(x) e^{-x^2/2} , \tag{78.20}$$

$$\langle p|n\rangle = \left(\sqrt{\pi} 2^n n! \right)^{-1/2} (-i)^n H_n(p) e^{-p^2/2} . \tag{78.21}$$

The states $|x\rangle$ and $|p\rangle$ are eigenstates of the quadrature operators x and p, (78.13) and (78.14).

Number states provide a frequently used representation of a pure quantum state

$$|\psi\rangle = \sum_{n=0}^{\infty} c_n|n\rangle , \tag{78.22}$$

or a mixed quantum state given by the density operator

$$\rho = \sum_{n,k} \rho_{nk} |n\rangle\langle k| \tag{78.23}$$

(Chapt. 7).

78.2.2 Coherent States

The coherent state is a specific superposition of number states. In contrast to a number state, a coherent state does not possess a definite number of photons: the photon distribution is Poissonian. For a large average photon number, the electric and magnetic fields have rather well defined amplitudes and phases with vanishing relative quantum fluctuations. Hence the Poissonian photon distribution frequently serves as a borderline between classical and nonclassical field states. Nonclassical states show a sub-Poissonian behavior. An extreme example is a field prepared in a number state. A parameter which quantifies the deviations from Poissonian behavior is the Q parameter introduced by *Mandel* [78.2].

We define the coherent state $|\alpha\rangle$ as an eigenstate of the annihilation operator

$$a|\alpha\rangle = \alpha|\alpha\rangle \tag{78.24}$$

with the complex amplitude $\alpha = |\alpha|e^{i\theta}$. The coherent state can be represented by

$$|\alpha\rangle = e^{\alpha a^\dagger - \alpha^* a}|0\rangle = D(\alpha)|0\rangle , \tag{78.25}$$

that is, by the action of the displacement operator $D(\alpha)$ on the vacuum.

The number state representation of $|\alpha\rangle$ reads

$$|\alpha\rangle = e^{-|\alpha|^2/2} \sum_{n=0}^{\infty} \frac{\alpha^n}{\sqrt{n!}} |n\rangle . \tag{78.26}$$

A coherent state $|\alpha_0\rangle$ that evolves in time according to the free field Hamiltonian (78.12) stays coherent, i.e.,

$$|\psi(t)\rangle = \exp\left(-iHt/\hbar\right) |\alpha_0\rangle = e^{-i\omega t/2}|\alpha(t)\rangle , \tag{78.27}$$

with amplitude $\alpha(t) = \alpha_0 \exp[-i\omega t]$.

Another important representation of a coherent state is the x representation

$$
\langle x|\alpha\rangle = \pi^{-1/4} \exp\left\{-[\mathrm{Re}(\alpha)]^2\right\}
$$
$$
\times \exp\left(-x^2/2 + \sqrt{2}\alpha x\right) , \tag{78.28}
$$

where $|x\rangle$ denotes again the x quadrature eigenstate.

The photon distribution in a coherent state

$$
|\langle n|\alpha\rangle|^2 = \frac{|\alpha|^{2n} \mathrm{e}^{-|\alpha|^2}}{n!} \tag{78.29}
$$

is a Poisson distribution with average photon number $\langle N\rangle = |\alpha|^2$ and variance $(\Delta N)^2 = \langle N^2\rangle - \langle N\rangle^2 = |\alpha|^2$. Hence the relative fluctuations $(\Delta N)/\langle N\rangle = \langle N\rangle^{-1/2}$ vanish for a large average photon number.

The Mandel Q parameter

$$
Q \equiv \frac{(\Delta N)^2 - \langle N\rangle}{\langle N\rangle} \tag{78.30}
$$

vanishes for a field in a coherent state. A nonclassical field may show sub-Poissonian behavior with $Q < 0$. As an example, the Schrödinger cat state is a *macroscopic* superposition of two coherent states

$$
|\mathrm{cat}\rangle = \left[2 + 2\cos\left(\alpha^2\sin\phi\right)\mathrm{e}^{-2\alpha^2\sin^2(\phi/2)}\right]^{-1/2}
$$
$$
\times\left[|\alpha\,\mathrm{e}^{\mathrm{i}\phi/2}\rangle + |\alpha\,\mathrm{e}^{-\mathrm{i}\phi/2}\rangle\right] , \tag{78.31}
$$

where α is assumed to be real. The Q parameter for this superposition state, shown in Fig. 78.1, takes on negative values for specific angles ϕ. The nonclassical behavior of such a $|\mathrm{cat}\rangle$-state can be explained [78.3] as a result of quantum interference between the two coherent states present in (78.31). The incoherent superposition described by the density operator

$$
\rho = \frac{1}{2}\left(|\alpha\,\mathrm{e}^{\mathrm{i}\phi/2}\rangle\langle\alpha\,\mathrm{e}^{\mathrm{i}\phi/2}| + |\alpha\,\mathrm{e}^{-\mathrm{i}\phi/2}\rangle\langle\alpha\,\mathrm{e}^{-\mathrm{i}\phi/2}|\right) \tag{78.32}
$$

does not have this nonclassical character: its Q parameter vanishes. Coherent states have a direct physical significance: the quantum state of a stabilized laser operating well above threshold can be approximated by a coherent state.

78.2.3 Squeezed States

Squeezed states [78.4–6] minimize the uncertainty product of the quadrature components of the electromagnetic field. The quadrature components x and p of the single mode field are defined in (78.13) and (78.14). They obey the commutation relation $[x, p] = \mathrm{i}$. Their uncertainties $(\Delta x)^2 \equiv \langle x^2\rangle - \langle x\rangle^2$ and $(\Delta p)^2 \equiv \langle p^2\rangle - \langle p\rangle^2$ fulfill the Heisenberg inequality

$$
\Delta x \Delta p \geq 1/2 . \tag{78.33}
$$

The coherent state is a special minimum uncertainty state with equal uncertainties $\Delta x = \Delta p = 1/\sqrt{2}$. Squeezed states comprise a more general class of minimum uncertainty states with reduced uncertainty in one quadrature at the expense of increased uncertainty in the other. These states $|\alpha, \epsilon\rangle$ are obtained by applying the displacement operator $D(\alpha)$ and the unitary squeeze operator

$$
S(\epsilon) = \mathrm{e}^{\frac{1}{2}\epsilon^* a^2 - \frac{1}{2}\epsilon a^{\dagger 2}} \tag{78.34}
$$

to the vacuum

$$
|\alpha, \epsilon\rangle = D(\alpha)S(\epsilon)|0\rangle . \tag{78.35}
$$

The squeeze operator $S(\epsilon)$ transforms a and $a^\dagger$ according to

$$
S^\dagger(\epsilon)a\,S(\epsilon) = a\cosh r - a^\dagger\,\mathrm{e}^{-2\mathrm{i}\phi}\sinh r , \tag{78.36}
$$
$$
S^\dagger(\epsilon)a^\dagger S(\epsilon) = a^\dagger\cosh r - a\,\mathrm{e}^{2\mathrm{i}\phi}\sinh r , \tag{78.37}
$$

where $\epsilon = r\,\mathrm{e}^{-2\mathrm{i}\phi}$. The rotated quadratures

$$
X_1 = x\cos\phi - p\sin\phi , \tag{78.38}
$$
$$
X_2 = p\cos\phi + x\sin\phi , \tag{78.39}
$$

transform according to

$$
S^\dagger(\epsilon)(X_1 + \mathrm{i}X_2)S(\epsilon) = X_1\mathrm{e}^{-r} + \mathrm{i}X_2\mathrm{e}^r , \tag{78.40}
$$

which yields the uncertainties

$$
\Delta X_1 = \mathrm{e}^{-r}/\sqrt{2} , \tag{78.41}
$$
$$
\Delta X_2 = \mathrm{e}^r/\sqrt{2} . \tag{78.42}
$$
Fig. 78.1 The Q parameter for a Schrödinger cat state (78.31) with amplitude $\alpha = 4$

In particular, for $\phi = 0$ the squeezed state $|\alpha, r\rangle$ is a minimum uncertainty state for the quadratures x and p with $\Delta x = e^{-r}/\sqrt{2}$ and $\Delta p = e^{r}/\sqrt{2}$. The degree of squeezing in the quadrature x is determined by the squeeze factor r.

The average photon number

$$\langle N \rangle = |\alpha|^2 + \sinh^2 r \tag{78.43}$$

of a squeezed state and its photon number variance

$$(\Delta N)^2 = \left| \alpha \cosh r - \alpha^* e^{-2i\phi} \sinh r \right|^2 + 2\cosh^2 r \sinh^2 r \tag{78.44}$$

contain the coherent contribution α as well as squeezing contributions expressed by r and ϕ. In particular, for $\phi = 0$, the Q parameter becomes negative for a large enough amplitude α and $r > 0$. The photon number distribution $W_n = |\langle \alpha, r|n \rangle|^2$ becomes narrower than the one for the corresponding coherent state with the same α. This sub-Poissonian behavior is one of the nonclassical features of a squeezed state. Furthermore, W_n shows oscillations [78.7] for larger squeezing. The two regimes with sub-Poissonian and oscillating photon statistics W_n are shown in Fig. 78.2.

A second representation of squeezed states has been introduced by Yuen [78.8]. In his notation, a squeezed state is an eigenstate of the operator

$$b = \mu a + \nu a^\dagger , \tag{78.45}$$

with $|\mu|^2 - |\nu|^2 = 1$ and eigenvalue β. This eigenstate can be written in the form

$$|\epsilon, \beta\rangle = S(\epsilon) D(\beta)|0\rangle , \tag{78.46}$$

which connects the squeezing operator $S(r e^{-2i\phi})$ with the parameters $\mu = \cosh r$ and $\nu = e^{-2i\phi} \sinh r$. In contrast to the definition (78.35), the displacement operator $D(\beta)$ and the squeezing operator $S(\epsilon)$ are applied now in reversed order. Nevertheless, the two equations (78.35) and (78.46) define the same state if the relation $\alpha = \beta\mu + \beta^*\nu$ is fulfilled.

Several experiments have demonstrated the generation of squeezed light. *Slusher* et al. [78.9] obtained squeezing in the sidemodes of a four-wave mixing process. An optical parametric oscillator below threshold has been used by *Wu* et al. [78.10] in order to generate squeezed light. Nonclassical features can also be found in a down conversion process. This second-order process creates so-called signal and idler photons from one pump photon. Signal and idler beam are distinguished by frequency or po-

larization. *Heidmann* et al. [78.11] have shown that the difference intensity of these twin beams may exhibit reduced quantum fluctuations. Pulsed twin beams also contain reduced noise in the difference of their intensities.

78.2.4 Phase States

The problem of a correct quantum mechanical description of phase has a long history in quantum mechanics [78.12]. First attempts to define a quantum phase are due to London and Dirac. The London phase state is

$$|\phi\rangle = \frac{1}{\sqrt{2\pi}} \sum_{n=0}^{\infty} e^{in\phi}|n\rangle , \tag{78.47}$$

which is an eigenstate of the exponential phase operator

$$\widehat{e^{i\phi}} = \sum_{n=0}^{\infty} |n\rangle\langle n+1| . \tag{78.48}$$

Since this operator is not unitary, it does not define a Hermitian operator $\hat{\phi}$ for the phase. Nevertheless many treatments of the phase of a quantum state $|\psi\rangle = \sum c_n |n\rangle$ are based on the London phase distribution

$$Pr(\phi) = |\langle \phi|\psi \rangle|^2 = \frac{1}{2\pi} \left| \sum_n c_n e^{-in\phi} \right|^2 . \tag{78.49}$$
Fig. 78.2 The photon number distribution W_n of a squeezed state $|\alpha, r\rangle$ with the coherent amplitude $\alpha = 7$. For a squeezing parameter $r = 0$, the Poisson distribution of a coherent state $|\alpha = 7\rangle$ is just visible. When r increases the photon distribution first becomes sub-Poissonian and then oscillatory

Later treatments [78.13] rely on the Hermitian operators

$$\widehat{\sin \phi} = \frac{1}{2i} \left(\widehat{e^{i\phi}} - \widehat{e^{i\phi}}^{\dagger} \right) , \tag{78.50}$$

$$\widehat{\cos \phi} = \frac{1}{2} \left(\widehat{e^{i\phi}} + \widehat{e^{i\phi}}^{\dagger} \right) , \tag{78.51}$$

for the sine and cosine function of the phase.

78.3 Quantum Coherence Theory

This section introduces the correlation functions of the electromagnetic field. Ideal photon correlation measurements can bring out the phenomenon of photon bunching and antibunching.

78.3.1 Correlation Functions

Correlation functions were originally introduced to describe an ideal photodetection process. Glauber [78.16] has presented a treatment based on an absorption mechanism in the detector which is sensitive to the positive frequency part E^+ of the electric field evaluated at the detector's space-time position $x \equiv (\boldsymbol{x}, t)$. This leads to an average field intensity

$$I(x) = \text{Tr} \left[\rho E^-(x) E^+(x) \right] \tag{78.52}$$

at point x. Here the density operator ρ describes the state of the field. The ordering of the operators, i. e., $E^- E^+ \sim a^{\dagger} a$, is known as normal ordering with all annihilation operators to the right of all creation operators.

The expression (78.52) now immediately generalizes to the correlation function of first order

$$G^{(1)}(x_1, x_2) = \text{Tr} \left[\rho E^-(x_1) E^+(x_2) \right] , \tag{78.53}$$

with $x_1 = (\boldsymbol{x}_1, t_1)$ and $x_2 = (\boldsymbol{x}_2, t_2)$. The classical interference experiments, such as Young's double slit experiment, can be described in terms of $G^{(1)}$. Furthermore, the correlation function of first order is connected to the power spectrum $S(\omega)$ of a quantized field via the Wiener–Khintchine theorem [78.17]. Under the assumption of a stationary process, i. e., when the autocorrelation function $\langle E^-(t) E^+(t') \rangle$ depends only on the time difference $\tau = t - t'$, then

$$S(\omega) = \frac{1}{2\pi} \int_0^{\infty} d\tau \langle E^-(\tau) E^+(0) \rangle e^{-i\omega\tau} + \text{c.c} . \tag{78.54}$$

This relation between the spectrum and the first-order correlation function is known as Wiener–Khintchine theorem.

Recently [78.14] a Hermitian phase operator was constructed starting from the phase state (78.47), restricted to a finite Hilbert space. An operational phase description has been proposed [78.15] in which a classical phase measurement is translated to the quantum realm by using an eight-port homodyne detector.

In order to analyze the Hanbury–Brown and Twiss experiment [78.18] it is necessary to define higher order correlation functions. The general nth order correlation function is defined by

$$
\begin{aligned}
& G^{(n)}(x_1, \dots, x_n, x_{n+1}, \dots, x_{2n}) \\
& = \text{Tr} \big[\rho E^-(x_1) \cdots E^-(x_n) \\
& \quad \times E^+(x_{n+1}) \cdots E^+(x_{2n}) \big] ,
\end{aligned}
\tag{78.55}
$$

where the field operators are again normal ordered.

These correlation functions fulfill a generalized Schwartz inequality

$$G^{(1)}(x_1, x_1) G^{(1)}(x_2, x_2) \geq \left| G^{(1)}(x_1, x_2) \right|^2 , \tag{78.56}$$

which becomes, for the nth order functions,

$$
\begin{aligned}
& G^{(n)}(x_1, .., x_n, x_n, .., x_1) \\
& \times G^{(n)}(x_{n+1}, .., x_{2n}, x_{2n}, .., x_{n+1}) \\
& \geq \left| G^{(n)}(x_1, .., x_n, x_{n+1}, .., x_{2n}) \right|^2 .
\end{aligned}
\tag{78.57}
$$

A field is said to be first-order coherent when its normalized correlation function

$$g^{(1)}(x_1, x_2) = \frac{G^{(1)}(x_1, x_2)}{\left[G^{(1)}(x_1, x_1) G^{(1)}(x_2, x_2) \right]^{1/2}} \tag{78.58}$$

satisfies $\left| g^{(1)}(x_1, x_2) \right| = 1$. In a Young type experiment, this case gives maximum fringe visibility. A more general definition of first order coherence is the condition that $G^{(1)}(x_1, x_2)$ factorizes

$$G^{(1)}(x_1, x_2) = \mathcal{G}^*(x_1) \mathcal{G}(x_2) , \tag{78.59}$$

where $\mathcal{G}$ denotes some complex function. This definition can be readily generalized to the nth order case. The nth order coherence applies when the relation

$$
\begin{aligned}
& G^{(n)}(x_1, \dots, x_{2n}) \\
& = \mathcal{G}^*(x_1) \cdots \mathcal{G}^*(x_n) \mathcal{G}(x_{n+1}) \cdots \mathcal{G}(x_{2n})
\end{aligned}
\tag{78.60}
$$

holds. A field in a coherent state possesses nth order coherence.

78.3.2 Photon Correlations

The Young experiment demonstrates the appearance of first-order correlations. However, experiments that can distinguish between the classical and quantum domains have to be based on measurements of second-order correlations. These experiments are of the Hanbury–Brown and Twiss type, and determine the arrival of a photon at detector position x and time t and another photon at time $t + \tau$. Following the theory of Glauber, the second-order correlation function

$$G^{(2)}(\tau) = \langle E^-(t) E^-(t+\tau) E^+(t+\tau) E^+(t) \rangle$$
(78.61)

is measured. In this formula we have omitted the variable for the position x. Usually the normalized correlation function

$$g^{(2)}(\tau) = \frac{G^{(2)}(\tau)}{\left[G^{(1)}(0) \right]^2}$$
(78.62)

is introduced. The function $g^{(2)}$ is always positive, which is true for classical as well as for quantum fields; but there exists a purely quantum domain given by

$$0 \leq g^{(2)}(0) < 1 \ .$$
(78.63)

78.4 Photodetection Theory

So far we have used a very simple theory of photodetection: any absorbed photon leads to a photoelectric emission which can be observed. But in any real experiment, these photons are counted over some time interval T and the observed photoelectric emissions are dominated by two statistics: (i) the statistics of photoelectric emission which is also present for a classical field and (ii) the specific quantum statistics of a quantized field. A detailed discussion of the quantum theory of photoelectric detection has been given by *Kelley* and *Kleiner* [78.19]. A central result is the formula

$$p(n, t, T) = \left\langle : \frac{I^n}{n!} \exp(-I) : \right\rangle$$
(78.66)

for the probability of counting n photoelectrons in the time interval from t to $t + T$. This photocounting distri-

For example, for a number state $|n\rangle$,

$$g^{(2)}_{|n\rangle}(0) = 1 - 1/n \ ,$$
(78.64)

with $n \geq 1$. In contrast, a coherent state $|\alpha\rangle$ yields $g^{(2)}_{|\alpha\rangle}(0) = 1$.

78.3.3 Photon Bunching and Antibunching

In a realistic theory (but not in an oversimplified one-mode model), the correlation function $G^{(2)}(\tau)$ always factorizes on a sufficiently long time scale, and $g^{(2)}(\tau) \to 1$. The photons are then no longer correlated, and they arrive randomly as in the case of coherent light; see for example (78.195).

If $g^{(2)}(0) > 1$, the photons show a tendency to arrive in bunches, an effect known as photon bunching. This effect has been observed for chaotic light. The opposite situation with $0 \leq g^{(2)}(0) < 1$ demonstrates the reverse effect, namely photon antibunching. As seen from (78.63), this is a regime only accessible to nonclassical light. An example is given by the resonance fluorescence of a two-level atom, treated in Sect. 78.13. Note that we can rewrite $g^{(2)}(0)$ with the help of Mandel's Q parameter

$$g^{(2)}(0) = \frac{\langle a^\dagger a^\dagger a \, a \rangle}{\langle a^\dagger a \rangle^2} = 1 + Q \ .$$
(78.65)

Hence, a field state with $Q < 0$ shows the effect of photon antibunching.

bution contains the integrated intensity operator

$$I = \eta \int\limits_t^{t+T} \mathrm{d}t' \ E^-(t') E^+(t')$$
(78.67)

containing the quantum efficiency η of the detector. The notation $\langle : \cdots : \rangle$ indicates a quantum average where the operators have to be normally ordered and time ordered. This operator ordering reflects the process on which a photodetector is based. It annihilates or absorbs photons, one after the other. A good treatment of photoelectric detection can be found in [78.20].

78.4.1 Homodyne and Heterodyne Detection

These detection methods allow the extraction of specific quantum features of a single mode quantum field,

the signal field. Figure 78.3 summarizes the principle of optical homodyning. Two quantum fields described by the annihilation operators a and b are mixed at a 50/50 beam splitter BS. Both fields have the same frequency. The mode a represents the signal mode whose quantum state is given by the density operator ρ. Mode b serves as a reference field, the local oscillator. The coherent state $|\alpha\rangle = ||\alpha| e^{i\theta}\rangle$ determines the quantum state of the local oscillator. Two ideal photodetectors 1 and 2 measure the number of photons in the output modes of the beam splitter. For a highly excited coherent state, i.e., a classical local oscillator, the statistics of the photocurrent difference ΔI can be described by the moments of the signal mode operator

$$X_\theta = \frac{1}{\sqrt{2}}\left(a\, e^{-i\theta} + a^\dagger\, e^{i\theta}\right). \qquad (78.68)$$
Fig. 78.3 The principle of optical homodyning

For example, the photocurrent difference

$$\langle \Delta I \rangle \sim \langle X_\theta \rangle = \mathrm{Tr}(\rho X_\theta) \qquad (78.69)$$

is proportional to the expectation value of X_θ. In particular, for $\theta = 0$ and $\theta = \frac{\pi}{2}$ one is able to measure all the moments of the two quadratures x and p (78.13) and (78.14) of the signal mode. In general, the statistics of the photocurrent ΔI reveal the probability distribution

$$Pr(X_\theta) = \langle X_\theta | \rho | X_\theta \rangle \qquad (78.70)$$

of the observable X_θ when the signal mode is in the state ρ. The states

$$|X_\theta\rangle = \pi^{-1/4} \exp\left[-X_\theta^2/2\right]$$
$$\times \sum_{n=0}^{\infty} \frac{1}{\sqrt{2^n n!}} H_n(X_\theta)\, e^{in\theta} |n\rangle \qquad (78.71)$$

are eigenstates of the operator X_θ, and are known as rotated quadrature states.

The heterodyne technique [78.21,22] relies on a similar mixing of a signal field with a local oscillator at a beam splitter, but this time the local oscillator frequency is offset by the intermediate frequency $\Delta\omega$ with respect to the frequency ω_0 of the signal mode. Filters select the beat frequency components in the photocurrent of the detectors. This photocurrent contains the quantum statistics of the two quadratures of the signal field [78.21, 22].

78.5 Quasi-Probability Distributions

Quasi-probability distributions play an important role in quantum optics for three reasons. First, they are a complete representation of the density operator of a quantum field. Second, they allow one to calculate expectation values in the spirit of classical statistical physics. Third, they offer the possibility of converting a master equation for the density operator into an equivalent c-number partial differential equation. In this section, we relate a specific quasi-probability function to a specific operator ordering.

78.5.1 *s*-Ordered Operators

A normally ordered product of a and $a^\dagger$ is a product of the form $(a^\dagger)^m a^n$: the annihilation operators a stand to the right of the creation operators $a^\dagger$. In an antinormally

ordered product like $a^n (a^\dagger)^m$, the order of a and $a^\dagger$ has changed. A generalized s-ordered product can be defined as

$$\left\{a^m (a^\dagger)^n\right\}_s \equiv \left(\frac{\partial}{\partial \xi}\right)^n \left(-\frac{\partial}{\partial \xi^*}\right)^m$$
$$\times D(\xi, \xi^*, s)\Big|_{\xi=\xi^*=0} \qquad (78.72)$$

with the generalized displacement operator

$$D(\xi, \xi^*, s) \equiv \exp\left(\xi a^\dagger - \xi^* a + \frac{1}{2} s \xi \xi^*\right). \qquad (78.73)$$

For $s = 1$ we find again normal ordering. The values $s = 0$ and $s = -1$ produce symmetric and antinormal ordered products. As an example we note $\{a^\dagger a\}_s = a^\dagger a - (s-1)/2$.

Expectation values of those *s*-ordered products are easily derived from the characteristic function

$$\chi(\xi, \xi^*, s) = \text{Tr}\big[\rho D(\xi, \xi^*, s)\big] \qquad (78.74)$$

via differentiation

$$\left(\frac{\partial}{\partial\xi}\right)^n \left(-\frac{\partial}{\partial\xi^*}\right)^m \chi(\xi, \xi^*, s)\Big|_{\xi=\xi^*=0}$$
$$= \langle\{(a^\dagger)^n a^m\}_s\rangle . \qquad (78.75)$$

The Fourier transform of χ yields the quasi-probability distribution of Cahill and Glauber [78.23]

$$W(\alpha, s) = \frac{1}{\pi^2} \int d^2\xi\, \chi(\xi, \xi^*, s)\, e^{\alpha\xi^* - \alpha^*\xi} , \qquad (78.76)$$

where $d^2\xi = d\,\text{Re}(\xi)\,d\,\text{Im}(\xi)$. With this distribution one is able to calculate the expectation value of any *s*-ordered operator product

$$\left\langle\left\{(a^\dagger)^n a^m\right\}_s\right\rangle = \int (\alpha^*)^n \alpha^m\, W(\alpha, s)\, d^2\alpha . \qquad (78.77)$$

We concentrate now on three important quasi-probability distributions, namely the cases $s = 1$, $s = 0$, and $s = -1$, corresponding to the Glauber–Sudarshan distribution, the Wigner function, and the Q function respectively. A detailed discussion of these three functions can be found in [78.24].

78.5.2 The *P* Function

The quasi-probability function $P(\alpha)$ was introduced [78.25, 26] as a diagonal representation of the density operator

$$\rho = \int P(\alpha)|\alpha\rangle\langle\alpha|\, d^2\alpha \qquad (78.78)$$

in terms of coherent states $|\alpha\rangle$, (78.26). It is related to the Cahill–Glauber function $W(\alpha, s)$ via

$$P(\alpha) = W(\alpha, s = 1) . \qquad (78.79)$$

The expectation value of any normally ordered operator product

$$\langle(a^\dagger)^m a^n\rangle = \int (\alpha^*)^m \alpha^n\, P(\alpha)\, d^2\alpha \qquad (78.80)$$

has a particularly simple form in terms of $P(\alpha)$. From (78.78) the P function of a coherent state $|\alpha_0\rangle$ becomes

$$P(\alpha) = \delta^{(2)}(\alpha - \alpha_0) \qquad (78.81)$$
$$= \delta\big[\text{Re}(\alpha) - \text{Re}(\alpha_0)\big]\delta\big[\text{Im}(\alpha) - \text{Im}(\alpha_0)\big] .$$

Quantized fields for which the P function is positive do not show nonclassical effects such as squeezing and anti-bunching. For nonclassical states, such as number states or squeezed states, the P function only exists in terms of

generalized functions, such as delta functions and their derivatives, which have a highly singular character.

The positive P-representation $P(\alpha, \beta)$ for a nondiagonal decomposition of a density operator is [78.27, 28]

$$\rho = \iint d^2\alpha\, d^2\beta\, \frac{|\alpha\rangle\langle\beta^*|}{\langle\beta^*|\alpha\rangle}\, P(\alpha, \beta) . \qquad (78.82)$$

The function $P(\alpha, \beta)$ is a direct generalization of the Glauber–Sudarshan function $P(\alpha)$, (78.78). $P(\alpha, \beta)$ exists for any physical density operator ρ [78.27] and is given by

$$P(\alpha, \beta) = \frac{1}{4\pi^2} \exp\left(-\frac{1}{4}|\alpha - \beta^*|^2\right)$$
$$\times \left\langle\frac{1}{2}(\alpha + \beta^*)\Big|\rho\Big|\frac{1}{2}(\alpha + \beta^*)\right\rangle . \qquad (78.83)$$

Here the state $|1/2(\alpha + \beta^*)\rangle$ denotes a coherent state with the complex amplitude $1/2(\alpha + \beta^*)$. Note that $P(\alpha, \beta)$ is always positive.

78.5.3 The Wigner Function

This quasi-probability was first introduced by Wigner [78.29] and may be defined as the distribution function for a symmetrically ordered operator product which is obtained in the case $s = 0$. The Wigner function plays an important role in other branches of physics, such as quantum chaology, and in particular in any semi-classical phenomenon when one considers the transition from quantum mechanics to classical mechanics.

Consider the Wigner function of a quantum mechanical particle of position

$$x = \sqrt{\frac{\hbar}{2m\omega}}(a + a^\dagger) , \qquad (78.84)$$

and momentum

$$p = i\sqrt{\frac{m\hbar\omega}{2}}(a^\dagger - a) . \qquad (78.85)$$

The Wigner function may be written in terms of position and momentum variables

$$W(x, p) = \frac{1}{\pi\hbar} \int_{-\infty}^{\infty} dy\, e^{-2ipy/\hbar}\langle x + y|\rho|x - y\rangle , \qquad (78.86)$$

where $|x \pm y\rangle$ denotes position eigenstates. The $s = 0$ Cahill–Glauber definition and the above definition of the Wigner function are related by

$$W(x, p) = \frac{1}{2}W\left(\alpha = \frac{m\omega x + ip}{\sqrt{2m\hbar\omega}},\, s = 0\right) . \qquad (78.87)$$

The position and momentum distributions of a particle, or equivalently the quadruture distributions in the case of a quantized field mode, are

$$Pr(x) = \int_{-\infty}^{\infty} W(x, p) \, dp ,$$ (78.88)

$$Pr(p) = \int_{-\infty}^{\infty} W(x, p) \, dx .$$ (78.89)

Furthermore, the scalar product

$$|\langle \psi_1 | \psi_2 \rangle|^2 = 2\pi\hbar \iint dx \, dp \, W_{|\psi_1\rangle}(x, p)$$
$$\times W_{|\psi_2\rangle}(x, p)$$ (78.90)

of two quantum states is expressed by the phase space overlap of the two corresponding Wigner functions. Consequently, any Wigner function $W(x, p)$ has to obey the necessary condition

$$\iint dx \, dp \, W(x, p) W_{|\psi\rangle}(x, p) \geq 0$$ (78.91)

for all $W_{|\psi\rangle}$ representing a pure state. For a normalized state $|\psi\rangle$,

$$\iint dx \, dp \left[W_{|\psi\rangle}(x, p) \right]^2 = \frac{1}{2\pi\hbar} .$$ (78.92)

Instead of solving the Schrödinger equation for the dynamics of a massive particle in a potential $V(x)$, we can try to solve the equation

$$\frac{\partial W}{\partial t} = -\frac{p}{m} \frac{\partial W}{\partial x} + \sum_{r=1,3,..} \frac{1}{r!} \left(\frac{i\hbar}{2} \right)^{r-1} \frac{\partial^r V}{\partial x^r} \frac{\partial^r W}{\partial p^r}$$ (78.93)

for its Wigner function $W(x, p, t)$. Note that here only the odd derivatives of the potential V enter. This equation is the quantum analogue of the classical Liouville equation, to which it reduces in the limit of $\hbar \to 0$. However, the initial distribution $W(x, p, t = 0)$ has to be a Wigner function in the sense of (78.86).

Furthermore the Wigner function of an energy eigenfunction in the potential $V(x)$ may be obtained from the equations

$$\left[\frac{p^2}{2m} + V(x) - \frac{\hbar^2}{8m} \frac{\partial^2}{\partial x^2} - \frac{\hbar^2}{8} \frac{\partial^2 V}{\partial x^2} \frac{\partial^2}{\partial p^2} \right] W(x, p)$$
$$+ \sum_{r=4,6,..} \frac{1}{r!} \left(\frac{i\hbar}{2} \right)^r \frac{\partial^r V}{\partial x^r} \frac{\partial^r W}{\partial p^r} = E W(x, p) ,$$ (78.94)

and

$$\left(-\frac{p}{m} \frac{\partial}{\partial x} + \frac{\partial V}{\partial x} \frac{\partial}{\partial p} \right) W(x, p)$$
$$+ \sum_{r=3,5,..} \frac{1}{r!} \left(\frac{i\hbar}{2} \right)^{r-1} \frac{\partial^r V}{\partial x^r} \frac{\partial^r W}{\partial p^r} = 0 .$$ (78.95)

The Wigner function has negative parts for most quantum states. For example, the Wigner function of a Fock state $|n\rangle$,

$$W_{|n\rangle}(\bar{x}, \bar{p}) = \frac{(-1)^n}{\pi} e^{-\bar{x}^2 - \bar{p}^2} L_n(2\bar{x}^2 + 2\bar{p}^2) ,$$ (78.96)

clearly becomes negative due to the oscillating Laguerre polynomial L_n as shown in Fig. 78.4. Note that we have introduced the dimensionless position $\bar{x} = \sqrt{m\omega/\hbar} \, x$ and momentum $\bar{p} = 1/\sqrt{m\omega\hbar} \, p$.

On the other hand, the Wigner function

$$W_{|\alpha,r\rangle}(\bar{x}, \bar{p}) = \frac{1}{\pi} \exp \left\{ -e^{2r} \left[\bar{x} - \sqrt{2} \operatorname{Re}(\alpha) \right]^2 - e^{-2r} \left[\bar{p} - \sqrt{2} \operatorname{Im}(\alpha) \right]^2 \right\}$$ (78.97)

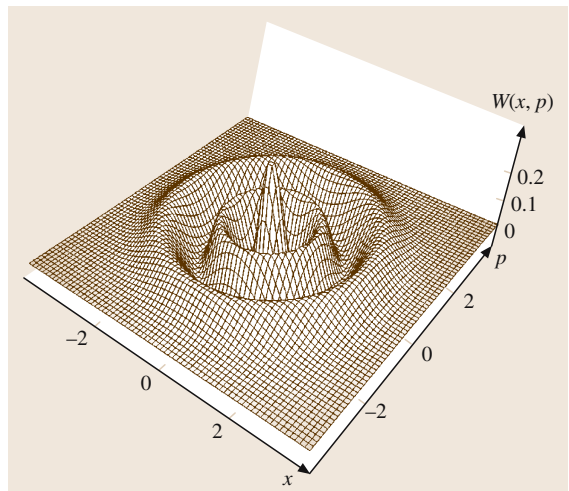
of a squeezed state (78.35) is always positive as shown in Fig. 78.5. It is a long thin ellipse in phase space (i. e. a Gaussian cigar). Concerning the negative parts of the Wigner function, the Hudson theorem [78.30] states that a necessary and sufficient condition for the Wigner function of a pure state $|\psi\rangle$ to be nonnegative is that it can be described by a wave function of the


Fig. 78.4 The Wigner function (78.96) of a Fock state $|n = 4\rangle$. The negative parts can be seen clearly
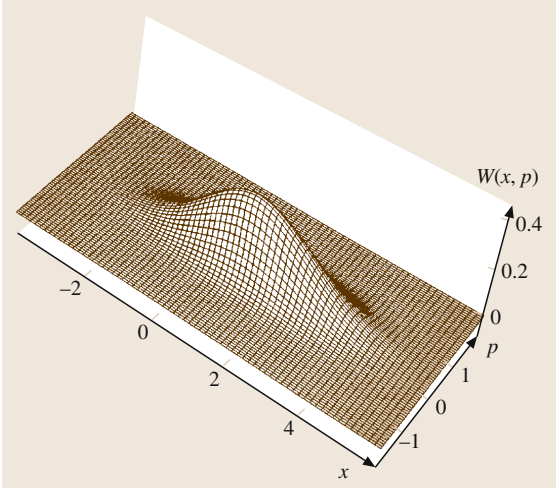

Fig. 78.5 The Wigner function of a squeezed state $|\alpha, r\rangle$ with coherent amplitude $\alpha = 1$ and squeezing $e^{2r} = 0.25$. For these values the phase space ellipse is oriented along the x-axis and squeezed in the p-direction. Note that this function is positive everywhere

form

$$\langle x|\psi\rangle = \exp\left[-\frac{1}{2}(ax^2 + bx + c)\right] . \tag{78.98}$$

Here a, b and c denote some constants with $\mathrm{Re}(a) > 0$.

Finally, the Kirkwood distribution function

$$K(x, p) = \frac{1}{\pi\hbar} \int\limits_{-\infty}^{\infty} \mathrm{d}y\, e^{-2ipy/\hbar} \langle x|\rho|x - 2y\rangle \tag{78.99}$$

is a phase space function that resembles the Wigner function. In the case of a pure state $\rho = |\psi\rangle\langle\psi|$ this function reduces to

$$K(x, p) = \psi(x)\tilde{\psi}(p)\, e^{-ixp/\hbar} , \tag{78.100}$$

where $\tilde{\psi}(p)$ denotes the Fourier transform of $\psi(x)$.

78.5.4 The Q Function

The Q function is defined by the diagonal matrix elements

$$Q(\alpha) = \langle\alpha|\rho|\alpha\rangle/\pi \tag{78.101}$$

of the density operator ρ, where $|\alpha\rangle$ denotes a coherent state. The $Q(\alpha)$ function is always a positive and bounded function, which exists for any density operator ρ. The Q function is also known as Husimi's function. It allows one to calculate expectation values of antinormally ordered operator products of the form

$$\left\langle a^n \left(a^\dagger\right)^m \right\rangle = \int \mathrm{d}^2\alpha\, \alpha^n (\alpha^*)^m\, Q(\alpha) . \tag{78.102}$$

Moreover, since the Q function corresponds to the case $s = -1$ of the Cahill–Glauber distribution,

$$Q(\alpha) = W(\alpha, -1) . \tag{78.103}$$

78.5.5 Relations Between Quasi-Probabilities

In general, the relation

$$W(\alpha, s) = \frac{2}{\pi(s' - s)} \int \mathrm{d}^2\beta \exp\left(-\frac{2|\alpha - \beta|^2}{s' - s}\right)$$
$$\times W(\alpha, s') \tag{78.104}$$

holds between two Cahill–Glauber distributions with the parameters $s' > s$. In particular, the non-negative Q function

$$Q(\alpha) = \frac{2}{\pi} \int \mathrm{d}^2\beta \exp[-2|\alpha - \beta|^2] W(\beta, s = 0) \tag{78.105}$$

turns out to be a smoothed Wigner function $W(\beta, s = 0)$. It is this smoothing process that washes out possible negative parts in the Wigner function.

78.6 Reservoir Theory

Reservoir theory treats the interaction of one system with a few degrees of freedom, called the system, with another system with many degrees of freedom, called the reservoir. A typical application of reservoir theory is a microscopic theory of damping: the system interacts with a reservoir, called the heat bath. The system dissipates energy into the heat bath whereas the heat bath introduces additional fluctuations to the system. Since the present chapter focuses on quantized field effects, the reservoir consists of the many modes of the radiation field in free space. Such a reservoir is modeled by a large number of independent harmonic

oscillators

$$H_r = \sum_i \hbar\omega_i \left(b_i^\dagger b_i + \frac{1}{2} \right) , \tag{78.106}$$

where b_i and $b_i^\dagger$ are the annihilation and creation operators for the ith harmonic oscillator of the reservoir. For convenience the interaction with the system is frequently approximated by a Hamiltonian of the form

$$H_{\text{int}} = \hbar \sum_i \left(g_i A \, b_i^\dagger + g_i^* A^\dagger b_i \right) , \tag{78.107}$$

where A is an operator of the small system and g_i is the coupling strength of this system to the ith oscillator of the reservoir. For example, A may be an annihilation operator if the system is a harmonic oscillator or a Pauli spin matrix in the case of a two-level atom coupled to the free space radiation field.

Reservoir theory has important applications, and a detailed discussion can be found in various books, for example [78.17, 20, 27, 28, 31–33].

78.6.1 Thermal Reservoir

The most commonly used reservoir is the thermal reservoir or thermal heat bath. Its characteristic properties

are

$$\langle b_i \rangle = \langle b_i^\dagger \rangle = \langle b_i b_j \rangle = \langle b_i^\dagger b_j^\dagger \rangle = 0 , \tag{78.108}$$

$$\langle b_i^\dagger b_j \rangle = \overline{n}_i \delta_{ij} . \tag{78.109}$$

Here

$$\overline{n}_i = \frac{1}{\exp\left(\hbar\omega_i / k_B T\right) - 1} \tag{78.110}$$

is the average number of photons at frequency ω_i, T is the temperature of the reservoir, and k_B denotes the Boltzmann constant.

78.6.2 Squeezed Reservoir

Another example of a reservoir is a squeezed vacuum or squeezed reservoir. If, for example, multiwave mixing is used to squeeze the radiation field, conjugate pairs of the reservoir operators b are correlated. Therefore, the expectation values $\langle b_i b_j \rangle$ and $\langle b_i^\dagger b_j^\dagger \rangle$ may be nonvanishing. Apart from the average number $\overline{n}_i$ of photons at frequency ω_i, which take into account nonvanishing expectation values $\langle b_i^\dagger b_i \rangle$, additional complex squeezing parameters are needed to describe the reservoir [78.28, 33, 34]. The characterization of a squeezed reservoir based on noise operators is discussed in Sect. 78.10.

78.7 Master Equation

In quantum mechanics, density operators are used to describe mixed states, and are discussed in Chapt. 7. Here we introduce the concept of the reduced density operator

$$\rho_s = \text{Tr}_r \left(\rho_{sr} \right) , \tag{78.111}$$

which is the density operator ρ_{sr} of the complete system traced over the degrees of freedom of the reservoir. The equation of motion for ρ_s in the Schrödinger picture is

$$\dot{\rho}_s(t) = -\frac{i}{\hbar} \text{Tr}_r \left\{ [H_{sr}, \rho_{sr}(t)] \right\} . \tag{78.112}$$

In the Born–Markov approximation the trace over the reservoir can be evaluated and leads to an equation of motion for ρ_s which no longer contains reservoir operators. This equation of motion is usually called the master

equation. The Born–Markov approximation consists of two different parts:

1. Born approximation: The coupling to the reservoir is assumed to be sufficiently weak to allow a perturbative treatment of the interaction between the reservoir and the system.
2. Markov approximation: The correlations of the reservoir are assumed to decay very rapidly on a typical time scale of the system, or equivalently, the reservoir has a very broad spectrum. This approximation involves the assumption that the modes of the reservoir are spaced closely together, so that the frequency ω_i is a smooth function of i.

Since a general treatment is rather technical, we consider two typical examples. A more general discussion can be found in [78.17, 20, 27, 28, 31–33]

78.7.1 Damped Harmonic Oscillator

The universally accepted Hamiltonian in nonrelativistic QED for a harmonic oscillator of frequency ω coupled to a reservoir consisting of a large number of harmonic oscillators is given by the total Hamiltonian [78.35, 36]

$$H_{\text{sr}} = \hbar\omega \left(a^\dagger a + \frac{1}{2} \right) + \sum_i \hbar\omega_i \left(b_i^\dagger b_i + \frac{1}{2} \right)$$
$$+ H_{\text{lc}} + H_{\text{si}} , \tag{78.113}$$

with the linear coupling term

$$H_{\text{lc}} = \hbar \sum_i g_i \left(a + a^\dagger \right) \left(b_i + b_i^\dagger \right) , \tag{78.114}$$

and the self-interaction term

$$H_{\text{si}} = \sum_i \frac{\hbar g_i^2}{\omega_i} \left(a + a^\dagger \right)^2 . \tag{78.115}$$

The approach used in quantum optics is to drop the term H_{si} and to make the rotating-wave approximation, that is, to drop the terms $a\, b_i$ and $a^\dagger b_i^\dagger$, see also Chapt. 68. Then the approximate total Hamiltonian reads

$$H_{\text{sr}} = \hbar\omega \left(a^\dagger a + \frac{1}{2} \right) + \sum_i \hbar\omega_i \left(b_i^\dagger b_i + \frac{1}{2} \right)$$
$$+ \hbar \sum_i g_i \left(a\, b_i^\dagger + a^\dagger b_i \right) . \tag{78.116}$$

Despite the problems with this approximate Hamiltonian (see Sect. V.D of [78.35, 36] for a discussion) we adopt it in the present context because it leads to the widely used master equation for the damped harmonic oscillator. We consider two reservoirs: a thermal bath and a squeezed bath.

Harmonic Oscillator in a Thermal Bath
Within the Born–Markov approximation the master equation is

$$\dot\rho = \frac{1}{2}\gamma \left(\bar{n} + 1 \right) \left(2a\rho a^\dagger - a^\dagger a\rho - \rho a^\dagger a \right)$$
$$+ \frac{1}{2}\gamma \bar{n} \left(2a^\dagger \rho a - a\, a^\dagger \rho - \rho a\, a^\dagger \right) , \tag{78.117}$$

where

$$\rho(t) = e^{i\omega a^\dagger a(t-t_0)} \rho_{\text{s}}(t)\, e^{-i\omega a^\dagger a(t-t_0)} \tag{78.118}$$

is the reduced density operator in the interaction picture. The damping constant γ is given by

$$\gamma = 2\pi \mathcal{D}(\omega)|g(\omega)|^2 , \tag{78.119}$$

where $g(\omega)$ denotes the coupling strength at frequency ω. The number of thermal photons at frequency ω is

$$\bar{n} = \frac{1}{\exp\left(\hbar\omega/k_{\text{B}}T \right) - 1} . \tag{78.120}$$

Thus the Born–Markov approximation replaces the discrete reservoir modes by a continuum of modes with a density $\mathcal{D}(\omega)$.

Harmonic Oscillator in a Squeezed Bath
Within the Born–Markov approximation, the reduced density operator (78.118) in the interaction picture satisfies the master equation

$$\dot\rho = \frac{1}{2}\gamma \left(\bar{n} + 1 \right) \left(2a\rho a^\dagger - a^\dagger a\rho - \rho a^\dagger a \right)$$
$$+ \frac{1}{2}\gamma \bar{n} \left(2a^\dagger \rho a - a\, a^\dagger \rho - \rho a\, a^\dagger \right)$$
$$- \frac{1}{2}\gamma \bar{m} \left(2a^\dagger \rho a^\dagger - a^\dagger a^\dagger \rho - \rho a^\dagger a^\dagger \right)$$
$$- \frac{1}{2}\gamma \bar{m}^* \left(2a\rho a - a\, a\rho - \rho a\, a \right) . \tag{78.121}$$

Here γ is again given by (78.119). The squeezed reservoir is characterized by a real number $\bar{n}$ and a complex number $\bar{m}$. Physically $\bar{n}$ is the number of photons at frequency ω, i.e., similar to the thermal reservoir, it measures the average energy at frequency ω. The complex number $\bar{m}$ determines the amount of squeezing. In general, the positivity of the density operator requires

$$|\bar{m}|^2 \leq \bar{n}\left(\bar{n} + 1 \right) . \tag{78.122}$$

A more quantitatively definition of $\bar{n}$ and $\bar{m}$ in terms of noise operators is given in Sect. 78.10.

78.7.2 Damped Two-Level Atom

The interaction of a two-level atom with a classical electromagnetic field is already discussed in Chapt. 68. For a quantum mechanical treatment of the field we only have to replace the classical field by its quantum mechanical counterpart (78.9). We then find in the rotating-wave approximation (Chapt. 68), that the dynamics of a two-level atom with a transition frequency ω_0 coupled to a reservoir consisting of a large number of harmonic oscillators is approximately described by the total Hamiltonian

$$H_{\text{sr}} = \frac{1}{2}\hbar\omega_0 \sigma_z + \sum_i \hbar\omega_i \left(b_i^\dagger b_i + \frac{1}{2} \right)$$
$$+ \hbar \sum_i \left(g_i \sigma_- b_i^\dagger + g_i^* \sigma_+ b_i \right) , \tag{78.123}$$

where

$$\sigma_+ = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad \sigma_- = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \tag{78.124}$$

$$\sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{78.125}$$

Again, two reservoirs are considered: a thermal bath and a squeezed bath.

Two-Level Atom in a Thermal Bath
Within the Born–Markov approximation, the master equation is

$$\dot{\rho} = \frac{1}{2}\gamma\,(\bar{n}+1)\,(2\sigma_-\rho\sigma_+ - \sigma_+\sigma_-\rho - \rho\sigma_+\sigma_-)$$
$$+ \frac{1}{2}\gamma\bar{n}\,(2\sigma_+\rho\sigma_- - \sigma_-\sigma_+\rho - \rho\sigma_-\sigma_+)\,, \tag{78.126}$$

where

$$\rho(t) = \mathrm{e}^{\mathrm{i}\omega_0\sigma_z(t-t_0)/2}\,\rho_{\mathrm{s}}(t)\,\mathrm{e}^{-\mathrm{i}\omega_0\sigma_z(t-t_0)/2} \tag{78.127}$$

is the reduced density operator in the interaction picture, and γ and $\bar{n}$ are given by (78.119) and (78.120).

Two-Level Atom in a Squeezed Bath
Within the Born–Markov approximation, the reduced density operator in the interaction picture, (78.127), satisfies the master equation

$$\dot{\rho} = \frac{1}{2}\gamma\,(\bar{n}+1)\,(2\sigma_-\rho\sigma_+ - \sigma_+\sigma_-\rho - \rho\sigma_+\sigma_-)$$
$$+ \frac{1}{2}\gamma\bar{n}\,(2\sigma_+\rho\sigma_- - \sigma_-\sigma_+\rho - \rho\sigma_-\sigma_+)$$
$$- \gamma\bar{m}\sigma_+\rho\sigma_+ - \gamma\bar{m}^*\sigma_-\rho\sigma_-\,, \tag{78.128}$$

where γ, $\bar{n}$ and $\bar{m}$ have the same meaning as in (78.121).

78.8 Solution of the Master Equation

78.8.1 Damped Harmonic Oscillator

We consider only a thermal reservoir and present the solution of the master equation (78.117). For $\bar{n} = 0$ it can be solved in terms of coherent states, see (78.26). For $\bar{n} \neq 0$ we give solutions in terms of quasi-probability distributions.

Coherent States
For $\bar{n} = 0$, which is a good approximation for optical frequencies, if the system is initially in a coherent state $|\alpha_0\rangle$ with a density operator

$$\rho(t_0) = |\alpha_0\rangle\langle\alpha_0|\,, \tag{78.129}$$

then there exists a simple analytical solution of the master equation (78.117)

$$\rho(t) = |\alpha_0\,\mathrm{e}^{-\gamma(t-t_0)/2}\rangle\langle\alpha_0\,\mathrm{e}^{-\gamma(t-t_0)/2}|\,. \tag{78.130}$$

A coherent state thus remains a coherent state with an exponentially decaying amplitude $\alpha_0 e^{-\gamma(t-t_0)/2}$. According to (78.78) a general solution

$$\rho(t) = \int \mathrm{d}^2\alpha_0\,P(\alpha_0)\,|\alpha_0\,\mathrm{e}^{-\gamma(t-t_0)/2}\rangle\langle\alpha_0\,\mathrm{e}^{-\gamma(t-t_0)/2}| \tag{78.131}$$

can be constructed for an initial density operator

$$\rho(t_0) = \int \mathrm{d}^2\alpha_0\,P(\alpha_0)\,|\alpha_0\rangle\langle\alpha_0|\,. \tag{78.132}$$

If the system is initially in a superposition

$$|\psi(t_0)\rangle = \sum_i c_i |\alpha_i\rangle \tag{78.133}$$

of coherent states, the time evolution is given by

$$\rho(t) = \sum_{i,k} c_i c_k^* \exp\left[-\frac{1}{2}\left(1 - \mathrm{e}^{-\gamma(t-t_0)}\right)|\alpha_i - \alpha_k|^2\right]$$
$$\times \exp\left[\mathrm{i}\left(1 - \mathrm{e}^{-\gamma(t-t_0)}\right)\mathrm{Im}\left(\alpha_i\alpha_k^*\right)\right]$$
$$\times |\alpha_i\,\mathrm{e}^{-\gamma(t-t_0)/2}\rangle\langle\alpha_k\,\mathrm{e}^{-\gamma(t-t_0)/2}|\,. \tag{78.134}$$

For $\gamma(t - t_0) \ll 1$, the interference terms $|\alpha_i\rangle\langle\alpha_k|$, $i \neq k$ decay with an effective decay constant $\gamma|\alpha_i - \alpha_k|^2/2$. Thus the damping constant is modified by the separation of the two coherent states in phase space.

Fokker–Planck Equation
A widely used procedure for solving the master equation for a damped harmonic oscillator, (78.117), or for similar problems, is to derive an equation of motion for the quasi-probability distributions $W(\alpha, \alpha^*; s)$ defined in (78.76) from the master equation. The operators a and $a^\dagger$ are replaced by appropriate differential operators. The substitution rules can be derived

from (78.73), (78.74) and (78.76) and are

$$\left(a^\dagger\right)^k a^\ell \rho \to \left(\alpha^* - \frac{s+1}{2}\frac{\partial}{\partial\alpha}\right)^k$$

$$\times \left(\alpha - \frac{s-1}{2}\frac{\partial}{\partial\alpha^*}\right)^\ell W \, ,$$

$$\rho \left(a^\dagger\right)^k a^\ell \to \left(\alpha - \frac{s+1}{2}\frac{\partial}{\partial\alpha^*}\right)^\ell$$

$$\times \left(\alpha^* - \frac{s-1}{2}\frac{\partial}{\partial\alpha}\right)^k W \, ,$$

$$a\rho a^\dagger \to \left(\alpha - \frac{s-1}{2}\frac{\partial}{\partial\alpha^*}\right)$$

$$\times \left(\alpha^* - \frac{s-1}{2}\frac{\partial}{\partial\alpha}\right) W \, ,$$

$$a^\dagger \rho a \to \left(\alpha^* - \frac{s+1}{2}\frac{\partial}{\partial\alpha}\right)$$

$$\times \left(\alpha - \frac{s+1}{2}\frac{\partial}{\partial\alpha^*}\right) W \, ,$$

$$a^\dagger \rho a^\dagger \to \left(\alpha^* - \frac{s+1}{2}\frac{\partial}{\partial\alpha}\right)$$

$$\times \left(\alpha^* - \frac{s-1}{2}\frac{\partial}{\partial\alpha}\right) W \, ,$$

$$a\rho a \to \left(\alpha - \frac{s-1}{2}\frac{\partial}{\partial\alpha^*}\right)$$

$$\times \left(\alpha - \frac{s+1}{2}\frac{\partial}{\partial\alpha^*}\right) W \, . \qquad (78.135)$$

In general, this procedure leads to equations of motion which involve higher derivatives of W as exemplified by the quantum mechanical Liouville equation (78.93) for the Wigner function. For simple Hamiltonians, however, this equation has the form of a Fokker–Planck equation which is well known in classical stochastic problems [78.27, 37] (Sect. 78.10.2). In particular, for a damped harmonic oscillator described by the master equation (78.117), one obtains

$$\frac{\partial W}{\partial t} = \frac{\gamma}{2}\left[\frac{\partial}{\partial\alpha}(\alpha W) + \frac{\partial}{\partial\alpha^*}(\alpha^* W)\right] + \gamma\bar{n}_s \frac{\partial^2 W}{\partial\alpha\partial\alpha^*} \, ,$$
$$(78.136)$$

where

$$\bar{n}_s = \bar{n} + \frac{1-s}{2} = \frac{1}{\exp(\hbar\omega/k_{\rm B}T)-1} + \frac{1-s}{2} \, .$$
$$(78.137)$$

The time-dependent solution of this Fokker–Planck equation has the form

$$W(\alpha, \alpha^*, t; s) = \int G(\alpha, \alpha^*, t | \alpha', \alpha'^*, t'; s)$$
$$\times W(\alpha', \alpha'^*, t'; s)\,{\rm d}^2\alpha' \, , \quad (78.138)$$

where

$$G(\alpha, \alpha^*, t | \alpha', \alpha'^*, t'; s)$$

$$= \frac{\exp\left(-\dfrac{\left|\alpha - \alpha' \, e^{-\gamma(t-t')/2}\right|^2}{\bar{n}_s \left[1 - e^{-\gamma(t-t')}\right]}\right)}{\pi\bar{n}_s \left(1 - e^{-\gamma(t-t')}\right)} \qquad (78.139)$$

is the Green's function of the Fokker–Planck equation (78.136). The steady-state solution is

$$W(\alpha, \alpha^*, t \to \infty; s) = \frac{1}{\pi\bar{n}_s}\, e^{-|\alpha|^2/\bar{n}_s} \, , \quad (78.140)$$

which is the distribution function of a harmonic oscillator in thermal equilibrium with a reservoir of temperature T.

78.8.2 Damped Two–Level Atom

The density operator

$$\rho = \begin{pmatrix} \rho_{ee} & \rho_{eg} \\ \rho_{ge} & \rho_{gg} \end{pmatrix} \qquad (78.141)$$

for a two-level atom can be written as

$$\rho = \begin{pmatrix} \frac{1}{2}[1 + \langle\sigma_z\rangle] & \langle\sigma_-\rangle \\ \langle\sigma_+\rangle & \frac{1}{2}[1 - \langle\sigma_z\rangle] \end{pmatrix} \, . \qquad (78.142)$$

Thus, a two-level atom is completely described by the expectation values

$$\langle\sigma_z\rangle = \rho_{ee} - \rho_{gg} \, ,$$
$$\langle\sigma_+\rangle = \rho_{ge} \, ,$$
$$\langle\sigma_-\rangle = \rho_{eg} \, . \qquad (78.143)$$

Hence the master equation (78.128) can be cast into the equations of motions for these expectation values

$$\frac{\rm d}{{\rm d}t}\langle\sigma_+\rangle = -\gamma\left(\bar{n} + \frac{1}{2}\right)\langle\sigma_+\rangle - \gamma\bar{m}^*\langle\sigma_-\rangle \, ,$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle\sigma_-\rangle = -\gamma\left(\overline{n}+\frac{1}{2}\right)\langle\sigma_-\rangle - \gamma\overline{m}\langle\sigma_+\rangle \,,$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle\sigma_z\rangle = -2\gamma\left(\overline{n}+\frac{1}{2}\right)\langle\sigma_z\rangle - \gamma \,, \qquad (78.144)$$

which can easily be solved for arbitrary initial conditions. In contrast to a thermal reservoir ($\overline{m} = 0$), a squeezed reservoir results in two different transverse decay constants $\gamma\left(\overline{n}+\frac{1}{2}+|\overline{m}|\right)$ and $\gamma\left(\overline{n}+\frac{1}{2}-|\overline{m}|\right)$ [78.34].

78.9 Quantum Regression Hypothesis

In the Schrödinger picture, time-dependent expectation values for system operators A_j can be calculated from the reduced density operator $\rho_s(t)$ via

$$\langle A_j\rangle = \mathrm{Tr}_s\left\{A_j\rho_s(t)\right\} \,. \qquad (78.145)$$

The reduced density operator, however, is not sufficient to calculate two-time correlation functions such as $\langle A_j(t+\tau)A_k(t)\rangle$. For a definition of two-time correlation functions, the Heisenberg picture is more appropriate. Here, expectation values follow from

$$\langle A_j\rangle = \mathrm{Tr}_{sr}\left[U_{sr}^\dagger(t,t_0)A_j(t_0)U_{sr}(t,t_0)\rho_{sr}(t_0)\right] \,, \qquad (78.146)$$

where $U_{sr}(t,t_0)$ describes the unitary time evolution of the complete system and $\rho_{sr}(t_0)$ is the density operator in the Heisenberg picture. Similarly, two-time correlation functions such as $\langle A_j(t+\tau)A_k(t)\rangle$ can be defined as

$$\langle A_j(t+\tau)A_k(t)\rangle$$
$$= \mathrm{Tr}_{sr}\left[U_{sr}^\dagger(t+\tau,t_0)A_j(t_0)U_{sr}(t+\tau,t_0)\right.$$
$$\left.\times U_{sr}^\dagger(t,t_0)A_k(t_0)U_{sr}(t,t_0)\rho_{sr}(t_0)\right] \,. \qquad (78.147)$$

The quantum regression hypothesis avoids the calculation of $U_{sr}(t,t_0)$. Two equivalent formulations exist, one based on the master equation for ρ_s and another based on the equation of motion for the expectation values $\langle A_j\rangle$, see for example [78.20, 27, 28, 31, 33].

78.9.1 Two-Time Correlation Functions and Master Equation

It follows from their definition (78.147) in the Heisenberg picture that two-time correlation functions $\langle A_j(t+\tau)A_k(t)\rangle$ for system operators A_j and A_k can be calculated with the help of the operator

$$R_s(t+\tau,t) = \mathrm{Tr}_r\left[U_{sr}(t+\tau,t)\right.$$
$$\left.\times A_k\rho_{sr}(t)U_{sr}^\dagger(t+\tau,t)\right] \,, \qquad (78.148)$$

where $U_{sr}(t+\tau,t)$ describes the unitary time evolution of the complete system between t and $t+\tau$. We find

$$\langle A_j(t+\tau)A_k(t)\rangle = \mathrm{Tr}_s\left[A_j R_s(t+\tau,t)\right] \,. \qquad (78.149)$$

Note, that in (78.148) and (78.149) we interpret A_j and A_k as operators in the Schrödinger picture and have omitted the argument t_0. Because the reduced density operator

$$\rho_s(t) = \mathrm{Tr}_r\left[U_{sr}(t,t_0)\rho_{sr}(t_0)U_{sr}^\dagger(t,t_0)\right] \qquad (78.150)$$

satisfies the master equation, it is plausible to assume, that when the time derivative is taken with respect to τ, the operator $R_s(t+\tau,t)$ also satisfies the master equation for ρ_s, subject to the initial condition $R_s(t,t) = A_k\rho_s(t)$. However, this requires the additional assumption that the approximations made in the derivation of the master equation for $\rho_s(t)$ are also valid for $R_s(t+\tau,t)$.

78.9.2 Two-Time Correlation Functions and Expectation Values

A second formulation of the quantum regression hypothesis asserts that two-time correlation functions $\langle A_j(t+\tau)A_k(t)\rangle$ obey

$$\frac{\partial}{\partial\tau}\langle A_j(t+\tau)A_k(t)\rangle$$
$$= \sum_\ell G_{j\ell}(\tau)\langle A_\ell(t+\tau)A_k(t)\rangle \,, \qquad (78.151)$$

provided that the expectation values of a set of system operators A_j satisfy

$$\frac{\partial}{\partial t}\langle A_j(t)\rangle = \sum_\ell G_{j\ell}(t)\langle A_\ell(t)\rangle \,. \qquad (78.152)$$

This is the form of the quantum regression hypothesis that was first formulated by *Lax* [78.38].

The equivalence of the two formulations follows from the interpretation of $R_s(t+\tau,t)$ on the right side of (78.149) as a "density operator". Then $\mathrm{Tr}_s\left\{A_j R_s(t+\tau,t)\right\}$ is an "expectation value" for which we assume that (78.152) is valid; i.e.,

$$\frac{\partial}{\partial\tau}\mathrm{Tr}_s\left\{A_j R_s(t+\tau,t)\right\}$$
$$= \sum_\ell G_{j\ell}(\tau)\mathrm{Tr}_s\left\{A_\ell R_s(t+\tau,t)\right\} \,. \qquad (78.153)$$

According to (78.149), this is identical to (78.151).

78.10 Quantum Noise Operators

The master equation is based on the Schrödinger picture in quantum mechanics: the state of the system described by a density operator is time-dependent, whereas operators corresponding to observables are time independent. If we use the Heisenberg picture instead and make similar approximations as in the derivation of the master equation, we arrive at equations of motion for the Heisenberg operators, see for example [78.17,28,31,32]. Due to the interaction with a reservoir these equations have additional noise terms and damping terms.

78.10.1 Quantum Langevin Equations

Again consider a damped harmonic oscillator. The equation of motion for the annihilation operator

$$\tilde{a}(t) = e^{i\omega(t-t_0)} a(t) \tag{78.154}$$

in the interaction picture follows from the Heisenberg equations for the operators a, $a^\dagger$, b_i and $b_i^\dagger$ and reads

$$\frac{d\tilde{a}}{dt} = -\sum_i |g_i|^2 \int_{t_0}^{t} e^{-i(\omega_i-\omega)(t-t')} \tilde{a}(t')\, dt'$$
$$-i\sum_i g_i^* e^{-i(\omega_i-\omega)(t-t_0)} b_i(t_0) . \tag{78.155}$$

In general, the noise operator

$$F(t) = -i\sum_i g_i^* e^{-i(\omega_i-\omega)(t-t_0)} b_i(t_0) \tag{78.156}$$

is not delta-correlated, and there are also memory effects in (78.155). The noise operator $F(t)$ can be used to classify the reservoir: if it is delta-correlated, that is, if the reservoir has a very broad spectrum, one speaks of white noise, see below. If the correlation time is finite so that there are memory effects, one speaks of colored noise.

If the spectrum of the noise is very broad (as in the derivation of the master equation for the reduced density operator), the operator $\tilde{a}(t)$ satisfies the quantum Langevin equation

$$\frac{d\tilde{a}}{dt} = -\frac{\gamma}{2}\tilde{a}(t) + F(t) , \tag{78.157}$$

with a damping term $-\gamma\tilde{a}(t)/2$ and a noise term $F(t)$. Note that a simple damping equation such as

$$\dot{\tilde{a}}(t) = -\frac{\gamma}{2}\tilde{a}(t) \tag{78.158}$$

is unphysical since it does not preserve the commutation relation $[\tilde{a}, \tilde{a}^\dagger] = 1$. It is the noise term which saves the commutation relation.

For a thermal reservoir with a sufficiently small correlation time, the standard derivations [78.32] give

$$\langle F(t)\rangle = \langle F^\dagger(t)\rangle = \langle F(t)F(t')\rangle = \langle F^\dagger(t)F^\dagger(t')\rangle = 0 ,$$
$$\langle F^\dagger(t)F(t')\rangle = \gamma\bar{n}\delta(t-t') ,$$
$$\langle F(t)F^\dagger(t')\rangle = \gamma(\bar{n}+1)\delta(t-t') , \tag{78.159}$$

where the averages are taken over the reservoir. The damping constant γ and the number of thermal photons $\bar{n}$ are given in (78.119) and (78.120). For more general relations, see [78.35, 36], where it is shown explicitly that correlation functions involving the fluctuation force do not in fact depend on the oscillator frequency. The condition of a sufficiently small reservoir correlation time requires that $\tau_c \approx \hbar/(k_B T)$ is small compared with the time scales of the systems. The only time scale in (78.157) is γ^{-1}. The relevant condition is therefore $\tau_c \ll \gamma^{-1}$. For typical applications in quantum optics, a is the annihilation operator and $a^\dagger$ is the creation operator of a single-mode cavity field. Here one can have quality factors of the cavity on the order of $Q = \omega/\gamma \approx 10^6$. In terms of the quality factor, the condition of sufficiently small reservoir correlation times requires $\hbar\omega/(k_B T) \ll Q$. For optical frequencies $(\omega \approx 3\times 10^{15}\,\text{Hz})$ and $T \approx 300\,\text{K}$ one has $\hbar\omega/(k_B T) \approx 75$. In the microwave regime $(\omega \approx 30\,\text{GHz})$ one can have temperatures as low as $T \approx 3\,\text{mK}$ and still have $\hbar\omega/(k_B T) \approx 75$. Therefore the assumption of delta-correlated noise is a good approximation for typical applications in quantum optics.

Similarly, for a squeezed reservoir one has

$$\langle F(t)\rangle = \langle F^\dagger(t)\rangle = 0 ,$$
$$\langle F(t)F(t')\rangle = \gamma\bar{m}\delta(t-t') ,$$
$$\langle F^\dagger(t)F^\dagger(t')\rangle = \gamma\bar{m}^*\delta(t-t') ,$$
$$\langle F^\dagger(t)F(t')\rangle = \gamma\bar{n}\delta(t-t') ,$$
$$\langle F(t)F^\dagger(t')\rangle = \gamma(\bar{n}+1)\delta(t-t') , \tag{78.160}$$

which gives a quantitative definition of the parameters $\bar{n}$ and $\bar{m}$ in the master equations (78.121) and (78.128). Again, a detailed discussion in [78.35, 36] shows that correlation functions involving the fluctuation forces do not depend on the oscillator frequency.

The Langevin equation (78.157) is based on the use of the approximate Hamiltonian given in (78.116),

i. e., it is based on the rotating-wave approximation and the neglect of self-interaction terms. The corresponding Langevin equation for $x = \sqrt{\hbar/(2m\omega)}\,(a+a^\dagger)$ may be calculated and, not unexpectedly, it disagrees with the Abraham–Lorentz equation which *Ford* and *O'Connell* [78.39] showed could be derived systematically using the exact Hamiltonian (78.113). In fact, Ford and O'Connell showed that an improved equation for the radiating electron (improved in the sense that it is second-order and is not subject to the analyticity problems and the problems with runaway solutions associated with the Abraham–Lorentz equation) may be obtained by generalizing the Hamiltonian (78.113) to include electron structure. The implications following from these different equations are presently under study.

78.10.2 Stochastic Differential Equations

In Sect. 78.10.1 we discussed one of the simplest quantum systems with dissipation, the damped harmonic oscillator. For more complicated systems the noise term can also contain system operators. In such cases there are two different ways to interpret the Langevin equation. In order to give a feeling for the two possible interpretations, we discuss the one dimensional classical Langevin equation

$$\frac{\mathrm{d}x}{\mathrm{d}t} = g(x,t) + h(x,t)F(t) \qquad (78.161)$$

for the stochastic variable $x(t)$ with delta-correlated noise $\langle F(t)F(t')\rangle = \delta(t-t')$. Due to the singular nature of delta-correlated noise, such a Langevin equation does not exist from a strictly mathematical point of view. A mathematically more rigorous treatment is based on stochastic differential equations [78.27, 28, 37]. The variable $x(t)$ is said to obey a stochastic differential equation

$$\begin{aligned}\mathrm{d}x(t) &= g(x,t)\,\mathrm{d}t + h(x,t)F(t)\,\mathrm{d}t \\ &= g(x,t)\,\mathrm{d}t + h(x,t)\,\mathrm{d}W(t)\,,\end{aligned} \qquad (78.162)$$

if, for all times t and t_0, $x(t)$ is given by

$$x(t) = x(t_0) + \int_{t_0}^{t} g(x(t'),t')\,\mathrm{d}t'$$

$$+ \int_{t_0}^{t} h[x(t'),t']\,\mathrm{d}W(t')\,. \qquad (78.163)$$

Here the last term is a Riemann–Stieltjes integral defined by

$$\int_{t_0}^{t} h[x(t'),t']\,\mathrm{d}W(t')$$

$$= \lim_{n\to\infty} \sum_{i=0}^{n-1} h[x(\tau_i),\tau_i]\left[W(t_{i+1}) - W(t_i)\right]\,, \qquad (78.164)$$

where τ_i is in the interval (t_i, t_{i+1}).

There are two different approaches to such problems: the Ito approach and the Stratonovich approach. They differ in the definition of stochastic integrals.

In the Stratonovich approach, one evaluates $h[x(\tau_i),\tau_i]$ at $\tau_i = (t_i + t_{i+1})/2$, whereas in the Ito approach one evaluates $h[(x(\tau_i),\tau_i)]$ at $\tau_i = t_i$. This slightly different definition of τ_i leads to different results because, as a consequence of the delta-correlated noise term, $x(t)$ is not a continuous path. However, there is a relation between the solution of a Stratonovich stochastic differential equation and an Ito stochastic differential equation. Suppose $x(t)$ is a solution of the Stratonovich stochastic differential equation

$$\mathrm{d}x(t) = g(x,t)\,\mathrm{d}t + h(x,t)\,\mathrm{d}W(t)\,. \qquad (78.165)$$

Then $x(t)$ satisfies the Ito stochastic differential equation

$$\begin{aligned}\mathrm{d}x(t) &= \left[g(x,t) + \frac{1}{2}h(x,t)\frac{\partial h(x,t)}{\partial x}\right]\mathrm{d}t \\ &+ h(x,t)\,\mathrm{d}W(t)\,.\end{aligned} \qquad (78.166)$$

Instead of dealing with stochastic differential equations, one can derive a Fokker–Planck equation for the conditional probability $P(x,t|x_0,t_0)$. For the Stratonovich stochastic differential equation (78.165), the Fokker–Planck equation is

$$\begin{aligned}\frac{\partial P}{\partial t} &= -\frac{\partial}{\partial x}\left[g(x,t) + \frac{1}{2}h(x,t)\frac{\partial h(x,t)}{\partial x}\right]P \\ &+ \frac{1}{2}\frac{\partial^2}{\partial x^2}\,h^2(x,t)P\,,\end{aligned} \qquad (78.167)$$

which takes the form

$$\frac{\partial P}{\partial t} = -\frac{\partial}{\partial x}\,g(x,t)P + \frac{1}{2}\frac{\partial^2}{\partial x^2}\,h^2(x,t)P\,, \qquad (78.168)$$

if (78.165) is interpreted as a stochastic differential equation in the Ito sense.

The two approaches have the following properties: (i) in most of the models used in physics the Stratonovich

definition of a stochastic integral is needed to give correct results, (ii) rules from ordinary calculus are applicable only in the Stratonovich approach, and (iii) for

Langevin equations with $h(x, t) = \text{const}$, as in (78.157), the Stratonovich interpretation and the Ito interpretation of stochastic integrals are equivalent.

78.11 Quantum Monte Carlo Formalism

The quantum Monte Carlo formalism was developed to solve numerically master equations of the Lindblad type [78.20, 40–44]

$$
\dot{\rho}_s = -\frac{i}{\hbar}[H_s, \rho_s]
$$
$$
+ \frac{1}{2}\sum_j \left(2C_j\rho_s C_j^\dagger - C_j^\dagger C_j\rho_s - \rho_s C_j^\dagger C_j\right) .
\tag{78.169}
$$

Here C_j are arbitrary system operators.

As an illustrative example, consider

$$
\dot{\rho}_s = -\frac{i}{\hbar}[H_s, \rho_s] + \frac{1}{2}\left(2C\rho_s C^\dagger - C^\dagger C\rho_s - \rho_s C^\dagger C\right) ,
\tag{78.170}
$$

where C is an arbitrary system operator. Instead of solving the master equation, one defines quantum trajectories or stochastic wave functions as follows. Starting from $|\psi(t)\rangle$, there are two possibilities for the time evolution during the interval dt:

1. The system evolves according to the non-Hermitian Hamiltonian $H_s - \frac{i\hbar}{2} C^\dagger C$; i. e.

$$
|\psi(t+dt)\rangle = \frac{\left[1 - i\,dt\left(H_s - \frac{i\hbar}{2} C^\dagger C\right)/\hbar\right]|\psi(t)\rangle}{\sqrt{1 - \langle\psi(t)|C^\dagger C|\psi(t)\rangle\, dt}} .
\tag{78.171}
$$

2. The system makes a jump; i. e.

$$
|\psi(t+dt)\rangle = \frac{C|\psi(t)\rangle}{\sqrt{\langle\psi(t)|C^\dagger C|\psi(t)\rangle}} .
\tag{78.172}
$$

Since both possibilities describe a nonunitary time evolution, $|\psi\rangle$ must be normalized after each step. For each time interval dt one of these two possibilities is randomly chosen according to the probability

$$
P(t)dt = \langle\psi(t)|C^\dagger C|\psi(t)\rangle\, dt
\tag{78.173}
$$

to make a jump between t and $t + dt$. We can now define a density operator

$$
\rho_s(t) = |\psi(t)\rangle\langle\psi(t)|
\tag{78.174}
$$

for a specific quantum trajectory $|\psi(t)\rangle$. The density operator

$$
\overline{\rho_s(t)} = \overline{|\psi(t)\rangle\langle\psi(t)|}
\tag{78.175}
$$

averaged over all trajectories (indicated by the bar) is then a solution of the master equation (78.170).

This method can easily be generalized to master equations of the form (78.169).

78.12 Spontaneous Emission in Free Space

Consider an atom which is initially in one of its excited states and which interacts with the quantized electromagnetic field of free space. Even if none of the modes of the electromagnetic field is excited, there are still the vacuum fluctuations which "interact" with the atom and give rise to important effects:

1. Spontaneous emission: the atom spontaneously emits a photon and decays from the excited state.
2. Natural linewidth: due to the finite lifetime of the atomic levels, the radiation from an atomic transition has a finite linewidth, called the natural linewidth.
3. Lamb shift: the energy levels of the atom are shifted.

The standard theory of spontaneous emission is the Wigner–Weisskopf theory [78.17, 32]. Here an initially

excited atomic state $|\ell\rangle$ decays exponentially according to

$$
|c_\ell(t)|^2 = e^{-\Gamma_\ell t} ,
\tag{78.176}
$$

where the decay constant Γ_ℓ is given by

$$
\Gamma_\ell = \sum_i \frac{\omega_{\ell i}^3 |\boldsymbol{d}_{\ell i}|^2}{3\pi\epsilon_0\hbar c^3} ,
\tag{78.177}
$$

and the sum is over all atomic states with an energy E_i lower than the energy E_ℓ of the state $|\ell\rangle$. $\omega_{\ell i} = (E_\ell - E_i)/\hbar$ is the transition frequency for the transition $|\ell\rangle \to |i\rangle$, and $\boldsymbol{d}_{\ell i} = e\langle\ell|\boldsymbol{r}|i\rangle$ is the corresponding dipole moment.

The same decay constant Γ_ℓ is also observed as a linewidth in the spectrum of the radiation scattered

by an atom when the incoming photon excites the atom to the level $|\ell\rangle$.

The energy level shift is more troublesome and needs the concept of mass renormalization, a standard problem in quantum electrodynamics. The theory and results are discussed in Chapt. 27 and Chapt. 28.

Recent calculations of *Pachucki* [78.45] based on fully relativistic quantum electrodynamics and includ-

ing two-loop corrections predict $1\,057\,838(6)$ kHz for the energy difference between the $2s_{1/2}$-state and the $2p_{1/2}$-state which is in excellent agreement with the experimental result of $1\,057\,839(12)$ kHz [78.46].

For a discussion of energy levels and transition frequencies in hydrogen and deuterium atoms see also Sect. 28.3.

78.13 Resonance Fluorescence

Consider a two-level atom driven by a continuous monochromatic wave which is treated classically. The excited state of the atom can decay by spontaneous emission into vacuum modes of the electromagnetic field. This emission is called resonance fluorescence. Of particular interest are the properties of the emitted light. For a detailed discussion of resonance fluorescence, see for example [78.20, 31–33].

The far field at position $\boldsymbol{R}$ emitted by an atom at the origin is proportional to its dipole moment and can be expressed in terms of the dipole operators σ_+ and σ_- according to the relation [78.20]

$$\boldsymbol{E}^+(\boldsymbol{R}, t) = -\frac{\omega_0^2}{4\pi\epsilon_0 c^2 R^3} \frac{(\boldsymbol{d} \times \boldsymbol{R}) \times \boldsymbol{R}}{} \sigma_-(t - r/c) ,$$

$$\boldsymbol{E}^-(\boldsymbol{R}, t) = -\frac{\omega_0^2}{4\pi\epsilon_0 c^2 R^3} \frac{(\boldsymbol{d}^* \times \boldsymbol{R}) \times \boldsymbol{R}}{} \sigma_+(t - r/c) ,$$

(78.178)

where

$$\boldsymbol{d} = e\langle g|\boldsymbol{r}|e\rangle \qquad (78.179)$$

is the atomic dipole matrix element and the field operators $\boldsymbol{E}^+(\boldsymbol{R}, t)$ and $\boldsymbol{E}^-(\boldsymbol{R}, t)$ as well as the dipole operators $\sigma_+(t)$ and $\sigma_-(t)$ are in the Heisenberg picture. Knowledge of the operators $\sigma_+(t)$ and $\sigma_-(t)$ is therefore sufficient to study the properties of the emitted light in the far field.

78.13.1 Equations of Motion

The total Hamiltonian for the system reads

$$H_{\mathrm{sr}} = \frac{1}{2}\hbar\omega_0\sigma_z + \sum_i \hbar\omega_i \left(b_i^\dagger b_i + \frac{1}{2}\right)$$

$$+ \hbar \sum_i \left(g_i\sigma_- b_i^\dagger + g_i^*\sigma_+ b_i\right)$$

$$- \frac{1}{2}\left(\mathrm{d}\,\mathcal{E}^*\sigma_- \mathrm{e}^{i\omega_0 t} + d^*\,\mathcal{E}\,\sigma_+ \mathrm{e}^{-i\omega_0 t}\right) ,$$

(78.180)

where a resonant driving term has been added to the Hamiltonian (78.123). Here d is the projection of the dipole matrix element $e\langle g|\boldsymbol{r}|e\rangle$ onto the polarization vector of the driving field with an amplitude $\mathcal{E}$. The corresponding master equation in the interaction picture is

$$\dot{\rho} = -\mathrm{i}\,\frac{1}{2}\Omega_1 \left[\sigma_+ + \sigma_-, \rho\right]$$

$$+ \frac{1}{2}\gamma \left(2\sigma_- \rho\sigma_+ - \sigma_+\sigma_-\rho - \rho\sigma_+\sigma_-\right) , \quad (78.181)$$

where $\Omega_1 = -\mathcal{E}\,d^*/\hbar$ is the Rabi frequency associated with the driving field. The vacuum modes of the field are described by a thermal reservoir at zero temperature.

The equations of motion for the expectation values $\langle\sigma_+\rangle$, $\langle\sigma_-\rangle$, and $\langle\sigma_z\rangle$ are the optical Bloch equations with radiative damping (Chapt. 68) and are

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle\sigma_+\rangle = -\frac{\gamma}{2}\langle\sigma_+\rangle - i\frac{\Omega_1}{2}\langle\sigma_z\rangle ,$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle\sigma_-\rangle = -\frac{\gamma}{2}\langle\sigma_-\rangle + i\frac{\Omega_1}{2}\langle\sigma_z\rangle ,$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle\sigma_z\rangle = -\gamma\left(\langle\sigma_z\rangle + 1\right) - i\Omega_1\left(\langle\sigma_+\rangle - \langle\sigma_-\rangle\right) .$$

(78.182)

These expectation values determine the density operator (78.142) of the two-level atom. Because (78.182) are a system of linear differential equations for $\langle\sigma_+\rangle$, $\langle\sigma_-\rangle$, and $\langle\sigma_z\rangle$, they can be solved analytically. Furthermore, the quantum regression hypothesis allows one to calculate two-time correlation functions as shown in Sect. 78.9.

78.13.2 Intensity of Emitted Light

According to (78.52)) and (78.178), the intensity of the fluorescence light at position $\boldsymbol{R}$ is given by

$$I = \langle E^-(\boldsymbol{R}, t)E^+(\boldsymbol{R}, t)\rangle \propto \langle\sigma_+\sigma_-\rangle , \qquad (78.183)$$

and can be decomposed into two parts: the coherent intensity

$$I_{\mathrm{coh}} \propto \langle\sigma_+\rangle\langle\sigma_-\rangle \qquad (78.184)$$

originating from the mean motion of the dipole, and the incoherent intensity

$$I_{\text{inc}} \propto \langle \sigma_+ \sigma_- \rangle - \langle \sigma_+ \rangle \langle \sigma_- \rangle \, , \tag{78.185}$$

which is due to fluctuations of the dipole motion around its average value. The steady state intensities are

$$I_{\text{coh}} \propto \frac{\Omega_1^2 \gamma^2}{\left(\gamma^2 + 2\Omega_1^2 \right)^2} \, , \tag{78.186}$$

and

$$I_{\text{inc}} \propto \frac{2\Omega_1^4}{\left(\gamma^2 + 2\Omega_1^2 \right)^2} \, . \tag{78.187}$$

For weak laser intensities (Ω_1 small) the intensity of the fluorescence light is dominated by the coherent part whereas for high intensities (Ω_1 large) it is dominated by the incoherent part.

78.13.3 Spectrum of the Fluorescence Light

The Wiener–Khintchine theorem (78.54) allows one to express the steady state spectrum of the fluorescence light as the Fourier transform of the correlation function $\langle \sigma_+(\tau)\sigma_-(0) \rangle_{\text{ss}}$ in the form

$$S(\omega) = \frac{1}{2\pi} \int_0^\infty e^{-i\omega\tau} \langle E^-(\tau) E^+(0) \rangle_{\text{ss}} \, d\tau + \text{c.c.}$$

$$\propto \frac{1}{2\pi} \int_0^\infty e^{-i(\omega-\omega_0)\tau} \langle \sigma_+(\tau)\sigma_-(0) \rangle_{\text{ss}} \, d\tau + \text{c.c.} \tag{78.188}$$

Again it consists of two contributions: a coherent part $S_{\text{coh}}(\omega)$, and an incoherent part $S_{\text{inc}}(\omega)$. The coherent part is

$$S_{\text{coh}}(\omega) \propto \frac{\Omega_1^2 \gamma^2}{\left(\gamma^2 + 2\Omega_1^2 \right)^2} \, \delta(\omega - \omega_0) \, . \tag{78.189}$$

The incoherent part of the fluorescence light has two qualitatively different spectra. For $\Omega_1 < \gamma/4$, it has a single peak at ω_0, whereas it consists of three peaks for $\Omega_1 > \gamma/4$. For $\Omega_1 \gg \gamma/4$ it is given by

$$\begin{aligned} S_{\text{inc}}(\omega) \propto \frac{1}{2\pi\gamma} \Bigg(& \frac{(\gamma/2)^2}{(\omega-\omega_0)^2 + (\gamma/2)^2} \\ & + \frac{1}{3} \frac{(3\gamma/4)^2}{(\omega-\omega_0+\Omega_1)^2 + (3\gamma/4)^2} \\ & + \frac{1}{3} \frac{(3\gamma/4)^2}{(\omega-\omega_0-\Omega_1)^2 + (3\gamma/4)^2} \Bigg) \, . \end{aligned} \tag{78.190}$$

The central peak at $\omega = \omega_0$ has a width of $\gamma/2$ whereas the width of the two side peaks at $\omega = \omega_0 \pm \Omega_1$ is $3\gamma/4$. Their heights are one third of the height of the central peak. This spectrum was predicted by *Burshtein* [78.47] and *Mollow* [78.48] and experimentally confirmed by *Schuda* et al. [78.49], *Wu* et al. [78.50], and *Hartig* et al. [78.51].

This triplet can be explained in terms of the dressed states $|1, n\rangle$ and $|2, n\rangle$ introduced in Chapt. 68 (78.50). If the driving field is resonant with the atomic transition, these states have the energies

$$E_{1,n} = \hbar \left(n + \frac{1}{2} \right) \omega_0 - \hbar R_n \, ,$$

$$E_{2,n} = \hbar \left(n + \frac{1}{2} \right) \omega_0 - \hbar R_n \, , \tag{78.191}$$

(78.52). The energy differences between the allowed transitions are

$$\begin{aligned} E_{2,n} - E_{2,n-1} &= \hbar\omega_0 + \hbar R_n - \hbar R_{n-1} \approx \hbar\omega_0 \, , \\ E_{2,n} - E_{1,n-1} &= \hbar\omega_0 + \hbar R_n + \hbar R_{n-1} \approx \hbar\omega_0 + \hbar\Omega_1 \, , \\ E_{1,n} - E_{2,n-1} &= \hbar\omega_0 - \hbar R_n - \hbar R_{n-1} \approx \hbar\omega_0 - \hbar\Omega_1 \, , \\ E_{1,n} - E_{1,n-1} &= \hbar\omega_0 + \hbar R_n - \hbar R_{n-1} \approx \hbar\omega_0 \, , \end{aligned} \tag{78.192}$$

where we have made the approximations

$$R_n - R_{n-1} \approx 0 \, ,$$

$$R_n + R_{n+1} \approx 2g\sqrt{\bar{n}+1} \approx \Omega_1 \, . \tag{78.193}$$

This is a good approximation for an intense driving field which can approximated by a highly excited coherent state with an average photon number $\bar{n}$.

Figure 78.6 shows these energy levels and the allowed transition. Obviously, the transitions correspond to frequencies ω_0, $\omega_0 - \Omega_1$ and $\omega_0 + \Omega_1$. The dressed
Fig. 78.6 Energy level diagram of dressed states. The transition frequencies are ω_0, $\omega_0 - \Omega_1$ and $\omega_0 + \Omega_1$

state picture also explains the 2:1 ratio for the integrated intensities of the central peak and the side peak in (78.190).

78.13.4 Photon Correlations

In addition to the spectrum which is based on the correlation function $\langle E^-(\tau)E^+(0)\rangle_{ss}$ in Sect. 78.13.3, the second-order correlation function

$$
\begin{aligned}
G_{ss}^{(2)}(\tau) &= \langle E^-(0)E^-(\tau)E^+(\tau)E^+(0)\rangle_{ss} \\
&\propto \langle \sigma_+(0)\sigma_+(\tau)\sigma_-(\tau)\sigma_-(0)\rangle_{ss}
\end{aligned}
\tag{78.194}
$$

can be measured to gain more insight into the fluorescence light, see also Sect. 78.3.2. Experimentally this is done by measuring the joint probability for detecting a photon at time $t = 0$ and a subsequent photon at time $t = \tau$. Again the result can be obtained from the quantum regression hypothesis and reads

$$
\begin{aligned}
g^{(2)}(\tau) &= \frac{G_{ss}^{(2)}(\tau)}{|G_{ss}^{(1)}(0)|^2} \\
&= 1 - e^{-3\gamma\tau/4}\left(\cos\delta\tau + \frac{3\gamma}{4\delta}\sin\delta\tau\right),
\end{aligned}
\tag{78.195}
$$

where δ is given by

$$
\delta = \sqrt{\Omega_1^2 - \gamma^2/4}\,.
\tag{78.196}
$$

For $\tau = 0$, $g^{(2)}(0) = 0$, indicating a tendency of photons to be separated. This tendency is known as photon antibunching and was first predicted by *Carmichael* and *Walls* [78.52, 53] and experimentally verified by *Kimble* et al. [78.54, 55]. Photon antibunching of radiation emitted from a two-level atom has a simple explanation: After the atom has emitted a photon it is in the ground state and must first be excited again before it can emit another photon.

78.14 Recent Developments

This chapter has discussed the fundamentals of the quantized electromagnetic field and applications to the broad area of quantum optics. However, in the last eight years, quantum optics has blossomed in several new directions particularly in the key role it is playing in recent investigations of the fundamentals of quantum theory and related applications. In particular, the superposition principle (the bedrock of quantum mechanics), entanglement, the quantum-classical interface, and precision measurements have become very topical research areas, especially in respect to their relevance to quantum information processing.

78.14.1 Literature

During the last eight years, several books on quantum optics [78.56–62] have been published. These books cover the topics of this chapter to some extent and take into account recent developments. For an introduction to the rapidly evolving fields of quantum information processing, we refer the reader to Chapt. 81 and [78.63–65].

78.14.2 Field States

Recently, number states of the radiation field were observed in a cavity-QED experiment [78.66].

78.14.3 Reservoir Theory

New research topics, such as quantum information processing, rely on the superposition principle and entangled quantum states. Since these states are very sensitive to decoherence, reservoir theory has attracted a lot of interest in recent years. Furthermore, as discussed in [78.67–72], decoherence is the physical process by which the classical world emerges from its quantum underpinning.

Many investigations in this area involve the presence of a reservoir (heat-bath/environment) and master equations are a ubiquitous tool. The familiar master equations of quantum optics are in Lindblad form [78.73], which guarantees that the density matrix is always positive definite during time evolution. In the derivation of this equation [78.74, 75], rapidly oscillating terms are omitted by the method of coarse-graining in time; the high frequencies correspond to the oscillator frequency ω_0 and, in the usual weak coupling limit, $\omega_0 \gg \gamma$, where γ is a typical decay constant. This is the rotating wave approximation (Sect. 66.3.2).

We have referred to the equations obtained prior to coarse-graining in time as pre-master (or pre-Lindblad) equations [78.74,76], and such equations have been used extensively in other areas of physics [78.77, 78]; other authors have simply referred to them as master equations

but, to avoid confusion, we reserve the latter term for equations in Lindblad form. Pre-master equations, like the master equations, describe an approach to the equilibrium state. This equilibrium state is the same in either case [78.76], but with pre-master (non-Lindblad) equations the approach can be through non-physical states of negative probability. However, as recently demonstrated, pre-master equations have other advantages vis à vis master equations:

(a) they lead to the exact expression for the mean value of $x(t)$ (as obtained from the exact Langevin equation for the problem);

(b) they lead, in the classical limit ($\hbar \rightarrow 0$), to the familiar Fokker–Planck equation of classical probability; and

(c) the exact master equation [78.79–83] is for long times of pre-master form. However, the general expectation (based on the time dependence of the coefficients) that the exact master equation preserves positivity for all times has not been realized since Ford and O'Connell have recently shown that, even in high temperature regime, the density matrix is not necessarily positive [78.84].

In traditional quantum optics, the emphasis has been on long-time $\left(t \gg \gamma^{-1}\right)$ phenomena, for which the use of either master or pre-master equations is justified. However, they are both inadequate for dealing with short-time $\left(t \ll \gamma^{-1}\right)$ phenomena (as can be shown most simply by calculating the mean-square displacement, a key ingredient in decoherence calculations), which are of much recent interest. Thus, it is desirable to use exact master equations. In that respect, the exact master equation of *Hu* et al. [78.79, 80] for an oscillator is an arbitrary dissipative environment has proved to be a popular and useful tool for which an exact solution has now been obtained [78.83]. However, it should also be mentioned that the solution of the initial value quantum Langevin equation gives all the same information as the exact master equation, and in fact, the solutions of the former were used to obtain the solutions of the latter [78.83].

The familiar two-level atom master equation is, of course, similar in form to the usual Lindblad-type master equation for the oscillator. However, motivated in particular by the desire to study decoherence and other short time phenomena, an exact master equation was derived [78.85] to study the non-Markovian dynamics of a two-level atom interacting with the electromagnetic field.

In addition, motivated by the desire to study a driven oscillator, the usual two-level atom master equation was generalized to include the case of an external force field [78.86, 87]. This generalized equation was then used not only to obtain the familiar zero-temperature Burshtein–Mollow spectrum, but also the corresponding high temperature results. For strong resonant driving at high temperature, the same three-peaked structure was observed in the zero temperature case, but a much larger width was found. The analysis, following other investigations, used the Lax formula for calculating two-time correlation functions. This formula is not a "quantum regression theorem" as it is often designated (see also Sect. 78.9), but simply an approximation (which more resembles an Onsager classical regression theorem [78.88]) which works very well in the case of weak coupling and for frequencies near a resonant frequency, but not otherwise [78.86, 87].

In Sect. 78.6, we stressed the usefulness of quasi-probability distributions instead of the density matrix, with particular attention to the Wigner distribution. In particular, for simple Hamiltonians, we pointed out that the equation for the corresponding Wigner function has the form of a Fokker–Planck equation and we considered the explicit form describing the usual master equation. The more general equations associated with an exact master equation and their solution was the subject of [78.83] and interesting limits of that equation, including the pre-master equation for both momentum coupling and coordinate coupling were discussed at length in [78.89, 90]. In the case of two-level systems, it is not convenient to use quasi-probability distributions; instead, it is found that the preferred tool is the polarization vector [78.91]. Surprisingly, it has not been generally adopted by the quantum optics community although its usefulness in that context has been demonstrated recently in [78.86, 87].

79. Entangled Atoms and Fields: Cavity QED

Although the concept of a "free atom" is of use as a first approximation, a full quantum description of the interaction of atoms with an omnipresent electromagnetic radiation field is necessary for a proper account of spontaneous emission and radiative level shifts such as the Lamb shift (Chapt. 27). This chapter is concerned with the changes in the atom–field interaction that take place when the radiation field is modified by the presence of a cavity. An atom in the vicinity of a plane perfect mirror serves as an example of cavity quantum electrodynamics [79.1–5].

The primary focus in this chapter is the two extreme cases of weak coupling and strong coupling, as exemplified by spontaneous emission.

In the weak coupling regime, the coupling of an excited atom to a broad continuum of radiation modes leads to exponential decay (Fig. 79.1a), as first described by *Weisskopf* and *Wigner* [79.6]. Spontaneous emission may be enhanced or suppressed in structures such as waveguides or "bad" cavities. Cavities also introduce van der Waals forces and the subtle Casimir level shifts [79.7].

In the strong coupling regime, the excited atom is strongly coupled to an isolated resonant cavity mode. In the absence of damping, an oscillatory exchange of energy between the atom and the field replaces exponential decay (Fig. 79.1b) with a coherent evolution in time. Experimental investigations of these effects began [79.8] with the development of suitable resonators and techniques for producing atoms with long lived excited states and strong dipole transition moments.

79.1 Atoms and Fields

79.1.1 Atoms

The essential features of cavity QED are elucidated by the two-level model atom discussed in Chapts. 68,

69, 70, and 77 (see also [79.9]). A ground state $|g\rangle$ and an excited state $|e\rangle$ are coupled to the radiation field by a dipole interaction. Using the formal equivalence to a spin-1/2 system, the Pauli spin operators

are

$$\sigma_x = \sigma^\dagger + \sigma \,,$$
$$\sigma_y = -\mathrm{i}\left(\sigma^\dagger - \sigma\right) \,, \qquad (79.1)$$
$$\sigma_z = \sigma^\dagger\sigma - \sigma\sigma^\dagger = [\sigma^\dagger, \sigma] \,,$$

with $\sigma^\dagger = |e\rangle\langle g|$ and $\sigma = |g\rangle\langle e|$. The quadratures (out of phase components) of the atomic polarization are given by σ_x and σ_y, while σ_z is the occupation number difference. The free atom Hamiltonian is

$$\mathcal{H}_{\mathrm{atom}} = \frac{1}{2}\hbar\omega_0\sigma_z \,, \qquad (79.2)$$

where $\hbar\omega_0 = E_e - E_g$ is the transition energy.

79.1.2 Electromagnetic Fields

Classical Fields
Classical electromagnetic fields have longitudinal and transverse components:

$$\boldsymbol{E}(\boldsymbol{r}, t) = \boldsymbol{E}^{\mathrm{l}}(\boldsymbol{r}, t) + \boldsymbol{E}^{\mathrm{t}}(\boldsymbol{r}, t) \,. \qquad (79.3)$$

In the Coulomb gauge, the longitudinal part is the instantaneous electric field. The transverse part is the radiation

Fig. 79.1a–d *Upper row*: Excitation probability of an excited atom. (**a**) Exponential decay in free space or bad cavities in the weak coupling limit. (**b**) Oscillatory evolution in good cavities or in the strong coupling case. *Lower row:* The spectral signature of exponential decay is a Lorentzian line shape (**c**) while the so-called vacuum Rabi splitting (**d**) is observed in the strong coupling case

field which obeys the wave equation

$$\left(\nabla^2 - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right)\boldsymbol{E}^{\mathrm{t}}(\boldsymbol{r}, t) = \frac{1}{\epsilon_0 c^2}\frac{\partial}{\partial t}\boldsymbol{j}(\boldsymbol{r}, t) \,. \qquad (79.4)$$

In empty space, the driving current density $\boldsymbol{j}(\boldsymbol{r}, t)$ vanishes, and the field may be expanded in a set of orthogonal modes as

$$\boldsymbol{E}^{\mathrm{t}}(\boldsymbol{r}, t) = \sum_\mu E_\mu(t)\,\mathrm{e}^{-\mathrm{i}\omega_\mu r}\boldsymbol{u}_\mu(\boldsymbol{r}) + \mathrm{c.c.} \,, \qquad (79.5)$$

with slowly varying amplitudes $E_\mu(t)$. The spatial distributions $\boldsymbol{u}_\mu(\boldsymbol{r})$ obey the vector Helmholtz equation

$$\left[\nabla^2 + \left(\frac{\omega_\mu}{c}\right)^2\right]\boldsymbol{u}_\mu(\boldsymbol{r}, t) = 0 \,, \qquad (79.6)$$

depending on geometric boundary conditions as imposed by conductive or dielectric mirrors, waveguides, and resonators. In free space, plane wave solutions $\boldsymbol{u}_\mu(\boldsymbol{r}, t) = \boldsymbol{u}_\epsilon\,\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}$ have a continuous index $\mu = (\boldsymbol{k}, \epsilon)$ with wave vector $\boldsymbol{k}$ and an index ϵ for the two independent polarizations. The orthogonality relation

$$\frac{1}{V}\int_V \boldsymbol{u}_\mu \cdot \boldsymbol{u}_\nu^* \mathrm{d}^3\boldsymbol{r} = \delta_{\mu\nu} \qquad (79.7)$$

applies. For a closed cavity, V is the resonator volume. In waveguides and free space, an artificial boundary is introduced and then increased to infinity at the end of a calculation, such that the final results do not depend on V.

Quantum Fields
The quantum analog of the classical transverse field in (79.4) is obtained through a quantization of its harmonic modes leading to a number state expansion. Field operators obey standard commutation relations $[a_\mu, a_\nu^\dagger] = \delta_{\mu,\nu}$, and for a single mode with index μ, the amplitude E_μ in (79.5) is replaced by the corresponding operator

$$E_\mu(t) = \mathcal{E}_\mu a_\mu \mathrm{e}^{-\mathrm{i}\omega t} \,, \qquad E_\mu^\dagger(t) = \mathcal{E}_\mu{}^* a_\mu^\dagger \mathrm{e}^{\mathrm{i}\omega t} \,. \qquad (79.8)$$

The normalization factor $\mathcal{E}_\mu$ is chosen such that the energy difference between number states $|n\rangle_\mu$ and $|n+1\rangle_\mu$ in the volume V is $\hbar\omega_\mu$, giving

$$\mathcal{E}_\mu\mathcal{E}_\mu{}^\dagger = \frac{\hbar\omega_\mu}{2\epsilon_0 V} \,. \qquad (79.9)$$

The Hamiltonian of the free field is

$$\mathcal{H}_{\mathrm{Field}} = \sum_\mu \hbar\omega_\mu\left(a_\mu^\dagger a_\mu + \frac{1}{2}\right) \,. \qquad (79.10)$$

In the Coulomb gauge, the vector potential $\boldsymbol{A}(\boldsymbol{r})$ is related to the electric field $\boldsymbol{E} = -\partial \boldsymbol{A}/\partial t$ by

$$\boldsymbol{A}_\mu(\boldsymbol{r}, t) = -\frac{\mathcal{E}_\mu}{\omega_\mu}\left(a_\mu \, \mathrm{e}^{-\mathrm{i}\omega t} + a_\mu^\dagger \, \mathrm{e}^{\mathrm{i}\omega t}\right)\boldsymbol{u}_\mu(\boldsymbol{r}) \ . \tag{79.11}$$

The ground state $|0\rangle_\mu$ is called the vacuum state. While the expectation value $\langle n|\boldsymbol{E}|n\rangle = 0$ for a number state, the variance is not zero, since $\langle n|\boldsymbol{E}\boldsymbol{E}^*|n\rangle > 0$, giving rise to nonvanishing "fluctuations" of the free electromagnetic field.

Dipole Coupling of Fields and Atoms

The combined system of atoms and fields can be described by the product quantum states $|a, n\rangle$ of atom states $|a\rangle$ and field states $|n\rangle$. The interaction Hamiltonian $\mathcal{H}_I$ of the atom and the radiation field is given by (The A^2-term plays an important role in energy shifts and can only be neglected when radiative processes involving energy exchange are considered.)

$$\mathcal{H}_\mathrm{I} = -\frac{q}{m}\boldsymbol{p}\cdot\boldsymbol{A}(\boldsymbol{r}) + \frac{q^2}{2m}\boldsymbol{A}^2(\boldsymbol{r}) \ . \tag{79.12}$$

This interaction causes the atom to exchange energy with the radiation field. In the dipole approximation, the coupling strength is proportional to the component of the atomic dipole moment $\boldsymbol{d}_{eg} = q\langle e|\boldsymbol{r}_{eg}|g\rangle$ along the electric field, with coupling constant

$$g_\mu(\boldsymbol{r}) = |\boldsymbol{d}_{eg}\cdot\boldsymbol{u}_\mu(\boldsymbol{r})\mathcal{E}_\mu|/\hbar \ . \tag{79.13}$$

In the rotating wave approximation (RWA) (Chaps. 68, 69, and 70),

$$\mathcal{H}_\mathrm{RWA} = \sum_\mu \hbar \left(g_\mu \sigma^\dagger a_\mu + g_\mu^* a_\mu^\dagger \sigma\right) \ , \tag{79.14}$$

where we have used the atomic operators of (79.1).

In a continuous electromagnetic spectrum, the atom interacts with a large number of modes having quantum numbers μ, yielding exponential decay of an excited atomic level at the rate [79.6]

$$\Gamma_{eg} = \frac{2\pi}{\hbar^2}\sum_{\tilde{\mu}}\sum_{\boldsymbol{k}}\left|g_\mu\right|^2 \delta\left(\omega_\mu - \omega_0\right) \ . \tag{79.15}$$

Here we have separated the discrete ($\tilde{\mu}$) and the continuous part (wave vector $\boldsymbol{k}$) of the mode index μ. If g_μ (79.13) does not vary much across a narrow resonance, then

$$\Gamma_{eg} \simeq 2\pi \left|g_\mu(\omega_0)\right|^2 \sum_{\tilde{\mu}}\rho_{\tilde{\mu}}(\omega_0) \ . \tag{79.16}$$

The density of states corresponding to the continuous mode index $\boldsymbol{k}$ of dimension ν can be evaluated on a ν-dimensional fictitious volume $V^{(\nu)}$ as

$$\rho_{\tilde{\mu}} = \sum_{\boldsymbol{k}}\delta(\omega_{\tilde{\mu},\boldsymbol{k}} - \omega) \rightarrow \frac{V^{(\nu)}}{(2\pi)^\nu}\int_0^\infty \mathrm{d}^\nu k \, \delta(\omega_{\tilde{\mu},\boldsymbol{k}} - \omega) \ , \tag{79.17}$$

provided $\omega(\boldsymbol{k})$ is known, and by converting the sum (This is formally accomplished by taking the limit of $\Delta k = 2\pi/l$ for large l, where l is a linear dimension of an artificial resonator, and the resonator volume is $V = l^3$. If the relation between mode spacing Δk and geometric dimension is nonlinear in a more complex geometry, this analysis can be very complicated.) over plane wave vectors $\boldsymbol{k}$ into an integral.

The Rate of Spontaneous Emission

In free space $[\omega(\boldsymbol{k})^2 = (ck)^2]$, the sum in (79.16) contributes a factor of two, due to polarization, to the total density of states in free space, $\rho_\mathrm{free}(\omega) = V\omega^2/\pi^2 c^3$. When the vector coupling of atom and field (79.13) is replaced by its average in isotropic free space, that is, by 1/3, the result

$$\Gamma_{eg} = A_{eg} = \frac{e^2 r_{eg}^2 \omega^3}{3\pi\epsilon_0\hbar c^3} \tag{79.18}$$

is obtained for the decay rate A_{eg} as measured by the natural linewidth Γ_{eg}.

79.2 Weak Coupling in Cavity QED

The regime of weak cavity QED generally applies when an atom is coupled to a continuum of radiation modes. This is always the case with mirrors, waveguides, or bad cavities. The signatures of weak cavity QED are modifications of the rate of spontaneous emission, as well as the existence of van der Waals and Casimir forces. Formally, this regime is well described by perturbation theory.

79.2.1 Radiating Atoms in Waveguides

Within the continuous spectrum of a waveguide, radiative decay of an excited atomic level remains exponential, and Γ_{eg} may be determined as in the preceding section. We now consider the modifications of spontaneous decay in a parallel plate waveguide. Ac-

cording to (79.16), the theoretical problem is reduced to a geometric evaluation of mode densities. Between a pair of mirrors it is convenient to distinguish TE_{nk} and TM_{nk} modes, where n is the number of half waves across the gap of width d. The dispersion relation $\omega(\boldsymbol{k})$ reflects the discrete standing wave part $(n\pi/d)$ and a running wave part as in free space,

$$\omega_{n,\boldsymbol{k}}^2 = c^2 \left(|\boldsymbol{k}|^2 + n\pi/d\right)^2 \quad \begin{array}{l} n = 0, 1, 2, \dots \text{ TM} \\ n = 1, 2, \dots \quad \text{TE} . \end{array}$$

$$(79.19)$$

The average mode density $[\boldsymbol{du} = 1, (79.13)]$ is evaluated $[(79.17), \nu = 2]$ with an appropriate quantization volume containing the area of the plates, $V = Ad$, giving

$$\rho^{TE}(\omega) = \frac{\omega_c[\omega]}{2\omega_c^2}\rho_{free}(\omega_c) ,$$

$$\rho^{TM}(\omega) = \frac{\omega_c[\omega+1]}{2\omega_c^2}\rho_{free}(\omega_c) ,$$

$$(79.20)$$

where $[x]$ is the largest integer in x, and $\omega_c = \pi c/d$ gives the waveguide cutoff frequency. Below ω_c, the TE-mode density clearly vanishes and, with the pictorial notion of turning off the vacuum introduced by *Kleppner* [79.10], inhibition of radiative decay is obvious. Figure 79.2 shows the calculated mode density for a parallel plate waveguide. The decay rate can be calculated from (79.16), with the spatial variation of g_μ included. This configuration was used for the first experiments which showed the suppression of spontaneous emission in both the microwave and the near optical frequency domain [79.11, 12] with atomic beams.
Fig. 79.2 Modification of the average vacuum spectral density ($\rho^{TE} + \rho^{TM}$) in a parallel plate cavity (*thick line*) compared with free space (*thin line*)

79.2.2 Trapped Radiating Atoms and Their Mirror Images

Boundary conditions imposed by conductive surfaces may also be simulated by appropriately positioned image charges. Inspired by classical electrodynamics, this image charge model can be successfully used to determine the modifications of radiative properties in confined spaces. In the simplest case, an atom is interacting with its image produced by a plane mirror. Trapped atoms and ions allow one to control their relative position with respect to a mirror to distances below the wavelength of light. Hence they are ideal objects for studying the spatial dependence of the mirror induced modifications of their radiative properties. In an experiment with a single trapped ion (see Fig. 79.3), its radiation field was superposed onto its mirror image [79.13, 14], yielding a sinusoidal variation of both the spontaneous decay rate and the mirror induced level shift with excellent contrast.

79.2.3 Radiating Atoms in Resonators

Resonators

In a resonator, the electromagnetic spectrum is no longer continuous and the discrete mode structure can also be resolved experimentally. While a resonator is only weakly coupled to external electromagnetic fields, it still interacts with a large thermal reservoir through currents induced in its walls. The total damping rate is due to resistive losses in the walls (κ_{wall}) and also due to transmission at the radiation ports, $1/\tau_\mu = \kappa_\mu = \kappa_{wall} + \kappa_{out}$. An empty resonator stores energy for times

$$\tau_\mu = Q/\omega_\mu ,$$

$$(79.21)$$

and the power transmission spectrum is a Lorentzian with width $\Delta\omega_\mu = \omega_\mu/Q_\mu$. The index μ, for instance, represents the TE_{lm} and TM_{lm} modes of a "pillbox" microwave cavity, or the TEM_{klm} modes of a Fabry–Perot interferometer (Fig. 79.4).

When cavity damping remains strong, $\Gamma_\mu \gg \Gamma_{eg}$, the atomic radiation field is "immediately" absorbed and Weisskopf–Wigner perturbation theory remains valid. In this so-called bad cavity limit, resonator damping can be accounted for by an effective mode density of Lorentzian width $\Delta\omega_\mu$ for a single isolated mode,

$$\rho_\mu(\omega) = \frac{1}{\pi}\frac{\omega_\mu/2Q_\mu}{(\omega - \omega_\mu)^2 + (\omega_\mu/2Q_\mu)^2} .$$

$$(79.22)$$

Bad and Good Cavities

The modification of spontaneous decay is again calculated from (79.16). For an atomic dipole aligned

parallel to the mode polarization, and right at resonance, $\omega_\mu = \omega_0$, the enhancement of spontaneous emission is found to be proportional to the Q-value of a selected resonator mode:

$$\frac{\Gamma_{eg}^{\mathrm{cav}}}{\Gamma_{eg}^{\mathrm{free}}} = \frac{\rho_\mu |\boldsymbol{u}(\boldsymbol{r})|}{\rho_{\mathrm{free}}} = \frac{3Q\lambda^3}{4\pi^2 V} |\boldsymbol{u}(r)|^2 = \frac{3Q\lambda^3}{4\pi^2 V_{\mathrm{eff}}} ,$$

(79.23)

where the effective mode volume is $V_{\mathrm{eff}} = V/|u(\boldsymbol{r})|^2$. The lowest possible value $V_{\mathrm{eff}} \simeq \lambda^3$ is obtained for ground modes of a closed resonator. For an atom located at the waist of an open Fabry–Perot cavity with length L, it is much larger. Special limiting cases for concentric and confocal cavities are $V_{\mathrm{eff}}^{\mathrm{conc}} = \lambda^2 L (R/D)$ and $V_{\mathrm{eff}}^{\mathrm{conf}} = \lambda L^2/2\pi$, respectively, where (R/D) gives the ratio of mirror radius to cavity diameter.

At resonance, the atomic decay rate Γ_μ grows with Q_μ, whereas the resonator damping time constant κ_μ is reduced. Eventually, the energy of the atomic radiation field is stored for such a long time that reabsorption becomes possible. Perturbative Weisskopf–Wigner the-

ory is no longer valid in this good cavity limit, which is separated from the regime of bad cavities by the more formal condition

$$\Gamma_{eg}^{\mathrm{cav}} > \kappa_\mu .$$

(79.24)

The strong coupling case is considered explicitly in Sect. 79.3.

Antenna Patterns

Since the reflected radiation field of an atomic radiator is perfectly coherent with the source field, the combined radiation pattern modifies the usual dipole distribution of a radiating atom. The new radiation pattern can be understood in terms of antenna arrays [79.15]. For a single atomic dipole in front of a reflecting mirror for example, one finds a quadrupole type pattern due to the superposition of a second, coherent image antenna. In some of the earliest experimental investigations on radiating molecules in cavities, modifications of the radiation pattern were observed [79.16].

79.2.4 Radiative Shifts and Forces

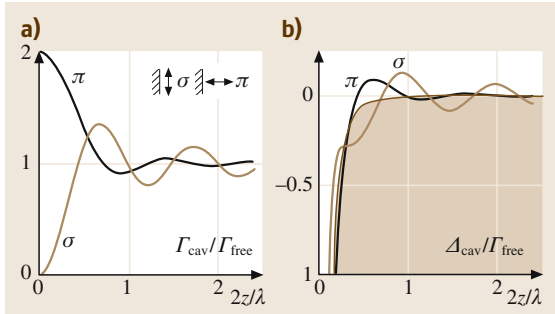
When the radiation field of an atom is reflected back onto its source, an energy or radiative shift is caused by the corresponding self polarization energy. An atom in
Fig. 79.3 Sinusoidal variation of the $\lambda = 493$ nm spontaneous emission rate of a single trapped Ba ion caused by self-interference from a retroreflecting mirror. The experimental arrangement is sketched at the bottom [79.13]
Fig. 79.4a,b Two frequently used resonator types for cavity QED: (**a**) Open Fabry–Perot optical cavity. (**b**) Closed "pillbox" microwave cavity


Fig. 79.5 (a) Normalized rate of modified spontaneous emission in the vicinity of a perfectly reflecting wall for σ and π orientation of the radiating dipole. **(b)** Corresponding energy shift of the resonance frequency. *Shaded area* indicates contribution of static van der Waals interaction

the vicinity of a plane mirror (Fig. 79.5) again makes a simple model system. Since the energy shift depends on the atom wall separation z, it is equivalent to a dipole force $\boldsymbol{F}_{\mathrm{dip}}$ whose details depend on the role of retardation. Here we distinguish between the two cases where no radiation energy is exchanged between the atom and the field (van der Waals, Casimir forces) and where the atomic radiation causes forces by self-interference.

The Unretarded Limit: van der Waals Forces

When the radiative round trip time $t_{\mathrm{r}} = 2z/c$ is short compared with the characteristic atomic revolution period $2\pi/\omega_{\mathrm{eg}}$, retardation is not important. In this quasistatic limit, van der Waals energy shifts for decaying atomic dipoles vary as z^{-3} with the atom–wall separation. Such a shift is also present for a nonradiating atom in its ground state. In perturbation theory, the van der Waals energy shift of an atomic level $|a\rangle$ is

$$\Delta_{\mathrm{vdW}} = -\frac{\langle a|q^2\left[(\boldsymbol{d}^2 \cdot \widehat{\boldsymbol{x}}_{\mathrm{t}})^2 + 2(\boldsymbol{d}^2 \cdot \widehat{\boldsymbol{z}})^2\right]|a\rangle}{64\pi\epsilon_0 z^3} \ .$$

$$(79.25)$$

Since the van der Waals force is anisotropic for electronic components parallel ($\widehat{\boldsymbol{z}}$) and perpendicular ($\widehat{\boldsymbol{x}}_{\mathrm{t}}$) to the mirror normal, the degeneracy of magnetic sublevels in an atom is lifted near a surface. The total energy shift is $\approx 1\,\mathrm{kHz}$ for a ground state atom at $1\,\mu\mathrm{m}$ separation, and very difficult to detect. However, the energy shifts grow as n^4 since the transition dipole moment scales as n^2. With Rydberg atoms, van der Waals energy shifts have been successfully observed in spectroscopic experiments [79.17].

The Retarded Limit: Casimir Forces

At large separation, retardation becomes relevant, since the contributions of individual atomic oscillation frequencies in (79.25) cancel by dephasing, thus reducing the Δ_{vdW}. A residual Casimir–Polder [79.18] shift may be interpreted as the polarization energy of a slowly fluctuating field with squared amplitude $\langle\mathcal{E}^2\rangle = 3\hbar c/64\epsilon_0 z^4$ originating from the vacuum field noise

$$\Delta_{\mathrm{CP}} = -\frac{1}{4\pi\epsilon_0}\frac{3\hbar c\alpha_{\mathrm{st}}}{8\pi z^4} \ ,$$

$$(79.26)$$

where α_{st} is the static electric polarizability. The vacuum field noise Δ_{CP} replaces Δ_{vdW} at distances larger than characteristic wavelengths, and is even smaller. Only indirect observations have been possible to date, relying on a deflection of polarizable atoms by this force [79.19, 20]. The Casimir–Polder force can also be regarded as an ultimate, cavity induced consequence of the mechanical action of light on atoms [79.21]. It is an example of the conservative and dispersive dipole force which is even capable of binding a polarizable atom to a cavity [79.22].

Radiative Self–Interference Forces

Spontaneous emission of atoms in the vicinity of a reflecting wall also provides an example of cavity induced modification of the dissipative type of light forces, or radiation pressure. If the returning field is reabsorbed, the spontaneous emission rate is reduced and a recoil force directed away from the mirror is exerted. If the returning radiation field causes enhanced decay, a recoil towards the mirror occurs due to stimulated emission.

If the photon is detected at some angle with respect to the normal vector connecting the atom with the mirror surface, two paths for the photon are possible: It can reach a detector directly, or following a reflection off the wall. At small atom–mirror separation these paths are indistinguishable, the atom is thus left in a superposition of two recoil momentum states.

79.2.5 Experiments on Weak Coupling

Perhaps the most dramatic experiment in weak coupling cavity QED is the total suppression of spontaneous emission. For the experiments which have been carried out with Rydberg atoms and for a low-lying near infrared atomic transition [79.11, 12], it is essential to prepare atoms in a single decay channel. In addition, the atoms must be oriented in such a way that they are only coupled to a single decay mode (see the model waveguide

in Fig. 79.4). This may be interpreted as an anisotropy of the electromagnetic vacuum, or as a specific antenna pattern.

An important problem in detecting the modification of radiative properties – changes in emission rates as well as radiative shifts – arises from their inhomogeneity due to the dependence on atom–wall separation. This difficulty has been overcome by controlling the atom–wall separation at microscopic distances through light forces [79.17], or by using well localized trapped ions [79.13, 14]. Furthermore, spectroscopic techniques that are only sensitive to a thin layer of surface atoms [79.23] have been used to clearly detect van der Waals shifts.

An atom emitting a radiation field in the vicinity of a reflecting wall will experience an additional dipole optical force caused by its radiation field. This force has been observed as a modification of the trapping force holding an ion at a fixed position with respect to the reflector [79.24].

Conceptually most attractive and experimentally most difficult to detect is the elusive Casimir interaction. Only for atomic ground states is this effect observable, free from other much larger shifts. The influence of the corresponding Casimir force on atomic motion has been observed in a variant of a scattering experiment, confirming the existence of this force in neutral atoms [79.19, 20].

The success of this experiment shows that spectroscopic techniques involving the exchange of photons are not suitable for the Casimir problem. A notable exception could be Raman spectroscopy of the magnetic substructure in the vicinity of a surface. In general, scattering or atomic interferometry experiments are more promising methods. The experiment by *Brune* et al. [79.25] may be interpreted in this way.

79.2.6 Cavity QED and Dielectrics

There are two variants of dielectric materials employed to study light-matter interaction in confined space: Conventional materials such as glass or sapphire, and artificial materials called photonic materials or metamaterials.

While dielectric materials are theoretically more difficult to treat than perfect mirrors, since the radiation at least partially enters the medium, they have a similar influence on radiative decay processes. One new aspect is, however, the coupling of atomic excitations to excitations of the medium, which was observed for the case of a surface-polariton in [79.26].

Cavities with dimensions comparable to the wavelength promise the most dramatic modification of radiative atomic properties, but micrometer sized cavities for optical frequencies with highly reflecting walls are difficult to manufacture. So-called whispering gallery modes of spherical microcavities [79.27] have been intensely studied, but no simple way of coupling atoms to these resonator modes has been found yet.

On the other hand, dielectric materials with a periodic modulation of the index of refraction may exhibit photonic bandgaps in analogy with electronic bandgaps in periodic crystals [79.28, 29]. Electronic phenomena of solid state physics can then be transferred to photons. For example, excited states of a crystal dopant or a quantum dot cannot radiate into a photonic bandgap, the radiation field cannot propagate, and the excitation energy remains localized. The bandgap behaves like an empty resonator, and if a resonator structure is integrated into the device, the regime of strong coupling [79.30, 31] can be achieved with such photonic structures. An overview of suitable systems can be found in [79.32].

79.3 Strong Coupling in Cavity QED

Strong coupling of atoms and fields is realized in a good cavity when $\Gamma_\mu < \Gamma_{eg}$ (79.24). The Hilbert space of the combined system is then the product space of a single two-level atom and the countable set of Fock-states of the field,

$$\mathcal{H} = \mathcal{H}_{\text{atom}} \otimes \mathcal{H}_{\text{field}} \,, \tag{79.27}$$

which is spanned by the states

$$|n; a\rangle = |n\rangle |a\rangle \,. \tag{79.28}$$

The interaction of a single cavity mode with an isolated atomic resonance is now characterized by the Rabi nutation frequency, which gives the exchange frequency of the energy between atom and field. For an amplitude $\mathcal{E}$ corresponding to n photons,

$$\Omega(n) = g_\mu \sqrt{n+1} \,. \tag{79.29}$$

This is the simplest possible situation of a strongly coupled atom–field system. The new energy eigenvectors are conveniently expressed in the dressed atom

model [79.33]:

$$|+, n\rangle = \cos\theta |g, n+1\rangle + \sin\theta |e, n\rangle \,,$$
$$|-, n\rangle = -\sin\theta |g, n+1\rangle + \cos\theta |e, n\rangle \,, \qquad (79.30)$$

with $\tan 2\theta = 2g_\mu \sqrt{n+1}/(\omega_0 - \omega_\mu)$. The separate energy structures of free atom and empty resonator are now replaced by the combined system of Fig. 79.6. At resonance, the new eigenstates are separated by $2\hbar\Omega_R$, where $\Omega_R = g_\mu$ is the vacuum Rabi frequency.

79.4 Strong Coupling in Experiments

In order to achieve strong coupling experimentally, it is necessary to use a high-Q resonator in combination with a small effective mode volume. This condition was first realized for ground modes of a closed microwave cavity [79.8], and later also for open cavity optical resonators (Fig. 79.6) [79.34]. It is interesting to control the interaction time of the atoms with the cavity field. In earlier experiments, this was typically achieved by selecting the passage time for an atom transiting the cavity. The advancement of atom trapping methods has also led to the observation of a truly one-atom laser at optical frequencies [79.35].

More recently, this situation has also been realized for artificial atoms including superconducting systems [79.36, 37] and quantum dots [79.30, 31].

79.4.1 Rydberg Atoms and Microwave Cavities

At microwave frequencies, very low loss superconducting niobium cavities are available with $Q \approx 10^{10}$. Resonator frequencies are typically several tens of GHz and can be matched by atomic dipole transitions between two highly excited Rydberg states. By selective field ionization, the excitation level of Rydberg atoms can be detected, and hence it is possible to measure whether a transition between the levels involved has occurred. The efficiency of this method approaches unity, so that experiments can be performed at the single atom level. The interaction or transit time T is usually much shorter than the lifetime τ_{Ry} of the Rydberg states involved. For this reason, circular Rydberg states with quantum numbers $l = m = n - 1$ are particularly suitable.

Rydberg atoms [79.38] are prepared in an atomic beam, selectively excited to an upper level, and then sent through a microwave cavity where the upper and lower levels are coupled by the electromagnetic field. If the atom is detected in the lower of the coupled levels as it leaves the resonator, the excitation energy has been stored in the resonator field. Thus the evolution of the resonator field is recorded as a function of the atomic interaction.

A microwave cavity in interaction with a single or a few Rydberg atoms is called a micromaser (formerly a one atom maser) [79.8]. The experimental conditions may be summarized as

$$g_\mu > 1/T > 1/\tau_{Ry} > \kappa_\mu \,. \qquad (79.31)$$

79.4.2 Strong Coupling in Open Optical Cavities

At optical wavelengths, a cavity with small V_{eff} in (79.23) is clearly more difficult to construct than at centimeter wavelengths. However, dielectric coatings are now available which allow very low damping rates ω_μ/Q_μ for optical cavities. Very high finesse $\mathcal{F} \simeq 10^7$ (which is a more convenient measure for the damping rate of an optical Fabry–Perot interferometer) has been achieved. By reducing the volume of such a high-Q cavity mode, strong coupling of
Fig. 79.6a,b Level diagram for the combined states of noninteracting atoms and fields (**a**) which are degenerate at resonance. Degeneracy is lifted by strong coupling of atoms and fields (**b**) yielding new "dressed" eigenstates

atoms and fields at optical frequencies has been demonstrated [79.34].

In open structures, the atoms can still decay into the continuum states with a rate γ. Therefore the condition for strong coupling in such systems is usually given as

$$\frac{g_\mu^2}{\kappa_\mu \gamma} > 1 . \tag{79.32}$$

79.5 Microscopic Masers and Lasers

In a microscopic laser, simple atoms are strongly coupled to a single mode of a resonant or near resonant radiation field. Collecting atomic and field operators from (79.2), (79.10), and (79.14), this situation is described by the Jaynes–Cummings model Hamiltonian [79.39, 40]

$$\begin{aligned}
\mathcal{H}_{JC} &= \mathcal{H}_{atom} + \mathcal{H}_{field} + \mathcal{H}_{RWA} \\
&= \frac{1}{2}\hbar\omega_0 \sigma_z + \hbar\omega_\mu \left(a_\mu^\dagger a_\mu + \frac{1}{2}\right) \\
&\quad + \hbar g_\mu (\sigma^\dagger a_\mu + a_\mu^\dagger \sigma) .
\end{aligned} \tag{79.33}$$

79.5.1 The Jaynes–Cummings Model

The Jaynes–Cummings model (79.33) represents the most basic and, at the same time, the most informative model of strong coupling in quantum optics. It consists of a single two-level atom interacting with a single mode of the quantized cavity field. The time evolution of the system is determined by

$$i\hbar \frac{\partial \psi}{\partial t} = H\psi . \tag{79.34}$$

This model can be solved exactly due to the existence of the additional constant of motion

$$N = a^\dagger a + \sigma_z + 1 , \tag{79.35}$$

i.e., conservation of the "number of excitations". Its eigenvalues are the integers N which are twofold degenerate except for $N = 0$. The simultaneous eigenstates of H and N are the pairs of dressed states defined in (79.30) which are not degenerate with respect to the energy H. The initial state problem corresponding to (79.34) is solved by elementary methods in terms of the expansion

$$|\Psi(t)\rangle = \sum_{n=0}^{\infty} \sum_{j=1}^{2} C_n^j(t)|n, j\rangle , \tag{79.36}$$

where the expansion coefficients are

$$\begin{aligned}
C_n^1(t) &= \left(C_n^1(0)\left\{\cos[\Omega(n)t] - i\frac{\delta}{2\Omega(n)}\sin[\Omega(n)t]\right\}\right. \\
&\quad \left. - i\frac{\sqrt{n}g_\mu}{\Omega(n)}C_{n-1}^2(0)\sin[\Omega(n)t]\right) \\
&\quad \times \exp\left[-i\omega_\mu\left(n - \frac{1}{2}\right)t\right] \tag{79.37}
\end{aligned}$$

and

$$\begin{aligned}
C_n^2(t) &= \left(C_n^2(0)\left\{\cos[\Omega(n+1)t]\right.\right. \\
&\quad \left. + i\frac{\delta}{2\Omega(n+1)}\sin[\Omega(n+1)t]\right\} \\
&\quad \left. - i\frac{g_\mu\sqrt{n+1}}{\Omega(n+1)}C_{n+1}^1(0)\sin[\Omega(n+1)t]\right) \\
&\quad \times \exp\left[-i\omega_\mu\left(n + \frac{1}{2}\right)t\right] , \tag{79.38}
\end{aligned}$$

with $\delta = \omega_\mu - \omega_0$ the detuning between the atom and cavity and $\Omega(n) = \frac{1}{2}(\delta^2 + 4g_\mu^2 n)^{1/2}$ is the generalized Rabi frequency. The coefficients $C_n^j(0)$ are determined by the initial preparation of atom and cavity mode. The result simplifies considerably for $\delta = 0$ to

$$\begin{aligned}
|\Psi(t)\rangle &= \sum_{m=0}^{\infty} \left\{C_m^1(0)\,e^{-i\omega_\mu(m-1/2)t}\right. \\
&\quad \times \left[\cos\left(g_\mu\sqrt{m}t\right)|m; 1\rangle\right. \\
&\quad \left. - i\sin\left(g_\mu\sqrt{m}\,t\right)|m-1; 2\rangle\right] \\
&\quad + C_m^2(0)\,e^{-i\omega_m u(m+1/2)t} \\
&\quad \times \left[\cos\left(g_\mu\sqrt{m+1}\,t\right)|m; 2\rangle\right. \\
&\quad \left.\left. - i\sin\left(g_\mu\sqrt{m+1}t\right)|m+1; 1\rangle\right]\right\} . \tag{79.39}
\end{aligned}$$

The coefficients $C_n^j(0)$ represent any initial state of the system, from uncorrelated product states to entangled states of atom and field. There exist numerous generalizations of this model which include more atomic levels and several coherent fields.

79.5.2 Fock States, Coherent States and Thermal States

We now illustrate the properties of the Jaynes–Cummings model by specifying the initial state. Assume that the atom and field are brought into contact at time $t = 0$ and that all correlations that might exist due to previous interactions are suppressed.

Rabi Oscillations

If the atom is initially in the excited state and the field contains precisely m quanta, then

$$C_n^j(t = 0) = \delta_{n,m}\delta_{j,2} . \tag{79.40}$$

The solution of (79.34) assumes the form

$$|\Psi(t)\rangle = e^{-i\omega_\mu(m+1/2)t}\big[\cos\big(g_\mu\sqrt{m+1}\,t\big)|m; 2\rangle \\ - i\sin\big(g_\mu\sqrt{m+1}\,t\big)|m+1; 1\rangle\big] . \tag{79.41}$$

The occupation probabilities of the atomic states evolve in time according to

$$n_2(t) = \langle\Psi(t)|2\rangle\langle 2|\Psi(t)\rangle = \cos^2\big(g_\mu\sqrt{m+1}\,t\big) , \tag{79.42}$$

$$n_1(t) = \langle\Psi(t)|1\rangle\langle 1|\Psi(t)\rangle = \sin^2\big(g_\mu\sqrt{m+1}\,t\big) . \tag{79.43}$$

The photon number and its variance are

$$\langle n(t)\rangle = \big\langle\Psi(t)a^\dagger a\Psi(t)\big\rangle = m + \sin^2\big(g_\mu\sqrt{m+1}\,t\big) , \tag{79.44}$$

$$\langle\Delta^2 n\rangle = \big\langle\Psi(t)\big(a^\dagger a - \langle a^\dagger a\rangle\big)^2\Psi(t)\big\rangle \\ = \frac{\sin^2\big(2g_\mu\sqrt{m+1}\,t\big)}{4} . \tag{79.45}$$

In the limit of large m, $g_\mu\sqrt{m+1}$ is proportional to the field amplitude and the classical Rabi oscillations in a resonant field are recovered. The nonclassical features of the states are characterized by Mandel's parameter

$$Q_M = \frac{\langle\Delta^2 n\rangle - \langle n\rangle}{\langle n\rangle} \geq -1 . \tag{79.46}$$

For the present example,

$$Q_M = -1 + \frac{1}{4}\frac{\sin^2\big(2g_\mu\sqrt{m+1}\,t\big)}{m + \sin^2\big(g_\mu\sqrt{m+1}\,t\big)} . \tag{79.47}$$

$Q_M \geq 0$ indicates the classical regime, while $Q \leq 0$ can only be reached by a quantum process.

The Coherent State

Consider the case where the field is initially prepared in a coherent state

$$|\alpha\rangle = \exp\big(\alpha a^\dagger - \alpha^* a\big)|0\rangle = e^{-|\alpha|^2/2}\sum_{n=0}^\infty \frac{\alpha^n}{\sqrt{n!}}|n\rangle , \tag{79.48}$$

while the atom starts from the excited state

$$C_n^j(0) = e^{-|\alpha|^2/2}\frac{|\alpha|^n}{\sqrt{n!}}\delta_{j,2} . \tag{79.49}$$

In this case, the general solution specializes to

$$|\Psi(t)\rangle = \sum_{n=0}^\infty \frac{\alpha^n}{\sqrt{n!}} e^{-i\omega(n+1/2)t} e^{-|\alpha|^2/2} \\ \times\big[\cos\big(g_\mu\sqrt{n+1}\,t\big)|n; 2\rangle \\ - i\sin\big(g_\mu\sqrt{n+1}\,t\big)|n+1; 1\rangle\big] , \tag{79.50}$$

and the occupation probability of the excited state is

$$n_2(t) = \frac{1}{2}\left[1 + \sum_{n=0}^\infty \frac{|\alpha|^{2n}}{n!} e^{-|\alpha|^2}\cos\big(2g_\mu\sqrt{n+1}\,t\big)\right] . \tag{79.51}$$

From here, detailed quantitative results can only be obtained by numerical methods [79.41]. However, if the coherent state contains a large number of photons $|\alpha|^2 \gg 1$, the essential dynamics can be determined by elementary methods. Initially, the population oscillates with the Rabi frequency $\Omega_1 \approx g_\mu|\alpha|$, which is proportional to the average amplitude of the field, as expected from its classical counterpart. With increasing time, the coherent oscillations tend to cancel due to the destructive interference of the different Rabi frequencies in the sum:

$$n_2(t) = \frac{1}{2}\left[1 + \cos(2g_\mu|\alpha|\,t) e^{-(gt)^2/2}\right] . \tag{79.52}$$

However, strictly aperiodic relaxation of $n_2(t)$ is impossible since the exact expressions, (79.36) and (79.37), represent a quasiperiodic function which, given enough time, approaches its initial value with arbitrary accuracy.

For short times, the oscillating terms in the sum cancel each other due to the slow evolution of their frequency with n. However, consecutive terms interfere constructively for larger times t_r, such that the phases satisfy

$$\phi_{n+1}(t_r) - \phi_n(t_r) = 2\pi . \tag{79.53}$$

For $|\alpha|^2 \gg 1$, the increment of the arguments is

$$\phi_{n+1} - \phi_n = g_\mu t_r/|\alpha| , \tag{79.54}$$

and therefore the first revival of the Rabi oscillations occurs approximately at $t_r = \pi|\alpha|/g_\mu$. A clear distinction of Rabi oscillation, collapses, and revivals requires a clear separation of the three time scales

$$t_1 \ll t_2 \ll t_3 ,\tag{79.55}$$

where $t_1 \approx (g_\mu|\alpha|)^{-1}$ for Rabi oscillation, $t_2 \approx g_\mu^{-1}$ for collapse, and $t_3 \approx |\alpha|/g_\mu$ for revival.

The typical features of the transient evolution starting from a coherent state are shown in Fig. 79.7. With time increasing even further, revivals of higher order occur which spread in time, and finally can no longer be separated order by order.

The Thermal State

Consider a microwave resonator brought into thermal contact with a reservoir, inducing loss on a time scale κ^{-1} and thermal excitation. The dissipative time evolution is described by the master equation

$$\begin{aligned}
\dot{\rho} &= (L_0 + L)\rho \\
&\equiv i[H, \rho]/\hbar + \kappa(n_{\text{th}}+1)\{[a, \rho a^\dagger] + [a\rho, a^\dagger]\} \\
&\quad + \kappa n_{\text{th}}\{[a^\dagger, \rho a] + [a^\dagger \rho, a]\} ,
\end{aligned}\tag{79.56}$$

where $n_{\text{th}} = [\exp(\beta\hbar\omega) - 1]^{-1}$, at $T = k_B\beta^{-1}$, is the equilibrium population of the cavity mode, L_0 symbolizes the unitary evolution according to the Jaynes–Cummings dynamics and L is a dissipation term.

The solution of this model can be expressed in terms of an eigenoperator expansion of the equation

$$L\rho = -\lambda\rho .\tag{79.57}$$

The eigenvalues λ that determine the relaxation rates, as well as the eigenoperators, are known in closed form for
Fig. 79.7 Rabi oscillations, dephasing, and quantum revival

the case of vanishing temperature [79.42]. Since energy is exchanged between the nondecaying atom and the decaying cavity mode, cavity damping is modified in a characteristic way due to the presence of the atom. The technical details can be found in [79.43].

79.5.3 Vacuum Splitting

In the classical case, the eigenvalues of the interaction free Hamiltonian are degenerate at resonance. The atom–field interaction splits the eigenvalues and determines the Rabi frequency of oscillation between the two states. One consequence is the existence of side bands in the resonance fluorescence spectrum [79.44]. In the quantum case, the field itself is treated as a quantized dynamical variable determined from a self-consistent solution for the complete system of atom plus field. The vacuum Rabi frequency $\Omega_{\text{vac}} = g_\mu$ remains finite, and accounts for the spontaneous emission of radiation from an excited atom placed in a vacuum. In the limiting case of a single atom interacting with the quantized field, the photon number n can only change by ± 1, and the population oscillates with the frequency $\Omega(n)$ given by (79.29). For an ensemble of N atoms, n can in principle change by up to $\pm N$. However, if the field and atoms are only weakly excited, the collective frequency of the ensemble is determined by the linearized Maxwell–Bloch equations. The eigenfrequencies are given by

$$\lambda^\pm = \frac{1}{2}\left[i(\gamma_\perp + \kappa) \pm \sqrt{4g_\mu^2 N - (\gamma_\perp - \kappa)^2}\right] ,\tag{79.58}$$

where $\gamma_\perp^{-1}$ is the phase relaxation time of the atom and κ^{-1} the decay time of the resonator. This is the polariton dispersion relation in the neighborhood of the polariton gap. The spectral transmission

$$T(\omega) = T_0\left|\frac{\kappa[\gamma + i(\omega_0 - \omega)]}{(\omega - \lambda^+)(\omega - \lambda^-)}\right|^2\tag{79.59}$$

of an optical cavity containing a resonant atomic ensemble of N atoms reveals the internal dynamics of the coupled system and a splitting of the resonance line occurs. T_0 is the peak transmission of the empty cavity. The splitting increases either with the number of photons, approaching $\sqrt{n+1}$ in the presence of a single atom, or with the number of atoms, approaching $\sqrt{N}$ in the resonator when the field is weak. The latter case is demonstrated in Fig. 79.8 [79.34] for an optical resonator with $1-10$ atoms interacting with a field that contains, on average, much less than a single photon.

79.6 Micromasers

Sustained oscillations of a cavity mode in a microwave resonator can be achieved by a weak beam of Rydberg atoms excited to the upper level of a resonant transition. For a cavity with a $Q \approx 10^{10}$, much less than a single atom at a time, on average, suffices to balance the cavity losses. Operation of a single atom maser has been demonstrated [79.8]. The atoms enter the cavity at random times, according to the Poisson statistics of a thermal beam, and interact with the field only for a limited time. In order to restrict the fluctuations of the atomic transit time, the velocity spread is reduced. This is achieved either by Fizeau chopping techniques, or by making use of Doppler velocity selection in the initial laser excitation process. Since most of the time no atom is present, it is natural to separate the dynamics into two parts [79.45]:

1. For the short time while an atom is present, the state evolves according to the Jaynes–Cummings dynamics, where H is defined in (79.33),

$$\dot{\rho}(t) = \mathrm{i}[H, \rho]/\hbar , \tag{79.60}$$

and damping can safely be neglected. The formal solution is abbreviated by $\rho(t) = F(t - t_0)\rho(t_0)$.

2. During the time interval between successive atoms, the cavity field relaxes freely toward the thermal equilibrium according to (79.56) with $L_0 = 0$:

$$\dot{\rho}(t) = L\rho , \tag{79.61}$$

with the formal solution $\rho(t) = \exp[L(t - t_0)]\rho(t_0)$.

The time development of the micromaser therefore consists of an alternating sequence of unitary $F(t)$ and dissipative $\mathrm{e}^{(Lt)}$ evolutions. Atoms enter the cavity one by one at random times t_i. Until the next atom enters at time t_{i+1}, the evolution t_i is given by

$$\rho(t_{i+1}) = \exp(Lt_p)F(\tau)\rho(t_i) , \tag{79.62}$$

where $t_p = t_{i+1} - t_i - \tau$, and τ is the transit time. If $\tau \ll t_{i+1} - t_i$ on average, then $t_p \approx t_{i+1} - t_i$. After averaging (79.62) over the Poisson distribution $P(t) = R \exp(-Rt_p)$ for t_p, where R is the injection rate, the mean propagator from atom to atom is

$$\langle \rho(t_{i+1}) \rangle = \frac{R}{R - L} F(\tau) \langle \rho(t_i) \rangle . \tag{79.63}$$

After excitation, the reduced density matrix of the field alone becomes diagonal after several relaxation times κ^{-1}:

$$\langle n | \mathrm{Tr}_{\mathrm{atom}}(\rho) | m \rangle = P_n \delta_{n,m} . \tag{79.64}$$

Due to the continuous injection of atoms, the field never becomes time independent, but may relax toward a stroboscopic state defined by

$$\langle \rho(t_{i+1}) \rangle = \langle \rho(t_i) \rangle . \tag{79.65}$$

The state of the cavity field can be determined in closed form by iteration:

$$P_n = N \prod_{k=1}^{n} \frac{n_{\mathrm{th}}\kappa + A_k}{(n_{\mathrm{th}} + 1)\kappa} , \tag{79.66}$$

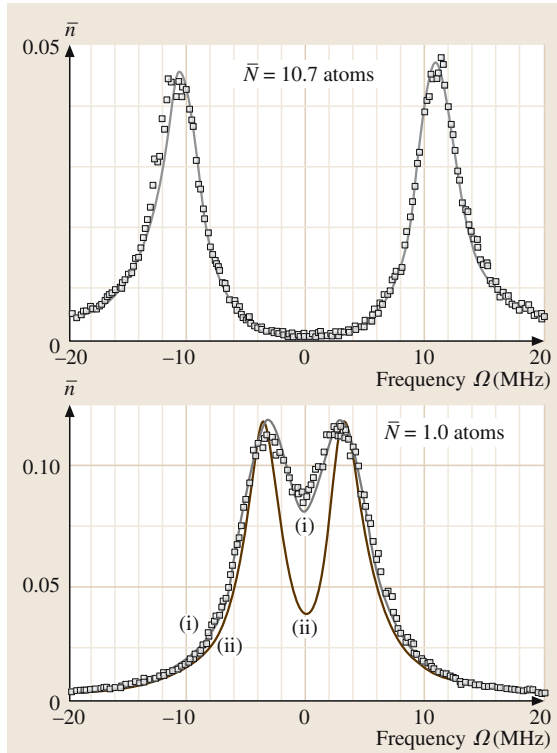
where N guarantees normalization of the trace and $A_k = (R/n)\sin^2(g_\mu \tau \sqrt{n})$, and exact resonance between


Fig. 79.8 Intracavity photon number (measured from a transmission experiment, [79.34]) as a function of probe frequency detuning, and for two values of N, the average number of atoms in the mode. *Thin lines* give theoretical fits to the data, including atomic number and position fluctuations. *Curve (ii)* in the *lower graph* is for a single intracavity atom with optimal coupling g_μ

cavity mode and atom is assumed. Since all off-diagonal elements vanish in steady state, (79.66) provides a complete description for the photon statistics of the field.

79.6.1 Maser Threshold

The steady state distribution determines the mean photon number of the resonator as a function of the operating conditions:

$$\langle n \rangle = \sum_{n=0}^{\infty} n P_n . \tag{79.67}$$

A suitable dimensionless control parameter is

$$\Theta = \frac{1}{2} g_\mu \tau \sqrt{R/\kappa} . \tag{79.68}$$

For $\Theta \ll 1$, the energy input is insufficient to counterbalance the loss of the cavity, effectively resulting in a negligible photon number. With increasing pump rate R, a threshold is reached at $\Theta \simeq 1$, where $\langle n \rangle$ increases rapidly with R. In contrast to the behavior of the usual laser, the single atom maser displays multiple thresholds with a sequence of minima and maxima of $\langle n \rangle$ as a function of Θ [79.46]. This can be related to the rotation of the atomic Bloch vector. When the atom undergoes a rotation of about π during the transit time τ, a maximum of energy is transferred to the cavity and $\langle n \rangle$ is maximized. The converse applies if the average rotation is a multiple of 2π. This behavior is shown in Fig. 79.9. The minima in $\langle n \rangle$ are at $\Theta \simeq 2n\pi$.

79.6.2 Nonclassical Features of the Field

Fluctuations can be of classical or of quantum origin. The variance of the photon number

$$\sigma^2 = \left(\langle n^2 \rangle - \langle n \rangle^2 \right) \tag{79.69}$$

is a measure of the randomness of the field intensity. Classical Poisson statistics require that $\sigma^2 \geq \langle n \rangle$. A value below unity indicates quantum behavior, which has no classical analog. In Fig. 79.10, the variance is plotted as a function of Θ. Regions of enhanced fluctuations $\sigma^2 > \langle n \rangle$ alternate with regions with sub-Poissonian character $\sigma^2 < \langle n \rangle$ [79.47]. When $\langle n \rangle$ approaches a local maximum it is accompanied by large fluctuations, while at points of minimum field strength the fluctuations are reduced below the classical limit. This feature is repeated with a period of $\Theta \simeq 2\pi$, but finally washes out at large values of Θ.

The large variance of n is caused by a splitting of the photon distribution P_n into two peaks, which gives
Fig. 79.9 Average photon number as a function of the normalized transit time defined by (79.68)
Fig. 79.10 Variance normalized on the average photon number $\sigma^{2\langle n \rangle}/\langle \sigma \rangle$. Values below unity indicate regions of nonclassical behavior

rise to bistability in the transient response [79.48]. The sub-Poissonian behavior of the field is reflected in an increased regularity of the atoms leaving the cavity in the ground state.

79.6.3 Trapping States

If cavity losses are neglected, operating conditions exist which lead directly to nonclassical, i. e., Fock states. If the cavity contains precisely n_q photons, an atom that enters the resonator in the excited state leaves it again in the same state provided the condition [79.49]

$$g_\mu \tau \sqrt{n_q + 1} = 2q\pi \tag{79.70}$$

is satisfied, i.e., the Bloch vector of the atom undergoes q complete rotations. If the maser happens to reach such a trapping state $|n_q\rangle$, the photon number n_q can no longer increase irrespective of the flux of pump atoms. With the inclusion of cavity damping at zero temperature, n_q still represents an upper barrier that cannot be overcome, since damping only causes downward transitions. Even in the presence of dissipation, generalized trapping states exist with a photon distribution that vanishes for $n > n_q$ and has a tail towards smaller photon numbers $n \leq n_q$. However, thermal fluctuations at finite temperatures destabilize the trapping states since they can momentarily increase the photon number and allow the distribution to jump over the barrier $n = n_q$. Nevertheless, even for $n_{\text{th}} < 10^{-7}$, remnants of the trapping behavior persist, and can be seen in the transient response of the micromaser (Sect. 79.6.4).

79.6.4 Atom Counting Statistics

Direct measurements of the field in a single atom maser resonator are not possible because detector absorption would drastically degrade its quality. However, the field can be deduced from the statistical signature of the atoms leaving the resonator.

The probability $P(n)$ of finding n atoms in a beam during an observation interval t is given by the classical Poisson distribution

$$P(n) = (Rt)^n \, e^{-Rt}/n! \,. \qquad (79.71)$$

Information on the field inside is then revealed by the conditional probability $W(n, |g\rangle, m, |e\rangle, T)$ of finding n atoms in the ground state and m atoms in the excited state during a time t. Since there are only two states, it is sufficient to determine the probability

$$W(n, |g\rangle, t) = \sum_{m=0}^{\infty} W(n, |g\rangle, m, |e\rangle, t) \qquad (79.72)$$

for being in the ground state [79.50]. For $n = 0$, the probability of observing no atom in the ground state during the period t is

$$W(0, |g\rangle, t) = \text{Tr}(\rho_{\text{stst}}) \exp\{L + R[O_{|g\rangle} + (1-\eta) O_{|e\rangle} - 1]t\} \,, \qquad (79.73)$$

where $O_{|j\rangle} = \langle j|F(\tau)|j\rangle$ (79.60) and ρ_{stst} is the steady state of the maser field. This probability is closely related to the waiting time statistic $P_2(0, |g\rangle, t)$ between two successive ground state atoms, a property which is easily determined in a start-stop experiment. For an atom detector with finite quantum efficiency η for state selective detection, the waiting time probability is

$$\begin{aligned} P_2(0, |g\rangle, t) &= \big\{\text{Tr}(\rho_{\text{stst}}) O_{|g\rangle} \\ &\quad \times \exp[L + R[O_{|g\rangle} + (1-\eta) O_{|e\rangle} - 1]T] O_{|g\rangle}\big\} \\ &\quad / \big[\text{Tr}(\rho_{\text{stst}}) O_{|g\rangle}\big]^2 \qquad (79.74) \end{aligned}$$

How a specific field state is reflected in the atom counting statistics will be illustrated for two situations: the region of sub-Poisson statistics and the region where the trapping condition is satisfied. Increased regularity of the cavity field $Q_{\text{M}} \leq 0$ manifests itself in increased regularity of ground state atoms in the beam. The statistical behavior exhibits "anti-bunching", i.e., $P_2(0, |g\rangle, t)$ has a maximum at finite t, indicating "repulsion" between successive atoms in comparison with a Poissonian beam. If the transit time τ is chosen in such a way that $g\tau \simeq 2\pi$, the chance of observing an initially excited atom in the ground state is negligible. At some point, however, an unlikely thermal fluctuation occurs, adding a photon. The rotation angle of the Bloch vector suddenly increases to $2\pi\sqrt{2} \simeq 3\pi$, and the atoms tend to leave the cavity in the ground state. After a typical cavity lifetime, the field decays and the trapping condition is restored again. Under this operation condition, the statistics of ground state atoms is governed by two time constants:

1. a short interval, in which successive atoms leave the cavity in the ground state after a thermal fluctuation;
2. a long time interval, in which the trapping condition is maintained and all atoms leave the resonator in their excited state until the next fluctuation occurs.

The probability $P_2(0, |g\rangle, t)$ is plotted in Fig. 79.11. The plot clearly shows the two time regimes that govern the imperfect trapping situation.

79.7 Quantum Theory of Measurement

When the object of interest consists of only a few atoms and a few photons, the puzzling consequences of quantum mechanical measurement become visible. In the case of the micromaser, the information on the state of the field is imprinted in a subtle way on the atomic beam. While photon counting is normally a destructive operation, the dispersive part of the photon-atom interaction may be used to determine the photon number inside
Fig. 79.11 Waiting time probability for atoms in the ground state while cavity is operated at vacuum trapping-state condition

a resonator without altering it, on average. Dispersive effects shift the phase of an oscillating atomic dipole without changing its state.

The phase shift due to the field in the resonator can be measured in a Ramsey-type experiment [79.51]. Consider an atom with two transitions $|g\rangle \rightarrow |e\rangle$ and $|e\rangle \rightarrow |i\rangle$. The first is far from resonance with the cavity and the second is close to resonance, but with a detuning $\delta_{ie} = \omega - \omega_{ie}$ large enough so as not to change the cavity photon number as the atom passes through. The dynamic Stark effect of the $|g\rangle \rightarrow |e\rangle$ transition frequency due to state $|i\rangle$ is then

$$\Delta\omega_{eg} = \left[g_{ie}\sqrt{n+1} \right]^2 / \delta_{ie} . \tag{79.75}$$

79.8 Applications of Cavity QED

79.8.1 Detecting and Trapping Atoms through Strong Coupling

From Fig. 79.8 it is obvious that an atom travelling through the cavity will modify the transmission properties of this cavity. Strong coupling thus enables the experimenter to detect the presence of a single atom dispersively by monitoring cavity transmission or reflection. Laser cooled atoms have low velocities and spend sufficient time in the cavity even in free flight to generate the transmission signal shown in Fig. 79.12. The signals correspond to individual atom transits, and the shape depends on the detuning of the probe laser from the resonantly interacting cavity-atom system.

If an atom absorbs a photon inside the cavity, a strong dipole force can be exerted due to the inhomogeneous

If the resonator is now placed between the two Ramsey cavities, which are tuned to $\omega_R \approx \omega_{eg}$, such that the polarization of the $|e\rangle \rightarrow |g\rangle$ transition is rotated by $\approx \pi/2$, then the additional phase shift $\Delta\omega_{eg}\tau$, where τ is the transit time through the optical resonator, can be measured, and hence the photon number n. Since Rydberg states have a large coupling constant g_μ, the phase shift due to a single atom is detectable [79.51].

A complete measurement of n requires a sequence of N atoms because a single Ramsey measurement only determines whether the atom is in state $|e\rangle$ or $|g\rangle$, and hence $\Delta\omega_{eg}\tau$ to within $\pm\pi/2$. Since each measurement provides one binary bit of information, a sequence of N measurements can in principle distinguish 2^N possible Fock states for the photon field. However, with a monoenergetic beam, integral multiples of 2π remain undetermined. A distribution of velocities, and hence transit times, is therefore desirable. An entropy reduction strategy for selecting an optimal velocity distribution, based on the outcome of previous measurements, is described in [79.52].

As a consequence of the uncertainty principle, a measurement of the photon number destroys all information about the phase of the field. In the present case, the noise in the conjugate variable (the phase) is prevented from coupling back on the measured one, and hence the measurement is called a quantum nondemolition experiment. Many other aspects of phase diffusion, entangled states, and quantum measurements in the micromaser are discussed in [79.53].

field distribution of the cavity mode. Trapping of atoms with a single photon was achieved [79.54], and from the time variation of the cavity transmission a reconstruction of atomic trajectories became possible.

79.8.2 Generation of Entanglement

In the middle of the 1990s, it was realized that fully controlled quantum systems could be used to implement a revolutionary type of information processing now called quantum computing [79.55]. From the beginning, cavity QED has conceptually played an important role for experimental realizations, since it offers a route to manipulate, in principle, all physical parameters of a coherently interacting system. With the well established microwave-cavity–Rydberg-atom system, it was proven
Fig. 79.12 Transmission of a strongly coupled cavity for individual atom transits. Caesium atoms and cavity are in perfect resonance at $\lambda = 852\,\text{nm}$ while the probe laser is increasingly detuned to the red side of the resonance from top to bottom 79.57

that the generation of correlated and nonlocal, so-called 'entangled' quantum states, is possible [79.56].

The first 'application' of cavity QED was the transfer of the strong coupling idea to the combined internal and motional quantum states of trapped ions [79.58]. Here the harmonic oscillation of the ion replaces the electric field of the conventional cavity-QED system. This quantum gate was realized with a system of two trapped ions coupled to each other by Coulomb forces [79.59].

Ideas about how to use the strong coupling of atoms and photons [79.60–62] for the generation of atom–photon, or atom–atom (by insertion of more than one atom) entanglement abound, but entanglement generation by means of cavity-QED with a controlled source of atoms or ions remains a challenge for the future.

79.8.3 Single Photon Sources

Coherent laser fields are considered the ultimate source of classical radiation fields, and they are characterized by the random arrival time of photons. Nonclassical light sources with, for instance, a regularized stream of photons offer interesting properties for low-noise measurement applications.

Cavity-QED systems offer an attractive light-matter process for the generation of such 'photon-bit-streams', or single photon sources [79.63]. In such devices, a single photon state can, for instance, be created by Raman processes involving a classical field, which serves as the control parameter for the process, and the vacuum field of the optical resonator. The Raman process leaves a single photon in the cavity, which only weakly interacts with the atom. If the resonator has suitable transmission properties, this photon will then escape with predetermined frequency, shape, and propagation direction. Deterministic single photon sources have been realized with quantum dots [79.64, 65], single molecules [79.66], and also with slow [79.67] or trapped [79.68] cold atoms and ions [79.69] inside optical cavities.

80. Quantum Optical Tests of the Foundations of Physics

Quantum mechanics began with the solution of the problem of blackbody radiation by Planck's quantum hypothesis: in the interaction of light with matter, energy can only be exchanged between the light in a cavity and the atoms in the walls of the cavity by the discrete amount $E = h\nu$, where h is Planck's constant and ν is the frequency of the light. Einstein, in his treatment of the photoelectric effect, reinterpreted this equation to mean that a beam of light consists of particles ("light quanta") with energy $h\nu$. The Compton effect supported this particle viewpoint of light by demonstrating that photons carried momentum, as well as energy. In this way, the wave–particle duality of quanta made its first appearance in connection with the properties of light.

It might seem that the introduction of the concept of the photon as a particle would necessarily also introduce the concept of locality into the quantum world. However, in view of observed violations of Bell's inequalities, exactly the opposite seems to be true. Here we review some recent results in quantum optics which elucidate nonlocality and other fundamental issues in physics.

In spite of the successes of quantum electrodynamics, and of the standard model in particle physics, there is still considerable resistance to the concept of the photon as a particle. Many papers have been written trying to explain all optical phenomena semiclassically, i.e., with the light viewed as a classical wave, and the atoms treated quantum mechanically [80.1–4]. We first present some quantum optics phenomena which exclude this semiclassical viewpoint.

80.1 The Photon Hypothesis

In an early experiment, Taylor reduced the intensity of a thermal light source in Young's two-slit experiment, until, on the average, there was only a single photon passing through the two slits at a time. He then observed a two-slit interference pattern which was identical to that for a more intense classical beam of light. In Dirac's words, the apparent conclusion is that "each photon then interferes only with itself" [80.6]. However, a coherent state, no matter how strongly attenuated, always remains a coherent state (Sect. 78.2.2); since a thermal light source can be modeled as a statistical ensemble of coherent states, a stochastic classical wave model yields complete agreement with Taylor's observations. The one-by-one darkening of grains of film can be explained by treating the matter alone quantum mechanically [80.2]; consequently, the concept of the photon need not be invoked, and the claim that this experiment demonstrates quantum interference of individual photons is unwarranted [80.7].

This weakness in Taylor's experiment can be removed by the use of nonclassical light sources; as discussed by *Glauber* [80.8], classical predictions diverge from quantum ones only when one considers counting statistics, or photon correlations. In particular, two-photon light sources, combined with coincidence detection, allow the production of single-photon ($n = 1$ Fock) states with near certainty. In the first such experiment [80.9], two photons, produced in an atomic cascade within nanoseconds of each other, impinged on two beam splitters, and were then detected in coincidence by means of four photomultipliers placed at all possible exit ports. In a simplified version of this experiment [80.5], one of the beam splitters and its two detectors are replaced with a single detector D_1 (Fig. 80.1). We define
Fig. 80.1 Triple-coincidence setup of *Grangier* et al. [80.5]

the anticorrelation parameter

$$\alpha \equiv N_{123}N_1/N_{12}N_{13} , \qquad (80.1)$$

where N_{123} is the rate of triple-coincidences between detectors D_1, D_2 and D_3; N_1 is the singles rate at D_1; and N_{12} and N_{13} are double-coincidence rates. Then from Schwarz's inequality [80.5, 7, 10], $\alpha \geq 1$ for any classical wave. In essence, since the wave divides smoothly, the coincidence rate between D_2 and D_3 is never smaller than the "accidental" coincidence rate, even when measurements are conditioned on an event at D_1. (The Hanbury–Brown and Twiss experiment [80.11] can be explained classically, because the thermal fluctuations lead to "bunching," or a mean coincidence rate which is greater than the mean accidental rate; Sect. 78.3.3.) By contrast, the indivisibility of the photon leads to strong anticorrelations between D_2 and D_3, making α arbitrarily small. In agreement with this quantum mechanical picture, *Grangier* et al. observed a 13-standard-deviation violation of the inequality [80.5], corroborating the notion of the "collapse of the wave packet" as proposed by *Heisenberg* [80.12].

80.2 Quantum Properties of Light

80.2.1 Vacuum Fluctuations: Cavity QED

The above considerations necessitate the quantization of the electromagnetic field, which in turn leads to the concept of vacuum fluctuations [80.4] (Sect. 78.1). Difficulties with this idea, such as the implied infinite zero-point energy of the universe, have led some researchers to attempt to dispense with this concept altogether, along with that of the photon, in every explanation of electromagnetic interactions with matter. Of course, it is impossible to explain all phenomena, such as

spontaneous emission and the Lamb shift, without some kind of fluctuating electromagnetic fields (Chapt. 78 and Sect. 79.2.4), but one can go a long way with an ad hoc ambient classical electromagnetic noise-field filling all of space, in conjunction with the radiation reaction [80.1, 4].

In particular, even the Casimir attraction between two conducting plates (Sect. 79.2.4), which has now been verified with high precision [80.13–19] can be explained semiclassically in terms of dipole forces between electrons in each plate as they un-

dergo zero-point motion that induce image charges in the other plate. Nevertheless, the effects of cavity QED (Chapt. 79) [80.20–22], including the influence of cavity-induced boundary conditions on energy levels and spontaneous emission rates, are most easily unified via quantization of the electromagnetic field.

By coupling highly excited Rydberg atoms to photons in a high-finesse superconducting microwave cavity, *Haroche* et al. have observed single-photon driven Rabi oscillations [80.23], and have used these to study decoherence effects [80.24], atom–photon entanglement [80.25], and quantum nondemolition measurements [80.26] (Sect. 80.5.2). *Kimble* et al. [80.27] and *Rempe* et al. [80.28] have performed similar experiments, coupling atoms to small optical cavities, and even trapping the atoms with light fields at the single-photon level [80.29, 30]. By monitoring the amplitude of the light transmitted through the cavity (which depends on the precise location of the atom inside the cavity volume), the trajectory of the atom can be determined with ultrahigh resolution, much smaller than an optical wavelength [80.31, 32].

80.2.2 The Down-Conversion Two-Photon Light Source

The quantum aspects of electromagnetism are made more striking with a two-photon light source, in which two highly correlated photons are produced in spontaneous parametric down-conversion, or parametric fluorescence [80.33–36]. In this process, an ultraviolet "pump" photon produced in a laser spontaneously decays inside a crystal with a $\chi^{(2)}$ nonlinearity into two highly correlated red photons, conventionally called the "signal" and the "idler" (Sect. 72.3.4). (The quantum state of the light is more correctly written as $|\psi\rangle \propto |vacuum\rangle + \epsilon|1\rangle_s|1\rangle_i + \epsilon^2|2\rangle_s|2\rangle_i + \dots$, but since the amplitude of the down-conversion process itself is very weak (ϵ is of order 10^{-6}), one often neglects the terms containing 2 or more pairs. However, recent experiments have begun to exploit these higher-order terms, e.g., to investigate 3-, 4-, 5-photon quantum effects [80.37–40]. Very recently, a stimulated down-conversion process [80.41] has indicated the presence of 12-photon entanglement [80.42].) As shown in Fig. 80.2, a rainbow of colored cones is produced around an axis defined by the direction of the uv beam (for the case of type-I phase-matching), with the correlated down-conversion photons always emitted on opposite sides of the UV beam (Sect. 72.2.2). Their emission times
Fig. 80.2 Conical emissions of down-conversion from a nonlinear crystal (for type-I phase-matching). Photon energy depends on the cone opening angle, and conjugate photons lie on opposite sides of the axis, e.g., the inner "circle" orange photon is conjugate to the outer "circle" deep-red photon, etc.

are within femtoseconds of each other, so that detection of one photon implies with near certainty that there is exactly one quantum present in the conjugate mode [80.43]. In type-I phase-matching the correlated photons share the same polarization, while in type-II phase-matching they have orthogonal polarizations . We will see below (Sect. 80.6.2) how both of these can enable the production of photons that are entangled in polarization, as well as in other degrees of freedom.

This production technique allowed for the first reconstruction of the Wigner distribution for a single photon [80.44], which is manifestly non-classical in that the quasiprobability for both quadratures of the field to vanish is negative. In contrast to an earlier demonstration of a negative Wigner function [80.45] (using atoms, not photons), this measurement was possible using essentially classical measurement techniques with no quantum assumptions, and is in this sense a direct demonstration of the non-classical nature of the electromagnetic field. Later work [80.46] used these techniques to demonstrate that a single photon forced to choose between two output ports of a beam splitter exhibits quantum correlations.

80.2.3 Squeezed States of Light

The creation of correlated photon pairs is closely related to the process of quadrature-squeezed light production (Sect. 78.2.2, and the review in [80.47]). For example, when the gain arising from parametric amplification in a down-conversion crystal becomes large, there is a transition from spontaneous to stimulated emission of pairs. This gain is dependent on the phase of amplified light relative to the phase of

the pump light. As a result, the vacuum fluctuations are reduced ("squeezed") below the standard quantum limit (SQL) in one quadrature, but increased in the other, in such a way as to preserve the minimum uncertainty-principle product [80.48]. This periodicity of the fluctuations at 2ω is a direct consequence of the fact that the light is a superposition of states differing in energy by $2\hbar\omega$ – the quadrature-squeezed vacuum state

$$|\xi\rangle = \exp\left(\frac{1}{2}\xi^* aa - \frac{1}{2}\xi a^\dagger a^\dagger\right)|0\rangle \qquad (80.2)$$

represents a vacuum state transformed by the creation $(a^\dagger a^\dagger)$ and destruction (aa) of photons two at a time. Essentially any optical processes operating on photon pairs (e.g., four-wave mixing [80.49, 50]) can also produce such squeezing.

Amplitude squeezing involves preparation of states with well-defined photon number, i. e., states lacking the Poisson fluctuations of the coherent state. The possibility of producing such states (e.g., via a constant-current-driven semiconductor laser [80.51]) demonstrates that "shot noise" in photodetectionshould not be thought of as merely the result of the probabilistic (à la Fermi's Golden Rule, Sect. 69.4) excitation of quantum mechanical atoms in a classical field, but as representing real properties of the electromagnetic field, accessible to experimental control.

The highest level of number-squeezing reported (-5.7 ± 0.1) dB, corresponding to a noise reduction 73% below the SQL) employed an asymmetric fiber loop to squeeze solitons [80.52]. The highest level of quadrature-squeezing reported has been (-7.0 ± 0.2) dB (80% below the SQL), using a $\chi^{(2)}$-crystal optical parametric oscillator [80.53]. This was a continuous-wave vacuum-squeezed beam – the same technique was used to produce -5.0 dB of bright continuous-wave squeezing locked for several hours.

Squeezed light has begun to have impact in metrology. A few examples suffice: the generation of audio-band squeezed light [80.54] and the demonstration of a squeezing-enhanced power-recycled Michelson interferometer [80.55], both suitable for gravity-wave interferometry (Sect. 80.9); the use of squeezing to measure displacement of a light beam below the standard quantum limit [80.56], suitable for atomic force microscopy; and demonstrations of squeezed light spectroscopy [80.57–59].

80.3 Nonclassical Interference

80.3.1 Single–Photon and Matter–Wave Interference

The first truly one-photon interference experiment [80.5] used the cascade source discussed in Sect. 80.1. One of the photons was directed to a "trigger" detector, while the other, thus prepared in an $n = 1$ Fock state, was sent through a Mach–Zehnder interferometer. The output photon, detected in coincidence with the trigger photon, showed fringes with a visibility $> 98\%$. Dirac's statement that a single photon interferes with itself is thus verified.

Of course, matter can also display interference, determined by the deBroglie wavelength (Chapt. 77). There have been significant recent advances in atomic matter–wave interferometry and its applications [80.60], ever since the early experiments of Pritchard, which used standing-light gratings and nanofabricated diffraction gratings to construct Mach–Zehnder-type interferometers for sodium atoms [80.61] and molecules [80.62] from a supersonic source. *Chu* and *Kasevich* introduced the use of STIRAP (Stimulated Raman Adiabatic fast Passage; Sect. 69.7) to produce coherent beam splitters for cold atomic beams, also in a Mach–Zehnder-type interferometer, but whose source were cesium atoms cooled in and launched from a magneto-optical trap (MOT) [80.63]. Matter–wave interferometry has now been applied to precision measurements of the acceleration g due to Earth's gravity [80.64], gravity gradiometry [80.65], and Sagnac matter–wave gyroscopes [80.66, 67].

To date some of the largest systems to display quantum interference are large molecules like carbon 60 ("Buckyballs") and carbon 70 [80.68]. These are significant in that the average deBroglie wavelength of the molecules, emitted from an oven, was 2.8 pm, actually about 350 times smaller than the molecule itself. *Arndt* et al. have also demonstrated multislit diffraction with the biological molecule porphyrin, and with fluorofullerenes ($C_{60}F_{48}$) [80.69]. With a mass of 1632 amu, the latter are currently the largest single objects to display interference. Looking ahead, others have suggested that it may be possible to put a micron-scale mirror (with $\approx 10^{14}$ atoms) into a superposition of resolvable spatial

locations [80.70] – the mirror, part of a high-finesse optical cavity forming one arm of a Michelson interferometer, could be mounted on a high-quality mechanical oscillator, whereby the interaction with a single photon would change the frequency of the oscillator.

Two other systems, demonstrating Bose–Einstein condensation (BEC) (see Chapt. 76), have also produced evidence of macroscopic quantum coherence. In the experiments of *Ketterle* et al., atoms from two different atomic vapor BEC clouds were allowed to fall onto the same detection region, and display interference fringes [80.71] (more recently interference from an array of 30 independent BECs has been observed [80.72]). In some ways this is the matter–wave equivalent of the famous *Pfleegor–Mandel* experiment [80.73], in which light from two separate lasers displays interference, even when attenuated to the single-photon level. The explanation in terms of the indistinguishability of the underlying processes is that one cannot ascertain from which laser source a given photon originated. However, this explanation must be applied carefully to the situation of the two atomic BECs: Unlike the lasers, the BEC clouds can – at least in principle – be prepared with a definite number of atoms, and it would therefore seem that one could in principle determine which cloud emitted a given detected atom. However, this determinacy is rapidly lost after a few atoms are detected [80.74]. Once the number becomes uncertain, a well-defined relative phase of the two BECs is established, according to the number-phase uncertainty relation $\Delta(N_2 - N_1)\Delta(\phi_2 - \phi_1) \gtrsim 1/2$. In fact, discussions have recently arisen over whether or not lasers should not also be viewed as incoherent number-state combinations, instead of the usual coherent state $|\alpha\rangle$ (the issue is that in principle there is nothing in a laser to break the symmetry and select a particular phase) [80.75–77].

Finally, quantum coherence (though not explicitly spatial interference as in the previous examples), has been detected in the operation of a Josephson-junction linked superconducting loop – the group of *Mooij* was able to prepare a superposition of clockwise and counterclockwise circulating electrical currents [80.78]. Since the $\approx 0.5\,\mu A$ currents corresponded to the motion of millions of Cooper pairs, this is arguably the largest system thus far to have displayed quantum coherence. This superconducting system also holds promise for quantum computing (see Chapt. 81), as Rabi oscillations between the different flux states have been observed [80.79, 80].

80.3.2 "Nonlocal" Interference Effects and Energy–Time Uncertainty

The energy–time uncertainty principle, $\Delta E \Delta t \geq \hbar/2$ has been tested in a down-conversion interference experiment [80.81]. The down-conversion process conserves energy and momentum:

$$\hbar\omega_0 = \hbar\omega_1 + \hbar\omega_2 \,, \tag{80.3}$$

$$\hbar\mathbf{k}_0 \approx \hbar\mathbf{k}_1 + \hbar\mathbf{k}_2 \,, \tag{80.4}$$

where $\hbar\omega_0$ ($\hbar\mathbf{k}_0$) is the energy (momentum) of the parent photon, and $\hbar\omega_1$ ($\hbar\mathbf{k}_1$) and $\hbar\omega_2$ ($\hbar\mathbf{k}_2$) are the energies (momenta) of the daughter photons; $\mathbf{k}_1$ and $\mathbf{k}_2$ sum to $\mathbf{k}_0$ to within an uncertainty given by the reciprocal of the crystal length [80.82]. Since there are many ways of partitioning the parent photon's energy, each daughter photon may have a broad spectrum, and hence a wave packet narrow in time. However, $\omega_1 + \omega_2 = \omega_0$ is extremely well-defined, so that the difference in the daughter photons' arrival times, and the sum of their energies can be simultaneously known to high precision. Thus, the daughter photons of a parent photon of sharp energy E_0 are in an energy-"entangled" state, a nonfactorizable sum of product states [80.83]:

$$|\Psi\rangle = \int\limits_0^{E_0} \mathrm{d}E \, A(E) \, |E\rangle \, |E_0 - E\rangle \,, \tag{80.5}$$

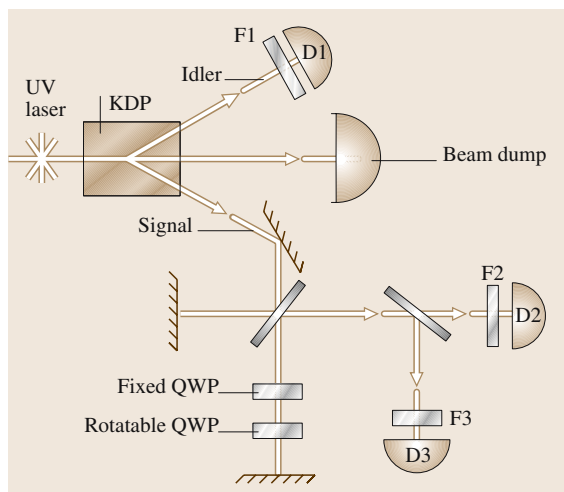
where $A(E)$ is the probability amplitude for the production of two photons of energies E and $E_0 - E$. A measurement of the energy of one of the photons to be E_1 can be interpreted as causing an instantaneous "collapse" of the system to the state $|E_1\rangle|E_0 - E_1\rangle$, implying an instantaneous increase of the width of the other photon's wave packet. (Of course, the notion of collapse need not be invoked to explain such results. One can view the detection of the trigger photon as conditionally selecting a particular subensemble of the pairs. However, as discussed in Sect. 80.6.3, it is not correct to interpret the down-conversion photons as possessing a well-defined energy prior to measurement.) In the experiment, one photon was used as a trigger, while the other was sent into an adjustable Michelson interferometer (Fig. 80.3), used to measure its coherence length. (The same apparatus was also used to demonstrate that Berry's phase in optics has a quantum origin [80.84].) If the trigger photon passed through an interference filter F1 of narrow width ΔE and was detected, then the conjugate photon occupied a broad wavepacket of duration $\Delta t \approx \hbar/\Delta E$, and displayed interference. When


Fig. 80.3 The energy–time uncertainty relation and wave function collapse were studied by investigating the effect of various filters before the detectors in a single-photon interference experiment [80.5, 81]

there was no trigger, no fringes were observed, implying a much shorter wave packet. This is a nonlocal effect in that the photons could in principle be arbitrarily far away from each other when the collapse occurs.

80.3.3 Two–Photon Interference

In the above experiments, interference occurs between two paths taken by a single photon. An early experiment to demonstrate two-photon interference using the down-conversion light source was performed by *Ghosh* and *Mandel* [80.85]. They looked at the counting rate of a detector illuminated by both of the twin beams. No interference was observed at the detector, because although the sum of the phases of the two beams emitted in parametric fluorescence is well defined (by the phase of the pump), their difference is not, due to the number-phase uncertainty principle. However, the rate of coincidence detections between two such detectors whose separation was varied did display high-visibility interference fringes. Whereas in the standard two-slit experiment, interference occurs between the two paths a single photon could have taken to reach a given point on a screen, in this case it occurs between the possibility that the signal photon reached detector 1 and the idler photon detector 2, and the possibility that the reverse happened. This experiment provides a manifestation of quantum nonlocality; interference occurs between alternate global histories of a system, not between local

fields. At a null of the coincidence fringes, the detection of one photon at detector 1 excludes the possibility of finding the conjugate photon at detector 2.

Such interference becomes clearer in the related interferometer of *Hong* et al. [80.86] (Fig. 80.4). The identically polarized conjugate photons from a down-conversion crystal are directed to opposite sides of a 50–50 beam splitter, such that the transmitted and reflected modes overlap. If the difference in the path lengths ΔL prior to the beam splitter is larger than the two-photon correlation length (of the order of the coherence length of the down-converted light), the photons behave independently at the beam splitter, and coincidence counts between detectors in the two output ports are observed half of the time – the other half of the time both photons travel to the same detector. However, when $\Delta L \approx 0$, such that the photon wave packets overlap at the beam splitter, the probability of coincidences is reduced, in principle to zero if $\Delta L = 0$. One can explain the coincidence null at zero path-length difference using the Feynman rules for calculating probabilities: add the probability amplitudes of indistinguishable processes which lead to the same final outcome, and then take the absolute square. The two indistinguishable processes here are both photons being reflected at the beam splitter (with Feynman amplitude $r \cdot r$) and both photons being transmitted (with Feynman amplitude $t \cdot t$). The probability of a coincidence detection is then

$$P_c = |r \cdot r + t \cdot t|^2 = \left| \frac{i}{\sqrt{2}} \cdot \frac{i}{\sqrt{2}} + \frac{1}{\sqrt{2}} \cdot \frac{1}{\sqrt{2}} \right|^2 = 0 ,$$

(80.6)

assuming a real transmission amplitude, and where the factors of i come from the phase shift upon reflection at a beam splitter [80.87, 88].

The possibility of a perfect null at the center of the dip is indicative of a nonclassical effect. Indeed, classical field predictions allow a maximum coincidence-fringe visibility of only 50% [80.89]. The tendency of the photons to travel off together at the beam splitter can be thought of as a manifestation of the Bose–Einstein statistics for the photons [80.90]. In practice, the bandwidth of the photons, and hence the width of the null, is determined by filters and/or irises before the detectors [80.82]. Widths as small as 5 μm have been observed, corresponding to time delays of only 15 fs [80.91]. Consequently, one application is the determination of single-photon propagation times with extremely high time resolution (Sect. 80.8).

80.4 Complementarity and Coherence

80.4.1 Wave–Particle Duality

The complementary nature of wave-like and particle-like behavior is frequently interpreted as follows: due to the uncertainty principle, any attempt to measure the position (particle aspect) of a quantum leads to an uncontrollable, irreversible disturbance in its momentum, thereby washing out any interference pattern (wave aspect) [80.93, 94]. This picture is incomplete though; no "state reduction," or "collapse," is necessary to destroy interference, and measurements which do not involve reduction can be reversible. One must view the loss of coherence as arising from an entanglement of the system wave function with that of the measuring apparatus (MA) [80.95]. Previously interfering paths can thereby become distinguishable, such that no interference is observed. Consider the simplest experiment, a Mach–Zehnder interferometer with a 90° polarization rotator in arm 1. If horizontally polarized light is input, the state before the recombining beam splitter is $(|1\rangle|V\rangle + |2\rangle|H\rangle)/\sqrt{2}$, where $|1\rangle$ and $|2\rangle$ indicate the path of the photon. Because the polarization – playing the role of the MA – labels the path, no interference is observed at the output. *Englert* [80.96] has introduced a generalized relation quantifying the interplay between the wave-like attributes of a system (as measured by the fringe visibility V) and the particle-like character (as measured by the distinguishability D of the underlying quantum processes):

$$V^2 + D^2 \le 1 \, . \tag{80.7}$$

The equality holds for pure input states. This relation has now been well verified in optical systems like that described above [80.97, 98], as well as in atom interferometry (Sect. 77.6) [80.99]. In the latter, the role of the polarization was played by internal energy states of an atom diffracted off a standing light wave.

80.4.2 Quantum Eraser

The interference lost to entanglement may be regained if one manages to "erase" the distinguishing information. This is the physical content of quantum erasure [80.100, 101]. The primary lesson is that one must consider the total physical state, including any MA with which the interfering quantum has become entangled, even if that MA does not allow accessible which-path information [80.102]. If the coherence of the MA is maintained, then interference may be recovered.

The first demonstration of a quantum eraser was based on the interferometer in Fig. 80.4 [80.92]. A half waveplate inserted into one of the paths before the beam splitter serves to rotate the polarization of light in that path. In the extreme case, the polarization is made orthogonal to that in the other arm, and the r·r and t·t processes become distinguishable; hence, the destructive interference which led to a coincidence null does not occur. The distinguishability can be erased, however, by using polarizers just before the detectors. In particular, if the initial polarization of the photons is horizontal, and the waveplate rotates one of the photon polarizations to vertical, then polarizers at 45° before both detectors restore the original interference dip. If one polarizer is at 45° and the other at −45°, interference is once again seen, but now in the form of a peak instead of a dip (Fig. 80.5). There are four basic measurements possible on the MA (here the polarization) – two of which yield which-path information, one of which recovers the initial interference fringes (here the coincidence dip), and one of which yields interference anti-fringes (the peak instead of the dip). In some implementations, the decision to measure wave-like or particle-like behavior may even be delayed until after detection of the original quantum, an irreversible process [80.103–105]. (This is an extension of the original delayed-choice discussion by
Fig. 80.4 Simplified setup for a Hong–Ou–Mandel (HOM) interferometer [80.86]. Coincidences may result from both photons being reflected, or both being transmitted. When the path lengths to the beam splitter are equal, these processes destructively interfere, causing a null in the coincidence rate. In a modified scheme, a half waveplate in one arm of the interferometer (at "A") serves to distinguish these otherwise interfering processes, so that no null in coincidences is observed. Using polarizers before the detectors, one can "erase" the distinguishability, thereby restoring interference [80.92] (Sects. 80.4.2 and 80.6.2)
Fig. 80.5 Experimental data and scaled theoretical curves (adjusted to fit observed visibility of 91%) with polarizer 1 at 45° and polarizer 2 at various angles. Far from the dip, there is no interference and the angle is irrelevant [80.92]

Fig. 80.6 Schematic of setup used in [80.109]. The idler photons from the two crystals are indistinguishable; consequently, interference fringes may be observed in the signal singles rate at detector D_s. Additional elements at *A* and *B* can be used to make a quantum eraser

Wheeler [80.106], and the experiments by *Hellmuth* et al. and *Alley* et al. [80.107, 108], in which the decision to display wave-like or particle-like aspects in a light beam may be delayed until after the beam has been split by the appropriate optics.) But in all cases, one must correlate the results of measurements on the MA with the detection of the originally interfering system. This requirement precludes any possibility for superluminal signaling.

In a related atom-optics experiment, researchers observed contrast loss in an atom interferometer when single photons were scattered off the atoms (yielding which-path information) [80.110]. They further demonstrated that the lost coherence could be recovered by observing only atoms that were correlated with photons emitted into a limited angular range, in essence realizing a quantum eraser.

80.4.3 Vacuum-Induced Coherence

A somewhat different demonstration [80.109, 111] of complementarity involves two down-conversion crystals, NL1 and NL2, aligned such that the trajectories of the idler photons from each crystal overlap (Fig. 80.6). A beam splitter acts to mix the signal modes. If the path lengths are adjusted correctly, and the idler beams overlap precisely, there is no way to tell, even in principle, from which crystal a photon detected at D_s originated. Interference appears in the signal *singles* rate at D_s, as any of the path lengths is varied. If the

idler beam from crystal NL1 is prevented from entering crystal NL2, then the interference vanishes, because the presence or absence of an idler photon at D_i then "labels" the parent crystal. One explanation for the effect of blocking this path is that coherence is established by the idler-mode vacuum field seen by both crystals.

Experiments have also been performed in which a time-dependent gate is introduced in the idler arm between the two crystals [80.112]. As one expects, the presence or absence of interference depends on the earlier state of the gate, at the time when the idler photon amplitude was passing through it.

80.4.4 Suppression of Spontaneous Down-Conversion

A modification [80.113] of this two-crystal experiment uses only a single nonlinear crystal (Fig. 80.7). A given pump photon may down-convert in its initial right-ward passage through the crystal, or in its left-going return trip (or not at all, the most likely outcome). As in the previous experiment, the idler modes from these two processes are made to overlap; moreover, the signal modes are also aligned to overlap. Thus, the left-going and right-going production processes are indistinguishable and interfere. The result is that fringes are observed in all of the counting rates (i.e., the coincidence rate and both singles rates) as any of the mirrors is translated. A different interpretation is as a change in the spontaneous emission of the down-converted photons, akin to the suppression of spontaneous emission in cavity QED demonstrations, discussed in Sects 80.2.1 and 79.2. Subsequent theoretical and experimental work has shown that, in a sense, there are always photons between the down-conversion crystal and the mirrors, even

in the case of complete suppression of the spontaneous emission process [80.114, 115]. This same conclusion should also apply in the atom case [80.116], though in contrast to that system, for the down-conversion experiment the distances to the mirrors are much longer than the coherence lengths of the spontaneously emitted photons.

One recent application of this phenomenon is to study effective nonlinearities at the single-photon level, which has enabled the construction of a 2-photon switch [80.117]. Finally, with the inclusion of waveplates to label the photons' paths, and polarizers to erase this information, an improved quantum eraser experiment was also completed, in which the which-path information for one photon was carried by the other photon [80.104].
Fig. 80.7 Schematic of the experiment to demonstrate enhancement and suppression of spontaneous down-conversion [80.113]

80.5 Measurements in Quantum Mechanics

80.5.1 Quantum (Anti–)Zeno Effect

A strong measurement of a quantum system will project it into one of its eigenstates [80.95]. If the system evolves slowly out of its initial state: $|\Psi(t=0)\rangle = |\Psi_0\rangle \rightarrow (1-t^2/\tau^2)^{1/2}|\Psi_0\rangle + t/\tau|\Psi_1\rangle$, then repeated measurements with an interval much less than τ can inhibit this evolution. If there are N total measurements within τ, then the probability for the system to still be in the initial state is $P(\tau) = \left(1-(\tau/N)^2/\tau^2\right)^N \rightarrow 1$ as $N \rightarrow \infty$. This phenomenon, known as the quantum Zeno effect [80.118], has been experimentally observed using 3 levels in $^9\text{Be}^+$ ions [80.119]. The ions were prepared in state $|i\rangle$, and weakly coupled to state $|f\rangle$ via RF radiation that induced a slow Rabi oscillation between the two states. Thus, in the absence of any intervening measurements, the ions evolved sinusoidally into state $|f\rangle$. When rapid measurements were made (by a laser strongly coupling state $|f\rangle$ to readout state $|r\rangle$, hence leading to strong fluorescence only if the atom was in state $|f\rangle$), the effect was to inhibit the $|i\rangle \rightarrow |f\rangle$ transition. Note that here it was the absence of fluorescent photons which projected the state at each measurement back into the state $|i\rangle$ (Sect. 80.5.3). Also, although we have explained the effect in terms of a repeated "collapse" of the wave function back into its initial state, equally valid explanations without such reductions are also possible [80.120, 121].

Koffman and *Kurizki* have pointed out that the above inhibition phenomenon depends on there being a bounded number of final states (the ion example had

only one). If instead the measurement process actually increases the number of accessible final states $|f\rangle$, then one obtains the "anti-Zeno" effect, in which the $|i\rangle \rightarrow |f\rangle$ rate is enhanced rather than suppressed by frequent measurements [80.122]. For example, this would be the case in the ion example if the $|i\rangle \rightarrow |f\rangle$ transition were spontaneous (allowing all frequencies) instead of driven (proceeding only at the driving Rabi frequency). The anti-Zeno effect has been observed by monitoring the survival time (against tunneling escape) of atoms trapped in an accelerating far-detuned standing wave of light [80.123].

80.5.2 Quantum Nondemolition

The uncertainty principle between the number of quanta N and phase ϕ of a beam of light,

$$\Delta N \Delta \phi \geq 1/2 , \tag{80.8}$$

implies that to know the number of photons exactly, one must give up all knowledge of the phase of the wave. In theory, a quantum nondemolition (QND) process is possible [80.124]: without annihilating any of the light quanta, one can count them. It might seem that this would make possible successive measurements on noncommuting observables of a single photon, in violation of the uncertainty principle; it is the unavoidable introduction of phase uncertainty by any number measurement which prevents this.

QND schemes [80.125] often employ the intensity-dependent index of refraction arising from the optical

Kerr effect (Sect. 72.4.2) – the change in the index due to the intensity of the "signal" beam changes the optical phase shift on a "probe" beam [80.126–128]. Other proposals include using the Aharonov–Bohm effect to sense photons via the phase shift their fields induce in passing electrons [80.129, 130]. To date the closest experimental realization [80.26] of a QND measurement – of the photon number in a microwave cavity – was performed by passing Rydberg atoms [80.131, 132] in a superposition of the ground and excited states through the cavity. The interaction with the cavity photon is adjusted to be equivalent to a 2π-pulse (Sect. 79.5). The result is that in the absence of any photon, the quantum state of the atoms after the cavity was unchanged; with a photon in the cavity, the ground state acquired an extra relative phase of π, which was then detected by measuring the atom's quantum state. An efficiency approaching 50% was achieved. Recently, it was suggested that optical QND measurements could enable scalable quantum computing [80.133].

80.5.3 Quantum Interrogation

The previous section described techniques to measure the presence of a photon without absorbing it. Now we discuss a method – quantum interrogation – to optically detect the presence of an object without absorbing or scattering a photon. The possibility that the absence of a detection event – a "negative-result" measurement – can lead to wavepacket reduction was first discussed by *Renninger* [80.134] and later by *Dicke* [80.135]. Here we consider the Gedankenexperiment proposed by *Elitzur* and *Vaidman* (EV), a simple single-particle interferometer, with particles injected one at a time [80.136]. The path lengths are adjusted so that all the particles leave a given output port (A), and never the other (B). Now suppose that a nontransmitting object is inserted into one of the interferometer's two arms – to emphasize the result, EV considered an infinitely sensitive "bomb", such that interaction with even a single photon would cause it to explode. By classical intuition, any attempt to check for the presence of the bomb involves interacting with it in some way, and, by hypothesis, inevitably setting it off.

Quantum mechanics, however, allows one to be certain some fraction of the time that the bomb is in place, without setting it off. After the first beam splitter of the interferometer, a photon has a 50% chance of heading towards the bomb, and thus exploding it. On the other hand, if the photon takes the path without the bomb, there is no more interference, since the nonex-

plosion of the bomb provides welcher Weg ("which way") information (see Sect. 80.4.1). Thus the photon reaches the final beam splitter and chooses randomly between the two exit ports. Some of the time (25%), it leaves by output port B, something which never happened in the absence of the bomb. This immediately implies that the bomb (or some nontransmitting object) is in place – even though (since the bomb is unexploded) it has not interacted with any photon; EV termed this an "interaction-free measurement". (We prefer the more general description "quantum interrogation", which then includes cases – e.g., detecting a semi-transparent or quantum object – where it may not be possible to logically exclude the possibility of an interaction.) It is the mere possibility that the bomb could have interacted with a photon which destroys interference. An initial experimental implementation of these ideas [80.137] used down-conversion to prepare the single photon states (Sect. 80.1), and a single-photon detector as the "bomb". Subsequently the technique was implemented incorporating focusing lenses, which would enable the image (more correctly, the silhouette) of an object to be determined with less than one photon per "pixel" being absorbed [80.138].

By adjusting the beamsplitter reflectivities in the above example, one can achieve at most a 50% fraction of measurements that are interaction-free. An improved method, relying on the quantum Zeno effect [80.118] (Sect. 80.5.1), was discovered with which one can in principle make this fraction arbitrarily close to 1 [80.137]. For example, consider a photon initially in cavity #1 of two identical cavities coupled by a lossless beam splitter whose reflectivity $R = \cos^2(\pi/2N)$. If the photon's coherence length is shorter than the cavity length, after N cycles the photon will with certainty be located in cavity #2, due to an interference effect (the equivalent of a π-pulse interaction). However, if cavity #2 instead contains an absorbing object (e.g., the ultra-sensitive bomb), at each cycle there is only a small chance $(= 1 - R)$ that the photon will be absorbed; otherwise, the *non* absorption projects the photon wave packet entirely back onto cavity #1. After all N cycles, the total probability for the photon to be absorbed by the object is $1 - R^N$, which goes to 0 as N becomes large. (In practice, unavoidable losses in the system limit the maximum number of cycles and hence the achievable performance [80.139].) The photon effectively becomes trapped in cavity #1, thus indicating umambiguously the presence of the object in cavity #2.

This quantum-Zeno version of interrogation was first implemented using the inhibited rotation of a pho-

ton's polarization (the object to be detected blocked one arm of a polarizing interferometer through which the photon was repeatedly cycled), achieving an efficiency of 75% [80.139]. A cavity-based implementation, in which the presence of the absorbing object inside a high-finesse cavity vastly increased the reflection off the cavity [80.140], detected the presence of the object with only 0.15 photons on average being absorbed or scattered [80.141].

80.5.4 Weak and "Protected" Measurements

Aharonov, *Albert*, and *Vaidman* extended quantum measurement theory by introducing "weak" measurement, a procedure that determines a physical property of a quantum system belonging to an ensemble that is both preselected and postselected [80.142, 143]. In the standard theory, a quantum system is measured by entangling its eigenstates with distinguishable pointer states of a measurement device, completely resolving the observable eigenvalue spectrum. The measurement can be weakened by increasing the overlap of the pointer states, consequently reducing the resolution of the eigenstates. When performed between two measurements this can give surprising results – in contrast to ordinary expectation values, the pointer can lie outside the range of the eigenvalue spectrum of the measured observable $\mathbf{O}$. The "weak value" $\mathbf{O}_w \equiv \langle \Psi_{\text{ini}}|\mathbf{O}|\Psi_{\text{fin}}\rangle / \langle \Psi_{\text{fin}}|\Psi_{\text{ini}}\rangle$ between preselected ($|\Psi_{\text{ini}}\rangle$) and postselected ($|\Psi_{\text{fin}}\rangle$) states completely characterizes the outcome of the weak measurement. Weak measurements do not disturb each other, so that the weak values of non-commuting observables can be measured simultaneously [80.144, 145]. Furthermore, they have proved to yield meaningful results in many different circumstances, e.g., Hardy's paradox of Sect. 80.6.5 [80.146], measurement of negative kinetic energies [80.147], and the "observation" of a single

particle in two locations [80.148]. One other potentially powerful application of weak measurements is the amplification of weak signals, which was first demonstrated by amplifying the birefringence-induced small displacement of optical fields [80.149, 150]. It was recently shown that weak measurements of this kind in fact arise naturally in fiber optics telecom networks, due to polarization-mode dispersion and polarization-dependent losses [80.151]. One recent proposal [80.152] suggests that the controversy over whether or not "welcher Weg" information may be obtained (and interference consequently destroyed) without disturbing a particle's momentum (Sect. 80.4.2) may be resolved by making weak measurements of momentum inside an interferometer.

The above results push us to reexamine our interpretation of wave functions. We customarily use the wave function only as a calculational tool, but we have also learned that it is in some sense physical, and should not be regarded merely as some distribution from classical statistics. One proposal [80.153, 154] suggests that the wave function of a single particle should be regarded as a real entity. When a state is "protected" from change, e.g., by an energy gap, and measurements are performed sufficiently "gently", one should be able to determine not just the expectation value of position, but the wave function at many different positions, without altering the state of the particle. (This idea of measuring the entire wave function of a single particle should not be conflated with *Raymer* et al.'s fascinating work on the reconstruction of the quantum state of a light field by repeated sampling of a large ensemble; see [80.155] and Sect. 78.4.) No violation of the uncertainty principle or the no-cloning theorem (Sect. 80.7.1) arises from this, as the ability to "protect" a state relies on some preexisting knowledge about the state; but it assigns a deeper significance to the wave function, one *Aharonov* terms "ontological," as opposed to merely epistemological (but see also [80.156]).

80.6 The EPR Paradox and Bell's Inequalities

80.6.1 Generalities

Nowhere is the nonlocal character of the quantum mechanical entangled state as evident as in the "paradox" of *Einstein*, *Podolsky*, and *Rosen* (EPR) [80.157], the version of *Bohm* [80.158], and the related inequalities by *Bell* [80.159, 160]. Consider two photons traveling off back-to-back, described by the entangled

state

$$|\psi^-\rangle = (|H_1, V_2\rangle - |V_1, H_2\rangle) / \sqrt{2} , \qquad (80.9)$$

where the letters denote horizontal (H) or vertical (V) polarization, and the subscripts denote photon propagation direction. This state, analogous to the singlet state of a pair of spin-1/2 particles, is isotropic – it has the same form regardless of what basis is used to describe

it. Measurement of any polarization component for one of the particles will yield a count with 50% probability; individually, each particle is unpolarized. Nevertheless, if one measures the polarization component of particle 1 in any basis, one can predict with certainty the polarization of particle 2 in the same basis, seemingly without disturbing it, since it may be arbitrarily remote. Therefore, according to EPR, to avoid any nonlocal influences one should ascribe an "element of reality" to every component of polarization. A quantum mechanical state cannot specify that much information, and is consequently an incomplete description, according to the EPR argument. The intuitive explanation implied by EPR is that the particles leave the source with definite, correlated properties, determined by some local "hidden variables" not present in quantum mechanics (QM).

For two entangled particles, a local hidden variable (LHV) theory can be made which correctly describes perfect correlations or anti-correlations (i. e., measurements made in the same polarization basis). The choice of an LHV theory versus QM is then a philosophical decision, not a physical one. However, in 1964 *John Bell* [80.159] discovered that QM gives different statistical predictions than does any LHV theory, for situations of nonperfect correlations (i. e., analyzers at intermediate angles). Bell's inequality (BI) constrains various joint probabilities given by any local realistic theory, and was later generalized to include any model incorporating locality [80.161, 162], and also extended to apply to real experimental situations [80.163, 164]. With the caveat of supplementary assumptions (Sect. 80.6.4), Bell's inequalities have now been tested many times, and the vast majority of experiments have violated them, in support of QM. One general interpretation is that the predictions of QM cannot be reproduced by any completely local theory. It must be that the results of measurements on one of the particles depend on the results for the other, and these correlations are not merely due to a common cause at their creation [80.165, 166].

80.6.2 Polarization–Based Tests

The first BI tests were performed with pairs of photons produced via an atomic cascade, and a later version incorporated rapid (albeit periodic) switching of the analyzers [80.167, 168]. Unfortunately, the angular correlation of the cascade photons is not very strong. In contrast, the strong correlations of the down-converted photons make them ideal for such tests, the first of which were performed using setups essentially identical to that already discussed in connection with quantum erasure (Fig. 80.4). Orthogonally polarized (e.g., horizontal and vertical) but otherwise identical photons are combined on a nonpolarizing 50–50 beam splitter. If one considers only the events with a single photon in each output (i. e., ignoring the cases for which both photons use the same beam splitter output port), one obtains the (postselected) entangled state (80.9) [80.169, 170]. (In fact, this technique is now used as a method for characterizing the indistinguishability of photons from independent sources, e.g., quantum dots [80.171] or independent down-conversion crystals [80.172, 173].)

Down-conversion schemes have also been developed to produce entangled states without the need to postselect out half of the photons. For example, consider a type-I phase-matched crystal (Sect. 72.2.2) that down-converts H-polarized pump photons into V-polarized pairs; and an adjacent, identical crystal that is rotated by 90°, thus down-converting V-polarized pump photons into H-polarized pairs. By coherently pumping the two crystals with light polarized at $|45\rangle \equiv (|V\rangle + |H\rangle)/\sqrt{2}$, one obtains the entangled state $(|HH\rangle + |VV\rangle)/\sqrt{2}$. (More generally, pumping $\alpha|V\rangle + e^{i\beta}\beta|H\rangle$ produces arbitrary nonmaximally entangled states of the form $\alpha|HH\rangle + e^{i\varphi}\beta|VV\rangle$ [80.174].) Such a source has produced the largest and fastest violations of Bell inequalities to date (over 200-σ violation in less than 1 second) [80.175, 176].

Using type-II phase-matching one also can produce polarization entanglement from a single crystal [80.177]. One member of each down-conversion pair is emitted along an ordinary polarized cone while the other is emitted along an extraordinary polarized cone. If the photons happen to be emitted along the intersection of the two cones, neither photon will have a definite polarization – they will be in the state $(|HV\rangle + |VH\rangle)/\sqrt{2}$. This entanglement source has now been used in a variety of quantum investigations, including Bell inequality tests [80.177, 178], quantum cryptography [80.179, 180] (Sect. 80.7.4 and Chapt. 81) and teleportation [80.181, 182], and as a resource for studying entanglement of more than 2 photons [80.37–42].

80.6.3 Nonpolarization Tests

The advent of parametric down-conversion has also led to the appearance of several nonpolarization-based BI tests, using, for example, an entanglement of the photon momenta (Fig. 80.8) [80.183]. By use of small irises (labeled 'A' in the figure), *Rarity* and *Tapster* examined four down-conversion modes: 1s, 1i, 2s, and 2i. Beams
Fig. 80.8 Outline of *Rarity* and *Tapster* apparatus used to demonstrate a violation of a Bell's inequality based on momentum entanglement [80.183]

1s and 1i correspond to one pair of conjugate photons; beams 2s and 2i correspond to a different pair. Photons in beams 1s and 2s have the same wavelength, as do photons in beams 1i and 2i. With proper alignment, after the beam splitters there is no way to tell whether a pair of photons came from the 1s–1i or the 2s–2i paths. Consequently, the coincidence rates display interference, although the singles rates at the four detectors indicated in Fig. 80.8 remain constant. This interference depends on the difference of phase shifts induced by rotatable glass plates P_i and P_s in paths 1i and 2s, respectively, and is formally equivalent to the polarization case considered above, in which it is the difference of polarization-analyzer angles that is relevant. By measuring the coincidence rates for two values for each of the phase shifters – a total of four combinations – the experimenters were able to violate an appropriate BI. One interpretation is that the emission directions of a given pair of photons are not elements of reality.

Momentum conservation in the down-conversion process (80.4) also leads to entanglement directly in the spatial modes in the correlated photons. For example, *Zeilinger* et al. [80.184, 185] and *White* et al. [80.186] have demonstrated entanglement between the orbital angular momentum of the photons, of the form $(|+1, -1\rangle + \epsilon|0, 0\rangle + |-1, +1\rangle)$, where 0 and ± 1 respectively denote modes with no orbital angular momentum (gaussian spatial profiles) and $\pm\hbar$ (Laguerre–Gauss-Vortex modes). Note that this enables one to investigate correlations for degrees of freedom that reside in larger Hilbert spaces than do the 2-level systems (e.g., polarization) discussed above. The nonlocal spatial correlations of the down-conversion photons have also given rise to many interesting experiments in the area of quantum imaging [80.187–190], where one is able to obtain spatial resolution beyond that predicted by the usual $\sqrt{N}$ shot-noise limitations.

Several groups [80.191, 192] have violated a BI based on energy–time entanglement of the photons [80.193]. In the method due to *Franson*, one member of each down-converted pair is directed into an unbalanced Mach–Zehnder-like interferometer, allowing both a short and long path to the final beam splitter; the other photon is directed into a separate but similar interferometer. There arises interference between the indistinguishable processes ("short–short" and "long–long") which could lead to coincidence detection. Using fast detectors to select out only these processes, the reduced state (80.9) is

$$|\psi\rangle = \frac{1}{2}\left(|S_1, S_2\rangle - e^{i\phi}|L_1, L_2\rangle\right) , \qquad (80.10)$$

where the letters indicate the short or long path, and the phase is the sum of the relative phases in each interferometer. Although no fringes are seen in any of the singles count rates, the high-visibility coincidence fringes (Fig. 80.9) lead to a violation of an appropriate BI. One conclusion is that it is incorrect to ascribe to the photons a definite time of emission from the crystal, or even a definite energy, unless these observables are explicitly measured.

This same sort of arrangement, modified to work with a pulsed pump, has been used to demonstrate the longest violation of local realism, in which *Gisin's* group has observed a 16-σ BI violation (modulo the detection and timing loopholes discussed in Sect. 80.6.4) with photons separated by 10.9 km [80.194]. In a related experiment, they have used a similar system to place limits on the "speed of collapse" of the 2-photon wave function, i. e., how fast a nonlocal "signal" would need to propagate from one side of the experiment to the other to account for the measured nonclassical correlations. Depending on some assumptions about the detection process and which inertial frame of reference is considered, the nonlocal-influence speed was constrained to be at least $10^4 c$ to $10^7 c$ [80.195]. In one interesting variant, the researchers arranged to have moving detectors, such that in the local reference frame of each detector, it was the other detector which initiated the collapse. (Due to the experimental difficulty of accelerating actual detectors to high velocities, a rapidly rotating absorbing disk was placed close to one output port of a polarizing beamsplitter; following ideas discussed in Sect. 80.5.3, the non-absorbance of the photon by the absorber was deemed sufficient to cause a reduction of the wave function.) As expected, the measured correlations were in no way reduced, but this experiment did rule out one alternative theory of nonlocal collapse [80.196, 197]. Finally,
Fig. 80.9 High-visibility coincidence fringes in a Franson dual-interferometer experiment [80.192] for two values of the phase in interferometer 2 as the phase in interferometer 1 is slowly varied. The curves are sinusoidal fits

by using more than two possible creation times, e.g., with a mode-locked pulsed laser, Gisin's group demonstrated entanglement for a two-photon state in a Hilbert space of at least dimension 11 [80.198].

EPR-like correlations have also been observed directly between two correlated field modes via homodyne tomography [80.199], though the joint Wigner function is positive-definite here. In contrast, a homodyne measurement on the state of a *single* photon split between two paths (Sect. 80.4.4) took advantage of the nonclassical nature of the initial state to violate a Bell inequality [80.46]. Like all existing Bell-inequality experiments, this work suffered from several loopholes (Sect. 80.6.4), but a new proposal suggests that the high efficiency of homodyne detection may provide a unique opportunity for a loophole-free test of Bell's inequalities [80.200].

80.6.4 Bell Inequality Loopholes

In fact, to date no single experiment has unambiguously violated a Bell inequality, due to the existence of two experimental challenges, the detection and locality "loopholes". All of the experiments discussed thus far have required supplementary assumptions, e.g., the "fair-sampling" assumption that the fraction of pairs detected is representative of the entire ensemble emitted by the source. [In fact, for the entangled photons emitted in the atomic cascade experiments, this assumption is manifestly false, because the strong polarization correlations only exist for those photons emitted nearly in opposite directions. If one were to collect all of the emitted photon pairs, they would not lead to a violation (see [80.201]

for a fuller discussion).] To close the locality (or "timing") loophole requires that the analyzer settings be switched rapidly and randomly, in order to guarantee that no (sub)luminal information transfer could account for the observed correlations. The necessary conditions have been met only in the down-conversion experiment by *Zeilinger* et al., which separated the photons by 400 m and used ultrafast random number generation and electronic polarization-analysis choice to ensure space-like separated observers [80.178]. However, in that experiment the detection efficiency was less than 5%.

In order to understand the detection loophole, consider the Clauser–Horne (CH) form of the Bell inequality [80.164], which relates the directly observable singles rates S_1 and S_2 and the coincidence rate C_{12}, rather than "inferred" probabilities, by

$$
\begin{aligned}
C_{12}(a, b) &+ C_{12}(a, b') + C_{12}(a', b) - C_{12}(a', b') \\
&\leq S_1(a) + S_2(b) ,
\end{aligned}
\tag{80.11}
$$

where a and a' (b and b') are any pair of analyzer (e.g., polarizer) settings at detector 1 (2). For certain choices of a, a', b, and b', quantum mechanics predicts the left hand side of the CH inequality can exceed the right hand side. However, in practice this is very difficult to observe, since the coincidence rates fall as η^2 (η is the detection efficiency), compared to the singles rates on the right hand side, which fall only as η. In order to close the detection loophole, one requires $\eta \geq 83\%$ [80.201] (for maximally entangled photons. (*Eberhard* has shown that the required detection efficiency may be reduced to 67% by using nonmaximally entangled quantum systems [80.202, 203]. The idea is that one can choose the analysis settings a and b to reduce the value of the RHS of the CH inequality.) In essence, one requires high detection efficiencies to ensure that the contributions from undetected events are not sufficient to cause the total ensemble to satisfy the Bell inequality even while the detected events violate it.

To date, only the entangled-ion experiment of *Wineland* et al. [80.204] has had sufficiently high efficiencies to close the detection loophole. In this experiment the entangled variables were the hyperfine energy levels of $^9\text{Be}^+$ ions. By employing a cycling transition that leads to the emission of many photons if the atom is in one of the states, a detection efficiency in excess of 98% was achieved, allowing an 8-σ Bell inequality violation. However, because the ions were separated by only 3 μm in the same linear Paul trap, and in fact were measured

using the same laser pulse, there was no possibility of closing the locality loophole. More recently, *Monroe* et al. have demonstrated the entanglement of a trapped ion and a photon [80.205], and have used this to violate a Bell inequality [80.206]. Similar experiments have also enabled the production of up to four entangled ions [80.207]. Though neither of the experimental loopholes was closed in these experiments, they are noteworthy as the first controlled demonstrations of entanglement in massive particles. Efforts are now underway to attempt a direct violation of (80.11) with no auxiliary assumptions using down-conversion photons and high-efficiency ($> 85\%$) single-photon detectors [80.208, 209], in addition to atomic schemes [80.210] and homodyne schemes [80.200] (Sect. 80.6.3), which enjoy even higher intrinsic efficiency.

80.6.5 Nonlocality Without Inequalities

In the above experiments for testing nonlocality, the disagreement between quantum predictions and Bell's constraints on local realistic theories are only statistical. *Greenberger*, *Horne*, and *Zeilinger* (GHZ) pointed out that in some systems involving three or more entangled particles, a contradiction could arise even at the level of perfect correlations [80.211, 212]. A schematic of one version of the GHZ Gedankenexperiment is shown in Fig. 80.10. The source at the center is posited to emit
Fig. 80.10 A three-particle Gedankenexperiment to demonstrate the inconsistency of quantum mechanics and any local realistic theory. All beam splitters are 50–50 [80.111]

trios of correlated particles. Just as the *Rarity–Tapster* experiment selected two pairs of photons (Fig. 80.8), the GHZ source selects two trios of photons; these are denoted by abc and $a'b'c'$. Hence, the state coming from the source may be written

$$|\psi\rangle = \left(|abc\rangle + |a'b'c'\rangle\right) / \sqrt{2} \,. \tag{80.12}$$

After passing through a variable phase shifter (e.g., ϕ_a), each primed beam is recombined with the corresponding unprimed beam at a 50–50 beam splitter. Detectors (denoted by Greek letters) at the output ports signal the occurrence of triple coincidences. The following simplified argument conveys the spirit of the GHZ result.

Given the state (80.12), one can calculate from standard QM the probability of a triple coincidence as a function of the three phase shifts:

$$P(\phi_1, \phi_2, \phi_3) = \frac{1}{8} \left[1 \pm \sin(\phi_a + \phi_b + \phi_c)\right] \,, \tag{80.13}$$

where the plus sign applies for coincidences between all unprimed detectors, and the minus sign for coincidences between all primed detectors. For the case in which all phases are 0, it will occasionally happen (1/8th of the time) that there will be a triple coincidence of all primed detectors. Using a "contrafactual" approach, we ask what would have happened if ϕ_a had been $\pi/2$ instead. By the locality assumption, this would not change the state from the source, nor the fact that detectors β' and γ' went off. But from (80.13) the probability of a triple coincidence for primed detectors is zero in this case; therefore, we can conclude that detector α would have "clicked" if ϕ_a had been $\pi/2$. Similarly, if ϕ_b or ϕ_c had been $\pi/2$, then detectors β or γ would have clicked. Consequently, if all the phases had been equal to $\pi/2$, we would have seen a triple coincidence between unprimed detectors. But according to (80.13) this is impossible: the probability of triple coincidences between unprimed detectors when all three phases are equal to $\pi/2$ is strictly zero! Hence, if one believes the quantum mechanical predictions for these cases of perfect correlations, it is not possible to have a consistent local realistic model.

Down-conversion experiments have enabled the production of 3- and 4-photon GHZ states, with results in good agreement with theory (the all-or-nothing arguments given above become inequalities in any real experiment) [80.37–39].

By similar arguments, *Hardy* has shown the inconsistency of quantum mechanics and local realism in a Gedankenexperiment with just two particles [80.213, 214]. When the arguments are suitably modified to

deal with real experiments, inequalities once again result; these have also been experimentally violated, using non-maximally entangled states from down-conversion [80.215, 216], further underscoring the inconsistency between quantum theory and locality.

80.7 Quantum Information

80.7.1 Information Content of a Quantum: (No) Cloning

The inherent nonlocality of particles in an entangled state cannot be used to transmit superluminal messages. For example, if A and B receive a polarization-entangled pair of photons, which A then collapses in a certain basis by performing a polarization measurement, B can only extract one bit of information from a measurement on his photon – this bit corresponds not to A's choice of basis, but to the (random) outcome of A's measurement. However, instantaneous communication would be possible if one could make copies ("clones") of a single photon in an unknown polarization state: by performing measurements on n copies of his photon, B could determine its polarization to a resolution of n bits, thereby accurately determining A's choice of basis. Taking into account quantum fluctuations [80.217], one finds that no physically allowed amplifier can make a sufficiently faithful copy for such a scheme to work – it is impossible to clone an unknown quantum state [80.218]. A simple proof is as follows. Consider an ideal cloner, initially in the state $|i\rangle_c$, which would take $|0\rangle|i\rangle_c \rightarrow |0\rangle|0\rangle_c$ and $|1\rangle|i\rangle_c \rightarrow |1\rangle|1\rangle_c$. For an accurate copier, one would expect $(|0\rangle + |1\rangle)|i\rangle_c \rightarrow (|0\rangle + |1\rangle)(|0\rangle_c + |1\rangle_c)$, but the linearity of quantum transformations instead yields $|0\rangle|0\rangle_c + |1\rangle|1\rangle_c$, i.e., an entangled state.

Although perfect cloning is impossible, it is nevertheless possible to create copies which are "pretty good". Specifically, using an optimal cloning strategy, one can in principle create a copy with a fidelity of 5/6 with the original state [80.219, 220]. Such a cloning procedure has been experimentally realized by several groups, e.g., relying on stimulated emission, or sending the photon to be cloned through a low noise optical amplifier, with results matching the theoretical predictions [80.221–223].

80.7.2 Super–Dense Coding

The previous considerations make the work by *Bennett* et al. on "quantum teleportation" and related effects all the more remarkable. In the quantum dense-coding protocol, a single photon can be used to transfer two bits of information, when it is part of an en-tangled EPR pair [80.224]. Again consider A and B, each possessing one photon of such a pair. By manipulating only her photon (via a polarization rotator and a phase shifter), A can convert the initial joint state $|\psi^-\rangle$ (80.9) into any of the four two-particle "Bell states" $[|\psi_{AB}^\pm\rangle = (|H_A, V_B\rangle \pm |V_A, H_B\rangle)/\sqrt{2}$, $|\phi_{AB}^\pm\rangle = (|H_A, H_B\rangle \pm |V_A, V_B\rangle)/\sqrt{2}]$, and then send her photon to B. By making a suitable measurement on both photons, B can then in principle determine which of the four states A produced [80.225]: A's single photon carried two bits. This protocol has been experimentally realized using down-conversion photons [80.226], though only two of the four Bell states could be reliably distinguished. (Standard polarization Bell state analysis is implemented by combining the two photons on a non-polarizing 50–50 beam splitter. For any of the triplet states $|\psi^+\rangle$, $|\phi^\pm\rangle$, the photons will both travel to the same output port due to the Hong–Ou–Mandel interference discussed in Sect. 80.3.3; only for the state $|\psi^-\rangle$ will the photons travel to different outputs, resulting in a coincidence detection.)

80.7.3 Teleportation

In the even more striking quantum teleportation effect [80.227], an unknown polarization state f (with its in-principle infinite amount of information) can be "teleported" from A to B, if each already possesses one photon of an EPR pair (e.g., in the singlet state $|\psi_{AB}^-\rangle$). First, A jointly measures her EPR photon and the photon F (whose state f is to be teleported) in the basis defined by the Bell states of these two photons. Via a mere two bits of classical information, A then informs B which of the four (equally probable) Bell states she actually measured. With this information, B can transform the state of his EPR particle into f. For example, if A found the singlet state $|\psi_{BF}^-\rangle$, then the polarization of her EPR photon must have been orthogonal to that of F (because the polarizations of particles in a singlet state are always perfectly anticorrelated, regardless of the quantization basis). But because the two EPR photons were initially also in a singlet state, their polarizations must also be orthogonal, so B's EPR photon is already in state f. If instead A found $|\phi_{BF}^-\rangle$,

for example, then *B* simply makes the same transformation (with a polarization rotator) that would have changed $|\psi_{AB}^-\rangle$ into $|\phi_{AB}^-\rangle$, again leaving his photon in the state f. Thus, although one may only extract one bit of (normally useless) information from an EPR particle, the perfect correlations may be used to transfer an infinite amount of information, i. e., precise specification of a point in the state space of the particle (the Poincaré sphere for a photon or the Bloch sphere for an electron). The "no-cloning" theorem (Sect. 80.7.1) is not violated, since *A* irrevocably alters the state of *F* by the measurement she performs, leaving only one particle in f.

A number of experiments have now experimentally realized quantum teleportation. The first of these used polarization-entangled down-conversion photons [80.181], but was limited by the impossibility to resolve all four Bell states using only linear optics. Teleportation of continous-variable states has also been observed [80.228], using twin-beam squeezed states (Sect. 80.2.3). Recently, the first teleportation in a matter system has been achieved: the groups of *Blatt* et al. [80.229] and *Wineland* et al. [80.230] have successfully teleported the (energy) quantum state of an ion to a separate ion. Although the overall distance was less than 1 mm, these challenging experiments are significant because they incorporate most of the techniques necessary for scalable quantum information processing in an ion-trap system (see Sect. 81.7.2).

In an interesting extension of the original teleportation protocol, one can ask what happens if the photon to be teleported is itself entangled to a 4th photon *G*. In this case, known as "entanglement swapping", a successful teleportation will lead to the entanglement of photons *G* and *B*, even though these have never directly interacted. Entangled down-conversion photons have been used to demonstrate such "entanglement swapping" achieving a violation of Bell's inequalities between the two noninteracting photons [80.231]; similar results have been achieved with continous variables as well [80.232]. Such procedures may one day enable construction of a quantum "repeater" which could enable the transmission of quantum information over long distances [80.233, 234].

A fundamental connection between quantum information and black holes has recently been suggested by Lloyd and Ng [80.235] and others. The basic idea is that every physical object, including a black hole, can be thought of as a quantum computer that unitarily transforms input states to output states; i. e., "in" quantum bits ("qubits") can always be reversibly interconverted into "out" qubits, thus obeying time-reversal symmetry. To resolve the paradox of the apparent loss of information of matter falling into a black hole, Lloyd and Ng propose that pairs of entangled photons can materialize at the event horizon of a black hole. One member of the photon pair flies outward to become the Hawking blackbody radiation; the other falls into the black hole and hits the singularity together with the matter that formed the hole. The annihilation of the infalling photon acts as a measurement on the infalling matter in a quantum teleportation-like process, transporting the information contained in the infalling matter to the outgoing Hawking radiation, using the Horowitz–Maldacena mechanism [80.236].

80.7.4 Quantum Cryptography

Although EPR schemes cannot send signals superluminally, they have other potential applications in cryptography. In the "one-time pad" of classical cryptography [80.237], two collaborators share a secret "key" (a random string of binary digits) in order to encode and decode a message. Such a key may provide an absolutely unbreakable code, provided that it is unknown to an eavesdropper. The problem arises in key distribution: any classical distribution scheme is subject to noninvasive eavesdropping, e.g., using a fiber-coupler to tap the line, without disturbing the transmitted classical signal. In quantum cryptography proposals, security is guaranteed by using single-photon states [80.238, 239], some of the schemes employing particles prepared in an EPR-entangled state. Each collaborator receives one member of each correlated pair, and measures the polarization (or whatever degree of freedom is carrying the information) in a random basis. After repeating the process many times, the two then discuss publicly which bases were used for each measurement, but not the actual measurement results. The cases where different bases were chosen are not used for conveying the key, and may be discarded, along with instances where one party detected no photon. In cases where the same bases were used, however, the participants will now have correlated information, from which a random, shared key can be generated. As long as single photons are used, any attempt at eavesdropping, even one relying on QND, will necessarily introduce errors due to the uncertainty principle. If the eavesdropper uses the wrong basis to study a photon before sending it on to the real recipient, the very act of measuring will disturb the original state.

Although one can perform quantum cryptography with single-photon states or even weak coherent states (Sect. 81.2.1), there are a number of advantages to using entanglement: there is inherent randomness; photons from different pairs show no correlations (unlike multiple photons in an attenuated coherent state, which may be used by an eavesdropper to gain information), and any information leaked to other degrees of freedom automatically shows up as increased error rate [80.240]. This last feature means that the sources are "self-checking" in a sense, and one could even let an adversary have control over the source, secure in the knowledge that any tampering would become evident in the nonlocal correlations. A number of quantum cryptography implementations using down-conversion photon pairs have been realized, either using polarization entanglement [80.179, 180, 241, 242], or energy–time entanglement [80.243, 244]. One main experimental challenge will be to increase the rates of entangled pair production (the typical source emission rate for these cryptography experiments is only 10 000 /s), to make them competitive with current weak coherent pulse schemes (which can easily operate at over 10 MHz).

80.7.5 Issues in Causality

Outstanding causal paradoxes in optics include the paradox of *Barton* and *Scharnhorst* [80.245], closely related to the Casimir effect (Sect. 79.2.4). In this case, the amplitude for light-by-light scattering is modified by the presence of closely-spaced parallel conducting plates. It appears that this can lead to propagation of light in vacuum (albeit a vacuum "colored" by the presence of the Casimir plates) faster than *c*. *Hegerfeldt* has pointed out similar paradoxes in connection with localization of any particle in a quantum field theory [80.246] and with the *Glauber* theory of photodetection (Sect. 78.4) [80.247]. However, at least for the simplest example – the interaction between two widely separated atoms – as long as one considers only probabilities that depend on the separation r, the second atom cannot be excited by light from the first until after a time r/c [80.248].

80.8 The Single–Photon Tunneling Time

80.8.1 An Application of EPR Correlations to Time Measurements

In this section we discuss experiments involving the quantum propagation of light in matter. Due to the sharp time correlations of the paired photons from spontaneous down-conversion, one can use the HOM interferometer (Sect. 80.3.3, and Fig. 80.4) to measure very short relative propagation delay times for the signal and idler photons. One early application was therefore to confirm that single photons in glass travel at the group velocity [80.91]. At least until recently, the only quantum theory of light in dispersive media was an ad hoc one [80.249–256]. The shift of the interference dip resulting from a medium introduced into one of the interferometer arms can be accurately measured by determining how much the path lengths must be changed to compensate the shift and recover the dip. This result suggests that when looking for a microscopic description of dielectrics, it is unnecessary to consider the medium as being polarized by an essentially classical electric field due to the collective action of all photons present, and reradiating accordingly. Linear dielectric response is not a collective effect in this sense – each photon interferes only with itself (as per Dirac's dictum) as it is partially scattered from the atoms in the medium. The single-photon group velocity thus demonstrates "wave–particle unity."

The standard limitation for measurements of short-time phenomena is that to have high time-resolution, one needs short pulses (or at least short coherence lengths), but these in turn require broad bandwidths and are therefore very susceptible to dispersive broadening. It is a remarkable consequence of the EPR energy correlations of the down-conversion photons (Sect. 80.6.3) that time measurements made with the HOM interferometer are essentially immune to such broadening [80.91, 257, 258]. In effect, the measurement is sensitive to the difference in emission times while the broadening is sensitive to the sum of the frequencies. While frequency and time cannot both be specified for a given pulse, the crucial feature of EPR correlations such as those exhibited by down-converted photons is that this difference and this sum correspond to commuting observables, and both may be arbitrarily well defined. The photon which reaches detector 1 could either have traversed the dispersive medium and been transmitted, or traversed the empty path and been reflected, leaving its twin to traverse the medium. The medium thus samples both of the (anticorrelated) frequencies, leading to an automatic cancellation of

any first-order (and in fact, all odd-order) dispersive broadening. Measurements can be more than 5 orders of magnitude more precise than would be possible via electronic timing of direct detection events, and in principle better than those performed with nonlinear autocorrelators (which rely on the same nonlinear physics as down-conversion, but do not benefit from a cancellation of dispersive broadening).

80.8.2 Superluminal Tunneling Times

Another well-known problem in the theory of quantum propagation is the delay experienced by a particle as it tunnels. There are difficulties associated with calculating the "duration" of the tunneling process, since evanescent waves do not accumulate any phase [80.259–261]. First, the kinetic energy in the barrier region is negative, so the momentum is imaginary. Second, the transit time of a wavepacket peak through the barrier, defined in the stationary phase approximation by

$$\tau^{(\phi)} \equiv \partial \left[\arg t(\omega)\, \mathrm{e}^{\mathrm{i}kd} \right] / \partial \omega \,, \qquad (80.14)$$

tends to a constant as the barrier thickness diverges, in seeming violation of relativistic causality. (Actually, it is shown in [80.88] that such saturation of the delay time is a natural consequence of time-reversal symmetry, and in [80.262] that one can deduce from the principle of causality itself that *every* system possesses a superluminal group delay, at least at the frequency where its transmission is a minimum.) For example, the transmission function for a rectangular barrier,

$$t(k, \kappa) = \frac{\mathrm{e}^{-\mathrm{i}kd}}{\cosh \kappa d + \mathrm{i}\frac{\kappa^2 - k^2}{2k\kappa} \sinh \kappa d} \,, \qquad (80.15)$$

leads in the opaque limit ($\kappa d \gg 1$) to a traversal time of $2m/\hbar k\kappa$, independent of the barrier width d. The same result applies to photons undergoing frustrated total internal reflection [80.88], when the mass m is replaced by $n^2 \hbar \omega / c^2$, and similar results apply to other forms of tunneling.

Some researchers have therefore searched for some more meaningful "interaction time" for tunneling, which might accord better with relativistic intuitions and perhaps have implications for the ultimate speed of devices relying on tunneling [80.263]. The "semiclassical time" corresponds to treating the magnitude of the (imaginary) momentum as a real momentum. This time is of interest mainly because it also arises in *Büttiker* and *Landauer's* calculation of the critical timescale in problems involving oscillating barriers, which they take to

imply that it is a better measure of the duration of the interaction than is the group delay [80.259]. The Larmor time [80.264] is one of the early efforts to attach a "clock" to a tunneling particle, in the form of a spin aligned perpendicular to a small magnetic field confined to the barrier region. The basic idea is that the amount of Larmor precession experienced by a transmitted particle is a measure of the time spent by that particle in the barrier. This clock turns out to contain components corresponding both to the distance-independent "dwell time" and the linear-in-distance semiclassical time. Curiously, the most common theories for tunneling times become superluminal in certain cases anyway, whether or not they deal with the motion of wave packets.

Here, we will restrict ourselves to discussing the time of appearance of a peak of a single-photon wave packet. While other tunneling-time experiments have been performed in the past [80.265], optical tests offer certain unique advantages [80.266], including the ease of construction of a barrier with no dissipation, very little energy-dependence, and a superluminal group delay. The transmitted wave packets suffer little distortion, and are essentially indistinguishable from the incident wave packets. At a theoretical level, the fact that photons are described by Maxwell's (fully relativistic) equations is an important argument against interpreting superluminal tunneling predictions as a mere artifact of the nonrelativistic Schrödinger equation. Also, one is denied the recourse suggested by some workers [80.267] of interpreting the superluminal appearance of transmitted peaks to mean that only the high-energy components (which, for matter waves, traveled faster even before reaching the barrier [80.268]) were transmitted.

80.8.3 Tunneling Delay in a Multilayer Dielectric Mirror

A suitable optical tunnel barrier can be a standard multilayer dielectic mirror. The alternating layers of low and high index material, each one quarter-wave thick at the design frequency of the mirror, lead to a photonic bandgap [80.269] analogous to that in the Kronig–Penney model of solid state physics (Sect. 79.2.6). The gap represents a forbidden range of energies, in which the multiple reflections will interfere constructively so as to exponentially damp any incident wave. The analogy with tunneling in nonrelativistic quantum mechanics arises because of the exponential decay of the field envelope within the periodic structure, i. e., the imaginary value of the quasimomentum. The same qualitative features arise for the transmission time: for thick barriers,

it should saturate at a constant value, as was verified in a recent experiment employing short classical pulses [80.270]. (A more direct analogy, that of waveguides beyond cutoff, yielded similar results in a classical microwave experiment [80.271], while another paper has reported superluminal effects related to the penetration of diffracted or "leaky" microwaves into a shadow region [80.272]. All these experiments involve very small detection probabilities, just as in *Chu* and *Wong's* pioneering experiment on propagation within an absorption line [80.273]. However, it has been predicted that superluminal propagation could occur without high loss or reflection [80.274–276], by operating outside the resonance line of an inverted medium (Sect. 70.1). One can understand the effect as off-resonance "virtual amplification" of the leading edge of a pulse.)

The phenomenon was investigated at the single-photon level by using the high time-resolution techniques discussed in Sect. 80.8.1 to measure the relative delay experienced by down-conversion photons [80.277] when such a tunnel barrier (consisting of 11 layers) was introduced into one arm of a HOM interferometer. The transmissivity of the barrier was relatively flat throughout the bandgap (extending from 600 nm to 800 nm; Fig. 80.11), with a value of 1% at the gap center (700 nm), where the experiment was performed. The HOM coincidence dip was measured both with the barrier (and its substrate) and with the substrate
Fig. 80.12 Coincidence profiles with and without the tunnel barrier map out the single-photon wave packets. The *lower profile* shows the coincidences with the barrier; this profile is shifted by ≈ 2 fs to negative times relative to the one with no barrier (*upper curve*): the average particle which tunnels arrives earlier than the one which travels the same distance in air

alone (Fig. 80.12). Each dip was subsequently fitted to a Gaussian, and the difference between their centers was calculated. When several such runs were combined, it was found that the tunneling peak arrived 1.47 ± 0.21 fs earlier than the one traveling through air, in reasonable agreement with the theoretical prediction of approximately 1.9 fs. Taking into account the 1.1 μm thickness of the barrier, this implies an effective photon tunneling velocity of $1.7\,c$. The results exclude the "semiclassical" time but are consistent with the group delay. An investigation of the energy-dependence of the tunneling time was also performed, by angling the dielectric mirror, thus shifting its bandgap [80.278]. The data confirm the group delay in this limit as well, and rule out identification of Büttiker's Larmor time with a peak propagation time, at least in this optical system.

80.8.4 Interpretation of the Tunneling Time

Even though a wave packet peak may appear on the far side of a barrier sooner than it would under allowed propagation, it is important to stress that no information is transmitted faster than *c*, nor on average is any energy. These effects occur in the limit of low transmission, where the transmitted wavepacket can be considered as a "reshaped" version of the leading edge of the incident pulse [80.273, 279, 280]. At a physical level, the
Fig. 80.11 Transmission probability for the tunnel barrier used in [80.277] (*heavy dotted curve*); *heavy black*, *dashed brown*, and *solid grey* curves show group delay, Larmor time, and semiclassical time. Also shown for comparison is the "causality limit" $d/c = 3.6$ fs (*horizontal line*)

reflection from a multilayer dielectric is due to destructive interference among coherent multiple reflections between the different layers. At times before the field inside the structure reaches its steady-state value, there is little interference, and a non-negligible fraction of the wave is transmitted. This preferential treatment of the leading ramp-up engenders a sort of "optical illusion," shifting the transmitted peak earlier in time. A signal, such as a front with a sharp onset, relies on arbitrarily high-frequency components, which would not benefit from this illusion, but instead travel arbitrarily close to the vacuum speed of light c. Even for a smooth wave packet, no energy travels faster than light; most is simply reflected by the barrier. Only if one considers the Copenhagen interpretation of quantum mechanics, with its instantaneous collapse, does one find superluminal propagation of those particles which happen to be transmitted. This leads to the question of whether it is possible to ask which part of a wave packet a given particle comes from.

One paper argued that transmitted particles do in fact stem only from the leading ramp-up of the wave packet [80.281]. While it is true that the transmission only depends on causally connected portions of the incident wave packet, further analysis revealed that simultaneous discussion of such particle-like questions and the wave nature of tunneling ran afoul of the complementarity principle [80.282]. In essence, labeling the initial positions of a tunneling particle destroys the careful interference by which the reshaping occurs (as in the quantum eraser, Sect. 80.4.1). However, one picture in which the transmitted particles really *do* originate earlier is the Bohm–de Broglie model of quantum mechanics [80.283, 284]. This theory considers Ψ to be a real field (residing however in configuration space, thus incorporating nonlocality) which guides pointlike particles in a deterministic manner. It reproduces all the predictions of quantum mechanics without incorporating any randomness; the probabilistic predictions of QM arise from a range of initial conditions. Bohm's equation of motion has the form of a fluid-flow equation, $\mathbf{v}(\mathbf{x}) = \hbar \nabla \arg \Psi(\mathbf{x})/m$, implying that particle trajectories may never cross, as velocity is a single-valued function of position. Consequently, all transmitted particles originate earlier in the ensemble than all reflected particles [80.282, 285]. This approach yields trajectories with well-defined (and generally subluminal) dwell times in the barrier region. However, the fact that the mean tunneling delay of Bohm particles diverges as the incident bandwidth becomes small, along with other interpretational issues [80.286, 287], leaves open the question of whether time scales as defined by the Bohm model have any physical meaning.

The "weak measurement" approach of *Aharonov* et al. [80.142, 143] or equivalently, complex conditional probabilitiy amplitudes obeying Bayes's theorem [80.288, 289], can be used to address the question of tunneling interaction times in an experimentally unambiguous way. The real part of the resulting complex times determine the effect a tunneling particle would have on a "clock" to which it coupled, while the imaginary part indicates the clock's back-action on the particle. They unify various approaches such as the Larmor and Büttiker–Landauer times, as well as Feynman-path methods. In addition, they allow one to discuss separately the histories of particles which have been transmitted or reflected by a barrier, rather than discussing only the wave function as a whole. Interestingly, these calculations do not support the assertion that transmitted particles originate in the leading ramp-up of a wave packet.

80.8.5 Other Fast and Slow Light Schemes

In addition to the case of tunneling described already, apparently superluminal propagation was observed in a Bessel-beam geometry [80.290], and in the case of an inverted medium [80.291], as described in [80.274–276]. While the former case may be explained geometrically, the latter – in which superluminal group velocities occur without significant gain, loss, or distortion – raises difficult questions about the speeds of propagation of both energy and information. For two contrasting perspectives, see [80.292] and [80.293]. Much more work has followed, including theoretical treatments of the role of quantum noise in preventing superluminal information transfer [80.294], and attempts to experimentally compare the velocity of information transfer with the group velocity [80.295]. The latter work seemed to verify the claim, previously tested only in an electronic analog [80.296], that even in the regime of superluminal propagation, new information was limited to causal speeds. Some dispute has persisted [80.297], and it seems clear that a more rigorous definition of information velocity is required; somewhere between the idealized extremes of infinitely sharp signal fronts and strictly finite signal bandwidths lies the real world, and neither the front velocity nor the group velocity should be expected to completely describe the behavior of actual information-carrying pulses. At the same time, the definition of the energy

velocity in active media cannot be resolved without reviving long-standing conundra about how to apportion energy between the propagating field and energy stored in the medium [80.298].

Since 1999, there has actually been much more excitement over so-called "slow light" than over "fast light" [80.299]. Building on the concepts of electromagnetically-induced transparency [80.300] (Sect. 69.7), two groups succeeded in that year in utilizing the steep dispersion curves which can be generated by extremely narrow holes in absorption lines to slow light by a remarkable factor, with group velocities as low as 17 m/s [80.301, 302]. Two years later, two experiments succeeded in bringing light to a standstill [80.303, 304]. This can be understood in terms of a "dark-state polariton" model, in which the propagating photon is adiabatically converted into a (stationary) metastable atomic excitation. In addition to the obvious possibilities for storage of optical pulses, particularly tantalizing at the quantum level [80.305], there have been several proposals for generating extremely strong optical nonlinearities in this system, perhaps directly applicable to quantum information processing [80.306, 307]. Both slow light and fast light have now been observed in solid-state systems [80.308, 309], as well. In both cases, the extension to the single-photon level remains a major goal, for both practical and theoretical reasons. For a recent review on anomalous optical propagation velocities, see [80.310].

80.9 Gravity and Quantum Optics

According to general relativity, gravitational radiation can be produced and detected by moving mass distributions [80.311–313]. However, gravitational radiation is coupled only to time-varying mass quadrupole moments in lowest order, since the mass dipole moment is $\sum_j m_j \boldsymbol{r}_j = M \boldsymbol{R}_{cm}$ and $\boldsymbol{R}_{cm}$ for a closed system can only exhibit uniform rectilinear motion. Current efforts focus on detecting gravitational waves (typically at 100 Hz to 1 kHz) from astrophysical sources, such as supernovae or collapsing binary stellar systems. For example, it is expected that in the nearby Virgo cluster of galaxies, several such events should occur per year, each yielding a fractional strain ($\Delta L/L$) of 10^{-21} on Earth. However, there are large uncertainties in this estimate.

Two main efforts have been pursued toward gravitational wave detection. The first type of detector, the resonant-mass detector (sometimes known as a "Weber bar," after its inventor), utilizes a large cylindrical mass whose fundamental mode of acoustical oscillation is resonantly excited by time-varying tidal forces produced by the passage of a gravitational wave. The induced motions are typically detected by piezoelectric crystals, or by SQUIDs (superconducting quantum interference devices) [80.314], yielding strain sensitivities better than $10^{-18}/\sqrt{\text{Hz}}$. Such detectors were first constructed in the 1960's [80.313], and are still in use (e.g., such as the 2.3-ton bar at Louisiana State University, ALLEGRO [80.315]), but to date no incontrovertible detections have been reported. (Attempts to improve the signal-to-noise ratio in resonant-mass GW detectors led to the consideration of back-action-evading sensors (a special case of QND measurements, Sect. 80.5.2) to circumvent the standard quantum noise limit [80.316].)

More recently, a large amount of research has been devoted to using optical interferometry to detect gravitational radiation. A passing gravitational wave alters the relative path length in the arms of a Michelson interferometer, thereby slightly shifting the output fringes. Although the effective gravitational mass of the light is much smaller than that of the Weber bar, very long interferometer arms (2–4 km, with a Fabry–Perot cavity in each arm to increase the effective length) more than make up for this disadvantage. The signal-to-noise ratio for the detection of a fringe shift depends on the power of the light. The US initiative, called LIGO (Laser Interferometer Gravitational-Wave Observatory [80.317]) uses 10 W from a Nd:YAG laser, and an additional external mirror to recirculate the unmeasured light, thus increasing the stored light power up to 10 kW.

There are three LIGO interferometers, located respectively in Hanford, Washington (with both a 2 km and a 4 km version) and Livingston, Louisiana (4 km version). The registration of coincident events at the separated interferometers allows one to rule out terrestial artifacts, but many problems involving seismic and thermal isolation, absorption and heating, intrinsic thermal noise and optical quality had to be addressed. The LIGO interferometers have had several preliminary science runs since Fall 2002; the first true "search run" is scheduled for 2005 [80.318]. The present sensitivities, which range from 10^{-21} to $10^{-22}/\sqrt{\text{Hz}}$ (at ≈ 200–300 Hz) are approaching the initial design goal of $3 \times 10^{-23}/\sqrt{\text{Hz}}$.

Other similar detectors nearing, or currently in, operation are VIRGO (in Pisa, Italy), GEO 600 (near Hannover, Germany), and TAMA (in Tokyo, Japan); planning for an instrument (ACIGA) in Australia is underway, as is planning for the NASA/ESA collaborative Laser Interferometer Space Antenna (LISA), currently aiming for launch in 2012 [80.319]); this space-based interferometer, with arms up to 5×10^6 km long, would probe frequencies from 10^{-4} to 10^{-1} Hz, inaccessible to terrestial experiments due to seismic and atmospheric disturbances.

Because the standard quantum noise limit of these detectors is ultimately determined by the vacuum fluctuations incident on the unused input ports of the interferometers, it is in principle possible to achieve reduced noise levels by using squeezed vacuum instead [80.313, 320] (Sect. 80.2.3).

This has been demonstrated experimentally in table-top experiments [80.55, 321], though there are no plans to incorporate it into the current version of LIGO.

It has also been suggested that matter waves which interact with gravity waves inside a matter–wave interferometer (Sect. 80.3.1) could lead to a sensitive method to detect gravitation radiation [80.322, 323]. Such a "Matter–wave Interferometric Gravitational-wave Observatory" (MIGO) may allow the detection of primordial gigahertz gravity waves arising from the Big Bang [80.324]. Moreover, quantum mechanical detectors based on the use of macroscopically coherent entangled states may enable quantum transducers which can interconvert between electromagnetic and gravitational radiations, based on time-reversal symmetry [80.325, 326].

81. Quantum Information

For many years atomic physicists had used quantum mechanics very successfully to calculate energy levels, cross sections and other practical quantities, and for the most part, left the philosophical issues of interpretation to others. But after the work of Bell in the 1960's showed that the peculiarly nonlocal nature of quantum correlations could be tested in the lab, a number of atomic physicists turned to the experimental study of entanglement and quantum measurement. A second phase began at the start of the 1990's when it was realized that correlations and quantum superpositions could be exploited in quantum information processing and secure communication. This has led to an explosive growth of the subject over the past 10 years, fuelled by the long-term prospects of quantum computing and the nearer goal of quantum cryptography. We review some of these developments in this chapter.

Quantum information theory is regarded as a mainly mathematics-based subject area which straddles the fields of theoretical physics (quantum mechanics and statistics), mathematics, and theoretical computer science. Its success stems from the introduction of novel methods into both physics and mathematics.

The fundamental quantity and resource in many applications in quantum information processing is quantum-mechanical entanglement between spatially separated subsystems. Entanglement is a purely quantum-mechanical effect and has led to numerous speculations about the validity of quantum mechanics itself for its apparent paradoxical implications. Most, if not all, of these difficulties have been resolved and can be mostly attributed to the simple fact that paradoxical behaviour is incompatible with common sense or everyday experience. This initial upsetting seems to be common to all revolutionary theories and has occurred most notably in Einstein's theory of relativity [81.1].

These quantum-mechanical correlations have numerous applications in quantum cryptography [or rather quantum key distribution (QKD)], quantum communication, dense coding, and act as the main resource in quantum computing. We will briefly touch upon some mathematical issues concerning separability, quantification of entanglement and channel capacities before describing how quantum key distribution, teleportation and dense coding work. After that, a brief discussion of single-qubit and two-qubit quantum gates

follows before we describe the simplest quantum algorithms. The issues of error correction and fault tolerant computation as well as DiVincenzo's checklist (which any realization should satisfy) provide the background for the discussion of some physical implementations.

We are acutely aware of the fact that we can give only a brief introduction into what has become a major field of investigation over the last decade. There are already a number of review articles and textbooks on the market that cover the vast literature on this emerging subject. Amongst those are the first quantum computing compendium by *Gruska* [81.2] and the quantum information textbooks by *Nielsen* and *Chuang* [81.3] and *Stolze* and *Suter* [81.4]. A regularly updated annotated bibliography on this subject, compiled by *Cabello*, forms an invaluable resource for those interested in the subject of this chapter [81.5, 6].

81.1 Quantifying Information

As already noted, entanglement comes about if a quantum-mechanical system can be divided into several parts. As an example, consider a two-photon emission process from a spin-zero particle by which two photons escape in opposite directions. Given that the photons are spin-one particles, their spin projections onto some axis must be mutually opposite. As there is no prior information about the actual orientation of the spin, the part of the photon wave function associated with the spin degree is therefore

$$|\psi\rangle = \frac{1}{\sqrt{2}} \left(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle \right) . \tag{81.1}$$

The striking feature of this type of quantum state is that it describes correlations of two spatially separated particles. If the polarization state of one photon is measured, the state of the other particle, which can be far away, is then instantly predetermined. These (nonlocal) correlations that exist between the particles are of purely quantum origin and are called entanglement. Note, however, that no information can be transmitted faster than the speed of light with this type of set up because the (classical) information concerning the measurement result on one particle needs to be transmitted via a necessarily causal classical channel.

The issue of nonlocality has been seen as a vital part in understanding the foundations of quantum mechanics itself (Chapt. 80). In 1935, *Einstein*, *Podolsky*, and *Rosen* argued on the basis of entangled states that quantum mechanics is incomplete [81.7]. They were most concerned about the existence of elements of reality within strongly correlated quantum systems and initiated the debate on quantum nonlocality. The non-existence of so-called local hidden variable theories for the description of states like (81.1) was finally demonstrated by *Bell* [81.8, 9]. He showed that maximally entangled states violate certain inequalities (now called Bell's in-

equalities) which local hidden variable models would have obeyed. Later experiments showed the correctness of Bell's demonstration [81.10–14].

In classical information theory, the unit of information is called a bit, which can be defined as the amount of information contained in a yes–no question. As a matter of fact, 'bit' is the abbreviation for 'binary digit' and refers to Boolean algebra in which the allowed states of a system are the logical 0 and the logical 1. Therefore, by abuse of language, one bit (as a unit) is the information carried by one bit (as a binary digit) [81.15].

In quantum mechanics, however, due to its inherent linearity, two 'quantum bits' (qubits for short) can be in superpositions of the logical states $|01\rangle$ and $|10\rangle$, or $|\uparrow\downarrow\rangle$ and $|\downarrow\uparrow\rangle$, as in the example above. This typical example of an entangled state shows that quantifying the amount of information contained in a quantum state is different from what is known in classical information theory because of the superposition property. The very same linearity prohibits us from copying an arbitrary quantum state. This effect is known as the no-cloning theorem [81.16]. However, universal copying machines can be constructed within the constraints of quantum mechanics [81.17].

81.1.1 Separability Criterion

From the above it is clear that entangled states play a major role in defining the differences between classical and quantum information. Let us begin by asking under which circumstances a particular given quantum state is entangled or not. For this, we need to give a criterion which allows one to decide this crucial question. Consider a bipartite quantum state, i. e., a state which is decomposed into two distinct, albeit possibly correlated, subsystems A and B. Note that these subsystems themselves might consist of ensembles of particles, in which

case we are looking at a bipartite cut through the whole system. Then we say that a bipartite state is not entangled and hence separable if its density operator can be written as a convex combination of tensor product states, viz.

$$\hat{\varrho} = \sum_i p_i \hat{\varrho}_A^i \otimes \hat{\varrho}_B^i , \quad \sum_i p_i = 1 . \tag{81.2}$$

The range of summation in (81.2) is limited by a theorem due to Caratheodory which states that every point in a convex set can be reached by suitable convex combinations of its extreme points. All states that cannot be written in the form of (81.2) are said to be entangled. Note that the set of separable states form a convex subset of the convex set of all possible states.

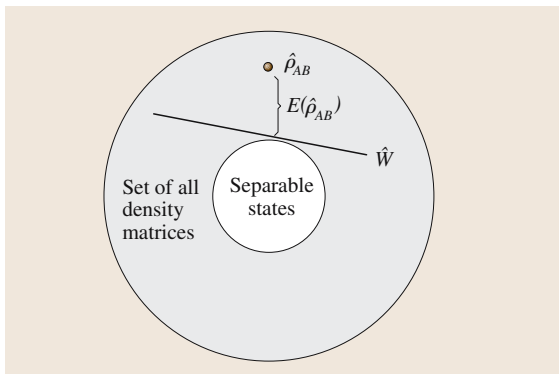
We will now give a simple criterion which decides whether a given state is actually separable or not. For this, one notes that by transposing the part of the density operator associated with the subsystem B, an operation which is called partial transposition, the resulting operator will not necessarily stay positive. However, if the density operator is separable, then its partial transpose is again a positive operator, and hence is a valid density operator. This condition of a state possessing a positive partial transpose is a necessary separability criterion [81.18] but sufficient only in the case of density matrices having Hilbert space dimensions 2×2 or 2×3 [81.19]. In higher-dimensional Hilbert spaces there exist states with positive partial transposes (PPT) which are nevertheless inseparable. This phenomenon is called bound entanglement [81.20, 21].


Fig. 81.1 Convex set of bipartite density matrices; the inner convex set represents the separable states. The witness operator $\hat{W}$ forms a hyperplane that separates $\hat{\varrho}_{AB}$ from the set of separable states

Because of the convexity of the set of separable states, one can construct an operator (a hyperplane) $\hat{W}$ that separates an entangled state from the disentangled states,

$$\mathrm{tr}\left(\hat{W}\hat{\varrho}_{AB}\right) < 0 \Leftrightarrow \hat{\varrho}_{AB} \text{ inseparable} ,$$
$$\mathrm{tr}\left(\hat{W}\hat{\varrho}_{AB}\right) \geq 0 \Leftrightarrow \hat{\varrho}_{AB} \text{ separable} . \tag{81.3}$$

Such an operator is called an entanglement witness [81.22, 23], and its existence is ensured by a consequence of the Hahn–Banach theorem [81.24].

A similar separability criterion can be found for a particularly interesting class of quantum states in infinite-dimensional Hilbert spaces, the Gaussian states. Gaussian states are most frequently encountered in quantum optics. They comprise all coherent, squeezed and thermal states, and combinations of them. Although being infinite-dimensional, these states permit a complete description in terms of their first and second moments. The characteristic function of a single-mode Gaussian state with $\boldsymbol{\lambda}^T = (x, p)$ is given by [81.25]

$$\chi(\boldsymbol{\lambda}) = \exp\left\{i\boldsymbol{m}^T\boldsymbol{\lambda} - \frac{1}{4}\boldsymbol{\lambda}^T\boldsymbol{V}\boldsymbol{\lambda}\right\} , \tag{81.4}$$

where $\boldsymbol{m}$ is a vector containing the first moments and $\boldsymbol{V}$ is the covariance matrix containing the second moments. A necessary and sufficient criterion for separability of a bipartite Gaussian state is that the partially transposed covariance matrix still possesses positive symplectic eigenvalues [81.26, 27].

81.1.2 Entanglement Measures

Once one has checked for inseparability, the obvious question to ask concerns the amount of entanglement, hence the amount of nonclassical correlations in the given state. For bipartite pure states the answer is unique and given by the von Neumann entropy of one subsystem, viz.,

$$E(|\psi_{AB}\rangle) = S_A(\hat{\varrho}_B) = S_B(\hat{\varrho}_A) , \tag{81.5}$$

with $S_A(\hat{\varrho}_B) = -\mathrm{tr}\,\hat{\varrho}_B \ln \hat{\varrho}_B$ where

$$\hat{\varrho}_{A(B)} = \mathop{\mathrm{tr}}_{B(A)} |\psi_{AB}\rangle\langle\psi_{AB}| .$$

The second equality in (81.5) follows from the left-hand side of the Araki–Lieb inequality [81.28]

$$|S_A - S_B| \leq S_{AB} \leq S_A + S_B \tag{81.6}$$

when noting that the entropy of a pure state vanishes. Obviously, since $S_{AB} = 0$, no information can be extracted from the total state, all information is contained in the correlations between the subsystems A and B which are revealed by performing a measurement on one of the subsystems.

For bipartite quantum systems prepared in mixed states the answer is not so obvious. However, some insight can already be gained by looking at the Schmidt decomposition of the state (which, for bipartite states, always exists) [81.29, 30], in particular, the number of elements in the decomposition, named the Schmidt number [81.31].

For a more precise definition of mixed bipartite entanglement, something more is needed. Recall that the set of separable density matrices forms a convex subset of all feasible density matrices. It therefore makes sense to look for a distance-type measure between the given state and the convex hull of product states. Note that the possibility of defining such a measure is provided by the convexity of the separable states and a consequence of the Hahn–Banach theorem [81.24]. Generally, agreement has been reached on what properties any feasible entanglement measure must fulfil [81.32–34]. Let $E(\hat{\varrho}_{AB})$ be a real-valued functional over the tensor-product Hilbert space of bipartite density matrices. If in addition $E(\hat{\varrho}_{AB})$ has the following properties:

1. $E(\hat{\varrho}_{AB}) = 0$ for all separable states;
2. $E(\hat{\varrho}_{AB})$ is invariant under local unitary transformations, viz., $E\big[\big(\hat{U}_A \otimes \hat{U}_B\big)\hat{\varrho}_{AB}\big(\hat{U}_A^\dagger \otimes \hat{U}_B^\dagger\big)\big] = E(\hat{\varrho}_{AB})$;
3. $E(\hat{\varrho}_{AB})$ is non-increasing under general local operations assisted by classical communication, viz., $E\big(\sum_i \hat{V}_A^i \otimes \hat{W}_B^i \hat{\varrho}_{AB} \hat{V}_A^{i\dagger} \hat{W}_B^{i\dagger}\big) \le E(\hat{\varrho}_{AB})$;
4. $E(\hat{\varrho}_{AB})$ reduces to the reduced von Neumann entropy for pure states,

then $E(\hat{\varrho}_{AB})$ is called an entanglement measure.

Important examples of widely used entanglement measures are the entanglement of formation [81.35]

$$E_{\mathrm{F}}(\varrho_{AB}) = \min_{\hat{\varrho}_{AB} = \sum_i p_i |\psi_i\rangle\langle\psi_i|} \sum_i p_i E(|\psi_i\rangle) , \quad (81.7)$$

and the relative entropy of entanglement [81.32, 33]

$$E_{\mathrm{R}}(\hat{\varrho}_{AB}) = \min_{\hat{\sigma} = \sum_i p_i \hat{\sigma}_i^A \otimes \hat{\sigma}_i^B} \mathrm{tr}\left[\hat{\varrho}_{AB}(\ln \hat{\varrho}_{AB} - \ln \hat{\sigma})\right] . \quad (81.8)$$

In general, both of these measures are hard to evaluate. Analytical formulas are known only in special cases. For qubits, the entanglement of formation is also a monotonic function of the concurrence [81.36, 37]. The definition of the entanglement of formation, (81.7), can also be extended to cover Gaussian states [81.38].

The number of singlets, i. e., states of the form (81.1), that can be distilled from an ensemble of non-maximally entangled states is called the entanglement of distillation [81.39]. The entanglement of formation and the entanglement of distillation differ by the amount of bound entanglement (Sect. 81.1.1).

In some instances, when it is not necessary to comply with all of the above properties of entanglement measures, other quantities can be used to assess the entanglement content of a bipartite state. Particularly useful is the logarithmic negativity [81.40, 41]

$$E_N(\hat{\varrho}_{AB}) = \log_2 \left\| \hat{\varrho}_{AB}^{\mathrm{P.T.}} \right\|_1 , \quad (81.9)$$

where $\|\cdot\|_1$ denotes the trace norm and $\hat{\varrho}_{AB}^{\mathrm{P.T.}}$ the partial transpose of $\hat{\varrho}_{AB}$. This measure is often used in connection with Gaussian states.

In close analogy to classical information theory, the amount of nonclassical correlations is measured in ebits when one computes entropies with the dual logarithm ($\log_2$). For example, a pure state with state vector

$$|\psi\rangle = \frac{1}{\sqrt{2}} (|01\rangle + |10\rangle) \quad (81.10)$$

in an abstract two-particle Hilbert space spanned by the basis states $\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\}$ contains 1 ebit of entanglement. It is also a maximally entangled state associated with this Hilbert space since the von Neumann entropy of any state in a Hilbert space of dimension N is bounded from above by $\log_2 \dim N$.

We have concentrated here on bipartite entanglement. The extension to multipartite systems is by no means trivial and much remains to be done on this subject [81.42–44].

81.2 Simple Quantum Protocols

In this section we describe the historically first and simplest quantum protocols – quantum key distribution, quantum teleportation, and super-dense coding – that make use of inherently 'quantum' properties of quantum-mechanical systems. These are either entanglement or, in the case of the simplest version of quantum

key distribution, properties of the quantum-mechanical measurement process. We should mention here the pioneering work of *Holevo* [81.45] who showed that there are fundamental limits on the amount of information that can be extracted by measurements. The application of his ideas to channel capacity and communication [81.46,47] are well described in [81.3] and space limitations prevent us from elaborating on it in this chapter.

81.2.1 Quantum Key Distribution

Historically, the earliest protocol that used quantum-mechanical features in order to realize some specific task that could not have been performed classically was a protocol for secure distribution of a key in cryptography, known as the BB84-protocol after its inventors *Bennett* and *Brassard* and the year of its invention [81.48]. Although it is commonly referred to as the first example of quantum information processing, it does not make use of entanglement which was only done some years later, by *Ekert* [81.49].

The BB84 protocol works in the following way. The sender *A* prepares a random sequence (or string) of single photons in a polarization state which is chosen out of a set of four basis states, horizontally and vertically (*H* and *V*) polarized, and 45° and 135° (*L* and *R*) polarized. In each of the two basis sets {*H*, *V*}, {*L*, *R*} one of the states is used to encode the logical value 0 (say in *H* and *L*) and the other states encode the logical value 1 (*V* and *R*). The random sequence is sent to the receiver *B* who performs measurements on the sequence of signals by randomly choosing analogous basis states. The result will be another string of 0's and 1's that generically does not coincide completely with the original string. To rectify this problem, sender and receiver communicate over a classical public channel where the sender announces the sequence of basis sets in which the photon states were prepared. The receiver compares its sequence of randomly chosen basis states with the announced string and keeps all measure-

ment results for which the choice of basis had been the same. In that way a common secret key is established (Table 81.1).

The security against eavesdropping of this simple protocol comes from the fact that even by knowing the measurement basis (say {*H*, *V*}) no information has been revealed about the choice of the actual bit value (*H* or *V*). Hence, it is the quantum-mechanical measurement process itself that provides security of the protocol. The first quantum key distribution experiments were reported in [81.50–52]. However, imperfections in the generation and detection of photons, transmission losses and polarization drift causes an actual experimental realization to be far from ideal. In practise, encodings other than polarization may be used (for example a time-binned interferometric basis [81.53]). Despite these error sources, unconditionally secure quantum key distribution can be [81.54–57] and has been achieved [81.58]. Some fiber-based systems have reached distances of more than 100 km [81.59, 60], but discussions of their security continue. For a review of theoretical and experimental aspects of quantum cryptography, see [81.61].

81.2.2 Quantum Teleportation

An important utilization of entanglement as a necessary resource can be found in what is commonly known as quantum teleportation. The task of teleportation is to transmit the complete information of an arbitrary unknown quantum state to a spatially different location with the aim of re-creating it. The simplest and obvious way to perform this task would be to take the quantum object which is prepared in the original state and physically transport it to a different location. But sometimes this is not possible because for example an ion needs to be stored in a trap and cannot be moved. The next obvious thing to do would be to measure the quantum state and to re-create it at a different position using the classical information obtained during the measurement. However, single measurements on a quantum system yield only partial information and multiple measurements on many identically prepared copies would have to be performed.

The protocol, which was originally proposed in [81.62] for qubits and later generalized to states in infinite-dimensional Hilbert spaces in [81.63], makes use of the existence of maximally entangled states. Let the unknown quantum state which is to be teleported be a qubit superposition state of the form

$$|\psi\rangle = \alpha|0\rangle + \beta|1\rangle , \quad |\alpha|^2 + |\beta|^2 = 1 . \quad (81.11)$$

Table 81.1 BB84 protocol for secret key distribution. The sender A sends information encoded in either of two basis sets. The receiver B randomly chooses a measurement basis which is publicly communicated. For those cases when sender and receiver chose the same basis, the receiver's measurement yields a secure bit

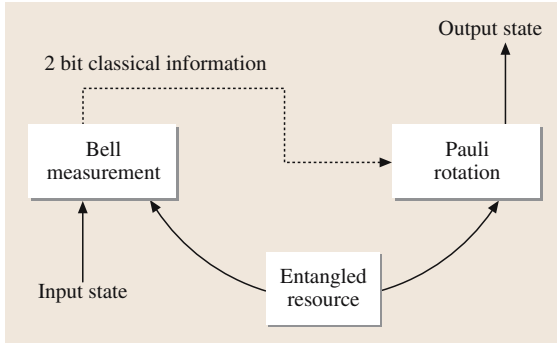
Sender A	↗	↑	↘	→	↗	↑	→
Receiver B	⊕	⊗	⊗	⊕	⊗	⊗	⊕
Key				1	1	0	1


Fig. 81.2 Schematic outline of an ideal teleportation protocol

Then one prepares a maximally entangled state of the form (81.10) which is one of the four so-called Bell states defined by

$$|\Psi^{\pm}\rangle = \frac{1}{\sqrt{2}}(|01\rangle \pm |10\rangle) ,$$

$$|\Phi^{\pm}\rangle = \frac{1}{\sqrt{2}}(|00\rangle \pm |11\rangle) . \tag{81.12}$$

We then form the tensor product state $|\psi\rangle|\Psi^+\rangle$ as

$$
\begin{aligned}
|\psi_A\rangle|\Psi^+_{BC}\rangle &= \frac{\alpha}{\sqrt{2}}(|0_A 0_B 1_C\rangle + |0_A 1_B 0_C\rangle) \\
&\quad + \frac{\beta}{\sqrt{2}}(|1_A 0_B 1_C\rangle + |1_A 1_B 0_C\rangle) \\
&= \frac{1}{2}\Big[(\alpha|0_C\rangle + \beta|1_C\rangle)|\Psi^+_{AB}\rangle \\
&\quad + (\alpha|0_C\rangle - \beta|1_C\rangle)|\Psi^-_{AB}\rangle \\
&\quad + (\alpha|1_C\rangle + \beta|0_C\rangle)|\Phi^+_{AB}\rangle \\
&\quad + (\alpha|1_C\rangle - \beta|1_C\rangle)|\Phi^-_{AB}\rangle\Big], \tag{81.13}
\end{aligned}
$$

where we have explicitly indexed the relevant subsystems. After performing a joint measurement on subsystems A and B in the Bell basis (this is called a Bell-state measurement [81.64, 65]) one obtains one of four possible results. If the measurement result was $|\Psi^+\rangle$, then the subsystem C is indeed prepared in the original unknown quantum state $|\psi\rangle$, hence the state has been 'teleported' from subsystem A to C. For all other measurement results the outcome is not exactly the same quantum state as intended, but the difference is just a unitary transformation which is uniquely determined by the outcome of the Bell measurement. For example, measuring $|\Psi^-\rangle$ means one has to perform a $\hat{\sigma}_z$-operation that flips the sign of the state $|1\rangle$, whereas on obtaining $|\Phi^+\rangle$ or $|\Phi^-\rangle$ the operations to be applied have to be $\hat{\sigma}_x$ or $\hat{\sigma}_z\hat{\sigma}_x$, respectively.

Note that this quantum teleportation protocol works with perfect fidelity only if a maximally entangled state has been used, i. e., a state containing 1 ebit of quantum information. In the course of the Bell measurement, the quantum information is used up, and two classical bits of information (the measurement result) have to be communicated to C in order to restore the original quantum state. In this sense, entanglement can be regarded as a resource or 'fuel' for certain tasks in quantum information processing. The first experimental demonstrations of teleportation of qubits were performed in [81.66–68] and of continuous variables in [81.69–71]. Recently, a teleportation experiment over 2 km standard telecommunication fibre has been reported [81.72]. A generalization of teleportation is entanglement swapping, in which EPR correlations are established between previously uncorrelated particles by Bell-state measurements [81.73, 74].

81.2.3 Dense Coding

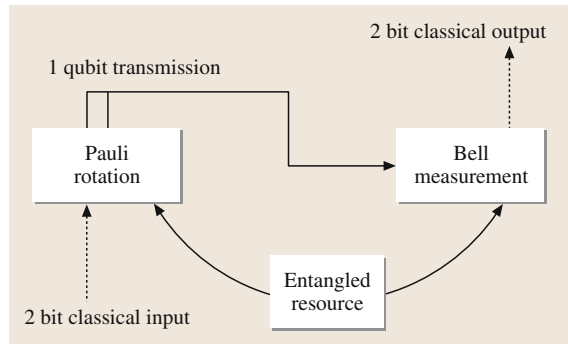
The complementary protocol to teleportation is characterized by the name of (super) dense coding [81.75]. The idea here is to transmit two classical bits of information at the expense of consuming 1 ebit of quantum information. The similarity to teleportation is best seen by noting that if the experimental apparatus of sender and receiver are interchanged and the protocol reversed (Fig. 81.3), then one reduces to the other. The mathematical equivalence of the teleportation and dense coding schemes has been beautifully shown in [81.76]. As in teleportation, sender and receiver initially share a two-particle maximally entangled state, i. e., one of the Bell states defined in (81.12). By acting with one of the four operations $\hat{I}$, $\hat{\sigma}_x$, $\hat{\sigma}_z$, or $\hat{\sigma}_z\hat{\sigma}_x$ on the qubit on the sender's side, the total


Fig. 81.3 Schematic outline of an ideal superdense coding protocol

two-qubit state is again in one of the four Bell states (81.12). Since they are mutually orthogonal to each other, the receiver can tell them apart by measuring in the Bell basis. In that way, two classical bits of information (the information about the single-qubit uni-taries) can be transmitted using only a single qubit at a time.

An experiment using entangled photon pairs was reported in [81.77], which demonstrated dense coding in practise.

81.3 Unitary Transformations

As in classical information theory, one has to define a certain set of allowed operations or maps between states of an information-carrying system. Classical information processing allows operations such as the NAND (Not-AND), which is defined by the Boolean operation $\overline{X_1 \wedge X_2 \wedge \cdots \wedge X_n}$ on the Boolean variables $X_1, X_2, \ldots, X_n$. This operation is not reversible in the sense that, given the outcome of the operation, there is no unique way of determining what the input was. Hence, such types of classical gates destroy information during the course of their operation.

Loss of information or irreversibility of an operation is accompanied by an increase in entropy of the state that has been operated on. For an initially pure quantum state having zero entropy, this means mixing the state and destroying its superposition nature and hence its quantum-mechanical entanglement. Therefore, the advantages of parallelism inherent in the superposition is lost. Thus, valid quantum operations in this sense can only be those that preserve the purity of states, hence unitary operations and partial projective measurements. Of course, in order to reset a quantum register, information has to be erased [81.78, 79]. This erasure procedure is described by a completely positive map (see, e.g. [81.3]). Note that any allowed quantum operation is completely positive; unitary operations are a special class of these. An example of how this constrains operations in quantum rather than classical information theory is the absence of a NOT operation in the former, as a NOT operation cannot be described in terms of completely positive maps [81.80].

81.3.1 Single-Qubit Operations

It is instructive to give an example of how to classify all possible unitary operations that can act on a single qubit. A unitary operation acting upon the basis states $\{|0\rangle, |1\rangle\}$ can be represented by a unitary (2×2)-matrix, hence a matrix that represents an element of the unitary group U(2). This group has four generators, the identity matrix and the three Pauli matrices. Hence, all unitary (2×2)-matrices are linear combinations of those four matrices. Given the way they act upon basis states, they can be written as

$$\hat{I} = |0\rangle\langle 0| + |1\rangle\langle 1| , \tag{81.14}$$

$$\hat{\sigma}_x = |0\rangle\langle 1| + |1\rangle\langle 0| , \tag{81.15}$$

$$\hat{\sigma}_z = |0\rangle\langle 0| - |1\rangle\langle 1| , \tag{81.16}$$

and, by virtue of the commutation rules for U(2)-generators, $\hat{\sigma}_y = i\hat{\sigma}_x\hat{\sigma}_z$. Sometimes, the short-hand notation $X \equiv \hat{\sigma}_x$, etc., is used.

A particularly useful single-qubit gate which is not just one of the Pauli operators is the Hadamard gate H. In terms of Pauli operators it is defined as $H = (X + Z)/\sqrt{2}$. Its purpose is to transform each basis state into equal superpositions of basis states, i. e., $|0\rangle \mapsto (|0\rangle + |1\rangle)/\sqrt{2}$ and $|1\rangle \mapsto (|0\rangle - |1\rangle)/\sqrt{2}$. The Hadamard gate is used to initialize an equal superposition of all possible N-qubit basis states from the state $|0\rangle^{\otimes N}$. Hence,

$$\bigotimes_{i=1}^{N} H_i |0\rangle^{\otimes N} = \frac{1}{\sqrt{N!}} \sum_k |x_k\rangle , \tag{81.17}$$

where the $|x_k\rangle$ are all $N!$ possible words of length N containing 0's and 1's.

81.3.2 Two-Qubit Operations

Similarly to the single-qubit case, one can write down all possible unitary operations on two qubits by noting that they constitute a representation of U(4). We will not give an exhaustive list of all 16 generators of this group since they can be found in the literature. Instead, we give examples of particularly useful two-qubit gates. Trivially, the group U(4) contains an 8-parameter subgroup U(2)×U(2) which consists of operations such as $X_1 \otimes X_2$, etc.

Particular examples of nontrivial two-qubit gates are the controlled-NOT and the controlled-phase gate,
Fig. 81.4 Symbol and truth table of the controlled-NOT gate. The target qubit is flipped depending on the state of the control qubit

defined in terms of Pauli operators as

$$\overline{C}_{12} = |0_1\rangle\langle 0_1| \otimes I_2 + |1_1\rangle\langle 1_1| \otimes X_2 \,, \tag{81.18}$$

$$\Pi_{12} = |0_1\rangle\langle 0_1| \otimes I_2 + |1_1\rangle\langle 1_1| \otimes Z_2 \,, \tag{81.19}$$

where in both cases qubit 1 acts as the 'control' and qubit 2 acts as the 'target' (Fig. 81.4). The net effect of the controlled-NOT gate is to interchange the states $|10\rangle \leftrightarrow |11\rangle$, whereas the controlled-phase gate changes the phase of the basis state $|11\rangle$ by π and leaves all other states unchanged. The controlled-NOT gate has an interpretation as a sum gate in that it performs a mapping $|x, y\rangle \mapsto |x, x \oplus y\rangle$ where the addition has to be taken modulo 2. Moreover, it acts as an entangling gate when acting on tensor products of superpositions.

81.3.3 Multi-Qubit Gates and Networks

To realize a unitary operation on many qubits for a particular algorithm one would need a network of single-particle and multi-particle quantum gates. Quantum networks enable a prepared input state to be transformed by the appropriate unitary operator to a final state which is then measured. Deutsch's model of quantum networks enables us to decompose the network into component gates in diagrammatic form [81.81]. The task is then to optimize the sequence of gates. One can treat quantum gates acting on N qubits as being elements of the group $\mathrm{U}(N^2)$ which has N^4 generators. This, however, is not a particularly transparent or useful way of looking at these gates. Much more useful, and of immense practical importance, is a result essentially from linear algebra which states that every N-qubit gate can be decomposed into a network of single-qubit and two-qubit operations [81.82]. As a matter of fact, there is an even deeper result which says that every N-qubit gate can be generated by a network that consists only of very few elementary building blocks, the so-called universal set of quantum gates [81.83–85]. This set contains all possible single-qubit rotations and one nontrivial two-qubit gate, such as the above-mentioned controlled-NOT or controlled-phase gate.

81.4 Quantum Algorithms

The search for algorithms that would run faster on a quantum computer than on any classical computer is a formidable task. When we say faster, we actually mean that the temporal complexity in performing a given task should be drastically reduced. The hope is that eventually one will find algorithms that provably run exponentially faster on a quantum computer compared to a classical computer.

81.4.1 Deutsch–Jozsa Algorithm

Let us give a particularly instructive example known as the Deutsch–Jozsa algorithm [81.86]. Let us suppose one is given a string of N bits and a Boolean N-bit function $f(x)$ such that $|x\rangle|y\rangle \mapsto |x\rangle|y \oplus f(x)\rangle$ for $x \in \{0, \ldots, 2^N - 1\}$. From $f(x)$ is known that it either returns always 0 or 1 (in which case one calls it 'constant') or returns 0 and 1 with equal probability (in which case it is 'balanced'). The task is to find out whether $f(x)$ is constant or balanced. Classically, one needs at least $2^{N-1} + 1$ strings to find the answer.

Quantum-mechanically, one prepares the trial input in a superposition of all possible computational basis states using the Hadamard gate from (81.17) and uses one function evaluation on all basis states simultaneously (Fig. 81.5). A measurement outcome other than 0 on any of the N query qubits then tells that the function $f(x)$ is balanced. If it were constant, the measurement outcome would be 0 in all query qubits. This quantum parallelism is at the heart of the increase in speed that occurs in quantum computation. Versions of the Deutsch–Jozsa
Fig. 81.5 Gate network for implementing the Deutsch–Jozsa algorithm

algorithm involving a few qubits have been implemented in nuclear magnetic resonance systems [81.87, 88] as well as ion traps [81.89].

81.4.2 Grover's Search Algorithm

In contrast to the preceding example, which always gives the desired answer after exactly one trial, the quantum search algorithm by *Grover* [81.90] uses a procedure that amplifies the sought after result by a method called 'inversion about average'. The goal of Grover's algorithm is to search an unsorted database with 2^N entries out of which only one fulfils a given criterion. As in the Deutsch–Jozsa algorithm described above, the query is simultaneously run on all 2^N possible N-qubit basis states, being prepared in an equal superposition. It is assumed that the state that satisfies the search criterion will acquire a phase shift of π. After this step, the inversion about average is carried out. It is represented by a diffusion operator

$$\hat{D} = 2\hat{P} - \hat{I} , \tag{81.20}$$

where $\hat{I}$ is the identity operator and $\hat{P}$ a projection operator that averages each input vector with respect to its components. Compared to the previous average value of probability amplitudes, after each of these steps the magnitude of the desired state increases by $\mathcal{O}(2^{-N/2})$. This procedure is repeated, and after only $\mathcal{O}(2^{N/2})$ steps a projective measurement yields the desired result with probability of $\mathcal{O}(1)$, or more precisely, of more than a half. This is a quadratic increase in speed compared to classical search algorithms, which need $\mathcal{O}(2^N)$ steps.

We have seen in these two examples that the use of quantum-mechanical superpositions can lead to a speed increase compared to the best classical algorithms. The most prominent example of such increases in speed is found in Shor's algorithm for factoring large numbers [81.91, 92]. Its core element is essentially a quantum Fourier transform to find the period of a Boolean string. This algorithm provides an exponential speed increase over any known classical algorithm. It should be noted, however, that the fastest known classical algorithm has not yet been proven to be optimal. Implementations in nuclear magnetic resonance systems with a few qubits have been reported for the quantum Fourier transform [81.93] as well as Shor's factoring algorithm [81.94].

It turns out that there exists a whole class of algorithmic problems, the hidden subgroup problems [81.95–97], whose quantum-mechanical analogues can lead to exponential increases in speed over their classical counterparts, a particular example of which is Shor's factoring algorithm. Another instance of quantum-mechanically exponentially faster processes is found in quantum random walks on hypercubes where hitting times, i. e., the traversal time of an excitation across the cube's diagonal, can be exponentially faster than for classical random walks [81.98].

81.5 Error Correction

As we have discussed, the essence of quantum information processing is the use of quantum superpositions, interference, and entanglement. But quantum interference is fragile. It appears in practice that it is very difficult to maintain a superposition of states of many particles in which each particle is physically separated from all the others. Entanglement turns out to be incredibly delicate. The reason for this is that all systems, quantum or classical, are not isolated; they interact with everything around them: local fluctuating electromagnetic fields, the presence of impurity ions, coupling to unobserved degrees of freedom of the system containing the qubit, etc. These fluctuations destroy quantum interference. A simple analogy is the interference of optical waves in Young's double slit experiment. In that apparatus waves from two spatially separated portions of a beam are brought together. If the two parts of the beam have the same phase, then the fringe pattern re-mains stable. But if the phase of one part of the beam is drifting with respect to the other, then the fringe pattern will be washed out. And the more slits there are in the screen, the lower the visibility for the same amount of phase randomization per pair of slits. The sensitivity of an N-qubit register to decoherence is even worse, as a maximally entangled N-particle state decoheres at a rate N times faster than a single particle [81.99], one of the reasons why the world around us appears so classical. A single bit of information lost to an unobserved degree of freedom will result in the reduction of the quantum superposition to a mixed state. Yet correcting errors due to environmental interactions is essential if a quantum computer is to be constructed: to do 'fault tolerant' computing we need to be able to execute many gate operations coherently within the decoherence time if we are to have a chance of building a scalable quantum register [81.100].

It might appear that the problem of stabilizing a register of qubits is hopeless, like trying to balance several pencils on their tips while on the deck of a ship in a storm. But, amazingly, quantum mechanics provides a way to solve this problem, through the use of even higher levels of entanglement. *Shor* and coworkers, and independently *Steane* showed in the mid-1990's that encoding information in entangled sets of qubits offered the opportunity to execute quantum error correction [81.101, 102]. That one can do this is a remarkable consequence of entanglement. In classical information processing, inevitable environmental noise is dealt with by error correction. In its simplest form, this involves repeating the message transmission or calculation until a majority result is obtained.

But there are more efficient ways, for example, use of a parity check on a block of bits. It turns out that a similar notion can be applied to a quantum register. However, the application is not straight forward because the contents of a register cannot be measured without destroying the superposition state encoded in it. The problem then is to determine what errors might be present in a quantum register without looking at the qubits. The elegant solution is to entangle the qubits in question with those in an ancillary register and measure the ancillary register. Because the two registers are correlated, the results of the measurement of the ancilla reveal any errors present in the processing register without destroying any coherent superpositions in the processing register itself.

The first experimental demonstration of quantum error correction used NMR techniques [81.103–105], but given the inherently mixed nature of NMR quantum computing [81.106], this has had limited impact on quantum information processing (QIP). However, very recently, Wineland's group in Boulder has succeeded in implementing quantum error correction using laser-cooled trapped ions [81.107].

Another way to prevent the register coherence from falling apart is to know a little about the sort of noise that is acting on it. If the noise has some very slow components (or those with very long wavelengths), then it is sometimes possible to find certain combinations of qubit states for which the noise on one qubit exactly cancels the noise on another. These qubit states live in a 'decoherence-free subspace' (DFS) [81.108–111]. A computer will then be immune to environmental perturbations if all the computational states lie in this DFS. The connection between DFS and quantum error correction codes has been shown in [81.112]. *Kwiat* [81.113], using photonic qubits, and Wineland's group [81.114], using trapped ions, have demonstrated the use of DFS experimentally.

Although these results are encouraging, we are still a long way from the figure of merit for gate time to decoherence time needed for fault tolerance.

81.6 The DiVincenzo Checklist

DiVincenzo gave a list of requirements that a physical implementation must fulfil in order to qualify as a sensible candidate for an implementation of quantum information processing [81.115].

81.6.1 Qubit Characterization, Scalability

Each physical implementation must be tested upon how qubits should be encoded. For a qubit being essentially a two-level system, this task is generally not too difficult. Several candidates, such as electronic or nuclear spin, photon polarization, choice of path in an interferometer, degenerate ground states of an atom or ion, charge or flux states in superconducting quantum interference devices (SQUIDs) or exciton population, have all been recently explored. Much more challenging will be the question as to whether there are fundamental or technological limitations of having many of those qubits being operated upon seperately, hence whether the system can be scaled up to contain potentially many qubits.

81.6.2 Initialization

Once the qubits have been specified, each quantum information processing or quantum computation task needs to be able to start from a well-defined state. This can be basically any quantum state of the many-qubit system as long as it is a product state and can be prepared error-free. Commonly, this state is then called the ground state and denoted by $|0\rangle^{\otimes N}$.

81.6.3 Long Decoherence Times

In order to ensure error-free computation without loss of purity of quantum superpositions, the decoherence times that are relevant for the quantum operation should be much longer than the gate operation time itself. In most

situations, decoherence limits the number of qubits that can be worked on simultaneously, thus affecting the scalability of the system. Typical examples of decoherence processes are heating mechanisms in ultracold systems, such as ion trap or atom chip experiments, spin relaxation in NMR-type experiments, or absorption in linear optical elements.

Generally, decoherence is unavoidable due to the basic principles upon which quantum information processing is supposed to work. Avoiding decoherence means isolating the system from the outside world, the environment. But controlling the interaction between subsystems always has the negative effect of bringing the system in contact with the environment and therefore necessarily introduces decoherence. Once one has accepted that decoherence is unavoidable, ways have to be found to guard against it. Several error-correction schemes have been proposed that can correct for certain small amounts of decoherence as described in Sect. 81.5.

81.6.4 Universal Set of Quantum Gates

A necessary prerequisite for quantum information processing and quantum computing is the ability to generate a set of quantum gates that can be considered universal. With such a set it will then be possible to generate all other quantum gates by concatenating them to form suitably arranged networks. The choice of which set out of the many possible is taken, depending on the physical implementation itself. Basically, it is determined by the operations that are intrinsically simple for the given interaction Hamiltonian. In some applications, such as the ion trap experiments, the controlled-NOT gate is preferred as the nontrivial two-qubit gate, whereas in linear optical networks one rather works with the controlled-phase gate.

81.6.5 Qubit-Specific Measurement

The last requirement is to be able to read out the result of the computation. That is, there has to be a way of providing a selective projective measurement. This proves to be a major challenge in most proposals for implementing quantum computing. Examples of the challenges involved are the necessity to provide photon-number resolving photodetectors, single-electron charge measurement devices, or single-spin measurements.

81.7 Physical Implementations

Quantum information theory regards relevant objects as abstract quantities in a Hilbert space of a certain dimension. The different strands in its development can be roughly divided into generalized spin systems (qubits, qudits, the d-dimensional generalization of qubits) living in finite-dimensional Hilbert spaces, and harmonic oscillator systems which naturally live in infinite-dimensional Hilbert space. The latter are hence called continuous-variable (cv) systems. Examples for generalized spin systems are polarization states of a photon, magnetic sublevels of atomic hyperfine states or, to a good approximation, electronic levels of atoms and ions. Harmonic oscillator systems can be found in atomic populations in optical lattices, electromagnetic-field modes or indeed any excitation of a bosonic quantized field.

Both strands have their own virtues and disadvantages. Harmonic oscillator systems are naturally abundant and, in their materialization as photons, rather easily accessible and manipulable. However, due to their Hilbert space dimensionality, the nonlinear operations that are required for quantum gates are generally hard to achieve. In contrast, spin-like systems (apart from

photon polarization) require more experimental effort in preparing them but, unlike harmonic oscillator systems, they can show effective nonlinearities due to the finite dimensionality of their Hilbert space (the nonlinearities appear when coupled to another physical system which can then be traced out).

81.7.1 Linear Optics

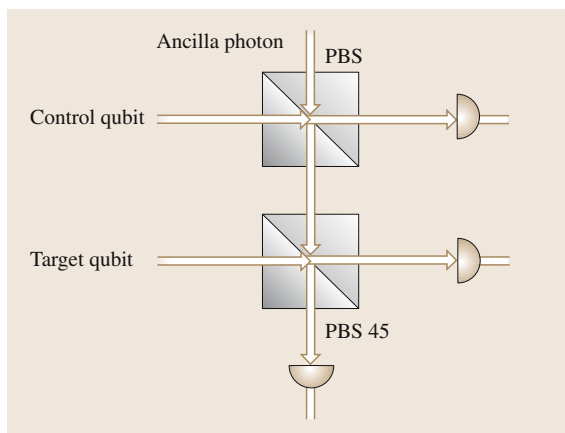
The use of photons as carriers of quantum information seems to be a straightforward matter for several reasons. First, they are easy to produce and to manipulate, and second, they both show spin-like behaviour (polarization) and can be treated as continuous-variable systems (Gaussian states). There exists, however, yet another possibility to store and manipulate quantum information in photons, namely when encoding information in number states or Fock states. But as noted before, for photons being bosonic systems, there are no natural nonlinearities (at least none which is strong enough) on the level of single or few photons. The trick here is to use conditional measurements or measurement-induced nonlinearities. The idea was first


Fig. 81.6 Schematic setup of an all-optical controlled-NOT gate. Control and target qubits are encoded in the polarization of single photons. These are fed into polarizing beam splitters (PBS), one of which is rotated by 45 degrees

put forward in [81.116, 117] and realized experimentally in [81.118, 119], where a polarization-encoding was used. Figure 81.6 shows the schematic setup of a simplified version of a controlled-NOT gate with one single ancilla photon (after [81.120]).

Measurement-induced nonlinearities make use of the fact that unitary transformations in a larger Hilbert space, e.g., with added auxiliary photon modes combined with photodetection, can yield effective nonlinearities [81.121]. The drawback is, however, that the wanted nonlinearity is conditioned on the appearance of a certain measurement pattern which means that these schemes work only with a certain probability. Bounds for certain classes of gates have been reported in [81.122–125].

The set of quantum gates that can be considered fundamental differs slightly from most other physical implementations. Within the qubit encoding in photon-number states the gates that can actually be implemented efficiently are those that act within Fock layers (subspaces of fixed total photon number), such as Z, the controlled-phase gate, or the swap gate. Other gates that do not fall into this class require excessively more resources unless other types of qubit encodings are used simultaneously.

Gate operation times can be very fast and are only limited by the gating times of the photodetectors. However, a major experimental challenge is mode-matching in larger networks and interferometric set-ups.

A complementary approach to the gate model is based on so-called cluster states which were originally

introduced to describe the properties in 3D optical lattices [81.126] (Sect. 81.7.4). In the cluster-state model the computational process is not described by a succession of elementary gates that act upon an (in principal arbitrary) input state, but by a well-defined sequence of single-qubit measurements performed on a maximally entangled 'cluster' of qubits. It has been realized that the cluster-state model represents an alternative model for quantum computing, the so-called 'one-way quantum computer' [81.127]. It was later found that there also exists a linear optical realization of the cluster-based approach [81.128, 129] which has been experimentally verified [81.130].

81.7.2 Trapped Ions

So far, the most advanced method in terms of the number of qubits and the number of gates that have been generated is by using ultracold ions stored in linear Paul traps (Chapt. 75) in which radio-frequency fields are used to generate confining potentials. The ions are trapped in the radial direction by electric quadrupole fields and in the axial direction by a static repulsive Coulomb force [81.131, 132]. The ions are cooled into their motional ground states by Doppler cooling [81.133, 134] and further cooled by resolved sideband cooling [81.135]. The qubits are encoded into two metastable electronic states. Various groups have used either transitions to metastable states or Raman coupling to avoid the decoherence that an upper-state lifetime would generate. The coupling between qubits is provided by the common vibrational motion in the Paul trap [81.136, 137]. For reviews of the dynamics of laser-cooled ions [81.138–141]. To date, a few qubits have been entangled and coherently manipulated. Simple quantum algorithms have been demonstrated [81.142] and teleportation achieved [81.143, 144].

81.7.3 Cavity QED

Cavity QED provided the very first examples of atom-field entanglement. Single atoms interacting with single cavity-field modes are well described by the Jaynes–Cummings model [81.145]. In this model, excitation is transferred periodically between atoms and field provided the Q-factor of the cavity is high enough (Chapt. 79). The Rabi flopping can be used to generate controlled superpositions, and the cavity field used as a catalyst to entangle atoms [81.146]. Although it is possible to coherently manipulate single or few qubits in cavity QED, scaling to large numbers of qubits would
Fig. 81.7 Counter-propagating laser beams induce a periodic spatially varying trapping potential through the AC Stark shift

seem very difficult. Nevertheless, trapped atoms within cavity QED environments offer great potential as local processors linked by quantum communication channels [81.147]. Progress towards this has been reported by several groups [81.148–151].

81.7.4 Optical Lattices, Mott Insulator

Another possible way of implementing quantum computation is with cold atom technology. This includes the application of optical lattices in a sufficiently cold cloud of atoms showing Bose–Einstein condensation (BEC).

In recent years it has been realized that Bose–Einstein condensates can undergo a phase transition if loaded into a three-dimensional periodic potential which, for example, can be realized by standing-wave optical fields [81.152, 153]. That is, one starts off with a BEC in its superfluid phase, in which the relative phases (or rather correlations) between the atoms are well-defined such that the whole ensemble of atoms can be described by a single macroscopic wave function (in first approximation). By loading this condensate into the optical lattice (Fig. 81.7) the number of atoms per lattice site is undetermined and can vary widely. However, when increasing the strength of the potential by increasing the power of the laser beams that create the standing-wave potential, eventually there will be a phase-transition to a state of the condensate in which each lattice site is occupied by a fixed and well-defined number of atoms (ideally we would like to have exactly one atom per site). In this so-called Mott-insulator phase, the relative phases (or correlations) between neighboring lattice sites are undetermined. Experimental evidence

of this phase-transition has been obtained in the beautiful experiments described in [81.154–156]. Although a Bose–Einstein condensate really exists only in three dimensions (since only there one finds a phase transition from a thermal cloud to a condensate), there are analogous systems, such as the quasi-condensate [81.157] and the Tonks–Girardeau gas [81.158] (for recent experiments, see [81.159, 160]), in one dimension that have similar properties.

Such a system is well described by the Bose–Hubbard Hamiltonian [81.152, 153], in which the collisional interaction between atoms at the same lattice site provides the necessary nonlinearity. Atoms trapped in a one-dimensional optical lattice could serve as an atomic register that promises well controlled single-qubit and two-qubit manipulability. A universal set of quantum gates can be realised by manipulations of the lattice potential with additional laser fields [81.161]. The different types of quantum gates could, for example, be realized if the atoms possess two degenerate ground states that are used for the qubit encoding (as sketched in Fig. 81.7). A Raman transition between the ground states would result in single-qubit operations, whereas controlled collisions between atoms in neighboring lattice sites would produce two-qubit gates. Recently, three-qubit gates [81.162] and global adressing of strings of qubits have been proposed [81.163].

The estimated gate evolution times in the adiabatic regime are roughly $\mathcal{O}(100\,\text{ms})$, which is just one to two orders of magnitude below the trapping lifetime measured in recent experiments [81.164–166]. The dominant loss effect is thereby a thermally induced spin flip mechanism that causes the atoms to leave the trapping region [81.167–169]. The gate evolution times could be reduced by several orders of magnitude in non-adiabatic regimes. The price to pay is that the temporal evolution of the laser pulse envelope has to be controlled much more precisely. Although quantum information processing using cold atom technology is still in its infancy, it promises to provide relatively long decoherence times. Moreover, scalability seems possible as rather long one-dimensional strings of atoms could be formed. Experimental evidence for this has of course yet to be shown.

81.8 Outlook

We have discussed the very basic ideas behind quantum information and described a few possible applications. However, the immense wealth of ideas and possible

routes have barely been touched upon. Quantum key distribution is already at a stage where private companies are selling component parts to set up commercial

QKD systems. Only a few qubits have been maximally entangled and manipulated experimentally, so far. But a great number of qubits has been partially entangled within optical lattices [81.170] or in atomic vapours [81.171]. The dynamics of qubit interactions in such systems is closely related to systems studied in phase-transition theory, pointing to yet another application of the subject. The simulation of many-particle quantum systems is of course intrinsically difficult and could well require a quantum computer for its analysis [81.172–175]. If and when a quantum computer can be built remains shrouded in mist. However, the ideas and methods that have already come out of quantum information theory provide useful tools for tackling other, seemingly unrelated, problems. One direction of current research regards many-body problems in condensed matter systems and quantum field theory (see, for example, [81.176]).

We have touched upon only a small part of a rapidly developing subject – one in which quantum effects are the enablers of new technology [81.177]. We are confident that much more remains to be discovered.

Application

Part G Applications

82. Applications of Atomic and Molecular Physics to Astrophysics

The range of physical conditions of density, temperature, and radiation fields encountered in astrophysical environments is extreme and can rarely be reproduced in a laboratory setting. It is not only reliable data on known processes that are needed but also a deep understanding so that the relevant processes can be identified and the influence of the conditions in which they occur fully taken into account.

We present here a summary of the processes that take place in photoionized gas, collisionally ionized gas, the diffuse interstellar medium, molecular clouds, circumstellar shells, supernova ejecta, shocked regions and the early Universe.

Almost all our information about the Universe reaches us in the form of photons. Observational astronomy is based on measurements of the distribution in frequency and intensity of the photons that are emitted by astronomical objects and detected by instrumentation on ground-based and space-borne telescopes. Information about the earliest stages in the evolution of the Universe before galaxies and stars had formed is carried to us by blackbody background photons that attended the beginning of the Universe. The photons that are the signatures of astronomical phenomena are the result of many processes of nuclear physics, plasma physics and atomic, molecular and optical physics. The processes that modify the photons on their journey from distant origins through intergalactic and interstellar space to the Earth belong mostly to the domain of atomic, molecular, and optical physics, as do the instruments that detect and measure the arriving photons and their spectral distribution. The spectra are used to classify galaxies and stars and to identify the astronomical entities and phenomena such as quasars, active galactic nuclei, grav-itational lensing, jets and outflows, pulsars, supernovae, novae, supernova remnants, nebulae, masers, protostars, shocks, molecular clouds, circumstellar shells, accretion disks and black holes.

Quantitative analyses of the spectra of astronomical sources of photons and of the atomic, molecular, and optical processes that populate the atomic and molecular energy levels and give rise to the observed absorption and emission require accurate data on transition frequencies and wavelengths, oscillator strengths, cross sections for electron impact, rate coefficients for radiative, dielectronic and dissociative recombination, and cross sections for heavy particle collisions involving charge transfer, excitation, ionization, dissociation, fine structure, and hyperfine structure transitions, collision-induced absorption and line broadening. Data on radiative association and ion–molecule and neutral particle reaction rate coefficients are central to the interpretation of measurements of chemical composition in molecular clouds, circumstellar shells and supernova ejecta.

82.1 Photoionized Gas

The Universe contains copious sources of energetic photons most often in the form of hot stars, and much of the material of the Universe exists as photoionized gas.

Photoionized gas produces the visible emission from emission nebulae, planetary nebulae, nova shells, starburst galaxies and probably active galactic nuclei [82.1].

Emission nebulae are extended regions of luminosity in the sky. They arise from the absorption of stellar radiation by the gas surrounding one or more hot stars. The gas is ionized by the photons and excited and heated by the electrons released in the photoionizing events. A succession of ionization zones is created in which highly ionized regions give way to less ionized gas with increasing distance from the central star as the photon flux is diminished by geometrical dilution and by absorption. The outer edge of a nebula is a front of ionization pushing out into the neutral interstellar gas. The densities are typically between 100 and 10 000 cm^{-3} and the temperatures between 5000 and 15 000 K. Nebulae are also called HII regions. At low densities, the luminosity is low, but the ionized regions can still be detected by radio observations.

Planetary nebulae are smaller in extent and more dense. They have a passing similarity in appearance to planets. Planetary nebulae are produced by the photoionization of shells of gas that have been ejected from the parent star as it evolved to its final white dwarf stage. Because the core of the parent star is very hot the irradiated gas is more highly ionized than are emisssion nebulae and has a distinctive spectrum.

Photoionized gas is also found around novae. Novae are stars that have undergone spasmodic outbursts and they are surrounded by faint shells of ejected gas, photoionized and excited by the stellar radiation. Some supernova remnants, which are what remains after a massive star has exploded, have spectra that also appear to be emanating from photoionized gas. The source of ionization may be synchrotron radiation. Figure 82.1 shows the X-ray emission spectrum of a supernova remnant.

The nuclei of starburst galaxies have spectra like those of emission nebulae. They result from gas photoionized by radiation from hot stars created in a period of rapid star formation. Active galactic nuclei, such as quasars, have a different spectrum characterized by broad lines indicating a large range of velocities. Photoionized gas is the most likely interpretation. The ionizing source may be an accretion disk around a compact object such as a black hole.

The ionization structure in a photoionized gas is determined by a balance of photoionization

$$X^{(m-1)+} + h\nu \rightarrow X^{m+} + e^- \tag{82.1}$$

and radiative

$$X^{m+} + e^- \rightarrow X^{(m-1)+} + h\nu \tag{82.2}$$

and dielectronic

$$X^{m+} + e^- \rightarrow \left(X^{(m-1)+}\right)^* \rightarrow X^{(m-1)+} + h\nu \tag{82.3}$$
recombination, and in plasmas with a significant population of neutral hydrogen and helium, by charge transfer recombination

$$X^{m+} + H \rightarrow X^{(m-1)+} + H^+ \tag{82.4}$$

$$X^{m+} + He \rightarrow X^{(m-1)+} + He^+ \, . \tag{82.5}$$
Fig. 82.1 X-ray spectrum of the supernova remnant Puppis A as observed by the Einstein satellite. Note the high level of ionization with hydrogen-like ions of oxygen and neon, suggesting a high temperature. After [82.2]

Many detailed calculations of the ionization structure of photoionized regions have been carried out [82.1].

The ionizing source spectra of hot stars can be obtained from calculations of stellar atmospheres Sect. 82.5. Approximate values of cross sections for photoionization for a wide range of atomic and ionic systems in many stages of ionization are available [82.3–6]. Calculations of higher precision and reliability that incorporate the contributions from autoionizing resonance structures exist for specific systems [82.7]. They are undergoing continual improvements as increasingly powerful computational techniques are brought to bear on the calculations.

The cross sections for radiative recombination are obtained by summing the cross sections for capture into the ground and excited states of the recombining system. Because of the contribution from highly excited states which are nearly hydrogenic, the rate coefficients are similar for different ions of the same excess nuclear charge. They vary slowly with temperature. In contrast, dielectronic recombination is a specific process whose efficiency depends on the energy level positions of the resonant states. For nebular temperatures, the rate coefficients vary exponentially with temperature. Explicit calculations have been carried out for many ionic systems [82.8–10]. Because the photoionization cross sections of the major cosmic gases hydrogen and helium diminish rapidly at high frequencies, multiply charged ions and neutral gas coexist in cosmic plasmas produced by energetic photons and charge transfer recombination may control the ionization structure. For multiply charged ions with excess charge greater than two, charge transfer is rapid. For doubly charged and singly charged ions, the cross sections are sensitive to the details of the potential energy curves of the quasimolecule formed in the approach of the ion and the neutral particle. Few reliable data exist. Some recent calculations may be found in the papers [82.11–13].

Photoionized gas is heated by collisions of the energetic photoelectrons and cooled by electron impact excitation of metastable levels, principally of O^+ and O^{++}, N^+ and N^{++}, and S^+ and S^{++}, followed by emission of photons which escape from the nebula. Considerable attention has been given to the determination of the rate coefficients [82.14]. The resulting cooling rates increase exponentially with temperature and keep the temperature of the gas between narrow limits. Some contribution to cooling occurs from recombination and from free-free emission by electrons moving in the field of the positive ions.

The luminosity of the photoionized gas comes from the photons emitted in the cooling processes and from radiative and dielectronic recombination. The radiative recombination spectrum of hydrogen extends from the Ly α line at 121.6 nm to radio lines at meter wavelengths.

The recombination spectrum can be predicted to high accuracy, and calculations for a wide range of temperature, density, and radiation environments have been carried out for diagnostic purposes [82.15–18]. Electron impact and proton impact induced transitions are important in determining the energy level populations and the resulting spectrum. Stimulated emission often affects the intensities of the radio lines, especially those from extragalactic sources. Comparisons of the predicted intensities in the visible and infrared with theoretical predictions yield information on interstellar extinction in the nebula and along the line of sight.

The relative intensities of the lines emitted by different metastable levels depend exponentially on the temperature. The relative intensities of the lines at 500.7 nm and 436.3 nm originating in the $^1D_2$ and $^1S_0$ levels of O^{++} vary as $\exp(33170/T)$, and are commonly used to derive the temperature T.

The electron density can be inferred from the lines emitted from neighboring levels with different radiative lifetimes for which there occurs a competition between spontaneous emission and quenching by electron impact. There are many possible combinations of lines. The lines at 372.89 nm and 372.62 nm emitted by the $^2D_{3/2}$ and $^2D_{5/2}$ levels of N^+ are readily observable and their relative intensity yields the electron density.

Radiative and dielectronic recombination lines are often seen in the spectra, as are a few lines due to charge transfer recombination. Fluorescence of starlight and resonance fluorescence of lines emitted in the nebula (called Bowen fluorescence by astronomers) also contribute to the spectra of photoionized gases. Many data are needed to adequately interpret the observations.

82.2 Collisionally Ionized Gas

Hot gas is found in the coronae of stars and particularly the Sun, and in young supernova remnants, in the hot phase of the interstellar medium, and in intergalactic space. In a hot gas the ionization is produced by the impact ionization of the fast thermal electrons and recombination is radiative and dielectronic [82.19].

The rate coefficients for electron impact ionization and for recombination for any given ionization stage are functions only of temperature, and hence so is the resulting ionization distribution. When ionization and recombination balance, coronal equilibrium is attained in which the ionization structure is specified by the temperature.

Recombination at high temperatures is dominated by dielectronic recombination. At high temperatures, dielectronic recombination is stabilized by transitions in which the core electrons are the active electrons. The associated emission lines lie close in frequency to that of the resonant transition of the parent ion. They are called satellite lines. Together with lines generated by electron impact excitation, they provide a powerful diagnostic probe of density and temperature. In many circumstances such as in supernova remnants, coronal equilibrium does not hold, and the ionization and re-combination must be followed as functions of time. The temperature also evolves as the hot plasma is cooled by electron impact excitation and ionization.

The recombining gas produces X-rays and extreme UV radiation which modify the ionization structure. There is a particular need for more reliable data on high energy photoionization cross sections, on collision cross sections for electrons and positive ions, and on

Fig. 82.2 Total emissivity and emissivity by element as a function of temperature in coronal equilibrium. The *heavy solid curve* is total emissivity and the *lighter lines* are contributions from individual elements. After [82.20]

the energy levels and transition probabilities of highly stripped complex ions. Figure 82.2 shows the emissivity of coronal gas.

82.3 Diffuse Molecular Clouds

Diffuse molecular clouds are intermediate between the hot phase of the galaxy and the giant molecular clouds where much of the gas resides. They are called diffuse because they have optical depths of order unity, so photons can penetrate from outside the cloud and affect the chemical composition. The atoms and molecules are observed in absorption against background stars. Translucent clouds with optical depths between about 2 and 5 are intermediate between diffuse and dark clouds where photons from the outside still affect the chemistry. They can be observed both in absorption against a background source or in emission in the radio.

The temperature is $100–200\,\mathrm{K}$ at the edges of a diffuse cloud with a density of about $100\,\mathrm{cm}^{-3}$. In a typical diffuse cloud the temperature decreases to about $30\,\mathrm{K}$ at the center while the density increases to about $300–800\,\mathrm{cm}^{-3}$. The chemistry is driven by ionization from interstellar UV photons and from cosmic rays.

Interstellar UV photons ionize species which have ionization potentials less then that of atomic hydrogen.

Atomic hydrogen is so pervasive in the galaxy that UV photons with energies higher than $13.6\,\mathrm{eV}$ are absorbed near the source. The UV flux is a very important parameter in determining the composition of a diffuse cloud. Photodissociation provides destruction which limits the buildup of more complex species and so diffuse clouds are dominated by simpler diatomic species.

Species with ionization potentials greater then hydrogen are mainly ionized by cosmic rays. Cosmic rays are high energy nuclei which stream through the galaxy. The cosmic ray ionization rate, the number of cosmic ray ionizations per second per particle, is an important parameter in interstellar chemistry. A lower limit to the cosmic ray ionization rate may be set by measured high energy cosmic rays reaching earth, giving an ionization rate of $\approx 10^{-17}\,\mathrm{s}^{-1}$. More realistic estimates of the cosmic ray ionization rate from looking at recombination lines suggest values of a few $\times 10^{-17}\,\mathrm{s}^{-1}$.

The hydroxyl radical OH is produced in a manner similar to that discussed below in Sect. 82.5, and removed by photodissociation. Thus in diffuse clouds,

OH may be used to measure the cosmic ray ionization rate, subject to uncertainties in the OH photodissociation rate and the H_3^+ recombination rate. The OH abundances give rates of several $\times 10^{-17}$ s^{-1} for many diffuse clouds.

The carbon chemistry begins with the ionization of C by UV photons:

$$C + h\nu \rightarrow C^+ + e^- \ . \tag{82.6}$$

The carbon ion cannot react directly with H_2 by

$$C^+ + H_2 \rightarrow CH^+ + H \ , \tag{82.7}$$

as this reaction is exothermic by 0.4 eV. Instead, the chemistry proceeds by the slow radiative association process

$$C^+ + H_2 \rightarrow CH_2^+ + h\nu \ . \tag{82.8}$$

The CH_2^+ ion may either dissociatively recombine

$$CH_2^+ + e^- \rightarrow CH + H \ , \tag{82.9}$$
or react with molecular hydrogen

$$CH_2^+ + H_2 \rightarrow CH_3^+ + H \ . \tag{82.10}$$
The CH_3^+ then undergoes dissociative recombination

$$CH_3^+ + e \rightarrow C + H_2 + H \tag{82.11}$$
$$\rightarrow CH + H + H \tag{82.12}$$
$$\rightarrow CH_2 + H \tag{82.13}$$
$$\rightarrow CH + H_2 \ , \tag{82.14}$$
where the products are listed in order of decreasing likelihood. The CH is removed by photodissociation

$$CH + h\nu \rightarrow C + H \tag{82.15}$$

and by photoionization

$$CH + h\nu \rightarrow CH^+ + e^- \ . \tag{82.16}$$

CH may also be removed by reactions with oxygen or nitrogen atoms to form CO and CN respectively.

One of the outstanding problems in diffuse clouds is to understand the large abundance of CH^+ relative to CH. The problem is producing the CH^+ without producing additional CH. Since most reaction paths go through reaction (82.7), this is the most likely candidate. What is needed is some extra energy to overcome the endothermicity. This energy must come from either hot C^+ or from hot or vibrationally excited H_2. The most popular model is gas heated by a shock, possibly a magnetic shock in which ions stream relative to the neutrals, giving a high effective energy. Unfortunately, though these shock models can reproduce the CH^+ abundances, they also predict relative velocities between the CH^+ and CH which are not often observed. Recently there have been suggestions that turbulence in the cloud could account for the CH^+ abundance.

The most comprehensive models of diffuse clouds are by *van Dishoeck* and *Black* [82.21]. A collection of photodissociation rates and photoionization rates is given in *Roberge* et al. [82.22].

The UV flux is predominantly from stars and may be as much as 10^5 times larger near an HII region Sect. 82.1 than it is in the general interstellar medium. Regions in which the chemistry is dominated by photons are referred to as *photon dominated regions* or *photodissociation regions* (PDR's). In the presence of high UV flux the cloud is much warmer than in a typical diffuse cloud. Temperatures may reach 1000 K near the edge of the cloud and 100 K far into the cloud. The chemistry differs from traditional diffuse cloud chemistry in that the high temperatures allow endothermic reactions to proceed. *Sternberg* and *Dalgarno* [82.23] have published a comprehensive model of photodominated regions.

82.4 Dark Molecular Clouds

Much of the mass of the galaxy is in the form of dark molecular clouds. The molecular clouds are sites of forming new stars. They are composed primarily of hydrogen, with about 10% helium and trace amounts of heavier elements. They have densities of approximately 10^3 or 10^4 cm^{-3} and temperatures between 10 and 20 K, and often contain denser clumps. The clouds are optically thick and so photons from the outside are absorbed on the surface of the clouds. The interiors are heated and ionized by cosmic rays which penetrate deep into the cloud.

The temperatures are too low to sustain much neutral chemical activity in the clouds, and cosmic ray ionization is important in driving the chemistry. In dense clouds, the cosmic rays both initiate the chemistry and limit it through the production of He$^+$ and through cosmic ray induced photons.

Table 82.1 is a list of molecules that have been observed in the interstellar medium, many of which have also been found in other galaxies. It is likely that all but H_2 are formed in the gas phase by ion–molecule re-

Table 82.1 Molecules observed in interstellar clouds

H_2	Hydrogen	CH	Methylidyne
CH^+	Methylidyne ion	OH	Hydroxyl
C_2	Carbon	CN	Cyanogen
CO	Carbon monoxide	CO^+	Carbon monoxide ion
NH	Amidogen	NO	Nitric oxide
CS	Carbon monosulphide	SiO	Silicon monoxide
SO	Sulphur monoxide	SO^+	Sulphur monoxide ion
NS	Nitrogen sulphide	SiS	Silicon sulphide
PN	Phosphorus nitride	HCl	Hydrogen chloride
SiN	Silicon nitride	NH_2	Amino radical
H_2O	Water	C_2H	Ethynyl
HCN	Hydrogen cyanide	HNC	Hydrogen isocyanide
HCO	Formyl	HCO^+	Formyl ion
N_2H^+	Protonated nitrogen	H_2S	Hydrogen sulphide
HNO	Nitroxyl	OCS	Carbonyl sulphide
SO_2	Sulphur dioxide	HCS^+	Thioformyl ion
C_2O	Carbon suboxide	C_2S	Dicarbon sulphide
N_2O	Nitrous oxide	H_2CN	Methylene amidogen
H_2CO	Formaldehyde	H_2CS	Thioformaldehyde
NH_3	Ammonia	HCNS	Isothiocyanic acid
HNCO	Isocyanic acid	$HOCO^+$	Protonated carbon dioxide
C_3H	Propynylidyne	C_3N	Cyanoethynyl
C_3S	Tricarbon sulphide	C_3O	Tricarbon monoxide
C_2H_2	Acetylene	H_3O^+	Hydronium ion
$HCNH^+$	Protonated hydrogen cyanide	C_3H_2	Cyclopropenylidene
CH_4	Methane	H_2CCC	Propadienylidene
HCOOH	Formic acid	CH_2CO	Ketene
HC_3N	Cyanoacetylene	HNCCC	Cyanoacetylene isomer
HCCNC	Ethynyl isocyanide	C_4H	Butadinyl
NH_2CH	Cyanamide	CH_2CN	Cyanomethyl radical
CH_2NH	Methanimine	CH_3CH	Methyl cyanide
H_2CCCC	Butatrienylidene	CH_3SH	Methyl mercaptan
C_5H	Pentynylidyne	HCC_2HO	Propynal
CH_3OH	Methyl alcohol	HC_3NH^+	Protonated cyanoacetylene
NH_2CHO	Formamide	CH_3C_2H	Methyl acetylene
CH_2CHCN	Vinyl cyanide	HC_5N	Cyanodiacetylene
C_6H	Hexatrinyl	CH_3NH_2	Methylamine
CH_3CHO	Acetaldehyde	$HCOOCH_3$	Methyl formate
CH_3C_3N	Methyl cyanoacetylene	CH_3C_4H	Methyl diacetylene
$CH_{32}O$	Dimethyl ether	CH_3CH_2CN	Ethyl cyanide
HC_7N	Cyanohexatriyne	CH_3CH_2OH	Ethyl alcohol
HC_9N	Cyano-octatetra-yne	HC_11N	Cyano-decapenta-yne

action sequences initiated by cosmic ray ionization. The fact that isomers such as HCN and HNC are seen in approximately equal abundances suggests a low density gas phase environment. Reactions on surfaces and the formation of grains are not well understood, but are surely important.

The chemistry of molecular clouds is dominated by ion–molecule reactions driven by cosmic ray ionization.

The cosmic rays primarily ionize H_2:

$$H_2 \rightarrow H_2^+ + e^- \,, \tag{82.17}$$

producing both H_2^+ and fast electrons. The fast electrons produce additional ionizations. The H_2^+ quickly reacts with H_2 to form H_3^+

$$H_2^+ + H_2 \rightarrow H_3^+ + H \,. \tag{82.18}$$

The H_3^+ reacts with other species by proton transfer, which then drives much of the interstellar chemistry.

As an example of the production of more complex molecules in interstellar chemistry, we examine the reaction networks leading to the production of water H_2O and the hydroxl radical OH. The H_3^+ ions formed by cosmic ray ionization react with atomic oxygen to form OH^+

$$O + H_3^+ \rightarrow OH^+ + H_2 \,, \tag{82.19}$$

which quickly reacts with H_2 to form H_3O^+ in an abstraction sequence

$$OH^+ + H_2 \rightarrow H_2O^+ + H \,, \tag{82.20}$$

$$H_2O^+ + H_2 \rightarrow H_3O^+ + H \,. \tag{82.21}$$

The H_3O^+ then undergoes dissociative recombination to form water and OH

$$H_3O+ + e^- \rightarrow H_2O + H \,, \tag{82.22}$$

$$\rightarrow OH + H_2 \,. \tag{82.23}$$
The water is removed by reactions with neutral or ionized carbon, which eventually lead to the production of CO. OH is primarily removed by reactions with atomic oxygen leading to O_2. The CO and O_2 are removed by reactions with He^+. The He^+, generated by cosmic ray ionization of helium, does not react with H_2 and so is available to remove species by reactions such as

$$CO + He^+ \rightarrow C^+ + O + He \,. \tag{82.24}$$

Water and OH are also removed by UV photons generated within the cloud. The clouds are too thick for external UV photons to penetrate, but cosmic rays excite H_2 into electronically excited states which decay through emission of UV photons. These internally generated photons play an important role in determining the composition of the cloud. *Gredel* et al. [82.24] have compiled a list of the photodissociation and photoionization rates for cosmic ray induced photons.

Modern chemical networks for molecular clouds include several hundred species and several thousand reactions. A standard set of reaction rates is provided by the UMIST (University of Manchester Institute of Science and Technology) dataset [82.25, 26]. The dataset may be obtained from the UMIST Astrophysics Group homepage (http://saturn.ma.umist.ac.uk:8000/).

The clouds also contain dust particles as evidenced by the extinction curves for clouds and the observed depletions of heavier elements. The importance of surface chemistry on these dust particles to interstellar clouds is still uncertain. Dust particles are the best candidate to be the site of formation of molecular hydrogen, because known gas phase reactions fail to produce H_2 in the quantities observed.

82.5 Circumstellar Shells and Stellar Atmospheres

The continuum emission from a star is very nearly that of a blackbody. This emission is then absorbed and redistributed by the atmosphere of the star. The spectrum of the star is thus determined by its atmosphere. In the hottest stars, most of the material is ionized and the absorption lines are predominantly those of ions, while in the coldest stars, molecular lines are prominent. *Kurucz* has calculated models with continuum spectra and the inclusion of a large number of absorption lines [82.27]. There are two major projects for calculating the required atomic data. In 1984 an international collaboration named the *Opacity Project* was set up to calculate accurate atomic data needed for opacity calculations [82.28, 29]. The other earlier project is called OPAL. The two sources of data are compared in [82.30, 31].

Low and intermediate mass stars eject circumstellar envelopes in their red giant phase near the end of their evolution. Circumstellar envelopes are an important part of astronomy and they are a likely location for dust formation. They provide an interesting environment for studying molecules because they represent a transition between very high density stellar atmosphere environments to low density interstellar environments. These objects evolve to become planetary nebulae Sect. 82.1.

We are fortunate in having one example, IRC 10216, which is very close to the Sun. The brightest $10\,\mu m$ source beyond the solar system, IRC 10216 is a carbon-

rich star surrounded by dust and gas it ejected in a strong stellar wind. The central star is so shielded that it is almost undetectable at optical wavelengths, and was not discovered until the $2\,\mu m$ survey. IRC 10216 is where most of the circumstellar molecules are detected, and has greatly increased our understanding of circumstellar envelopes.

The envelopes are ejected by the red giant in its final phase of evolution. The mass loss rates increase to $\sim 10^{-4}$ solar masses per year and temperatures in the envelope are of order $1000\,K$. Close to the star, the density is high and the chemistry is characteristic of thermal equilibrium. The situation is quite unlike any interstellar environments. For example in IRC 10216, the HNC is over one hundred times less abundant than HCN, whereas in molecular clouds, they have about the same abundance.

If the star is oxygen-rich, large amounts of H_2O are formed and if it is carbon-rich, C_2H_2. This high temperature environment forms both molecules and grains.

The high obscuration of the central source indicates that grains are formed in these envelopes. Polycyclic aromatic hydrocarbons (PAH's) or some similar species are observed in carbon rich planetary nebulae. These large molecules must have been produced when the object was a carbon rich circumstellar envelope.

As the material flows out from the star the density and temperature decrease. As the density becomes lower, three body reactions become less important and at some point the products of these reactions are frozen out in a similar manner to the evolution of molecules in the early universe (Sect. 82.10). In the outermost portions of the circumstellar envelope, molecules are dissociated by interstellar UV photons. The penetrating UV radiation is shielded by dust, H_2, and CO. The relative abundances can vary rapidly with radius, and observations provide abundance and radial distribution, a wealth of data for modelers. Circumstellar chemistry is reviewed by Omont [82.32] and recent chemical models are given in [82.33–35].

82.6 Supernova Ejecta

A supernova, the explosion of a massive star following core collapse, is one of the most spectacular displays in the Universe. The explosion occurs when the iron core of a massive star collapses to form a neutron star and the rebound shock and neutrino flux eject the outer portion of the star. The ejected portions of the star are rich in heavy elements produced in the interior of the progenitor star.

We are fortunate to have had in our lifetime a supernova which was close and in an unobscured line of sight. Supernova 1987A, the first supernova observed in 1987, went off in the Large Magellanic Cloud, a small satellite galaxy to our own. It was the first supernova visible to the naked eye in nearly 400 years (since the Kepler supernova in 1604). Using the full range of modern astronomical instruments has allowed us to get detailed spectra of the evolving ejecta which has greatly increased our knowledge of supernovae. We will use SN1987A as an example of supernova ejecta.

Initially the temperature of the ejecta of SN1987A was high, $\approx 10^6\,K$, but it quickly cooled through adiabatic expansion and radiation from the photosphere. The temperature leveled off at several thousand degrees because of heating by radioactive nuclei, first ^{56}Ni and then ^{56}Co, formed in the explosion. The dynamics is homologous free expansion: the velocity scales linearly

with the radius $r(t) = vt$ where v the velocity and t the time since the explosion.

The ejecta at first were optically thick and the spectrum resembled that of a hot star continuum with absorption lines from the surface. After a few days, the temperature dropped, but the ejecta remained optically thick and continued to show strong continuum emission. As the ejecta expand, the temperature drops, the ejecta become optically thin, and the spectrum is dominated by strong emission lines, superficially resembling an emission nebula Sect. 82.2. The emission is dominated by neutral atoms and singly ionized species.

The gas is heated and ionized by the gamma rays from radioactive decay. The gamma rays Compton scatter, producing X-rays and fast electrons. The X-rays further ionize the gas and produce multiply charged ions through the Auger process. These multiply charged ions recombine through charge transfer with neutral atoms. Further charge transfer determines the relative ionization of different species, with the lowest ionization potential species more ionized than the higher ionization potential species. The development of the infrared and optical spectrum of Supernova 1987A has been recently reviewed by *McCray* [82.36].

One of the great surprises in the spectrum of Supernova 1987A was the discovery of molecules in the

infrared region. CO, SiO and possibly H_3^+ have been identified. In the absence of grains, molecules must be formed through either three-body or radiative processes. In the supernova ejecta, the densities are too low for three-body processes to be effective and molecules are formed through radiative association reactions. The molecules are removed by reactions with He^+ and the molecular abundances put a constraint on how much helium can be mixed back into the region with carbon and oxygen [82.37].

82.7 Shocked Gas

Shock waves occur in compressible fluids when the pressure gradients are large enough to generate supersonic motion, or when a disturbance is propagating through the fluid at supersonic velocities. Because information about the disturbance cannot propagate upstream in the fluid faster than the speed of sound, the fluid cannot respond dynamically until the shock arrives. The shock then compresses, heats, and accelerates the fluid. The boundary separating the hot compressed gas and the upstream gas is the shock front in which the energy of directed motion of the shock is converted to random thermal energy.

Shocks are ubiquitous in the interstellar medium where they are driven by the ionization fronts of expanding H II regions or nebulae, by outflowing gas accompanying stellar birth and evolution, and by supernova explosions. If the shock velocity is above 50 km/s, the shock gas is excited, dissociated, and ionized. The subsequent recombination and cooling radiation produces photons that may ionize and dissociate the gas components ahead of and behind the shock. This precursor radiation modifies the effects of the shock and influences its dynamical and thermal evolution. Fast shocks destroy all molecules by dissociating H_2 by collisions with H, H_2 and He and with electrons. Exchange reactions with H atoms destroy the other molecular species. At low densities, radiative stabilization occurs and dissociation is less efficient. Molecules reform in the cooling postshock gas. Slower shocks do not cause ionization or dissociation, but the chemical composition and the ion composition are modified by reactions taking place in the warm gas. The response of the interstellar gas to slow shocks is significantly affected by the presence of a magnetic field. In some ionization conditions, a magnetic precursor may occur in which a magnetosonic wave carries information about the shock, and the ionized and neutral components of the gas react differenly to the shock. Many different kinds of shock have been identified [82.38].

A very fast shock with a velocity of hundreds of km/s such as are driven by supernova explosions, creates a hot dilute cavity in the interstellar medium with a temperature of millions of degrees. The density is low and the gas cools and recombines slowly. Overlapping supernova-induced cavities may be responsible for the hot gas that occupies a considerable volume of the interstellar medium in the Galaxy and in some external galaxies. The conditions are far from coronal equilibrium as the gas cools more rapidly than it recombines. The cooling radiation appears as soft X-rays and UV emission lines with a characteristic spectrum.

As the gas cools below 10 000 K, molecular formation occurs. Molecular hydrogen is formed on the surfaces of grains as in molecular clouds and by the negative ion sequence that is effective in the early Universe Sect. 82.8. With the formation of H_2 in a still warm gas, the chemistry is driven by exothermic and endothermic reactions with H_2. Thus OH is produced by the reaction of O atoms, and H_2O by the further reaction of OH with H_2. Enhanced abundances of other neutral and ionic molecules are the products of subsequent reactions with OH. The reactions of S^+ and S with OH lead to SO^+ and SO, and their simultaneous presence may be an indicator of a dissociative shock. There are in addition physical indicators of shocks, such as asymmetric line profiles indicating high velocities.

In a nondissociative shock in a molecular gas, reactions with warm H_2 dominate the chemistry as it does in the cooling zone of a dissociative shock. The composition is controlled by the post shock temperature and the H/H_2 ratio. The warm H_2 changes the ionic composition by converting C^+ into CH^+. Evidence for a nondissociative shock is the infrared emission from H_2. The thermal emission from collisionally excited vibrational levels in shock-heated gas is readily distinguished from that discussed in Sect. 82.3 arising from UV pumping in a PDR. Emission from H_2 has been detected in numerous objects in the Galaxy and in many distant external galaxies. In external galaxies, X-rays may contribute to the H_2 infrared sprectrum through heating the gas and through excitation by photoelectron pumping to excited states followed by a downward cascade [82.39, 40].

82.8 The Early Universe

Molecules appeared first in the Universe after the adiabatic expansion had reduced the matter and radiation temperature to a few thousand degrees and recombination occurred, creating a nearly neutral Universe. The small fractional ionization that remained was essential to the formation of molecules. Molecular hydrogen formed through the sequences

$$H^+ + H \rightarrow H_2^+ + h\nu \tag{82.25}$$

$$H_2^+ + H \rightarrow H_2 + H^+ \tag{82.26}$$

and

$$H + e^- \rightarrow H^- + h\nu \tag{82.27}$$

$$H^- + H \rightarrow H_2 + e^- , \tag{82.28}$$

the protons and electrons acting as catalysts. Many other atomic and molecular processes occurred Fig. 82.3, some involving excited hydrogen atoms. Thus

$$H^* + H_2 \rightarrow H_3^+ + e^- \tag{82.29}$$

was a source of H_3^+.
Fig. 82.3 Diagram showing the important reactions in the production of hydrogen molecules in the early Universe

The Universe contained trace amounts of deuterium and ^{7}Li nuclei with which heteronuclear molecules could be made. Molecules with dipole moments may leave an imprint on the cosmic blackbody background radiation that occupies the Universe. The deuterated molecules HD form from

$$D^+ + H_2 \rightarrow HD + H^+ , \tag{82.30}$$

and H_2D^+ from

$$D + H_3^+ \rightarrow H_2D^+ + H , \tag{82.31}$$

$$HD^+ + H_2 \rightarrow H_2D^+ + H , \tag{82.32}$$

and

$$HD + H_2^+ \rightarrow H_2D^+ + H . \tag{82.33}$$
Lithium hydride is formed through

$$Li + H \rightarrow LiH + h\nu \tag{82.34}$$

$$Li + H^- \rightarrow LiH + e^- \tag{82.35}$$

$$Li^- + H \rightarrow LiH + e^- . \tag{82.36}$$

There are many destruction processes, of which

$$LiH + H \rightarrow Li + H_2 \tag{82.37}$$

may be the most severe, though its rate coefficient is uncertain. The chemistry of the early Universe is summarized in [82.41].

The formation of molecules was a crucial step in the fragmentation of the first gravitationally collapsing objects which separated out of the cosmic flow. Three-body recombination

$$H + H + H \rightarrow H_2 + H \tag{82.38}$$

$$Li + H + H \rightarrow LiH + H \tag{82.39}$$

may be a major source of molecules as the density increases.

82.9 Recent Developments

While the core atomic and molecular process outlined are still unchanged, our understanding of the astrophysical environment has been greatly enhanced by a number of recent satellites. The Wilkinson Microwave Anisotropy Probe (WMAP) has given us the best map of the universe at the time of recombination and given us general confirmation of the Big Bang model. Perhaps the most surprising result is that stars seem to have

formed much sooner than would have been expected, about 180 million years after the big bang [82.42]. This makes it even more difficult to understand how the universe goes from the relative uniformity at the time of recombination to the collapse and formation of the first objects so quickly, a problem which is certainly controlled by atomic and molecular processes. The relevant atomic and molecular processes have been recently re-

viewed by *Lepp*, *Stancil* and *Dalgarno* [82.43]. Two recent X-ray satellites, Chandra and XMM-Newton, both launched in 1999, have greatly increased our ability to detect hot ionized gas in stars, supernova remnants, active galaxies and other regions [82.44]. In particular, Chandra has allowed us for the first time to directly observe the hot gas between galaxies [82.45]. The Infrared Space Observatory (ISO) has provided a tremendous amount of data on cold regions in our own galaxy and allowed us to directly observe the icy mantles of dust grains [82.46].

Since the detection of molecules in SN 1987A, there have been many more observations of CO molecules in Type II supernova and they may even occur in every Type II [82.47]. CO has also been observed in a Type Ic supernova [82.48]. It remains a puzzle as to why the molecules are not rapidly removed by helium ions. A recent calculation of the $O + He^+$ system [82.49] finds that radiative charge transfer is much faster then direct charge transfer

for temperatures below 10^6 K, but still too slow to significantly reduce the helium ion abundance in supernova ejecta. The most likely explanation remains that mixing is not complete in supernova ejecta, and the molecules survive in regions of relatively low helium abundance.

The state of modeling photoionized clouds has been recently reviewed by Ferland [82.50]. He also highlights the great need for atomic and molecular data for analyzing these clouds. New satellite data along with continued ground observations continually raise new astrophysical puzzles, puzzles which are controlled and probed by atomic and molecular processes. The astrophysical community owes a great debt to both atomic and molecular laboratory measurements and theoretical models of energy levels, reaction rates, and transition probabilities. In order to continue to progress in our understanding of the universe we will need to continue to fund the understanding of the atomic and molecular processes which control it.

82.10 Other Reading

Astronomy is one of the oldest sciences and one of the fastest evolving. Advances in technology are rapidly increasing the sensitivity and resolution of our instruments and so new observations and more sophisticated models lead to an ever greater understanding of the Universe. This means that books will often be somewhat dated when they appear. However, the series *Annual Review of Astronomy*

and Astrophysics is a good source of recent review articles.

In addition, good introductions or overviews of a particular field are given in [82.1, 51–56]. Many sources of atomic and molecular data are listed and discussed in [82.7]. For details on atomic spectroscopy, see [82.57, 58]. For details on molecular spectroscopy, see [82.59, 60].

Comets

83. Comets

With the exception of the in situ measurements made by the *Giotto* and *Vega* spacecraft at comet 1P/Halley (the P/ signifies a periodic comet) during March 1986, all determinations of the volatile composition of the coma are derived from spectroscopic analyses. Detailed modeling is then used to infer the volatile composition of the cometary nucleus. This chapter focuses on the principal atomic and molecular processes that lead to the observed spectrum as well as the needs for basic atomic and molecular data in the interpretation of these spectra. The largely collisionless and low density coma, with no gravity or magnetic field, is a unique spectroscopic laboratory, as evidenced by the discovery of C_3 before its identification in terrestrial laboratories [83.1]. Many key discrepancies remain to be resolved concerning the basic molecular composition and the elemental abundances of both the volatile and refractory components of the cometary nucleus, as well as the comet–to–comet variation (particularly between "new" and evolved periodic comets) of these quantities. These issues (and many others) are discussed in the recent

analytical review of *Festou* et al. [83.2, 3] or in the compendia of Halley results [83.4]. The former also contains a comprehensive bibliography. Other sources concentrating largely on the physics and chemistry of comets include the volumes edited by *Wilkening* [83.5] and *Huebner* [83.6] and the pre–Halley review of *Mendis* et al. [83.7].

Comets are small bodies of the solar system believed to be remnants of the primordial solar disk. Formed near the orbits of Uranus and Neptune and subsequently ejected into an "Oort cloud" of some 40 000 AU in extent, these objects likely preserve a record of the volatile composition of the early outer solar system, and so are of great interest for the physical and chemical modeling of solar system formation. The comets arrive in the inner solar system as a result of galactic perturbations. The cometary volatiles are vaporized as their orbits bring them closer to the sun and it is solar radiation that initiates all of the processes that lead to the extended coma. Gas vaporization also leads to the release of dust into the coma, and the scattering of sunlight by dust is the major source of the visible coma and dust tail of comets. Somewhat fainter, and much more extended, is the plasma tail, resulting from photoionization by solar extreme UV radiation of the neutral volatiles and their subsequent interaction with the solar wind.

83.1 Observations

In a review in 1965, *Arpigny* [83.8] summarized the known molecular and atomic emissions detected in the visible region of the spectrum (here defined as 3000 to 11 000 Å) as follows:

radicals: OH, NH, CN, CH, C_3, C_2, and NH_2
ions: OH^+, CH^+, CO_2^+, CO^+, and N_2^+;
metals: Na, Fe .

The only known atomic feature was the O I forbidden red doublet at 6300 and 6364 Å. From the radicals and ions one could infer the presence of their progenitor "parent" molecules such as H_2O, NH_3, HCN, CO and CO_2, directly vaporizing from the comet's nucleus. The metals, seen only in comets passing close to the sun, were assumed to come from the vaporization of refractory grains. The inventory of metals was soon expanded to include K, Ca^+, Ca, V, Cr, Mn, Ni and Cu, from observations of the sun-grazing comet Ikeya-Seki (C/1965 S1) [83.9, 10] and H_2O^+ was identified in comet Kohoutek (C/1973 E1). This latter comet was also the first to be extensively studied at wavelengths both shortward and longward of the visible spectral range.

The first parent molecule to be directly identified was CO, which fluoresces in the Fourth Positive system $\left(A\,^1\Pi_u - X\,^1\Sigma^+\right)$ in the VUV [83.11], although the in situ neutral mass spectrometer measurements made of Halley disclosed the presence of an extended, dominant source of CO [83.12] whose origin is still being debated [83.13]. Ideally, the molecular species should be detectable through their radio and sub-mm rotational transitions or through the detection of vibrational bands or individual ro-vibrational lines in the near IR. Water was first directly detected through ro-vibrational lines near 2.7 μm in comet Halley and again in comet Wilson (C/1986 P1) [83.14, 15]. However, due to the low column densities of the other expected species, typically ≈1 or less than that of H_2O, the direct detection of species such as H_2CO, H_2S and CH_3OH has only recently been made possible by the development of more sensitive instrumental techniques together with the fortuitous apparitions of two bright comets, C/1996 B2 (Hyakutake) and C/1995 O1 (Hale-Bopp) in 1996 and 1997. To date, more than two dozen parent molecules have been identified [83.16]. Isotope ratios, particularly the D/H ratio, in molecules such as HDO have been determined from sub-millimeter observations [83.17].

The ultimate result of solar photolysis (and to a lesser degree, the interaction with the solar wind) is the reduction of all of the cometary volatiles to their atomic constituents. The atomic inventory is somewhat easier to derive as the resonance transitions of the cosmically abundant elements H, O, C, N and S all lie in the VUV and, in principle, the total content of these species in the coma can be determined by an instrument with a suitably large field of view. Of course, a fraction of the atomic species of each element will be produced directly in ionic form, and will not be counted using this approach. In addition, another fraction exists in the coma in the solid grains, and this component will also not be included,

except for a small amount volatilized by evaporation or sputtering by energetic particles. The composition of the grains, though not the absolute abundance, has been determined from in situ measurements made by the Halley encounter spacecraft [83.18], and can be inferred, though not unambiguously, from reflection spectroscopy of cometary dust in the 3−5 μm range.

The advent of space-borne platforms for observations in the VUV has produced a wealth of new information about the volatile constituents of the coma. The $A\,^2\Sigma^+ - X\,^2\Pi$ (0, 0) band of the OH radical at ≈ 3085 Å was well known from ground-based spectroscopic observations, but as this wavelength lies very close to the edge of the atmospheric transparency window, the strength of this feature (relative to that of other species) was not appreciated until 1970 when comet Bennett (C/1969 Y1) was observed from space by the Orbiting Astronomical Observatory (OAO-2). The OAO-2 spectrum also showed a very strong, broadened H I Ly-α emission from H, the other principal dissociation product of H_2O. The broad shape of Ly-α seen in the OAO-2 spectrum is due to the large spatial extent of the atomic H envelope, the result of a high velocity acquired in the photodissociation process and a long lifetime against ionization. Later, at the apparition of comet Kohoutek (C/1973 E1), atomic O and C were identified in the spectra and direct UV images of the H coma, as well as of the O I and C I emissions, were obtained from sounding rocket experiments. These experiments were repeated for comet West (C/1975 V1) and led to the first detection of CO [83.11].

Between 1978 and 1996, over 50 comets were observed spectroscopically over the wavelength range 1200−3400 Å by the International Ultraviolet Explorer (IUE) satellite observatory [83.19, 20]. Most of the spectra were obtained at moderate resolution ($\Delta\lambda = 6{-}10$ Å), although high dispersion echelle spectra ($\Delta\lambda = 0.2{-}0.3$ Å) are useful for some studies, particularly those of fluorescence equilibrium (Sect. 83.2.2). For Halley alone, over 200 UV spectra were obtained from September 1985 to July 1986. The launch of the *Hubble Space Telescope* (HST) in 1990, together with subsequent enhancements to the spectroscopic instrumentation that were made on-orbit, marked another advance in sensitivity as well as the ability to observe in a small field-of-view very close to the nucleus. This yielded the first detection of CO Cameron band emission, a direct measure of CO_2 being vaporized from the nucleus [83.21]. For an overview of a cometary spectrum, a composite spectrum of 103P/Hartley 2 spanning the region from H I Ly-α to 7000 Å taken with

the Faint Object Spectrograph of HST, using five separate gratings, is shown in Fig. 83.1. The launch of the *Far Ultraviolet Spectroscopic Explorer* (FUSE) in 1999 provides access to the spectral region between 900 and 1200 Å at very high spectral resolution, and has led to the detection of H_2 (Sect. 83.2.4), upper limits on Ar and N_2, and some three dozen unidentified emission lines [83.22, 23].

Several other satellite observatories have contributed unique cometary observations in the UV and sub-mm spectral windows. The *Solar and Heliospheric Observatory* (SOHO) has two valuable instruments: The SWAN (Solar Wind Anisotropies) instrument provides sky maps in H I Ly-α at $1°$ resolution and has observed over 20 comets since 1996 [83.25]. The UVCS (Ultraviolet Coronograph Spectrometer) provides far-uv spectra and images of comets close to the Sun, where HST and FUSE are prohibited from observing, and has recently detected C^{++} in the tail of comet C/2002 X5 (Kudo-Fujikawa) [83.26]. The direct detection of H_2O in the fundamental rotational line at 557 GHz in several comets was made by the *Submillimeter Wave Astronomy Satellite* (SWAS) [83.27] and the *Odin satellite* [83.28]. This line cannot be observed from ground-based telescopes because of the strong absorption by water vapor in the terrestrial atmosphere.

Prior to 1996, X-rays had not been detected in comets and the conventional wisdom was that they were unlikely to be produced in the cold, rather thin cometary atmosphere. The discovery of soft X-ray emission ($E < 2$ keV) from comet Hyakutake (C/1996 B2) by the *Röntgen Satellite* (ROSAT) thus came as a surprise [83.29]. Since then, X-ray emission has been detected from over a dozen comets using ROSAT and four other space observatories, the *Extreme Ultraviolet Explorer*, *BeppoSAX*, the *Chandra X-ray Observatory* (CXO), and *Newton-XMM* [83.30]. The earliest observations were at very low spectral resolution, making it difficult to select amongst the possible excitation mechanisms: charge exchange, scattering of solar photons by attogram dust particles, energetic electron impact and bremsstrahlung, collisions between cometary and interplanetary dust, and solar X-ray scattering and fluorescence. The more recent CXO observations, at higher spectral resolution, favor the charge exchange of energetic minor solar wind ions such as O^{6+}, O^{7+}, C^{5+}, C^{6+}, and others, with cometary gas, principally H_2O, CO, and CO_2, as the primary mechanism. This mechanism would explain why the X-ray intensity appears to be independent of the gas
Fig. 83.1 Composite FOS spectrum of comet 103P/Hartley 2. After [83.24]

production rate of the comet, and that the peak emission is offset from the location of the comet's nucleus. This conclusion is also supported by recent laboratory work on the charge transfer of highly ionized species with cometary molecules [83.31] and by theoretical calculations of state specific cascades [83.32]. The X-ray emission thus tells us more about the solar wind than about the gaseous composition of comets.

83.2 Excitation Mechanisms

83.2.1 Basic Phenomenology

Coma abundances may be derived from spectrophotometric measurements of either the total flux or the surface brightness in a given spectral feature. The uncertainty in the derived abundances includes not only the measurement uncertainty, but also uncertainties in the atomic and molecular parameters and, in the case of surface brightness measurements, uncertainties in the model parameters used. Thus relative abundances, derived from observations of different comets with the same instrument and under similar geometrical conditions, are often more reliable.

Atoms and ions in the cometary coma emit radiation primarily by means of resonance re-radiation of solar photons. For the cosmically abundant elements H, C, N, O, and S, their strongest resonance transitions are in the VUV. The few exceptions are noted below. Assume that the coma is optically thin in these transitions. The total number of species i in the coma is

$$M_i = Q_i \tau_i(r) , \tag{83.1}$$

where Q_i is the production rate (atoms or molecules s^{-1}) of species i and $\tau_i(r)$ is its lifetime at heliocentric distance r, $\tau_i(r) = \tau_i(1 \, \text{AU})r^2$. The r dependence arises from photolytic destruction processes induced by solar UV radiation, and to a lesser degree by the solar wind, as described in Sect. 83.3.1.

The luminosity, in photons s^{-1}, in a given transition at wavelength λ, is then

$$L_{i\lambda} = M_i g_{i\lambda}(r) , \tag{83.2}$$

where the fluorescence efficiency, or "g-factor", $g_{i\lambda}(r) = g_{i\lambda}(1 \, \text{AU})r^{-2}$, is

$$g_{i\lambda}(1 \, \text{AU}) = \frac{\pi e^2}{mc^2} \lambda^2 f_\lambda \pi F_\odot \tilde{\omega}$$
$$\text{photons } s^{-1} \text{atom}^{-1} , \tag{83.3}$$

where f_λ is the absorption oscillator strength, $\pi F_\odot$ is the solar flux per unit wavelength interval at 1 AU and $\tilde{\omega}$ is the albedo for single scattering, defined for a line in an atomic multiplet as

$$\tilde{\omega} = \frac{A_j}{\sum_j A_j} , \tag{83.4}$$

where A_j is the decay rate. If a given multiplet is not resolved, then $\tilde{\omega} = 1$. For diatomic molecules, fluorescence to other vibrational levels becomes important and the evaluation of $\tilde{\omega}$ depends on the physical conditions in the coma, as discussed in Sect. 83.2.2. Thus, for a comet at a geocentric distance Δ, the total flux from the coma for the transition is

$$F_{i\lambda} = \frac{L_{i\lambda}}{4\pi \Delta^2} = \frac{Q_i g_{i\lambda}(r) \tau_i(r)}{4\pi \Delta^2} , \tag{83.5}$$

and the product $g_{i\lambda}(r)\tau_i(r)$ is independent of r.

Unfortunately, the scale lengths (the product of lifetime and outflow velocity) of almost all of the species of interest in the UV are $\approx 10^5 - 10^6$ km at 1 AU. Thus, total flux measurements require fields of view ranging from several arc-minutes to a few degrees. This has been done only in the case of a few isolated sounding rocket experiments. Most information about the UV spectra comes from observations made by orbiting satellite observatories whose spectrographs have small apertures (e.g., $10'' \times 20''$ for IUE) and thus sample only a very small part of the total coma. In this case, again assuming an optically thin coma, the measured flux $F'_{i\lambda}$ in the aperture can be converted to an average surface brightness $B_{i\lambda}$ (in units of Rayleighs):

$$B_{i\lambda} = 4\pi 10^{-6} F'_{i\lambda} \Omega^{-1} , \tag{83.6}$$

where Ω is the solid angle subtended by the aperture. The brightness, in turn, is related to $\overline{N}_i$, the average column density of species i within the field of view by

$$B_{i\lambda} = 10^{-6} g_{i\lambda}(r) \overline{N}_i . \tag{83.7}$$

The evaluation of Q_i from $\overline{N}_i$ requires the use of a model of the density distribution of the species i (Sect. 83.3.2).

A similar treatment can be applied to the excitation of the near infrared vibrational transitions of cometary parent molecules since the direct pumping by solar IR radiation far exceeds the indirect pumping of ground state vibrational levels through electronic transitions excited by the solar UV flux [83.16]. However, this does not apply to the rotational transitions which are controlled by collisional excitation, primarily collisions with H_2O. In this case, the observed rotational temperature may be regarded as a reliable measure of the kinetic temperature of the coma gas.

83.2.2 Fluorescence Equilibrium

In the case of low resolution spectroscopy, where an atomic multiplet or molecular band is unresolved, the evaluation of the g-factor (83.3) does not require knowledge of the population of either atomic fine structure levels or molecular rotational levels in the ground state of the transition. Furthermore, the assumption that the solar flux does not vary over the multiplet or band allows us to use the total transition oscillator strength. This assumption is more often than not invalid because of the Fraunhofer structure of the solar spectrum in the near uv and visible region and the emission line nature of the spectrum below 2000 Å. For high resolution spectra, the g-factors for each individual line must be calculated separately and the relative populations of the ground state levels must be included. There are three cases to be considered:

1. The g-factor, or probability of absorption of a solar photon, is less than the probability that the species will be dissociated or ionized, i. e., $g_{i\lambda} < (\tau_i)^{-1}$. In this case, the ground state population is not affected by fluorescence and a Boltzmann distribution at a suitable temperature (typically $\approx 200\,\mathrm{K}$ at 1 AU) corresponding to the production of the species may be used. This is often the case in the far UV, where the solar flux is low, such as for the Fourth Positive band system of CO. For atomic transitions from triplet ground states, such as is found with O, C and S, downward fine structure transitions are fast enough to effectively depopulate all but the lowest fine structure level.

2. The species undergoes many photon absorption and emission cycles in its lifetime, and the ground state population is determined (usually after 5 or 6 cycles) by the fluorescence branching ratios. This is the condition of fluorescence equilibrium, which applies for almost all radicals observed in the visible and near UV regions. The general procedure is to solve a set of coupled equations of the form

$$\frac{\mathrm{d}n_a}{\mathrm{d}t} = -n_a \sum_{b=1}^{N} p_{ab} + \sum_{b=1}^{N} n_b p_{ba} , \qquad (83.8)$$

where n_a is the relative population of level a and p_{ab} and p_{ba} are transition rates out of and into this level, respectively. The n_a are normalized to unity. The steady state, obtained after many cycles, is given by $\mathrm{d}n_a/\mathrm{d}t = 0$. Since the downward transition rates are determined only by quantum mechanics, while the absorption rates depend on the magnitude of the solar flux, the steady state population varies with distance from the sun with higher rotational levels (as for the case of CN [83.8]) populated closer to the sun. In some cases, where only a few cycles occur, the equations are integrated numerically. As the g-factor varies with time, it also effectively varies with the position of a species in the coma. Care must also be taken when spectra taken with small apertures are analyzed as the transit time for an atom or molecule to cross the aperture may be $\lesssim g_{i\lambda}(r)^{-1}$. In practice, these considerations are often not important.

3. The same as 2. except that the density is sufficiently high that collisional transitions must be included in addition to the radiative transitions between levels. However, as the collisional rates are poorly known, in practice a "collision sphere" is defined such that a molecule traveling radially outward from this sphere suffers only one collision with other molecules or atoms. Outside this sphere, fluorescence equilibrium is assumed to hold, while inside a thermal distribution of ground state levels is used. A rough estimate of the radius R_c of the collision sphere, based on the radial outflow model of Sect. 83.3.2 is given by [83.2, 3]

$$R_c = 10^3 \frac{Q}{10^{29}}\ \mathrm{km} , \qquad (83.9)$$

where Q is the total production rate in molecules s^{-1}.

83.2.3 Swings and Greenstein Effects

Swings [83.33] first pointed out that because of the Fraunhofer absorption lines in the visible region of the solar spectrum, the absorption of solar photons in a molecular band would vary with the comet's heliocentric velocity $\dot{r}$, leading to differences in the structure of a band at different values of $\dot{r}$ when observed at high resolution. In (83.8), this corresponds to evaluating the $p_{ba} = p_{ba}(\dot{r})$. For typical comets observed near 1 AU, $\dot{r}$ can range from –30 to +30 km/s, while in certain cases of comets with small perihelia the range can be twice as large. This effect of the Doppler shift between the sun and the comet is commonly referred to as the Swings effect. Even for observations at low resolution, the Swings effect must be taken into account in the calculation of the total band g-factor, and this has been done for a number of important species such as OH, CN and NH. A particularly important case, that of the OH $A\,^2\Sigma^+ - X\,^2\Pi$ (0,0) band at ≈ 3085 Å, which is often used to derive the water production rate of a comet,

is illustrated in Fig. 83.2, which also shows the dependence of fluorescence equilibrium on heliocentric distance [83.34].

While this effect was first recognized in the spectra of radicals in the visible range, a similar phenomenon occurs in the excitation of atomic multiplets below 2000 Å, where the solar spectrum makes a transition to
Fig. 83.2 OH (0,0) band g-factor as a function of heliocentric velocity. After [83.34]

Fig. 83.3 Solar flux and fluorescence efficiency for O I λ1302 as a function of heliocentric velocity. After [83.35]

an emission line spectrum. For example, the three lines of O I λ1302 have widths of ≈ 0.1 Å, corresponding to a velocity of ≈ 25 km/s, so that knowledge of exact solar line shapes is essential for a reliable evaluation of the g-factor for this transition [83.35], as illustrated in Fig. 83.3.

A differential Swings effect occurs in the coma since atoms and molecules on the sunward side of the coma, flowing outward towards the sun, have a net velocity that is different from those on the tailward side, and so, if the absorption of solar photons takes place on the edge of a line, the g-factors will be different in the two directions. Differences of this type appear in long-slit spectra in which the slit is placed along the sun-comet line (the *Greenstein* effect [83.36]). Again, an analogue in the far UV has been observed in the case of O I λ1302 [83.37], as can be seen in Fig. 83.3. Although it is also possible to explain the observation by nonuniform outgassing, this was considered unlikely as all of the other observed emissions had symmetric spatial distributions. The measurement of the Greenstein effect leads immediately to a determination of the mean outflow velocity of the given species.

83.2.4 Bowen Fluorescence

Figure 83.3 also demonstrates that for heliocentric velocities > 30 km/s, the Doppler shift reduces the solar flux at the center of the absorption line to a very small value, so that the O I λ1302 line is expected to appear weakly, if at all, in the observed spectrum. Thus, it was a surprise that this line appeared fairly strongly in two comets, Kohoutek (C/1973 E1) and West (C/1975 V1), whose values of $\dot{r}$ were both > 45 km/s at the times of observation. The explanation invoked the accidental coincidence of the solar H I Ly-β line at 1025.72 Å with the O I ^{3}D $- ^3$P transition at 1025.76 Å, cascading through the intermediate ^{3}P state as shown in the simplified energy level diagram of Fig. 83.4 [83.35]. This mechanism, well known in the study of planetary nebulae, is referred to as *Bowen* fluorescence [83.38]. The g-factor due to Ly-β pumping is an order of magnitude smaller than that for resonance scattering, as shown in Fig. 83.3, but sufficient to explain the observations and to confirm that H_2O is the dominant source of the observed oxygen in the coma.

Ly-β is also coincident with the P1 line of the (6,0) band of the H_2 Lyman system $\left(B\,^1\Sigma_u^+ - X\,^1\Sigma_g^+ \right)$ leading to fluorescence in the same line of several (6,v'') bands, the strongest being that of the (6,13) band at 1608 Å [83.39]. This line is, however, difficult to ob-
Fig. 83.4 Simplified O I energy level diagram showing transitions of interest in cometary spectra

serve because of the nearby strong CO Fourth Positive bands. Recently, the shorter wavelength (6,1), (6,2), and (6,3) bands have been detected in three comets using FUSE and the derived H_2 column abundance was found to be consistent with a water photodissociation source [83.22, 23]. Another interesting example occurs for Ne I, where the second resonance transition at 629.74 Å coincides with the strong solar O V line at 629.73 Å. This line was used to set a sensitive upper limit on the Ne abundance in the coma of comet Hale-Bopp (C/1995 O1) [83.40].

83.2.5 Electron Impact Excitation

The photoionization of the parent molecules and their dissociation products leads to the formation of a cometary ionosphere whose characteristics are only poorly known. Planetary ionospheres serve only as a poor model since the cometary atmosphere is gravitationally unbound and there is no constraining magnetic field. The in situ measurements of Halley provided order of magnitude confirmation of the theoretical modeling. In principle, electron impact excitation, which is often

the dominant source of airglow in the atmospheres of the terrestrial planets Chapt. 84, also contributes to the observed emissions, particularly in the UV, and so must be accounted for in deriving column densities from the observed emission brightnesses. However, one can use a very simple argument, based on the known energy distribution of solar UV photons, to demonstrate that electron impact excitation is only a minor source for the principal emissions. Since the photoionization rate of water (and of the important minor species such as CO and CO_2) is $\approx 10^{-6}$ s^{-1} at 1 AU, and the efficiency for converting the excess electron energy into excitation of a single emission is of the order of a few percent, the effective excitation rate for any emission will be $\approx 10^{-8}$ s^{-1} or less at 1 AU [83.41]. Since the efficiencies for resonance scattering or fluorescence for almost all the known cometary emissions are much larger, electron impact may be safely neglected except in a few specific cases.

The cases of interest are those of forbidden transitions, where the oscillator strength, and consequently the g-factor, is very small. Examples include the O I $^5S_2 - {}^3P_{2,1}$ doublet at 1356 Å, which was observed in comets West and Halley by rocket-borne spectrographs and more recently in comets Hyakutake and Hale-Bopp, the O I $^1D - {}^3P$ red lines at 6300 and 6364 Å, observed in many comets, and the CO Cameron bands [83.21]. However, the excitation of these latter two is dominated by prompt emission in the inner coma, the same region of the coma where electron excitation is important, as described in the next section.

83.2.6 Prompt Emission

In cases where the dissociation or ionization of a molecule leaves the product atom or molecule in an excited state, the decay of this state with the prompt emission of a photon provides a useful means for tracing the spatial distribution of the parent molecule in the inner coma. The products of interest for the water molecule are described in Sect. 83.3.1. Prompt emission includes both allowed radiative decays (such as from the $A\,{}^2\Sigma^+$ state of OH) as well as those from metastable states such as O(^1D), since the latter will move $\sim$150 km (for a comet at a geocentric distance of 1 AU, 1 arcsecond corresponds to a projected distance of 725 km) in its lifetime. The O I $^1D - {}^3P$ transition at 6300 and 6364 Å Fig. 83.4 has been used extensively as a ground-based monitor of the water production rate with the caveat that other species such as OH, CO and CO_2 may also contribute to the observed red line emission.

In addition, when the density of H_2O is sufficient to produce observable red line emission, it is also sufficient to produce collisional quenching of the ^1D state, and this must also be considered in the interpretation of the observations. The analogous $^1D - ^3P$ transitions in carbon occur at 9823 and 9849 Å and provide similar information about the production rate of CO. Carbon atoms in the ^1D state, whose lifetime is $\approx 4000\,s$, are known to be present from the observation of the resonantly scattered $^1P^o - ^1D$ transition at 1931 Å [83.42], and the 9849 Å line has been detected in comet Hale-Bopp [83.43].

The OH $A\,^2\Sigma^+ - X\,^2\Pi$ prompt emission competes with that produced by the resonance fluorescence of OH and is difficult to detect, except close to the nucleus (inside 100 km) where the density of water molecules exceeds that of OH by a few orders of magnitude [83.44]. Again, the reason is that at the wavelengths below the threshold for simultaneous dissociation and excitation, the sun has much less flux than at the resonance wavelength. On the other hand, only a few rotational lines are excited in fluorescence equilibrium [83.34], while the prompt emission is characterized by a very "hot" rotational distribution, so in principle the two components

may be separated although observations at very high spatial and spectral resolution are required. OH prompt emission has also recently been detected in the infrared at 3.28 µm [83.45].

83.2.7 OH Level Inversion

An important consequence of fluorescence equilibrium in the OH radical is the UV pumping of the hyperfine and Λ-doublet levels of the $X\,^2\Pi_{3/2}(J = 3/2)$ ground state, which results in a deviation of the population from statistical equilibrium [83.34]. Depending on the heliocentric velocity, this departure may be either "inverted" or "anti-inverted" giving rise to either stimulated emission or absorption against the galactic background at 18 cm wavelength. This technique has been used extensively since 1974 to monitor the OH production rate in comets, even of those that appear close to the sun [83.46]. The resulting radio emissions are easily quenched by collisions with molecules and ions, the latter giving rise to a fairly large R_c that must be accounted for in interpreting the derived OH column density. Nevertheless, the radio and UV measurements give reasonably consistent results [83.46].

83.3 Cometary Models

83.3.1 Photolytic Processes

As an example of the photolytic destruction processes occurring in the coma, consider the dominant molecular species, water. Water vapor is assumed to leave the surface of the nucleus with some initial velocity v_0 and flow radially outward, expanding into the vacuum, and increasing its velocity according to thermodynamics [83.7]. Even though collisions are important at distances typically up to 10^4 km (depending on the density and consequently, on the total gas production rate), the net flow of H_2O molecules is radially outward, such that the density varies as R^{-2} near the nucleus, where R is the cometocentric distance. This is the basis for spherically symmetric coma models (the number of particles flowing through a spherical surface is conserved), which assume isotropic gas production, but appears to hold equally well for the case of Halley, which clearly was not outgassing uniformly over its surface [83.4].

The photolysis of H_2O can proceed by:

a	$H_2O + h\nu \rightarrow OH + H$	2424.6 Å
a'	$\rightarrow OH(A\,^2\Sigma^+) + H$	1357.1 Å

b	$H_2O + h\nu \rightarrow H_2 + O(^1D)$	1770 Å
b'	$\rightarrow H_2 + O(^1S)$	1450 Å
b''	$\rightarrow H + H + O(^3P)$	1304 Å
c	$\rightarrow H_2O^+ + e^-$	984 Å
d	$\rightarrow H + OH^+ + e^-$	684.4 Å
e	$\rightarrow H_2 + O^+ + e^-$	664.4 Å
f	$\rightarrow OH + H^+ + e^-$	662.3 Å
The right-hand column gives the energy threshold for each reaction, in wavelength units. The products are subsequently removed by:

g	$OH + h\nu \rightarrow O + H$	2823.0 Å
h	$\rightarrow OH^+ + e^-$	928 Å
i	$H_2 + h\nu \rightarrow H + H$	844.79 Å
j	$\rightarrow H_2^+ + e^-$	803.67 Å
k	$\rightarrow H + H^+ + e^-$	685.8 Å
l	$O + h\nu \rightarrow O^+ + e^-$	910.44 Å
m	$H + h\nu \rightarrow H^+ + e^-$	911.75 Å
Reactions l and m can also occur by resonant charge exchange with solar wind protons. Reactions a', b and b' correspond to the production of prompt emission, as

discussed in Sect. 83.2.6. The determination of column densities of H, O and OH simultaneously was convincing evidence that the dominant volatile species in the cometary nucleus was H_2O, long before the direct infrared detection of this species in the coma.

Detailed cross sections for the absorption of UV photons by each of the reactants, including proper identification of the final product states, is necessary for the evaluation of the photodestruction rate in the solar radiation field of each of the above reactions. These rates are evaluated at 1 AU using whole disk measurements of the solar flux by integrating the cross section

$$J_d = \int_0^{\lambda_{th}} \pi F_\odot \sigma_d \, d\lambda \, . \tag{83.10}$$

Another quantity of interest in coma modeling is the excess velocity (or energy) of the dissociation or ionization products, and this requires knowledge of the partitioning of energy between internal and translational modes for each reaction [83.47].

Qualitatively, the photodissociation and photoionization rates can be estimated from the threshold energies given in the table above, since the solar flux is decreasing very rapidly to shorter wavelengths, as can be seen in Fig. 83.1. It is customary to specify the lifetime against photodestruction τ_i, of species i, which is just

$$(\tau_i)^{-1} = \sum_j (J_d)_j \, , \tag{83.11}$$

where the sum is over all possible reaction channels, as well as the lifetimes into specific channels. Processes with thresholds near 3000 Å have lifetimes $\approx 10^4$ s, those with thresholds near 2000 Å an order of magnitude longer, while those with thresholds below Ly-α, such as most photoionization channels, have lifetimes $\approx 10^6$ s, all at 1 AU. In addition to uncertainties in the details of the absorption cross sections, further uncertainty is introduced into the calculation of J_d by the lack of knowledge of the solar flux at the time of a given observation due to the variability of the solar radiation below 2000 Å, and most importantly, below Ly-α, where there have not been continuous space observations for more than a decade. The solar UV flux is known to vary considerably both with the 27-day solar rotation period and with the 11-year solar activity cycle. Also, at any given point in its orbit, a comet sees a different hemisphere of the sun than what is seen from Earth. *Huebner* et al. [83.48] have compiled an extensive list of useful

photodestruction rates using mean solar fluxes to represent the extreme conditions of solar minimum and solar maximum. They also include the excess energies of the dissociation products. A detailed analysis of the rates for H_2O and OH, using surrogate solar indices such as the 10.7 cm solar radio flux, or the equivalent width of the He I line at 1.083 µm, is in good agreement with observations [83.49]. Similar analyses still remain to be carried out for other important species, such as CO and NH_3.

83.3.2 Density Models

For parent molecules produced directly by sublimation from the surface of the comet, a spherically symmetric radial outflow model is often adopted. Such a model assumes a steady-state gas production rate Q_i and a constant outflow velocity v, and gives rise to a density distribution as a function of cometocentric distance R given by

$$n_i(R) = \frac{Q_i}{4\pi v R^2} e^{-R/\beta_i} \, , \tag{83.12}$$

where $\beta_i = v\tau_i$ is the scale length of species i. The basic validity of this model was demonstrated by the *Giotto* neutral mass spectrometer measurements of H_2O and CO_2 [83.4], although detailed analysis revealed that the velocity of the water molecules increased from 0.8 km/s at about 1000 km from the nucleus to 1.1 km/s at a radial distance of 10 000 km. The dependence of outflow velocity on heliocentric distance remains uncertain, although *Delsemme* [83.50] has suggested an $r^{-1/2}$ dependence based on thermodynamic arguments. Sub-millimeter observations of H_2O have sufficient spectral resolution to permit the mapping of outflow velocities along various lines-of-sight to the comet [83.28].

For the dissociation products, the modeling is more complex. The simplest model assumes continued radial outflow, although at a different velocity, such as to maintain a constant flux of the initial particle across an arbitrary spherical surface surrounding the nucleus [83.51]. This model, which is valid only at distances equal to a few β_i, is widely used as the densities can be easily expressed in analytical form. However, as surface brightness measurements are often made with small fields of view close to the nucleus, this model can lead to a factor of two error from the neglect of the dissociation kinematics. Since the solar photodissociation often leaves the product fragments with 1–2 eV of kinetic energy [83.47, 48], the resultant motion (which is assumed to be isotropic in the parent molecule's rest frame), will contain a large nonradial

component. Several approaches have been developed to account properly for the kinematics; notably, the vectorial model of *Festou* [83.52], and the average random walk model (a Monte Carlo method) of *Combi* and *Delsemme* [83.53]. The latter model has been extended to include time-dependent gas kinetics so as to properly account for regions of the coma where the gas is not in local thermodynamic equilibrium [83.54].

In addition to the photodestruction chains, chemical reactions, particularly ion-molecule reactions, can alter the composition within the collision zone defined in Sect. 83.2.2. While such reactions may produce numerous minor species, they do not erase the signatures of the original parent molecules. In fact, detailed chemical models have clearly demonstrated the need for complex molecules to serve as the parents of the observed C_2 and C_3 radicals in the coma, strengthening the connection between comet formation and molecular cloud abundances. Thus, the photochemical chains provide a valid means of relating the coma composition to that of the nucleus.

83.3.3 Radiative Transfer Effects

The results of a model calculation for the density of a species must be integrated over the line of sight to obtain the column density at a given projected distance from the nucleus, and then integrated over the instrumental field of view for comparison with the observed average surface brightness or derived average column density $\overline{N_i}$. This assumes that the coma is optically thin, and that all atoms or molecules have an equal probability of absorbing a solar photon. In practice, this is true for all molecular emissions except perhaps within 1000 km of the nucleus (i. e., for observations made at better than $1''$ resolution). Since the cross sections at line center can be very large for an atomic resonance transition, the optical depth for the abundant species can exceed unity and radiative transfer along both the line of sight to the sun and that to the Earth must be considered. This is not a trivial problem as the velocity distribution of the atoms, particularly the component due to the excess energy of the photodestruction process, must be well known, as must be the shape of the exciting solar line. The most thoroughly studied case to date is that of H I Ly-α, whose angular extent, in direct images, can exceed several degrees on the sky [83.55].

An interesting case arises for resonance transitions between an excited $^3S_1$ state and the ground $^3P_{2,1,0}$ state, as for O and S, particularly the latter, as its concentration near the nucleus can be quite large due to the rapid decay of one of its parents, CS_2. For S I the three lines at 1807, 1820 and 1826 Å are not observed to have their statistical intensity ratio of 5:3:1, except at large distances from the nucleus. This is explained by noting that fine structure transitions will lead to all of the S atoms reaching the $J = 2$ ground state in a time short compared with that for absorbing a solar photon, and that the emitted 1807 Å photons will be re-absorbed and can then branch into the other two lines. The detailed solution to this problem has led to the conclusion that H_2S was the primary source of sulfur rather than CS_2, whose other product, CS, was simultaneously observed in the UV [83.56]. Millimeter and sub-millimeter observations of comet Hale-Bopp (C/1995 O1) subsequently showed that SO, SO_2, and OCS were also minor sources of atomic sulfur, comparable in abundance to CS_2 [83.57]. Another minor source is S_2, initially observed in only one comet, IRAS-Araki-Alcock (C/1983 H1) [83.58], but recently seen in three additional comets by HST. The origin of S_2 in the cometary nucleus remains a puzzle.

83.4 Summary

This brief chapter can only hint at the wealth of observational data spanning the entire electromagnetic spectrum now routinely acquired at almost every comet apparition allowing for a statistically significant assessment of comet diversity and formation scenarios. Reference [83.59] will bring the interested reader up to date on all aspects of comet science. The next few years will see several spacecraft missions to comets, *Stardust*, *Deep Impact* and *Rosetta*, whose primary objective is the study of the cometary nucleus whose properties can only be inferred from remote observations. Nevertheless, Earth-based observations of comets will continue to play an important role in understanding the physical and chemical environments of these objects left over from the formation of the Solar System. There are still significant challenges in understanding the atomic and molecular physics of the cometary atmosphere, an example being the identification of the large number of unidentified lines seen in high resolution spectra in both the far UV [83.22, 23] and visible [83.60] regions of the spectrum.

Aeronomy

We describe here the neutral and ionic structures of atmospheres, including the processes that determine the atmospheric layers, the distribution of the species, and the temperature profiles. We focus on the upper atmosphere, which comprises the thermosphere and the ionosphere, two regions which overlay and interact with each other. We describe the interaction of near and extreme ultraviolet solar photons and energetic electrons with the atmosphere and their role in ionization and dissociation of atmospheric species. We also review the production and loss processes that are important in the formation of the different layers of the dayside and nightside ionospheres, including ion and neutral diffusion. The processes that determine the neutral, ion and electron temperatures are discussed. We review the processes that are important in production of the luminosity of the upper atmospheres, including dayglow, nightglow and auroras. Finally, we describe atmospheric escape processes, including thermal and non-thermal mechanisms.

84.1 Basic Structure of Atmospheres

84.1.1 Introduction

In a stationary atmosphere, the force of gravity is balanced by the plasma pressure gradient force in the vertical direction, and the variation of pressure $P(z)$ with altitude above the surface z is governed by the hydrostatic relation

$$\frac{\mathrm{d}P(z)}{\mathrm{d}z} = -\rho(z)g(z) , \qquad (84.1)$$

where $\rho(z) = n(z)m(z)$ is the mass density, $n(z)$ is the number density, and $m(z)$ is the average mass of the atmospheric constituents. In general, variables such as P, ρ, g, n and even m are functions of altitude, although it will often not be shown explicitly in the equations that follow for the sake of compactness. The acceleration of gravity g is usually taken to be the vector sum of the gravitational attraction per unit mass and the centrifugal acceleration due to the rotation of the planet:

$$g(r) = GM/r^2 - \omega^2 r \cos^2 \phi , \qquad (84.2)$$

where $r = r_0 + z$ is the distance from the center of the planet, r_0 is the planetary radius, M is the planetary mass, $G = 6.670 \times 10^{-8} \, \mathrm{dyn\, cm^2\, g^{-2}}$ is the gravitational constant, ϕ is the latitude, and ω is the angular velocity of the planet.

When the hydrostatic relation (84.1) is combined with the ideal gas law in the form

$$P = nk_\mathrm{B}T , \qquad (84.3)$$

where k_B is Boltzmann's constant and T is the temperature, and integrated, the the barometric formula

$$P(z) = P_0 \exp \left(-\int_{z_0}^{z} \frac{1}{H(z')} \, \mathrm{d}z' \right) , \qquad (84.4)$$

for the pressure $P(z)$ above a reference level (denoted by the subscript 0) as a function of altitude results. The pressure scale height $H(z)$ is defined as

$$H(z) = \frac{k_B T}{mg} . \qquad (84.5)$$

In the lower and middle atmosphere, the mass m in (84.5) is the weighted average mass of the atmospheric constituents.

When the ideal gas law (84.3) is substituted into the barometric formula (84.4), the altitude distribution

$$n(z) = n_0 \frac{T_0}{T(z)} \exp \left(-\int_{z_0}^{z} \frac{1}{H(z')} dz' \right) , \qquad (84.6)$$

for the number density $n(z)$ above a reference altitude is obtained. Integration of (84.1) or (84.6) from z to infinity shows that the column density above that altitude is approximately $N(z) = n(z)H(z)$. Thus the scale height can be thought of as the effective thickness of the atmosphere.

In its lower and middle regions, the homosphere, the atmosphere is well-mixed by convection and/or turbulence. The upper boundary of this region is called

the homopause (or turbopause), and above this level, the major transport process is diffusion. The homopause is defined as the level at which the time constants for mixing and diffusion are equal, and usually occurs at $n(z) \sim 10^{11}$–10^{13} cm^{-3}, depending on the strength of vertical mixing for a given planet. Since molecular diffusion coefficients vary from one species to another, the exact altitude of the homopause is species-dependent, with smaller species having lower homopause altitudes. In the terrestrial atmosphere, the homopause is near 100 km at $n(z) \sim 10^{13}$ cm^{-3}. Below the homopause, the mixing ratios (or fractions by number) of the constituent gases, apart from those minor or trace species whose density profiles are determined by photochemistry or physical loss processes, are fairly constant with altitude.

Throughout the atmosphere, gravity exerts a force on each particle that is proportional to its mass. Below the homopause, however, the tendency of the species to separate out under the force of gravity is overpowered by large scale mixing processes, such as convection and turbulence. Above the homopause, each species is distributed according to its own scale height. Characteristics of the homopauses of the planets are presented in Table 84.1.

Table 84.1 Homopause characteristics of planets and satellites

Planet	Altitude (km)	K (cm^2/s)	T (K)	n_t (cm^{-3})	P (μbar)	Composition (Fraction by number)
Venus[b]	135	4(7)[a]	199	1.4(11)	4.7(-3)	CO_2(76), N_2(7.6), O(9.3), CO(6.7), N(0.16), C(0.01)

84.1.2 Atmospheric Regions

The division of atmospheres into regions is based on the temperature structure of the terrestrial atmosphere, which is shown in Fig. 84.1. In the troposphere of a planet, above the boundary layer, T decreases at close to the adiabatic lapse rate (Γ) for the constituent gases from the surface to the tropopause. For an atmosphere that is a mixture of ideal gases, $\Gamma = g/c_p$, where c_p is the specific heat of the gas mixture at constant pressure. The presence of a condensible constituent, such as water vapor in the terrestrial troposphere, and ammonia or methane in the atmospheres of the outer planets and satellites, decreases Γ because upward motion leads to cooling and condensation, which releases latent heat. On Earth, the dry adiabatic lapse rate is about 10 K/km and the moist adiabatic lapse rate is about $4-6$ K/km in the lower to middle troposphere. The average lapse rate is about 6.5 K/km, and the altitude of the tropopause varies from about 9 to 16 km from the poles to the equator. The composition of the lower atmosphere of the Earth is given in Table 84.2.

Above the terrestrial tropopause lies the stratosphere, a region of increasing T that is terminated at the stratopause, near 50 km. This increase in T is caused by absorption of solar near UV radiation by ozone in the Hartley bands and continuum ($200-310$ nm). In the terrestrial mesosphere, which lies above the stratosphere, T decreases again to an absolute minimum at the mesopause, where $t \approx 180$ K and $n(z) \approx 10^{14}$ cm^{-3}. Above the mesopause, in the thermosphere, T increases

Fig. 84.1 Vertical distribution of temperature in the terrestrial atmosphere. The altitudes of the tropopause, stratopause and mesopause are indicated. The thermospheric temperatures depend on solar activity and profiles are shown for four values of the $F_{10.7}$ index, from 75 (low solar activity) to 250 (high solar activity). The *solid* and *dashed curves* are for noon and midnight, respectively. After the MSIS model of *Hedin* [84.17]

rapidly to a constant value, the exospheric temperature, T_∞. The value of T_∞ in the terrestrial atmosphere depends on solar activity and is usually between about 700 and 1500 K. Fig. 84.1 also shows altitude profiles of the noon and midnight thermospheric temperature for four values of the $F_{10.7}$ index, (the 2800 MHz flux in units of 10^{-22} Wm^{-2}Hz^{-1} at 1 AU), which represent different levels of solar activity.

The exosphere is a nearly collisionless region of the thermosphere that is bounded from below by the exobase. A particle traveling upward at or above the exobase will, with high probability, escape from the gravitational field of the planet. The exobase on Earth is located at about $450-500$ km, depending upon solar activity. The surface P and T on Mars are about 6 mbar

and 230 K, respectively. Due to the effect of dust storms, the extent of the Martian troposphere is highly variable, with a lapse rate that is $2-3$ K/km compared with the adiabatic lapse rate of 4.5 K/km and a variable thickness of $20-50$ km [84.19]. The atmosphere of Mars, like many planetary atmospheres, does not have a stratosphere. A roughly isothermal mesosphere extends from the tropopause to the base of the thermosphere at about 90 km. The thermospheric T is sensitive to solar activity and, since Mars has a very eccentric orbit, to heliocentric distance; T_∞ varies from about 180 to 350 K.

Near the surface of Venus, $T \gtrsim 700$ K and $P \sim 95$ bar. T decreases with a mean lapse rate of 7.7 K/km, compared with the adiabatic lapse rate of 8.9 K/km, from the surface to about 50 km. The region from 50 to 60 km contains the major cloud layer, and the tropopause is usually considered to be at about 60 km. In the mesosphere, between about 60 and 85 km, T decreases slowly from about 250 K to 180 K, and is nearly constant from 85 km to the mesopause at 100 km. The daytime exospheric temperature is only weakly dependent on solar activity, varying from about 230 to 300 K from low to high solar activity. The slow retrograde rotation of the planet, which results in a period of darkness that lasts 58 days, leads to the relative isolation of the nightside thermosphere, where T is found to decrease above the mesopause to an exospheric $T \approx 100$ K. Because of this, the nightside Venus thermosphere has been called the "cryosphere". The compositions of the lower atmospheres of Mars and Venus are given in Table 84.3.

The giant planets, Jupiter, Saturn, Uranus and Neptune do not have solid surfaces, so their atmospheric regions are defined either in terms of pressure, altitude above the 1 bar level, or altitude above the cloud tops. The temperature structures of all but Uranus are influenced by internal heat sources that the terrestrial planets do not possess. The temperature structures near the tropopause can be determined from IR observations and radio occultation data, and at thermospheric altitudes from ultraviolet solar and stellar occultations performed by the Voyager spacecraft. In between these regions, there is a substantial gap in which only average temperatures can be inferred. Thus the location and temperature of the mesopauses are largely unknown.

Below 300 mbar on Jupiter, the lapse rate is close to adiabatic (1.9 K/km). T at 1 bar is about 165 K, and the tropopause occurs near 140 mbar, where $T \approx 110$ K. At 1 mbar, T again reaches $160-170$ K. Temperature inversions have been reported in the stratosphere, and are probably due to absorption of solar radiation by dust or aerosols. Temperatures derived from the Voyager UV

stellar and solar occultations show that T increases from about 200 K near 1 µbar to an exospheric value of about 1100 K [84.2].

For $P > 500$ mbar on Saturn, the lapse rate approaches the adiabatic value of 0.9 K/km, and the tropopause, near the 100 mbar level, is characterized by $T \approx 80$ K. Above the tropopause the temperature increases to about 140 K near a $P \approx 1$ mbar, and above that altitude there are no measurements of T up to a pressure of about 10^{-8} bar, about 1000 km above the 1 bar level, where T is again about 140 K. Application of the hydrostatic equation to the altitude range $300-1000$ km yields an average temperature near 140 K for the region. Above 1000 km, T increases to a $T_\infty \approx 800$ K [84.2]. The mixing ratios of the species in the lower atmospheres of Jupiter and Saturn are given in Table 84.4.

The tropopauses on both Uranus and Neptune occur near 100 mbar, where $T \approx 50$ K. The lapse rates in the troposphere are 0.7 and 0.85 K/km for Uranus and Neptune, respectively. The temperatures in the Uranus thermosphere range from 500 K near 10^{-7} bar (about 1000 km above the 1 bar level) to an exospheric value of about 800 K. At 300 km on Neptune, T attains a nearly constant value in the range 150 to 180 K. At 600 km where $P \approx 1$ µbar, T increases again to a value that is

analysis of the Voyager 1 solar occultation experiment showed that, above the tropopause, the temperature increases to a peak value of about 176 K at an altitude of about 300 km. The temperature then decreases to a T_∞ of 153–158 K [84.9]

Triton is a satellite of Neptune. It also has an N_2 atmosphere with small amounts of methane, CO, H_2, and other species. The mixing ratios at 10 km are given in Table 84.7. The surface P is about 14–19 μbar. Methane in the troposphere is in equilibrium with a surface methane frost at about 38–50 K. The tropopause temperature is about 36 K, and occurs in the 8 to 12 km region. The middle atmosphere is isothermal with a temperture of about 52 K from 25 to 50 km, increasing to 78 K near 150 km [84.30]. T rises to an T_∞ of about 100 K.

Io and Europa are satellites of Jupiter. Both have transient atmospheres, with mean lifetimes of 2–3 days. The radius of Io is about 1821 km, and its atmosphere is

mostly SO$_2$, which is produced by volcanic plumes. One model predicts that the average column density of SO$_2$ is about 10^{16} cm^{-3}, and is larger at the equator than at the poles [84.31]. The atmospheric temperatures range from 100 to 2000 K, and the exospheric temperature is about 1800 K. The altitude of the exobase is about 1400 km. A plot of the number density and temperature as a function of altitude is shown in Figure 80−9 k. Europa is characterized by a radius of 1596 km. The atmosphere is mostly O$_2$ with column density of 5×10^{14} cm^{-2} and a scale height of 145 km. The O$_2$ is produced by sputtering of the ice-covered surface, and is removed in sputtering by torus thermal ions [84.32]. The ionosphere is produced by impact of electrons in Jupiter's magnetosphere, and the maximum density of electrons is about 4×10^4 cm^{-3} [84.33].

Mercury does not have a troposphere, mesosphere, or stratosphere; The pressure at the surface is on the order of a picobar; thus the surface of the planet is the exobase. Nevertheless, several atomic species have been identified in fluorescence. They are listed in Table 84.8. Among the possible sources of atmospheric species are evaporation, ion sputtering, meteoroid bombardment, and photon-stimulated desorption. Ions produced by photoionization of neutrals may be picked up by the solar wind and lost from the atmosphere.

Pluto and its satellite Charon form what is sometimes referred to as a double planet system. The radius of

Table 84.8 Number densities of species at the surface of Mercury[a]

[b] Variable spatially and temporally

Pluto is 1150−1200 km, and that of Charon is about 600 km. The atmosphere of Pluto is mostly N$_2$, with small amounts of methane, CO, H$_2$, and H. Only upper limits are available for the mixing ratio of CO. The surface pressure and temperature are in the ranges 1 to 10 μbar and 35 to 57 K, respectively. Although the pressure at the surface is approximately the same as that of the base of the thermosphere on most planets, the thermal structure of the atmosphere is influenced by the large thermal escape flux at the top of the atmosphere and by adiabatic cooling. T maximizes near 1200−1260 km radius at about 100 K due to absorption of solar UV radiation. Above that radius, T decreases asymptotically to a value of about 80 K [84.35, 36].

84.2 Density Distributions of Neutral Species

84.2.1 The Continuity Equation

The density distribution of a minor neutral species j in an atmosphere is determined by the continuity equation:

$$\frac{\partial n_j}{\partial t} + \nabla \cdot \boldsymbol{\Phi}_j = P_j - L_j \,, \tag{84.7}$$

where $\boldsymbol{\Phi}_j$ is the flux of species j, and P_j and L_j are the chemical production and loss rates, respectively. If only the vertical direction is considered, the divergence of the flux becomes $\partial \Phi_j / \partial z$, and $\Phi_j = n_j w_j$, where w_j is the vertical velocity of the species and n_j is its number density. In one-dimensional models, transport due to turbulence and other macroscopic motions of air masses is often parametrized like molecular diffusion, using an eddy diffusion coefficient K in place of the molecular diffusion coefficient D_j. The total transport velocity w_j is then the sum of the diffusion velocity w_j^{D}

and the eddy diffusion velocity w_j^{K}:

$$w_j = w_j^{\mathrm{D}} + w_j^{\mathrm{K}} \,. \tag{84.8}$$

If there are no net flows of major constituents, w_j^{D} and w_j^{K} satisfy the equations

$$w_j^{\mathrm{D}} = -D_j \left(\frac{1}{n_j} \frac{\mathrm{d}n_j}{\mathrm{d}z} + \frac{1}{H_j} + \frac{(1+\alpha_j^T)}{T} \frac{\mathrm{d}T}{\mathrm{d}z} \right) \,, \tag{84.9}$$

$$w_j^{\mathrm{K}} = -K \left(\frac{1}{n_j} \frac{\mathrm{d}n_j}{\mathrm{d}z} + \frac{1}{H_{\mathrm{avg}}} + \frac{1}{T} \frac{\mathrm{d}T}{\mathrm{d}z} \right) \,. \tag{84.10}$$

In these expressions, α_j^{T} is the thermal diffusion factor (the ratio of the thermal diffusion coefficient to the molecular diffusion coefficient), and the pressure scale height H_{avg} for a mixed atmosphere is given by (84.5) with $m = m_{\mathrm{avg}}$, the average molecular mass.

For a stationary atmosphere, if molecular diffusion greatly exceeds eddy diffusion and if photochemistry can be neglected, then $w_j^D = 0$. The resulting number density distribution is called diffusive equilibrium, and is given by

$$n_j(z) = n_j(z_0) \left(\frac{T_0}{T}\right)^{\left(1+\alpha_j^T\right)} \exp\left(-\int_{z_0}^{z} \frac{dz'}{H_i}\right) .$$

(84.11)

When mixing processes dominate and $w_j^K = 0$, the distribution is given by (84.6), with $H = H_{avg}$.

84.2.2 Diffusion Coefficients

In the thermosphere of a planet, above the homopause, the major transport mechanism is diffusion, or transport by random molecular motions. The characteristic time τ_D for molecular diffusion is approximately H_j^2/D_j. The diffusion coefficient for a species j in a multicomponent mixture is usually taken as a weighted mean of binary diffusion coefficients D_{jk}

$$\frac{1}{D_j} = \sum_{k \neq j} \frac{f_k}{D_{jk}} ,$$

(84.12)

where f_k is the mixing ratio of species k. The binary diffusion coefficient can be expressed as

$$D_{jk} = \frac{3k_B T}{16 n_t \mu_{jk} \Omega_{jk}} ,$$

(84.13)

where μ_{jk} is the reduced mass

$$\mu_{jk} = \frac{m_j m_k}{m_j + m_k}$$

(84.14)

and $n_t = n_j + n_k$ is the total number density. The collision integral Ω_{jk} is given by

$$\Omega_{jk} = \frac{1}{2\pi^{1/2}} \left(\frac{\mu}{2k_B T}\right)^{5/2}$$
$$\times \int_0^\infty Q^D(v) v^5 \exp\left(-\mu v^2/2k_B T\right) dv$$

(84.15)

where v is the relative velocity of the particles, $Q^D(v)$ is the diffusion or momentum transfer cross section

$$Q^D(v) = 2\pi \int_0^\pi \sigma_{jk}^{el}(\theta, v)(1 - \cos\theta) \sin\theta \, d\theta ,$$

(84.16)

and $\sigma_{jk}^{el}(\theta, v)$ is the differential cross section for elastic scattering of species j and k through angle θ. In practice, D_{jk} is often expressed as b_{jk}/n_t where n_t is the total number density and b_{jk} is the binary collision parameter, which is usually given in tabulations in the semi-empirical form $b = A T^s$. Here A and s ($0.5 \leq s \leq 1.0$) are parameters that are fit to the data. The binary collision parameter appears, for example, in the expression for the diffusion limited flux of a light species to the exobase of a planet (Sect. 84.7).

84.3 Interaction of Solar Radiation with the Atmosphere

84.3.1 Introduction

The source for all atmospheric processes is ultimately the interaction of solar radiation, either photons or particles, with atmospheric gases. Since visible photons arise from the photosphere of the sun, which is characterized by $T \approx 6000$ K, the solar spectrum in the visible and IR is similar to that of a black body at 6000 K. At longer (radio) and shorter (UV and X-ray) wavelengths, the photons arise from parts of the chromosphere and corona where the temperatures are higher (10^4 to 10^6 K). Thus the photon fluxes differ substantially from those which would be predicted for a 6000 K black body. Photons in the extreme and far UV regions of the spectrum are absorbed in the terrestrial thermosphere and X-rays in

the lower thermosphere and mesosphere. The solar Lyman α line at 1216 Å penetrates through a window in the O_2 absorption cross sections to about 75 km. Near UV photons are absorbed by ozone in the stratosphere, and visible radiation is not appreciably attenuated by the atmosphere.

The wavelength ranges that are most important for aeronomy are the UV and X-ray regions. A solar spectrum in the UV and soft X-ray regions at low solar activity is presented in Fig. 84.2a, and the ratio of a high solar activity photon fluxes to those at low solar activity is shown in Fig. 84.2b. The ratio is near unity at wavelengths longward of 2000 Å, but increases to factors that range between 2 and 3 over much of the extreme UV. At wavelengths between about 100 and

550 Å, the ratio of high to low solar activity fluxes reaches values as high as 100. The fluxes at X-ray wavelengths arise principally from solar flares and can increase by orders of magnitude from low to high solar activity.

The sun also emits a stream of charged particles, the solar wind, which flows radially outward in all directions, and consists mostly of protons, electrons, and alpha particles. The average number density of solar wind protons is about $5\,\text{cm}^{-3}$, and the average speed is about $400-450\,\text{km/s}$ at Earth orbit (1 AU). The interaction of these particles with the magnetic field (either induced or intrinsic) of a planet, and ultimately with the atmosphere, is the source of auroral activity. Terrestrial auroras arise mostly from precipitation of electrons with energies in the kilovolt range, although measured spectra vary widely. An example of a pri-

mary electron auroral spectrum is shown in Fig. 84.3. Terrestrial auroral emissions maximize in the midnight sector, but dayside cusp auroras are produced by lower energy electrons, and diffuse proton auroras are also observed.

Since charged particles are constrained to move along magnetic field lines, for planets with intrinsic magnetic fields, auroras usually occur in an oval near the magnetic poles, where the dipole field lines enter the atmosphere. For Venus, which has no intrinsic magnetic field, auroras are seen as diffuse and variable emissions on the nightside of the planet. On Earth, low latitude auroras, which arise from heavy particle precipitation, have also been observed. The primary particles that are responsible for Jovian aurora may be heavy ions originating from its satellite Io, protons, or electrons. Due to charge transfer, heavy particles spend part of their lifetime as neutral species, and their paths may then diverge from magnetic field lines. In any case, a large fraction of the effects of auroral precipitation is due to secondary electrons, regardless of the identity of the primary particles. In addition to producing emissions of atmospheric species in the visible, UV and IR portions of the spectrum, auroral particles ionize and dissociate atmospheric species and contribute to heating the neutrals, ions and electrons.

84.3.2 The Interaction of Solar Photons with Atmospheric Gases

The number flux of solar photons in a small wavelength interval around λ at an altitude z can, for the most part, be computed from the Beer–Lambert absorption law

$$F_\lambda(z) = F_\lambda^\infty \exp[-\tau(\lambda, z)] , \qquad (84.17)$$

where F_λ^∞ is the solar photon flux outside the atmosphere, and $\tau(\lambda, z)$ is the optical depth which, in the plane parallel approximation, is given by

$$\tau(\lambda, z) = \sum_j \int_z^\infty n_j(z')\sigma_j^a(\lambda) \sec \chi \, dz' . \qquad (84.18)$$

Here, $\sigma_j^a(\lambda)$ is the absorption cross section of species j at wavelength λ, and the solar zenith angle χ is the angle of the sun with respect to the local vertical.

For χ greater than about $75°$, the variation of the solar zenith angle along the path of the radiation cannot be neglected; the optical depth must be computed by numerical integration along this path in spherical geometry. For $\chi \le 90°$ the optical depth is

$$\tau(\lambda, z) = \sum_j \int_z^\infty n_j(z')\sigma_j^a(\lambda)$$
$$\times \left[1 - \left(\frac{r_o + z}{r_o + z'} \right)^2 \sin^2 \chi \right]^{-0.5} dz' .$$
$$(84.19)$$

For χ larger than $90°$, the optical depth is given by

$$\tau(\lambda, z) = \sum_j \left\{ 2 \int_{z_s}^\infty n_j(z')\sigma_j^a(\lambda) \right.$$
$$\times \left[1 - \left(\frac{r_o + z_s}{r_o + z'} \right)^2 \sin^2 90° \right]^{-0.5} dz'$$
$$- \int_z^\infty n_j(z')\sigma_j^a(\lambda)$$
$$\left. \times \left[1 - \left(\frac{r_o + z}{r_o + z'} \right)^2 \sin^2 \chi \right]^{-0.5} dz' \right\} ,$$
$$(84.20)$$

where z_s is the tangent altitude, the point at which the solar zenith angle is $90°$ for the path of solar radiation through the atmosphere.

In a one-species atmosphere, the rate of absorption of solar photons of wavelength λ is

$$q^a(\lambda) = F_\lambda \sigma^a(\lambda) n . \qquad (84.21)$$

For an isothermal atmosphere in which $H(z) \approx$ const., the absorption maximizes where $\tau(\lambda, z) = 1$. This is a fairly good approximation even for regions of the atmosphere where the $H(z)$ is not constant. The altitude of unit optical depth is shown for wavelengths from X-rays to the near UV for overhead sun in the terrestrial atmosphere in Fig. 84.4a. Similar plots for Venus, Mars and Jupiter are shown in Fig. 84.4b, Fig. 84.4c, and Fig. 84.4d, respectively. N_2 does not absorb longward of about $100\,nm$, so in the terrestrial atmosphere, O_2 and O_3 are the primary absorbers between 100 and $220\,nm$, while ozone dominates the absorption for wavelengths in the range 220–$320\,nm$. On Venus and Mars, CO_2 is the main absorber of FUV and EUV radiation, although at wavelengths less than about $100\,nm$, N_2, CO, and O also contribute. On Titan, methane is the primary absorber of UV radiation between $1400\,\text{Å}$ and the absorption threshold of N_2, near $1000\,\text{Å}$.

The interaction of UV photons with atmospheric gases produces ions and photoelectrons through photoionization, which may be represented as

$$X + h\nu \rightarrow X^+ + e^- , \qquad (84.22)$$

and photodissociative ionization

$$AB + h\nu \rightarrow A^+ + B + e^- . \qquad (84.23)$$
In these equations, X represents any atmospheric species; A is either an atom or a molecular fragment and AB a molecule. The energy of the photoelectron in reaction (84.22) is given by

$$E_{pe} = h\nu - I_X - E_{ex} \qquad (84.24)$$

and in reaction (84.23) is

$$E_{pe} = h\nu - E_d - I_A - E_{ex} , \qquad (84.25)$$

where I_j is the ionization potential of species j, E_d is the dissociation energy of molecule AB, and E_{ex} is the internal excitation energy of the products. Neutral fragments, which may be reactive radicals, are also produced in photodissociation

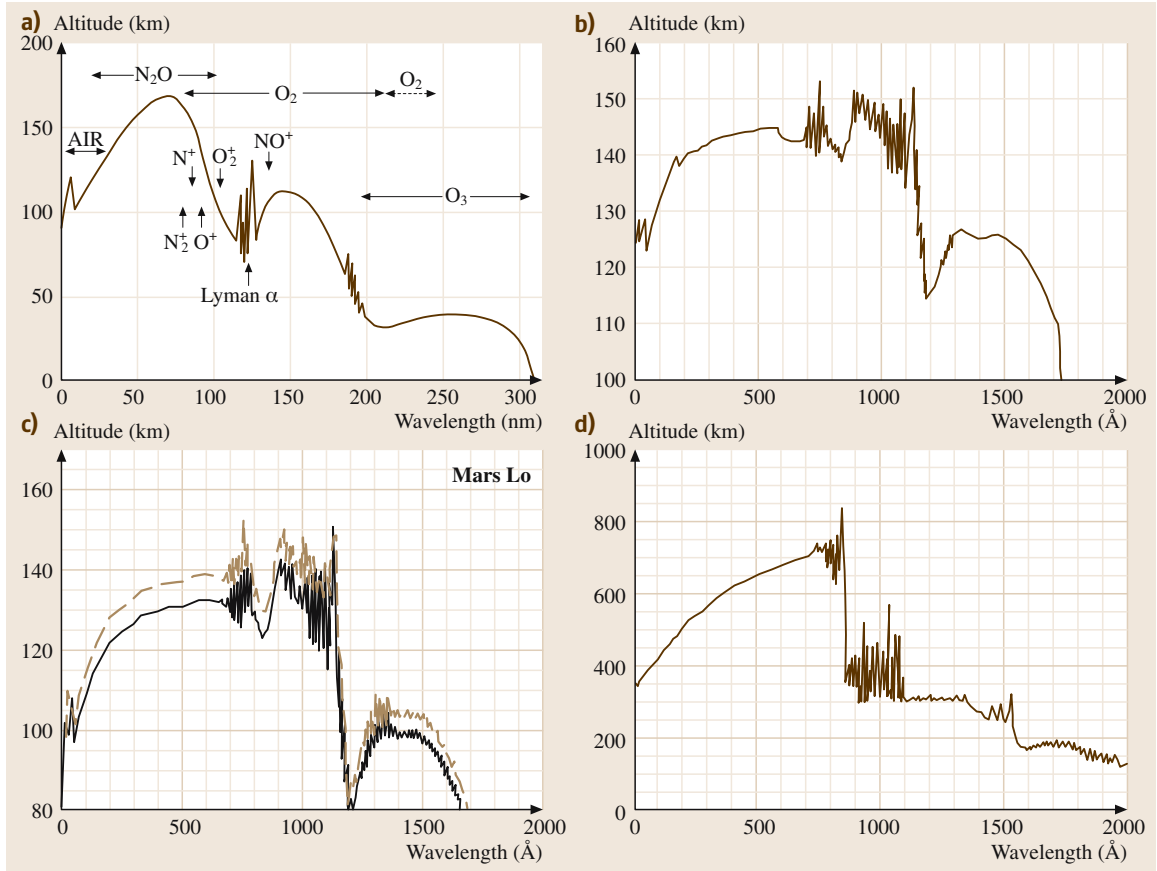
$$AB + h\nu \rightarrow A + B . \qquad (84.26)$$


Fig. 84.4a–d The altitude where $\tau = 1$ versus wavelength (**a**) Earth [84.39] (**b**) Venus (**c**) Mars [84.40] (**d**) Jupiter (Y. H. Kim, unpublished)

The rate of ionization of a species j by a photon of wavelength λ at an altitude z is given by

$$q_j^i(\lambda, z) = F_\lambda(z)\sigma_j^i(\lambda)n_j(z) , \qquad (84.27)$$

where $\sigma_j^i(\lambda)$ is the photoionization cross section. The rate for photodissociation is given by a similar expression, with the photoionization cross section replaced by the photodissociation cross section. The expression above must be integrated over the solar spectrum to give the total rate. In addition, it is often necessary to take into account ionization and/or dissociation to different final internal states of the products, so the partial cross sections or yields are needed.

In the atmospheres of magnetic planets, photoelectrons may travel upward along the magnetic field lines to the conjugate point, where the field line re-enters the atmosphere. In order to model this effect, the differential (with respect to angle) cross sections for photoionization

$\sigma_j^i(\lambda, \theta)$ are necessary. The differential cross section is sometimes expressed as

$$\sigma_j^i(\lambda, \theta) = \frac{\sigma_j^i(\lambda)}{4\pi}[1 - \frac{1}{2}\beta(\lambda)P_2(\cos\theta)] , \qquad (84.28)$$

where θ is the angle between the incident photon beam and the ejected electron, P_2 is a Legendre polynomial, and β is an asymmetry parameter.

84.3.3 Interaction of Energetic Electrons with Atmospheric Gases

Suprathermal electrons, which are denoted here e^{*-}, and include both photoelectrons and auroral primary electrons, can also ionize species through electron-impact ionization

$$X + e^{*-} \rightarrow X^+ + e^- + e'^- \qquad (84.29)$$
and electron-impact dissociative ionization

$$AB + e^{*-} \rightarrow A^+ + B + e^- + e'^- . \qquad (84.30)$$
In these reactions, e^- represents the energy degraded photoelectron or primary electron, and e'^- the secondary electron. The energy of the secondary electron $E_{e'}$ in an electron-impact ionization process (84.29) is given by

$$E_{e'} = E_{e*} - I_X - E_{ex} - E_e , \qquad (84.31)$$

where E_{e*} is the energy of the primary or photoelectron, E_e is the energy of the degraded primary or photoelectron, and E_{ex} is the internal excitation energy of the product ions and/or neutral fragments. For the dissociative ionization process (84.30) the dissociation energy of the molecule must also be subtracted as well.

Energetic electrons can also dissociate atmospheric species. In this process

$$AB + e^{*-} \rightarrow A + B + e^- \qquad (84.32)$$

the energy of the degraded electron is

$$E_e = E_{e*} - D_{AB} - E_{ex} , \qquad (84.33)$$

where D_{AB} is the dissociation energy of molecule AB. Collisions with suprathermal electrons can also promote species to excited electronic, vibrational or rotational states:

$$AB + e^{*-} \rightarrow AB^{\dagger} + e^- , \qquad (84.34)$$

where the dagger denotes internal excitation. The energy lost by the electron is thus the excitation energy of the species.

In determining the rate of ionization, dissociation and excitation by photoelectrons, the local energy loss approximation, that is, the assumption that the electrons lose their energy at the same altitude where they are produced, is fairly good near the altitude of peak photoelectron production. The mean free path of an electron near 150 km is about 30 m. Substantially above the altitude of peak production of photoelectrons, transport of electrons from below is important, and use of the local energy loss assumption causes the excitation, ionization, and dissociation rates to be underestimated. For keV auroral electrons, the computation of the energy deposition of the electrons must consider their transport through the atmosphere. Thus the elastic total and differential cross sections for electrons colliding with neutral species must be employed, as well as the inelastic cross sections, and the angles through which the electrons scatter must be taken into account.

In general, the excitation rate $q_j^k(z)$ of a species j to an excited level k with a threshold energy E_k at an altitude z by electron impact is given by:

$$q_j^k(z) = n_j(z) \int_{E_k}^{\infty} \sigma_j^k(E) \frac{dF(z, E)}{dE} dE , \qquad (84.35)$$

where $\sigma_j^k(E)$ is the excitation cross section at electron energy E, and $dF(z, E)/dE$ is the differential flux of electrons (between energies E and $E + dE$). The ionization rate $q_j^i(z)$ of a species with ionization potential I_j due to electron impact is given by

$$q_j^i(z)$$
$$= n_j(z) \int_{I_j}^{\infty} \int_{0}^{(E-I_j)/2} \frac{d\sigma_j^i(E)}{dW_s} \frac{dF(z, E)}{dE} dW_s dE ,$$
$$(84.36)$$

where $d\sigma_j^i(E)/dW_s$ is the differential cross section for production of a secondary electron with energy W_s by a primary electron with energy E. The integral over secondary energies W_s terminates at $(E - I_j)/2$ because the secondary electron is by convention considered to be the one with the smaller energy. Since the average energy of photoelectrons is less than 20 eV, the error incurred in cutting off the integrals in equations (84.35) and (84.36) at 200 eV or so, rather than $(E - I_j)/2$ is not serious, although for high energy auroral electrons a larger upper limit may be required.

An estimate of the number of ionizations in a gas produced by a primary electron with energy E_p is E_p/W_{ip}, where W_{ip} is the energy loss per ion pair produced, which approaches a constant value as the energy of the electron increases. Empirical values are available for W_{ip} for many gases, and usually fall in the range 30–40 eV [84.41].

The total loss function or stopping cross section for an electron with incident energy E in a gas j is given by the expression

$$L_j(E) = \sum_k \sigma_j^k(E) W_j^k$$
$$+ \int_{0}^{(E-I_j)/2} (I_j + W_s) \frac{d\sigma^{i_j}(E)}{dW_s} dW_s ,$$
$$(84.37)$$

where W_j^k is the energy loss associated with excitation of species j to excited state k. The differential cross

Part G | 84.3

section is usually adopted from an empirical formula that is normalized so that

$$\sigma_j^i(E) = \int_0^{(E-I_j)/2} \frac{d\sigma_j^i(E)}{dW_s} \, dW_s \, , \tag{84.38}$$

where $\sigma_j^i(E)$ is the total ionization cross section at primary electron energy E. One formula in common use is that employed by *Opal* et al. [84.42] to fit to their data:

$$\frac{d\sigma_j^i(E)}{dW_s} = \frac{A(E)}{1 + \left(W_s/\overline{W}\right)^{2.1}} \, , \tag{84.39}$$

where $A(E)$ is a normalization factor and $\overline{W}$ is an empirically determined constant, which has been found to be equal to within a factor of about 50% to the ionization potential for a number of species.

For energy loss due to elastic scattering by thermal electrons, an analytic form of the loss function such as that proposed by *Swartz* et al. [84.43] may be used:

$$L_e(E) = \frac{3.37 \times 10^{-12}}{E^{0.94} n_e^{0.03}} \left(\frac{E - k_B T_e}{E - 0.53 k_B T_e}\right)^{2.36} \, , \tag{84.40}$$

where T_e is the electron temperature and n_e is the number density of ambient thermal electrons.

For high energy auroral electrons, the rate of energy loss per electron per unit distance over the path s of the electrons in the atmosphere can be estimated using the continuous slowing down approximation (CSDA) as

$$-\frac{dE}{ds} = \sum_j n_j(z) L_j(E) \sec\theta + n_e(z) L_e(E) \sec\theta \, , \tag{84.41}$$

where θ is the angle between the path of the primary electron s and the local vertical. In the CSDA, all the electrons of a given energy are assumed to lose their energy continuously and at the same rate. The rate of energy loss $(-dE/ds)$ is integrated numerically over the path of the electron, which degrades in energy until it is thermalized. In this approximation, inelastic processes are assumed always to scatter the electrons forward, so cross sections that are differential in angle are not required. Because electrons actually lose energy at different rates, however, and because elastic and inelastic scattering processes do change the direction of the electrons, the CSDA gives an estimate for the rates of electron energy loss processes that is increasingly inaccurate as the energy of the electron decreases.

In practice, discrete energy loss of electrons can be easily treated numerically if the local energy loss

approximation is valid. The spectrum of electrons is divided into energy bins that are smaller than the energy losses for the processes, and the integrals in (84.35, 36) are replaced by sums over energy bins. Since elastic scattering of electrons by neutrals changes mostly the direction of the incident electron, and not its energy, only inelastic processes need be considered. In order to compute excitation and dissociation rates, only integral cross sections are required; the scattering angle is unimportant. For ionization, of course, the energy distribution of the secondary electrons must be considered, but not the scattering angles of either the primary or secondary electrons. Below the lowest thresholds for excitations, energetic electrons lose their energy in elastic collisions with thermal electrons. The process of energy loss to thermal electrons is often approximated as continuous, rather than discrete.

The collision frequency ν_j^k for a discrete electron-impact excitation process k of a species j is given by

$$\nu_j^k(E) = n_j(z) v_e(E) \sigma_j^k(E) \, . \tag{84.42}$$

For energy loss due to elastic scattering from thermal electrons, a pseudo-collision frequency ν_e may be defined as

$$\nu_e(E) = \frac{1}{\Delta E}\left(-\frac{dE}{dt}\right) \, , \tag{84.43}$$

where ΔE is the grid spacing in the calculation, and the energy loss rate is

$$-\frac{dE}{dt} = v_e(E) n_e L_e(E) \, , \tag{84.44}$$

where L_e is taken from (84.40).

Since the energy bins should be smaller than the typical energy loss in order to obtain accurate rates for the excitation processes, it is often convenient to treat rotational excitation also as a continuous process, with a pseudo-collision frequency similar to that for elastic scattering from ambient electrons (84.43) with

$$-\frac{dE}{dt} = v_e(E) n_j L_j^{rot}(E) \, , \tag{84.45}$$

where the loss function for rotational excitation is given by

$$L_j^{rot}(E) = \sum_J \eta_j^J \sum_{J'} \sigma_j^{J,J'}(E) W_j^{J,J'} \, . \tag{84.46}$$

In this expression, η_j^J is the fraction of molecules j measured or computed cross section for electron-impact excitation of species j from rotational state J to rotational state J', and $W_j^{J,J'}$ is the associated energy loss.

The slowing down of high energy auroral primary electrons or photoelectrons arises from both elastic and inelastic scattering processes, and cannot be treated using the local energy loss approximation. In solving the equations for electron transport, the angle through which the primary electron is scattered, as well as the change in energy of the primary electron and the production of any secondaries, must be taken into account. Thus differential cross sections for the elastic and inelastic scattering of electrons by neutral species are required. The detailed equations for electron transport have been presented by, for example, *Rees* [84.44].

Several methods for approximating the energy deposition of auroral electrons are currently in use. The CSDA has already been discussed, but it provides only a rough approximation to the depth of penetration of the electrons, and the rates of excitation, ion production, and other energy loss processes. In the two-stream approximation, the electrons are assumed to be scattered in either the forward or backward direction [84.45]. Implementation of this method requires only the backscattering probabilities, rather than complete differential cross sections. The method has been generalized to multi-stream models, in which the solid angle range of the electrons is divided into 20 or more intervals, so more or less complete differential cross sections are required [84.46,47]. Monte Carlo methods have also been used to model auroral precipitation [84.48].

84.4 Ionospheres

84.4.1 Ionospheric Regions

The division of the ionosphere into regions is based on the structure of the terrestrial ionosphere, which consists of overlapping layers of ions. These layers are the result of changes both in the composition of the thermosphere and in the sources of the ionization, and are shown schematically in Fig. 84.5. The major molecular ion layer is the F_1 layer, which is produced by absorption of EUV (100–1000 Å) photons by the major thermospheric species, and occurs where the ion production maximizes. The E layer is below the F_1 layer and is produced by shorter and longer wavelength photons that are absorbed deeper in the atmosphere: soft X-rays and Lyman β, which can ionize O_2 and NO (Fig. 84.4a). In the D region, the densities of negative ions ecome appreciable and large densities of positive cluster ions appear. These ions are produced by harder X-rays, with $\lambda \lesssim 10$ Å, and Lyman α, which penetrates to about 75 km, where it ionizes NO. The highest altitude peak in the terrestrial ionosphere is the F_2 peak, which occurs near or slightly below 300 km, where the major ion is O^+. The peak density occurs where the chemical lifetime of the ion is equal to the characteristic time for transport by diffusion ($\sim H^2/D$).

84.4.2 Sources of Ionization

As discussed in Sect. 84.3, ionization can be produced either by solar photons and photoelectrons during the daytime or by energetic particles and secondary electrons during auroral events. Photoelectrons have suf-
Fig. 84.5 Ionospheric regions and primary ionization sources. After *Bauer* [84.49]

ficient energy to carry out further ionization if they are produced by photons with $\lambda \lesssim 500$ Å. These photons penetrate further and exhibit larger solar activity variations than longer-wavelength ionizing photons. Thus

the ionization rate due to photoelectrons peaks below the main photoionization peak. Primary flux spectra of photoelectrons produced near the F_1 peak (172 km) and below the ion peak (100 km) are shown in Fig. 84.6. The primary spectrum at the ion peak consists mostly of low energy electrons, whereas at 100 km, the low energy primaries are depleted, and there are relatively larger fluxes of electrons with $E \gtrsim 50$ eV. Figure 84.7 shows the primary and steady-state photoelectron spectra near the ion peaks on Venus and Titan.

The major ions produced in the ionospheres of the earth and planets are usually those from the major thermospheric species: N_2^+, O_2^+, and O^+ on Earth; CO_2^+, O^+, N_2^+, and CO^+ on Venus and Mars; and H_2^+, H^+, and He^+ on the outer planets; N_2^+, N^+, and CH_4^+ in the ionosphere of Titan, and N_2^+, N^+, and C^+ in the ionosphere of Triton. In the presence of sufficient neutral densities, however, ion–molecule reactions transform ions whose parent neutrals have high ionization potentials to ions whose parent neutrals have low ionization potentials. This is a rigorous rule only for charge transfer reactions, but it applies more often than not in other ion–molecule reactions as well.

Because of transformations by ion–molecule reactions, the major ions in the F_1 regions of the ionospheres of Earth, Venus and Mars are O_2^+ and NO^+, in spite of the large differences in composition between the thermosphere of the earth and the thermospheres of Venus and Mars. A diagram illustrating the ion chemistry in the ionospheres of the terrestrial planets is shown in Fig. 84.8. The vertical positions of the ions in this figure represent the relative ionization potentials of the parent neutrals. In regions where there are sufficient neutral densities the ionization flows downward.

Table 84.9 shows ionization potentials (I_P) for several major and minor species present in planetary thermospheres. Major atmospheric species generally have $I_P \gtrsim 12-13$ eV ($\lambda < 900-1000$ Å). Only a few species can be ionized by the strong solar Lyman alpha line (1216 Å, 10.2 eV), including NO, and a few small hydrocarbons and radicals, such as CH_3 and C_2H_5. Metal atoms, which are produced in the lower thermospheres and mesospheres of planets from ablation of meteors, have very low ionization potentials, and some can be ionized by photons with wavelengths longer than 2000 Å.

Fig. 84.6 Primary photoelectron spectrum for the terrestrial atmosphere at 172 km (near the F_1 peak) and at 100 km. The spectrum at 100 km is significantly harder than that at 172 km

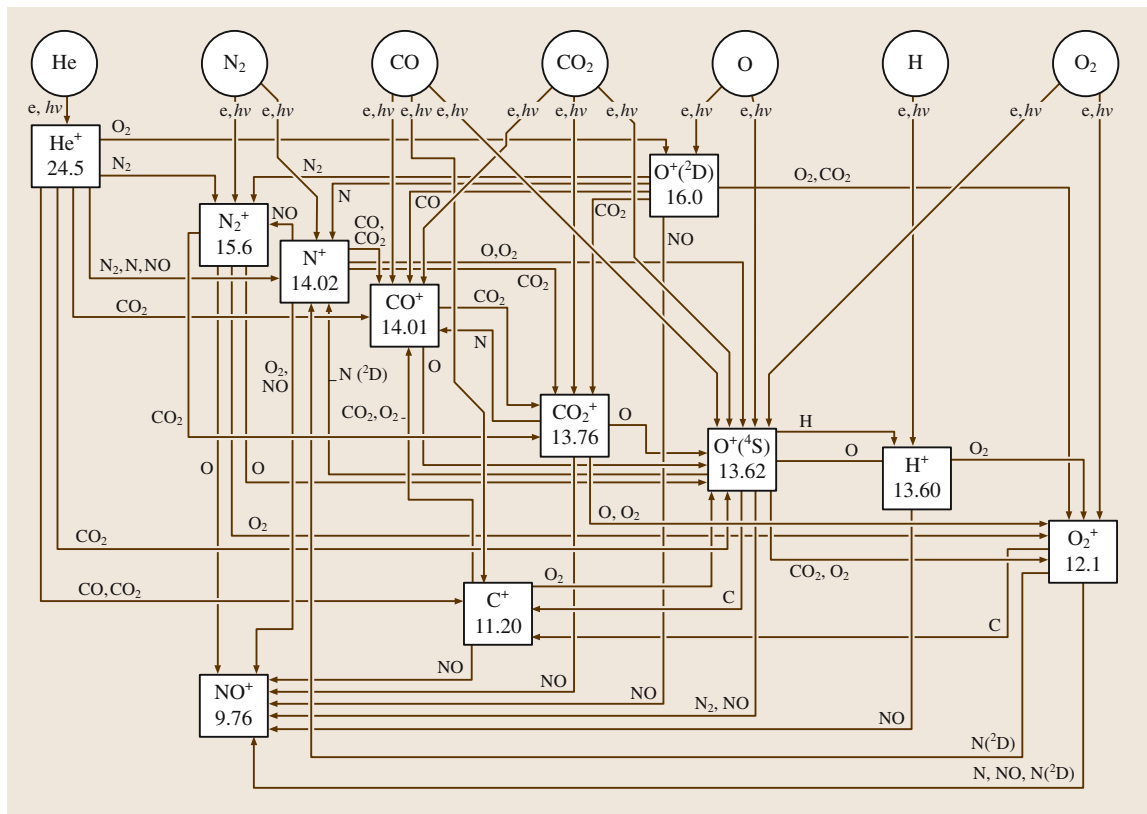
Fig. 84.7 Computed primary and steady-state spectra for photoelectrons near the F_1 peak on Venus at 1 eV resolution (*top*), and Titan at 0.5 eV resolution (*bottom*). The steady-state spectra are averaged over three intervals in both plots


Fig. 84.8 Diagram illustrating the ion chemistry in the ionospheres of the terrestrial planets. The numbers under the names of the ions indicate the ionization potentials of the parent neutral. In the presence of sufficient neutral densities, the ionization flows downward, the importance of dissociative recombination for the molecular ions increases as the ionization potentials of the parent neutrals decrease

Table 84.9 Ionization potentials (I_P) of common atmospheric species[a]

High I_P		Medium I_P		Ionized by Ly α	
Species	I_P (eV)	Species	I_P (eV)	Species	I_P (eV)
He	24.59	CH_4	12.61	C_4H_2	10.18
Ne	21.56	CH_4	12.51	CH_3	9.84

O	13.62	CH	10.64	trans-HCNH	7.0[b]
H	13.60	C_2H_4	10.51	cis-HCNH	6.8[b]
HCN	13.60	CH_2	10.40	Ca	6.11
OH	13.00	S	10.35	Na	5.14

[a] Computed with data taken from [84.50], except as noted;   [b] From [84.51]

In ionospheres where hydrogen is abundant and sufficient neutral densities are present, ionization flows to species formed by protonation of neutrals that have large proton affinities. There are no *in situ* measurements of the ion composition of the outer planets, but models predict that H_3^+ and hydrocarbon ions dominate the lower ionospheres. In regions where meteor ablation occurs, metal ions may also be found.

Many ion–molecule reactions proceed at or near gas kinetic (or collision) rates. The interaction of an ion with a nonpolar molecule is dominated by the ion-induced-dipole interaction, for which the interaction potential is $-\frac{1}{2}\alpha_d q^2/r^4$, where α_d is the polarizability of the neutral, q is the charge on the ion, and r is the distance between the particles. The Langevin rate coefficient is then given by

$$k_L = 2\pi q(\alpha_d/\mu)^{1/2} , \qquad (84.47)$$

where μ is the reduced mass of the two species. For a singly charged ion, with α_d in Å^3 and μ in atomic mass units, this formula reduces to $2.34 \times 10^{-9}(\alpha_d/\mu)^{1/2}$. The rate coefficient for an ion with a polar molecule is

$$k_d = \frac{2\pi q}{\mu^{1/2}}\left[\alpha_d^{1/2} + c\mu_d\left(\frac{2}{\pi k_B T}\right)^{1/2}\right] , \qquad (84.48)$$

where μ_d is the dipole moment and c is a constant that is unity in the locked dipole approximation and is about 0.1 in the average dipole orientation (ADO) theory. Theories for ion–quadrupole interactions have also been developed, and the resulting formulas can be found in, for example, the review by *Su* and *Bowers* [84.59]. Measured rate coefficients for ion–molecule reactions have been compiled by *Anicich* et al. [84.60] and *Ikezoe* et al. [84.61].

Loss of ionization in planetary atmospheres proceeds mainly by dissociative recombination of molecular ions, which may be represented by

$$AB^+ + e^- \rightarrow A + B . \qquad (84.49)$$

Dissociative recombination coefficients are characteristically large, about $10^{-7}\,\text{cm}^3/\text{s}$, at the electron temperatures T_e typical of planetary ionospheres, which are usually within a factor of two or so of the neutral $T \approx 200–2000\,\text{K}$ near the molecular ion density peak. Daytime peak electron densities are usually in the range $10^4–10^6\,\text{cm}^{-3}$, and fractional ionizations are small, about 10^{-5}, near the F_1 peak.

The relative importance of ion–molecule reactions and dissociative recombination in the destruction of a particular ion is determined by the relative densities of electrons and neutrals with which the ions can react. In general, molecular ions whose parent neutrals have high I_P are transformed by ion–molecule reactions preferentially to loss by dissociative recombination, and their peak densities occur higher in the atmosphere. Ions for which dissociative recombination is an important loss mechanism near the ion peaks of the terrestrial planets include NO^+ and O_2^+, and in the atmospheres of the outer planets, H_3^+ and hydrocarbon ions. For ions with very high I_P, such as N_2^+ and H_2^+, dissociative recombination is rarely important as a loss process, except at very high altitudes. It may, however, be important as a source of vibrationally or electronically excited fragments or hot atoms.

Atomic ions may be destroyed by radiative recombination:

$$X^+ + e^- \rightarrow X + h\nu , \qquad (84.50)$$
but the rate coefficients are small, about $10^{-12}\,\text{cm}^3/\text{s}$ at the typical T_e of planetary ionospheres [84.62]. Atomic ions may dominate at high altitudes, where neutral densities are low, but in such regions, loss by downward diffusion is more important than chemical recombination. The ions diffuse downward to altitudes where the neutral densities are higher and are then destroyed in ion–molecule reactions. The major ions in the topside ionospheres of the planets tend to be atomic ions: O^+ in the ionospheres of Earth and Venus, and H^+ in the iono-

Fig. 84.9a–k Model thermospheres for the Earth and planets. spheres of the outer planets. On Mars, however, the O^+ peak density does not exceed that of O_2^+ even at high altitudes.

Model thermospheres for Earth and selected planets and satellites are shown in Fig. 84.9a–k. Measured or computed ion density profiles for the Earth and selected planets and satellites are shown in Fig. 84.10a–h.

84.4.3 Nightside Ionospheres

Nightside ionospheres can result from several sources including remnant ionization from dayside, like O^+ in the terrestrial ionosphere. While the lower molecular ion layers recombine, the F_2 peak persists through the night, although it rises and the peak density is reduced by a factor of 10. Electron density profiles for day and night at high and low solar activities are shown in Fig. 84.11. In the auroral regions of the Earth, the precipitating electrons may also produce significant ionization, which maximizes in the midnight sector of the auroral oval.

The nightside ionosphere of Venus is highly variable, but has been shown to contain the same ions as the dayside ionosphere. The densities are, however, lower by factors of 10 or more than those of the dayside ionosphere, and the average peak in the electron density profile is about $(1 \text{ to } 2) \times 10^4 \text{ cm}^{-3}$. It is produced by a combination of precipitation of suprathermal electrons that have been observed at high altitudes in the umbra, and transport of atomic ions (mostly O^+) at high altitudes from the dayside. For Mars, only a narrow range of solar zenith angles near the terminator at low solar activity has been measured by the radio occultation experiments on the Viking spacecraft [84.63], the Mariner 9 spacecraft, and more recently by the Mars Global Surveyor (MGS) spacecraft radio sciences (RS) experiment [84.64]. The electron densities are apparently low, and no composition information is available. At this time, there is no information available about the nightside ionospheres of the other planets.

84.4.4 Ionospheric Density Profiles

Density profiles of molecular ions can often be approximated as idealized Chapman layers. A Chapman layer of ions is one in which the ions are produced by photoionization and lost locally by dissociative recombination. The ionization rate q^i in a one-species Chapman layer for monochromatic radiation is given by

$$q^i = F\sigma^i n ,\qquad (84.51)$$

where σ^i is the ionization cross section, and $F = F^\infty \exp[-\tau(z)]$ is the local solar flux. For an isothermal atmosphere, the scale height is approximately constant and therefore $n = n_0 \exp(-z/H)$. Sometimes an ionization efficiency η^i is defined such that

$$\sigma^i = \eta^i \sigma^a .\qquad (84.52)$$

Near threshold, the ionization efficiency for molecules is usually about 0.3–0.7 but it increases rapidly to 1.0 at shorter wavelengths.

Since the maximum ionization rate in an isothermal atmosphere occurs where the optical depth ($\tau = nH\sigma^a \sec \chi$) is unity and therefore $n = 1/(\sigma^a H \sec \chi)$, the maximum ionization rate in a Chapman layer is

$$q^i_{\max,\chi} = \frac{F^\infty}{e} \frac{\sigma^i}{\sigma^a H \sec \chi} = \frac{q^i_{\max,0}}{\sec \chi} .\qquad (84.53)$$

If the altitude of maximum ionization for overhead sun is defined as $z = 0$, then $n_0 = (\sigma^a H)^{-1}$, and, expressing F^∞ in terms of $q^i_{\max,0}$, the ionization rate is

$$q^i(z) = q^i_{\max,0} \exp\left(1 - \frac{z}{H} - \sec\chi\, e^{-z/H}\right) .\qquad (84.54)$$

It is apparent that at high altitudes ($z \to \infty$) the ionization profile follows that of the neutral density, and below the peak ($z \to -\infty$), the ionization rate rapidly approaches zero. As the solar zenith angle increases, the peak rises and the magnitude of the density maximum decreases. Figure 84.12 shows a production profile for an idealized Chapman layer on both linear and semilog plots. The asymmetry with respect to the maximum is more obvious for the semilog plot.

If photochemical equilibrium prevails, the production rate of the major ion is equal to the loss rate due to dissociative recombination

$$q^i(z) = \alpha_{dr} n_i n_e = \alpha_{dr} n_i^2 ,\qquad (84.55)$$

where α_{dr} is the dissociative recombination coefficient, n_i is the ion density, and n_e is the electron density. Therefore the density of an ion in a Chapman layer (in the photochemical equilibrium region) is given by

$$n_i(z) = \left(\frac{q^i(z)}{\alpha_{dr}}\right)^{1/2}$$
$$= \left(\frac{q^i_{\max,0}}{\alpha_{dr}}\right)^{1/2} \exp\left(\frac{1}{2} - \frac{z}{2H} - \frac{1}{2}\sec\chi\, e^{-z/H}\right) .\qquad (84.56)$$

Actual ionization profiles differ from the idealized Chapman profile for several reasons. First, ionization is

produced by photons over a range of wavelengths, which do not all reach unit optical depth at the same altitude. Second, thermospheres are often not isothermal near the altitude of peak ion production. Third, photoionization is supplemented by photoelectron-impact ionization, which peaks lower in the atmosphere; and finally, the major ion produced is often transformed by ion–molecule reactions before it can recombine dissociatively. Nonetheless, the idealized concept of the Chapman profile is useful in understanding the general shape of ion profiles and their behavior as the solar zenith angle changes. In addition, ion layers produced by auroral precipitation may take on a similar appearance to a Chapman-type layer, although energetic electrons are not always extinguished, as are photons, in ion production.

84.4.5 Ion Diffusion

Above the photochemical equilibrium layer of the ionosphere, upward and downward transport of ions must be considered. The motions of ions, neutrals, and electrons are coupled, and the momentum equation, which determines the fluxes or velocities of the ions must take into account these interactions. The interaction of an ion, denoted by a subscript i, with a neutral species de-
Fig. 84.12 Chapman production profile as a function of altitude on linear (*top*) and semilog (*bottom*) plots. The production rate is divided by the maximum production rate and the altitude by the scale height H, which is assumed to be constant. The origin on the altitude scale corresponds to the point of maximum absorption for overhead sun

noted by a subscript n, is through the ion-induced-dipole attraction or, for the diffusion of an ion through its parent neutral, by resonant charge transfer. For the former process, the ion–neutral diffusion coefficient is given by

$$D_{in} = \frac{k_B T}{m_i \overline{\nu}_{in}} , \qquad (84.57)$$

where m_i is the mass of the ion, and the ion–neutral momentum transfer collision frequency

$$\overline{\nu}_{in} = 2.21\pi \frac{n_n m_n}{m_{i+m_n}} \left(\frac{\alpha_n e^2}{\mu_{in}} \right)^{1/2} , \qquad (84.58)$$

where α_n is the polarizability of the neutral species (*Dalgarno* et al. [84.70]; *Schunk* and *Nagy* [84.71]). For the resonant charge transfer interaction, the diffusion

coefficient is

$$D_{in}^{ct} = \frac{3(\pi/2)^{1/2}}{8 n_n \overline{Q_{in}^{ct}}} \left(\frac{k_B T_i}{m_i} \right)^{1/2} \frac{1}{(1 + T_n/T_i)^{1/2}} , \qquad (84.59)$$

where $\overline{Q_{in}^{ct}}$ is the average charge transfer cross section [84.72].

The momentum transfer collision frequency for Coulomb interactions between an ion i and another ion or electron denoted by the subscript s is

$$\overline{\nu}_{is} = \frac{16\pi^{1/2}}{3} \frac{n_s m_s}{m_i + m_s} \left(\frac{\mu_{is}}{2 k_B T_{is}} \right)^{3/2} \frac{e_i^2 e_s^2}{\mu_{is}^2} \ln \Lambda , \qquad (84.60)$$

where e_s is the charge on species s, $\ln \Lambda$ is related to the Debye shielding length, and $T_{is} = (m_s T_i + m_i T_s)/(m_i + m_s)$ is a reduced temperature. Numerically, $\ln \Lambda$ is about 15, and the collision frequency is approximately [84.71]

$$\overline{\nu}_{is} = 1.27 \frac{Z_i^2 Z_s^2 \mu_{is}^{1/2} n_s}{m_i T_{is}^{3/2}} \; s^{-1} , \qquad (84.61)$$

where Z is the species charge number, μ and m are in amu, and the number density is in units of cm^{-3}.

The ion densities can be computed by solving the ion continuity equation, which is similar to (84.7) for neutral species, and in one dimension is

$$\frac{\partial n_i}{\partial t} + \frac{\partial \Phi_i}{\partial z} = P_i - L_i , \qquad (84.62)$$

where the ion flux is given by $\Phi_i = n_i w_i$. In general it is impossible to solve the momentum equation for the ion diffusion velocity w_i in closed form, except for the special cases of a single major ion and of a minor ion moving through a dominant ion species. If motion of the ions only parallel to magnetic field lines is considered, the vertical velocity of a dominant ion (for which $n_i \approx n_e$) moving through a stationary neutral atmosphere is

$$w_i = -D_a \sin^2 I$$
$$\times \left(\frac{1}{n_i} \frac{dn_i}{dz} + \frac{m_i g}{k(T_e + T_i)} + \frac{1}{T_e + T_i} \frac{d(T_e + T_i)}{dz} \right) , \qquad (84.63)$$

where I is the magnetic dip angle and the ambipolar diffusion coefficient defined as

$$D_a = \frac{k_B (T_e + T_i)}{m_i \overline{\nu}_{in}} . \qquad (84.64)$$

For a minor ion i diffusing through a major ion species j, its velocity is given by

$$w_i = -\frac{k_B T_i / m_i}{\overline{\nu}_{ij} + \overline{\nu}_{in}} \left(\frac{1}{n_i} \frac{dn_i}{ds} + \frac{T_e/T_i}{n_e} \frac{dn_e}{ds} + \frac{m_i g}{k_B T_i} + \frac{1}{T_i} \frac{d(T_e + T_i)}{ds} \right) - \frac{\overline{\nu}_{ij} w_j}{\overline{\nu}_{ij} + \overline{\nu}_{in}} . \quad (84.65)$$

For regions in which there are large gradients in the ion or electron temperatures, thermal diffusion may also be important in determining the ion density profiles, especially those of light ions such as H^+ and He^+. Equations for ion distributions in which thermal diffusion is included have been presented by, for example, *Schunk* and *Nagy* [84.71] and references therein.

84.5 Neutral, Ion and Electron Temperatures

The temperature distribution in planetary thermospheres/ionospheres can be modeled by solving the equation for conservation of energy, which, in simplified form in the vertical direction is

$$n_m \frac{\mathcal{N}}{2} k_B \frac{\partial T_m}{\partial t} - \frac{\partial}{\partial z} \left(\kappa_m \frac{\partial T_m}{\partial z} \right) = Q_m - L_m \quad (84.66)$$

where $\mathcal{N}$ is the number of degrees of freedom (3 for an atom, and 5 for a diatomic molecule), the subscript m refers to the neutrals, ions or electrons, κ_m is the thermal conductivity, Q_m is the volume heating rate, and L_m is the volume cooling rate. If horizontal variations are considered, the model becomes multidimensional and advective terms must be added to the equations. The T_n are also affected by compression or expansion due to subsidence or upwelling, respectively. Viscous heating may be a factor where there are local regions of intense energy input, such as in auroral arcs. These terms are not shown in the energy equation above, but may be found in standard aeronomy texts, such as *Banks* and *Kockarts* [84.72] or *Rees* [84.44] and *Schunk* and *Nagy* [84.73]. For planets with intrinsic magnetic fields, the electrons and ions are constrained to move along magnetic field lines, and the second term on the left-hand side of (84.66) must be multiplied by a factor $\sin^2 I$.

The neutral thermospheres of planets are mostly heated by absorption of solar radiation in the 10 to 2000 Å range, although on planets with powerful auroras, electron precipitation may be an important source of heat. Absorption of EUV radiation $(100-1000\,\text{Å})$ largely results in ionization of the major thermospheric species, in which most of the excess energy is carried away by the photoelectron. The photoelectron, however, may produce further dissociation or excitation of neutral species along the path to thermalization, and these processes may result in neutral heating. Photons near and longward of ionization thresholds in the FUV may lose their energy in photodissociation, in which the excess energy of the photon appears as kinetic or internal energy of the fragments.

Chemical reactions that follow ionization or dissociation release much of the absorbed solar energy as heat. Although the partitioning of kinetic energy released between the product species can be determined easily by conservation of energy and momentum, the fraction of energy that appears as internal or kinetic energy must be determined by measurements or theoretical calculations. If vibrationally or electronically excited states are produced in these interactions, however, the energy may be radiated to space, thus producing cooling. This may occur promptly if the radiative lifetime is short, or subsequent to an energy transfer process from a long-lived metastable species to a species for which radiation to a lower state is allowed. If the metastable species is quenched, however, its energy can also appear as heat. Thus the energy partitioning in chemical reactions and in the interactions of photons and photoelectrons with atmospheric species is important in understanding the temperature structure of thermospheres.

A heating efficiency ϵ is often defined as the fraction of energy absorbed at a given altitude that appears locally as heat. The heating efficiencies are in the range 30–40% in the terrestrial lower thermosphere. Above 200 km, the heating efficiency decreases because the energy of the important metastable species $O(^1D)$ is lost as radiation rather than by quenching [84.74]. The heating efficiencies in the thermospheres of Venus and Mars are about 20% from 100 to 200 km [84.75, 76], and on Titan, they range from 20 to 30% from 800 to 2000 km. A column averaged heating efficiency for the Jovian thermosphere has been computed as 53% [84.77].

On Venus and Mars, CO_2 is the major absorber of far UV radiation, whereas on the Earth, O_2 plays that role. In the F_1 regions of the ionospheres of the terrestrial planets, dissociative recombination of molecular ions tends to be the major source of heating. Below the F_1 peak, photodissociation and neutral-neutral reactions, including quenching of metastable species, dominate. Since CH_4 is a very strong absorber, the major heating

mechanisms in the thermosphere of Titan are photodissociation and neutral-neutral reactions, both above and below the F_1 peak. The few data that exist suggest that electron-impact dissociation is unimportant as a source of neutral heating, although further measurements would certainly be of benefit.

Profiles of the heat sources in the terrestrial thermosphere and that of Mars are also shown in Fig. 84.13.

Important cooling processes in planetary thermospheres include downward transport of heat by molecular and eddy conduction and infrared cooling from rotational and vibrational excitation of IR active species such as NO, CO and CO_2. Excitation of the fine structure levels of atomic oxygen and subsequent emission at 63 and 147 μm also plays a role in cooling the neutral species in the thermospheres of the terrestrial planets. In the outer planets and their satellites, hydrocarbon molecules such as CH_4 and C_2H_2 are the primary thermospheric IR radiators. The global circulation may play a role in redistributing the heat that is deposited in the dayside or auroral thermosphere [84.78, 79].

In order to model heating rates, cross sections for processes in which solar photons or photoelectrons interact with neutral species, and rate coefficients and product yields for chemical reactions of ions and neutral atmospheric species are necessary. In addition, it is necessary to know, for example, how much of the energy released appears as internal energy of the products in chemical reactions and how much appears as kinetic energy of the products. Knowledge of energy transfer processes, including vibration–vibration (V–V) and translation–vibration (T–V) transfer between atmospheric species is also important. For example, a particularly important cooling process for the thermospheres of the terrestrial planets is excitation of the CO_2 15 μm bending mode in collisions with energetic O, and subsequent radiation [84.80]. The de-excitation rate is several percent of gas kinetic, which is anomalously large for a V–T process [84.81].

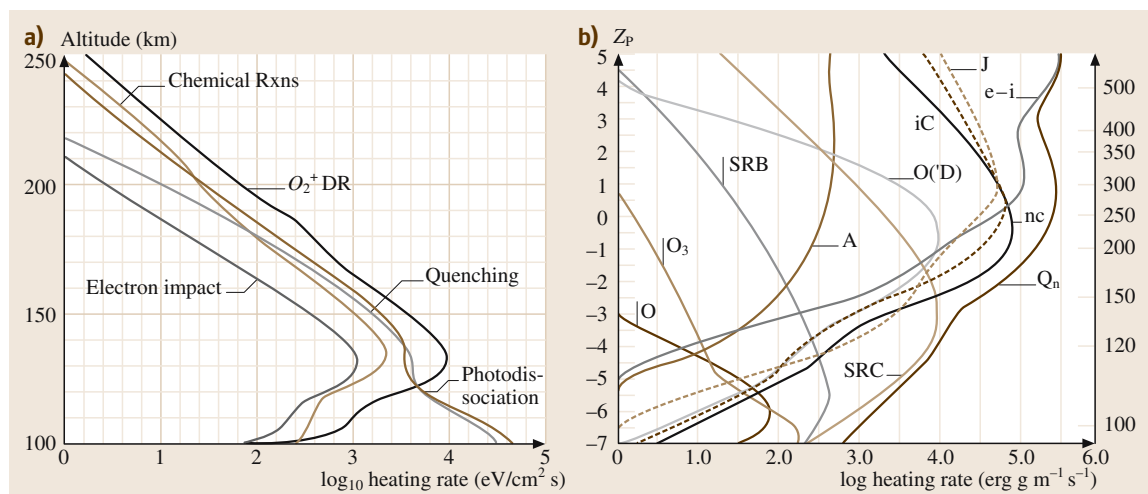
In the lower ionosphere, the electrons and ions are in thermal equilibrium with the neutral species, but at higher altitudes the plasma temperatures deviate from the neutral temperatures. Near the F_1 peak, T_e is usu-


Fig. 84.13a,b Heating rates for the thermospheres of (a) Mars and (b) Earth. In (b), the curve labeled Q_n is the total heating rate; e–i is the heating rate due to collisions between the neutrals and electron and ions, iC and nc are the heating rates due to exothermic ion–neutral and neutral–neutral chemical reactions, respectively; J is that due to Joule heating for a superimposed electric field of 3.6 mV m^{-1}; A is that from auroral particle precipitation; $O(^1D)$ is the heating due to quenching of $O(^1D)$; SRC and SRB are the heating rates due to absorption in the Schumann Runge continuum and bands, respectively; O is the heating from recombination of atomic oxygen; O_3 is the heating rate due to absorption of photons by O_3 in the Hartley bands. After [84.74]. In (a) the curve labeled "O_2^+ DR" is the heating rate due to dissociative recombination of O_2^+; that labeled "photodissociation" is heating due to the production of energetic neutrals in photodissociation; the curve labeled "quenching" is that due to quenching of metastable species, such as $O(^1D)$; and "chemical reactions" denotes heating due to exothermic chemical reactions other than quenching of metastable species. After [84.76]

ally larger than T_i, but T_i begin to diverge from T_e at slightly higher altitudes. The energy source for the electrons on the dayside is largely photoionization, which, as discussed above, produces electrons with average energies in the 15 to 20 eV range. In slowing down, these energetic electrons lose their energy in inelastic processes with neutrals until $E \approx 1-2$ eV. At this point, elastic scattering by the thermal electron population becomes the dominant energy loss process for the suprathermal electrons and the major source of heat for the thermal electrons. Other electron heating mechanisms include deactivation of electronically or vibrationally excited species, and, for the terrestrial planets, quenching of the fine structure levels of O.

As for the neutrals, heat in the electron gas is redistributed by conduction at a rate that depends on the electron thermal conductivity. This quantity is inversely proportional to the sum of the momentum transfer collision frequencies of electrons with ions, neutrals, and ambient electrons. Cooling mechanisms for thermal electrons include Coulomb collisions with ions, rotational excitation of molecules, and, for the terrestrial planets, excitation of the fine structure levels of O. Because of the large mass difference, elastic collisions between neutrals and electrons are not effective in transferring kinetic energy.

T_i in the ionosphere is elevated above T_n at high altitudes principally because of Coulomb collisions with energetic electrons. Another potentially important source of heat input to the ions near the ion peak is exothermic ion–neutral reactions, including quenching of metastable ions, such as $O^+(^2D)$, by neutrals. In the presence of electric fields, joule heating may be important and can cause T_i to exceed T_e.

The ions cool in elastic collisions and resonant charge transfer with neutral species, which are characterized by lower temperatures than the ions. The cooling rate for elastic collisions is

$$L_{in} = -2n_i \frac{m_i}{m_i + m_n} \overline{v}_{in} \frac{3}{2} k_B (T_i - T_n) . \qquad (84.67)$$

Collisions between ions and neutrals (other than their parents) are dominated by the ion-induced-dipole interaction. The momentum transfer collision frequency is thus given by (84.58). Resonant charge transfer between an ion and its parent neutral, such as

$$O^{+*} + O \rightarrow O^* + O^+ , \qquad (84.68)$$

leads to very effective ion cooling, which dominates at sufficiently high temperatures.

Examples of T_i and T_e profiles are shown in Fig. 84.14a–c for Earth, Venus and Titan. The International Reference Ionosphere (IRI) temperatures profiles
Fig. 84.14a–c Ion and electron temperature profiles. (**a**) Neutral (*dot-dashedcurve*), ion (*dashed curve*) and electron (*solid curve*) temperatures for the terrestrial ionosphere from the International Reference Ionosphere for equinox, noon and low and high solar activities. The electron temperature is found not to vary substantially with solar activity. After *Bilitza* and *Hoegy* [84.82] with kind permission from Elsevier Science Ltd., Kidlington UK. (**b**) Smoothed median ion (*dashed curve*) and electron (*solid curve*) temperatures in the Venus ionosphere as measured by the PV retarding potential analyzer and the Langmuir probe, respectively. The electron temperature profile is essentially constant with solar zenith angle. The ion temperature profile applies to solar zenith angles between 0 and 90°. After [84.83]. (**c**) Computed electron and ion temperatures for the ionosphere of Titan, including only solar photoionization as the source of electron heating. After [84.84]

for the terrestrial thermosphere show the close coupling between the electrons, ions and neutrals at low altitudes and the ions and electrons at high altitudes. T_i increases with increasing solar activity at low altitudes and approaches T_e at high altitudes. The values of T_e and T_i are about 3000 K at 1000 km [84.82]. Electron and ion temperatures in the terrestrial ionosphere are discussed in *Rees* [84.44], *Banks* and *Kockarts* [84.72], and *Whitten* and *Popoff* [84.85].

T_e and T_i in the Venus atmosphere were measured by instruments on the Pioneer Venus spacecraft. T_i, which approaches values of 2000–2500 K at high altitudes, has been found to be insensitive to solar zenith angle, except near the antisolar point, where it increases to values of 5000–6000 K [84.83]. T_e also does not vary appreciably with solar zenith angle; the high altitude values are in the range 4000–6000 K [84.86].

The retarding potential analyzer (RPA) on the Viking spacecraft found that T_i on Mars decouples from the T_n near 180 km, and approach values of about 3000 K at high altitudes [84.66]. T_e is predicted to diverge from the T_n in the lower ionosphere, and to approach values of 3000–4000 K at high altitudes [84.87].

There are no measurements of plasma temperatures in the ionospheres of the outer planets. The plasma temperatures on Titan have been predicted by a model [84.84]. The computed T_i are grater than T_n near the n_e maximum near 1000 km, but approach values of about 300 K at high altitude. For the solar source only, T_e increases rapidly to a constant value of about 800 K near 1200 km. Electrons from Saturn's magnetosphere may interact with the Titan ionosphere during the part of its orbit that is within the magnetosphere, and in this case T_e up to about 5000 K near 2000 km are predicted.

84.6 Luminosity

The luminosity that originates in the atmospheres of the planets is generally classified as dayglow, nightglow, or aurora. Dayglow is the luminosity of the dayside atmosphere that occurs as a more or less direct result of the interaction of solar radiation with atmospheric gases. Among the sources of dayglow are photodissociative excitation and simultaneous photoionization and excitation. Dayglow may also include scattering of solar radiation by processes that are selective, such as resonance scattering by atoms and fluorescent scattering by molecules, but the term generally excludes nonselective scattering processes, such as Rayleigh scattering.

In resonance scattering, the absorption of a photon by an atom in the ground state, causes a (usually dipole allowed) transition to a higher electronic state:

$$A + h\nu \rightarrow A^* , \tag{84.69}$$

followed by the emission of a photon as the state decays back to the ground state:

$$A^* \rightarrow A + h\nu . \tag{84.70}$$
The wavelength of the emitted radiation is very nearly the same as the wavelength of the radiation absorbed. The cross section for absorption of a line in the solar spectrum is

$$\sigma_{12}^a(\nu) = \frac{\varpi_2}{\varpi_1} \frac{c^2}{8\pi\nu^2} A_{21} \phi(\nu) , \tag{84.71}$$

where the subscript 1 indicates the lower state and 2 the upper state, ϖ is the statistical weight of the state and

$\nu = c/\lambda$ is the frequency of the transition. A_{21} is the Einstein A coefficient for the transition, and $\phi(\nu)$ is the lineshape function, which in this equation is normalized so that the integral over all frequencies is unity.

If the linewidth is determined by the spread of velocities of the species, the lineshape $\phi(\nu)$ is a Doppler (Gaussian) profile

$$\phi_D(\nu) = \frac{c}{u\nu_0\sqrt{\pi}} \exp\left[-\left(\frac{\nu-\nu_0}{\nu_0}\right)^2 \frac{c^2}{u^2}\right] , \tag{84.72}$$

where ν_0 is the frequency at line center. The variable $u = (2k_B T/m)^{1/2}$ is the modal velocity of a gas in thermal equilibrium at temperature T. The width of the line at half maximum, $\Delta\nu_D$ is

$$\Delta\nu_D = \frac{2\nu_0 u}{c} (\ln 2)^{1/2} . \tag{84.73}$$

If the linewidth is determined by the natural lifetime, the profile is a Lorentzian

$$\phi_L(\nu) = \frac{\Delta\nu_L/2\pi}{(\nu-\nu_0)^2 + (\Delta\nu_L/2)^2} , \tag{84.74}$$

where $\Delta\nu_L = \Gamma_R/2\pi$ is the line width at half maximum, and

$$\Gamma_R = \Gamma_2 + \Gamma_1 , \tag{84.75}$$

where Γ_2 and Γ_1 are the inverse radiative lifetimes of the levels 2 and 1, respectively. Collisional broadening also results in a Lorentzian lineshape. If both Doppler

and natural broadening mechanisms are important, the lineshape is a convolution of the two profiles, called a Voigt profile:

$$\int_{-\infty}^{\infty} \phi_D(\nu')\phi_L(\nu - \nu')\,d\nu' . \tag{84.76}$$

The absorption cross section σ_{12}^a integrated over all frequencies is proportional to the absorption oscillator strength f_{12}:

$$\int_{0}^{\infty} \sigma_{12}^a(\nu)\,d\nu = \frac{\pi e^2}{m_e c} f_{12} , \tag{84.77}$$

where m_e is the mass of the electron. A_{21} is related to the oscillator strength through

$$A_{21} = \frac{\varpi_1}{\varpi_2}\frac{8\pi^2 e^2 \nu^2}{m_e c^3} f_{12} = \frac{\varpi_1}{\varpi_2}\frac{8\pi^2 e^2}{m_e c \lambda^2} f_{12} . \tag{84.78}$$

The excitation rate q_2 of an upper level 2 by resonance scattering is given by

$$q_2 = F(\nu)\frac{\pi e^2}{m_e c} f_{12} = F(\lambda)\frac{\varpi_2}{\varpi_1}\frac{\lambda^4}{8\pi c} A_{21} , \tag{84.79}$$

where $F(\nu)$ is the solar flux in units of photons $cm^{-2}\,s^{-1}\,Hz^{-1}$ and $F(\lambda)$ is the flux in units of photons $cm^{-2}\,s^{-1}$ per unit wavelength interval. It should be noted that for radiative transfer purposes the photon flux that we have called $F(\nu)$ is sometimes denoted $\pi F(\nu)$. It is customary in aeronomy to define a "g-factor," which is the probability per atom that a photon will be resonantly scattered in a particular transition:

$$g_{21} = q_2 A_{21} \Big/ \sum_i A_{2i} , \tag{84.80}$$

where the sum in the denominator is over all the lower states i that are accessible from the upper state 2. The g-factor for unattenuated solar radiation is often quoted at the mean sun-earth distance or at a particular planet. The volume emission rate $\varepsilon_{21}(z)$ for resonance scattering of a solar photon is then given by

$$\varepsilon_{21}(z) = g_{21}n_1(z) , \tag{84.81}$$

where $n_1(z)$ is the number density of atoms in level 1.

In fluorescent scattering, a photon is absorbed by a molecule in a vibrational state v producing an excited electronic state with a vibrational quantum number v'

$$AB(v) + h\nu \rightarrow AB^*(v') . \tag{84.82}$$
This is followed by emission, at wavelengths that are usually the same as or longer than that of the absorbed photon, to a range of vibrational levels v'' of a lower state

$$AB^*(v') \rightarrow AB(v'') + h\nu' . \tag{84.83}$$
The volume emission rate of a transition from a level v' of the upper electronic state to a vibrational level v'' of a lower electronic state at an altitude z is given by

$$\varepsilon_{v'v''}(z) = n(z)g_{v'v''} = n(z)q_{v'}\frac{A_{v'v''}}{\sum_{v''} A_{v'v''}} , \tag{84.84}$$

where $A_{v'v''}$ is the transition probability, $n(z)$ is the number density of the molecular species at altitude z, and $q_{v'}$ is the excitation rate of vibrational level v' of the upper electronic state from a range of lower states v. The latter quantity is

$$q_{v'} = \sum_v \eta_v F(\lambda)\frac{\pi e^2}{m_e c^2}\lambda^2 f_{vv'} , \tag{84.85}$$

where η_v is the fraction of molecules in the v vibrational level.

Dayglow also includes emissions that are the result of the interaction of atmospheric species with the photoelectrons produced in solar photoionization, either by direct excitation

$$A + e^{*-} \rightarrow A^* + e^- , \tag{84.86}$$

or by simultaneous dissociation and excitation

$$AB + e^{*-} \rightarrow A^* + B + e^- , \tag{84.87}$$
or ionization and excitation

$$X + e^{*-} \rightarrow X^{+*} + e^- . \tag{84.88}$$

Electron impact processes are particularly important in producing excited states that are connected to the ground state by dipole forbidden transitions, whereas resonance and fluorescent scattering are largely limited to transitions that are dipole allowed. Dayglow emissions may also result from prompt chemiluminescent reactions, which occur when fragments or ions produced by dissociation or ionization recombine with the emission of a photon.

As an example, the dayglow spectrum of the earth from 1200 to 9000 Å is shown in Fig. 84.15. An ultraviolet spectrum of Mars as measured by the Mariner 9 spectrometer is shown in Fig. 84.16a, and the UV dayglow of Saturn and Uranus, which were measured by the Voyager spacecraft, are compared in Fig. 84.16b.

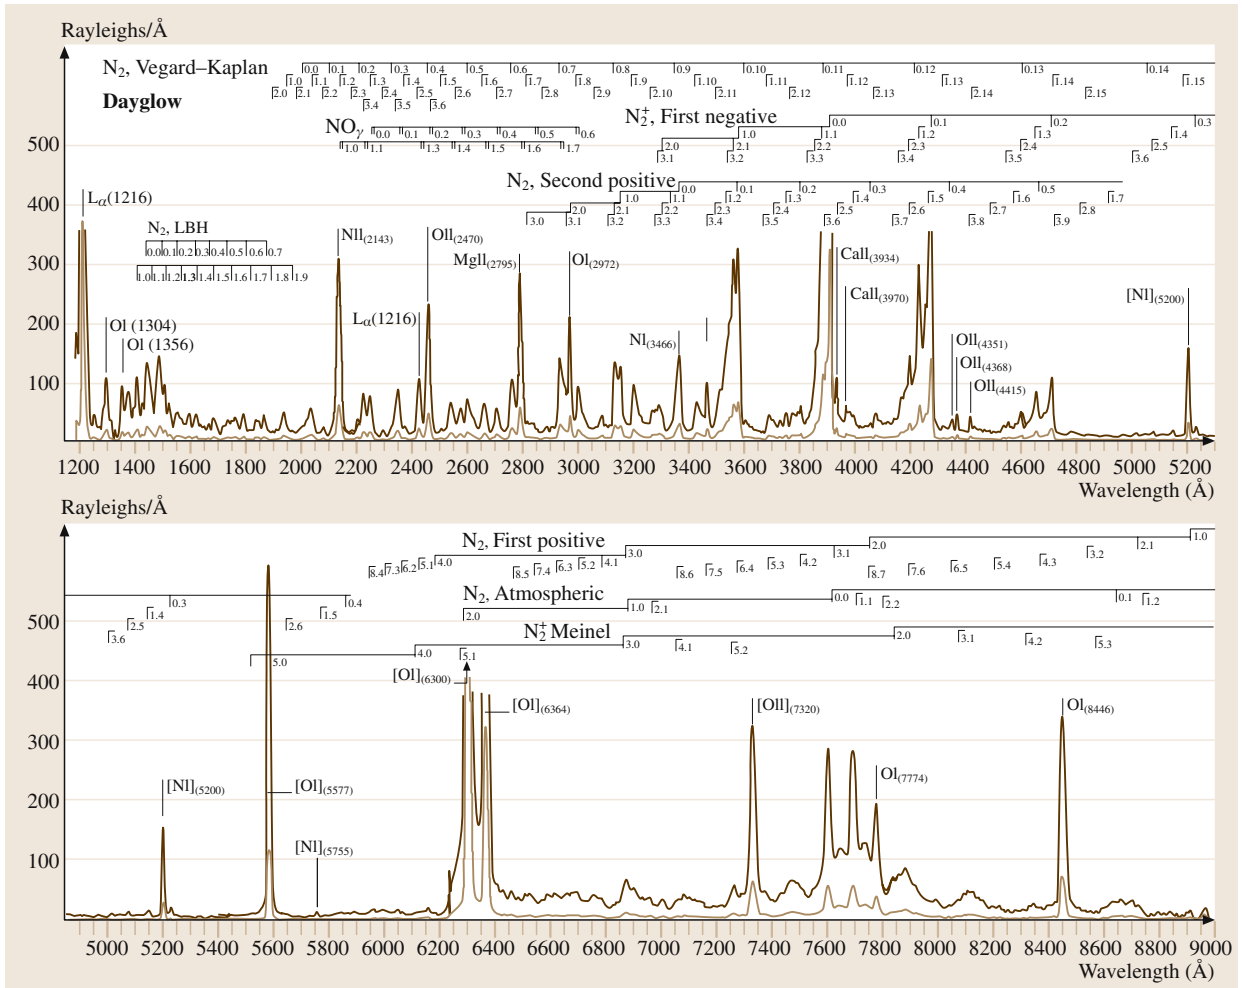
Nightglow arises from chemiluminescent reactions of species whose origin can be traced to species produced during the daytime or which have been transported


Fig. 84.15 Terrestrial dayglow spectrum measured in a single 32-second exposure by the Arizona Imager/Spectrograph on board the Space Shuttle [84.88]

from the dayside. For example, on Venus, O and N produced on the dayside are transported by the subsolar to antisolar circulation to the nightside, where they subside and radiatively associate:

$$N + O \rightarrow NO + h\nu , \qquad (84.89)$$

producing emission in the δ and γ bands of NO (e.g., *Stewart* et al. [84.89]). The Venus UV nightglow spectrum is shown in Fig. 84.17. Similar phenomena have recently been observed by the ultraviolet spectrometer on the Mars Express spacecraft [84.90].

Auroral emissions are defined here as those produced by impact of particles other than photoelectrons. Although aurorae are usually thought of as confined to the polar regions of the Earth and the outer planets, Venus, which does not have an intrinsic magnetic field, exhibits UV emissions on the nightside that are highly variable and cannot be explained as nightglow. It has been proposed that the emissions are produced by precipitation of soft electrons into the nightside thermosphere. Mars has recently been observed to exhibit auroral emissions, which are concentrated over magnetic field anomalies in the martian crust [84.91].

The intensities of airglow and aurora are usually measured in units of brightness called Rayleighs. One Rayleigh is an apparent column emission rate at the source of 10^6 photons $cm^{-2} s^{-1}$ integrated over all angles, or $10^6/4\pi$ photons $cm^{-2} s^{-1} sr^{-1}$. A comparison

Fig. 84.16a,b Dayglow spectra of selected planets. (**a**) Martian airglow spectrum recorded by Mariner 9 at 15 Å resolution. After [84.92]. (**b**) Comparison of dayglow spectra from Uranus (*heavy line*) and Saturn (*thin line*) recorded by Voyager 2 [84.4]▶
Fig. 84.17 Far ultraviolet nightglow spectrum of Venus obtained with the Pioneer Venus orbiter ultraviolet spectrometer. The predicted responses for three different band systems are also shown. After [84.93]

of auroral and dayglow emissions as measured by the Cassini UVIS as the spacecraft flew by Jupiter is shown in Fig. 84.18. (A. I. F. Stewart, private communication, 2004).

A discussion of terrestrial airglow and auroral emissions can be found in *Rees* [84.44]. *Meier* [84.94] has reviewed spectroscopy and remote sensing of the terrestrial ultraviolet emissions. The airglows of Mars and Venus have been discussed by *Barth* [84.19], by *Fox* [84.95] and by *Paxton* and *Anderson* [84.40]. Airglow and auroral emissions on the outer planets have been reviewed by *Atreya* et al. [84.96], *Atreya* [84.2], and
Strobel [84.4]. Airglow in the atmospheres of the planets has been reviewed by by *Slanger* and *Wolven* [84.97].

84.7 Planetary Escape

Escape of species from atmospheres can occur by thermal and nonthermal mechanisms. Thermal processes include Jeans escape and hydrodynamic escape. Jeans escape is essentially evaporation of the energetic tail of the Maxwell–Boltzmann distribution, while hydrodynamic escape is a large-scale "blow-off" of the

atmosphere that occurs when the average molecular velocity is near or above the escape velocity. Although Jeans escape still occurs for light species in the thermospheres of small planets, hydrodynamic escape is thought to have occurred only in the early history of the terrestrial planets when the solar flux in the UV was
Fig. 84.18 Spectra of the northern aurora (*heavy line*) and the equatorial airglow (*light line*) taken by the UVIS spectrometer the Cassini spacecraft on closest approach on 30 December 2000. In both spectra, the Lyman and Werner bands of molecular hydrogen are prominent. They are excited by photoelectron impact in the airglow, and by primary and secondary auroral electrons. Locations of some of the brighter bands are indicated by *dotted lines*. Also shown are the Lyman-alpha and -beta lines of atomic hydrogen. At wavelengths longer than 1550 Å, the airglow spectrum is swamped by reflected UV sunlight; some solar lines are indicated. At shorter wavelengths, UV sunlight is absorbed by methane and acetylene, rather than reflected. The solar signal is much weaker in the auroral spectrum than in the equatorial, due to the higher angles of incidence and emission in the former [84.99]

higher. Nonthermal escape mechanisms, which dominate for heavy species on smaller bodies such as Mars and Titan, and for all species on Venus and Earth, include both photochemical and mechanical processes. A pedagogical discussion of escape processes can be found in *Chamberlain* and *Hunten* [84.98]

Because of the exponential rate of change of density with altitude in atmospheres, escape is sometimes assumed to occur only at and above the exobase. The exobase is mathematically defined as the altitude where the mean free path $l = (n\sigma^c)^{-1}$ (where σ^c is the collision cross section), is equal to the atmospheric scale height. The probability that a particle, moving upward from the exobase with sufficient velocity will actually escape without suffering another collision is $1/e$. The condition $l = H$ therefore reduces to $nH\sigma = 1$ or, equivalently, to $N = (\sigma^c)^{-1}$, where N is the column density. Since a typical collision cross section is about 3×10^{-15} cm^2,

the exobase is located near the altitude above which the column density is about 3.3×10^{14} cm^{-3}, although the collision cross section and thus the location of the exobase is different for different escaping species.

Whether the trajectory of a particle moving upward at the exobase is ballistic (bound) or escaping (free) is determined by its total energy E, which is the sum of its kinetic and potential energies:

$$E = \frac{1}{2}mv_c^2 + \int_\infty^{r_c} \frac{mGM}{r^2}\, \mathrm{d}r\,, \tag{84.90}$$

where the symbols have the same meaning as in equation (84.2), and the subscript c refers to the critical level or exobase. If $E < 0$, the particle is bound. Expression (84.90) reduces to

$$E = \frac{1}{2}mv_c^2 - mg_c r_c \tag{84.91}$$

where g_c is the gravitational acceleration at the exobase. The escape velocity at the exobase, v_{esc}, is then defined by the condition $v_{esc} = (2g_c r_c)^{1/2}$. Particles with velocities greater than the escape velocity are assumed to escape if their velocity vector is oriented in the upward hemisphere and if they undergo no further collisions. The radius, gravitational acceleration, escape velocities and scale height at the equatorial exobases of the planets are given in Table 84.10.

In the Jeans process, escape occurs when particles in the high energy tail of the Maxwellian distribution attain the escape velocity. The escape flux, Φ_J is given by

$$\Phi_J = \frac{n_c u}{2\sqrt{\pi}} (1 + \lambda_c) \exp(-\lambda_c) , \tag{84.92}$$

where $u = (2k_B T/m)^{1/2}$ is the modal velocity and λ is the gravitational potential energy in units of $k_B T$

$$\lambda = \frac{GMm}{r k_B T} = \frac{mgr}{k_B T} = \frac{r}{H} . \tag{84.93}$$

Table 84.10 Exobase properties of the planets

Planet	r_c (km)	g_c^a (cm s^{-2})	$v_{esc,c}^a$ (km s^{-1})	$H_{avg}^{a,b}$ (km)
Mercury[c]	2439	378	4.29	–
Venus[d]	6250	831	10.2	17
Earth[e]	6878	842	10.8	71
Mars[f]	3593	333	4.89	17
Jupiter[g]	73 000	2236	57.2	250
Saturn[h]	67 000	731	31.3	910
Uranus[i]	31 800	561	18.9	66
Neptune[j]	27 300	919	22.4	250
Titan[k]	4175	51.4	2.07	116
Triton[l]	2222	28.9	1.13	140

[a] Values given are those at the equatorial exobase, and assume that the thermosphere co-rotates with the planet.

[b] Average value computed from $H_{avg} = k_B T/m_{avg} g$, but does not represent the local pressure scale height, except for cases where there is one major constituent.

[c] Exobase is at the surface.

[d] Model from *Hedin* et al. [84.3] for $F_{10.7}$=150, 45° solar zenith angle.

[e] MSIS model for $F_{10.7}$=150, equator, 45° Solar Zenith Angle [84.17].

[f] Model from *Nier* and *McElroy* [84.8], and pertains to low solar activity conditions.

[g] Model from [84.2, 14].

[h] Model from *Atreya* [84.2].

[i] Model from [84.55].

[j] Model from [84.56].

[k] Model from *Strobel* et al. [84.10].

[l] Model from *Krasnopolsky* et al. [84.15]

Sometimes a correction factor is applied to the expression for the escape flux to account for the suppression of the tail of the distribution due to the escape of the energetic particles [84.100, 101].

Photochemical processes that produce energetic fragments include photodissociation and photodissociative ionization, photoelectron impact dissociation and dissociative ionization, as well as exothermic chemical reactions. The most important example of the latter are dissociative recombination reactions, which are very exothermic and tend to produce neutral fragments with large kinetic energies. Charge transfer processes such as

$$H^{+*} + O \rightarrow O^+ + H^* \tag{84.94}$$

can produce fast neutrals if the ion temperature is larger than the neutral temperature, as is usually the case near the exobase of a planet. In modeling these processes, the kinetic energy distribution of the product species is important, as well as the cross sections or reaction rates.

Physical or collisional escape mechanisms include sputtering and "knock-on." Sputtering can occur when a heavy ion picked up by the solar wind collides with an atmospheric species near or above the exobase, and in the process produces a "back-splash" in which the accelerated neutral may be ejected from the atmosphere. In knock-on, hot atmospheric neutral species, such as O atoms produced in exothermic chemical reactions near the exobase can collide with a lighter species, such as H, imparting sufficient kinetic energy to allow it to escape. Modeling these processes requires knowledge of the ion–neutral or neutral–neutral collision cross sections.

The escape rate of a light species from a planetary atmosphere may be controlled by diffusion of the species from the lower atmosphere to the exobase, rather than by the escape process itself [84.102]. The limiting upward flux, ϕ_l of a species i with mixing ratio f_i can be estimated as

$$\phi_l \approx b_i f_i / H_a , \tag{84.95}$$

where H_a is the average scale height of the atmosphere and b_i is the binary collision parameter introduced in Sect. 84.2.2. Equation (84.95) above is usually evaluated at the homopause, with the mixing ratio taken from a suitable altitude in the middle atmosphere, but above the cold trap (where the species condenses), if one exists. The limiting flux obtains if and only if the mixing ratio is constant with altitude. The effect of photochemistry can be accounted for if all chemical forms of the species are considered in the calculation of f_i.
Fig. 84.19 Spectrum of the oxygen green line taken on the nightside of Venus taken by the Keck/HIRES on 20 November 1999. The individual terrestrial and Doppler-shifted Venusian components are shown by the *dashed lines* (from *Slanger* et al. 84.103)

Even if energetic particles released at the exobase of a planet do not have enough energy to escape, they may travel to great heights along ballistic orbits before falling back to the atmosphere. These particles are said to form a hot atom "corona". Hot H and O coronas have been found to surround the Earth and Venus, and have been predicted for Mars (Fig. 84.19). Reviews of the H and O coronas of Venus have been presented by *Fox* and *Bougher* [84.79] and by *Nagy* et al. [84.104]. See *Chamberlain* and *Hunten* [84.98] for a detailed discussion of planetary coronal population processes.

85. Applications of Atomic and Molecular Physics to Global Change

While there has been a general understanding and appreciation of the science involved in both global warming and stratospheric ozone depletion by atmospheric scientists for some time, detailed understanding and rigorous proof has often been lacking. Over the last ten years, there have been many advances made in filling in the details and there will continue to be rapid advances in the future. This means that any article or book discussing this topic becomes out of date as soon as it is written. Nevertheless several recent references on these topics are recommended [85.1–3].

Atomic and molecular structure and spectroscopy, as well as collision processes involving atoms, molecules, ions and electrons, are important to the study of all planetary atmospheres. For additional information on this topic, see Chapt. 84 in this volume.

Part G | 85

85.1 Overview

85.1.1 Global Change Issues

Over the last several decades there has been increasing concern about the global environment and the effect of human perturbations on it. This whole area, which involves a wide range of scientific disciplines, has become known as *Global Change*. Knowledge of processes taking place in the atmosphere, oceans, land masses, and plant and animal populations, as well as the interactions between these various earth-system components is essential to an overall understanding of global change – both natural and human-induced.

The processes of atomic and molecular physics find greatest application in the area of atmospheric global change. The two major issues which have received significant attention in both the media and the scientific literature are: (1) global warming, due to the buildup of infrared-active gases; and (2) stratospheric ozone de-

pletion due to an enhancement of destructive catalytic cycles. Although both of these problems are thought to be caused by atmospheric pollutants due to industrialized human society, the general problem of air pollution and its direct effects on plant and animal populations will not be addressed here.

85.1.2 Structure of the Earth's Atmosphere

The vertical temperature structure of the earth's atmosphere shown in Fig. 85.1 provides an important nomenclature that is widely used [85.4]. The atmosphere is divided into regions called "-spheres", in which the sign of the temperature gradient with respect to altitude, dT/dz, is constant. The regions in which the temperature gradient changes sign are called "-pauses". The precise altitude pertaining to each of these regions can vary depending upon latitude and the time of year.
Fig. 85.1 Vertical temperature profile of the atmosphere

In the troposphere, covering the range from 0 to ≈ 15 km above the earth, the temperature steadily decreases with altitude. This is the most complex region of the atmosphere, as it interacts directly with plant and animal life, land masses and the oceans. It is the region in which weather occurs.

The change in sign of the temperature gradient at the tropopause to a positive dT/dz in the stratosphere is due to heating by absorption of solar ultraviolet radiation which photodissociates O_2 and O_3. The stratosphere, extending from ≈ 15 to 50 km above the earth, contains the ozone layer which shields the earth's surface from harmful ultraviolet radiation in the range of 280–320 nm.

At the stratopause, the heating processes have become too weak to compete with the cooling pro-

cesses, and throughout the mesosphere, approximately 50–85 km, the temperature again decreases with increasing altitude. Cooling processes, which will be discussed in Sect. 85.2.2, involve collisional excitation of molecular vibrational modes which decay by radiating to space. The coldest temperatures in the atmosphere are found at the mesopause, where the temperature gradient once again becomes positive. From approximately 70 km upward, a very diffuse plasma called the ionosphere exists due to photoionization of atoms and molecules by short wavelength (UV and EUV) solar radiation.

Throughout the thermosphere, which extends from approximately 90 km upward, heating occurs because the atmosphere has become so thin that there are very few collisions and thus inefficient equilibration of the highly translationally excited atoms and ions with the molecular species which can radiate in the infrared. This "bottleneck" for energy loss causes increased heating. In the thermosphere and ionosphere, the thermal inertia is very small and there are huge temperature variations, both diurnally, and with respect to solar activity.

The densities are low enough in the thermosphere, ionosphere, and mesosphere, that the primary processes determining the chemical and physical characteristics of these regions are two-body processes and "half-collision events" discussed elsewhere in this volume: dissociative recombination, photoionization, photodissociation, charge transfer, and collisional excitation of molecular rotation and vibration. As the altitude decreases, the density increases. Then three-body interactions, interactions on surfaces (of aerosols and ices), and complex chemical cycles together with dynamical effects such as winds determine the chemical and physical characteristics of the stratosphere and troposphere.

85.2 Atmospheric Models and Data Needs

While models are absolutely essential to the study of any system as complex as the earth's atmosphere, they play a particularly fundamental role in exploring global change issues. Models not only provide predictions of future changes, but also allow exploration of sensitivities to particular parameters. Comparing the results of a model with observations ultimately tests and challenges scientific understanding. Of critical importance is the atomic and molecular data which goes into the models.

Generally, atmospheric models become increasingly complex as altitude decreases. General Circulation Models (GCMs), incorporating thousands of chemical reactions, global wind patterns, and abundances of large numbers of trace species, require supercomputers in order to model aspects of the troposphere and stratosphere. Tropospheric chemistry and transport models, such as GEOS-CHEM [85.5], model the sources, evolution, transport, and sinks of pollution, as well as the oxidative capacity of the troposphere.

85.2.1 Modeling the Thermosphere and Ionosphere

The data necessary for modeling of the thermosphere and ionosphere are described here. The primary components of such a model include: a solar spectrum of photon fluxes as a function of wavelength, concentrations of neutral species, photoabsorption, photodissociation and photoionization cross sections as a function of wavelength. The computer code brings all these elements together, calculating opacity as the solar radiation propagates downward through the atmosphere, keeping track of ion production and electron production. Additional steps are required to calculate the abundances of trace species such as NO^+, necessitating the inclusion of all relevant ion-neutral reactions. Electron energy degradation can be tracked by including inelastic collisions of electrons with ions, atoms, and molecules.

The primary neutral species are N_2, O_2, O, and He. Below about 100 km, the atmosphere is fully mixed by turbulence in the ratio 78% N_2, 21% O_2 and 1% trace species such as O_3 and CO_2. Above 100 km, turbulence dies out and the atmospheric species are in diffusive equilibrium, distributed by their molecular weight, with atomic oxygen dominating above ≈ 150 km and He dominating much higher. The major ions are N_2^+, O_2^+, O^+ and NO^+.

85.2.2 Heating and Cooling Processes

In the upper atmosphere, heating occurs through absorption of short wavelength solar radiation to produce ionization and dissociation, and is mediated by collisions between electrons, ions, and neutrals. Ions and electrons are created during the daytime and to a great extent disappear during the night with the absence of solar radiation. Processes such as dissociative recombination, the primary electron loss mechanism, heat the gas:

$$e + O_2^+ \rightarrow O(^3P) + O(^3P) + 7\,eV \,, \qquad (85.1)$$

$$e + N_2^+ \rightarrow N(^4S) + N(^4S) + 6\,eV \,. \qquad (85.2)$$
Cooling takes place when the kinetic energy of the gas is transformed through collisions into internal energy which can then be radiated away. The primary coolant above ≈ 200 km is the fine structure transition of atomic oxygen, $O(^3P_1) \overset{h\nu}{\rightarrow} O(^3P_2)$, which is excited by thermal collisions and radiates at 63 μm. From approximately 120 km to 200 km, the fundamental band of NO, $v = 1 \rightarrow v = 0$, which is excited by collisions with atomic oxygen and radiates at 5.3 μm, dominates the cooling. Below 120 km and throughout the mesosphere and stratosphere, the primary coolant is the ν_2 band of CO_2 radiating at 15 μm. This transition is excited by collisions of CO_2 and atomic oxygen. Cooling throughout most of the atmosphere is accomplished through trace species because the major molecular species, N_2 and O_2, are not infrared active.

85.2.3 Atomic and Molecular Data Needs

Knowledge of rate coefficients for ion-neutral and neutral-neutral reactions as a function of vibrational and rotational excitation of the reactants is becoming increasingly important, as there is recent evidence of more internal excitation of molecular species than had previously been thought [85.6]. Accurate photoabsorption, photodissociation and photoionization cross sections as a function of wavelength for all the relevant species are important parameters determining the reliability and ultimate accuracy of an atmospheric model. Compilations of data, such as that by *Conway* [85.7] and *Kirby* et al. [85.8] are very useful, but can become rapidly outdated. The Smithsonian Astrophysical Observatory maintains the world standard database, HITRAN, for molecular line parameters and absorption cross sections from the microwave through the ultraviolet for analysis of atmospheric spectra [85.9]. Discussions of the needs for atomic and molecular data in the context of space astronomy, but including applications to atmospheric physics, can be found in a book edited by *Smith* and *Wiese* [85.10].

85.3 Tropospheric Warming/Upper Atmosphere Cooling

85.3.1 Incoming and Outgoing Energy Fluxes

The overall temperature of a planet is determined by a balance between incoming and outgoing energy fluxes.

In a steady state, the planet must radiate as much energy as it absorbs from the sun. The Earth, radiating as a black-body at an effective temperature T_E, obeys the Stefan–Boltzmann law in which the energy emitted is expressed as $\sigma T_E^4 4\pi R_E^2$, with σ the Stefan–Boltzmann

constant, and R_E the radius of the earth. An equation expressing the equality of energy absorbed and energy emitted can be written [85.11] as

$$F_s \pi R_E^2 (1 - A) = \sigma T_E^4 4\pi R_E^2 \,, \qquad (85.3)$$

where A is the albedo of the earth (the fraction of solar radiation reflected from, rather than absorbed by, the Earth), F_s is the solar flux at the edge of the earth's atmosphere, and πR_E^2 is the Earth's area normal to the solar flux. Solving this equation for T_E, one obtains $T_E \cong 255\,\text{K}\,(-18\,°\text{C})$.

The sun, which has a surface temperature of approximately 6000 K, emits most of its radiation in the $0.2–4.0\,\mu\text{m}$ region of the spectrum (200–4000 nm). The upper atmosphere of the Earth (thermosphere, ionosphere, mesosphere, and stratosphere) absorbs all the solar radiation shortward of 320 nm. The atmosphere of the earth absorbs only weakly in the visible region of the spectrum where the solar flux peaks.

The Earth, with an effective radiating temperature of 255 K, emits mainly long-wavelength radiation in the $4–100\,\mu\text{m}$ region. Molecules naturally present in the atmosphere in trace amounts, such as carbon dioxide, water and methane, absorb strongly in this wavelength region [85.12]. Radiation coming from the Earth is thus absorbed, reradiated back to the surface, and thermalized through collisions with the ambient gas. This trapping of the radiation produces an additional warming of 33 K. Thus the mean surface temperature of the Earth is 288 K, not 255 K as found for T_E above. This effect of the Earth's atmosphere is known as the greenhouse effect. The greenhouse effect is what makes Earth habitable for life as we know it. Gases, both natural and man-made, which absorb strongly in the $4–100\,\mu\text{m}$ region, are known collectively as greenhouse gases.

85.3.2 Tropospheric "Global" Warming

According to a 2000 National Research Council Report, "the global-mean temperature at the earth's surface is estimated to have risen by 0.25 to 0.4 °C during the past 20 years" [85.13]. The Intergovernmental Panel on Climate Change (IPCC) has also concluded that global surface temperatures have increased and that "there is new and stronger evidence that most of the warming over the last 50 years is attributable to human activities" [85.14]. The Arctic region has warmed by an estimated 1 °C in the past two decades, leading to substantial changes in the cryosphere [85.15]. Antarctic sea ice was stable from

1840 to 1950, but has since declined sharply. Sea ice extent shows a 20% decline since about 1950 [85.16,17].

From air bubbles trapped at different depths in polar ice, it is possible to determine carbon dioxide and methane concentrations several thousand years ago. Over the last two hundred years, CO_2 levels have increased by 20%, from 280 to 330 ppm. Over the next century the total amount of CO_2 in the atmosphere since 1900 is expected to double to as much as 600 ppm [85.18]. This increase is due primarily to the burning of fossil fuels.

Although methane is present at levels several orders of magnitude less than CO_2, it is increasing much more rapidly. Methane concentrations have more than doubled over the last two hundred years due to industrial processes, fuels, and agriculture [85.18].

The man-made chlorofluorocarbons (CFCs), which have been widely used as refrigerants and in industry, have been increasing in the atmosphere at a rate of over 5% per year since the 1970s. Only recently has there been an indication that this trend is slowing down [85.19].

Ozone, which is a primary component of chemical smog, is a pollutant when it occurs in the troposphere and an effective greenhouse gas. It has been increasing worldwide also.

This buildup of CO_2, CH_4, CFCs and tropospheric O_3 causes a problem. In much of the spectral region from $5–100\,\mu\text{m}$, there is 100% absorption of radiation by the atmosphere – due mainly to naturally occurring water vapor. There is, however, a region of rather weak absorption, from $\approx 7–15\,\mu\text{m}$, known as the "atmospheric window". Increased concentrations of the greenhouse gases strengthen the absorption in this region, tending to "close" this window, thus increasing the infrared opacity of the atmosphere. The increased opacity causes an immediate decrease in the thermal radiation from the planet-atmosphere system, forcing the temperature to rise until the energy balance is restored [85.20].

It is difficult to prove that the buildup of greenhouse gases is the cause of the observed temperature rise. Other possible causes include slight changes in solar activity and irradiance, and changes in ocean currents, which may have a profound effect on global temperature and climate. These are areas of active research.

Given the increase in concentrations of greenhouse gases that has occurred and is predicted to continue, the change in radiative heating of the troposphere can be calculated. Models generally predict an increase in tropospheric temperatures ranging from 1.5 to 4.5 °C, upon doubling the CO_2 concentrations over the next cen-

tury. The $3\,°C$ range in temperature is due to the ways that different models incorporate climate feedbacks. Climate feedbacks include water vapor, snow and sea ice, and clouds. Rising temperatures increase the concentration of water vapor, which is itself a greenhouse gas, producing further warming. Rising temperatures reduce the extent of reflective snow and ice, thus reducing the Earth's albedo. This leads to increased absorption of solar radiation, further increasing temperatures. Clouds both contribute to the albedo, thereby reducing the solar flux reaching the Earth, and absorb infrared radiation causing temperatures to rise. The modeling of clouds and their radiative properties is very difficult, and is one of the largest sources of uncertainty in the climate models. Understanding the role that the ocean, with its giant heat capacity, plays in global warming, and identifying and quantifying the various interactions occurring at the ocean-atmosphere interface, are vital areas of research which will affect the size of the predicted temperature increase. At present, there are few obvious opportunities for traditional atomic and molecular physics to play a significant part in global-warming research.

85.3.3 Upper Atmosphere Cooling

The buildup of CO_2 has an even greater effect on the temperature in the upper atmosphere than on that in the troposphere [85.21]. As discussed in the Sect. 85.2.2, CO_2 is a coolant in the stratosphere, mesosphere and thermosphere, but as a greenhouse gas is involved in heating the troposphere. The explanation for this revolves around the collision physics issue of quenching versus radiating.

In the troposphere, CO_2 absorbs infrared radiation coming from the Earth, exciting the ν_2 vibrational bending mode at $15\,\mu m$. The excited molecule can either reradiate or collisionally de-excite. In the lower atmosphere where densities are large, the lifetime against collisions is very short and the excited molecule is rapidly quenched. This transfer of energy from radiation through collisions into the kinetic energies of the colliding partners results in a net heating.

In the stratosphere and above, atomic oxygen collisions with CO_2 excite this same bending mode. But at these higher altitudes, densities are lower and quenching is greatly reduced. The excited molecule radiates and the radiation escapes to space. A net cooling results because the opacity is low at these altitudes.

Roble and co-workers [85.22, 23] have investigated the doubling of CO_2 and CH_4 concentrations (as predicted for the next century) in the mesosphere and at

the lower boundary of the thermosphere. Using sophisticated atmospheric general circulation models, they predict that the stratosphere, mesosphere and thermosphere will show significant cooling — the largest cooling of $40–50\,°C$ occurring in the thermosphere.

The extent of this cooling very much depends on the rate coefficient for the $O + CO_2$ excitation of the ν_2 bending mode. *Rishbeth* and *Roble* [85.22] assumed a value for this rate coefficient of $1 \times 10^{-12}\,cm^3/s$, intermediate between the value of *Sharma* and *Wintersteiner* [85.24] ($6 \times 10^{-12}\,cm^3/s$) and an earlier value of $2 \times 10^{-13}\,cm^3/s$ used by *Dickenson* [85.25]. The Sharma and Wintersteiner value, based on observations of $15\,\mu m$ emission in the atmosphere around $100–150\,km$, was recently confirmed by *Rodgers* et al. [85.26], but *Pollock* et al. [85.27] obtain a value of $1.2 \times 10^{-12}\,cm^3/s$ in laboratory experiments. Using the larger rate coefficient would result in even greater cooling [85.28].

The overall consequences of such a large temperature decrease in the upper atmosphere have not been fully explored — particularly the question as to how the dynamics of the atmosphere will be affected. Since many chemical reactions depend on temperature, there may be considerable readjustments in the vertical distribution of minor species in the atmosphere. Cooler temperatures cause the atmosphere to contract, reducing densities and, consequently, satellite drag. Cooler temperatures may also increase the occurrence of polar stratospheric clouds, thereby affecting ozone depletion (Sect. 85.4).

Most significantly, tropospheric warming and upper atmosphere cooling both result from a buildup of CO_2. The size of the predicted cooling is greater by an order of magnitude than the amount of the predicted heating. Thus it may be possible to monitor the global warming trend by observing the predicted cooling in the upper atmosphere.

There is evidence in the mesosphere that this cooling has already begun. Temperatures appear to have decreased by $3–4\,°C$ over the last decade [85.29, 30]. *Gadsden* [85.31] has also found that the frequency of occurrence of noctilucent clouds, the highest-lying clouds in the atmosphere, has more than doubled over the last twenty-five years. He has calculated that this change could result from a decrease in the mean temperature at the mesopause of $6.4\,°C$ during this time period. However, increased concentrations of water produced by oxidation of increased amounts of methane may be responsible for the more frequent appearance of the clouds. This is an ongoing area of research.

85.4 Stratospheric Ozone

85.4.1 Production and Destruction

Ozone production takes place continually in the strato-
sphere during daylight hours, as molecular oxygen is
photodissociated and the resulting oxygen atoms un-
dergo three-body recombination with O_2:

$$O_2 + h\nu \rightarrow 2O , \tag{85.4}$$

$$O + O_2 + M \rightarrow O_3 + M . \tag{85.5}$$
Ozone can be destroyed through photodissociation:

$$O_3 + h\nu \rightarrow O_2 + O , \tag{85.6}$$
but because an oxygen atom is produced which imme-
diately recombines with another O_2 to form O_3, no net
loss of O_3 results. The photodissociation of O_2 and O_3
are important heating processes in the stratosphere.

The amount of ozone in the stratosphere is quite
variable, changing significantly with the seasons and
with latitude. In the lower stratosphere, much of the
ozone is created over the equatorial regions and then
transported toward the poles.

Besides being photodissociated, O_3 is destroyed by
reactions with radicals that are involved in catalytic cy-
cles. The short-hand notation for the major cycles, NO_x,
HO_x, ClO_x (BrO_x) refers to the catalytically active forms
involved in the cycles. Our knowledge about the relative
importance of these catalytic cycles in ozone destruc-
tion has increased dramatically over the last decade.
A number of these cycles are given below, with the
ozone-destroying step listed first, and the rate-limiting
step closing the catalytic cycle and regenerating the
ozone-destroying radical, listed last. The net effect in
each of these cases is to convert ozone and atomic oxy-
gen (otherwise known as odd-oxygen) into molecular
oxygen:

$$NO + O_3 \rightarrow NO_2 + O_2$$
$$NO_2 + O \rightarrow NO + O_2$$
$$\text{NET: } O_3 + O \rightarrow 2O_2 , \tag{85.7}$$

and

$$NO + O_3 \rightarrow NO_2 + O_2$$
$$NO_2 + O_3 \rightarrow NO_3 + O_2$$
$$NO_3 + h\nu \rightarrow NO + O_2$$
$$\text{NET: } 2O_3 \rightarrow 3O_2 . \tag{85.8}$$

$$OH + O_3 \rightarrow HO_2 + O_2$$
$$HO_2 + O_3 \rightarrow OH + 2O_2$$
$$\text{NET: } 2O_3 \rightarrow 3O_2 , \tag{85.9}$$
and the halogen cycle, in which $Z = Cl$ or Br:

$$Z + O_3 \rightarrow ZO + O_2$$
$$ZO + O \rightarrow Z + O_2$$
$$\text{NET: } O_3 + O \rightarrow 2O_2 . \tag{85.10}$$
The following series of reactions couples the HO_x and
halogen cycles:

$$HO_2 + ZO \rightarrow HOZ + O_2$$
$$HOZ + h\nu \rightarrow OH + Z$$
$$Z + O_3 \rightarrow ZO + O_2$$
$$OH + O_3 \rightarrow HO_2 + O_2$$
$$\text{NET: } 2O_3 \rightarrow 3O_2 . \tag{85.11}$$
Finally the reaction set

$$BrO + ClO \rightarrow Br + Cl + O_2$$
$$Br + O_3 \rightarrow BrO + O_2$$
$$Cl + O_3 \rightarrow ClO + O_2$$
$$\text{NET: } 2O_3 \rightarrow 3O_2 \tag{85.12}$$
is also important in the halogen destruction cycle. The
coupling between these different cycles by reactions
such as

$$HO_2 + NO \rightarrow OH + NO_2 \tag{85.13}$$
turns out to be very important in understanding the
details of ozone destruction, such as how much each
mechanism contributes to the destruction as a func-
tion of altitude and in the presence of aerosols.
Wennberg et al. [85.32] have recently shown that cat-
alytic destruction by NO_2, which for two decades
was considered to be the predominant loss process,
accounted for less than 20% of the O_3 removal in
the lower stratosphere during May 1993. They further
show that the cycle involving the hydroxyl radical ac-
counted for nearly 50% of the total O_3 removal and
the halogen-radical chemistry was responsible for the
remaining 33%.

The NO_x and HO_x cycles are naturally occurring,
whereas the ClO_x and BrO_x cycles are due mainly to
man-made chemicals – the CFCs and halons. The am-
plification that takes place through a catalytic cycle is the

reason that these chemicals, which are only present at the level of parts per trillion, can have such a destructive effect.

It is useful to think in terms of a total chemical budget for a radical such as Cl which enters into a cycle. Chlorine is put into the stratosphere when chemicals such as CF_2Cl_2 are released into the atmosphere. Such compounds are chemically inert and insoluble in water, and therefore are not easily cleansed out of the lower atmosphere. In the stratosphere, however, the CF_2Cl_2 is subjected to solar UV radiation and is photodissociated, producing the Cl radical. Chlorine exists in the upper atmosphere in catalytically active forms, Cl and ClO, as well as in stable, reservoir species, HCl and $ClONO_2$. The total chlorine budget consists of both the catalytically active plus reservoir species. Reactions which reduce the formation of reservoir species, or convert reservoir species to catalytically active forms, contribute to the ozone destruction. Photolysis of stable reservoir species, such as $ClONO_2$, can produce catalytically active forms. Bromine has an identical cycle to that of chlorine, but is 50 to 100 times more destructive than Cl because it does not react readily to go into its reservoir form, HBr. A knowledge of the photodestruction rates of all such species is important to an understanding of the overall ozone photochemical depletion problem.

Studies of the Antarctic ozone hole show that gas phase photochemical cycles, as given above, are not the whole story with respect to ozone depletion. Heterogeneous chemistries taking place on the surfaces of ice crystals and sulfate aerosols play an important role also. These are discussed briefly in Sect. 85.4.2 and Sect. 85.4.4.

85.4.2 The Antarctic Ozone Hole

The ozone depletion problem was largely theoretical until the discovery of the ozone hole over Antarctica. Following the 1985 announcement by *Farman* et al. [85.33] of ground-based observations of significant decline in O_3 concentrations during springtime in the Southern Hemisphere, it was possible to map this event using archived satellite data beginning in 1979. The data depict a worsening event throughout the early 1980s. In 1987, 70% of the total O_3 column over Antarctica was lost during the month of September and early October, and the areal extent of the hole was $\approx 10\%$ of the Southern Hemisphere. The ozone hole has continued to grow in depth and width [85.34]. Recent data shows that this phenomenon continues, with the 2003 ozone

hole the second largest observed to date (the largest yet observed was on September 10, 2000) [85.35].

The causal link between the release and buildup of man-made CFCs and the ozone hole over Antarctica has been quite convincingly established by *Anderson* et al. [85.36] through in situ observations from high altitude aircraft flights into the polar vortex during the end of polar night and the beginning of Antarctic spring in 1987.

The polar vortex is a stream of air circling Antarctica in the winter, creating an isolated region which becomes very cold during the polar night. Flights into the vortex were able to document a heightened, increasing level of ClO and a monotonically decreasing O_3 concentration over a 3–4 week time period during late September and early October.

The mechanism which appears to be repartitioning the chlorine from its reservoir form into its catalytically active form is a heterogeneous process occurring on the surfaces of polar stratospheric clouds. At the cold temperatures during the polar night, polar stratospheric clouds form, consisting of ice and nitric acid trihydrate. Gaseous $ClONO_2$ collides with HCl that has been adsorbed onto the surface of the cloud crystals. Chlorine gas is liberated and the nitric acid formed in the reaction remains in the ice [85.36]:

$$HCl + ClONO_2 \rightarrow Cl_2(g) + HNO_3 \ . \qquad (85.14)$$
As solar radiation starts to penetrate the region at the beginning of spring, the Cl_2 molecules are rapidly photodissociated, producing Cl atoms which initiate the catalytic destruction of O_3.

As there are no oxygen atoms around to complete the catalytic cycles, several mechanisms for regenerating the Cl and Br radicals have been proposed which involve only the ClO and BrO molecules themselves.

Mechanism I [85.37]

$$
\begin{aligned}
ClO + ClO + M &\rightarrow (ClO)_2 + M \\
(ClO)_2 + h\nu &\rightarrow Cl + ClOO \\
ClOO + M &\rightarrow Cl + O_2 + M \\
2 \times (Cl + O_3 &\rightarrow ClO + O_2) \\
\text{NET: } 2O_3 &\rightarrow 3O_2 \ ;
\end{aligned}
\qquad (85.15)
$$

Mechanism II [85.38]

$$
\begin{aligned}
ClO + BrO &\rightarrow Cl + Br + O_2 \\
Cl + O_3 &\rightarrow ClO + O_2 \\
Br + O_3 &\rightarrow BrO + O_2 \\
\text{NET: } 2O_3 &\rightarrow 3O_2 \ .
\end{aligned}
\qquad (85.16)
$$
While Mechanism I accounts for 75% of the observed ozone loss, the sum of I and II yields a destruction rate in harmony with the observed O_3 loss rates [85.36].

85.4.3 Arctic Ozone Loss

The region around the North Pole does not appear to exhibit an ozone hole as severe as that found in the Antarctic. Several factors lessen the probability of a significant ozone hole developing in the Arctic. First, a stable polar vortex does not get well established due to increased atmospheric turbulence from the greater land surface area in the Northern Hemisphere. Second, temperatures during the Arctic winter do not get as cold as during the Antarctic winter, so that polar stratospheric clouds (PSCs) do not form as easily. As seen in the preceding section, the surfaces of PSCs play an essential role in the O_3 destruction mechanisms in the Antarctic.

However, ozone levels are showing 20–25% reductions during February and March [85.39] over a much larger area around the North Pole than in the South. Thus ozone destruction is taking place during the transition from polar winter to spring in the Arctic but the phenomenon is more widespread, diffuse, and not as well-contained as in the Antarctic.

85.4.4 Global Ozone Depletion

Over the last twenty-five years, satellite instruments have measured the total ozone column in the atmosphere. During this time ozone levels have been steadily decreasing globally, especially at mid- to high-latitudes. Recent analysis indicates the first evidence of recovery of stratospheric ozone levels, with diminished rates of ozone loss at altitudes of 35–45 km, coupled with a slowdown in the increase in stratospheric loading of chlorine [85.40].

Heterogeneous reactions on aerosol surfaces, as well as the homogeneous gas phase chemical cycles mentioned earlier, must be invoked to explain the global decline in ozone levels. A particularly important reaction appears to be the hydrolysis of N_2O_5 on sulfate aerosols. This occurs very rapidly, converting reactive nitrogen, NO_2, into its reservoir species HNO_3:
$$N_2O_5 + H_2O \xrightarrow{\text{sulfate aerosol}} 2HNO_3 \ . \qquad (85.17)$$

The N_2O_5 is formed at night by reaction of NO_2 and NO_3. Following the hydrolysis of N_2O_5, there is less reactive NO_2 around to convert ClO into its reservoir species, $ClONO_2$, and less NO_2 around to convert OH into the reservoir species, HNO_3. A heightened sensitivity of the ozone to increasing levels of CFCs develops [85.41]. It has been shown that certain regions of significantly depleted ozone also show high concentrations of sulfate aerosols. In addition, measurements of the ratio of catalytically active nitrogen to total nitrogen can be reproduced using the above heterogeneous reaction, and not by using gas phase processes alone. Study of further mechanisms at varying altitudes and latitudes is an active area of research.

Record low global ozone measurements, 2% to 3% lower than any previous year, were reported beginning in 1992 [85.42] and continuing well into 1993. The increase in naturally occurring aerosols due to the eruption of Mount Pinatubo in June 1991 appears to explain this decline. During the winter of 1993–1994, total ozone levels returned to levels slightly above normal [85.43], presumably because the excess aerosols had been removed from the stratosphere by natural sedimentation processes.

The continuing buildup of CO_2 is predicted to contribute to increased cooling of the stratosphere. Declining temperatures in the stratosphere may increase the frequency of formation of polar stratospheric clouds which drive the destructive heterogeneous chemistry creating the Antarctic ozone hole. An increased occurrence of these clouds outside of the polar regions could affect ozone levels globally. There are also indications that certain ozone depletion chemistries taking place on the surface of sulfate aerosols may also be enhanced by lower temperatures [85.41].

Ozone itself is the dominant heat source in the lower stratosphere. Decreasing the amount of ozone drives temperatures still lower [85.44]. It is unfortunate that the two most significant atmospheric global change effects — the buildup of CO_2 and the enhanced ozone destruction due to man-made CFCs — both cause decreasing temperatures in the stratosphere which may further enhance the destructiveness of the ozone photochemical cycles.

85.5 Atmospheric Measurements

Ground-based observations, as well as measurements made by instruments carried aloft in satellites, balloons, and high-flying aircraft, allow one to explore the atmosphere.

Measurements may be made either in situ or by remote-sensing techniques. The region of the atmosphere from $\approx 60\,\mathrm{km}$ to $120\,\mathrm{km}$, encompassing the mesosphere and lower thermosphere and ionosphere, cannot be studied in situ as it is too high for balloons and aircraft, and too low (i. e., too much drag) for satellites. For this region, remote sensing experiments are essential and a comprehensive book on the subject is recommended [85.45].

Most of the instruments used to make atmospheric measurements have been developed in molecular physics and spectroscopy laboratories. Even experiments utilizing sophisticated techniques, such as laser induced fluorescence, and instruments, such as Fourier transform spectrometers, are being flown on payloads. An excellent compendium of ozone-measuring instruments for stratospheric research has been assembled by *Grant* [85.46].

A combination of good laboratory experiments, theoretical calculations, and ingenuity are necessary to extract accurate information from measurements made in the atmosphere. For instance, in order to understand the complicated interactions of the different photochemical cycles involved in ozone chemistry, spectroscopic emissions and absorptions of the many trace species are used to measure concentration profiles. An accurate knowledge of the emission spectroscopy of species such as OH, HO_2, H_2O_2, H_2O, O_3, HNO_3, NO_2, N_2O, N_2O_5, HNO_3, $ClNO_3$, BrO, HCl, $HOCl$, and ClO is essential. Such measurements provide a rigorous test of atmospheric models. The recently-launched NASA EOS Aura satellite carries instruments that will make global measurements of a number of these species [85.47].

In order to analyze the data and deconvolve some of the line profiles to give information on concentrations as a function of altitude, molecular data such as line strengths and pressure broadening coefficients are needed [85.9].

Until recently, it has been impossible for remote-sensing experiments to distinguish between ozone occurring in the stratosphere (where it is formed naturally) and ozone occurring in the troposphere (where it is a pollutant). Satellite instruments such as the ESA Global Ozone Monitoring Experiment (GOME), the Scanning Imaging Absorption Spectrometer for Atmospheric Chartography (SCIAMACHY) and the Ozone Monitoring Instrument (OMI) have broad enough spectral coverage and high enough resolution that the temperature dependence of the ozone absorption features from $300-340\,\mathrm{nm}$, known as the Huggins bands, can be used to separate out the ozone concentrations in the middle and lower atmospheres [85.48, 49].

86. Atoms in Dense Plasmas

When plasma densities are high enough that inter-particle separations are comparable to atomic dimensions, there are important "environmental" consequences for atomic structure and atomic processes. Such conditions are found not only within stars and giant planets but, nowadays, also in the laboratory − especially in experiments related to the quest for inertial confinement fusion. After introducing important plasma concepts, we examine these consequences in regard to several issues: modification of atomic bound states, ionization balance, equation of state, and radiative and collisional processes that regulate transport coefficients and the spectral emission of non-equilibrium plasmas. Finally, we describe modern simulation methods that are being used to tackle various many-body problems in this subject. For nearly every issue we raise there is a need for better

understanding and for more, and more precise, data.

Ionized gases, or plasmas, are the predominant form of matter throughout the universe, and physical conditions in laboratory and cosmic plasmas vary greatly. No single experimental methodology or theoretical construct suffices to explore all aspects of the plasma state.

Systematic study of plasmas began early in the 20th century, but until recently the physics of atoms in plasmas has been largely synonymous with the physics of isolated ions. This perspective is valid as long as the interparticle spacing is very much larger than the relevant atomic dimensions, typically a few to a few tens of Bohr radii. For example, ions are isolated in this sense in interstellar space where the electron density $n_e \approx 1\,\mathrm{cm}^{-3}$, or even in a tokamak, where $n_e \approx 10^{14}\,\mathrm{cm}^{-3}$. For neutral and moderately charged atoms, data such as energy levels, oscillator strengths, and collision cross sections have long been obtained from traditional kinds of experiments and quantal calculations, as discussed elsewhere in this book. Progress in these areas continues to be made, with the X-ray spectrum of highly-charged Fe [86.1] and the Lamb shift in U^{+91} [86.2] being noteworthy examples of the kinds of accurate measurements that can now be made using electron beam ion traps and storage rings.

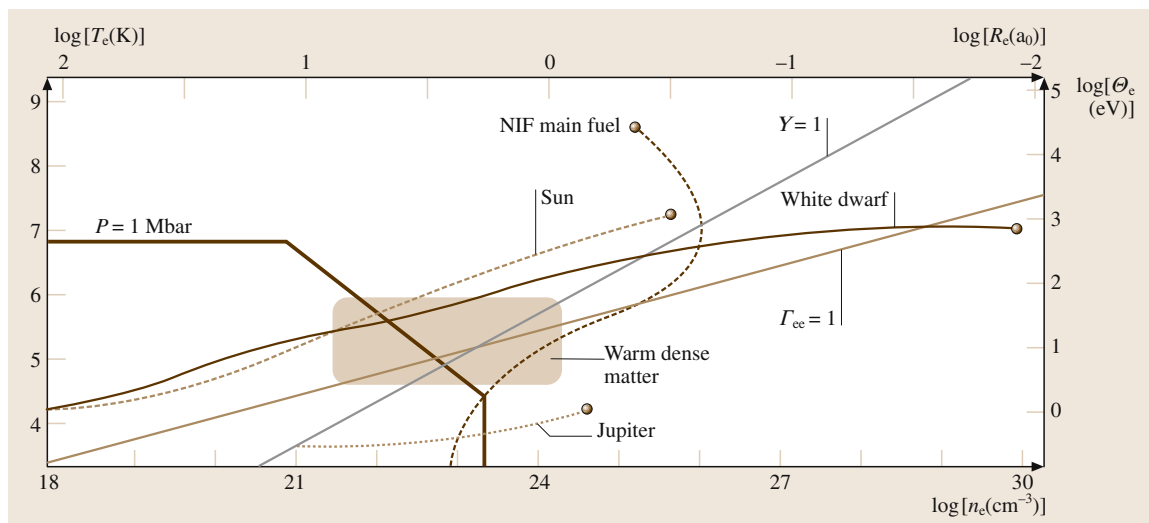
The focus of the present chapter is partially ionized matter in which important atomic phenomena are influenced by a dense plasma environment. As Fig. 86.1 (which is discussed in detail below) reveals, the densities in many laboratory and astrophysical plasmas are high enough to invalidate the presumption of isolated systems. The interaction of intense laser or particle beams with solid matter produces rapidly evolving, hot, and dense plasmas [86.3] that mimic some of the most extreme conditions in nature, including the thermonuclear environment of stellar interiors; these plasmas, as well as some produced in z-pinch implosions [86.4], are the basis of world-wide inertial confinement fusion (ICF) efforts. Dense plasmas also can be transient gain media for amplified spontaneous emission at X-ray wavelengths [86.5]. Additional impetus for the study of atoms in dense plasmas now comes from experiments involving irradiation of solids by ultra-short (sub-picosecond) laser pulses [86.6]. The moderate temperatures (tens of eV) but high (near-solid) densities typical of this so-called warm dense matter (WDM) regime [86.7] produce severely perturbed bound ionic states.


Fig. 86.1 Plasma conditions discussed in the text are identified on this temperature-density plane. Plasmas below the line $\Gamma_{ee} = 1$ are strongly coupled, and those below the line $\Upsilon = 1$ contain degenerate electrons. The HEDP regime, which lies above and to the right of the line marked $P = 1$ Mbar, includes some conditions characteristic of warm dense matter. Also plotted are tracks representing conditions (as a function of radius) within the Sun, Jupiter and a typical white dwarf star; time-dependent conditions are also shown – from early compression through ignition – within the main (DT) fuel of a prototype target capsule for the National Ignition Facility

Dense cosmic plasmas – specifically, the interiors of stars and giant planets – are very large and have very long lifetimes. Their thermodynamic variables change only slowly with position or time and, hence, macroscopic regions can be considered as statistical systems evolving through a succession of states in local thermodynamic equilibrium (LTE). The equation of state (EOS), and the radiation and heat transport coefficients, viz. the opacity and thermal conductivity, are key to understanding the behavior of LTE plasmas. A recent monograph [86.8], plus comprehensive articles by *More* et al. [86.9], by *Rogers* and *Iglesias* [86.10], and by *Saumon* et al. [86.11] discuss many of the high density consequences for the opacity and for EOS.

In contrast, the short lifetimes of dense plasmas created by intense beam irradiation or by explosive pinch devices often preclude the establishment of a thermal distribution of atomic level populations; in extreme cases, there is not even enough time to establish a Maxwellian distribution of particle velocities. Populations in highly nonequilibrium (non-LTE) laboratory plasmas, which must be found by solving rate equations [86.12, 13], are essential information for using X-ray line emission to diagnose conditions in ICF targets, or for identifying likely gain media for X-ray lasing. And, as we discuss in Sect. 86.3, the dense

plasma environment modifies transition rates themselves, further complicating the interplay of numerous collisional and radiative processes in such atomic kinetics calculations.

The topics addressed here are needed for understanding non-LTE situations, as well as LTE ones. After characterizing the perturbing plasma environment in Sect. 86.1, we summarize well-known prescriptions for atomic structure and ionization balance in Sect. 86.2, and then discuss modified transition rates in Sect. 86.3 for ions in dense plasmas. Finally, we review in Sect. 86.4 how simulations are now being used to address a wide array of issues needed to accurately describe atoms in dense plasmas.

There are several periodic meetings devoted to various aspects of this subject, and especially relevant ones include: Atomic Processes in Plasmas; Radiative Properties of Hot, Dense Matter; Spectral Line Shapes; and Strongly Coupled Coulomb Systems. Printed proceedings of these conferences are an excellent guide to recent developments in the topics discussed here, as well as numerous other, related ones. Additionally, three recent textbooks [86.14–16] provide detailed treatments of many of the subjects surveyed here.

The present topic is an important part of what is now being termed "high energy-density physics"

(HEDP). Conventionally this interdisciplinary subject, which involves collective and/or non-linear phenomena in many-body systems, is defined as the study of matter in regimes where the total (matter plus electromagnetic field) pressure exceeds one megabar; this boundary is also marked in Fig. 86.1. Reference [86.17] is a recent National Research Council report on key issues and opportunities in HEDP.

86.1 The Dense Plasma Environment

Most plasmas are charge neutral, so the mean number densities n_i and n_e of constituent ions (charge $Z_i e$, mass m_i) and electrons (charge $-e$, mass m_e) satisfy

$$\sum_a Z_a n_a = 0 \, , \tag{86.1}$$

where the sum ranges over all particle species. Moreover, plasma conditions usually change slowly enough that each of the species is able to establish a thermal distribution of velocities, fixed by its temperature $\Theta_a = k_B T_a$ (in energy units). Here, we assume these conditions hold.

86.1.1 Plasma Parameters

A few key quantities characterize the plasmas under consideration. Derivations, and discussions of the roles of these and other auxiliary quantities can be found in standard plasma physics texts [86.18, 19], as well as a recent tutorial article [86.20].

1. The plasma frequency

$$\omega_p = \left[\sum_a 4\pi n_a (Z_a e)^2 / m_a \right]^{1/2}$$
$$= \left(\sum_a \omega_a^2 \right)^{1/2} \tag{86.2}$$

defines a timescale $\left(\sim \omega_e^{-1} \right)$ for the particle oscillations in response to a non-equilibrium charge density in the plasma.

2. The Debye length

$$\lambda_D = \left[\sum_a 4\pi n_a (Z_a e)^2 / \Theta_a \right]^{-1/2}$$
$$= \left(\sum_a D_a^{-2} \right)^{-1/2} \tag{86.3}$$

is the distance beyond which plasma particles effectively screen any localized charge imbalance.

3. The ion-sphere (or electron-sphere) radius

$$R_a = \left(\frac{3}{4\pi n_a} \right)^{1/3} \tag{86.4}$$

defines a spherical volume associated with a single particle and is a measure of interparticle spacing (among particles of species "a").

4. The Fermi energy

$$\Theta_F = \frac{\hbar^2 \left(3\pi^2 n_e \right)^{2/3}}{2 m_e} \tag{86.5}$$

characterizes the highest occupied energy level in a zero temperature system of electrons. A dimensionless measure of degeneracy is $\Upsilon = \Theta_F / \Theta_e$. Velocity distributions are either Maxwellian or Fermi–Dirac in the limits $\Upsilon \ll 1$ or $\Upsilon \gg 1$, respectively.

5. The Coulomb coupling parameters

$$\Gamma_{ab} = \frac{Z_a Z_b e^2}{R_{ab} \Theta_{ab}} \tag{86.6}$$

give the average ratio of potential to kinetic energies between species a and b. The reduced ion-sphere radius and temperature are $R_{ab} = \frac{1}{2}(R_a + R_b)$ and $\Theta_{ab} = (m_a \Theta_b + m_b \Theta_a)/(m_a + m_b)$, respectively. When Γ_{ab} is greater (less) than 1, that species is said to be strongly (weakly) coupled. And, when the number of particles a in a sphere of radius D_a (a Debye sphere), $\left[4\pi n_a D_a^3 / 3 \right] = 1/(3\Gamma_{aa})^{3/2}$, is small, discreteness of the charge density can be important in describing certain plasma phenomena.

Figure 86.1 shows that dense plasmas can be strongly or weakly coupled; further, some of these plasma conditions involve degenerate electrons while others do not. And, in WDM, one encounters the situation where $\Upsilon \sim 1$ and $\Gamma_{ee} \sim 1$, which is particularly difficult to treat theoretically because several effects are competing amongst each other. In this figure, we plot the run of (n_e, Θ_e) values for the sun, for Jupiter, and for a typical white dwarf star (0.6 solar mass, pure C/O core, H/He outer layers). Also plotted is the track of DT fuel conditions in an imploding ICF capsule designed for the National Ignition Facility. Note that all of these systems sample wide portions of parameter space, and therefore an accurate description of each requires some very different plasma models.

86.1.2 Quasi–Static Fields in Plasmas

A simple, yet useful description of the plasma environment is given by the one-component plasma (OCP) model [86.22], in which particles of a single kind (Z_a, m_a) move against a smooth background of matter having on average the opposite charge density, $\rho(r) = -Z_a e n_a$. Most plasma phenomena can be described within the context of either this or the two-component model (electrons and their parent ions, with $n_i = n_e / Z_i$). In the more realistic, two-component picture, electron screening of the (slower moving) ions is established on a timescale $\omega_e^{-1} \ll \omega_i^{-1}$, so it makes sense to speak of screened, quasi-static ionic fields.

When there are many electrons in each Debye sphere, the electrostatic potential $\Phi(r)$ near a test charge Ze placed in an otherwise uniform, neutral plasma is exponentially reduced from the Coulomb expression, viz.,

$$\Phi_D(r) = \frac{Ze}{r} \exp\left(-r/D_e\right) . \tag{86.7}$$

(A more elaborate version of this formula, for partially ionized atoms, has recently been proposed [86.23].) This "Debye screening" obtains only in weakly coupled plasmas and applies only to a test charge at rest. The faster the charge Ze moves, the less effective is the plasma at screening it, since only plasma particles with higher velocities can form the shielding cloud [86.18, 24].

In the opposite limit of large Γ-values, quasi-static screening is better described by the ion-sphere (IS) picture [86.19], in which each stationary ion of charge $Z_i e$ is surrounded by Z_i electrons, uniformly distributed throughout a sphere of radius R_i, to produce the potential

$$\Phi_{IS}(r) = Z_i e\left[1/r - (1/2R_i)\left(3 - r^2/R_i^2\right)\right] \tag{86.8}$$

inside the sphere, and zero potential outside.

Consideration of a plasma's electric microfield illustrates these concepts. Moreover, microfields are a key ingredient in calculations of spectral line broadening in plasmas – an important subject discussed in Chaps. 59, 19 and in [86.14–16].

Local fluctuations in the density of any species about its mean value n_a create a microscopic electric field $\tilde{E}_a(r, t)$. There is a probability distribution $P(\tilde{E}_a)$ that characterizes the strengths of these microfields, which are quasi-static within time intervals short compared with the fluctuation timescale, $1/\omega_i$. Holtsmark first calculated this distribution at an arbitrary position in an infinite, isotropic gas of noninteracting particles, and *Chandrasekhar* [86.25] gives a thorough account of this famous stochastic problem. Holtsmark's formula is

$$P_H(\varepsilon) = (2\varepsilon/\pi) \int\limits_0^\infty x \sin(\varepsilon x) \exp\left[-x^{3/2}\right] dx , \tag{86.9}$$

where $\varepsilon = \tilde{E}_a / \left[(8\pi/25)^{1/3} E_a\right]$ is the scaled field, and $E_a = |Z_a| e / R_a^2$. The mean Holtsmark field is $\langle \varepsilon \rangle \simeq 2.99$, and for $\varepsilon \gg 1$, $P_H(\varepsilon)$ is well approximated by the distribution of fields due to a single nearest-neighbor in the gas,

$$P_{nn}(\varepsilon) \simeq 3/\left(2\varepsilon^{5/2}\right) . \tag{86.10}$$

Both of these distributions ignore the interactions among charged particles that become increasingly important as Γ_{ii} grows, because particle positions then tend to be correlated. Quasi-static ion microfields – at the position of an ion – therefore become weaker, on average, as the coupling increases. Figure 86.2 illustrates this point and shows distributions computed with the
Fig. 86.2 The probability distribution $P(\varepsilon)$ of scaled microfield strengths ε for different plasma conditions. The curve marked H represents the Holtsmark distribution, which applies to an idealized case of non-interacting particles (i. e., $\Gamma = 0$). The other two curves, with $\Gamma = 0.2$ and $\Gamma = 2.0$, represent distributions determined by the APEX model for interacting ions (charge $Z = 1$) that are Debye-screened by plasma electrons. In these latter two cases, the ion density and temperature are, respectively, $1.0 \times 10^{18}\,\text{cm}^{-3}$ and $1.15\,\text{eV}$, and $2.6 \times 10^{24}\,\text{cm}^{-3}$ and $16\,\text{eV}$. After [86.21]

APEX method [86.26, 27], which uses a parameterized, two-particle distribution function "tuned" to yield the exact second moment $\langle \varepsilon^2 \rangle$ for the distribution function of field strengths experienced by any one ion in a plasma whose ions are all Debye-screened by electrons only.

The potentials and microfields discussed above are based on classical statistical mechanics, even though dense plasmas are inherently quantum many-body systems. Reference [86.28] provides a careful discussion of the merits and limitations of this approach.

86.1.3 Coulomb Logarithms and Collision Frequencies

It is well known that the total cross section for elastic scattering of two charged particles, $Z_a e$ and $Z_b e$, diverges at any collision energy ε, as a consequence of the infinite range of the Coulomb interaction. Plasma transport coefficients (e.g., electrical conductivity and thermal conductivity), however, which depend ultimately upon momentum transfer in this elementary process, are finite. This comes about because scattering at small center-of-mass angles ϕ, or, correspondingly, at large impact parameters b, is diminished by plasma screening, as in (86.7) and (86.8).

Following *Spitzer* [86.29], we argue that there is some minimum effective scattering angle $\phi_{\min}$. And, since the analysis will be based on classical formulae, there is some maximum scattering angle $\phi_{\max}$ beyond which quantum effects are important. Between these limits the Coulomb interaction is taken to be unscreened and Rutherford's differential cross section $\sigma_R(\phi)$ is applicable. By assuming that $\phi_{\max}$ also is small, it follows that the momentum transfer cross section can be approximated as

$$\sigma_m(\varepsilon) = 2\pi \int_{\phi_{\min}}^{\phi_{\max}} d\phi \, [\sin\phi \, (1 - \cos\phi) \, \sigma_R(\phi)]$$

$$\approx \pi a^2 \ln\left(\frac{\phi_{\max}}{\phi_{\min}}\right) , \tag{86.11}$$

where $a = |Z_a Z_b e^2| / \varepsilon$ is a characteristic length. The familiar result $(a/2b) = \tan(\phi/2) \approx (\phi/2)$ gives σ_m in terms of minimum and maximum impact parameters, $b_{\min} = a$ (from $\phi_{\max} = 1$) and $b_{\max} = \lambda_D$.

Finally, if the actual collision energy in the argument of the logarithm, (λ_D/a), is replaced by its mean value, $\varepsilon = \frac{3}{2}\Theta$, the momentum transfer cross section takes the simple form

$$\sigma_m(\varepsilon) = \pi \left(\frac{Z_a Z_b e^2}{\varepsilon}\right)^2 \ln \Lambda ; \tag{86.12}$$

for a two-component, electron-ion plasma, the argument of this Coulomb logarithm is

$$\Lambda \approx 1/2 \, \Gamma_{eZ}^{3/2} \approx (\text{\# particles in Debye sphere}) . \tag{86.13}$$

Spitzer's result for σ_m yields the simplest expression for the frequency ν_{eZ} of electron-ion collisions in a two-component plasma, defined [86.18] as the mean value of the reciprocal of the time between collisions,

$$\nu_{eZ} = \frac{n_Z Z^2 e^4}{\sqrt{m_e}} \left(\frac{\pi}{2\Theta}\right)^{3/2} \ln \Lambda . \tag{86.14}$$

Equation (86.12) is commonly used to determine transport coefficients in weakly coupled plasmas, where $\ln \Lambda \gg 1$. In the dense plasma regime, however, the Coulomb logarithm can be small or even negative at high enough density, which yields meaningless results for the cross section. Physically, a small $\ln \Lambda$ arises from a small λ_D (high density and/or low temperature), which means that collisions can only occur at very small separations where the Coulomb potential is largest. Strong collisions can be included in the above analysis simply by not making a small-angle approximation in the evaluation of the cross section; the result is [86.30]

$$\sigma_m(\varepsilon) = \frac{\pi}{2} \left(\frac{Z_a Z_b e^2}{\varepsilon}\right)^2 \ln\left[1 + \Lambda^2\right] . \tag{86.15}$$

In obtaining this result – which no longer yields a negative cross section – no assumption need be made about the value of $\phi_{\max}$. One must still choose, however, $b_{\max}$, which will not generally be given by λ_D, since Debye screening is invalid in the dense plasma regime. Strong collisions at small separations also bring in the effects of quantal scattering. These issues are best circumvented by obtaining the cross section directly from a quantal calculation involving the chosen screened potential [86.30, 31]. (Note that the formulae in [86.31] actually describe the scattering of one unscreened charge by another charge that is screened, so they are most relevant to the scattering of fast electrons by slow ions.)

Eventually, even this formulation will fail when plasma kinetic processes affect the collision. For example, hard collisions can alter the velocity distribution function and collective modes can modify

the static screened interaction potential. Furthermore, strong coupling introduces ionic structure that correlates the collisions. Accurate calculations must consider the collision process in the context of an appropriate kinetic equation [86.30, 32–34]. When such a process is carried out, the result can be inverted to yield "effective" or "generalized" Coulomb logarithms that typically are process dependent [86.18]. *Li* and *Petrasso* [86.32] obtained high-order correction terms for the Fokker–Planck equation, for example, and *Boercker* et al. [86.33] generalized the collision term in the Lenard–Balescu quantum kinetic equation to include strong coupling effects. Additionally, *Berkovsky* and *Kurilenkov* [86.34] extended the strong coupling description to also include "strong" collisions (those poorly treated within the Born approximation).

The physics of collisions is directly measured by resistivity experiments, which employ some method to heat a solid and attempt to tamp the high-pressure plasma that is formed. The resistivity is then measured either by the reflectivity or directly through current and voltage probes. A review of these methods has recently been given by *Benage* [86.35].

86.2 Atomic Models and Ionization Balance

A pervasive issue in the study of both laboratory and astrophysical plasmas is ionization balance: What is the distribution of charge states Z_i of atomic ions in a particular plasma? Answers impact subjects as diverse as cosmic abundances deduced from astrophysical spectra, and the temporal behavior of laser-heated foils. Table 86.1 lists the charge-state dependence of several plasma quantities [86.36]. Here, $\langle Z \rangle$ and $\langle Z^2 \rangle$ denote the mean and mean square ionic charge, respectively, viz.,

$$\langle Z^n \rangle = \sum_{\text{ions}} Z_i^n n_i \Big/ \sum_{\text{ions}} n_i \tag{86.16}$$

For a dense plasma, experimental determination of actual charge-state distributions, or even $\langle Z \rangle$, has proven difficult. Traditional spectroscopic methods (as described in the next section) require large atomic data bases and sophisticated kinetics models, which typically are run several times to find the best match to measured line shapes and intensities. Recently, however, an X-ray scattering method (based on the Compton effect) has been developed to determine $\langle Z \rangle$ in rapidly evolving plasmas [86.37]. Instead of detailed atomic data, this method requires accurate knowledge of the plasma's dynamic structure factor [86.18], which in general must be obtained from a molecular dynamics simulation (as discussed in Sect. 86.4).

86.2.1 Dilute Plasma Models

Consider a nondegenerate plasma in thermal equilibrium at a temperature Θ (for instance, some region of a star's interior). The time independent ionization balance for each element is given by the Saha–Boltzmann formula [86.38]

$$\frac{n_{Z+1}}{n_Z} = \frac{1}{n_e} \left(\frac{2G_{Z+1}}{G_Z} \right) \left(\frac{m_e \Theta}{2\pi\hbar^2} \right)^{3/2} \exp(-I_Z/\Theta) , \tag{86.17}$$

for the density ratio of successive charge states, where G_Z and I_Z are, respectively, the partition function and ionization potential for the Z-times ionized atom.

The solution of (86.17) is shown in Fig. 86.3 (top panel) for the case of solid density aluminum over a wide range of temperatures. The partition functions were determined from atomic states of the ground configuration only. The aluminum plasma is predominantly neutral at temperatures in the few electron volt range and ionizes stage by stage until it is nearly fully ionized just above one kilovolt. Of course, real aluminum is not an insulator at solid density and low temperatures, as Fig. 86.3 would suggest. Major corrections to (86.17) are evidently needed to incorporate the physics of WDM ($\Gamma \sim 1$, $\Upsilon \sim 1$), especially corrections for partial electron degeneracy. We will return to this problem in later subsections.

When conditions change too rapidly for LTE to be established, the plasma may evolve through a succession of "steady states" in which the relative abundances of dif-

Table 86.1 Some plasma quantities that depend on its ionization balance

Quantity	Z-scaling (fixed nucleon density)
(Ideal) gas pressure	$\sim (\langle Z \rangle + 1)$
Electrical resistivity	$\sim \langle Z^2 \rangle / \langle Z \rangle$
Thermal conductivity	$\sim \langle Z \rangle / \langle Z^2 \rangle$
Ionic viscosity	$\sim 1/\langle Z^2 \rangle^2$
Bremsstrahlung	$\sim \langle Z \rangle \langle Z^2 \rangle$

ferent ion stages are determined by a balance of certain ionization and recombination rates. Then, in order to answer the straightforward question of what are the relative abundances of atomic ionization stages, one needs a vast data base of atomic energy levels, plus collisional and radiative rates. A set of rate equations must be solved to determine the populations $n_Z(\alpha)$ for each quantum state α of each ion stage Z. Each equation involves transitions to and from all other states [86.12, 13].

The balance of photoionizations and dielectronic plus radiative recombinations in low-density, steady-state plasmas is termed nebular equilibrium, because these are the conditions appropriate to astrophysical nebulae – regions of ionized gas surrounding hot stars [86.39]. The balance of collisional ionizations and dielectronic plus radiative recombinations in low-density, steady-state plasmas is termed coronal equilibrium, because these are the conditions appropri-

ate to the solar corona. Most tokamak plasmas also are in coronal equilibrium. Under coronal conditions, essentially all ions are in their respective ground states and the ionization balance is a function only of the plasma temperature [86.40]. As the plasma density increases, three-body collisions become important, and the resulting steady-state ionization balance, which depends on density as well as temperature, is termed collisional-radiative equilibrium [86.12]. This situation exists in most ICF experiments.

Finally, conditions in sub-picosecond laser-plasma experiments can change so rapidly that none of the above simplifications apply. Ionization is strongly time-dependent, and may involve multiphoton processes.

As we describe below, a dense plasma environment vastly complicates the determination of ionization balance. In LTE cases, energy levels are changed and partition functions are truncated by the phenomenon of continuum lowering. In non-LTE cases these effects still occur, but, in addition, radiative and collisional rates themselves are altered.

86.2.2 Dense Plasma "Chemical" Models

There are two distinct strategies taken to extend the results of the previous section. One strategy, known as the "chemical picture", formulates the Saha–Boltzmann equation in terms of a free energy $F(T, V, \{n_a\})$, where the species populations $\{n_a\}$ are to be determined, and various corrections due to couplings and degeneracy can be added to yield a thermodynamically consistent equation of state that includes atomic physics [86.41].

Because plasma screening attenuates the Coulomb interaction at long range, atoms and ions no longer have an infinite number of bound (Rydberg) states, and atomic partition functions are truncated in a natural way. The simplest chemical picture is that the onset of continuum energies has been "lowered" by some amount ΔI (relative to the atom's ground state). When ΔI is a fixed quantity, continuum lowering eliminates bound states whose (unscreened) ionization potentials were less than ΔI, and moves all remaining states closer to the continuum by this same amount. Thus, levels get shifted but spectral lines do not. Schemes that use an effective, single-particle potential to determine a spectrum of modified eigenstates produce distinct plasma shifts for different levels and, hence, spectral line shifts. Experiments show, however, that almost all such predictions have been inaccurate: actual plasma-induced shifts are very small and, for most applications, ignorable ([86.14, Sect. 4.10], [86.15, Sect. 3.5]).
Fig. 86.3 The *top panel* shows fractional abundances of different charge states of aluminum in thermal equilibrium at solid density over a range of temperatures, as computed with the ideal Saha–Boltzmann equation (86.17). The corresponding mean charge $\langle Z \rangle$ is shown in the *lower panel*, in addition to the result from Thomas–Fermi theory, as given by (86.18). Also shown is a modified Saha formulation that includes continuum lowering shifts

A variety of arguments has been put forth to quantify continuum lowering, including in particular:

1. determine ΔI from the last distinct spectral line near a series limit (the Inglis–Teller formula [86.42]);
2. determine ΔI from the atom's dipolar interaction with the plasma's microfield [86.41];
3. determine ΔI from the binding energy of the ground state in some specified, screened Coulomb potential [86.43, 44];
4. determine ΔI from a rigorous, statistical mechanical treatment of the atomic partition functions [86.45].

Figure 86.3 (lower panel) illustrates the effect of continuum lowering on the average ionization state $\langle Z \rangle$; here, we solve (86.17) for solid density aluminum with the ionization potentials shifted by an amount determined by electron screening in the Debye approximation, $\Delta I = \langle Z \rangle e^2 / D_e$. Although we do not plot $\langle Z \rangle$ for this case when the number of particles in a Debye sphere is less than ten, it is obvious that a somewhat higher degree of ionization exists when continuum lowering is accounted for.

A recent experiment [86.46] suggests that the Inglis–Teller prescription for line merging accurately describes the disappearance of the uppermost members of a spectral series. But simply truncating the number of bound states and, hence, the internal partition function, does not yield a self-consistent thermodynamic description of the plasma [86.41, 47]. In this regard, the true situation in dense plasmas is far more complicated for two reasons, and both give rise to a gradual disappearance of high-lying bound states.

First, excited ionic states can be strongly perturbed by one or more nearby ions, which means that (as the density increases) bound, quasi-molecular states form and eventually evolve to a conduction band. Models with names such as "incipient Rydberg states" [86.48], "quasi-localized states" [86.45], "cluster states" [86.49], "negative-energy continuum states" [86.50], and "collectivized states" [86.51] have been developed to capture the complicated physics of this intermediate regime. Second, space- and time-dependent density fluctuations give rise to different perturbing configurations, which means that the plasma is more accurately described by the average of an ensemble of perturbed ionic states than by the individual states of an ion experiencing the mean (usually spherical) perturbation. In the chemical picture, the most common approach [86.41, 51, 52] reduces the effective statistical weight of each (unperturbed) ionic state by a factor representing the probability that the plasma's microfield is sufficiently strong to Stark ionize it.

The actual inclusion of dynamical plasma screening effects on ionic bound states requires a much more elaborate model [86.53] that, as yet, has not been incorporated into computer codes simulating high energy-density plasma experiments. Other computational studies, involving simple continuum lowering prescriptions [86.54, 55], indicate that an accurate treatment of this phenomenon is essential for understanding non-LTE, as well as LTE, situations.

86.2.3 Dense Plasma "Physical" Models

An alternative strategy abandons the distinction between atomic and plasma electrons; this is known as the "physical picture" [86.47]. The simplest model that accomplishes this is that of a nucleus centered in a charge-neutral, spherical cell of radius R_s. An electronic structure calculation for the total electron density $n_e(r)$ at temperature Θ, subject to the boundary condition $\mathrm{d}n_e(R_s)/\mathrm{d}r = 0$, is carried out and, once the density is known, various physical quantities can be obtained. The advantage of this approach is that effects such as continuum lowering and degeneracy are naturally and self-consistently incorporated. Models of this kind are referred to as either "statistical" models or as "average atom" (AA) models depending on the manner in which the electronic structure is determined. The accuracy of the approach depends on both the sophistication with which the density is computed and the validity of the spherical cell boundary condition.

The simplest way to obtain the electronic density is with a statistical model, such as the finite-temperature Thomas–Fermi approximation and its various extensions to include exchange ("Thomas–Fermi–Dirac") and gradient corrections ("Thomas–Fermi–Dirac–Weizsacker"); these models are covered in detail in Chapt. 20 for free atoms at $\Theta = 0$. Briefly, the Thomas–Fermi (TF) model describes atomic charge densities by treating all electrons as a partially degenerate Fermi gas subject to a spherical, self-consistent electrostatic potential $\Phi_{\mathrm{TF}}(r)$ resulting from the nuclear charge $Z_n e$ and the electrons themselves. Given the simplicity of the TF model, agreement with experiment (for binding energies) is surprisingly good, usually well within a factor of two for the thousands of ions in the periodic table.

Feynman and coworkers [86.56] were the first to use such models to describe hot, compressed atoms and their thermodynamic properties. Quantities such as the

internal energy, free energy, and pressure are readily computable. Extended Thomas–Fermi models are useful for describing properties of matter in dense, cold stars [86.57], for example. As we have emphasized, a quantity of particular interest is the average ionization state $\langle Z \rangle$ of the plasma, which can be determined from the electronic density that extends from cell to cell, viz.,

$$\langle Z \rangle = \frac{4\pi}{3} R_s^3 n_e(R_s) . \tag{86.18}$$

The definition (86.18) is not unique, however, and some authors prefer to define bound electrons as all those in negative energy states [86.58, 59].

It is interesting to note that this intuitive definition of $\langle Z \rangle$, (86.18), is considerably different from that used in the Saha formulation. This $\langle Z \rangle$ generally will have a nonzero value even at $\Theta = 0$, a phenomenon known as "pressure ionization," because the ionization occurs solely due to the finite value of R_s. More [86.59] published a convenient prescription for finding ionization potentials and total energies, as predicted by the TF model, of ions with net charge $Z_i e$ between $0.1 Z_n e$ and $0.9 Z_n e$. In the lower panel of Fig. 86.3 we show $\langle Z \rangle$ based on the More/TF result. There is general agreement with Saha at high temperatures, where ionic bound states are much smaller than the interparticle spacing, but important differences occur at low temperatures.

Average atom models extend the statistical models by directly employing the Schrödinger equation for the electron structure. Typically, a self-consistent electronic structure calculation is carried out such that the single-particle levels are thermally populated according to a Fermi–Dirac distribution. These models describe atomic shell structure, which is absent in the statistical models. Modern versions of AA are detailed quantum mechanical calculations based on, usually, finite-temperature density functional theory (DFT), with some approximation for the exchange-correlation potential. A good review of the finite-temperature DFT approach has been given by *Gupta* and *Rajagopol* [86.60], and [86.61] contains several numerical comparisons. This approach was pioneered by *Rozsnyai* [86.62, 63], who employed a TF approximation for the free electrons, and by *Liberman* [86.64] who constructed an AA based on a self-consistent field model with a thermal population of Dirac orbitals for all states.

There are two major weaknesses of the AA method. First, the spherical cell neglects asymmetrical ionic configurations in the plasma and assumes that no ion can penetrate within the radius R_s. And, the AA does not straightforwardly yield the distribution of ionic stages, which is important for opacity and transport calculations. *Ying* and *Kalman* [86.65] have introduced a model that addresses the $\langle Z \rangle$ issue while also incorporating strong ionic correlations from neighboring ions. A DFT-based model that describes both strong coupling and the distribution of ionic stages also has been published [86.66].

86.3 Elementary Processes

In a truly equilibrium plasma, atomic transitions do not modify the plasma's physical state. However, the evolution of LTE and nonequilibrium plasmas is regulated by the time rate of change of quantities such as Θ and n_e, and these in turn depend on transport coefficients such as the radiative opacity and the thermal conductivity.

The processes controlling these coefficients are induced by various radiative and collisional interactions. Indeed, so many processes can occur that a major task is the identification of those which are most important in a particular situation. The plasma environment may also alter rates applicable to isolated atoms, through the perturbation of the atomic states involved and/or the screening of long-range Coulomb forces. Further complicating the usual two-body collision picture is the close proximity of many scattering centers in a dense plasma. Presently, analysis of any of these many-body problems requires considerable simplification.

86.3.1 Radiative Transitions and Opacity

For a radiative transition between atomic states α and β, the absorption and emission rates are proportional to quantities of the form $(\Delta E)^n |\langle \alpha | \boldsymbol{d} | \beta \rangle|^2$ summed over degenerate substates, where $\boldsymbol{d}$ is the electric dipole operator Chapt. 10, and $n = 1$ or 3 for the Einstein B and A coefficients, respectively. In a dense plasma, changes in these radiative quantities are due primarily to changes in the atomic wave functions. Theory predicts that plasma screening reduces line strengths, and that the reduction factor increases toward the series limit [86.67, 68].

Also, the cross section for photoejection of an electron bound by any screened Coulomb potential must vanish at threshold – in marked contrast to the nonzero photoionization cross sections of isolated atoms and ions. Since the oscillator strength sum rule still holds, any diminution of the total bound-bound oscillator strength must be offset by an increase in the bound-free contribution; continuum lowering partly accounts for this latter increase.

Spectroscopic observations of the reduction of decay rates by plasma screening have been reported [86.69]. But, the plasma densities evidently were too low for this effect to clearly manifest itself, and alternative explanations have since been given [86.70, 71]. In addition, there is the more fundamental question of whether static screening models are even appropriate for the description of radiative processes. As discussed below, this issue also arises in connection with inelastic collision processes in dense plasmas.

Several large-scale computer codes are in wide use to calculate the opacity of hot, dense matter (in LTE). Among these, we note the code HOPE [86.62], which is based on the average atom model; the code LEDCOP [86.72], which uses accurate (Hartree–Fock) atomic term data; and the code OPAL [86.73], which uses detailed configuration accounting and parametric, (static) screened potentials to compute wave functions and energy levels. Also, there are some published results from the new code IDEFIX [86.74], which is based on a non-spherical (di-center) screened potential arising from the radiating ion and its nearest neighbor. When making comparisons among these models, it should be realized that the codes use quite different line-broadening and continuum lowering prescriptions.

86.3.2 Collisional Transitions

Various screened Coulomb interactions also can be used to study plasma effects on inelastic scattering. References [86.31, 75] and citations therein use either Debye or ion-sphere potentials, and Born, distorted-wave, or close coupling approximations, to investigate excitation processes in plasmas; however, bound states were left unperturbed. More elaborate static potentials and perturbed bound states were treated by *Davis* and *Blaha* [86.76, 77], but they did not self-consistently screen the interaction between projectile and target. For excitations involving a small transition energy ΔE, *Kitamura* [86.78] has recently published a self-consistent treatment of both (1) the quasi-static perturbations of

the target ion by the microfield, and (2) the dynamically screened electron-target interaction.

The use of static screening models is invalid when $\Delta E \gg \hbar\omega_e$ because the collision duration is too short for any average description of the plasma's screening to apply. In such cases, ionization being a particular example, one must consider the response of the target to electrodynamic disturbances [86.79]. Reference [86.80] gives a thorough discussion of this issue, and presents numerical examples of the effects of projectile and target screening in ionizing collisions.

Bremsstrahlung is another important plasma collision process for which static screening models have been extensively used [86.81–83]. Unfortunately, most bremsstrahlung radiation emanating from hot plasmas represents free–free transitions in which $\Delta E \gg \hbar\omega_e$ (lower frequency emission being attenuated), and in these situations static screening models are suspect. In contrast, the formation of laser plasmas occurs mainly through inverse bremsstrahlung (free–free absorption) under conditions such that $\Delta E = \hbar\omega_{\text{laser}} \gtrsim \hbar\omega_e$, making static screening models relevant here.

More sophisticated treatments of bremsstrahlung in dense plasmas [86.84–86] include one or more of the following: strong coupling effects among the plasma ions (introduced via radial distribution functions [86.22]), dynamic screening effects involving the electrons (introduced via frequency-dependent dielectric response functions [86.18]), possible degeneracy effects (introduced via Fermi–Dirac distribution functions for occupation probabilities of initial and final states), and only partial screening of the nuclear charge by the target ion's bound electrons (introduced via a form factor for the target (Chapt. 56)). Calculations for plasmas with moderate coupling parameters ($\Gamma \le$ few) reveal that the first three of these effects tend to reduce free-free emission and absorption rates, while the last effect tends to enhance the rates. At larger Γ-values, strong ion-ion coupling tends to drive these rates back up [86.87].

Advances in simulation capability (which we discuss next) are yielding ever more realistic descriptions of the dense plasma environment, but what is proving difficult to improve upon is the ubiquitous use of the Born approximation to treat all electron-ion scattering events (see, however, *Berkovsky* and *Kurilenkov* [86.34]). Strong collisions, i. e., those in which the photon energy $\hbar\omega$ is comparable with the relative kinetic energy of the collision, are particulary important for radiative losses from plasmas, but these also are just the collisions most likely to be poorly described by the Born approximation.

86.4 Simulations

Most of the challenges pertaining to atomic phenomena in dense plasmas arise from the many-body nature of the atom-plasma interaction. Simple models are therefore subject to inaccuracies that may arise from inconsistencies or severe approximations which, in turn, degrade our understanding of experimental data. Because of this complexity, simulations are playing an increasingly important role in this field.

Historically, simulations of dense plasmas have used simplified plasma models to address issues ranging from equations of state [86.88, 89] to plasma microfields [86.27, 28, 90]. Atomic physics is typically ignored within the simulation by assuming that an average charge $\langle Z \rangle$, somehow known, can be assigned to each ion. For these simulation methods, there are many excellent textbooks that introduce the basic ideas [86.91–93]. Here, we focus instead on simulations that attempt to describe both the dense plasma and the atomic physics self-consistently. These simulation methods are categorized in terms of the underlying algorithm used and fall either into Monte Carlo or molecular dynamics methods; we discuss each in turn.

86.4.1 Monte Carlo

Monte Carlo is a method to evaluate average quantities in thermodynamic equilibrium using random numbers. For example, to obtain a property of a classical system we might write

$$\langle \mathcal{O} \rangle = \frac{\int d^{3N}r \, d^{3N}p \, \mathcal{O}\left(r^{3N}, p^{3N}\right) \exp\left(-\beta \mathcal{H}\right)}{\int d^{3N}r \, d^{3N}p \, \exp\left(-\beta \mathcal{H}\right)} \, , \tag{86.19}$$

and, in principle, we could sample the multidimensional integral randomly to obtain a good estimate of the average value of $\mathcal{O}$ given a many-body Hamiltonian $\mathcal{H}$. In practice, however, there are large portions of phase space that give very little contribution to the average and some method of "importance sampling" must be carried out. This problem was originally solved by *Metropolis* and coworkers [86.94] who introduced the Metropolis method, which uses a Markov chain of states in phase space that preferentially migrates towards states of higher probability [86.92].

The computation of properties of atomic systems in dense plasmas requires a quantum Monte Carlo (QMC) method because atomic systems are inherently quantum systems and the plasma itself can be degenerate. Al-

though there are a variety of QMC methods [86.93, 95], the most important for our purposes is the path-integral Monte Carlo (PIMC) method, which is formulated at finite temperatures and, in fact, exploits this condition by constructing an equivalent system of many more particles at a higher effective temperature. This is achieved by writing spatial matrix elements of the quantal version of the Boltzmann factor of (86.19) as

$$\langle r | \exp\left(-\beta \hat{\mathcal{H}}\right) | r' \rangle$$
$$= \int d^3 r'' \, \langle r | \exp\left(-\beta \hat{\mathcal{H}}/2\right) | r'' \rangle$$
$$\times \langle r'' | \exp\left(-\beta \hat{\mathcal{H}}/2\right) | r' \rangle \, . \tag{86.20}$$

This expression can be used recursively to obtain matrix elements evaluated at higher and higher temperatures; this allows a high-temperature approximation to be made, albeit at the expense of having many more matrix elements to evaluate. It can be shown that in the simplest approximation each quantum particle can be replaced by a polymer of M classical particles linked by springs; this picture is referred to as the "classical isomorphism" [86.96]. All electrons in the system (bound and free) are treated on an equal footing.

Although the PIMC method is, in principle, simple to implement and can be quite accurate, there are several issues that arise when it is applied to dense plasmas. There are difficulties with the deep attractive Coulomb well that is crucial for describing atomic physics; this leads to the need for enormous numbers of fictitious classical particles. A partially analytical or numerical solution can greatly mitigate this problem [86.93, 97]. PIMC also suffers from difficulty when treating fermion systems because of the so-called fermion sign problem in which many terms of opposite sign arise from the antisymmetric form of the N-electron wave function. Progress has been made in this direction as well [86.95]. Finally, the long-ranged nature of the Coulomb potential causes additional difficulties for describing bulk systems with periodic boundary conditions [86.98]. When these additional considerations are taken into account, good agreement with other methods is found, and results have led to important conclusions about experiments [86.99], which are detailed below.

86.4.2 Molecular Dynamics

Molecular dynamics is a simulation method based on the time evolution of a many-body system [86.91–93].

The vast majority of MD simulations are based on the solution of Newton's equations for N classical particles in a main cell with periodic boundary conditions. Simulations can be carried out in various ensembles and one assumes that long simulations in the canonical ensemble will correctly sample canonical averages in the same manner as (86.19). Atomic properties in dense plasmas are usually obtained in the Born–Oppenheimer approximation, which freezes the ionic dynamics between time-steps and performs an electronic structure calculation to obtain the electronic density for that particular ionic configuration. The ions are then advanced using the forces from the resulting electronic density, and the procedure is repeated. Many methods are available, including basic TF [86.100], Hartree–Fock [86.101], and tight-binding [86.102] to compute the electronic structure. A commonly-used DFT code for warm matter is the Vienna Ab-Initio Simulation Package (VASP), which is widely distributed [86.103]. In contrast to most PIMC implementations, the deep Coulomb potential is often treated in VASP by softening the electron-ion interaction with some form of pseudopotential [86.103, 104]. These methods trade between accuracy and range of validity; for example, TF theory is less accurate than DFT-MD, but is useful at higher temperatures ($\Theta > 50\,\mathrm{eV}$) and for very dense plasmas.

There are three advantages to the MD method. First, the MD approach greatly extends the AA model by including many nuclear centers in the main simulation cell, and these centers may arise from different elements. (This can also be done with PIMC.) Furthermore, DFT-MD, which can be very accurate for cold systems ([86.105], p. 117), has the additional advantage that single-particle (Kohn–Sham) orbitals can be used in formulae for linear, frequency-dependent response properties, such as the electrical conductivity. (It may seem paradoxical that electron dynamical information can be obtained from a static calculation. Strictly speaking this is not possible, although reasonable results can be obtained for some quantities [86.105, p. 49]). And finally, MD has the additional advantage that dynamical ionic properties can be obtained from the time evolution that is simulated. For example, DFT-MD simulations for the computation of the self-diffusion coefficient of dense hydrogen [86.106] have recently been performed; in principle, a wide range of other dynamical ionic properties are available, such as viscosity, thermal conductivity, and collective behavior.

Quantum simulations beyond the Born–Oppenheimer approximation that treat electrons and ions on an equal, dynamical footing are much more difficult since they involve a numerical solution of the N-body Schrödinger equation. Such simulations are necessary, however, for obtaining dynamical electron properties, especially under nonequilibrium conditions – those with time-dependent temperatures or nonthermal momentum distributions. Furthermore, these simulations can describe electronic properties, such as atomic physics, strong scattering, and degeneracy.

Very simple models have been developed by *Deutsch* and coworkers, who constructed effective interactions between the electrons that yield some known property, such as the high-temperature pair correlation function [86.107]. These interactions can then be used directly in a simulation, but with modified equations of motion – an approach pioneered for dense plasmas by *Hansen* and coworkers [86.108]. Diffractive and symmetry effects can be accounted for in the high-temperature limit. For example, one model of the diffractive potential for the electron-ion interaction is

$$v_{\mathrm{ei}}(r) = -\frac{Ze^2}{r}\left[1 - \exp\left(-r/\lambda\right)\right] , \qquad (86.21)$$

where λ is on the order of the electron deBroglie wavelength. This potential is finite at the origin, which prevents the classical collapse of a neutral system during the simulation. Unfortunately, such a method suffers from several weaknesses, including being limited to high temperatures, only describing Pauli exclusion by pair-interactions, and having incorrect atomic binding energies.

There have been several attempts to improve upon simple potentials of the form (86.21). Since one of the main features of quantum mechanics is that conjugate space- and momentum-dependent quantities do not commute, it is natural to construct potentials $v(r, p)$ that depend on both r and p. Such momentum-dependent potentials have been formulated in the context of nuclear physics and have recently been applied to dense plasmas by *Ebeling* and coworkers [86.109]. Although quite good atomic properties can be obtained, these potentials suffer from the fact that they are ad hoc, and one does not know how to choose adjustable parameters for unexplored conditions.

A direct approach is to solve the time-dependent, many-particle Schrödinger equation, albeit approximately. This can be done by reducing the (infinite) degrees of freedom to a smaller, more manageable set. For example, *Heller* [86.110] first suggested using a Gaussian wavepacket to describe electron semiclas-

sical dynamics. This has been applied to ionization in a dense plasma by *Ebeling* [86.111]. In general, a many-body, antisymmetric wave function can be parametrized in terms of a few parameters for each particle and a time-dependent variational principle can be used to obtain the equations of motion of the parameters. For example, each particle in a Slater determinant can be chosen to be a Gaussian with a width $w(t)$ with its conjugate momentum $p_w(t)$. This method is referred to as "Fermion molecular dynamics" or "wavepacket molecular dynamics" (WPMD). A review of this approach has recently been given by *Feldmeir* and *Schnank* [86.112]. Wavepacket shapes other than Gaussians, which can better reproduce atomic properties, have been proposed by *Murillo* and *Timmermans* [86.113].

86.4.3 The Deuterium EOS Problem

Experiments can be notoriously difficult to perform in the dense plasma regime because of the enormous pressures produced. Recently, experiments on compressed deuterium have been performed that pass from the molecular fluid phase into the dense plasma phase and therefore probe the physics of atomic and molecular states in a dense environment. The first of these was conducted at Livermore [86.114] using the Nova laser to shock compress liquid deuterium to 2 Mbar. The experiments indicated a higher compressibility compared with commonly used equation of state properties. These interesting results led to new experiments, again at Livermore [86.115], with pressures exceeding 3.0 Mbar, and at Sandia using a magnetically driven flyer plate on the Z machine [86.116] to achieve 0.7 Mbar. The Sandia results did not show the unexpected higher compressibility. Later, additional laser-based experiments were carried out at the Naval Research Laboratory [86.117] to 6 Mbar, which agreed with the orignial laser-based experiments but had significant error bars. The Livermore and Sandia results are shown in Fig. 86.4. (Error bars are not shown.) Interpreting these experiments has, in turn, led to increased activity in the use and development of various simulation methods.

Also shown in Fig. 86.4 are results from PIMC and WPMD simulations. Early PIMC results, which treated the Fermion sign problem using properties of free particles, did not agree well with either experiment. A later calculation [86.99] improved upon that treatment and
Fig. 86.4 The equation of state of shocked deuterium; here pressure (in Mbars) versus density (in g/cm^3) is plotted along the Hugoniot. Results from two experiments are shown: Sandia (*triangles*) and Livermore (*circles*). Also shown are the results from two simulations: path integral monte carlo (*diamonds*) and wavepacket molecular dynamics (*squares*)

showed that details of antisymmetric wave functions become important below 2 Mbar. These results are shown in the figure, and better agreement with the Sandia result is found. Also shown in the figure are results from a WPMD calculation [86.118], which tend to agree with the Livermore data. The WPMD calculations, however, did not include full antisymmetrization of the electron-electron interaction. The temperatures predicted by the simulations tend to be in the fraction of an eV range at the lower part of the figure and up to tens of eV toward the top of the figure; thus the experiments and the simulations are probing the very interesting WDM regime in which molecular and atomic species are heated into a cool plasma state.

Together with experiments on resistivity and $\langle Z \rangle$, a more complete picture of the physics of atoms in dense plasmas is emerging. But, more theoretical and experimental developments are needed before we can tackle with confidence the wide range of dense plasmas that occur in the HEDP regime.

87. Conduction of Electricity in Gases

The conduction of electricity through gases has played ubiquitous roles in science and technology. It was responsible for many of the fundamental discoveries in atomic and molecular physics; gas discharge lighting is essential to every night operations; gas discharge lasers are still important in research and manufacturing; and all of advanced microelectronics depends on plasma enhanced processing. To a large extent, the efficiencies of the above cited applications of gaseous electronics depend on the maintenance of the distinct non-equilibrium between the electrons and the gas or vapor. This non-equilibrium can be achieved by operating at low pressures or under pulsed excitation, where the duration of the energy input is less than the energy equilibration time between the electrons and the heavy particles. The term gas discharge originally described a transient or spark condition, but has been extended to mean the continuous conduction of electricity through gases.

Section 87.1 treats the electron-velocity distribution and its effect on various measurements involving a swarm or distribution of electron velocities. In this section, low fractional ionization ($<10^{-6}$) is assumed; electron-ion collisions are negligible relative to electron-atom (and electron-molecule) collisions in so far as they affect electron mobility, diffusion or energy loss.

Section 87.2 introduces the glow discharge and considers the cold cathode and hot cathode discharge phenomena. Section 87.3 discusses

ionization by electron collision, electron attachment, ion mobility, ion-ion and electron-ion recombination, and other important processes that affect the conduction of electricity in gases. Section 87.4 illustrates the importance of gaseous electronics with several important phenomena and technical applications.

Part G | 87

The physics and chemistry of the conduction of electricity in ionized gases involves the interactions of the electrons and ions in the gas among themselves, with ground-state and excited-state gas atoms or molecules, with any surfaces that may be present, and with any electric or magnetic fields that are externally applied or generated by movement of the charged species. The electron collision-induced excitation and dissociation can result in new compounds being formed at rates which are orders of magnitude larger than those without a plasma present. For a gas pressure of 1 torr, the electron mean free path λ_{mfp} between collisions is ~ 1 mm ($\sim 10^9$ collisions/second). The assumption that λ_{mfp} is small relative to the plasma physical dimensions is usually valid, however it is often comparable to, or larger than the space charge sheaths that form near electrodes and surfaces.

Since the electron-atom interactions, in most cases of interest, have ranges shorter than the average gas-atom

separation, they may be treated as binary collisions and the effects of neighboring gas atoms on a given electron–atom encounter can be neglected. Quantities involving such interactions in a partially ionized gas, where the electrons are distributed both in velocity and position, can be directly related to the corresponding quantities in beam experiments, where the collisions are binary and the electrons have a defined velocity. The measurements and calculations of the electron velocity distributions, or of the electron energy distribution functions (EEDF), are therefore of fundamental importance in the description of partially ionized gases.

87.1 Electron Scattering and Transport Phenomena

87.1.1 Electron Scattering Experiments

In 1903, *Lenard* [87.1] determined the attenuation of a beam of mono-energetic electrons by several gases. He measured the fraction of an electron beam that was transmitted without scattering through a field-free region containing the gas. Let an electron beam of density n_e electrons/cm^3, traveling with velocity v, pass a distance dx through the gas. Let N be the number of atoms/cm^3. The loss of electrons by scattering per unit time due to collisions with atoms is then given by

$$\frac{dn_e}{dt} = -Nv\sigma n_e , \qquad (87.1)$$

where σ is the collision cross section for electrons of velocity v. Writing $v\,dt = dx$, we obtain

$$n_e = n_{e0}\,e^{-N\sigma x} . \qquad (87.2)$$

In relation to the conduction of electricity in gases, a more useful concept than σ is the momentum transfer cross section σ_m. In general, σ_m is not equal to σ. Experimental determinations of σ_m, generally from electron swarm experiments, are summarized in [87.2]. Results for the noble gases are presented in Fig. 87.1 and for representative diatomic gases in Fig. 87.2. Above energies of about 10 eV, σ_m decreases as the electron energy increases. Towards higher electron energies in the monatomic gases, σ_m is inversely proportional to the ionization potential and directly proportional to the gas polarizability. The fact that σ_m has extremely low values in certain gases at low energies is known as the Ramsauer–Townsend (RT) effect. This can be explained by partial wave scattering theory as the point where the radial wave function has exactly one more oscillation inside the interaction potential well than does the corresponding free function. Outside the well the two functions are indistinguishable and there is no $\ell = 0$ (s-wave) scattering [87.3] (Sect. 45.2.7). For the scattering potentials of the heavier noble gases, this occurs at
Fig. 87.1 Momentum transfer cross section for noble gases
Fig. 87.2 Momentum transfer cross section for some diatomic gases

low energies where the partial cross sections for the higher angular momenta ($\ell = 1, 2, \ldots$) are still negligible. Methane and silane (Fig. 87.3, [87.4, 5]) and possibly other nonpolar polyatomic gases, also display Ramsauer–Townsend (RT) minima. There is great similarity between the σ_m curves for atoms and molecules with similar external electron arrangements. The σ_m curves for H_2, O_2, N_2 and CO (Fig. 87.2) show that these cross sections are large over the range 0.1 to 10 eV. Around 1.5 eV, N_2 and CO display resonances which are associated with the formation of temporary negative ions followed by efficient vibrational excitation of these molecules [87.6].

87.1.2 Electron Transport Phenomena

Electron transport phenomena in an ionized gas, such as diffusion under the influence of a density gradient and drift under the influence of an electric field, are directly related to the electron current density Γ_e which is caused by these influences. In order to calculate Γ_e, it is necessary to know the electron spatial and velocity density distribution $f(\boldsymbol{v}, \boldsymbol{r}, t)$. The electron density n_e and current density Γ_e are given by

$$n_e(\boldsymbol{r}, t) = \int f(\boldsymbol{v}, \boldsymbol{r}, t)\, d^3 v \,, \tag{87.3}$$

$$\Gamma_e(\boldsymbol{r}, t) = \int \boldsymbol{v} f(\boldsymbol{v}, \boldsymbol{r}, t)\, d^3 v \,. \tag{87.4}$$
Fig. 87.3 Momentum transfer cross section for CH_4 and SiH_4

The electron drift velocity w_d is related to Γ_e and n_e by

$$w_d = \Gamma_e / n_e \,. \tag{87.5}$$

The electron drift velocity is usually small compared with the electron random velocity. The other limiting case is important in connection with ionic mobilities. It can also occur in electron transport in Ramsauer gases or gas mixtures that are used in fast particle counters [87.7]. The theoretical analysis of electron motion in gases uses primarily the Boltzmann transport equation approach [87.8]. Mean free path methods [87.9] and Monte-Carlo methods [87.10] have also been applied.

87.1.3 The Boltzmann Equation

The electron density distribution $f(\boldsymbol{v}, \boldsymbol{r}, t)$ of a given kind of particle in phase space (configuration and velocity space) is determined by the combined effect of all the interactions to which the particle is subjected. If there are no sources or sinks, the number of particles in a volume element of the six-dimensional space which moves with the particles does not change with time. In configuration space, the continuity equation for $f(\boldsymbol{v}, \boldsymbol{r}, t)$ is

$$\frac{\partial f}{\partial t} + \nabla_r \cdot \boldsymbol{v} f = 0 \,; \tag{87.6}$$

in phase space, it has the form

$$\frac{\partial f}{\partial t} + \nabla_r \cdot \boldsymbol{v} f + \nabla_v \cdot \boldsymbol{a} f = 0 \,, \tag{87.7}$$

where the subscripts on the divergence operators denote the independent variable, $\boldsymbol{v}$ is the particle flow velocity in configuration space, and $\boldsymbol{a}$ is the particle acceleration (i.e., the flow velocity velocity space). This may be written as $q(\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B})/m$ for a particle of charge q and mass m in the presence of electric and magnetic fields, $\boldsymbol{E}$ and $\boldsymbol{B}$ respectively. If there are sources or sinks of particles, then terms representing these appear on the right-hand side of (87.7).

In principle, the effect of elastic and inelastic collisions may be included in the expressions for $\boldsymbol{E}$ and $\boldsymbol{B}$, but they are usually treated as source terms which transport the colliding particles instantaneously from one volume element of velocity space to another. This is a good approximation, for example, in the case of electron–atom collisions, but it is not valid for the longer range electron–ion and electron–electron interactions in the presence of high-frequency electric fields. Other collisions, such as ionizing collisions, act to change the total n_e as well as transporting electrons from one element of velocity space to another.

The electron–electron collisions will produce a Maxwellian velocity distribution when the fractional ionization is sufficiently large. For molecular gases, this generally requires $n_e/N_0 > 10^{-5}$. Since the electron–electron Coulomb collision frequency varies as v^{-3}, these collisions are especially effective in the low energy elastic regime where there are no inelastic energy loss processes, and they may have an influence for n_e/N_0 as low as 10^{-7} for the noble gases [87.11]. *Spitzer* [87.12], *Dreicer* [87.13], and *Butler* and *Buckingham* [87.14] treat cases where the electron–electron term is included explicitly. A full treatment of this subject is given by *Shkarofsky* [87.15].

Using $\nabla_v \cdot \boldsymbol{a} = 0$, and including collisions as a source term, (87.7) becomes

$$\frac{\partial f}{\partial t} + \boldsymbol{v} \cdot \nabla_r f + \boldsymbol{a} \cdot \nabla_v f = \left(\frac{\partial f}{\partial t}\right)_{\text{collisions}} , \qquad (87.8)$$

where the subscript 'collisions' identifies the source term due to all types of collisions.

87.1.4 Electron–Atom Elastic Collisions

For electrons in a weakly ionized gas, where only electron–atom elastic collisions need be explicitly considered, the collision term is given by the Boltzmann collision integral [87.16]. This integral describes the rate at which electrons are brought into and removed from an element of volume in velocity space in terms of the differential elastic scattering cross section .

The Boltzmann equation may be solved by a perturbation method [87.8] in which $\boldsymbol{E}$, $\boldsymbol{B}$, and the density gradients are the perturbations, starting from

$$f(\boldsymbol{v}, \boldsymbol{r}, t) \approx f_0(v, \boldsymbol{r}, t) + \frac{\boldsymbol{v}}{v} \cdot \boldsymbol{f}_1(v, \boldsymbol{r}, t) , \qquad (87.9)$$

where f_0 is the unperturbed isotropic term and $\boldsymbol{f}_1$ is the anisotropy due to $\boldsymbol{E}$ and $\boldsymbol{B}$. Substituting into (87.8) and equating terms of the same angular type then yields

$$\frac{\partial f_0}{\partial t} + \frac{v}{3}\nabla_r \cdot \boldsymbol{f}_1 - \frac{e}{3mv^2}\frac{\partial}{\partial v}\left(v^2 \boldsymbol{E} \cdot \boldsymbol{f}_1\right)$$
$$= \frac{g}{2v^2}\frac{\partial}{\partial v}\left[v^3 \nu_m \left(f_0 + \frac{k_B T_g}{mv}\frac{\partial f_0}{\partial v}\right)\right] \qquad (87.10)$$

and

$$\frac{\partial \boldsymbol{f}_1}{\partial t} + v\nabla_r f_0 - \frac{e\boldsymbol{E}}{m}\frac{\partial f_0}{\partial v} + \boldsymbol{\omega}_B \times \boldsymbol{f}_1 = -\nu_m \boldsymbol{f}_1 , \qquad (87.11)$$

where $\nu_m = eE/(w_d m)$ is the momentum transfer collision frequency from the Boltzmann collisions integral,

$\boldsymbol{\omega}_B = e\boldsymbol{B}/m$ is a vector whose magnitude is the cyclotron frequency, and $g = 2m/(M+m)$ controls the partition of kinetic energy in an elastic collision between particles with masses M and m.

The right-hand term of (87.10) is the first-order correction due to elastic kinetic energy exchange between electrons and atoms. The $\boldsymbol{E} \cdot \boldsymbol{f}_1$ term arises from work done by $\boldsymbol{E}$ on the electrons, and the $\nabla_r \cdot \boldsymbol{f}_1$ term accounts for particle loss from the volume element in phase space due to electric field drift and density gradients. Similarly, in (87.11), the $\boldsymbol{E}$ term accounts for loss due to electric field acceleration, and the $v\nabla_r f_0$ term accounts for changes due to electron drift across a density gradient. The $-\nu_m \boldsymbol{f}_1$ term results from randomization of the electron velocity direction in electron–atom collisions.

The neglect of higher order terms in (87.9) is justified if $\delta\mathcal{T}_e/\mathcal{T}_e \ll 1$, where $\mathcal{T}_e$ is the gain in electron kinetic energy between collisions, and $\delta f_0/f_0 \ll 1$, where δf_0 is the change in f_0 over λ_{mfp}. For the case of static $\boldsymbol{E}$ and $\boldsymbol{B}$ with $\boldsymbol{E} \perp \boldsymbol{B}$, the orbital time $1/\omega_B$ replaces the time between collisions if it is shorter, making the above conditions less stringent. However, for an ac field with the resonant frequency ω_B, the original conditions apply. The off-resonant case in between. See [87.8, 17] for a further discussion of validity.

87.1.5 The Electron Drift Current

Transport properties of a partially ionized gas are calculated from the moments of $f(\boldsymbol{v}, \boldsymbol{r}, t)$. To obtain Γ_e, (87.11) must be solved for $\boldsymbol{f}_1$. Assume that $\omega_B = 0$ and that $\boldsymbol{E}$ is constant in time. Then, since f_0 usually changes slowly compared with ν_m, $\partial \boldsymbol{f}_1/\partial t$ may be neglected to a first approximation, and

$$\boldsymbol{f}_1 \simeq -\frac{1}{\nu_m}\left(v\nabla_r\left(n_e f_v^0\right) - \frac{e\boldsymbol{E}}{m}n_e\frac{\partial f_v^0}{\partial v}\right) , \qquad (87.12)$$

where $n_e(\boldsymbol{r}, t)f_v^0(v, \boldsymbol{r}, t) = f_0(v, \boldsymbol{r}, t)$. Use of (87.3) gives

$$\Gamma_e = -\nabla_r(D_e n_e) - n_e \mu_e \boldsymbol{E} , \qquad (87.13)$$

which defines the electron free diffusion coefficient

$$D_e = \int \frac{v^2}{3\nu_m} f_v^0 4\pi v^2 \, dv = \frac{\langle v^2 \rangle}{3\nu_m} , \qquad (87.14)$$

and the static electron mobility

$$\mu_e = -\frac{e}{m}\int \frac{v}{3\nu_m}\frac{\partial f_v^0}{\partial v} 4\pi v^2 \, dv . \qquad (87.15)$$

In (87.13), ∇_r should be interpreted as acting only on that part of D_e whose spatial dependence enters through an

energy change, such as a variation of $\mathcal{T}_e$ with position (as in the theory of striations [87.18], but not on variations due to pressure gradients which would affect ν_m [87.8]).

Electron Free Diffusion

When the ionization density is low enough, the electrons diffuse freely to the walls, being unaffected by the space charge field caused by the heavier ions, which diffuse more slowly than the electrons. Setting $\boldsymbol{E} = 0$ in (87.13), the electron current due to diffusion is

$$\Gamma_e = -\nabla_r(D_e n_e) . \tag{87.16}$$

Since the electron heating and elastic recoil terms in (87.10) do not contribute to a net gain or loss of electrons, integration of (87.10) over $\boldsymbol{v}$ gives

$$\frac{\partial n_e}{\partial t} + \nabla_r \cdot \Gamma_e = \frac{\partial n_e}{\partial t} - \nabla_r^2(D_e n_e) = 0 , \tag{87.17}$$

for a decaying electron density. This equation is identical in form to the thermal conductivity equation, which can be solved analytically for certain simple geometries. For the case of a long cylindrical container of radius R, the equation becomes

$$\frac{\partial n_e}{\partial t} = D_e \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial n_e}{\partial r} \right) , \tag{87.18}$$

if D_0 is constant and n_e depends only on r. The general solution for n_e satisfying $n_e(R, t) = 0$ is

$$n_e = \sum_{m=0} b_m \exp\left(-\frac{t}{t_m} \right) J_0 \left(\frac{a_m r}{R} \right) , \tag{87.19}$$

where $t_m = [D_e(a_m/R)^2]^{-1}$, and J_0 is the zeroth-order Bessel function with roots $J_0(a_m) = 0$, $a_{m+1} > a_m$. The b_m are determined by the radial dependence of n_e at $t = 0$. (If the coaxial wall of radius $r_0 < R$ confines the plasma to an annular region $r_0 < r < R$, the general solution must also include the zeroth-order Bessel function of the second kind, Y_0, to satisfy the boundary conditions). The time constants t_m decrease rapidly with increasing m so that for sufficiently long t, the density distribution relaxes (e.g., after the microwave or static excitation is switched off) to

$$n_e \approx b_0 \exp\left(-\frac{t}{t_0} \right) J_0 \left(\frac{a_0 r}{R} \right) . \tag{87.20}$$

This is called the fundamental diffusion mode. The above treatment gives a good approximation to $n_e(r)$ provided that $\lambda_{\text{mfp}} \ll R$.

When ν_m is velocity-independent and f_0 is the Maxwellian of temperature T_e, (87.14) becomes

$$D_e = \frac{k_B T_e}{m \nu_m} . \tag{87.21}$$

For the case where a magnetic field is applied to the ionized gas, parallel to the cylinder axis so as to impede the electron diffusion to the walls, the free-diffusion coefficient in equation (87.18) is replaced by

$$D_{eB} = \int \frac{\nu_m v^2 f_v^0}{3(\nu_m^2 + w_B^2)} 4\pi v^2 \, \mathrm{d}v = \left\langle \frac{\nu_m v^2}{3(\nu_m^2 + w_B^2)} \right\rangle . \tag{87.22}$$

In this case, the electrons cannot diffuse to the walls unless they make collisions that interrupt their spiraling motion.

Electron DC Mobility in Static Fields

From (87.13), the electron particle current induced by an electric field $\boldsymbol{E}$ is $\Gamma_e = -n_e \mu_e E$, and the electron drift velocity is

$$w_d = \frac{\Gamma_e}{n_e} = -\mu_e E . \tag{87.23}$$

Measurement of w_d by a time-of-flight measurement can in principle, through the use of (87.14), provide some information about ν_m, provided that f_v^0 is known. Since a static electric field may perturb considerably the distribution function, and since n_e is low in such measurements, f_v^0 should be determined using (87.10) after having eliminated $\boldsymbol{f}_1$ using (87.11). In the case where ν_m is independent of v, (87.15) after integration by parts, reduces to

$$\mu_e = \frac{e}{m \nu_m} \int f_v^0 4\pi v^2 \, \mathrm{d}v = \frac{e}{m \nu_m} , \tag{87.24}$$

which is independent of f_v^0.

In general, w_d exhibits a complex dependence on E/N, as shown for some example gases in Fig. 87.4 [87.19]. The high mobility of electrons in methane is of technical interest because of potential applications in plasma switches used for current interruption [87.20]. The local maximum of w_d in methane for $E/N = 3$ Td (1 Townsend $= 10^{-17}$ Vcm^2) and its decrease with further increase of E/N arise because of the onset of inelastic collisions due to vibrational excitation at an energy close to the energy of the RT minimum [87.21]. As shown in Fig. 87.4, the drift velocities are generally in the range of 10^6–10^7 cm/s.

A detailed summary of electron drift velocities measured in many pure gases and gas mixtures of technical interest is given in [87.22, 23], and the techniques are elaborated in [87.24, 25].

The classic article on the drift velocity of ions in electric fields measured by a transit time technique is that
Fig. 87.4 Electron drift velocities in polyatomic gases

Fig. 87.5 Calculated u_{av} and D_e/μ_e coefficients in H_2

of *Hornbeck* [87.26]. He showed that in some instances earlier workers had identified molecular ions as atomic ions. Contemporary measurements often use the guided ion beam (GIB) technique to measure such quantities as the symmetric charge transfer cross sections [87.27]. A review of measurement data has been given [87.28].

The Ratio of D_e/μ_e for Electrons

From (87.14) and (87.15),

$$\frac{D_e}{\mu_e} = -\frac{m}{e} \frac{\int_0^\infty (v^4/\nu_m) f_v^0 \, dv}{\int_0^\infty (v^3/\nu_m) \partial f_v^0/\partial v \, dv} . \qquad (87.25)$$

The above ratio of the free-diffusion coefficient to the mobility is termed the characteristic energy and it is a measure of the average electron energy in certain cases. When f_v^0 is Maxwellian, then

$$D_e/\mu_e = k_B T_e/e \qquad (87.26)$$

becomes a direct measure of the electron energy, independent of ν_m. Since the average electron energy $u_{av} = \frac{3}{2} k_B T_e$, (87.26) becomes

$$D_e/\mu_e = \frac{2}{3} u_{av}/e . \qquad (87.27)$$

In this form it is known as the Einstein relation. Furthermore, if ν_m is independent of velocity, (87.27) applies regardless of the velocity distribution.

Values of D_e/μ_e can be determined from experiments where a static electric field E_z is applied to electrons drifting under steady state conditions of diffusion. If D_e is taken to be independent of position, then

the generalization of (87.17) is

$$\nabla^2 n_e = -\frac{\mu_e}{D_e} E_z \frac{\partial n_e}{\partial z}. \qquad (87.28)$$

Solutions to this equation for n_e were for many years used to deduce D_e/μ_e from the measurements [87.29]. However, *Wagner* et al. [87.30] showed that there are two effective diffusion coefficients D_L and D_T in the longitudinal and transverse directions with $D_L \ll D_T$. For H_2, N_2 and He, $D_L \approx D_T/2$, while for Ar, $D_L \approx D_T/8$. See [87.31, 32] for a quantitative discussion. The different coefficients arise because n_e and w_d are functions of $\partial n_e/\partial z$.

For H_2, f_v^0 is fairly well approximated by a Maxwellian distribution. A comparison of the average and characteristic energies u_{av} and D_e/μ_e calculated from the Boltzmann transport equation for H_2 is shown in Fig. 87.5.

Ambipolar Diffusion

In the case of electron free diffusion discussed above, diffusion of the electrons (and ions) is unaffected by space-charge fields caused by an imbalance of positive and negative charges. When the charge density is high, this no longer holds. The resulting electric field caused by space-charge separation retards the electron diffusion and enhances the positive ion motion. In the steady state the flows of positive ions and of electrons are equal, i. e., $\Gamma_e = \Gamma_+$. For electrons in the absence of temperature gradients,

$$\Gamma_e = -D_e \nabla n_e - n_e \mu_e E , \qquad (87.29)$$

where D_e and μ_e are given by (87.14) and (87.15) respectively. The analogous equation for the positive ions is

$$\boldsymbol{\Gamma}_+ = -D_+ \nabla n_+ - n_+ \mu_+ \boldsymbol{E} \, . \tag{87.30}$$

Eliminating $\boldsymbol{E}$ between the two equations and setting $n_e \approx n_+ = n$, and $\boldsymbol{\Gamma}_e \approx \boldsymbol{\Gamma}_+ = \boldsymbol{\Gamma}$ gives

$$\boldsymbol{\Gamma} = -\left(\frac{D_+ \mu_e + D_e \mu_+}{\mu_e + \mu_+} \right) \nabla n \, . \tag{87.31}$$

The quantity in parentheses is a diffusion coefficient that is applicable both to the electrons and to the ions. Since they are interacting, they diffuse together. This quantity is termed the ambipolar diffusion coefficient:

$$D_a = \frac{D_+ \mu_e + D_e \mu_+}{\mu_e + \mu_+} \, . \tag{87.32}$$

Franklin, however, has proposed that the term ambipolar flow is a more correct physical description [87.33]. In the case where the electrons have a temperature T_e and the ions a temperature T_+,

$$\frac{D_+}{\mu_+} = \frac{k_B T_+}{e} \, , \quad \frac{D_e}{\mu_e} = \frac{k_B T_e}{e} \, , \tag{87.33}$$

and since $\mu_e \gg \mu_+$,

$$D_a \approx D_+ \left(1 + \frac{T_e}{T_+} \right) \, . \tag{87.34}$$

If $T_e \gg T_+$, then $D_a \approx \mu - k_B T_e / e$, i.e., the ambipolar diffusion is determined by the ion mobility and the electron energy. *Allis* and *Rose* [87.34] have studied the transition from free to ambipolar diffusion as the electron density is increased.

For the case in which the electrons and ions are diffusing together in the radial direction across a static B_z, and the electron–atom and ion collision rates may be assumed to be independent of T_e, the magneto-ambipolar diffusion coefficient is given by

$$D_{aB} = \frac{D_a}{1 + \mu_+ \mu_e B^2} \, . \tag{87.35}$$

References [87.35, 36] review theoretical and experimental work on diffusion in a magnetic field.

Debye Shielding

Consider an ensemble of positive ions and electrons in thermal equilibrium. Each ion repels other ions in its neighborhood, but attracts electrons. The space charge around each ion (assumed stationary) is $e(n_+ - n_e)$, which by Poisson's equation creates a potential ϕ satisfying

$$\nabla^2 \phi = -\frac{e}{\epsilon_0}(n_+ - n_e) \, , \tag{87.36}$$

where n_+ is the average ion density. For time independent fields in the absence of collisions, (87.8) becomes

$$\boldsymbol{v} \cdot \nabla_r f + e \boldsymbol{E} \cdot \nabla_v f = \boldsymbol{v} \cdot \nabla_r f - e \nabla_r \phi \cdot \nabla_v f = 0 \, . \tag{87.37}$$

Assuming a solution of the form

$$f = f_0 \exp\left(-\frac{e\phi}{k_B T_e} \right) \, , \tag{87.38}$$

where f_0 is Maxwellian, and using $\int f_0 \, d^3v = n_e$ gives

$$\left(-\frac{e}{k_B T_e} \boldsymbol{v} \cdot \nabla_r \phi + e \nabla_r \phi \cdot \frac{\boldsymbol{v}}{k_B T} \right) f \equiv 0 \, . \tag{87.39}$$

Hence,

$$\int f \, d^3v = n_e \exp\left(-\frac{e\phi}{k_B T_e} \right) \, . \tag{87.40}$$

Since the assembly is macroscopically neutral, $n_e = n_+$, and

$$\nabla^2 \phi = -\frac{e}{\epsilon_0} n_+ \left[1 - \exp\left(-\frac{e\phi}{k_B T_e} \right) \right] \, . \tag{87.41}$$

If $e\phi \ll k_B T_e$, then

$$\nabla^2 \phi \approx \frac{e^2}{\epsilon_0} n_+ \frac{\phi}{k_B T_e} \, . \tag{87.42}$$

If spherical symmetry is assumed,

$$\phi = \frac{e}{4\pi\epsilon_0 r} \exp\left(-\frac{r}{\lambda_D} \right) \, , \tag{87.43}$$

where

$$\lambda_D = \left(\frac{\epsilon_0 k_B T_e}{n_+ e^2} \right)^{1/2} \tag{87.44}$$

is the Debye shielding length for the Coulomb potential. λ_D arises from the screening effect of the electron cloud

about each ion. The dimensions of a plasma must be much larger than λ_D for the electrons to act collectively, i. e., to undergo plasma oscillations.

87.1.6 Cross Sections Derived from Swarm Data

The use of transport theory to unfold low energy electron collision cross sections from experimentally measured electron transport data was originally introduced by *Townsend* [87.29]. Beginning with trial input values for the cross sections as a function of energy, the electron transport coefficients are calculated and compared with experiments (such as w_d, D_e, ϵ_k, and ionization/attachment coefficients, measured as a function of E/N). The input cross sections are then adjusted in the appropriate energy range, and the comparison procedure is iterated until theory and experiment come into agreement. The above trial and error procedure was greatly advanced by the use of computers to solve the Boltzmann equation [87.37,38]. A large body of fairly complete sets of low energy cross sections has been obtained in this way [87.23].

Assuming that the electron kinetics are accurately described by the solution of the Boltzmann equation, the above unfolding procedure is severely limited by the lack of uniqueness in the derived cross sections (especially in the molecular gases where many inelastic processes dominate in determining the electron energy distribution). For the noble gases, the method works well for He and Ne at low energies, where only elastic scattering occurs [87.24]. For Ar, Kr, and Xe, the method becomes questionable again for electron energies near the RT minimum. The slow redistribution of electron energies leads to lack of sensitivity of the calculated transport coefficients to the σ_m.

It has been shown that the swarm analyses of He-Ramsauer noble gas mixtures lead to unique σ_m of the Ramsauer noble gases (Ar, Kr, Xe) [87.39]. The measured electron drift velocity data in He-Xe mixtures shown in Fig. 87.6 satisfy the two important requirements (1) high sensitivity of the drift velocity data in gas mixtures over that in either pure He and Xe, and (2) the σ_m of He is very accurately known, to warrant the uniqueness of the derived σ_m of Xe.

Once the cross sections of the Ramsauer noble gases have been more accurately defined by the above approach, the RT minimum can be used to advantage in addressing the uniqueness problem for molecular gases. The electron transport data in molecular-gas–rare-mixtures exhibit large sensitivity due to the low
Fig. 87.6 Measured electron drift velocities in He–Xe mixtures

energy inelastic collisions in the molecular gas (which increase the f_1 component of the electron energy distribution) [87.21,40]. Since the cross sections of the buffer noble gas are now accurately defined, the demanding fits to the mixture transport data can be conveniently exploited to enhance the accuracy of the cross sections of the molecular gases.

The application of the two-term approximation in many papers treating molecular gases has been criticized [87.41]. Fortunately, methods are now available for the use of multi-term and Monte Carlo approaches to solve the collisional Boltzmann equation. These approaches do require differential cross sections. *Schmidt* et al. [87.42] report that their experiments using both electric fields and crossed electric and magnetic fields allow the extraction of the drift velocity, the Lorentz deflection angle, the longitudinal and transverse diffusion coefficients, and the ionization coefficient. This approach has lead to a fully automated procedure for extraction of cross sections from accurate experimental transport data.

When approximate answers (20% or so) are needed for comparisons with measurements on complex discharges, rather than measurements on transport properties, the program Bolsig and its database provided by *Morgan* [87.43] and the Paul Sabatier University plasma group [87.44] are justifiably popular.

Under very high E/n conditions, approximate answers can be obtained quickly using the completely anisotropic beam assumption.

87.2 Glow Discharge Phenomena

87.2.1 Cold Cathode Discharges

The cold cathode discharge operates because of feedback by the electrons that are generated by ion bombardment of the cathode (secondary electron emission) in turn generating sufficient ions that flow to the cathode to keep the process going. There can be contributions to secondary electron emission from photons and metastable atoms which are created by electron collisions with the gas. Since the secondary emission coefficients are functions of the cathode material, ion species, and ion energy, the magnitude of the needed accelerating potential between the plasma and the cathode varies. This potential creates a space charge sheath, and various excitation features occur near the cold cathode. The potential required is typically 200–600 V. The electrons from the cathode (called primaries) are accelerated through the sheath and acquire sufficient energy to excite the gas efficiently, resulting in a region termed the negative glow. As one moves further from the cathode, the light from the negative glow tapers off due to the degradation of the primaries in creating slow electrons (termed secondaries and ultimates). A sufficiently high density of electrons is usually created to satisfy the external circuit continuity at very low fields (or even slight field reversal). Since the low energy electrons do not create visible excitation, the region to the anode side of the negative glow forms the Faraday dark space. At even greater distance from the cathode, where the slow electron density has decayed by drift, diffusion, recombination, and in some gases by attachment, the electric field increases and the discharge develops long diffuse bright regions which occupy the remainder of the inter-electrode space. This is termed the positive column. If one increases the inter-electrode spacing, the cathode regions remain essentially constant and the positive column extends with average uniform properties. Temporal variations called moving striations are common in all gases, and spatial variations called standing striations, or ionization waves are frequently observed in molecular gases. The different cathodic regions occur because the abrupt boundary conditions create local discharge conditions of excitation and ionization which are not in equilibrium with the local electric field. Even in the so-called uniform positive column, the ionization waves correspond to nonlocal equilibrium solutions of the discharge equations that permit more efficient discharge ionization and conductivity than would be given by local equilibrium
Fig. 87.7 Illustration of the appearance of a hot cathode discharge

with the electric field. The ionization waves can be absolutely or convectively stable, and have dispersion properties of forward or backward waves (the latter corresponding to opposite directions of phase and group velocities).

At any plasma boundary a positive space charge sheath is usually formed in order to equalize the fluxes of ions and electrons to the boundary. *Bohm* [87.45], and much earlier *Langmuir* [87.46], showed that in a collisionless sheath, to avoid oscillatory solutions, the ions must enter the sheath with velocities at least equal to the ion sound speed ($\sqrt{kT_e/m_i}$). The Bohm criterion continues to attract research activity. The review paper by *Riemann* [87.47] treats the issues addressed up to that time. There are important recent studies on satisfying the neutrality boundary conditions in electro-negative gases and in gas discharges with multiple positively- and negatively-charged species [87.48].

87.2.2 Hot Cathode Discharges

Low pressure, high current discharges are important in thyratrons and other high current switches. The hot cathode permits much higher current densities than are usually obtained from a cold cathode. The voltage drop of the cathode sheath is much less, and a discharge will operate if the applied potential exceeds I_P for the gas. Hot cathode discharges with low P and Γ_e show three groups of electrons: the primaries, which are beam electrons that essentially have retained the energy acquired in the cathode sheath; secondaries which are randomized electrons with T_e approximately proportional to the energy of the primaries ($\approx 5\,\text{eV}$ for $30\,\text{eV}$ primaries) and approximately independent of the gas; and the ultimates which are the bulk of the electrons with $T - E < 1\,\text{eV}$. The primaries degrade slowly with distance from the cathode, provided that $\Gamma_e \leq 40\,\text{mA}$ for argon at $10\,\mu\text{m}$ (or more generally when the density of the beam elec-

trons is still less than n_e). Above this critical current (a function of the gas and its pressure), the discharge adopts a definite new structure. The beam is no longer quasi-homogeneous but displays a meniscus about 7 mm from the cathode (Fig. 87.7). Langmuir probe measurements show that the primary electrons are abruptly scattered in energy at the meniscus. The energy scattering of the fast electrons by the electrostatic waves far exceeds the electron–atom collisional scattering. Spectroscopic measurements in argon, for example, with a cathode fall of 26 V, show the Ar spectrum throughout the discharge, whereas the Ar^+ lines appear only to the anode side of the meniscus. The Ar^+ lines appear even though the minimum energy required to excite them is 34.8 to 39.9 eV and the total voltage across the discharge can be 5 to 10 V lower. Coincident with onset of the meniscus, distinct GHz and MHz frequency oscillations are detected. These frequencies have been interpreted as electron- and ion-plasma oscillations, respectively.

87.3 Atomic and Molecular Processes

If the cross section for a given process is σ_j, then the rate of excitation per electron for that process is

$$Z_j = N \int_0^\infty \sigma_j(v) v f_v(v, \mathbf{r}, t) 4\pi v^2 \, \mathrm{d}v \, . \tag{87.45}$$

For inelastic processes, $\sigma_i(v) = 0$ for velocities below the threshold energy. The ionization threshold is the ionization potential I_P. The ionization cross sections typically increase monotonically with energy from threshold to about 100 eV. An exception to this is the alkali metal group for which the ionization cross section maximum occurs below 15 eV.

Assuming that the discharge excitation conditions are spatially uniform, the electron conservation equation is

$$\frac{\mathrm{d}n_e}{\mathrm{d}t} = (Z_i - Z_a - Z_d)n_e - Z_r n_e^2 \, , \tag{87.46}$$

where $Z_i n_e$ is the total rate of ionization, $Z_a n_e$ is the rate of attachment, $Z_d n_e$ is the net diffusion rate out of the region considered, and $Z_r n_e^2$ is the rate of recombination, all per unit volume. The coefficients are usually functions of both P and E, either directly or indirectly. We consider these processes separately in Sect. 87.3.1 to Sect. 87.3.3.

87.3.1 Ionization

The ionization frequency (in s^{-1}) for a Maxwellian distribution of electron velocities is given by [87.49]

$$Z_i \approx 9 \times 10^7 a \, P \exp\left(-\frac{I_P}{\Theta}\right) \Theta^{1/2} I_P \, , \tag{87.47}$$

where $\Theta = (k_B T_e/e)$ and a is the initial slope of the ionization efficiency curve in electron energy (ion pairs/Torr/V/electron). (The ionization efficiency is defined as the number of ion pairs produced per electron per cm of path at 1 Torr and 0°C. The ionization efficiency is proportional to the ionization cross section.) For a Maxwellian distribution, the quantity

$$\frac{\mathrm{d}Z_i}{\mathrm{d}\Theta} = Z_i \frac{(V_i + \Theta/2)}{\Theta^2} \, , \tag{87.48}$$

together with Z_i, is useful in estimating the electron density and electric field for steady state discharges, or the onset of ionization instabilities [87.18].

If more accuracy is desired in estimating the ionization rate, a numerical solution of the Boltzmann equation is needed to calculate f_v^0. An energy balance calculation can then be performed by integrating the electron kinetic equation over all electron energies. The electron

energy balance and the average electron energy are independent of n_e in a weakly ionized gas. Therefore the energy transfer into different excitations can be treated on a single electron basis. The total power density in the discharge as a function of E/N is then given by

$$\mathbf{J} \cdot \mathbf{E} = e w_d \frac{E}{N} N n_e . \tag{87.49}$$

The relative contributions of the various electron loss processes are then obtained. Figure 87.8 shows the fractional input power deposition into the principal electron loss channels of hydrogen [87.50] as a function of the normalized electric field. Over a wide range of E/N, a large fraction of the discharge energy goes into vibrational excitation. Significant energy deposition into dissociation occurs only above 40 Townsends. This explains why it is necessary to use a capillary tube discharge (or Wood's tube) to obtain the atomic spectrum, or to provide a source of atomic hydrogen. The higher diffusion losses of the narrow bore cause the discharge to run at high E/N in order to maintain the electron density. The high E/N also provides large dissociation rates.

To obtain the total rate of excitation at high Γ_e, it is necessary that an assessment of the excited state densities also be made. This is most important for excited states that are known to be metastable so that the effec-

tive lifetimes are determined by collisional quenching or diffusion. The metastables can be very important in the excitation of higher states and in ionization. First, the threshold to ionize a metastable is usually much less than the I_P of the ground state. Second, the cross section for ionization of an excited state is often much larger than that of the ground state. Evaluations [87.51] of the low pressure helium discharge above 1 torr show that at current densities above a few mA cm^{-2} the two-step ionization through metastable states (proportional to n_e^2) exceeds the single step ionization (proportional to n_e) from the ground state. A multi-temperature approximation introduced by *Vriens* [87.52] has proven to be very useful in analyzing noble gas-alkali discharges and also noble gas discharges. The decreasing electric field required at higher discharge currents (higher n_e) is thus due to a combination of more efficient ionization through the metastables and increased gas heating.

Also, molecular dissociation changes the ionization rate through a combination of changes in f_v^0. At high energy density depositions (≈ 0.1 eV/molecule), the ionization rate and the dissociation rate are influenced by the degree of vibrational excitation, and by the changed Franck-Condon probabilities. However, the dissociation rate is changed primarily by two processes: collisions of the second kind [87.49]

$$e_{(\text{slow})} + N_2(v) \rightarrow e_{(\text{fast})} + N_2(v = 0) , \tag{87.50}$$
which increase the number of fast electrons, and by increased anharmonic pumping of vibrational states to the dissociation limit [87.53]. Anharmonic pumping [87.54] occurs when large populations of vibrationally excited states are created in a molecular gas (usually diatomic) with a small amount of anharmonicity between adjacent levels, and the translational energy of the molecules is low. Because of the anharmonicity, the vibrational energy exchange favors the transfer from low vibrational levels to higher vibrational levels. This process is the basis of infrared laser action in carbon monoxide [87.54].

For discharges in gas mixtures, the component with the larger inelastic cross section and lower threshold tends to control the mean energy of the electron energy distribution. This situation is of common occurrence in discharge lasers. Numerical solutions of the Boltzmann equation have been obtained for a large number of gas mixtures of technical interest [87.55, 56]. Usually the two-term approximation in (87.9) is adequate, although there are circumstances where higher order terms are needed [87.57].
Fig. 87.8 Fractional power deposited into the different inelastic modes of hydrogen as a function of E/N. The labels V, D, E, R, and I correspond to vibrational, dissociation, electronic, rotational, and ionization processes respectively. The remainder is transferred into elastic collisions

87.3.2 Electron Attachment

The phenomenon of electron attachment to a neutral atom or molecule to form a negative ion is a common occurrence for gases whose outer electronic shells are nearly filled. The energy of formation of a negative ion is called the electron affinity (E_A). This varies from about $3.5\,\text{eV}$ (for the halogens) to nearly zero among the gases that exhibit electron attachment. Atoms having closed electronic shells do not form negative ions. These atoms, which have $^1S_0$ ground states, include the noble gases. Molecules in the $^1\Sigma$ ground state also do not form permanent negative ions.

A general experimental technique for measurement of attachment coefficients involves passing electrons through a gas target and measuring the attenuation of the electrons due to attachment, and usually also the negative ions produced [87.6]. Mass spectrometers are often included to identify the ions. A comprehensive survey of negative ions is available in the revised edition of *Massey*'s text [87.58], and an update with emphasis on discharge lasers has been given by *Chantry* [87.55, 59]. There is not as yet any experiment [87.41] that can measure separately the flux and reactive components of swarm transport when nonconservative interactions are present. The problem becomes more complex in inhomogeneous fields when the negative ions are weakly bound and experience collisional detachment in higher field regions. Plasma etching almost always involves electro-negative gases. The effects of negative ions in positive column discharges have been described by *Franklin* [87.48]. The discharge radial profile is sensitive to the relative values of ionization, attachment, detachment, and recombination. Additional discharge instability modes are possible, including an ionization-attachment-detachment mode that gives rise to distinct high and low field regions that have been observed in oxygen discharges and in other electro-negative gas discharges.

87.3.3 Recombination

One of the most common loss mechanisms for ions is the recombination of negative ions and electrons with positive ions. The loss of ions due to recombination is proportional to the product of their concentrations:

$$\frac{\mathrm{d}n_+}{\mathrm{d}t} = \frac{\mathrm{d}n_-}{\mathrm{d}t} = -\alpha n_- n_+ \,. \tag{87.51}$$

Here α is called the recombination coefficient and n_- is the negative ion or electron density. The value of α is quite different for negative ions and electrons. If there is only one negative ion species, and the positive and negative ion species have equal concentrations, then

$$\frac{\mathrm{d}n}{\mathrm{d}t} = -\alpha n^2 \,, \tag{87.52}$$

which on integration gives

$$n^{-1} = n_0^{-1} + \alpha t \,, \tag{87.53}$$

where n_0 is the initial ion concentration at $t = 0$. Recombination phenomena therefore often exhibit a linear relation between $1/n$ and t after switch-off of a discharge.

The three primary processes for positive ion–negative ion recombination are: three body recombination

$$A^+ + B^- + M \rightarrow AB + M \,; \tag{87.54}$$

radiative recombination

$$A^+ + B^- \rightarrow AB + \text{photon} \,; \tag{87.55}$$

mutual neutralization

$$A^+ + B^- \rightarrow A^* + B^* \,. \tag{87.56}$$

There are two additional processes for positive ion–electron recombination: dissociative recombination

$$e + AB^+ \rightarrow [AB]^* \rightarrow A + B \,; \tag{87.57}$$

dielectronic recombination

$$e + A^+ \rightarrow A^{**} \rightarrow A + \text{photon} \,. \tag{87.58}$$
87.4 Electrical Discharge in Gases: Applications

Some of the many different plasma sources have been reviewed by *Conrads* and *Schmidt* [87.60]. The various discharge types are well described by *Raizer* [87.61]. In the examples of rf discharges, many of the appli-

cations employ control of power input to the plasma by means of automatic impedance matching networks. We present some notes on the more important technical plasma sources.

87.4.1 High Frequency Breakdown

In the theory of high frequency breakdown, the electron energy distribution function is calculated as a function of the applied ac electric field E, using (87.12) and (87.13). From this the ionization frequency is derived, so that the rate of ion production can be expressed in terms of E. At breakdown, the ionization rate equals the sum of the losses due to diffusion, attachment and recombination. The μ_e, ν_e and attachment coefficients, as well as the various rate constants producing new species, depend on E. The electron continuity equation is solved to obtain the breakdown field. (In the absence of appreciable pre-ionization, the electron loss is governed by free diffusion. When the electron loss is controlled by ambipolar diffusion, the operating field of the discharge is obtained. This effect, in addition to cumulative ionization and gas heating, gives an operating field lower than the breakdown field)

Rewriting (87.13) for a constant ν_m, and assuming a Maxwellian velocity distribution, the electron current density becomes

$$J = -e\Gamma_e = \frac{n_e e^2 E_0 e^{-i\omega t}}{m(\nu_m - i\omega)} , \qquad (87.59)$$

where the time dependence of E is written explicitly. The power P gained per unit volume is the time average

$$P = \langle J \cdot E \rangle = \frac{n_e e^2 \nu_m}{m(\nu_m^2 + \omega^2)} \frac{E_0^2}{2} . \qquad (87.60)$$

For a given E, P has a maximum at $\nu_m = \omega$. Equation (87.60) can also be written as

$$P = n_e \frac{e^2 E_{\text{eff}}^2}{m\nu_m} , \qquad (87.61)$$

where the effective electric field is defined by

$$E_{\text{eff}}^2 = \frac{E_0^2}{2} \left(\frac{\nu_m^2}{\nu_m^2 + \omega^2} \right) . \qquad (87.62)$$

E_{eff} is useful for comparing the relative heating effect of alternating and static fields. These considerations are carried further by *MacDonald* [87.62], and are important in determining microwave antenna breakdown fields at high altitudes.

87.4.2 Parallel Plate Reactors and RF Discharges

A situation of interest for plasma deposition and etching is the discharge between two parallel plates driven by a rf power supply. The industrial standard excitation frequency is 13.56 MHz. There have been several quite different approaches. One of the first models due to *Bell* [87.63] treats the discharge as a circuit element, and applies the boundary condition that the sum of the conduction and displacement currents remain constant:

$$J = \sigma E + \epsilon_0 \frac{\partial E}{\partial t} . \qquad (87.63)$$

Substituting for σ, E and $\partial E/t$ in (87.63) for the case where electrons are the major current carriers, and assuming a velocity-independent ν_m, the amplitude of the electric field as a function of position becomes

$$E = \frac{J}{\epsilon_0 \omega} \left(\frac{(1+q^2)}{(\delta-1)^2 + q^2} \right)^{\frac{1}{2}} , \qquad (87.64)$$

where $\delta = \omega_p^2(x)/\omega^2$ (86.2) and $q = \nu_m/\omega$. At high electron densities or low frequency fields, $\delta \gg 1$ and

$$E = E_0 \left(\frac{(\delta_0 - 1)^2 + q^2}{(\delta-1)^2 + q^2} \right)^{\frac{1}{2}} , \qquad (87.65)$$

where E_0, δ_0 denote values at the centre of the discharge. At low densities or high frequency fields, $\delta \ll 1$ and $E = J/(\epsilon_0 \omega)$, i.e. the system acts like a capacitor. It is also necessary to consider the self-bias that the electrodes acquire under the influence of an applied electric field. The bias arises because of the requirement that, averaged over time, no net charge can collect at the electrode. Since the anode current-voltage characteristic is very nonlinear, application of a sinusoidal voltage to the electrode creates at each electrode a negative dc bias approximately equal to the peak amplitude of the rf voltage. The system therefore acts like a hollow cathode discharge with modulated sheath voltages. The ions from the plasma are accelerated across these sheaths and, over most of the rf cycle, acquire sufficient energy to cause secondary electron emission at the electrodes.

The ion flux and energy distribution hitting the substrate depend on the plasma conditions: the values of the dc and rf bias voltages, and the ratio of the transit time of the ions across the sheath to the period of

the rf excitation frequency. The anisotropy and selectivity of the etching processes are determined by the ion energy and its directionality, the etching radical, and the substrate materials. Above energies of several hundred volts, ion bombardment of the substrate causes sputtering, which is relatively unselective. Pure chemical etching by radicals alone may be selective, but it is relatively isotropic. The aim in discharge enhanced processing is to obtain plasma conditions that generate selected radicals with high efficiency, concurrent with bias voltages that provide highly directional ions to prepare the substrate for etching. The combination of these processes gives etch rates that are typically an order of magnitude higher than the sum of the individual processes. The microstructures that can be fabricated using processing are critical to all of high density integrated circuit manufacturing. The achievements are illustrated by 0.2 μm wide trenches in silicon that are 4 microns deep with vertical sides [87.64].

On the other hand, the electrons form an energy-modulated fast electron beam that is injected into the plasma region. These fast electrons maintain much of the ionization in a symmetrically excited, equal electrode area reactor. In principle, it is possible to develop a complete self-consistent model of the rf discharge, consisting of the Boltzmann equation for the energy distribution function of the electrons, positive ions, and negative ions coupled to the Poisson's equation for the electric field. Simpler models based on moments of the Boltzmann equation have been developed for higher pressures [87.65] (where a fluid approximation is more appropriate) and particle-in-cell Monte-Carlo simulations for low pressures [87.64, 66]. The above studies have led to the identification of four principal mechanisms affecting energy deposition. These involve:

1. the impedance of the bulk plasma;
2. the energy deposition by fast electrons created by secondary emission due to ion bombardment of the electrodes;
3. collisionless absorption due to the asymmetrical sheath boundary-plasma electron interaction; and
4. wave-riding, or collisional sheath interactions causing electron heating in the sheath modulated electric field. The electron is regarded as surfing on the expanding sheath field.

Processes (3) and (4) are related, with the difference being that in (4) electron collisions occur during the sheath expansion. There is also an additional interaction due to the changes in the complex impedance (capacitive sheaths and resistive bulk plasma) of the discharge and the consequent changes in the power transferred from the rf generator. The mechanism of collisionless heating is an active research area [87.67]. It is proposed that low pressure rf plasmas can be maintained mainly by collisionless heating in the rf modulated sheaths, and that electron inertia plays a dominant role.

Other less general plasma modes occur due to resonance when the electric field and period are such that one electron transit requires one half period of the rf cycle. Under these conditions at very low pressures, when λ_{mfp} is larger than the gap spacing, and secondary electron emission can occur, one has the multipactor discharge mode. Otherwise, when λ_{mfp} corresponds approximately to small integral fractions of the gap spacing, plasmoid modes are excited.

Dielectric Barrier Discharge

In many applications, such as ozone generation (for water treatment), distributed uv sources, and the creation of radicals for surface treatments, there are economic incentives to operate at high pressures, especially at atmospheric pressure. The dielectric barrier discharge (DBD, also called the silent discharge in earlier literature) is a high voltage of very short pulse duration (1–10 ns) or an ac discharge between two electrodes where at least one of the electrodes is covered with a dielectric [87.68]. The dielectric acts like a high value impedance which prevents discharge current runaway and tends to distribute the average current fairly uniformly across the surface area. The charge transferred by the streamer to the dielectric essentially compensates for the external electric field and limits the discharge duration. Close examination shows that the current terminations on the cathode dielectric are many microdischarges; the termination at the dielectric anode is usually diffuse. The cathode spot diameters are typically only 200 μm so that with a peak current of 0.1 A, the current density is hundreds of A/cm². However, because of the usually very low duty cycle, the neutral gas temperature is close to ambient. The electron temperatures during the discharge pulse are estimated in the range of 1–10 eV, so the DBD is a very non-equilibrium plasma. The charge transferred to the dielectric on the previous pulse strongly affects the next pulse. The high field discharge is efficient at producing excitation, dissociation, and ionization. Miniature DBDs are used in plasma display panels; these are discharges between electrode arrays coated with dielectric and separated by typically 100 μm in a Penning gas mixture at about 500 Torr [87.69].

87.5 Conclusions

The study of the conduction of electricity in gases has had several renaissances because of application incentives. Discharge lighting technology science and development are described by *Waymouth* [87.70]. Atmospheric plasma physics and cosmic plasma physics are covered by *Rees* [87.71] and *Alfvén* [87.72], respectively. The role of plasma physics in gas discharge laser development was recently reviewed [87.73], and the fundamental interactions in laser generated plasmas are detailed by *Hughes* [87.74]. The scaling of discharge volumes to many liters is again of interest because of applications to large area surface treatments and thin films. The discharge enhanced chemistry of complex gas mixtures is of particular relevance to etch processing used for most microelectronics fabrication. Work on discharge-generated and -trapped particulates in microelectronics processing plasmas has re-established links with cluster physics and space plasmas [87.75]. The physics of many of the effects was formulated earlier by *Emeleus* and *Breslin* [87.76]. Future prospects for further exploitation of non-equilibrium gas discharge physics include waste/toxic hazard decontamination, fabrication of defined complex molecules, some with strain energy, selected cluster morphologies, and the further development of large area plasma flat panel displays.

88. Applications to Combustion

However, there have been two major advances in combustion research which contain new ideas and directions in detailed chemistry and physics. The first is the use of powerful computers for the numerical solutions to combustion problems, so that a predictive description can be built beginning with fundamental physical principles. The second is the use of laser diagnostic techniques for the determination of the detailed properties of the combustion system, especially temperature, velocity, and composition, including both major components and trace chemical intermediates. These have not only provided tests of the computational models, but have also furnished new insights and approaches to an understanding of combustion. This has occurred by measuring properties of the system not previously available, or via improved scales of spatial and temporal resolution.

This chapter concentrates on these two areas of physical models and laser diagnostics, and the outstanding physical questions that remain. Each is greatly influencing the development of the two important combustion science issues: describing turbulent flows and incorporating realistic chemistry.

Combustion processes are vital to the operation of present-day society. Although there exist alternative energy sources, combustion of a variety of fuels is worldwide a major mode of energy production, and will remain so for many years to come. Despite a well-established technology, combustion is not without need of improvement. The pollutant emissions associated with burning pose major barriers to more widespread use. Increasingly stringent environmental regulations make this a current focus of combustion research and development.

Both scientific inquiry and empirical solutions will be important in advancing combustion in the future. Most of the progress in combustion technology has been made without benefit of an understanding of the science involved; rather, it has been accomplished through an approach of trial and error, which has led to many ingenious, innovative solutions to problems. In fact, as witnessed by the early development of thermodynamics, the technology has often driven the science rather than the other way around. Nonetheless, future advances in combustion are expected to rely more and more on

a planned implementation of fundamental knowledge of physics and chemistry.

Combustion may be thought of as self-sustaining reactive flow, in which chemical energy is converted into extractable, useful heat. This is usually accompanied by an abrupt change in properties of the system in space and/or time, particularly the chemical composition and the temperature. The description of combustion processes involves the subdisciplines of thermochemistry, chemical kinetics, fluid mechanics, and transport. The major challenge is to apply the known principles from these to a description and understanding of the entire combustion process. This endeavor involves three approaches: experiment, computation, and theory, the latter two differentiated via the characteristic of numerical versus analytical solutions. Each part now plays an important role in combustion science.

The efficiency of combustion processes, be they steady state such as a burner flame or rocket motor, or transitory such as an explosion or internal combustion engine, is generally governed by the overall thermochemistry, fluid dynamics, and heat transfer

characteristics of the system. Details of the chemical reactions and the role of trace intermediates are usually unimportant for this question. The latter do play a key part, however, when considering problems of pollutant formation (emission of NO_x, SO_x, soot, toxic organic compounds), and flame ignition and inhibition. The current challenges in combustion science are solutions to these problems of efficiency and pollution, with advancement likely to occur through two major thrusts: a better understanding of turbulent reactive flow, and the incorporation of detailed chemical kinetics into combustion models (as contrasted to simplified versions such as one- or two-step reaction schemes). Additionally, new areas of science involve combustion under unusual conditions (e.g., microgravity combus-

tion aboard the space shuttle) and new applications (e.g., flame synthesis of exotic materials such as diamond films).

From the viewpoint of the basic science, most of the general, qualitative understanding of behavior at the molecular scale needed to describe combustion is at hand. In many engineering applications, an empirical approach is taken in which a quantitative description of that behavior is condensed and parametrized, using previously acquired experimental data acquired directly on the system of interest. As models become more detailed (often through computational advances), there is a need for further quantitative supporting molecular data, such as improved values of transport properties of molecules.

88.1 Combustion Chemistry

The addition of detailed chemical kinetics to flame models will greatly advance our understanding of combustion, at least for nonturbulent flows. Detailed chemistry is becoming a part of codes describing systems of greater and greater complexity. Numerical integration packages, including full chemistry for a one-dimensional flow, are routinely available [88.1], and progress is being made for the two-dimensional case. A sensitivity analysis enables the modeler to examine the value predicted for some variable (e.g., concentration of a transient species) at a given point in the flame as a function of the rate coefficients and other input variables. This facilitates interpreting the output in terms of physically meaningful variables, and extrapolating the model predictions to other applications.

The quality of the predictions of a combustion model is a strong function of the quality of the reaction rate coefficients for important elementary reaction steps, and the thermochemical properties of reactive species, especially free radicals. A flame chemical mechanism can be quite complex: a current methane/air model [88.2] containing reactions involving only hydrogen, oxygen and carbon (i. e., no nitrogen chemistry) contains 30 species and 177 reactions (plus their reverses). Although it is necessary to include most of these steps in the reaction scheme, a much smaller number play dominant roles in determining any given parameter such as flame speed. The determination of sufficiently accurate rate coefficients for those important reactions is made difficult by the complexity of the reactions, and the difficult conditions (high temperature) and reactants (usually free radicals) that are involved.

There are many unimolecular reactions and their reverses that play important roles in combustion chemistry, including the recombination of fuel-derived radicals such as $CH_3 + H + M \rightarrow CH_4 + M$, and low temperature decomposition/recombination reactions important in ignition, e.g., $H + O_2 + M \rightarrow HO_2 + M$, compared with chain-branching steps. Under most combustion conditions, the important reactions in this class are either in the low pressure limit, where the rate constant is proportional to total pressure P of collider M, or in the fall-off region between that limit and the P-independent high pressure limit. Knowledge of the collisional energy transfer characteristics for highly excited vibrational levels of polyatomic molecules is apropos to a fundamental understanding of these reactions. For purposes of combustion models, these rate constants can be formulated in a modified Arrhenius mode, requiring as many as nine parameters to describe correctly the combined P, T dependence needed for a realistic range of combustion conditions.

A further complication is posed by the multiple potential energy surfaces that can be accessed by many reactions. For example, two methyl radicals can combine to form not only C_2H_6, but also $C_2H_5 + H$. Measurements are often made of the overall rate coefficient (in this case, disappearance of CH_3) but seldom are determinations made of branching ratios into these multiple paths. Especially, the temperature dependence of that branching is rarely known accurately enough. Since reaction rate coefficients can change orders of magnitude over the range of temperatures encountered in combustion, simple extrapolations are seldom sufficient.

Theoretical chemistry has begun addressing these problems. Electronic structure calculations provide thermochemical properties of transient, reactive species. Using theories which include semi-empirical adjustments, enthalpies of formation of free radicals and potential barriers on reactive surfaces can be calculated with accuracies of about 2 kcal/mole, sufficient for modeling purposes. Multidimensional potential surfaces provide starting points for conventional transition state theory calculation of rate coefficients, as well as variational transition state approaches. Theoretical calculations may be useful for understanding the energy transfer questions of unimolecular and recombination rate theory. Also useful are recent laser experiments which examine the foundations of rate theory. These include laser photolysis investigations of the reaction rate coefficient as a function of energy just above threshold [88.3], and the formation of molecules from dissociating complexes on subpicosecond scales [88.4], as well as stimulated emission pumping experiments which probe the density of states and energy transfer in high vibrational levels of diatomic and polyatomic molecules [88.5].

We conclude this section with brief comments on some individual combustion systems. Flames of H_2 and CO burning in (moist) O_2 are relatively simple, and their mechanisms are important subsets of reaction networks for more complex systems. The chemistry of these flames is relatively well understood on a fundamental basis. So, generally, is that of methane, although there remain crucial questions, for example, the rates for $CH_3 + OH$, a multisurface reaction producing singlet and triplet $CH_2 + H_2O$, as well as CH_2OH. For hydrocarbon fuels more complex than methane, the complexity of the mechanism rapidly escalates, due to the many possible ways to combine radicals containing multiple carbon-carbon bonds. For a fuel such as isooctane (where few rate coefficients are known)

it is necessary to use a computer algorithm simply to write down the mechanism without making mistakes or omissions [88.6].

Many pollutant emissions are produced by reactions of trace intermediate species. Nitric oxide has received much recent attention due to increasingly stringent environmental standards. NO is formed in combustion processes in three ways: (i) so-called thermal (or Zeldovich) NO, formed by reaction of $O + N_2$, $N + O_2$, and $OH + N_2$, where the atoms and OH are usually present at nonequilibrium, kinetically controlled concentrations; (ii) prompt NO, which begins with the $CH + N_2$ reaction breaking the strong N-N bond to form N atoms which react with O_2 and HCN, which is oxidized to NO in a series of steps; (iii) and fuel-nitrogen NO, which is formed from the nitrogen present in coal and coal-derived fuels, usually entering the combustion process as HCN. NO can be dealt with through catalytic reduction, staged combustion (burning at a series of mixing ratios), reburning at a later stage with additional fuel, and injection of compounds such as NH_3 or cyanuric acid, $(HOCN)_3$. Progress has been made in the determination of the rate coefficients of many pertinent elementary reactions for each of these processes, but significant gaps remain. Examples are the full T, P dependence of the complex-forming reaction $CH + N_2$, and the complicated reaction pathways in the $NH_2 + NO$ reaction important in de-NO_x through ammonia injection.

The mechanism of soot formation is a matter of dispute; unsaturated chains containing 4 or 5 carbons, aromatic rings, ions, and C_3H_3 radicals have all been suggested as precursors. Ignition (and engine knock) chemistry occurs at low temperatures and probably involves hydroperoxy (HO_2) and alkylperoxy (RO_2) radicals. The mechanism of production of toxic organic compounds such as aldehydes is poorly known, and few relevant rate coefficients are at hand.

88.2 Laser Combustion Diagnostics

The advent of the laser has altered much of experimental combustion science. Laser Doppler velocimetry, which employs particle scattering to measure directed flow velocity, is available in the form of commercial systems. Coherent anti-Stokes Raman scattering (CARS) is widely used in engineering laboratories to study practical combustors, including jet engines, industrial furnaces, internal combustion engines, and burning propellants. Laser-induced fluorescence (LIF) has come

into prominence for the study of combustion systems and related chemical kinetics.

The spectroscopically based techniques of most interest in atomic, molecular, and optical physics are CARS, LIF, and the related recently emerging method of degenerate four wave mixing (DFWM). Each may be used to determine individual molecular species or temperature. Each is highly selective, due to its spectroscopic nature; they provide good spatial resolution, often

on the order of a mm^3 or less; the use of pulsed lasers yields excellent time resolution, $\approx 10\,\text{ns}$. When used properly, they are nonintrusive, perturbing neither the flow dynamics nor flame chemistry. They can be used in very hostile environments (corrosive atmospheres, high temperatures) where physical probes would not survive.

LIF and CARS also have separate, complementary features. CARS is suitable for the determination of major species (fuel, O_2, CO_2, H_2O, and, in air-breathing combustion, N_2). It may be used for accurate temperature measurements, including measurements on a single laser shot when operated in a broadband mode. This makes CARS especially useful for problems in which fluid dynamics and flow patterns are most important. Because CARS produces a coherent, laser-like beam, spatial filtering can be used to discriminate against background radiation such as the intense thermal emission from hot combustor walls. LIF is highly sensitive and is useful for measurements on reaction intermediates present at low concentrations. It may be used in an imaging mode to obtain instantaneous two-dimensional patterns of radical species in rapidly time-varying flows.

Despite their utility, LIF and CARS are not user-friendly technologies. At present, considerable nurturing of the equipment, knowledge of the theory, and care in the data analysis are needed for accurate measurements, and nearly all such measurements are made by scientists trained in physics, chemistry, or physics-oriented engineering departments. Both methods (and DFWM) are examined here with an emphasis on the physics questions in their continued development and application.

88.2.1 Coherent Anti–Stokes Raman Scattering

CARS depends on the nonlinear polarization induced in molecules by the intense electric fields of lasers, exploiting resonant effects in the third order nonlinear susceptibility $\chi^{(3)}$. $\chi^{(3)}$ mixes the fields from a pump laser at frequency ω_1 and a Stokes beam at frequency ω_2 to form a third beam at $\omega_3 = 2\omega_1 - \omega_2$. $\chi^{(3)}$ is strongly enhanced when the difference $\omega_1 - \omega_2$ is tuned to a vibrationally or rotationally resonant frequency in the ground state of a molecule. This is usually accomplished using the intense green beam of a frequency doubled Nd:YAG laser for ω_1, and a dye laser Stokes shifted by the vibrational frequency of the molecule of interest for ω_2. In general, the signal in the visible region of the spectrum contains a combination of a nonresonant $\chi^{(3)}$ due to the electronic polarizability of the medium (mostly

N_2 for air-breathing combustion) and the resonant part. For high concentrations c_A (e.g., $\sim 70\% \, N_2$ in air based flames), the signal is a Lorentzian-shaped resonance on top of the flat nonresonant term, proportional to c_A^2/Γ where Γ is the linewidth. For lower concentrations (e.g., a few percent CO_2 in exhaust gases) the resonant and nonresonant amplitudes interfere, so that the signal is dispersion shaped with a magnitude $\propto c_A/\Gamma$.

A very useful and popular application of CARS operates the Stokes laser in a broadband mode. This generates the entire coherent anti-Stokes spectrum at once, which is then dispersed through a spectrometer and detected with an array. T may be determined from the rotational structure and the appearance of vibrational hot bands. These measurements are generally performed on the N_2, almost always present in large quantity in any combustion system of practical interest. This is the most reliable, accurate method for determination of pointwise temperatures with a single laser shot.

The nonlinear, coherent nature of CARS, in which interfering amplitudes are added, means that spectral details can have a significant influence on the observed spectrum. These include the concentration of all contributing species (including nonresonant background) and the widths of individual Raman lines. The linewidths must be dealt with correctly in order to deduce temperatures accurately from the spectral shapes. It has only been in the past five years that linewidths as a function of rotational level have been available for N_2, at the accuracy needed for application of the spectral fitting codes used for T determination. As P is increased, the lines broaden enough to begin to overlap; at high enough P (several atm for N_2) collisions occur so rapidly that the spectrum collapses to a single broad line. To make T measurements at high pressure, one must deal with both these P broadening and collisional narrowing effects; this requires an understanding of the underlying collision dynamics and energy transfer, generally on a rotational level state specific basis. Both energy transfer and dephasing collisions contribute to the linewidths. For molecules other than N_2, there is scant information on Raman linewidths even at atmospheric pressure, at accuracies needed for modeling CARS spectra. Molecules of particular interest are O_2, CO_2, H_2O, CO, and, in the future, hydrocarbon fuels. In some cases, especially H_2O, further spectral information for high rotational lines (populated at high temperature) is also needed.

Most of the treatments of CARS spectra assume a monochromatic laser. Finite bandwidth effects of real lasers must be taken into account for accurate theoret-

ical treatments (and thus accurate T and concentration determinations). There are several nonequivalent theoretical treatments to convolute the frequency dependence of $\chi^{(3)}$ with the bandwidths of the pump and Stokes lasers.

88.2.2 Laser–Induced Fluorescence

LIF is much more sensitive than CARS, relying on resonant excitation to a real, emitting electronically excited state. The use of a tunable laser to scan the molecular excitation spectrum makes LIF also highly selective for small species that have characteristic, identifiable line spectra. Thus LIF is suitable for measurement of reactive intermediates of importance in understanding flame chemistry. Concentrations determined by LIF range from parts per billion to parts per thousand. Detectable species are diatomics such as OH and CH, triatomics including HCO, NCO, and NH_2, and a few larger molecules including CH_3O. Most of the pertinent molecular electronic transitions are in the UV or blue region of the spectrum. Because VUV radiation cannot penetrate flame gases, atoms (such as H and O) must be detected via two-photon absorption to a high-lying electronic state of the same symmetry as the ground state, which then radiates in the visible or near IR to another excited state.

A list of all molecules through teratomics composed of the five main atoms naturally occurring in combustion (H, C, O, N, and S), and detected to date by LIF, is given in Table 88.1. This forms a large fraction of the small reactive intermediates important in combustion chemistry, so that LIF has the ability to characterize fairly completely a combustion reaction mechanism. It would be particularly desirable to add certain other species; noteworthy are HO_2, C_2H, CH_3, and triplet CH_2, although suitable fluorescing electronic transitions for these molecules are not currently known. In addition to the species listed in Table 88.1, there are many other combustion-related compounds that can be seen with LIF. These include metal atoms and their compounds, species present in specialized combustion situations such as boron or chlorine containing radicals, and some polyatomic, partially oxidized hydrocarbon molecules.

LIF may be employed in several ways to study flames. With a pulsed laser, very rapid time resolution is achievable. Pointwise, single shot measurements (usually of OH) in turbulent flames may be interpreted on a statistical basis for comparison with flame models incorporating simplified chemistry. Two dimensional planar imaging (usually of OH, CH, or NO) is accomplished by focusing the laser into a sheet of radiation which passes through the flame. Imaging the illuminated region at right angles onto a two-dimensional array produces an instantaneous snapshot of the distribution of the radical throughout the flame. This may be used to understand flow patterns under conditions of rapid time variation, such as turbulence or flame spread following ignition.

On the other hand, turbulent flows are far too complex for an investigation of fine details of the combustion chemistry. This is best accomplished via experiments in laminar flames, where LIF is used to obtain spatial profiles (one- or two- dimensional) of reactive species, made as a function of height above a burner surface. Absolute or relative profiles provide highly constraining tests of detailed models of flame chemistry. Operation at reduced P spreads out the active flame front region, furnishing excellent spatial resolution for these profiles. The T profile, used as input to the model, is measured using rotational excitation scans. The OH radical, present throughout much of any given flame contain-

Table 88.1 Combustion chemistry intermediates detectable by laser-induced fluorescence

Molecule	Excitation wavelength (nm)	Molecule	Excitation wavelength (nm)
H*	205	NCO*	440
C*	280	HCO*	245
O*	226	HCN	189
N*	211	HNO	640
S	311	NH_2^*	598
OH*	309	C_3	405

SO*	267	CCN	470
O_2^*	217	NH_3^*	305
S_2^*	308	NO_3	570
C_2^*	516	$C_2H_2^*$	220
$^1CH_2^*$	537	CH_2O^*	320

An asterisk denotes that LIF detection has been performed in a flame

ing hydrogen and oxygen, is an ideal LIF thermometer. LIF may also be used in a semiquantitative way, so that simply the detection of some species at an approximate concentration can reveal new information about the chemical mechanism [88.7]. An example is LIF detection of NS in flames containing minor amounts of N and S compounds, indicating the importance of this radical in linking the chemistry of NO_x and SO_x formation.

LIF measurements involve quantitative knowledge of molecular spectroscopic characteristics and collisional behavior. Identification of the absorbing molecule requires assignment of the vibrational and rotational structure of the electronic transition in question. For weak signals, particularly in the presence of a strong absorber/fluorescor (e.g., CH_3O in the presence of OH near 310 nm), it may be necessary to scan many lines to ensure identification. The fluorescence spectrum is also valuable since selective detection of fluorescence may be used to discriminate between two molecules absorbing at the same wavelength. In many cases, the detailed spectroscopy of molecules of interest is well established in the literature; in other cases, it may be necessary to make studies via flow cells. A recent example is an LIF study of the $B–X$ ultraviolet system of the HCO molecule [88.8], a radical whose reactions are important in controlling the hydrogen atom concentration in hydrocarbon flames. In some cases (e.g., NCO) LIF spectroscopic studies in flames themselves have been useful, in that high rotational and vibrational levels are populated and thus readily accessed. In addition to spectral line and band identification, rotational line strengths and vibrational band transition probabilities (including possible effects of an electronic transition moment that varies with internuclear distance) provide the Einstein A and B coefficients needed for the data analysis. Accurate values are especially important in the determination of T via excitation scans, since systematic errors in oscillator strengths can lead to errors of hundreds of degrees, but are not discernible through statistical goodness-of-fit criteria. Such large errors in T render meaningless any attempts to compare measurements with predictions that include detailed chemical kinetics.

Of considerable consequence for LIF measurements is an understanding of the collisional effects governing the fluorescence quantum yield. For example, in a flame at atmospheric pressure, approximately three of each thousand OH molecules excited by the laser will fluoresce; the remainder is removed nonradiatively by collisions with the ambient flame gases. Furthermore, to reduce interference or background, fluorescence detec-tion is often accomplished using a filter or spectrometer with a bandpass encompassing only a portion of the total fluorescence. Vibrational and rotational energy transfer collisions of the excited radical with the surrounding gases may determine the fraction of emission into that particular bandpass.

Because of the extreme importance of the OH radical to combustion chemistry (and also in the atmosphere), its collisional behavior has been investigated extensively, although not yet completely. The results show definite quantum state and translational energy dependence of energy transfer and quenching cross sections. These are not only crucial to quantitative measurements of this radical, but they are also important in understanding molecular collision dynamics. OH is small enough that its interactions are amenable to quality ab initio calculations, at least with simple colliders like noble gases and H_2. Quantum scattering calculations may then be compared with experimental results; the state-to-state detail provided by this open shell radical furnishes valuable tests of those calculations. Furthermore, they may be compared with spectroscopic characteristics and half-collision dynamics of van der Waals complexes of OH with noble gases (and, in the future, molecular partners).

Quenching of the $A\ ^2\Sigma^+$ excited state of OH is the major factor determining the fluorescence quantum yield. Measurements have been made over a wide range of temperatures, from 200–2500 K, using cooled and room temperature flow cells, laser flash heated cells, flames, and shock tubes [88.9]. For nearly all collision partners the quenching cross section decreases with increasing T, i.e., increasing collision velocity. This shows that attractive forces are involved in the collision, and the form of the variation for most colliders can be explained in terms of a collision complex formation mechanism. The $A\ ^2\Sigma^+$ state of NO behaves similarly, but quenching of the $A\ ^2\Delta$ state of CH increases with T, showing that a barrier exists on the potential surfaces; the $A\ ^3\Pi$ state of NH exhibits more varied behavior.

Quenching also varies with rotational level for OH and NH, as does vibrational transfer ($v = 1 \rightarrow v' = 0$) for OH. This appears to be a dynamic, not energetic, effect, and has been ascribed to a rotational averaging of the effects of the highly anisotropic surface on which these polar hydrides interact with colliders. Vibrational transfer in OH has been studied in both the excited and ground electronic states. It is found to be much faster in the upper $A\ ^2\Sigma^+$ state for all colliders, by factors of 100–1000. This is perhaps related to the fact that, according to ab initio calculations on OH–Ar, there is a much deeper well for interaction of the excited radical

than in the ground state. Rotational transfer in OH has been shown to have some definite propensities, including parity conservation for some collisions with He that is reproduced in quantum scattering calculations.

Such a wealth of detail is not yet available for other free radical combustion intermediates, although they are beginning to be investigated. Of particular current interest is NO and the major precursor to its formation, CH. The details of quenching by a variety of colliders are probably known well enough that quantum yields for OH, NO, and CH may be calculated reasonably accurately, given the local temperature and major species flame composition at the point of measurement. There are enough data to compute quenching rates to within about 30–50% for many flames; this is partly because H_2O, when present, accounts for the majority of the quenching for all three radicals. When the local environment (especially T) is not known, the situation is worse. This would arise for an instantaneous two-dimensional image of a radical in a flame. Even so, the net quenching rate for OH rarely varies more than threefold through the entire flame, so useful semiquantitative information can still be obtained.

If absolute LIF measurements are desired, some means of calibration is necessary. Stable compounds (NO, CO) can simply be introduced into the flames or corresponding cold flows. Free radicals pose a greater problem. OH is often present in sufficient quantity that absorption measurements in a stable, laminar one-dimensional flame can be performed, but this is generally not possible for other species. The recently introduced technique of cavity ring down spectroscopy may alter this situation [88.10]. Burnt gases, in thermal equilibrium at a measured T, furnish a reliable source of known concentrations of OH, H, and O but generally not other radicals (which are consumed earlier in the flame).

Two-photon excitation is used for detection of atomic species and the CO molecule. The high laser flux needed for two-photon absorption, together with the uv wavelengths required for the pertinent transitions, often leads to problems with photochemical interferences. Sometimes these produce the same species that is being measured, e.g., dissociation of vibrationally excited O_2 at the wavelength of atomic oxygen detection, with subsequent excitation of the spurious O atom. In other cases, especially in complex hydrocarbon fuels, a parent compound or partially oxidized fragment may be excited directly or photolyzed to yield an emitting product. Excitation scans and measurements as a function of laser power are needed to discern and avoid these interferences.

88.2.3 Degenerate Four-Wave Mixing

DFWM is a nonlinear process like CARS; but like LIF, it operates on real transitions. It combines some of the attributes of both methods: production of a coherent signal beam that can be spatially filtered to discriminate against background, and high sensitivity so that trace radical species may be detected [88.11]. It depends on $\chi^{(3)}$, as does CARS, and can be used in a broadband mode. Like LIF, it can produce two-dimensional images, with the proper laser sheet arrangement. DFWM adds some of its own advantages, especially a Doppler-free nature enhancing the spectral resolution and thus the molecular selectivity. Three laser beams are used to generate the DFWM signal, all the same frequency, and tuned to an absorption transition of the species of interest. Two pump beams create an interference pattern in the medium, and a probe beam scatters off the resulting grating to form the signal. The interference pattern may be in the ground/excited state populations or may exploit polarization phenomena. Rapid quenching of the excited state may produce a thermal grating in the medium; the probe beam can then scatter from the resulting variation in the index of refraction. DFWM depends only on absorption and may be used for sensitive detection in a nonfluorescing or poorly fluorescing case (e.g., a predissociative state or ir vibrational transition).

The interpretation of DFWM signals to obtain molecular concentrations or temperatures requires knowledge of the underlying physical phenomena. Because they are governed by $\chi^{(3)}$, the DFWM amplitudes interfere, and an understanding of molecular collisions, motion, and the effects of the laser power are needed for accurate modeling of DFWM spectra. Collisional effects are of particular interest due to the Doppler-free character of the technique. Signal intensities can be dramatically influenced by line broadening due to quenching, energy transfer, and dephasing collisions. The magnitude of the influence depends sensitively on the degree of optical saturation. A cohesive picture of these effects is currently being sought through a combination of measurement and theory. Furthermore, nearly all current theoretical treatments assume single-mode lasers; however, real lasers contain intensity and frequency fluctuations within each laser pulse. The effects of these fluctuations on the nonlinear wave-mixing process must be accounted for in a proper description of DFWM. Furthermore, because collisions affect the signal only during the laser pulse, rapid (ps) measurements may provide excellent sensitivity under very high P conditions.

The articles and books [88.7,9,11–18] are of a review or overview nature. In addition, archival articles illustrating the state of the combustion field can be found in the biennial International Symposia volumes published by the Combustion Institute, Pittsburgh, now referred to as the Proceedings of the Combustion Institute.

88.3 Recent Developments

In the last eight years, there have been but two important advances in fundamental combustion laser diagnostics. The first of these is the publication of a book [88.19] containing an in-depth discussion of state of the art laser diagnostics. It includes eight chapters on basic experimental methods, nine chapters on applications, which is presently the largest growing area, and nine chapters on perspectives, future needs, and emerging applications. The interested reader is referred to this comprehensive treatise on the topic.

In recent years, there has indeed been a number of new applications of LIF and CARS to practical combustors (see the Applications chapters of [88.19]). LIF has been extended to only a few new molecules but has been refined for several (see Chapt. 2 of [88.19] for a listing of all pertinent LIF molecules). DFWM has not found significant new applications, and efforts for nonfluorescing molecules have diverted to cavity ringdown spectroscopy. New laser sources are important, especially those in the infrared.

The major experimental advance has been the advent of cavity ring-down spectroscopy (see Sect. 43.2). This topic is covered in [88.20], and its particular applications to flame diagnostics are discussed in Chap. 4 of [88.19]. This method can be used on nonfluorescing molecules which do absorb available laser wavelengths. A recent article on CH in flames [88.21] discusses experimental methodology, references earlier papers, and compares this technique with LIF.

89. Surface Physics

This chapter describes various applications of atomic and molecular physics to phenomena that occur at surfaces. Particular attention is placed on the application of electron- and photon-atom scattering processes to obtain surface specific structural and spectroscopic information.

The study of surfaces and interfaces touches on many fields of pure and applied science. In particular there are applications in the fields of semiconductor processing, thin film growth, catalysis, corrosion and fundamental physics in two-dimensions. A number of recent texts cover surface physics in general [89.1–4] as well as specific areas such as experimental techniques [89.5], surface electron spectroscopies [89.6, 7], and the application of synchrotron radiation to surface science [89.8]. Also a number of book series that deal with areas of particular interest are published at regular intervals, such as surface chemistry [89.9], surface vibrations [89.10] and stimulated desorption processes [89.11].

89.1 Low Energy Electrons and Surface Science

To obtain information specific to the first few layers of atoms at the surface of a solid, techniques must be devised that discriminate between signals from the surface and from the bulk of the material. If a solid has dimensions of $\approx 1\,\mathrm{cm}^3$, then only approximately one atom in 10^7 is located at the surface. This makes the application of bulk techniques to the study of surfaces (e.g. X-ray diffraction [89.12]) problematic.

There are several experimental approaches to achieving surface sensitivity. If the probe used is an atom or molecule that can be scattered from or desorbed from the surface, then these species can be analyzed by techniques such as mass spectrometry or resonant ionization. A more recent innovation has been the use of scanning probe microscopies [89.13] (e.g., the scanning tunneling microscope and its variants) which exploit a surface sensitivity such as the surface valence electron density. However the most common surface analytical techniques use the intrinsic surface sensitivity of low energy (10–2000 eV) electrons.

The surface specificity of low energy electrons arises from the very short inelastic mean free path (MFP) for these electrons in a solid. This property can be seen in Fig. 89.1 which plots measured values of the inelastic MFP for a number of materials and electron energies between 1 and 2000 eV. The curve is called "universal" because the same general trend of short inelastic MFP is observed for nearly all materials [89.14]. The dominant energy loss mechanisms are valence band excitations (plasmons and electronic excitations), and since most materials have similar valence electron densities, the resultant inelastic scattering MFP is to a good approximation, material independent.

The very short inelastic MFPs for low energy electrons has the result that any that escape from the solid without having undergone inelastic scattering can only
Fig. 89.1 The variation of the inelastic mean free path with electron kinetic energy ("universal curve"). Based on *Briggs* and *Seah* [89.14]

have originated very close to the surface, usually within a few atomic layer spacings. Many of the surface analysis techniques described in this chapter use this surface sensitivity to obtain surface structural and spectroscopic information. The same techniques are easily applicable to conducting and semiconducting materials, and can also be applied to insulating materials, if the charging effects are dealt with in some manner.

89.2 Electron–Atom Interactions

89.2.1 Elastic Scattering: Low Energy Electron Diffraction (LEED)

The elastic scattering of low energy (20–500 eV) electrons at surfaces is historically important in physics as the experiments of Davisson and Germer provided early experimental evidence of the wave nature of electrons. After these initial experiments, the technique was largely unused until the advent of cleaner ultra-high vacuum systems and surface preparation techniques in the 1960's. LEED is one of the most important and widely used surface characterization techniques due to its surface sensitivity and wide utility [89.5].

Diffraction from a two-dimensional net of scatterers results in a two-dimensional array of reciprocal lattice "rods" oriented normal to the surface. All kinematically allowed rods intersect the Ewald sphere at all energies — unlike the case in bulk X-ray diffraction. The short inelastic MFP for scattering low energy electrons yields the surface sensitivity of LEED for a crystal surface. The kinematic theory used in X-ray diffraction is not directly applicable to LEED since the low energy electrons can undergo several elastic collisions in the surface region. The elastic MFPs for low energy electrons are comparable in magnitude to the inelastic mean free paths shown in Fig. 89.1. This "multiple scattering" does not affect the positions of the diffraction beams, but does alter their intensities due to interference effects.

Kinematic analysis is sufficient to determine the diffraction beam positions for a proposed structure, and this is the most common use for LEED. A diffraction pattern is often sufficient to determine the surface periodicity and unit mesh size. However determining the

surface crystal basis from the intensities of the diffracted LEED beams requires moderately sophisticated calculations to be performed for proposed structures.

Quantitative LEED generally compares measured "I(V) curves" (the intensity I of a particular diffraction beam as a function of electron energy measured in volts) with a calculated I(V) profile for a proposed surface crystal structure. These calculations determine the propagating electron wave functions Ψ_{LEED} that take into account electron-ion core scattering cross sections and phase shifts, available multiple scattering pathways, inelastic scattering cross sections and Debye-Waller effects. The structural parameters are varied systematically until agreement can be reached with the experimental I(V) curves [89.15, 16]. These calculations can yield surface atom positions to better than 0.1 Å vertically and 0.2 Å horizontally. Over 1000 surface structures have been determined using LEED and associated techniques [89.17].

Clean surfaces often have a different crystallography than simple termination of the bulk crystal structure. Due to the absence of neighbors above the surface, the surface atoms can undergo both relaxation (change in interlayer spacing) and reconstruction (changes in periodicity and bonding) [89.2]. While relaxation and reconstruction do occur on all types of surfaces, the reconstructions found on semiconductors are most striking. The strong covalent bonds that are broken when a semiconductor is cleaved give rise to high energy "dangling bonds". The surface energy is minimized by having the surface reconstruct to reduce the total number of these bonds. The resultant structure is formed through a balance between eliminating as many dangling bonds as possible and the resultant stress caused in other bonds due to the dis-

placements of the surface atoms. One example of this is the clean Si(111) surface, in which 49 surface atoms form a new periodic arrangement to make up the reconstructed Si(111)–(7×7) unit cell [89.2]. The number of dangling bonds is thereby reduced from 49 to 19.

89.2.2 Inelastic Scattering: Electron Energy Loss Spectroscopy

Low energy surface excitations such as phonons, plasmons and electron-hole pair excitations can be studied using inelastic electron scattering. High resolution electron energy loss spectroscopy (HREELS) [89.18] uses incident electron beam energies of 1–300 eV with energy resolutions of 1–10 meV. Inelastic scattering phenomenon are divided into three types: dipole, impact and resonant scattering. Surface vibrations are also studied using infra-red absorption spectroscopy and inelastic atomic beam scattering techniques [89.19].

Dipole Scattering

In dipole scattering HREELS, the incident electron $(1 < E_i < 20 \,\text{eV})$ undergoes a long range Coulomb interaction with dipole fields associated with a dynamic dipole moment. The main characteristic of dipole scattering is that the inelastically scattered electrons have an angular distribution that is strongly peaked (width $\Delta\theta \approx \hbar\omega/E_i$) close to the specular direction $(\theta_i = \theta_f)$. In this limit there is no momentum exchange with the surface vibrational mode (i. e., $\mathbf{k}_\parallel = 0$ in the bandstructure), so dipole scattering HREELS is similar to infrared spectroscopy in that only ir active vibrational modes at the zone center can be studied. At the surface of a conductor, dielectric screening guarantees that only ir active modes having a component perpendicular to the surface are visible — modes having dipole moments parallel to the surface are screened by the surface and so cannot be excited by dipole scattering. This "quasi-selection rule" allows the site symmetry for some systems to be decided [89.18]. Dipole scattering is most commonly used in the study of vibrations of molecules on surfaces, which often have dipole-active vibrational modes that are both intrinsic and caused by adsorption (i. e., frustrated translations and rotations).

Impact Scattering

In impact scattering, the incident electron samples the short-range interatomic potential, and is not restricted to dipole-active vibrational modes [89.18]. Higher electron energies are used $(30 < E_i < 300 \,\text{eV})$ since the cross section for impact scattering generally increases with en-

ergy. The inelastically scattered electrons are distributed at all angles, and so there can be exchange of parallel momentum $(\mathbf{k}_\parallel)$ with the surface, allowing the mapping of surface excitation bandstructure $\hbar\omega(\mathbf{k}_\parallel)$. The cross sections for impact scattering HREELS can be calculated using an approach similar to LEED, but now considering the normal displacements of atoms from equilibrium positions. The scattering potential $V(\mathbf{r}, [\mathbf{R}])$ (where $[\mathbf{R}]$ is the set of position vectors of the N atoms in the surface region) can be expanded in terms of the normal displacements $\boldsymbol{\mu}_i$ from equilibrium according to

$$
\begin{aligned}
V(\mathbf{r}, [\mathbf{R}]) &= V(\mathbf{r}, [\mathbf{R}_0]) \\
&+ \sum_{i=1}^{N} \left(\nabla_{\mu_i} V(\mathbf{r}, [\mathbf{R}]) \right)\Big|_{[\mathbf{R}_0]} \cdot \boldsymbol{\mu}_i + \cdots .
\end{aligned}
\tag{89.1}
$$

The first term is responsible for elastic scattering (LEED) and the second term is the dominant term for impact scattering. The inelastic cross section for mode i is then [89.20]

$$
\frac{d\sigma}{d\Omega} = |\langle \Psi_{\text{LEED}}^*(\mathbf{k}_f) | \frac{\partial V}{\partial \mu_i} | \Psi_{\text{LEED}}(\mathbf{k}_i) \rangle|^2
\tag{89.2}
$$

using electron wave functions calculated using the same formalism as LEED. The symmetry properties of this matrix element can be used to determine the polarization direction of surface vibrational modes by searching for systematic absences in the inelastic intensity in particular high symmetry direction of the surface [89.20]. Impact scattering studies are most commonly made in the study of surface phonon bandstructure and the vibrational modes of adsorbed molecules that are not dipole-active.

Resonant Scattering

Resonant electron scattering at surfaces [89.21, 22] is usually applied to the study of adsorbed molecules, and has much in common with resonant scattering from gas-phase atoms and molecules (see Chapt. 47). In resonant scattering, the incident electron combines with a target molecule to form a short-lived molecular ion, which subsequently decays and can leave the molecule vibrationally or electronically excited. The cross sections for this process have a typical profile. For example, in a shape resonance the formation of the temporary negative ion intermediate corresponds to adding the incident electron to a particular unoccupied orbital of the target molecule. The study of the angular dependence of resonance scattering cross sections [89.22] can yield information on the orientation of molecules on surfaces,

since the electron capture and emission cross sections are fixed by the molecular orientation and the resonance symmetry.

89.2.3 Auger Electron Spectroscopy

Auger electron spectroscopy (AES) is one of the most widely used surface science techniques due to its chemical and surface sensitivity [89.5, 14, 23]. Core holes are created in near surface atoms using a high energy electron beam (2–5 keV, 1–100 μA) or less commonly, an X-ray source. For these low binding energy core holes, the Auger decay mode is highly probable (Sect. 61.2). Although the Auger energy and lineshape can give spectroscopic information, in surface science this is seldom used – rather it is the chemical fingerprint of the atoms which is of interest.

Auger electron spectroscopy is a surface sensitive technique by virtue of the low kinetic energy (50–1000 eV) of the emitted Auger electrons. Auger electrons from atoms more than a few Ångstroms below the surface are inelastically scattered and so not detected by the energy selective detector. The kinetic energy of the Auger electrons is

$$\mathcal{T}_e = E_A - E_B - E_C - U \tag{89.3}$$

where E_A is the binding energy of the initial core electron and E_B, E_C are the binding energies of the other electrons (one or both are valence levels) involved in the Auger process. Energy shifts and relaxation are accounted in the term U which includes hole-hole interactions and atomic and solid state (dielectric) screening of the holes, and hence can be sensitive to the local chemical environment.

Auger spectra are typically obtained in derivative mode [i. e., $N' \, dN(E)/\, dE$] to separate the Auger transitions from the secondary electron background, and comparison is made to reference spectra [89.24]. The raw chemical sensitivity of AES is very high, and surface concentrations of ≈1% of many common chemical species can be detected. Semiquantitative measurements may be made by comparison to these reference spectra, but such comparisons only give atomic concentrations within a factor of 2 (or worse) since the measured AES signal can be modified by a number of factors. More precise quantitative measurements can be made by calibration of the AES intensity for the atomic constituents at a surface [89.5]. The AES sensitivity to atoms A on a clean substrate (atoms B) can be determined if the absolute quantity of A can be established by some other means.

The chemical sensitivity of AES can also be exploited as a form of chemical microscopy (scanning Auger microscopy) since the exciting electron beam that is used may be focused to a very small size. The Auger signal from the small target volume can be analyzed for specific chemical components. By rastering the incident electron beam, a chemical map of the surface can be made.

89.3 Photon–Atom Interactions

89.3.1 Ultraviolet Photoelectron Spectroscopy (UPS)

Photoelectron spectroscopy (PES) (Sect. 61.1) has been historically divided into UV photoelectron spectroscopy for low photon energies (generally the study of valence electron states) and X-ray photoelectron spectroscopy (study of core electron levels). The use of low energy photons ($5 < h\nu < 50$ eV) for PES of solids has the advantage that the photons have a negligible momentum ($k \approx 0$). This allows straightforward band mapping since the transitions are vertical in momentum space:

$$h\nu = E_f(k+G) - E_i(k) \tag{89.4}$$

where k is the electron state wavevector and G is a reciprocal lattice vector.

Most UPS studies are done using angle-resolved photoelectron detection (also called angle resolved photoelectron spectroscopy or ARPES). The kinetic energy $\mathcal{T}_e$ and emission angle θ of the photoelectrons are measured, allowing the initial state binding energy and momentum parallel to the surface $(k_\parallel)$ to be determined from

$$k_\parallel = \sqrt{\frac{2m\mathcal{T}_e}{\hbar^2}} \sin\theta \, . \tag{89.5}$$

The mean free path of the photoelectrons from valence levels allows both surface and bulk electron states to be studied. Separation of the surface from bulk bands can be accomplished in several ways [89.5]. Since a crystal surface has two-dimensional symmetry, only the $k_\parallel$ component of momentum is a good quantum number for the surface states. Also, in transporting the surface or

bulk state photoelectron of momentum $\boldsymbol{k}$ through the surface to the detector, only the $\boldsymbol{k}_\parallel$ component is conserved. A bulk state disperses in three-dimensions, requiring knowledge of $\boldsymbol{k} = \boldsymbol{k}_\parallel + \boldsymbol{k}_\perp$. The magnitude of $\boldsymbol{k}_\perp$ cannot be determined unless the inner potential (change in potential normal to the surface) is known by some other means. This property allows bulk and surface states to be distinguished since surface states remain fixed in energy for a constant $\boldsymbol{k}_\parallel$, while bulk states disperse if $\boldsymbol{k}_\perp$ is changed while $\boldsymbol{k}_\parallel$ is kept constant. This is done by measuring the photoelectron spectrum for a range of UV photon energies at a fixed value of $\boldsymbol{k}_\parallel$ (often at $\theta = 0$ so $\boldsymbol{k}_\parallel = 0$). Bulk states disperse since $\boldsymbol{k}_\perp$ varies as the photon energy is changed, but the surface states remain at a fixed binding energy in the photoelectron spectrum.

The photoelectron transition matrix element between initial and final states $|i\rangle$ and $|f\rangle$ due to the incident photon vector potential $\boldsymbol{A}$ is

$$I \propto \left| \langle f | \boldsymbol{A} \cdot \boldsymbol{p} + \boldsymbol{p} \cdot \boldsymbol{A} | i \rangle \right|^2 \approx \left| \langle f | 2\boldsymbol{A} \cdot \boldsymbol{p} | i \rangle \right|^2 . \quad (89.6)$$

The spatial variation of $\boldsymbol{A}$ near the surface (the surface photoeffect) can be neglected, although this is not strictly valid at these low photon energies [89.26].

Due to the low photoelectron kinetic energies in most UPS work, precise calculation of photoelectron spectrum intensities is rather difficult due to multiple scattering and phase shifts sensitive to valence electrons. However, the initial electron state symmetries can be determined using the symmetry properties of the matrix element (89.6). Selection rules allow the state symmetries to be determined by measuring the photoemission spectrum along high symmetry directions of the surface using polarized UV radiation [89.5].

The valence electron states of adsorbed molecules can also be studied using UPS. Peaks in the photoelectron spectrum due to valence levels of adsorbed molecules tend to have larger linewidths (≈ 1 eV typically) than in the gas phase due to solid state and instrumental effects, so vibrational structure is seldom resolved. The positions of the molecular valence states are shifted in energy due to the surface work function and solid state relaxation (dielectric screening) effects. In addition to these rigid shifts, chemical shifts are also observed due to bonding (chemisorption) interactions between the molecule and surface. The molecular character of the valence orbitals is often retained from the gas phase, so the shifted levels can be identified by using the symmetry properties of the photoemission matrix element. For example, photoemission from gas phase CO shows three valence states: 5σ, 1π and 4σ in order of increasing binding energy. A series of photoemission

spectra [89.25] for gas phase CO, solid CO and CO chemisorbed on several transition metal surfaces (in order of increasing CO–surface binding energy) is shown in Fig. 89.2. For solid CO and weakly chemisorbed CO/Ag(111) all three valence orbitals of molecular CO are well resolved, though the adsorbed CO spectrum is shifted rigidly in energy by relaxation effects. Since CO is chemisorbed more strongly on Cu(111) and Pd(111), the 1π and 5σ valence states shift relative to one another. The strongly overlapping 1π and 5σ states observed for chemisorbed CO can be individually resolved by using the photoemission selection rules and linearly polarized UV radiation [89.25]. The origin of the chemical shift between the 5σ and 1π levels has been ascribed to bond formation involving the CO 5σ level and σ-symmetry d-electron states on the transition metal surfaces [89.2].

89.3.2 Inverse Photoemission Spectroscopy (IPES)

Inverse photoemission spectroscopy is properly classified as an incident electron technique but is included here
Fig. 89.2 A set of UPS spectra for CO adsorbed on various surfaces, as well as gas phase and solid CO. The peak labeled "su" is a shake-up satellite peak. After [89.25]

as a natural companion to UPS. IPES utilizes low energy electrons (5–50 eV) incident on a surface. Transitions from a high-lying initial electron state in the continuum to a lower unoccupied state cause a UV photon to be emitted. By detecting the emitted photon intensity as a function of energy, the joint density of states is measured [89.7]. IPES is used to study the unoccupied portion of surface and bulk bandstructure, particularly the region between the Fermi level and the vacuum level, which is difficult to access by other means. This allows the study of unoccupied states of adsorbed molecules (e.g., antibonding molecular levels) as well as intrinsic surface states such as the Rydberg-like states of electrons trapped in the image potential at the surface [89.7].

89.3.3 X–Ray Photoelectron Spectroscopy (XPS)

X-ray photoelectron spectroscopy allows the study of the energy of atomic core levels via the Einstein photoelectric equation $\mathcal{T}_e = h\nu - E_b$, where $\mathcal{T}_e$ is the kinetic energy of the photoemitted electron and E_b is the binding energy of the core level. Atoms bound in different chemical environments (e.g., at particular sites on a surface) experience different chemical shifts, and so are measured at slightly different binding energies. This sensitivity to chemical environment allows XPS to characterize the different types of binding sites for similar atoms, and measure their abundance by measuring the relative intensities of XPS emission from different species.

Shifts in $\mathcal{T}_e$ arise from two sources: intra-atomic and inter-atomic relaxation shifts. The intra-atomic relaxation E_a is due to screening of the core hole by other electrons in the emitter atom. The inter-atomic relaxation E_r is important in solids (particularly for metals) and is due to screening of the core hole by the dielectric response of the surrounding medium. These relaxation shifts (on the order of a few eV) tend to increase the kinetic energy of the emitted photoelectron, so the kinetic energy in the adiabatic limit is

$$\mathcal{T}_e = h\nu - E_b + E_a + E_r \, . \tag{89.7}$$

Since photoemission is a rapid process, nonadiabatic processes lead to shakeup and shakeoff features in which other electrons are excited to higher energy levels, causing the photoelectron to have lower kinetic energy [89.5] (see Sect. 62.4.4). It is also possible to excite discrete excitations of the solid, such as plasmons and a continuum of low energy electron-hole excitations, causing the XPS peak to have an asymmetric lineshape. The over-

all XPS distributions of $\mathcal{T}_e$ thus contain contributions from the adiabatic channel, and lower energy photoelectrons in a series of discrete peaks or a continuum from nonadiabatic processes.

The chemical abundance of a species can be determined from the sum rule that the total XPS cross section is proportional to the sum of the adiabatic peak and all the shake-up and shake-off components. However it is usually only convenient to measure the intensity of the adiabatic peak. If comparisons are made between chemical species in different chemical environments, the shake-up and shake-off intensities may differ. Hence the adiabatic channel intensities might not reflect the true abundance. Very often this problem can be minimized by careful calibration, and chemical analyses can be made to an accuracy of a few percent.

The surface sensitivity of XPS is due to the short inelastic MFP for the photoelectrons, which can be made to have energies in the range 10–1000 eV by appropriate choice of the X-ray wavelength. The XPS signal is proportional to $\exp[-z/(\lambda \cos\theta)]$, where z is the depth of the emitter, λ is the inelastic mean free path of the photoelectron and θ is the angle measured from the surface normal.

The popularity of XPS as a surface analysis technique is due to the availability of convenient and sufficiently intense monochromatic X-rays from lab sources (usually Al and Mg K_α X-ray lines at 1486.6 and 1253.6 eV). The increasing availability of continuously tunable X-rays from synchrotron radiation sources allows improved measurements due to the ability to tune the X-rays to slightly above threshold, where the XPS cross-sections are maximized, the inelastic MFP is shorter (hence more surface specific) and electron monochromators can operate with higher resolution [89.5].

As an example of the chemical sensitivity of XPS, photoelectron spectra of the $4f_{7/2}$ core levels of W(111) and Ta(111) are shown in Fig. 89.3. The spectra show discrete peaks from both bulk and surface atoms. The binding energies of the surface atoms are affected by the adsorption of hydrogen.

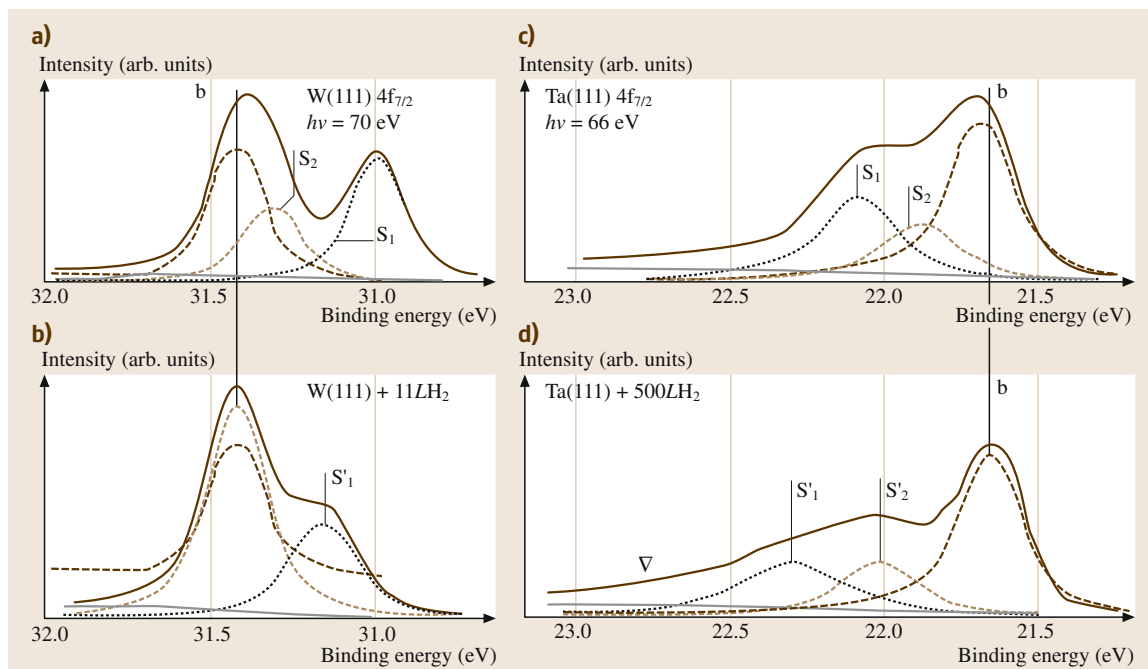
XPS can also be used to give local structural information due to elastic scattering of the photoemitted electron in the region near the emitter [89.5]. One form of this is the use of forward scattering from a buried emitter. A high energy XPS photoelectron is focused in the direction of nearby atoms due to a lower effective potential close to the atomic core. Angular scanning of the XPS detector will then detect a more intense signal along the bond axis. This method has proved useful in


Fig. 89.3 XPS spectra of the $4f_{7/2}$ states of W(111) and Ta(111). Contributions from the bulk (b) and surface (S1,S2) atoms can be distinguished, and the surface atom peaks are shifted by the adsorption of hydrogen. After [89.28]

studying the orientation of adsorbed molecules and the structure of hetero-epitaxial thin films [89.27].

89.3.4 X–Ray Absorption Methods

X-ray absorption methods [89.8] measure the decay of the core hole rather than the intensity of emitted photoelectrons, since that XPS process is complicated by a number of possible final state processes, as discussed above. To obtain surface sensitivity, the X-ray absorption is measured using a low energy electron emitting channel such as an Auger electron emission or the total electron yield, which are proportional to the overall X-ray absorption. These methods require an intense and tunable source of monochromatic x-radiation near the excitation edge for the core level of a particular atom, and so are usually performed using synchrotron radiation. Synchrotron sources have the additional benefit of linearly polarized light, which is crucial for NEXAFS and useful for SEXAFS discussed next.

SEXAFS: Measurement of Bond Lengths

The surface extended X-ray absorption fine structure (SEXAFS) technique is most commonly used to measure the bond lengths for atoms adsorbed on a surface.

SEXAFS utilizes the elastic backscattering of the emitted XPS photoelectron from nearby atoms that surround the emitter. Elastically scattered waves arrive back at the emitter and add coherently (constructively and destructively) to the outgoing wave, thus modifying the matrix element for the transition to the final state [89.29]. Experimentally, the cross section $\sigma(h\nu)$ for X-ray absorption above the threshold photon energy is modified by an oscillatory structure. The 'atomic' contribution to the absorption cross section can be removed using

$$\chi = \frac{\sigma - \sigma_0}{\sigma_0} , \qquad (89.8)$$

where σ and σ_0 are the measured surface and free atom X-ray absorption cross sections. If only single scattering events are involved in backscattering to the emitter then the fine structure function χ is

$$\chi(k) = \sum_{i=1}^{N} A_i(k) \sin\left[2kR_i + \phi_i(k)\right] , \qquad (89.9)$$

where k is the magnitude of the photoelectron wavevector and the sum is done for N 'shells' of atoms surrounding the emitter. The distance R_i is the radius of the ith shell and $2kR_i$ is the associated phase factor

for the backscattered photoelectron, with an amplitude $A_i(k)$. The phase shift $\phi_i(k)$ is required due to the backscattering path through the potential surrounding the emitter and scattering from the atom at R_i. If the ϕ_i could be ignored, then a simple Fourier transform of $\chi(k)$ would reveal the radial distribution function and the bond lengths R_i [89.29]. In practice, the phase shifts cannot be neglected, but very often these can be found by studying chemically similar systems in which the bond lengths are known. The phase shifts for photoelectrons well above the absorption edge (having kinetic energies greater than ≈ 50 eV) are dominated by the atomic ion cores, and so are not sensitive to the valence electronic structure. The phase shifts can also be calculated in a straightforward way since this problem is essentially the same as done in LEED multiple scattering calculations.

The amplitudes $A_i(k)$ due to scattering from shell i at distance R_i from a point source emitter are [89.29]

$$A_i(k) = \frac{N_i^*}{kR_i^2} |f_i(\pi, k)| \exp\left(-2\langle u^2\rangle_i k^2\right)$$
$$\times \exp\left(-2R_i/\lambda\right), \qquad (89.10)$$

where N_i^* is an effective number of atoms and $\langle u^2\rangle_i$ is the mean-square displacement of the atoms in shell i. The backscattering amplitude $|f_i(\pi, k)|$ has been separated from its phase factor $\phi_i(k)$ in (89.9). The inelastic mean free path for the photoelectrons reduces the contribution from successive shells by a factor $\exp(-2R_i/\lambda)$, and it is this term that allows the kinematic single-scattering approach to be used. Multiple scattering paths involve longer trajectories and so are more strongly attenuated by this exponential factor. If the near-edge energy region of the absorption cross section is not included in the analysis, then the scheme outlined in (89.9) and (89.10) is reasonable. The near-edge region (within ≈ 50 eV of the absorption edge) is troublesome, not only because of multiple scattering, but also because the phase shifts $\phi_i(k)$ for low energy photoelectrons are more sensitive to valence electron distributions, and so are more sensitive to the details of the local chemical environment.

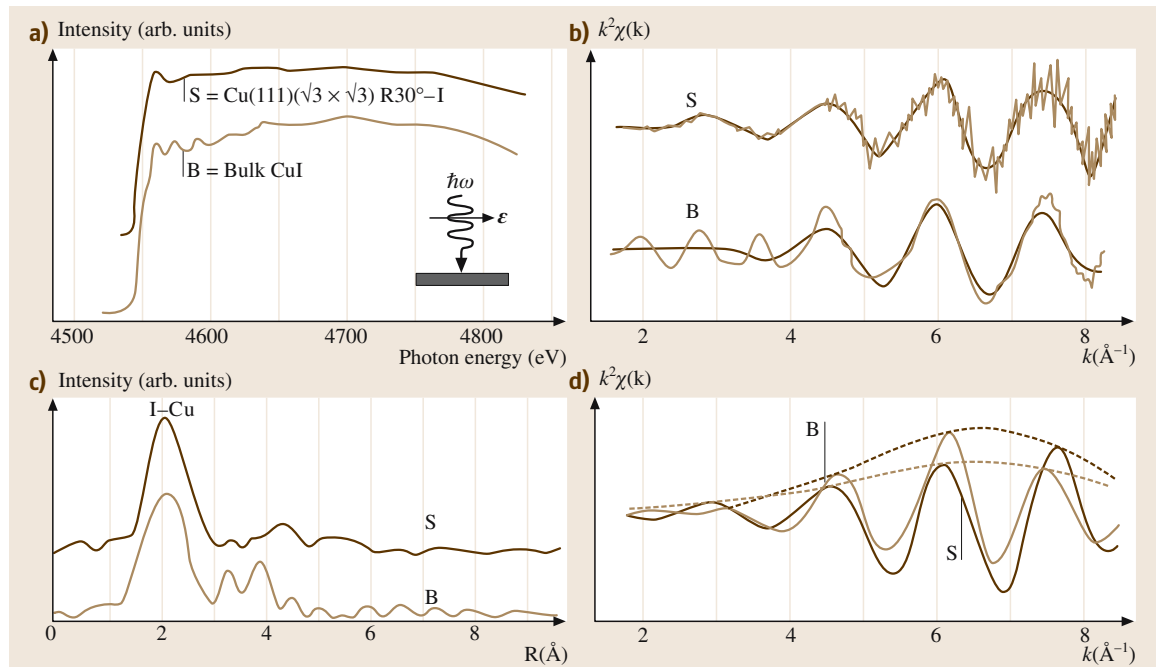
The SEXAFS method is illustrated with the data of Fig. 89.4 for iodine adsorbed on Cu(111). Panel (a) shows the measured X-ray absorption $\sigma(h\nu)$ for both the surface system Cu(111)–I and bulk CuI. The extracted $\chi(k)$ and their Fourier transforms are shown in (b)


Fig. 89.4 (a) X-ray absorption data taken near the iodine edge for bulk CuI and Cu(111)–I. (b) The extracted fine structure function $\chi(k)$, shown multiplied by k^2 to enhance the high k structure. (c) The Fourier transform of $\chi(k)$ showing the location of the first shell of Cu atoms from the I emitters. (d) Back-transformed $k^2\chi(k)$ after applying a filter to extract the nearest neighbor data. After [89.30]

and (c). The Cu–I nearest neighbor bondlength is clearly shown by the peak in (c), and is found to be 0.07 Å longer than in bulk CuI. SEXAFS is most commonly applied to atomic adsorption systems since molecular systems are difficult to analyze, as they can contain several similar bond lengths, and the shells containing different atoms are difficult to model.

NEXAFS: Molecular Orientation at Surfaces

In SEXAFS, the X-ray absorption close to the excitation edge is avoided due to the problems of multiple scattering, and phase shifts that are chemically sensitive to valence electrons. The study of near-edge X-ray absorption fine structure (NEXAFS) can avoid these difficulties by using only the symmetry properties of the transition matrix element without concern for the absolute amplitudes [89.32]. For isolated molecules, unoccupied molecular states having σ or π symmetry are very commonly found close to or just below the threshold for photoemission. These 'molecular resonances' often remain for adsorbed molecules, and the symmetry properties of the absorption intensity $I \propto |\langle f|\boldsymbol{A}\cdot\boldsymbol{p}|i\rangle|^2$ can be used to determine the molecular orientation.

For the overall matrix element to be nonzero, it must be totally symmetric. Using linearly polarized synchrotron radiation, the direction of polarization $\boldsymbol{A}$ can be varied by rotating the crystal. For example, the K-edge X-ray absorption of CO on the Ni(100) surface in Fig. 89.5 shows final state resonances A (π-symmetry) and B (σ-symmetry). The intensity of these features depends of the direction of polarization of the incident X-rays. X-rays with a polarization vector parallel to the surface ($\theta = 90°$) strongly excite the π-symmetry absorption while the σ-symmetry absorption is absent. For grazing incidence X-rays polarized normal to the surface, the σ-resonance is prominent. From dipole selection rules, this polarization dependence of the X-ray absorption is evidence that the CO molecule is adsorbed
Fig. 89.5 Near-edge X-ray absorption data from the C K-edge from CO adsorbed on Ni(100) as function of incident photon angle θ. The molecular π (peak A) and σ (peak B) resonances are observed. The polarization dependence of the absorption allows the CO orientation to be determined. After [89.31]

with its bond perpendicular to the plane of the Ni(100) surface.

The σ-resonance final state in NEXAFS corresponds to multiple scattering of the photoelectron along the bond axis. The overall phase shift for this final state is approximately

$$\int \sqrt{E - V(r)}\, \mathrm{d}r \approx \sqrt{E - V(r)}\, R = \text{const.} \quad (89.11)$$

where R is the bond length. This sensitivity of the final state phase shift to bond lengths allows the σ-resonance energy to be used as a measure the molecular bond length [89.33]. A plot of the σ-resonance energy vs. $1/R^2$ shows a linear relationship, as is found in the case of simple hydrocarbons in the gas phase and adsorbed on a Cu(100) surface [89.32].

89.4 Atom–Surface Interactions

89.4.1 Physisorption

The binding interactions between atoms and surfaces can be classified as physisorption (long range attractive dispersion forces) and chemisorption, in which chemical bonds are formed. The long-range dispersion force between a polarizable atom and a conducting surface give rise to the leading term of the van der

Waals potential $V(z) \propto -1/z^3$. At smaller atom-surface separations, the location of the reference image plane needs to be included, resulting in an attractive potential $V(z) = -C_v/|z - z_i|^3$ where z_i is the distance from the last atomic plane to the image plane, typically 2–3 Å. In principle, the constant C_v is calculable from the dielectric properties of the substrate and the atomic polarizability, but experiments have found values of C_v

40% less than expected [89.34]. The cause of this discrepancy has not been clarified, although contributions from surface roughness have been suggested.

At larger atom-surface separations, retardation effects must be taken into account in the dispersion interaction (the Casimir–Polder force, Sect. 79.2.4), and here theory predicts a $1/z^4$ interaction potential. This form for the potential has been confirmed experimentally [89.35].

As the atom approaches the surface, wave function overlap eventually causes repulsion. In the absence of chemical bond formation, the repulsive potential is simply proportional to the surface electron density $n(z)$, resulting in the overall physisorption potential

$$V(z) = Kn(z) - \frac{C_v}{|z - z_i|^3} .$$ (89.12)

The surface charge density $n(z)$ decreases exponentially above the surface [89.2], and the constant K can be determined to reasonable accuracy by an effective medium theoretical approach [89.36]. This shallow physisorption potential well has been studied experimentally in atomic beam (often He) scattering experiments. Under certain scattering conditions, it is possible for an incident atom to be 'selectively adsorbed' on the surface by making transitions into and out of bound states of the potential well of (89.12). The incident atom with wavevector $\boldsymbol{k}$ is diffracted by a surface reciprocal lattice vector $\boldsymbol{G}_{hk}$ into a bound state E_n of the potential well [89.2]. The diffracted atomic beam intensities due to scattering via selective adsorption show strong variations which can be related to the quantum numbers (n, h, k), and give information on the shape of the physisorption potential well.

89.4.2 Chemisorption

Many atoms and molecules will chemisorb when brought sufficiently close to a surface, forming chemical bonds (covalent or ionic) that are much stronger than the physisorption bond [89.3]. In chemisorption, there is charge transfer between the adsorbate and the surface, modifying the electronic structure of both. Valence electronic levels of the adsorbate are shifted in energy and also broadened by resonant interactions with the delocalized valence electrons at the surface (e.g., free electron-like s–p states). For many transition metal surfaces, interactions with the more localized d–states are also important.

The adsorbate-surface bond energies are most commonly studied by thermal desorption spectroscopy (TDS) [89.37, 38]. In this method, the adsorbate covered surface is heated using a linear temperature ramp, and the desorption rate of a particular species is measured using a mass spectrometer. By using a range of heating rates β, not only can the desorption energy be measured, but the kinetics governing the desorption process can be uncovered. For example, in the simplest case of a coverage-independent adsorption energy and first order kinetics, if the peak desorption rate occurs at a temperature T_0 then [89.39]

$$\frac{\nu}{\beta} = \frac{E_d}{k_B T_0^2} \exp\left(\frac{E_d}{k_B T_0}\right)$$ (89.13)

where E_d is the desorption energy and ν is the 'attempt frequency' for desorption. Since both ν and E_d are unknown, values for both can be found by measuring TDS spectra using two different heating rates β or by estimating ν (often $\nu \approx 10^{13}\,\text{s}^{-1}$). More complex desorption kinetics are studied by utilizing the full desorption profile, and a range of heating rates and initial adsorbate coverages. These kinetic data are also applicable to adsorption if the adsorption and desorption are reversible processes. For irreversible adsorption systems, it is possible to measure the adsorption energies directly [89.40] by monitoring the ir radiation emitted from a surface as a submonolayer quantity of atoms or molecules is adsorbed.

89.5 Recent Developments

Surface Physics has both rapidly matured and expanded its connections with other disciplines in the last eight years. A number of notable review works have been published recently [89.41–45]. The application of surface science techniques has expanded rapidly in a number of technological areas, such as semiconductor devices, catalysis, and magnetic materials. The emerging field of nanotechnology has drawn heavily from the techniques of surface science. Important advances have been made in a large number of areas, including biosurfaces [89.46,47], cluster science [89.48], carbon fullerene materials [89.49, 50], electrochemistry [89.51], and surface photochemistry [89.52].

Continuing advances have been made in the application of light from synchrotron radiation sources — so

much so that a complete catalog of applicable techniques would be difficult to compile. Many new facilities have been constructed, with higher brightness sources allowing the development of a large number of new techniques using synchrotron radiation from the ir through the soft and hard X-ray regimes [89.53, 54].

90. Interface with Nuclear Physics

For an atom with a small to moderately large atomic number Z, the typical length scale a_0/Z of the innermost core orbitals is so much larger than typical nuclear length scales that the corrections to the energy levels and wave functions arising from the non−zero electric charge radius of the nucleus can accurately be computed using first−order perturbation theory, as is described in Sect. 90.1. Nonetheless, these relatively small shifts can sometimes have a profound effect on processes in atomic and/or nuclear physics, particularly if two or more energy levels are very close. For example, as is discussed in Sect. 90.2, the presence of the electron cloud makes energetically possible the β−decay of ^{187}Re to ^{187}Os, and significantly modifies the energy distribution of products in the β−decay of tritium in various chemical environments. Also, electronic screening can greatly enhance the cross−sections of low−energy nuclear reactions relative to what they would be for bare nuclei.

In isotopes of hydrogen, the replacement of an electron by a muon, with $m_\mu \approx 207 m_e$, results in a tiny neutral 'atom' which can closely approach another nucleus, thereby catalyzing nuclear fusion. For example, the rate of deuterium−tritium fusion is enhanced by 77 orders of magnitude if a single electron is replaced by a muon. A rich variety of bound−state properties and scattering processes for these exotic atoms and molecules has been extensively investigated, as is reviewed in Sect. 90.3.

A reader interested in the interface between atomic and nuclear physics should also consult

Chapt. 27 (Quantum Electrodynamics), Chapt. 28 (Tests of Fundamental Physics), and Chapt. 29 (Parity Nonconserving Effects in Atoms) in this Handbook.

That nuclei are not infinitesimally small, structureless particles causes small but perceptible shifts in the electronic structure of atoms and molecules. Even for nuclei with small nuclear charge Z, the effects are readily detectable through modern high precision spectroscopy, and their magnitude grows as $Z^{14/3}$. Conversely, the presence of electrons tightly bound to atomic nuclei can alter the ordering of nuclear energy levels or make them unstable to β decay.

Atomic effects can also influence nuclear branching ratios into the product channels. Nominally small atomic effects have been shown to affect the complicated chain of nuclear reactions responsible for the generation of energy in the sun. Setting bounds to the rest mass of the neutrino from the endpoint of the β-decay spectrum of tritium requires a precise understanding of atomic and molecular structure and scattering processes.

The great disparity between nuclear scales of energy (several MeV) and distance (10^{-5} to 10^{-4} Å) and the corresponding atomic scales (several eV and 1 Å, respectively) usually allows the separate treatment of nuclear and atomic effects. However, since not absolute energies but energy differences determine the magnitudes of perturbative effects, near coincidences in energy differences can greatly enhance the interplay between the two regimes. Such comparable differences of energies account for the important role of nuclear structure in the Lamb shift splitting between the $2s_{1/2}$ and $2p_{1/2}$ states of hydrogen (see Chapt. 27), and the influence of atomic structure on nuclear processes (see Sects. 90.1 and 90.2).

For the case of muonic atoms and molecules, the interplay is enhanced by the much larger mass of a muon relative to an electron. This decreases the distance scale by a factor of m_e/m_μ and increases the energy scale by a factor of m_μ/m_e. Small corrections such as the vacuum polarization part of the Lamb shift are amplified even more ($\approx (m_\mu/m_e)^3$ for low Z).

Besides the areas where atomic physics effects play an important role in nuclear physics, or vice versa, it is worth remembering that atomic and molecular physicists and nuclear physicists can benefit from knowing the theoretical techniques which have been developed in each others' fields. For example, it is well-known that group theoretical methods are widely employed in formulating and solving many-body problems in nuclear, atomic, and molecular physics. To take another case, the coupled-cluster method, which was first proposed in the late 1950s by *Coester* and *Kummel* in the context of nuclear theory [90.1–3], was applied a decade later to electronic structure problems in atomic and molecular physics and quantum chemistry by *Cizek*, *Paldus*, and *Shavitt* [90.4–6], and in the 1970s and 1980s was widely developed by Bartlett and coworkers at the University of Florida. Quite recently, 'quantum halos', which are very loosely bound states for which most of the probability density is spread diffusely over the classically forbidden region, have been treated in a unified manner for both nuclear and molecular systems [90.7].

90.1 Nuclear Size Effects in Atoms

90.1.1 Nuclear Size Effects on Nonrelativistic Energies

Interest in the influence of a finite nuclear charge distribution on the energy levels of the hydrogen atom goes back to the measurement of the Lamb shift [90.8–11], and even earlier indications that the fine structure of hydrogen did not quite agree with the predictions of the Dirac equation for a point nucleus [90.12–15]. The finite proton size does in fact raise the energy of the $2s_{1/2}$ state relative to $2p_{1/2}$, but the shift is only $\approx 0.012\%$ of the dominant electron self-energy contribution (Chapt. 27). It must nevertheless be taken into account in high precision tests of QED.

Early derivations were given by several authors [90.16–19] and generalized by *Zemach* [90.20] (see also [90.21]) to a form involving integrals over the nuclear electric and magnetic form factors. The basic result is illuminated by the following argument. Let $\rho(\boldsymbol{r})$ be the electron density, which may have no spatial symmetry properties in the particular case of a polyatomic molecule, and $\rho_n(\boldsymbol{r}_n)$ be the charge density of a nucleus, which obeys

$$\int \mathrm{d}^3 r_n \, \rho_n(\boldsymbol{r}_n) = Z \,. \tag{90.1}$$

Assume that $\rho_n(\boldsymbol{r}_n)$ has no permanent electric dipole moment, so that

$$\int \mathrm{d}^3 r_n \, \boldsymbol{r}_n \, \rho_n(\boldsymbol{r}_n) = \boldsymbol{0} \,. \tag{90.2}$$

By writing the Coulomb potential for a pointlike nucleus as

$$-\frac{Z}{r} = -\int \mathrm{d}^3 r_n \, \frac{Z \delta^{(3)}(\boldsymbol{r}_n)}{|\boldsymbol{r} - \boldsymbol{r}_n|} \,, \tag{90.3}$$

the first-order shift of the electronic energy due to the replacement of the pointlike nucleus by an extended nucleus is

$$\Delta E_{\mathrm{nuc}} = \int \mathrm{d}^3 r \int \mathrm{d}^3 r_n \, \frac{Z \delta^{(3)}(\boldsymbol{r}_n) - \rho_n(\boldsymbol{r}_n)}{|\boldsymbol{r} - \boldsymbol{r}_n|} \, \rho(\boldsymbol{r}) \,. \tag{90.4}$$

Since the Fourier transform, defined by

$$\hat{\rho}_n(\boldsymbol{k}) = \int \mathrm{d}^3 r_n \, \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_n} \, \rho_n(\boldsymbol{r}_n) \,, \tag{90.5}$$

preserves inner products within a factor of $(2\pi)^3$ and maps convolutions to simple products, the integral in (90.4) reduces to

$$(2\pi)^3 \int \mathrm{d}^3 k \, [Z - \hat{\rho}_n(\boldsymbol{k})] \frac{4\pi}{k^2} \, \hat{\rho}(\boldsymbol{k}) \,, \tag{90.6}$$

where the hats denote the Fourier transforms of the densities and $4\pi/k^2$ is the Fourier transform of the Coulomb potential $1/r$. Since $Z = \int d^3r_n\, \rho_n(\mathbf{r}_n)$, the energy shift can be reexpressed as

$$(2\pi)^3 \int d^3k \int d^3r_n\, (1 - e^{-i\mathbf{k}\cdot\mathbf{r}_n})\, \rho_n(\mathbf{r}_n) \frac{4\pi}{k^2}\, \hat{\rho}(\mathbf{k})\,, \tag{90.7}$$

which is still an exact first-order perturbation expression. Since typical nuclear length scales are much smaller than typical nonrelativistic atomic length scales, it is legitimate to expand the exponential in a Taylor series. The zeroth-order term, -1, is canceled by the $+1$. The linear term, $i\mathbf{k}\cdot\mathbf{r}_n$, contributes nothing by the hypothesis that the nuclear charge distribution has no permanent electric dipole moment. The first nonvanishing term is

$$(2\pi)^3 \int d^3k \int d^3r_n\, \frac{1}{2}(\mathbf{k}\cdot\mathbf{r}_n)^2\, \rho_n(\mathbf{r}_n) \frac{4\pi}{k^2}\, \hat{\rho}(\mathbf{k})\,. \tag{90.8}$$

If $\rho(\mathbf{r})$ is nonzero at the nucleus, then for large k the leading behavior of $\hat{\rho}(\mathbf{k})$ is that of a spherically symmetric s-wave with a radial dependence proportional to k^{-4}. The angular integration in the variable $\mathbf{k}$ leads to the replacement of $(\mathbf{k}\cdot\mathbf{r}_n)^2$ by its average value $\frac{1}{3}k^2r_n^2$, so that expression (90.8) reduces to

$$\frac{2\pi}{3}(2\pi)^3 \int d^3k\, \hat{\rho}(\mathbf{k}) \int d^3r_n\, r_n^2\, \rho_n(\mathbf{r}_n)\,, \tag{90.9}$$

which can be further simplified by observing that

$$(2\pi)^3 \int d^3k\, \hat{\rho}(\mathbf{k}) = (2\pi)^3 \int d^3\mathbf{k}\, e^{i\mathbf{0}\cdot\mathbf{k}}\, \hat{\rho}(\mathbf{k}) = \rho(0)\,, \tag{90.10}$$

and by definition

$$\int d^3r_n\, r_n^2\, \rho_n(\mathbf{r}_n) = Z\langle r_n^2\rangle\,, \tag{90.11}$$

thus yielding the final expression

$$\Delta E_{\text{nuc}} = \frac{2\pi}{3} Z e^2 \rho(0) \langle r_n^2\rangle\,, \tag{90.12}$$

with

$$\rho(0) = \left(\frac{\mu}{m_e}\right)^3 \frac{Z^3}{\pi n^3}\, a_0^{-3} \tag{90.13}$$

for a hydrogenic ion with reduced mass μ. This derivation is independent of the specific nuclear model or the assumption of spherical symmetry of the electron density. Since $\langle r_n^2\rangle$ scales as $Z^{2/3}$, ΔE_{nuc} then scales as $Z^{14/3}$. For a molecule with several nuclei, the contributions (90.12) from each nucleus should be summed.

For the helium atom, $\rho(0) = \langle\delta(\mathbf{r}_1) + \delta(\mathbf{r}_2)\rangle$ can be accurately calculated from high precision variational wave functions (Chapt. 11). For the $1s^2\ {}^1S_0$ ground state, $\rho(0) \simeq (\mu/m_e)^3[3.620\,8586 - 0.182\,37(\mu/M)]a_0^{-3}$ where M is the nuclear mass. Results for other states up to $n = 10$ are tabulated in [90.22]. Combined with high precision isotope shift measurements, the results can be used to extract differences in nuclear radii for pairs such as ${}^3\text{He}/{}^4\text{He}$, ${}^6\text{Li}/{}^7\text{Li}$, and H/D [90.23–26]. The method has recently been applied to the short-lived, neutron-rich nuclei ${}^6\text{He}$, ${}^8\text{Li}$, and ${}^9\text{Li}$ [90.27, 28].

Expression (90.12) works well for atoms with small Z, since relativistic corrections to the electron density are small. However, it breaks down for heavier nuclei, for which relativistic wave functions are needed.

90.1.2 Nuclear Size Effects on Relativistic Energies

The preceding analysis breaks down for relativistic wave functions because they are singular at a point nucleus, making $\rho(\mathbf{0})$ infinite. In this case, the Dirac equations with Hamiltonians H_0 and H for the point nucleus and distributed nucleus cases, respectively, can be combined to obtain

$$(E - E_0)\Psi^\dagger\Psi_0 = \Psi^\dagger H\Psi_0 - \Psi^\dagger H_0\Psi_0\,. \tag{90.14}$$

If a finite radius r_s is now chosen such that $H = H_0$ outside the sphere $r = r_s$, then this equation can be integrated from r_s outward to yield [90.29]

$$\Delta E_{\text{nuc}} = \frac{\hbar c\, (g f_0 - f g_0)_{r=r_s}}{\int_{r_s}^\infty (g g_0 + f f_0)\, dr} \tag{90.15}$$

where f and g are the large and small radial components of Ψ (Chapt. 9), and the numerator is the surface term that remains after integrating by parts the $c\boldsymbol{\alpha}\cdot\mathbf{p}$ term in H. The units are $\hbar c/a_0 = \alpha m_e c^2$. The solutions can be further expanded in terms of Bessel functions, or the Dirac equation can simply be integrated numerically.

For hydrogenic ions up to moderately large Z, the results are reasonably well represented by [90.30, 31]

$$\Delta E_{\text{nuc}} = \frac{2}{3n^3}(Z\alpha)^2 m_e c^2$$
$$\times \left[\delta_{\ell,0} + C_2(Z\alpha)^2\right]\left(Z^2\langle r_n^2\rangle/a_0^2\right)^\gamma \tag{90.16}$$

with $\gamma = \left[1 - (Z\alpha)^2\right]^{1/2}$, and $C_2 \simeq 0.50$, 1.38, and 0.1875 for the $1S_{1/2}$, $2S_{1/2}$, and $2P_{1/2}$ states, respectively. Extensions to higher-order terms are discussed in [90.32]. The above formula was used in the tabulations of *Mohr* [90.31] for $10 \leq Z \leq 40$, while *Johnson* and *Soff* [90.33] used the numerical integration method for Z up to 110. The nuclear electric and magnetization density distributions are tabulated in [90.34], nuclear moments in [90.35], and nuclear masses in [90.36]. In the absence of better data, the rms nuclear radius can be estimated from $\langle r_n^2 \rangle^{1/2} \approx 0.777 A^{1/3} + 0.778 \pm 0.06$ fm, where A is the atomic mass number.

90.1.3 Nuclear Size Effects on QED Corrections

Recent progress in the experimental study of transition energies in heavy ions stripped of most of their electrons [90.37–39] has inspired theoretical work on modifications of QED corrections due to an extended nuclear charge distribution. Calculations based on propagators expanded in terms of basis splines [90.40–42] (Sect. 8.1.1) have led to relatively rapid convergence with the number of angular functions.

90.2 Electronic Structure Effects in Nuclear Physics

90.2.1 Electronic Effects on Closely Spaced Nuclear Energy Levels

The presence of a nearby cloud of electrons can significantly affect nuclear processes involving closely spaced nuclear energy levels. One of the most dramatic cases involves the β-decay process $^{187}\text{Re} \rightarrow ^{187}\text{Os} + e^- + \bar{\nu}_e$, which is energetically forbidden by about 12 keV for bare nuclei, but becomes allowed for the neutral atoms when the difference in electronic binding energies is included. The nuclear charges are $Z = 75$ for ^{187}Re and $Z = 76$ for ^{187}Os. There is also the possibility of the electron being captured into a bound state of ^{187}Os, as opposed to the continuum β-decay process.

The electronic binding energies of heavy atoms can be estimated from the Thomas–Fermi result $E_{\text{TF}} \simeq -20.93 Z^{7/3}$ eV for a neutral atom of charge Z. The difference between the energies of two atoms with nuclear charges $Z + 1$ and Z, respectively, is then

$$E_{\text{TF}}(Z+1) - E_{\text{TF}}(Z) \simeq -48.83 Z^{4/3} \text{ eV}, \quad (90.17)$$

which amounts to -15.4 keV at $Z = 75$. This is more than sufficient to overcome the 12 keV energy deficit in the otherwise energetically forbidden β-decay of ^{187}Re.

The general theory of bound state β-decay is discussed by *Bahcall* [90.43], who also calculated the ratio ρ of bound state β-decay to continuum β-decay for bare nuclei. In the case of $^{187}\text{Re} \rightarrow ^{187}\text{Os}$, ρ is of importance in estimating changes in the half-life for β-decay of ^{187}Re under various conditions of ionization, since the measured isotope ratios $^{187}\text{Re} / ^{188}\text{Re}$ and $^{187}\text{Os} / ^{188}\text{Os}$ from terrestrial rocks and meteorites can be used to determine not only the age of the solar system, but also the age of our galaxy [90.44, 45]. Estimates based on a modified TF model [90.46] indicate that $\rho \simeq 0.01$, and further multiconfiguration Dirac–Fock calculations give $\rho = 0.005$ to 0.007 [90.47–49]. See [90.47–49] for further details and references.

90.2.2 Electronic Effects on Tritium Beta Decay

The mass of the neutrino, normally taken to be zero in the Standard Model, can be determined in principle from analysis of the β-decay process $^3\text{T} \rightarrow ^3\text{He}^+ + e^- + \bar{\nu}_e$. An early measurement based on this method [90.50–52] yielded a neutrino mass of ≈ 25 eV. Several independent tests of this result were initiated soon thereafter. Since the experiments are performed not on bare tritons but on tritium gases and solids under various conditions, it is essential to understand quantitatively the atomic and molecular processes that affect the distribution of the highest-energy electrons produced from various initial states [90.53, 54].

Martin and *Cohen* [90.55] used a Stieltjes imaging technique to calculate shake-up and shake-off probabilities for the β-decay of T_2 into $^3\text{HeT}^+$. Simultaneously, extensive calculations were carried out [90.56] using potential energy curves for the reactant T_2 and TH molecules and the product $^3\text{HeT}^+$ and $^3\text{HeH}^+$ molecules and accounting for the production of electronically and rovibrationally ground and excited final states, as well as resonant states. Nuclear motion was found to have a small but detectable effect on the results, and solid-state effects for frozen T_2 were also investigated and found to be small. These calculations played a crucial role in the interpretation of the experiments [90.57–61], which indicated that the neutrino

mass is less than $\approx 10\,\text{eV}$. In 1998 there was published evidence from the super-Kamiokande experiment that the three flavors of neutrinos oscillate, as further confirmed by the Sudbury Neutrino Observatory. This implies that neutrinos have a nonzero rest mass [90.62]. Subsequently, upper bounds of the order of a few eV to the neutrino mass have been derived from measurements of tritium beta decay [90.63, 64] and from cosmological considerations [90.65].

90.2.3 Electronic Screening of Low Energy Nuclear Reactions

The cross section $\sigma(E)$ for a nuclear reaction involving charged reactants drops very rapidly for collision energies E below the Coulomb barrier. A WKB treatment shows that for low collision energies, the dependence of $\sigma(E)$ can be conveniently expressed as

$$\sigma(E) = S(E)\,E^{-1}\,\mathrm{e}^{-2\pi\eta}\,, \tag{90.18}$$

where $S(E)$ is the astrophysical factor, and

$$\eta = Z_1 Z_2 \alpha c\,(\mu/2E)^{1/2} \tag{90.19}$$

is the Sommerfeld parameter, which depends on the charge numbers Z_1 and Z_2 of the projectile and target nuclides, their reduced mass μ, and the cm energy E. For nuclear reactions involving light nuclei, it is found that $S(E)$ typically varies slowly with E except close to resonances. Thus the accurate determination of $S(E)$ at moderately low E can be used to extrapolate $\sigma(E)$ to much lower energies, which are beyond the reach of laboratory experiments but are of great relevance to the nuclear reactions that occur in stars.

However, electron screening effects can greatly enhance cross sections for nuclear reactions as measured in the laboratory at low energy [90.66], because at least the target nucleus is almost always surrounded by a cloud of electrons which screen the Coulomb repulsion between nuclei. The effect has been observed in various low-energy reactions such as $^3\mathrm{He}(\mathrm{d},\mathrm{p})^4\mathrm{He}$, $^6\mathrm{Li}(\mathrm{p},\alpha)^3\mathrm{He}$, $^6\mathrm{Li}(\mathrm{d},\alpha)^4\mathrm{He}$, and $^6\mathrm{Li}(\mathrm{p},\alpha)^4\mathrm{He}$ [90.67–70]. Since reactions in stars involve bare nuclei, the laboratory data must be carefully corrected for screening effects.

Analysis of the data for the $^3\mathrm{He}(\mathrm{d},\mathrm{p})^4\mathrm{He}$ reaction indicates that the effect of screening is always greater than that predicted in the adiabatic limit [90.71–73]. A more general theoretical treatment of the $\mathrm{d}+{}^2\mathrm{H}$ and $\mathrm{d}+{}^3\mathrm{He}$ reactions [90.74], using a time-dependent Hartree–Fock method for the electrons screening and classical motion for the nuclei found less enhancement than that observed. An improved treatment taking account of electron correlation and quantum-mechanical effects on the nuclear motion will likely be needed. This remains an important area of development for the future.

For some recent work on the subject of electronic screening of low-energy nuclear reactions, see [90.75–80].

90.2.4 Atomic and Molecular Effects in Relativistic Ion–Atom Collisions

High-energy accelerators can now produce beams of atomic ions partly or completely stripped of their electrons, even for Z as high as 92. The collisions of such beams of highly charged ions with fixed targets involve a broad array of atomic and molecular processes, such as excitation, ionization, charge transfer, and, in the extreme relativistic case, pair production. A similarly broad array of theoretical techniques is required to study these topics. A thorough review of them, including comparisons with experimental data where available, is given in [90.81, 82].

A topic of particular recent interest is the first experimental observation of the capture of electrons from electron-positron pair production in the extreme relativistic collision of a $0.96\,\text{GeV}$ / nucleon U^{92+} beam with gold, silver, copper, and Mylar targets [90.83]. The energy and angular distributions of the positrons were also measured. For the gold target, the cross section for capture was nearly as large as that for pair production without capture, and it was found to vary with the nuclear charge Z_t of the target nucleus roughly as $Z_\mathrm{t}^{2.8(\pm 0.25)}$. Neither the dependence on Z_t nor the relatively great probability for capture is in agreement with perturbation theory, which highlights the need for further exploration of this exotic system.

90.3 Muon–Catalyzed Fusion

Exotic muonic atoms and molecules are more suitable subjects than electronic atoms and molecules for probing some physical effects. The muon μ^- is a leptonic elementary particle like the electron except that

it is 206.768 times more massive and has a finite lifetime ($\tau_0 = 1/\lambda_0$, where λ_0 is the rate of decay) of $2.197\,\mu\text{s}$. This lifetime is amply long for most experiments. In normal atoms, the fine-structure splitting

(due to $\boldsymbol{L} \cdot \boldsymbol{S}$ coupling) is much larger than the hyperfine splitting (due to $\boldsymbol{s}_{\mathrm{nuc}} \cdot \boldsymbol{s}_{\mathrm{e}}$ coupling); this relation is reversed in muonic atoms. Likewise, vacuum polarization, relativistic, finite-nuclear-size, and nonadiabatic effects are enhanced. (*Note*: the muonic Bohr radius $\hbar^2/m_\mu e^2 \approx 1/207\, a_0$ is similar in size to the Compton wavelength $\hbar/m_{\mathrm{e}}c \approx 1/137\, a_0$.) Remarkably, muonic molecules make nuclear fusion possible at room temperature. In the phenomenon of muon-catalyzed fusion (μCF), there are both indirect and direct interactions between the atomic and molecular physics and the nuclear physics. Indirectly, the atomic and molecular densities and transition rates control the nuclear fusion rates, and, in turn, the kinetic energies of the fusion products affect the atomic and molecular kinetics. Directly, the nuclear structure affects some molecular energy levels that determine important resonant rates and the boundary condition on the muonic wave functions used to calculate the muon "sticking" loss.

In comparison with μCF, hot fusion schemes are made difficult by the electrostatic (Coulomb) repulsion between nuclei. In the two conventional approaches to controlled fusion, magnetic and inertial confinement, this barrier is partially surmounted by energetic collisions. (*Note*: the particle densities N and confinement times τ in the hot plasmas ($T \gtrsim 10^8$ K) are typically more than ten orders of magnitude different for these two schemes, but the product of the two required for d-t fusion is $N\tau \gtrsim 10^{14}$ s/cm^3 in either case. For muon-catalyzed fusion, effectively $N\tau \approx 10^{25}$ s/cm^3, but this criterion doesn't tell the real story.) On the other hand, in μCF the objective is to tunnel through the barrier without the benefit of kinetic energy. This feat is enabled by binding two hydrogenic nuclei (p, d, or t) in an exotic molecule like H_2^+ with the electron replaced by a negative muon.

Since the molecular size is inversely proportional to the mass of the binding particle, the average distance between nuclei in ppμ is $\approx 1/200$ Å (500 fm) instead of 1 Å as in ppe (i. e., H_2^+). This distance, which would be reached in a d + d collision at ≈ 3 keV ($\approx 3 \times 10^7$ K), is still large compared with the separation of a few fm where the nuclear strong forces cause fusion, but fusion occurs rapidly because of the increased vibrational frequency and, more important, the increased probability of tunneling per vibration. The vibrational frequency is $(m_\mu/m_{\mathrm{e}})^{3/2} \approx 3 \times 10^3$ times faster than for the corresponding electronic molecule. (*Note*: for comparison, the muonic/electronic energy scales as m_μ/m_{e} and the rotational energy scales as $(m_\mu/m_{\mathrm{e}})^2$. These relations [90.84] are based on the Born–Oppenheimer

approximation, which is not very accurate for muonic molecules.) The effect on the tunneling probability depends on the nuclear masses; for dtμ, which has the largest nuclear matrix element (astrophysical S factor, Sect. 90.2.3), the increase is by a factor of $\approx 10^{77}$ compared with DT, and the consequential fusion rate is $\lambda^{\mathrm{f}}_{\mathrm{dt}\mu} \approx 10^{12}$ s^{-1}.

Just on the basis of the fusion rate, one would expect a yield of $\lambda^{\mathrm{f}}_{\mathrm{dt}\mu}/\lambda_0 \approx 10^6$ muon-catalyzed d-t fusions for the average muon. While this number indeed provides an upper limit, the actual average number of fusions, ≈ 150 for dtμ, is much smaller and is determined by the atomic and molecular physics of the catalysis cycle (though the energy released in the nuclear fusion does play an important role here). Some of the atomic and molecular processes in the μCF cycle are quite ordinary, but others, like atomic capture and resonant molecular formation, have no counterpart with "normal" atoms.

Muon-catalyzed fusions of all pairs of hydrogen isotopes, except two protons, have been observed. Based on the experiments and theory, the reaction products are:

$$\mathrm{pd}\mu \rightarrow \begin{cases} ^3\mathrm{He}(0.005) + \mu + \gamma(5.49) & (92\% - 89\%) \\ ^3\mathrm{He}(0.20) + \mu(5.29) & (8\% - 11\%) \end{cases}$$
$$(90.20)$$

$$\mathrm{dd}\mu \rightarrow \begin{cases} \mathrm{t}(1.01) + \mathrm{p}(3.02) + \mu & (41\% - 53\%) \\ ^3\mathrm{He}(0.82) + \mu + \mathrm{n}(2.45) & (59\% - 47\%) \end{cases}$$
$$(90.21)$$

$$\mathrm{pt}\mu \rightarrow \begin{cases} ^4\mathrm{He}(0.05) + \mu + \gamma(19.76) & (60\% - 76\%) \\ ^4\mathrm{He}(0.59) + \mu(19.22) & (23\% - 14\%) \\ ^4\mathrm{He} + \mu + \mathrm{e}^+ + \mathrm{e}^- (19.81\text{total}) \\ \qquad\qquad\qquad\qquad\quad (17\% - 10\%) \end{cases}$$
$$(90.22)$$
(*Note*: the last reaction of (90.22) has been theoretically predicted [90.85], but has not been observed.)

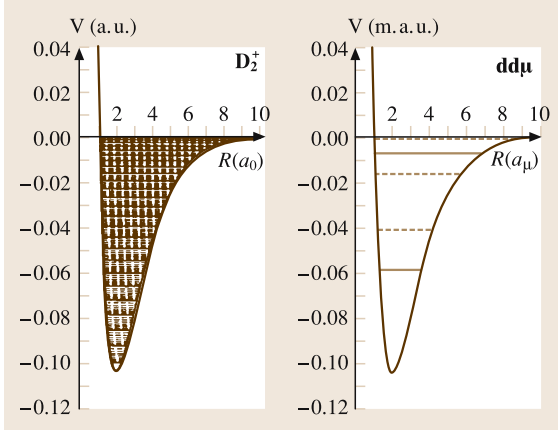
$$\mathrm{dt}\mu \rightarrow {}^4\mathrm{He}(3.54) + \mu + \mathrm{n}(14.05) \qquad (90.23)$$
$$\mathrm{tt}\mu \rightarrow {}^4\mathrm{He} + \mu + 2\mathrm{n}(11.33\text{total}) \ . \qquad (90.24)$$
Here the product particle kinetic energies (in MeV) are given in parentheses. A μ without an energy designated is a spectator, i. e. serves to bring the nuclei together but plays no significant role in the kinematics of the reaction – such a μ may actually be bound (stuck) to one of the product nuclei. As indicated, the branching fractions


Fig. 90.1 Rovibrational energy levels for D_2^+ and $dd\mu$. The $J = 0$ levels are shown as *solid lines* and the $J > 0$ levels are shown *dashed*. For D_2^+, all 28 vibrational levels are displayed, but the associated rotational levels are displayed only up to the next higher vibrational level. All levels of $dd\mu$ are displayed; the $(J = 1, v = 1)$ level is barely discernible below the $V = 0$ axis

Fig. 90.2 The simplified d-t muon-catalyzed fusion cycle. The times are for density $\phi = 1$ (liquid hydrogen density) and tritium fraction $c_t = 0.4$. τ_c is the cycle time, and τ_0 is the muon-decay time

depend somewhat on the target parameters (isotopic composition, density, and temperature) [90.86–88].

Each reaction is of special interest in its own right: $pd\mu$ and $pt\mu$ for the contribution of μ conversion, and $tt\mu$ for the correlation of the two final state neutrons. Only the $dd\mu$ and $dt\mu$ molecular formations are resonant; i.e., their formation can occur in a one-body state because they, and only they, possess a loosely bound state such that the muonic binding energy can go into rovibrational energy of the electronic molecule. That the existence of such a state really is fortuitous can be seen in Fig. 90.1 where the bound rovibrational states of $dd\mu$ (1 m.a.u. = 5626.5 eV) are compared with the rovibrational states of D_2 (1 a.u. = 27.2 eV). Though both $dd\mu$ and $dt\mu$ can be formed resonantly, $dt\mu$ is unique in having a rapid (as compared with muon decay) formation rate and also in having a small sticking loss. The sticking loss is due to the possibility that the negatively charged muon may form a bound state with the positively charged fusion product. The relatively low branching fraction ($< 1\%$) for $dt\mu \to {}^4He\mu + n$ is due simply to the high speed of the outgoing ${}^4He$ (α particle).

90.3.1 The Catalysis Cycle

A diagram of the μCF cycle for a d-t mixture is shown in Fig. 90.2. The basic steps in the cycle are

1. Atomic capture to form $d\mu$ or $t\mu$ (initially in a highly excited state, $n \gtrsim 14$).
2. Transfer of the μ from d to t, if necessary.
3. Resonant molecular formation, shown schematically. Here the $dt\mu$ is so small (in reality) that is can be considered to be a pseudo-nucleus in the electronic molecule.
4. Nuclear fusion.
5. Sticking ($\alpha\mu$ formation) or recycling.

The reaction times shown are at liquid hydrogen density ($\phi = 1$ in the conventional LHD units) and a tritium fraction $c_t = 0.4$, which is close to the value that maximizes the number of cycles. The times for muonic atom formation and deexcitation, $\approx$ ps, are short compared with the times for muon transfer and molecular formation, $\approx$ ns, which in turn are short compared with the muon decay time $\approx \mu$s.

Thus the time for a cycle is mainly given by the average time the μ spends as $d\mu$ waiting to transfer to t plus the average time it then spends as $t\mu$ waiting to form $dt\mu$,

$$\tau_c \approx \tau_{d\mu} + \tau_{t\mu} , \qquad (90.25)$$

or, in terms of rates,

$$\frac{1}{\lambda_c} \approx \frac{q_{1s}c_d}{\lambda_{dt}c_t} + \frac{1}{\lambda_{dt\mu}c_d} , \qquad (90.26)$$

where c_d and c_t are the fractions of deuterium and tritium ($c_d + c_t = 1$), λ_{dt} is the d-to-t transfer rate in the 1s state, q_{1s} is the fraction of dμ atoms reaching the 1s state (before transfer), and $\lambda_{dt\mu}$ is the molecular formation rate. The factor q_{1s} takes into account the fact that any transfer in excited states is rapid (of necessity, since it must compete with the rapid deexcitation).

The cycle rate λ_c along with the sticking fraction ω_s constitute the two basic parameters of the catalysis cycle. The average number of fusions per muon Y is given by

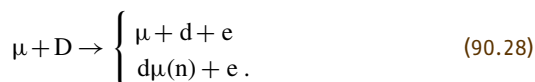
$$\frac{1}{Y} \approx \frac{\lambda_0}{\lambda_c} + \omega_s \tag{90.27}$$

where $\lambda_0 (\equiv 1/\tau_0)$ is the muon-decay rate. (*Note*: more precisely, W should appear in (90.27) in place of ω_s. W may include other losses, e.g., muon capture by impurities, but we will restrict the present discussion to ω_s, which is fundamental and normally dominant.) Coincidentally, the limits imposed on the yield by the cycling rate and by sticking are similar; for $\phi \approx 1$ and $T \approx 300$ K, $\lambda_c/\lambda_0 \approx 300$ and $1/\omega_s \approx 200$ for dtμ. More than 100 muon-catalyzed d-t fusions per muon have been observed. Similar considerations apply to the ddμ cycle, and, by further coincidence, the two limits are similar there as well, $\lambda_c^{dd\mu}/\lambda_0 \approx 7$ and $1/\omega_s^{eff(dd\mu)} \approx 14$. (*Note*: the effective sticking probability (per cycle) in the ddμ cycle takes into account that in only 58% of the fusion reactions is a ^{3}He produced that can remove the μ by sticking. Sticking to t or p is possible but would facilitate rather than terminate the cycling.) The four experimental "knobs" are the temperature (T), density (ϕ), isotopic fractions (c_t, c_d, and c_p), as well as the molecular fractions (c_{D_2}, c_{DT}, c_{T_2}, $\cdots$) in the case of a target not in chemical equilibrium.

Each stage of the cycle is discussed in the following sections. The reader is referred to reviews [90.84, 89–92] for details of the theoretical and experimental methods and extensive values of the relevant parameters.

90.3.2 Muon Atomic Capture

The μCF process starts with a free muon, injected into a mixture of hydrogen isotopes, being stopped to form a muonic atom (stopping power is discussed in Sect. 91.1.1). The slowing and capture occur primarily by ionization, e.g.,

$$\mu + D \rightarrow \begin{cases} \mu + d + e \\ d\mu(n) + e \, . \end{cases} \tag{90.28}$$


The muon is captured into an orbital with $n \gtrsim \sqrt{m_\mu/m_e} \approx 14$, which has about the same size and energy as that of the displaced electron.

Methods for hydrogen and helium atoms have been reviewed in [90.93]; the brief discussion here emphasizes the correct intuitive understanding. Until 1977 most calculations were done using the Born or Coulomb–Born approximation [90.94]. These methods are not very accurate for μ$^-$ at velocities below 1 a.u., but, more importantly, their implementation treated slowing down and capture inconsistently. The upshot was prediction of capture of muons typically with kinetic energies of hundreds of eV, whereas it turns out that most captures actually occur at energies below 100 eV.

The perturbative methods fail because of the great electron charge redistribution that occurs during the capture process. Six other approaches have led to accurate treatment:

1. Adiabatic ionization with straight-line trajectories (AI-slt) [90.95],
2. Adiabatic ionization with curved trajectories (AI-ct) [90.93, 96],
3. Diabatic states (DS) [90.97, 98],
4. Classical-trajectory Monte Carlo (CTMC) [90.96],
5. Time-dependent Hartree–Fock (TDHF) [90.99],
6. Classical-quantal coupling (CQC) [90.100].

The first three are models tailored for the muon capture problem (the first two of these specialized for the hydrogen-atom target). The results for all six methods are shown in Fig. 90.3.

The early study by *Wightman* [90.95] shed a great deal of light on the capture process. His method, known as adiabatic ionization (AI), followed on the observation of *Fermi* and *Teller* [90.101] that there exists a critical strength of the dipole eR_c, formed by the negative muon and positive proton at distance $R_c = 0.639 \, a_0$, for binding the electron. In collisions where the μ$^-$ approaches closer than this distance, the electron is assumed to escape adiabatically, and, if the electron carries off more energy than the muon's initial kinetic energy, the pμ atom is formed. This cross section is thus

$$\sigma_{AI\text{-slt}} = \pi R_c^2 \, , \tag{90.29}$$

and μ$^-$ capture results if and only if $E < 0.5$ a.u., the target ionization energy.

The AI-slt model has three major shortcomings: (1) it does not take into account trajectory curvature, which is caused by the Coulomb attraction of μ$^-$ toward the nucleus and can be large at the low trajectory velocities where capture usually occurs, (2) the adiabatically

escaping electron takes off no kinetic energy, and (3) ionization occurs with unit probability if the approach is closer then R_c. The first failing is easy to remedy. The cross section with curved adiabatic trajectories (AI-ct) is just [90.96]

$$\sigma_{\text{AI-ct}} = \frac{\pi R_c^2}{E} \left(E + \frac{1}{R_c} - 0.5 \text{ a.u.} \right) \qquad (90.30)$$

as long as the collision energy E in the center-of-mass system is greater than 0.03 a.u. (0.8 eV). Hence trajectory curvature increases the capture cross section by a factor $1 + \frac{1.06}{E}$ (for E in a.u.), which is over a factor of three even at the highest collision energy (0.5 a.u.) where adiabatic capture can occur. For $E < 0.03$ a.u., the centrifugal barrier in the effective potential,

$$V_{a(\text{eff})}(R, b) = V_a(R) + \frac{b^2}{R^2} E , \qquad (90.31)$$

restricts penetration and reduces the cross section below the value given by (90.30) [90.93].

Cures for the second and third failings are less trivial. These two assumptions can be avoided by using the diabatic-states (DS) model [90.97, 98]. The adiabatic electronic energy no longer increases once it reaches the continuum ceiling; however, in view of the μ^- acceleration by the Coulomb attraction, the electron cloud actually does not have enough time

to adjust adiabatically. In recognition of this situation the diabatic electronic energy crosses into the continuum at a distance larger than R_c and continues to rise smoothly. The concomitant probability of ionization is given by the ionization width, obtained by a Fermi-golden-rule-like formula. The first three approaches are somewhat specialized models, while the next three are general methods. The most economical in terms of computer time is the classical-trajectory Monte Carlo (CTMC) method [90.96] discussed in Chapt. 58. This method treats the dynamics of all particles completely classically. The time-dependent Hartree–Fock (TDHF) method discussed in Sect. 50.2 is purely quantum mechanical [90.99], but neglects correlation, which turns out to be important in the present problem. This deficiency is remedied by the classical-quantal coupling (CQC) method, which makes only the seemingly well-justified approximation of treating the muon classically while retaining the quantum treatment of the electron [90.100].

Real μ^- capture experiments are done with molecules (H_2, DT, etc.). The naive notion that the H_2 cross section is simply twice that of H is quite unrealistic for slow ($v \ll 1$ a.u.) collisions. In the past decade there has been a major advance in the understanding of μ^- capture by hydrogen, which is the first step in μCF. The captures by the H atom and the H_2 molecule, previously thought to differ by less than a factor of two, have been shown theoretically to be quite different [90.102]. For a comprehensive review of all methods used to threat capture of negative particles see the review article [90.103]. This difference is primarily due to the vibrational degree of freedom, which enables the molecule to capture μ^- at collision energies up to ≈ 40 eV with $n \gtrsim 9$, whereas atomic capture cuts off above ≈ 14 eV with $n \gtrsim 14$. There is a corresponding isotope effect in the molecule, which is absent in the atom. Experiments may be conducted in the near future on the analogous capture of antiprotons by H and H_2 [90.104].

90.3.3 Muonic Atom Deexcitation and Transfer

The muon is captured in a highly excited state but normally must reach the 1s configuration of the heavier isotope (in case of mixtures like D/T) before the muonic molecule is formed. In the 1s configuration there are two hyperfine levels – the ground state with the nuclear and μ^- spins antiparallel and an excited state with spins parallel. Resonant molecular formation rates in the two states can be quite different and also depend strongly on the atom's kinetic energy. Thus there are several

Fig. 90.3 Comparison of different capture cross sections for $\mu^- + H$ collisions: adiabatic ionization with straight-line trajectories(AI-slt), adiabatic ionization with curved trajectories (AI-ct), diabatic states with polarized orbital (DS), classical-trajectory Monte Carlo (CTMC), time-dependent Hartree-Fock (TDHF), and classical-quantal coupling (CQC)

types of muonic atom collisions that must be taken into account: (1) elastic scattering in the ground and excited states, (2) isotopic transfer in excited states, (3) deexciting transitions (which may also occur radiatively), (4) isotopic transfer in the 1s state, and (5) hyperfine transitions. Cross sections for most of these processes have been calculated. The bulk of the calculations have been done by expanding in adiabatic (or modified adiabatic) eigenfunctions, but there also exist some calculations using the coupled-rearrangement-channel, Faddeev, and hyperspherical approaches (see [90.84] for references).

The cascade of the initially formed muonic atom, especially in mixtures, is a complicated process not yet completely characterized. It constitutes a crucial part of the $d-t$ μCF cycle in that it determines the parameter q_{1s} in (90.26). This parameter is essential to experimental analysis, but it was evident that early calculations yielded values of q_{1s} too small to be consistent with experiments. Recent calculations [90.105] suggest the explanation is that the excited muonic atoms are not thermalized. Epithermal atoms have three effects here: (1) the normal transfer rates are smaller, (2) the transfer is reversible down to lower principal quantum numbers n where E still exceeds the threshold for excitation of the next-higher level, and (3) excited-state [from $(t\mu)^*$] resonant formation of $(dt\mu)^*$ molecules that can predissociate back to $d\mu$ is enhanced [90.106]. (*Note*: the isotopic energy splittings are $134.7/n^2$ for $d\mu$-$p\mu$, $182.8/n^2$ for $t\mu$-$p\mu$, and $48.0/n^2$ for $t\mu$-$d\mu$.) The q_{1s} is determined by competition between transfer and deexcitation, which depend on the kinetic energies that result from further competition between superelastic deexcitation and thermalizing elastic collisions. It appears that the stage of the cascade most crucial to q_{1s} is $n \approx 4$ for normal muon transfer and $n = 2$ for the resonant sidepath.

For muons, the elastic cross sections are more difficult to calculate than the inelastic ones. The inelastic transitions occur at short range (a few a_μ) where the effects of electronic structure are negligible. However, electronic effects are not negligible for low energy (< 1 eV) elastic scattering where $\lambda_{dB} \approx 1\,a_0$. They have been taken into account for ground state but not yet excited state scattering. In doing so, it is not necessary to solve the general problem directly because of the following simplifications: (1) this energy is below the vibrational threshold so the molecular target can be taken as a rigid rotor and (2) the relative smallness of the muonic atoms makes the sudden approximation adequate.

If the 1s state is reached without muon transfer to the heavier isotope already having occurred, the transfer takes significant time and plays an important role in determining the tritium fraction c_t that optimizes the fusion yield. All of the 1s isotopic-exchange cross sections display the characteristic $\approx 1/v$ velocity dependence at thermal energies so that the corresponding rate $v\sigma$ is independent of temperature.

In muon-catalyzed d–d and d–t fusions, the resonant molecular formation rates in different hyperfine structure (hfs) states can differ by two or more orders of magnitude at low T due to their different energy levels. The hfs also has important effects on thermalization and diffusion via the different elastic cross sections. Under usual μCF experimental conditions, the hyperfine quenching (or "spin flip") is irreversible; the hfs splittings are 0.1820, 0.0485, and 0.2373 eV for $p\mu$, $d\mu$, and $t\mu$, respectively. Theoretically, it is expected that transitions between hfs levels mainly occur in symmetric collisions since muon exchange suffices in such collisions [90.107]; e.g.,

$$t\mu(\uparrow\uparrow) + t(\downarrow) \rightarrow t(\uparrow) + t\mu(\downarrow\uparrow) \qquad (90.32)$$
(the usual terminology here is "muon exchange" although it might seem more logical to refer to the reaction as "triton exchange" since it is the identity of the tritons that enables the reaction). As in the case of the isotopic exchange cross sections, the behavior is $\approx 1/v$ at thermal energies, so the rates are nearly independent of temperature.

90.3.4 Muonic Molecule Formation

Until the prediction by *Vesman* [90.108] of a resonant formation for $dd\mu$, it was thought that all muonic molecules were formed by an Auger process of the type

$$d\mu + D_2 \rightarrow [(dd\mu)\,de]^+ + e^- . \qquad (90.33)$$
Unlike the resonant process for $dd\mu$ and $dt\mu$, the nonresonant process generally depends weakly on the temperature of the target, the hyperfine state of the muonic atom, and the "spectator" atom X in the molecule DX, where X can be H, D, or T. The nonresonant rate at low (liquid hydrogen) temperature for $dd\mu$ formation is about $3 \times 10^4\,\mathrm{s}^{-1}$ and for $dt\mu$ is about $6 \times 10^5\,\mathrm{s}^{-1}$. These rates are competitive with the resonant rates at low T for $d\mu(\uparrow\downarrow) + D_2$ and $t\mu(\uparrow\uparrow) + D_2$, but are 2 to 3 orders of magnitude smaller than the resonant rates for $d\mu(\uparrow\uparrow) + D_2$ and $t\mu(\uparrow\downarrow) + D_2$, respectively. The $(\uparrow\downarrow)$ state is the ground state; thus hfs quenching plays an important role in low-temperature experiments, especially for $dd\mu$. At room temperature, resonant formation

is dominant for both the ground and excited hyperfine states of dμ and tμ.

In the Vesman mechanism the binding energy of the muonic molecule goes into rovibrational excitation of the electronic host molecule instead of into ionization of a molecular electron. The process is resonant since the collision energy must be tuned to match the energy of the final discrete state. For the compound molecule formed, two sets of rovibrational quantum numbers are needed, e.g.,

$$(t\mu)_F + [D_2]_{K_i \nu_i} \rightarrow \left[(dt\mu)_{J\nu}^{FS} dee\right]_{K_f \nu_f}, \quad (90.34)$$

where (K_i, ν_i), and (K_f, ν_f) are the initial and final quantum numbers of the electronic molecule, (J, ν) are the quantum numbers of the muonic molecule, F is the spin of the muonic atom, and S is the total spin of the muonic molecule. The energetics of this process is shown in Fig. 90.4.

The resonant condition is achieved at the collision energy

$$\epsilon_{res} (t\mu + D_2) = \epsilon_{11}^{FS}[dt\mu]$$
$$+ E_{K_f \nu_f}[(dt\mu) dee] - E_{K_i 0}[D_2], \quad (90.35)$$

where it is explicitly recognized that $(J, \nu) = (1, 1)$ is the only muonic level that can satisfy the resonant energy condition and that only $\nu_i = 0$ is populated at ordinary temperatures. Accurate calculations require values of ϵ_{res} to within about 0.1 meV. The rovibrational energies $E_{K\nu}$ of the electronic molecule, as well as the Coulomb contributions to the binding energy of the muonic molecule, ϵ_{11}^{FS}, are now known to this high accuracy. However, ϵ_{11}^{FS} is subject to corrections due to relativity, vacuum polarization, nuclear charge distributions and polarizabilities, the hyperfine interaction, and
Fig. 90.4 Diagram of energy levels for the resonant reaction $t\mu + [D_2]_{K_i=0, \nu_i=0} \rightarrow [(dt\mu)_{J=1, \nu=1}^{F=0, S=1} dee]_{K_f \nu_f}$. The rovibrational quantum numbers are designated by (J, ν) for the muonic molecule and (K, ν) for the electronic molecules

the finite size and shape of the muonic molecule in the complex. The present overall accuracy is ≈ 1 meV. Some of the resulting values of ϵ_{res} are given in Table 90.1. The calculated cross section for reaction (90.34) is sharply peaked at E_{res}, but must be averaged over a kinetic energy distribution (e.g. Maxwellian) to obtain the observable rate. Still, the rate will display a characteristic resonant dependence on T.

Because the E_{res} are different for each target molecule (D_2, DT, T_2, $\cdots$), the effective molecular formation rate in a mixture depends on the molecular composition in addition to the isotopic fractions ($c_d, c_t, \cdots$) if the target is not in chemical equilibrium.

Table 90.1 Resonant (quasiresonant if negative) collision energies ϵ_{res} (in meV) calculated using (90.35)[a]

$d\mu + D_2$		$t\mu + D_2$				$t\mu + DT$

[a] Note: $kT = 1$ meV for $T = 11.6$ K							

The rate of ddμ and dtμ resonant molecular formation is calculated from

$$\lambda^{mf}(T) = N \sum_f \int \Big\{ d\epsilon \, 2\pi \, |\langle i|H'|f\rangle|^2$$
$$\times f(\epsilon, T) \, I(\epsilon - \epsilon_{if}, T) \Big\} \,, \qquad (90.36)$$

where N is the target density, $\langle i|H'|f\rangle$ is a transition matrix element, $f(\epsilon, T)$ is the collisional energy distribution, ϵ_{if} is the energy of the unperturbed resonance, and $I(\Delta\epsilon, T)$ is the intensity at energy $\Delta\epsilon$ relative to the unperturbed energy. H' has usually been taken to be the dipole interaction ("post" form of the rearrangement-collision Hamiltonian using the dtμ bound state as the zeroth-order Hamiltonian [90.109]),

$$H' = e^2 \boldsymbol{d} \cdot \boldsymbol{E} \,, \qquad (90.37)$$

where $\boldsymbol{d}$ is the dipole operator of the dtμ (or ddμ) system and $\boldsymbol{E}$ is the electric field at the dtμ (or ddμ) center of mass due to the "spectator" nucleus and electrons [90.110]. Conservation of angular momentum thus requires [90.111]

$$\boldsymbol{L} + \boldsymbol{K}_i = \boldsymbol{J} + \boldsymbol{K}_f \qquad (90.38)$$

where $\boldsymbol{L}$ is the orbital angular momentum of relative motion for tμ + D$_2$ in reaction (90.34). At low T, $L = 0$ is predominant so that $K_f = K_i \pm 1$. This is simply the case for dμ + D$_2$ → (ddμ) dee where the most probable transition is $(K, \nu) = (0, 0) \rightarrow (1, 7)$. For dtμ the vibrational state of the electronic molecule changes by only $\Delta\nu_i = 2$ or 3 instead of 7, so the matrix element of (90.37) and the resulting rate are considerably larger than for ddμ. However, it can be seen in Fig. 90.4 that if D$_2$ is in its ground state ($K_i = 0$), the first level energetically accessible for (dtμ) dee has $K_f = 3$. If, as proves to be adequate in the case of ddμ, the intensity distribution I is taken to be a δ function, the lower levels are eliminated from (90.36). There are two possible solutions to this problem, whose importances have not been fully resolved: (1) the less likely $L > 0$ collisions contribute or (2) the levels with smaller K_f play a role even though they lie "below threshold".

The latter case is termed "quasiresonant". Theoretically the levels below threshold can contribute (1) directly if they are broadened so that they extend to positive energy [90.112–114] or (2) indirectly if configurations with different K_f are mixed [90.115]. Broadening can occur either inhomogeneously due to the finite lifetime (mainly with respect to Auger emission of an electron in the complex) or homogeneously due to collisions with neighboring molecules. Interactions

with neighboring molecules also can mix the different K_f states, so the $K_f = 3$ state may "borrow" some intensity from the lower K_f states. Three-body molecular formation facilitated by neighboring molecules leads to a density dependence of the formation rate (normalized to LHD) that has been observed in experiments.

Experimentally, the resonant $dt\mu$ formation has now been observed directly [90.116]. Previously the experimental evidence for this mechanism derived from the magnitude and the temperature dependence of the μCF cycling rate. The new experiment, at TRIUMF, obtained the energy-dependent molecular-formation rate by measuring the time of flight between a cryogenic layer where the $t\mu$ atom was formed and a second cryogenic layer where the $dt\mu$ molecule was formed and fusion occurred.

90.3.5 Fusion

Usually the nuclear fusion rate in muonic molecules is calculated by a separable method; i.e., the united-atom limit of the molecular wave function is determined ignoring nuclear forces and then simply multiplied by a single number extracted from nuclear scattering experiments [90.117]. Fusion of d − t is strongly dominated by the $I^\pi = \frac{3}{2}^+$ resonance of ^{5}He. For dtμ we have

$$\lambda^{\mathrm{f}}_{\mathrm{dt\mu}} = A \lim_{r_{\mathrm{dt}} \to 0} \int |\psi_{\mathrm{dt\mu}}|^2 \, d^3 r_\mu \,, \qquad (90.39)$$

where A is simply related to the low-energy limit of the astrophysical S factor by

$$A = \frac{\hbar}{\pi e^2 M_{\mathrm{r}}} \lim_{E \to 0} S(E) \,, \qquad (90.40)$$

where M_{r} is the reduced mass of the nuclei. $S(E)$ is usually obtained by fitting the d + t fusion cross section observed in beam experiments to the form of (90.18).

The above formulation has yielded fusion rates in good agreement with another formulation – more accurate in principle – where a complex molecular wave function and energy are obtained directly incorporating the nuclear forces. In the latter approach,

$$\lambda^{\mathrm{f}}_{\mathrm{dt\mu}} = -2 \, \mathrm{Im}(E_{\mathrm{dt\mu}})/\hbar \,, \qquad (90.41)$$

where $E_{\mathrm{dt\mu}}$ is the complex eigenvalue (the imaginary part is $-\Gamma/2$, where Γ is the width). The nuclear effect in this formulation is taken into account by two different techniques: (1) using a complex optical potential [90.118, 119] (Sect. 48.2), and (2) using the nuclear R-matrix as an interior boundary condition [90.120–122] (Sect. 47.1.5). In the optical potential

method, a short-range complex potential, determined by fitting experimental nuclear scattering data, is added to the three-body Coulomb potential; the real part describes elastic scattering and the imaginary (absorptive) part describes the fusion reaction. Then the eigenvalue problem is solved over all space with a regular boundary condition at the origin. In the R-matrix method, the same nuclear scattering data are used to determine a complex boundary condition at a distance characteristic of the nuclear forces, say $r_{dt} = a_{dt}$ where $a_{dt} \approx 5$ fm. The muonic eigenvalue problem is then formulated with the boundary condition at $r_{dt} = a_{dt}$ and solved over the space excluding $r_{dt} < a_{dt}$. The two methods can be used with similar basis sets to expand the wave function, which can also be used to calculate the sticking probability (Sect. 90.3.6).

The relation of other μCF cross sections to normal beam experiments is somewhat more complicated. In the cases of ddμ and ttμ, the fusion may occur in $J=1$ states, since the $J=1$ to $J=0$ transition is forbidden in molecules with identical nuclei. In this case the relevant information from beam experiments resides in the p-wave anisotropy, which is relatively small at low energies where σ is dominated by the s wave. It is then necessary to carry out the analysis in terms of the partial-wave transition amplitudes rather than the fit of the integrated σ via the S factor [90.123].

Fusions in pdμ and ptμ present a different complication [90.117]. There is a significant $E0$ contribution from muon conversion in addition to the $M1$ γ-ray contribution seen in p + d and p + t beam experiments (see Sect. 12.1 for discussion of multipole moments). The $E0$ contribution cannot be expressed through cross sections observed in the beam experiments, but has been determined using the bound-state nuclear wave functions of ^{3}He (or ^{4}He) and scattering wave functions of p + d (or p + t). For pdμ there is the additional complication that two different p − d spin states contribute significantly. For ptμ, theory [90.117] predicts that the probability of the fusion energy going into a $e^+ e^-$ pair is competitive with that of muon conversion, though the former has not yet been observed.

90.3.6 Sticking and Stripping

The fundamental mechanism of muon loss from the catalysis cycle, other than by particle decay, is via sticking to a helium nucleus, ^{4}He$(\equiv \alpha)$ or ^{3}He, produced in the fusion reaction. Especially in the case of dtμ, where the charged particle is fast and the sticking probability is already small, subsequent collisions may strip the

muon. Thus the sticking probability is determined by two steps

$$ (90.42) $$
The initial sticking probability ω_s^0 depends only on intramolecular dynamics, but the stripping conditional probability depends on collisions. (Note that ω_s^0 is not the sticking in the zero-density limit since R is still finite in this limit.) The net sticking is then

$$ \omega_s = \omega_s^0 (1 - R) . \qquad (90.43) $$

Since the nuclear reaction is very rapid compared with the atomic and molecular dynamics, the probability of sticking in a given state ν is given adequately by the sudden approximation,

$$ P_\nu = \left| \left\langle \psi_\nu^{(f)} | \psi^{(i)} \right\rangle \right|^2 , \qquad (90.44) $$

where the initial wave function $\psi^{(i)}$ is the normalized molecular wave function in the limit $r_{dt} \to 0$ and the final wave function $\psi_\nu^{(f)}$ is given by

$$ \psi_\nu^{(f)} = \phi_{n\ell m}(\mathbf{r}) \, e^{i\mathbf{q}\cdot\mathbf{r}} \qquad (90.45) $$

in which $\phi_{n\ell m}$ is an atomic wave function of $\left(^4\text{He}\mu\right)^+$ and the plane wave with momentum $\mathbf{q}$ represents its motion with respect to the initial molecule (recoil determined by conservation of energy and momentum). The total sticking is then

$$ \omega_s^0 = \sum_\nu P_\nu . \qquad (90.46) $$

The $\left(^4\text{He}\mu\right)^+$ wave function is known analytically since it is hydrogenic. Most of the labor goes into determination of the muonic molecule wave function. In the Born–Oppenheimer approximation this is simply "$\left(^5\text{He}\mu\right)^+$" and results in $\left(\omega_s^0\right)_{\text{BO}} = 1.20\%$ for dtμ [90.124]. More accurate nonadiabatic calculations show that the muonic motion lags behind that of the nuclei and reduces ω_s^0 to 0.886% [90.125, 126]. After inclusion of nuclear effects, the best current theoretical value of ω_s^0 is 0.912% [90.122, 127].

Since the ground state (Heμ)$^+$ ion is bound by 11 keV, it takes a quite energetic collision to strip off

the muon. The reactivation fraction R is determined basically by competition between collisional processes that slow down the muonic ion and those that lead to stripping. Calculation of R requires a full kinetic treatment of the fast $(He\mu)^+$ ion, starting with its distribution among various states $(1s, 2s, 2p, \cdots, n \approx 10)$. The most important processes are stopping power (due mainly to ionization of the medium) and muon ionization or transfer in collisions of the $(He\mu)^+$ ion with an isotope of H, but inelastic (excitation and deexcitation), Auger deexcitation, and ℓ-changing collisions as well as radiative deexcitation are also involved. The initial sticking occurs mostly in the 1s state (77% of the $\alpha\mu$'s from $dt\mu$ fusion), but the excited states have larger ionization cross sections. Most of the muons stripped from $\alpha\mu$ originally stuck in the 1s state, but a significant number are promoted to excited states before being ionized (so-called "ladder ionization"). The metastable 2s state is significant for its role in prolonging the excited state populations. The resulting values of R and ω_s are shown as a function of density in Fig. 90.5.

Most experiments on d-t μCF have been done with neutron detection [90.137–139], where λ_c and the muon loss probability per cycle W can be deduced from the time structure of the neutron emissions. The analysis is indirect and requires a theoretical model. What is actually measured is the product $W\phi\lambda_c$; the extraction of ω_s requires corrections for other loss mechanisms and separate determination of λ_c. Thus it is desirable to have other experimental diagnostics. Two types of
Fig. 90.5 Theoretical sticking fraction *(solid curve)* and reactivation probability *(dashed curve)* for d-t μCF

corroborating experiments detect either X-rays from the $\alpha\mu$ formed by sticking or detect the species $(\alpha)^{2+}$ and $(\alpha\mu)^+$ by the different effects of their double and single electrical charges.

The theoretical sticking is compared in Table 90.2 with that from all three types of experiments. For a more meaningful comparison of measurements at different densities ϕ, the theoretical R has been used to convert all values to ω_s^0. The theoretical values are slightly, but significantly, higher than the observations. This discrepancy has not yet been resolved.

One intriguing explanation for the lower-than-predicted value of ω_s may be that a significant fraction of the fusions might occur in muonically excited bound

[a] Experimental values of ω_s^0 without error bars were obtained assuming the theoretical stripping [90.135, 136]
  In cases of two error estimates, the first is statistical and the second is systematic
  The extraction of ω_s from the X-ray experiments requires theoretical scaling

or resonant states for which the initial sticking is lower than in the ground state [90.140].

A recent experiment has systematically studied muon-catalyzed fusion in solid deuterium and tritium mixtures as a function of temperature and tritium concentration [90.141]. An unexpected decrease in the muon cycling rate (λ_c) *and* an increase in the muon loss (W) were observed. The former is likely due to the freezing out of phonons contributing to the resonance energy. The latter is especially intriguing. It is inconceivable that ω_s^0 for fusion in a given state of $dt\mu$ could depend on temperature, but this observation could imply either an unexpected effect of temperature on the muonic state in which fusion occurs *or* an unpredicted temperature dependence of the thermalization kinetics (e.g., due to ion channeling). It should be noted that the experimental analysis does not reject the possibility of some correlation between the extracted values of λ_c and W [90.140].

90.3.7 Prospectus

There is still a great deal to be learned from the less-studied μCF cycles, like those of p-d, p-t, and t-t, but more quantitative work is also needed on some key processes in the d-t μCF cycle: in particular, three-body effects on molecular formation at high densities, the excited-state cross sections and kinetics that go into the determination of the cascade factor q_{1s}, and the remaining discrepancy in the sticking factor ω_s which might have a theoretical or experimental resolution. Experimentally it is of interest to push on to higher temperatures and densities to see if more surprises lurk there. There have been a few schemes proposed to enhance stripping of stuck muons artificially, but none has been subjected to experiments yet.

The currently observed yield of about 150 d-t fusions (releasing 17.6 MeV each) per muon produces an energy return 25 times the rest-mass energy of the muon, but is only about one-third of that required for breakeven in a pure-fusion reactor. This conclusion is based on the estimated energy cost of producing a muon, ≈ 8 GeV [90.142, 143]. Other possible practical uses include a hybrid (fusion-fission) reactor [90.142, 143] or an intense 14 MeV neutron source [90.144].

Apart from such technological applications, the study of μCF is fruitful for a number of reasons including (1) bridging the gap between atomic and nuclear physics, (2) enabling nuclear reactions (including p-waves) at room temperature, (3) allowing precise studies under unusual physical conditions, (4) observing a compound electronic-muonic molecular environment, and (5) exhibiting phenomena spanning nine orders of magnitude in distance and energy. The experimental possibilities are far from exhausted even though the holy grail of pure fusion energy now appears just beyond reach.

91. Charged–Particle–Matter Interactions

In the description of the interaction of fast charged particles with matter, two aspects can be distinguished: the effects on the particle, usually energy losses and deflections, and the spatial distribution of the energy lost by the particle in the absorber.

This Chapter discusses concepts needed in the operation of charged particle detectors and in describing radiation effects (Chapt. 92). Specifically, the radiation effects used for the instantaneous observation (i. e., within fractions of a millisecond) of the passage of a charged particle are described. Delayed effects, such as chemical reactions (e.g., biological effects, chemical dosimeters, photographic emulsions), metastable states, etc. are not discussed. It is assumed that particle speeds have been determined with, e.g., magnetic analyzers or by measurement of the time of flight. A measurement of particle ranges can also be used to determine the initial speed. The description is restricted to fast charged particles, defined by speeds $v > 6v_B$ (v_B is the Bohr speed), or $\beta = v/c > 0.04$. Interactions and cross sections at smaller speeds are discussed, e.g., by *Rudd* et al.[91.1] and in [91.2].

The present Chapter primarily considers energy loss straggling, rather than the stopping powers discussed by *Fano* [91.3].

It is important to understand that the mean energy-loss is not a suitable concept to use in the description of energy-loss spectra for thin absorbers. The most probable energy-loss should be used instead. The methods described here can be used to calculate reliable data for detector applications. No attempt is made to present a complete review. Anecdotal, qualitative examples of various effects are described. The following definitions are used:

1. The number of atoms or molecules per unit volume $N = N_A \varrho / A$, with A the molecular weight (in g/mole) of the absorber (with Z_2 electrons per molecule), ϱ its density, and N_A is Avogadro's number;

2. The relativistic factors β and γ for particles with rest mass M_0, speed $v = \beta c$ and kinetic energy $\mathcal{T}$:

$$\beta^2 = \left(\mathcal{T}/M_0 c^2 \right) \left(2 + \mathcal{T}/M_0 c^2 \right) \Big/ \left(1 + \mathcal{T}/M_0 c^2 \right)^2 ,$$

$$\gamma = M/M_0 = 1 + \mathcal{T}/M_0 c^2 ,$$

$$\gamma^2 = 1/\left(1 - \beta^2 \right) ,$$

$$\beta^2 \gamma^2 = \gamma^2 - 1 ;$$

3. The coefficient of the Rutherford equation:

$$k_R = \frac{2\pi Z_1^2 e^4}{m_e c^2} = 2\pi r_0^2 m_e c^2 Z_1^2$$
$$= 2.549\,55 \times 10^{-19} Z_1^2 \text{ eV cm}^2 , \qquad (91.1)$$

where m_e is the rest mass of an electron, $-e$ its charge, $Z_1 e$ the charge of the incident particle, and $r_0 = \alpha^2 a_0$ is the classical electron radius; and

4. The maximum energy loss of a heavy particle to an electron: $E_{max} \sim 2m_e c^2 \beta^2 \gamma^2$ [91.4].

91.1 Experimental Aspects

91.1.1 Energy Loss Experiments and Radiation Detectors

After passing through a thickness x of material, an initially monoenergetic beam of particles acquires a distribution of energies described by a probability density function

$$F(\Delta) = \frac{d\mathcal{N}(\Delta)}{d\Delta} , \qquad (91.2)$$

where Δ is the energy loss per particle, and $d\mathcal{N}(\Delta)$ is the number of particles in the range Δ to $\Delta + d\Delta$. The straggling function $F(\Delta)$ represents the spectrum of energy losses Δ, such that $\int F(\Delta)\, d\Delta = \mathcal{N}$, the total number of particles observed. It can be characterized by the quantities

1. the most probable energy loss Δ_{mp},
2. the full width at half maximum Γ,
3. the moments [91.8]

$$\mu_\nu = \frac{1}{\mathcal{N}} \int F(\Delta) \Delta^\nu \, d\Delta , \qquad (91.3)$$

and the central moments

$$C_\nu = \frac{1}{\mathcal{N}} \int F(\Delta)(\Delta - \mu_1)^\nu \, d\Delta . \qquad (91.4)$$

Then $\mu_1 = \langle \Delta \rangle$ is the mean energy loss, $C_2 = \sigma^2$ is the variance and $\gamma_1 = C_3/C_2^{3/2}$ is the skewness. The fluence spectrum $\phi(\mathcal{T})$ is the complementary function describing the distribution of residual energies $\mathcal{T}$ of the particles.

As an example, Fig. 91.1 shows $F(\Delta)\,d\Delta$ for 1.27 GeV protons passing through a 32 µm thick silicon wafer [91.5]. The measured quantity is the ionization J resulting from the creation of electron–hole pairs in the silicon, so that $\Delta = JW$ is the energy deposited, where W is the energy required to create an electron–hole pair. For $\Delta < 15$ keV, the energy deposited differs little from the energy lost by the protons. For larger Δ, some of the secondary electrons may escape from the silicon, making the apparent energy deposited less than the energy

lost [91.9]. The spectrum has a long tail extending up to a maximum energy loss of 4.6 MeV. This accounts for the large value of $\langle \Delta \rangle = 12.8$ keV, and the even larger value $C_2^{1/2} = 43$ keV for the standard deviation, relative to $\Delta_{mp} = 7.4$ keV and $\Gamma = 5.2$ keV.

In losing energy, the beam particles also suffer angular deflections, but for heavy particles, the deflections are usually small. For electrons, angular deflections are quite important, and are discussed in Chaps. 47, 64, and 65. Nuclear reactions cause large effects but are quite infrequent. Further examples of straggling spectra are given in [91.5, 10–12] for thin, extremely thin, moderately thick, and thick absorbers respectively.

Only for thick absorbers, the stopping power $S(\mathcal{T}) = -d\mathcal{T}/dx$ (i. e., the mean energy lost per unit thickness) provides a convenient measure of the energy loss process. For a beam with incident energy $\mathcal{T}_0$ and
Fig. 91.1 Energy loss straggling functions $F(\Delta)\,d\Delta$ for 1.27 GeV protons traversing a 32 µm silicon detector, with $d\Delta = 0.21$ keV. The experimental data are shown by *circles*. Three calculated functions normalized to the same peak height are shown for comparison [91.5]. The *solid line* was calculated with the Bethe cross section Fig. 91.3 with $\Delta_{mp} = 7.4$ keV, $\Gamma = 5.2$ keV, and $\langle \Delta \rangle = 12.8$ keV. The *broken line* is the Landau function [91.6] and the *dotted line* is the Blunck–Leisegang modification [91.7]

$\langle\Delta\rangle < 0.1\mathcal{T}_0$, $S(\mathcal{T})$ is often approximated by

$$S(\mathcal{T}_0 - \langle\Delta\rangle/2) \simeq \langle\Delta\rangle/x \,, \tag{91.5}$$

provided that $x \gg a_0$ (Sect. 91.4). The stopping power $S(\mathcal{T})$ depends on the absorber properties, especially the electron density NZ_2. The radiation dose $D(x)$ at a distance x into the material is given by

$$D(x) = \int \phi(\mathcal{T}, x) S(\mathcal{T}) \, d\mathcal{T} \,, \tag{91.6}$$

where $\phi(\mathcal{T}, x)$ is the fluence spectrum. $D(x)$ is used in radiation dosimetry and protection [91.15, 16].

$S(\mathcal{T})$ ceases to be useful for very thin absorbers, such as microscopic biological specimens, micro- or nano-devices, or thin ionization chambers. Instead Δ_{mp} and Γ should be used. No simple equations can provide Δ_{mp} and Γ. They must be found from calculated or experimental $F(\Delta)$. Calculations of $F(\Delta)$ are described in 91.4.2 and 91.6.

A detailed theoretical description of the energy deposition process requires cross sections for the various scattering events in the target, the most important being collisions with electrons. The Rutherford cross section for the collision of a particle with a free electron is only useful for $\Delta \gtrsim 30\,U_Z$, where U_Z is the binding energy of a target electron ($\sim 500\,\text{eV}$ for outer shell electrons). Various modifications to the Rutherford cross section for smaller Δ are discussed in Sect. 91.2.

91.1.2 Inelastic Scattering Events

If a beam of $\mathcal{N}$ monoenergetic particles with speed v passes through an absorber of infinitesimal thickness dx, the average number of particles experiencing a collision with energy loss between E and $E + dE$ is given by

$$d\mathcal{N}(E) = \mathcal{N} N \sigma(E) \, dE \, dx \,, \tag{91.7}$$

where $\sigma(E)$ is the collision cross section per molecule differential in E; it depends on β. Using this equation, $\sigma(E)$ can be obtained from measurements [91.17, 18] with extremely thin absorbers where particles on the average suffer less than one collision. If particles pass through a thicker absorber, they make several collisions with energy losses E_i; and the total energy loss is $\Delta = \sum E_i$ (Sect. 91.4.2).

Large differences exist between a gas and a solid of the same composition due to changes in the valence shell electrons. In isolated atoms [91.14], the smallest energy losses are to discrete excited electronic states. Ionizations occur for energy losses exceeding the binding energies U_l for each atomic shell l

and the released electrons are given a kinetic energy $\delta = E - U_l$. For ionization, energy losses are continuous (Fig. 91.2). If atoms are brought closer together to form a liquid or a solid, their valence electrons come under the influence of the cores of surrounding atoms. A core is defined to consist of the nucleus and all the electrons inside the valence shell. For C, O, or H_2O, the core consists of two electrons in the K-shell, for Al or Si it contains two electrons in the K-shell and eight electrons in the L-shell. For metals, the valence electrons form a conduction band where they are nearly free. If a charged particle moves through the solid, the transfer of very small energies to the electron by Rutherford scattering is not observed. Instead, many thousands of them are excited at a time. For metals, this process is called plasmon excitation, for insulators, collective excitation (Fig. 91.2). For most substances, the plasmon excitation energy E_p is much larger than the energy of the lowest excited state of the atom E_1. For example, for Be, $E_1 = 3.6\,\text{eV}$ [91.13], while $E_p = 19\,\text{eV}$ [91.17]. Similarly, for silicon, $E_1 = 3.6\,\text{eV}$ [91.13] and $E_p = 16.7\,\text{eV}$ [91.5].

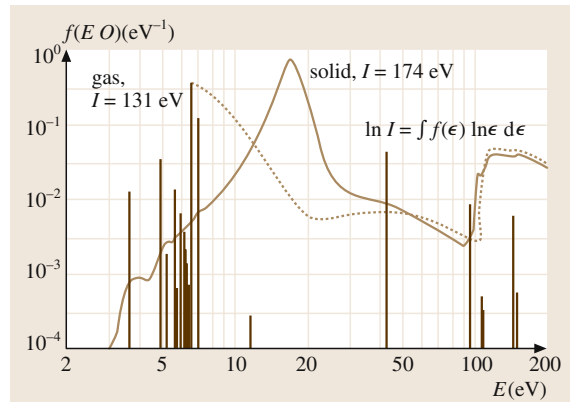
For molecules, measurements of electron energy losses [91.18] provide information about the difference in the structure of $\sigma(E)$ between gas and solid. For example, for benzene (C_6H_6) the vapor shows distinct structures for excitations to several discrete states, and


Fig. 91.2 Comparison of the dipole oscillator strength spectra for atomic and solid silicon. Discrete atomic excitations are shown by vertical lines, continuum excitations by the *dotted line*. Data for the atom are based on calculations [91.13]. Data for the solid are from [91.5]. The broad peak at $\approx 17\,\text{eV}$ represents the plasmon excitations. Uncertainties may exceed 10%. The discrete atomic excitations disappear in the solid. The photoionization cross section is $\sigma(E) = 109.8\, f(E)\,\text{Mb}$ [91.14]

a broad peak at about 16 eV which appears to be equivalent to a collective excitation. For the solid, the structures are broadened, and the major peak for the collective excitations shifts to 21 eV. Data for water can be found in [91.19].

For energy losses well above E_p, $\sigma(E)$ decreases smoothly until the ionization energy of the next electron shell is reached, as shown in Fig. 91.2. In a molecular substance such as $CaCO_3$, several broad peaks appear between 7 and 40 eV, followed by narrow peaks at 280 eV (carbon K-shell), 345 eV (Ca L-shells), 530 eV (oxygen K-shell) and 4 keV (Ca K-shell) [91.17].

While there are large changes in the structure of the excitation of the valence electrons as the atoms are coalesced into a solid (Fig. 91.2), changes are less important for the inner shells because the binding energies of these shells are much larger than chemical energies. As an example, for an amorphous thin carbon film, the K-edge is at 284 eV [91.17], and K-shell excitation shows essentially just one peak at ≈ 296 eV. For the three biologically important molecules adenine, uracil and thymine, several peaks appear [91.20], all located between 284 and 300 eV. Thus there is at most a small change in the energy of the K-shell excitation, but the number of peaks as well as their locations changes considerably. For Al above the K-edge (1.56 keV), a structure with several peaks appears [91.21], with separations of about 40 eV. This structure, called extended X-ray absorption fine structure (EXAFS) [91.22], is caused by the presence of nearby atomic cores which backscatter the photoelectrons and thus change their wave functions. The discrete excitations of the atom below the K-edge disappear completely. Thus solid state and chemical effects are very important for valence shell electrons, and less so for inner-shell electrons.

91.2 Theory of Cross Sections

The cross section for the collision of two free charged particles is given by the Rutherford expression. If charged particles collide with electrons bound in atoms, molecules or solids, the cross section can be written as a modified Rutherford cross section. A plausible way of describing these interactions is to consider the emission of virtual photons by the fast particle, which then are absorbed by the material in the Fermi virtual photon method (FVP) [91.23]. The collision cross section then is proportional to the photo absorption cross section of the molecules. *Bohr* [91.24] described this as a "resonance" effect.

A variety of models has been used to obtain theoretical $\sigma(E)$ for bound electrons. Here, three of them will be described and compared with each other. Examples are shown in Fig. 91.3. Few analytic functions and methods are available to calculate cross sections (Chapt. 47). Usually, numerical calculations must be made to obtain reliable data for real absorbers.

91.2.1 Rutherford Cross Section

The cross section for close collisions of fast charged particles with loosely bound electrons is well approximated by the cross section for the collision of a charged particle with a free electron at rest. The nonrelativistic Rutherford cross section $\sigma_R(E)$ for an energy loss E in the collision of a charged particle with speed v in the laboratory frame is given by [91.25–28]

$$\sigma_R(E) = \frac{2\pi Z_1^2 e^4}{mv^2} \frac{1}{E^2} = \frac{k_R}{\beta^2} \frac{1}{E^2} . \tag{91.8}$$

Since the secondary electron receives all the energy E lost by the incident particle, the momentum transfer is $q = \sqrt{2mE}$. The cross section $\sigma_R(E)$ does not depend on particle mass M. The leading relativistic correction (For $\gamma > M/m$, further terms must be included [91.29–31]) is

$$\sigma_R'(E) = \sigma_R(E)\left(1 - \beta^2 \frac{E}{E_{max}} x\right) . \tag{91.9}$$

91.2.2 Binary Encounter Approximation

A simple correction to $\sigma_R(E)$ can be achieved by taking into account the velocity of the bound electrons. With binding energy U_b, average kinetic energy $\mathcal{T}_e$, and average speed u of the electrons, the expression is

$$\sigma_L(E) = \sigma_R(E)\left(1 + \frac{4}{3}\frac{\mathcal{T}_e}{E}\right) , \quad E > U_b , \tag{91.10}$$

which is valid for $v \gg u$. The total cross section for a molecule includes contributions from each electron shell. Variants of this approach are described in [91.32, 33]. Figure 91.3 shows an example.
Fig. 91.3 Inelastic cross sections $\sigma(E)$ for single collisions in solid silicon, for incident protons with an energy $\mathcal{T} = 100\,\text{MeV}$, calculated using different theories. The *horizontal line* at 1.0 represents the Rutherford cross section from (91.8). The other curves are Bethe theory (*solid line*); FVP approximation (*dashed line*); binary encounter approximation from (91.10) [91.32] (*dotted line*). The curves extend to $E_{\max} = 230\,\text{keV}$

91.2.3 Bethe Model of Cross Section

The Bethe model [91.34] derives from the first Born approximation for inelastic scattering, which becomes essentially exact at high energies. In terms of the inelastic form factor $|\mathcal{F}(E, \mathbf{K})|^2$, the energy loss cross section is

$$d\sigma(E, Q) = \sigma_{\mathrm{R}}(Q)|\mathcal{F}(E, \mathbf{K})|^2\,dQ\,, \qquad (91.11)$$

where $Q = q^2/2m_{\mathrm{e}}$, and $\hbar\mathbf{K}$ is the momentum transfer vector. The generalized oscillator strength (GOS) is defined by

$$f(E, K) = E|\mathcal{F}(E, \mathbf{K})|^2/Q\,, \qquad (91.12)$$

such that $f(E, K)$ reduces to the optical dipole oscillator strength $f(E, 0) \equiv f(E)$ in the limit $K \to 0$. Then

$$d\sigma(E, Q) = \sigma_{\mathrm{R}}(E)E f(E, K)\,d\ln Q\,. \qquad (91.13)$$

For hydrogenic atoms, $f(E, K)$ is well known [91.34–38], and a model spectrum is shown in Fig. 10 of [91.27, 28]. For more complicated atoms, many-electron effects introduce small corrections, as shown in Fig. 91.4 for Si using a Hartree–Fock approximation. Adding the contributions from all shells yields

the Bethe result in Fig. 91.3 [91.5]. Similar results are given in [91.39] for Al. For the outermost electrons in metals, the electron gas model can be used to generate cross sections [91.40–42]. For semiconductors and insulators a model has been derived using the tight binding approximation for the ground state wave function and orthogonalized plane waves for excited states [91.41]. The dipole oscillator strength is derived from the data for optical absorption coefficients; for solids [91.43] and gases [91.44–46] see Chapt. 61.

91.2.4 Fermi Virtual Photon Method

In the Fermi virtual photon (FVP) method, $f(E, K)$ is approximated by $f(E, 0)$ for $Q < E$, with a delta function at $Q = E$ [91.23, 47–50] (Fig. 91.4). Then $\sigma(E)$ is given by [91.48]

$$\sigma(E) = \sigma_{\mathrm{R}}(E)\left[E f(E, 0)\ln\left(\frac{2mv^2}{E}\right) + \int_0^E f(E', 0)\,dE'\right], \qquad (91.14)$$

and so only $f(E)$ need be known, or equivalently $\mathrm{Im}(-1/\epsilon)$, where ϵ is the complex dielectric constant of the absorber. Data can be extracted from a variety of optical measurements [91.43, 44, 51], and from electron
Fig. 91.4 Generalized oscillator strength (GOS) $f(E, K)$ (*solid line*) for longitudinal excitations of the 2p-shell of Si atoms (with a binding energy $U_{\mathrm{L}} = 8\,\text{Ry}$), calculated with the Hartree–Fock–Slater potential. The energy transfer is $E = 650\,\text{eV}$. The hydrogenic approximation is given by the broken line; $f(E, K)$ peaks at $(Ka_0)^2 \approx E - U_{\mathrm{L}}$. In the FVP model, (91.14), the GOS is replaced by a δ-function at $Ka_0 = E^{1/2}$ and by $f(E, 0)$ for $0 < Ka_0 < E^{1/2}$ (*straight lines*)

energy loss measurements [91.52]. A cross section calculated with this model is given in Fig. 91.3. The $\sigma(E)$ differ by as much as 50% from the Bethe result, but the moments differ by at most 10% (Table 91.1). It is evidently a better approximation than that given by the binary encounter approximation of (91.10).

Table 91.1 The coefficient $\tau(\beta) = M_0 \beta^2/(NZ k_R)$ for pions with $M_\pi = 139.567\,\text{MeV/c}^2$, calculated in the FVP approximation. For comparison, the Si (GOS) results were calculated from the complete $F(E, K)$ generalized oscillator strengths. The estimated accuracies are $\approx 1\%$ for Si (GOS) and $\sim 30\%$ for the others. The values are the same for all heavy particles with the same β; they differ slightly for electrons. For Si $(\varrho = 2.329\,\text{g/cm}^3)$, $NZk_R = 17.82\,\text{eV/\mu m}$, for the gases (at STP), $NZk_R = 6.3828\,Z\,\text{eV/cm}$. Units of $\tau(\beta)$ are eV^{-1}

91.3 Moments of the Cross Section

Various moments of $\sigma(E)$ are defined by [91.5, 53]

$$M_\nu \equiv N \int E^\nu \sigma(E)\,\mathrm{d}E\,. \tag{91.15}$$

where the range of integration covers all non vanishing $\sigma(E)$, including a summation over discrete excited states. Then $M_0 = N\sigma_{\text{tot}} = 1/\lambda_{\text{mfp}}$, where σ_{tot} is the total collision cross section and λ_{mfp} the mean free path between collisions, and $M_1 = S$, the stopping power. M_2 and M_3 give the width and skewness of $F(\Delta)$.

Higher moments are not very useful [91.53] except for special applications [91.54–56]. For incident electrons, a further averaging of energy loss over different paths must be performed because of multiple angular scattering.

91.3.1 Total Collision Cross Section M_0

A simple result for M_0 is obtained with the Rutherford cross section

$$
\begin{aligned}
{}_R M_0 &= NZ_2 \int \sigma_R(E)\,\mathrm{d}E \\
&= NZ_2 \frac{k_R}{\beta^2}\left(\frac{1}{E_{\text{min}}} - \frac{1}{E_{\text{max}}}\right)\,. \tag{91.16}
\end{aligned}
$$

Clearly, ${}_R M_0$ is very sensitive to the choice of E_{min}, and there is no simple prescription for choosing it, as is evident from Fig. 91.3. The same applies to the binary encounter approximation [91.32]. From the Bethe model, a good relativistic approximation to M_0 is given by [91.27, 28, 57]

$$
\begin{aligned}
M_0 &= NZ_2 \frac{k_R}{\beta^2} g_0 \\
&\quad \times \left[\ln\beta^2\gamma^2 - \beta^2 + h_0 + 11.227\right] \\
&= NZ_2 \frac{k_R}{\beta^2}\tau(\beta)\,. \tag{91.17}
\end{aligned}
$$

Values for g_0 and h_0 may be found in [91.57]. For Si, He, Ar, ethane, and butane, values of τ_β, calculated by numerical integration of $\sigma(E)$ obtained with the FVP method, are given in Table 91.1. For Si, comparison values calculated with the Bethe model are also given. The quantity $\tau(\beta)$ is more suitable for interpolation than M_0. An extensive description of cross sections are given for liquid water in [91.58].

91.3.2 Stopping Power M_1

The stopping power is usually written in the form

$$M_1 = S = NZ_2 \frac{k_R}{\beta^2} 2B , \tag{91.18}$$

where B is called the stopping number. M_1 calculated with the Rutherford cross section is

$$_R M_1 = NZ_2 \int_{E_1}^{E_{max}} E\sigma_R(E) \, dE = NZ_2 \frac{k_R}{\beta^2} \ln \frac{E_{max}}{E_1} . \tag{91.19}$$

To obtain realistic values, it is evident from Fig. 91.3 that a small value must be chosen for E_1 to compensate for the peaks in $\sigma(E)$. Note that for most applications in high energy physics (e.g. Time Projection Chambers [91.59, 60]) M_1 is not useful [91.4].

The Bethe Model
In the Bethe model of stopping powers, $d\sigma(E, K)$ from (91.13) must be integrated over both E and $Q = \hbar^2 K^2 / 2m$ [91.37, 38]. Since $f(E, K)$ is nearly constant near $K = 0$ [91.61] (Fig. 91.4), the integral may be broken into four parts according to

$$S = \frac{\mathcal{N} k_R}{\beta^2} \int dE \left\{ \int_{Q_m}^{Q_1} f(E, 0) \frac{dQ}{Q} + \int_{Q_1}^{\infty} f(E, K) \frac{dQ}{Q} \right.$$
$$+ \int_0^{Q_1} [f(E, K) - f(E, 0)] \frac{dQ}{Q}$$
$$\left. - \int_0^{Q_m} [f(E, K) - f(E, 0)] \frac{dQ}{Q} \right\} , \tag{91.20}$$

where $Q_m \approx E^2 / 2mv^2$ [91.27, 28], and Q_1 is chosen such that $f(E, K)$ differs little from $f(E, 0)$ in the interval $0 \le K \le \sqrt{2mQ_1}/\hbar$ [91.36, 62]. Collisions with $Q < Q_1$ are "distant" and those with $Q > Q_1$ are "close". The integrals simplify by interchanging the order of integration in the second and third terms, and by using the sum rule [91.27, 28, 34]

$$\int_0^{\infty} f(E, K) \, dE = Z_2 , \tag{91.21}$$

for all K. The last term of (91.20) is then small and the second last vanishes exactly. The remaining two terms give

$$S = \frac{NZ_2 k_R}{\beta^2} \left(\ln \frac{2mv^2 Q_1}{\mathfrak{I}^2} + \ln \frac{Q_{max}}{Q_1} \right) , \tag{91.22}$$

where $\mathfrak{I}$ is the logarithmic mean excitation energy defined by

$$Z_2 \ln \mathfrak{I} = \int f(E) \ln E \, dE , \tag{91.23}$$

and $Q_{max} = 2m_e c^2 \beta^2 \gamma^2$ is the maximum energy loss (for electrons, $Q_{max} = \frac{1}{4} m_e c^2 \beta^2 \gamma^2$ [91.3]). Including relativistic and other correction terms, the final result for $M_1 \gg m_e$ is

$$S = \frac{\mathcal{N} Z_2 k_R}{\beta^2} 2 \left\{ B_0 - \frac{C(\beta)}{Z_2} + Z_1 L_1(\beta) + Z_1^2 L_2(\beta) \right.$$
$$\left. + \frac{1}{2} [G(M_1, \beta) - \delta(\beta)] \right\} , \tag{91.24}$$

where

$$B_0 = \ln \frac{2mc^2 \beta^2 \gamma^2}{\mathfrak{I}} - \beta^2 \tag{91.25}$$

is the uncorrected stopping number. In the limit $\beta \to 0$, $2B_0$ reduces to the terms in brackets in (91.22). The other correction terms are as follows [91.31].

The Shell Correction. $C(\beta)$ accounts for the last term in (91.20), together with modifications of $d\sigma(E, Q)$ near $Q = E_{max}$ [91.3]. It can be estimated on a shell-by-shell basis [91.63–66] using nonrelativistic hydrogenic calculations for the K- and L-shells [91.35, 37, 38], and rescaling methods for the outer shells which have not been calculated directly [91.63, 64, 67]. The effects are important for small β, but simple formulas are not known. A calculation for Al and Si based on a model more realistic than the hydrogenic one is given in [91.68].

The Barkas Term. $L_1(\beta)$ arises from polarization of the target electrons by the incident particle [91.69, 70]. Various approximating functions and fits to experimental data are described in [91.71].

The Bloch Term. $L_2(\beta)$ arises from corrections to the approximation that for close collisions, the electrons can be represented by plane waves [91.72]. Confinement of the electrons to the interior of a cylinder of atomic dimensions introduces transverse momentum components, resulting in the widely used correction

$$Z_1^2 L_2(\beta) = -q^2 \sum_{j=1}^{\infty} 1 / \left[j \left(j^2 + y^2 \right) \right] \tag{91.26}$$

with $y = Z_1\alpha/\beta$. For $y = 0$, the sum is $\zeta(3) \simeq 1.202\,057$. A new approach can be found in [91.73, 74]. The need for the L_1 and L_2 terms was established experimentally in [91.75], and discussed in a more general context in [91.76].

The Mott Term. $G(M_1, \beta)$ is a kinematic recoil correction which becomes important for relativistic projectiles. In the limit of a point-like spinless nucleus, the correction is

$$G(M_1, \beta) = -\ln(1 + 2t) - t\beta^2/\gamma^2 , \tag{91.27}$$

where $t = m\gamma/M_1$ [91.29]. The correction is negligible for $\gamma < 100$ and $M_1 > m_p$.

The Density Correction. $\delta(\beta)$ arises from the dielectric response of a solid absorber as a whole to the electric field of the projectile, and the work done by the interaction [91.3, 29]. Sternheimer's algorithm [91.77, 78] is usually used, as summarized in [91.29].

The remaining parameter to be discussed in (91.24) is $\Im$. If the oscillator strength distribution $f(E)$ is known, then $\Im$ can be calculated directly from (91.23). Results for many gases are given in [91.45]. The values give good agreement with experimental stopping powers [91.79]. For solids, the definition [91.3]

$$\ln \Im = \frac{2}{\pi(\hbar\omega_p)^2} \int_0^\infty E \, \text{Im}\left[\frac{-1}{\epsilon(E)}\right] \ln E \, dE \tag{91.28}$$

may be used, where $\hbar\omega_p$ is the plasma energy for all the electrons, defined by $(\hbar\omega_p)^2 = 830.4 \varrho Z/A$ with $\hbar\omega_p$ in eV. For metals, this is substantially larger than the plasmon energy associated with the conduction electrons. Only for Al [91.80] and for water [91.81] have sufficiently good measurements of $\text{Im}[-1/\epsilon(E)]$ been available to permit the use of this method. For other materials, $\Im$ can be deduced from measurements of S, provided that the other corrections in (91.24) are known sufficiently well. A list of values for all elements and many compounds is given in [91.66]. See also [91.25, 63–65, 79, 82–87].

For rough estimates of $\Im$, the approximation [91.88]

$$\Im \approx \begin{cases} 11.7 + 11.2/Z_2 \, \text{eV} , & Z_2 \leq 13 \\ 9.5 \pm 1 \, \text{eV} , & Z_2 > 13 \end{cases} \tag{91.29}$$

is useful, together with the Bragg rule

$$n_e \ln \Im = \sum_i n_i \ln \Im_i \tag{91.30}$$

for compounds and composite materials, where n_i is the electron density associated with element i. However, chemical shifts may be as large as 10% [91.89].

The Fermi Virtual Photon Method

From (91.14), the nonrelativistic FVP approximation to the stopping number $B(\beta)$ is

$$B(\beta) = \frac{1}{2} \ln \left(\frac{2m_e v^2}{\Im}\right)$$
$$+ \frac{1}{2Z_2} \int_{E_{\text{min}}}^{E_{\text{max}}} \frac{dE}{E} \int_0^E f(E') \, dE' . \tag{91.31}$$

Although the integrals must now be calculated numerically, the full $f(E, K)$ is not required, and in the case of silicon, the results are in close agreement with the corresponding Bethe model.

Stopping Power at Small Speeds

For small speeds, the various correction terms in the stopping number B, (91.24), become large compared with B_0 [91.63, 64, 68]. In particular, for $2mv^2 = \Im$, B_0 becomes zero. For example, for α-particles in U ($\Im = 840$ eV), $B_0 = 0$ at $T = 1.5$ MeV, and B then consists only of correction terms. For smaller energies, empirical approaches are used to describe S. Many of the tables referenced above give such data.

Mean Energy Loss per Collision

The quantity $\langle E \rangle = M_1/M_0$ is the mean energy loss per collision. For substances with $Z < 20$, $\langle E \rangle \sim 50$–$100$ eV. It changes at most by a factor of 1.5 for $\beta\gamma > 0.1$. In order to choose a suitable method for calculating straggling functions, it is useful to estimate the number of collisions in a thickness x of absorber. For less than 2000 collisions, the convolution method of Sect. 91.4.2 should be used (Fig. 15 in [91.5]).

91.3.3 Second Moment M_2

The relativistic result calculated with the Rutherford cross section is

$$_R M_2 = NZ_2 \frac{k_R}{\beta^2} \left(1 - \beta^2/2\right) E_{\text{max}} \tag{91.32}$$

$$= 2NZ_2 k_R mc^2 \frac{1 - \beta^2/2}{1 - \beta^2}$$

$$= 0.156\,915 \frac{Z_1^2 Z_2}{A} \frac{1 - \beta^2/2}{1 - \beta^2} \, \text{MeV}^2 \, \text{cm}^2/\text{g} .$$

For small β, $_R M_2$ is practically independent of β. A better approximation can be achieved with the binary

encounter method:

$$_b M_2 = N Z_2 \frac{k_R}{\beta^2} E_{max} \left[1 - \frac{\beta^2}{2} \right.$$

$$\left. + \sum_l \frac{4 Z_l U_l}{3 Z_2 E_{max}} \left(\ln \frac{E_{max}}{_l E_{min}} - \beta^2 \right) \right] , \tag{91.33}$$

where the summation extends over atomic shells l. For $_l E_{min}$ the ionization energy J_l for shell l can be used, while U_l represents the kinetic energy of the electrons in shell l. This approximation is only useful for relatively large x [91.5]. By using sum rules, *Fano* [91.3, (72)] achieved a better approximation, which corresponds to the Bethe approximation for the stopping power [91.5, 90]. Hydrogenic values of M_n are calculated in [91.53].

91.4 Energy Loss Straggling

91.4.1 Straggling Parameters

Parameters for Thick Absorbers

Straggling is due to the stochastic nature of the energy losses of the charged particles. Because the single collision spectrum is highly skewed (the most probable energy loss is $\approx 20\,\text{eV}$, the mean value $\approx 100\,\text{eV}$), straggling functions will also be skewed. Four parameters are useful in a preliminary study of straggling problems [91.47]. The parameter

$$\xi = N Z_2 \frac{k_R}{\beta^2} x = 153.537 \frac{Z_1^2}{\beta^2} \frac{Z_2}{A} x \,\text{keV cm}^2 \tag{91.34}$$

gives the energy loss [calculated with $\sigma_R(E)$] which, on the average, is exceeded once for each particle in its passage through an absorber of thickness x, i.e., for $\Im \ll \xi \ll E_{max}$,

$$x N Z_2 \int_{\xi}^{E_{max}} \sigma_R(E) \, dE = 1 . \tag{91.35}$$

The parameter $\kappa = \xi / E_{max}$ is related to the skewness of the straggling function: $\gamma_1^2 = 1/4\kappa$. The mean energy loss is

$$\langle \Delta \rangle = x M_1 = 2\xi 2B = 2\kappa E_{max} B , \tag{91.36}$$

and the standard deviation of $F(\Delta)$ is

$$\omega^2 = x M_2 \sim x N Z_2 \frac{k_R}{\beta^2} E_{max} = \xi E_{max} = \kappa E_{max}^2 . \tag{91.37}$$

For thick absorbers, the straggling function becomes approximately Gaussian [91.5, 24]. The requirement for this to occur is $\gamma_1 \to 0$, thus $\kappa \to \infty$, also $\langle \Delta \rangle \to \infty$, and $x \to \infty$.

Parameters for Thin Absorbers

The parameters described above are not suitable for describing $F(\Delta)$ for very thin absorbers. Instead, Δ_{mp} and Γ are used. Values for pions traversing Ar are given as a function of thickness x in Tables 91.2, 91.3. However, before comparing with experimental data, values of Δ must be converted into ionization values, and the detector and amplifier noise must be added [91.5] (Sect. 91.7). *Landau* [91.6] gave an expression for the most probable energy loss as a function of particle speed. It was modified in [91.5] to

$$\Delta_L = \xi \left(\ln \frac{2mc^2 \beta^2 \gamma^2}{I} + \ln \frac{\xi}{I} + 0.200 - \beta^2 - \delta \right) . \tag{91.38}$$

Table 91.2 Calculated most probable energy loss Δ_{mp} of pions with $Z_1 = \pm 1$ and kinetic energy $\mathcal{T}$ passing through a distance x of argon gas (at 760 Torr, 293 K, $\varrho = 1.66\,\text{g/dm}^3$). For heavy ions ($\alpha$, C^+), the values scale as $Z_1^{1.3}$ (for a better approximation, see Table V in [91.5]). Units of Δ_{mp} are keV. The quotient Δ_{mp}/x increases with x

$\mathcal{T}$ (MeV)	x(cm) 0.5	1	2	4	8
1	29.373	63.341	130.662	265.062	533.811

3×10^4	0.983	1.615	2.548	4.314	7.956
1×10^5	1.040	1.701	2.689	4.666	8.399
Fig. 91.5 The dependence of most probable energy-loss values $\Delta_{\mathrm{mp}}(\beta\gamma; x)/x >$ for segments of length x. *Solid line* BB: the Bethe–Bloch function $\mathrm{d}E/\mathrm{d}x(\beta\gamma)$ [91.4]. *Other lines* are for the segment lengths x marked at right. The functions are scaled with a factor $g(x)$ such that they concide at minimum ionization

More accurate functions Δ_{mp} are obtained with the collision spectra of Fig. 91.3, and are called Bichsel functions [91.59]. For sufficiently large ξ, Δ_{mp}, and Δ_{L} agree within a few %. Examples are shown in Fig. 91.5, and for comparison the Bethe-Bloch function $\mathrm{d}E/\mathrm{d}x$ [91.4] is given.

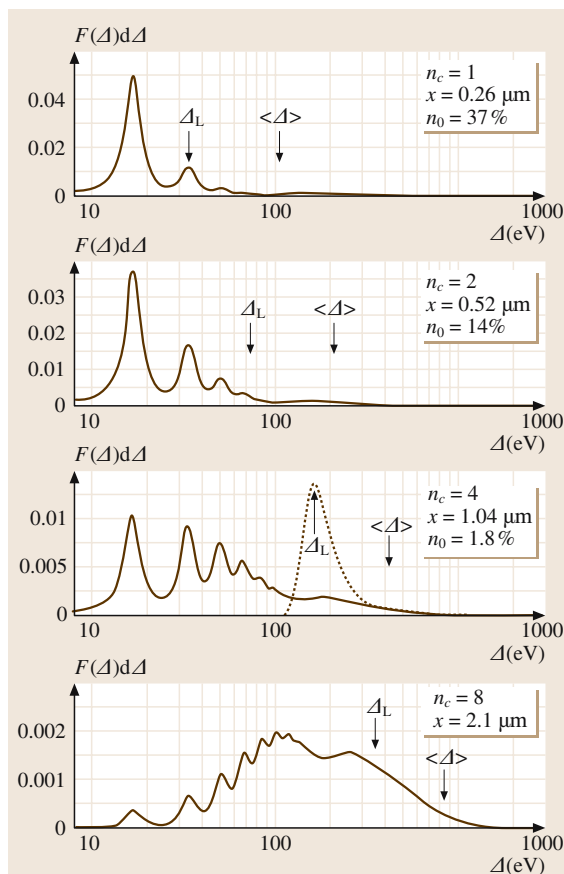
Parameters for Extremely Thin Absorbers
If the number n_{c} of collisions in the absorber is less than about 16, $F(\Delta)$ still shows the details of $\sigma(E)$ (Fig. 91.6).


Fig. 91.6 Calculated straggling functions $F(\Delta)$ for 1 GeV pions traversing four thicknesses x of silicon. The average number of collisions is n_{c}, with $\langle E \rangle = 106$ eV, the mean energy loss is $\langle \Delta \rangle = n_{\mathrm{c}}\langle E \rangle$, shown by an arrow. The number of particles traversing the absorber without a collision is n_0. The peak heights do not follow a Poisson distribution because successive convolutions give a broader distribution. The Landau function [91.6] for $n_{\mathrm{c}} = 4$ is shown by the broken line. For all, the most probable energy loss calculated according to Landau, Δ_{L} (91.38), is shown

The most probable energy losses are much less than $\langle \Delta \rangle$. Functions of this type have been observed with electron microscopes [91.10]. For comparison, the Landau straggling function [91.6] is also shown. This result, derived from $\sigma_{\mathrm{R}}(E)$, does not show the structure of a realistic spectrum.

Detector noise and energy loss to ionization conversions introduce important changes [91.91–94] to the energy loss spectrum. In particular, if $n_{\mathrm{c}} < 4$, a large

fraction of the particles do not lose any energy in the absorber.

91.4.2 Analytic Methods for Calculating Energy Loss Straggling Function

Three principal methods are convolutions, Laplace transforms and the use of moments [91.5]. They are practical for different thicknesses of absorbers, as indicated.

Convolutions
For this method, a complete collision cross section must be available [91.47,50], and numerical calculations are required. The probability density function for particles having suffered n collisions is given by the n-fold convolution of the single collision spectrum [91.5, 95]:

$$\sigma^{*n}(\Delta) = \int_0^\Delta \sigma(E)\sigma^{*(n-1)}(\Delta - E)\,\mathrm{d}E , \qquad (91.39)$$

with

$$\sigma^{*0}(\Delta) = \delta(\Delta) , \quad \sigma^{*1}(\Delta) = \sigma(\Delta) . \qquad (91.40)$$

Assuming that successive collisions are statistically independent, the number of collisions is described by the Poisson distribution

$$P_n^{n_c} = \frac{n_c^n}{n!}\mathrm{e}^{-n_c} , \qquad (91.41)$$

where $P_n^{n_c}$ gives the fraction of particles suffering n collisions, and $n_c = xM_0$ is the average number of collisions for all particles. The complete straggling function is then

$$F(x, \Delta) = \sum_{n=0}^\infty P_n^{n_c}\sigma^{*n}(\Delta) . \qquad (91.42)$$

Usually, this method is only used for absorbers thin enough that the single collision cross section changes negligibly during the passage through the absorber.

This approach would become quite complex for large n_c. The doubling method [91.96] uses the following procedure: the function for an absorber of thickness $2x$ is calculated by convoluting $F(x, \Delta)$ with itself, viz.

$$F(2x, \Delta) = \int_0^\Delta F(x, \Delta - g)F(x, g)\,\mathrm{d}g . \qquad (91.43)$$

An initial distribution is calculated for an extremely thin absorber of thickness $\mathrm{d}x$ from

$$F(\mathrm{d}x, \Delta) = \delta(\Delta)(1 - M_0\,\mathrm{d}x) + \sigma(\Delta)\,\mathrm{d}x , \qquad (91.44)$$

where $\delta(\Delta) = F(0, \Delta)$ and $M_0\,\mathrm{d}x \approx 0.001$.

For Si, the convolution method has been tested and compared with experiments for as many as 10^4 collisions [91.5]. The limitations of the algorithm are $\approx 10^5$ collisions. Since $P_0^{n_c} = \mathrm{e}^{-n_c}$, there will be particles that pass through an absorber without making a collision.

Laplace Transforms
The Laplace transform method is mathematically equivalent to the convolution method. The method, as implemented by *Landau* [91.6], is based on $\sigma_R(E)$. The implicit number of collisions is therefore too large, and the Landau function is too narrow, as shown in Figs. 91.1 and 91.6. A refinement proposed in [91.7] gives straggling functions which are too wide (Fig. 91.1).

Use of Moments
If the skewness γ_1 is not small, a Gaussian function is not a good approximation to a straggling function. This can be remedied by using a modified Gaussian of the form [91.55, 56]

$$f(y) = \frac{\tilde{\delta}}{\sqrt{2\pi}}\frac{1}{\sqrt{y^2+1}}$$
$$\times \exp\left\{-\frac{1}{2}\left[\tilde{\gamma} + \tilde{\delta}\ln\left(y + \sqrt{y^2+1}\right)\right]^2\right\} , \qquad (91.45)$$

where $y = (\Delta - \langle\Delta\rangle)/\sigma$ and $\tilde{\gamma}$ and $\tilde{\delta}$ are related to M_2 and M_3 [91.55, 56] such that the second and third moments are reproduced exactly.

The moments can be calculated as a function of particle speed, and thus the method is useful for mean energy losses up to about $0.7\mathcal{T}_0$. At these losses, some particles reach their full range and thus disappear from the beam. The moments are then distorted and other procedures are needed [91.11, 97].

Thick Absorbers, Ranges and Range Straggling
In radiation therapy with charged particles, a parallel beam is directed at the body. Usually, the energy $\mathcal{T}_0$ of the particles is adjusted to penetrate a given distance into the body. A primary measure of this distance is the mean range R calculated with the continuous slowing down approximation (CSDA)

$$R(\mathcal{T}_0) = \int_0^{\mathcal{T}_0} \frac{\mathrm{d}T}{S(T)} . \qquad (91.46)$$

Because of energy-loss straggling, there also is straggling in range amounting to a few percent of R [91.84].

In the practical application, a depth-dose curve is needed. At a given depth, the dose D is given by (91.6). For the first 50% of the range, the spread in energy of the beam is relatively small, and the dose is approximated closely by the stopping power $S(\mathcal{T})$ for the mean energy of the beam. For larger thicknesses, a detailed transport calculation must be made in order to find $\phi(\mathcal{T}, x)$ [91.11]. Range straggling functions can then also be obtained. Close agreement between measurement and calculation has been achieved [91.97]. Similarly, the mean energy loss $\mathcal{T}_1$ in a thick absorber is given implicitly by

$$x = \int_{\mathcal{T}_1}^{\mathcal{T}_0} \frac{\mathrm{d}T}{S(T)} \,. \tag{91.47}$$

Usually, values are obtained from a range energy table. Such tables may be found in [91.25, 63–65, 79, 82–87].

91.4.3 Particle identification (PID)

In particle physics the determination of particle types produced in the collisions of fast particles is needed [91.59]. Since the cross sections in Sect. 91.2 only depend on particle speed β and charge $Z_1 e$, energy deposition measurements combined with the measurement of particle momentum p can be used to determine particle masses. This process is called particle identification. A large amount of empirical information about PID has been accumulated, but little effort has been made to correlate this information with the theory described here. A major problem is the dependence of Δ_{mp}/x, Table 91.2, on x. In addition, Δ_{mp}/x is less than $\mathrm{d}E/x$ and its dependence on particle speed, Fig. 91.5, differs from that of $\mathrm{d}E/\mathrm{d}x$, Fig. 91.5. Comparisons of calculated and measured functions $F(\Delta)$ can be used to diagnose problems of the performance of the particle detector.

91.5 Multiple Scattering and Nuclear Reactions

Coulomb scattering of particles heavier than electrons by nuclei and electrons usually produces many, but very small angular deflections [91.4, 98].

The Molière theory [91.99] giving the distribution $f(\theta)$ of angular deflections θ agrees well with experimental data [91.100]. As a first approximation, a Gaussian distribution $f(\theta) = \mathrm{e}^{-y^2}$, where $y = \theta/\theta_0$, can be used. The value θ_0 is given by $\theta_0^2 = \theta_1^2 B_M$, where

$$\theta_1^2 = 0.157 \frac{Z_2(Z_2+1)}{A} Z_1^2 \frac{x\gamma^2}{\left(Mc^2\beta^2\right)^2} \text{radians} \tag{91.48}$$

and B_M has values of the order of 10. A more detailed description plus several tables is given in [91.84].

For a broad beam of particles, multiple scattering produces only a minor correction in the range. In a narrow "pencil" beam, it causes a broadening, e.g., a 320 MeV proton beam spreads to a width of about 2 cm after traveling through 40 cm of water [91.101].

It may be necessary to take into account the influence of nuclear interactions. As a first approximation, the total cross section is roughly [91.25]

$$\sigma_{\mathrm{tot}} = \pi \left(1.3 \times 10^{-13} A^{1/3} + \lambdabar\right)^2 \text{cm}^2 \,, \tag{91.49}$$

where $\lambdabar = \lambda_{\mathrm{d}B}/2\pi$.

91.6 Monte Carlo Calculations

In Monte Carlo calculations, the interactions occurring during the passage of the particles through matter can be simulated one at a time, collision by collision, and including those for the δ-rays [91.102, 103]. Particles travel random distances x_i between successive collisions, calculated by selecting a random number r_i and determining the distance to the next collision from

$$x_i = -\lambda_{\mathrm{mfp}} \ln r_i \,. \tag{91.50}$$

The energy loss E_i is selected with a second random number from the integrated collision spectrum

$$Q(E) = \int_0^E \frac{\sigma(E)}{M_0} \, \mathrm{d}E \,. \tag{91.51}$$

This process is repeated until $\sum x_i$ exceeds the absorber thickness. The total energy loss Δ of the particle is $\Delta = \sum_i E_i$.

91.7 Detector Conversion Factors

For all detectors, a study must be made of the process in which energy lost by the particles is converted into the observable signal, see Chapt. 92. The primary products of collisions are excited states, electron–ion and electron–hole pairs, and secondary electrons also called δ-rays. Secondary products are chemical species, fluorescent photons and Auger electrons. An important problem is the export of energy from the volume under observation by secondary radiations (δ-rays, mesons, X-rays, neutrons). Prominent among the effects [91.104] are ionization currents measured under applied electrical fields (in gaseous and solid state ionization chambers), photo effects by fluorescent radiation (scintillators), measurements of chemical yields (ferrous sulphate dosimeters, photographic emulsions, etc.), and the release of light by stored crystalline defects in thermoluminescent measurements.

The effect J can be related to the energy deposited D by a conversion factor W as $J = D/W$, where W represents the amount of energy needed to produce a unit of observable effect (e.g., an electron–ion pair). W depends on the absorber, particle type, and speed. For ionization, typical values are $W \approx 25$ eV gases, $W \approx 3.5$ eV semiconductors [91.84, 105].

For chemical effects [91.106], J is sometimes written as $J = YD$. Usually Y is given as the "yield per 100 eV". A typical value for a Fricke dosimeter is that, for fast electrons, 15 ferrous ions are converted into ferric ions per 100 eV of deposited energy. Usually, Y depends on time after the passage of the particles, and the full values are only reached after say 1 μs. For slow ions, Y is much smaller. Light emission (scintillations) has been observed from gases (typically, $W \approx 20$ eV), liquids and solids (typically, $W \approx 1000$ eV) [91.104].

The subsequent measurements of these radiation effects are done with current or charge amplifiers, proportional avalanche amplification, photo multipliers, channel plates, etc. [91.104].

92. Radiation Physics

Radiation physics entails studies of the interactions of ionizing radiation with matter. The term ionizing radiation refers to any energetic particles, either charged or uncharged, that can ionize atoms or molecules in matter. These particles include photons in the ultraviolet, X-ray, or γ-ray spectral region; electrons and positrons; mesons; protons and deuterons; α-particles; heavier ions including molecular ions; and neutrons. The matter under consideration includes substances in every phase of atomic aggregation (i.e., gas, liquid, solid, or plasma). Strictly speaking, the term "ionization" signifies an event in which at least one electron leaves an atom or molecule and eventually becomes free. This notion applies to a dilute gas, but not to condensed matter, for which it would be more precise to use the term "electronic activation" encompassing all modes of excitation, as sketched in Sect. 92.3.5.

Part G | 92

92.1 General Overview

The motivation for studying the interactions of radiation with matter and their consequences is manifold. First, nuclear and particle physics experiments often require radiation detectors – devices that detect, score, or analyze energetic particles. The working principles of these detectors rest on knowledge of elementary processes of radiation interactions with matter [92.1]. Second, measurements of radiation fields, called dosimetry [92.2], are important to many purposes, including the protection of workers in industry and medicine, as well as of the general public; risk estimates for exposures to radiation from natural sources (such as cosmic rays and terrestrial radioactivity) or from artificial sources (such as accelerators, man-made radioisotopes, and nuclear-power facilities); and good performance of radiation diagnosis and therapy. The principles of dosimetry are largely based on radiation physics. Finally, ionizing radiation is useful for processing materials such as plastics

and semiconductors, to endow desirable properties. To optimize methods of radiation processing, knowledge of radiation physics is highly valuable.

Atomic, molecular, and optical physics provides important underpinnings for radiation physics in two general contexts: instrumentation for the measurement of radiation and its effects on matter on the one hand, and elucidation of the atomic and molecular mechanisms leading to the effects on the other. The term instrumentation here means all devices that enable one to detect, identify, and quantify consequences of radiation interactions, such as particle kinetic energies and ionization, luminescence, and spectral analyses of atomic and molecular species produced. Conversely, needs in radiation physics have led to new atomic and molecular techniques such as resonance ionization spectroscopy [92.3], which was originally developed to determine the yield of excited atoms in gases exposed to radiation, but is

now regarded as a branch of multiphoton spectroscopy valuable for studies of excited states of atoms and molecules (Chapt. 74). Thus, the instrumentation development constitutes a mutually beneficial interface between atomic, molecular, and optical physics and radiation physics.

The elucidation of microscopic mechanisms of radiation effects requires a grand synthesis of knowledge from various areas ranging from atomic, molecular, and optical physics to condensed matter physics, statistical physics, chemical kinetics, and molecular biology [92.4, 5]. Yet, the role of atomic, molecular, and optical physics is most fundamental [92.6, 7]. Interactions of radiation with matter lead to numerous collisions of energetic particles with atoms and molecules, and result in the production of various excited and ionized states, as well as electrons and other secondary particles. These have a wide range of kinetic energies, and

in turn collide with atoms and molecules to generate further products. A detailed analysis of the chain of these early events demands knowledge in three topical areas: first, spectroscopic data (i. e., energy values and quantum numbers) of excited and ionized states; second, modes of decay and relaxation of these states, such as luminescence, molecular dissociation, and internal conversion and the branching ratios of each mode; and finally, the cross sections for all of the processes involved. All such knowledge is, in a broad sense, the fruit of work in atomic, molecular, and optical physics.

The following sections will concern key topics in basic radiation physics selected from a vast range of possibilities. The treatment will concentrate on basics and principles, and examples are meant to be illustrative rather than exhaustive; yet, the author hopes that the discussion will convey the charm and challenges of current research.

92.2 Radiation Absorption and its Consequences

92.2.1 Two Classes of Problems of Radiation Physics

It is useful to distinguish between two classes of problems in radiation physics [92.6], as illustrated in Fig. 92.1. Problems of Class I concern the fate of radiation after interactions with matter. Problems of Class II concern the fate of matter after interactions with radiation.

Problems of Class I are exemplified by the determination of the energy losses of particles penetrating matter, and the attenuation of a beam of photons in matter. Experimental studies on these problems are straightforward in principle; one only needs to analyze the kinetic energies of transmitted particles in the first problem and to count the number of transmitted photons in the second problem. Problems of Class I are also often simple to treat theoretically; for instance, in the Bethe theory of stopping power, discussed in Chapt. 91, the use of sum rules enables one to bypass detailed knowledge about excited and ionized states. As a consequence, many of the problems of Class I have been solved. Furthermore, many of the applications of radiation physics are based on the established knowledge of solutions of problems of Class I. For instance, diagnostic uses of X-ray photons in medicine and industry rest on the firm knowledge of the attenuation of photons in matter (more precisely, on its dependence on the atomic number).

In sharp contrast, problems of Class II are fundamentally difficult; indeed, none of them has been solved completely. Reasons for the difficulty are manifold. First, any piece of irradiated matter is a new material that needs to be fully characterized. Second, irradiated matter is in general in a nonequilibrium state that changes physically and chemically with time. Finally, existing tools and techniques, both experimental and theoretical, for material characterization are limited.

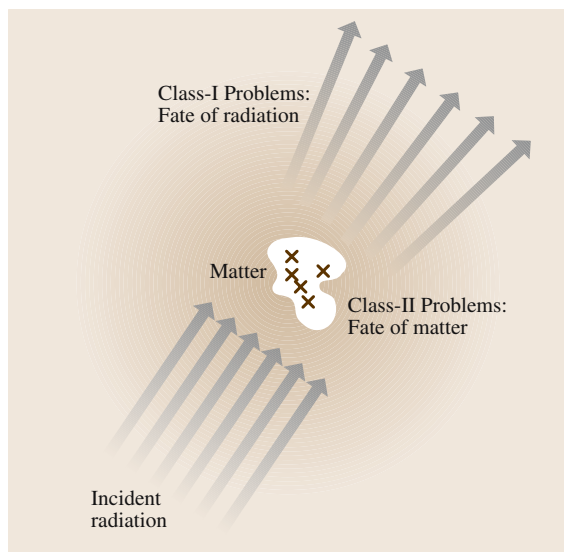
To illustrate the nature of Class II problems, it is useful to consider a prototype problem that has been treated reasonably well, but certainly not completely. Suppose a single electron with energy 10 keV enters a dilute hydrogen gas of a sufficiently large volume. The incident electron will collide with a hydrogen molecule. Possible outcomes include excitation of molecular states, ionization leading to H_2^+ in various vibrational and rotational states, and ionization leading to dissociation into $H^+ + H$ (in various excited states or in the ground state). An electron resulting from an ionizing event may have enough kinetic energy to cause further excitation and ionization. Eventually, all the liberated electrons will lose enough energy to become subexcitation electrons unable to excite even the lowest electronic level of H_2 at 9.5 eV. Table 92.1 summarizes the various atomic and molecular species produced. To produce this answer, it was necessary to survey all the spectroscopic and electron collision data on H_2, and to


Fig. 92.1 Schematic diagram showing the definition of Class I and Class II problems. Incident radiation comes from the lower left, interacts with matter, and travels toward the upper right, having been scattered. The crosses symbolize interaction events taking place within matter

carry out an analysis of electron transport. Problems of this kind will be further discussed in Sect. 92.3.2 and Sect. 92.3.3.

92.2.2 Photons

High-energy photons (i. e. X-rays, γ-rays, or a major part of synchrotron radiation), are important as the ionizing radiation most frequently used in applications. Their initial interactions with matter result in a spectrum of energetic electrons. Detailed discussion is given in Chaps. 61 and 62.

92.2.3 Charged Particles

Energetic charged particles penetrating matter cause ionization and electronic excitation of atoms and molecules as they lose kinetic energy (Chapt. 65). The most fundamental index to characterize the energy loss process is the total cross section for inelastic collisions, which is the mean number of inelastic collisions per unit path length in a material of unit molecular density. The next fundamental index is the stopping power, which is the mean energy loss per unit path length. For many purposes, a more de-

tailed description of particle penetration is necessary. An example is energy loss straggling, fully discussed in Chapt. 91.

Ionization is generally accompanied by the production of secondary electrons, which in general have a broad energy spectrum. This topic is reviewed by Rudd and coworkers [92.9–11].

92.2.4 Neutrons

Neutrons with kinetic energies in the MeV domain cause nuclear reactions, generally leading to the production of a number of charged particles. Neutrons of any kinetic energies collide with nuclei in matter elastically (viz., without causing nuclear reactions) and transfer substantial kinetic energy to nuclei. Consequently, neutrons may be regarded as a source of charged particles of various kinds, most importantly protons and light nuclei, all having broad energy spectra [92.12, 13].

Table 92.1 The mean number N_j of initial species produced in molecular hydrogen upon complete degradation of an incident electron at 10 keV, and the energy absorbed E_{abs} (in percent).[a] The left column of this table indicates kinds of species tersely. For instance, "Lyman" here means the $B^1\Sigma_u^+$ state, which emits the Lyman band. The term "Werner" means the $C^1\Pi_u$ state, which emits the Werner band. The designation "H(2p)" means the production of hydrogen atoms in the 2p state. The designation "Slow H(2s)" means the production of hydrogen atoms in the 2s state with no appreciable kinetic energy. The designation "Fast H(2s)" means the production of hydrogen atoms with kinetic energies of several eV. The designation "Triplet" means all the triplet states combined. The designation "Subexcitation electrons" means all the electrons that are not energetic enough to cause further electronic excitation

Initial species j	N_j	E_{abs}
$H_2(B^1\Sigma_u^+)$ (Lyman)	96.8	11.7
$H_2(C^1\Pi_u)$ (Werner)	112.1	14.0
H(2p)	5.6	0.8
Slow H(2s)	29.6	4.4
Fast H(2s)	5.3	1.7
H ($n=3$)	3.2	0.5
Higher excited states	12.2	1.7
Ions	295.6	45.9
Triplets	102.6	10.0
Subexcitation electrons	295.6	9.4

[a] Adapted from *Douthat* [92.8]

92.3 Electron Transport and Degradation

92.3.1 The Dominant Role of Electrons

In many Class II problems (i.e., radiation actions on molecular substances such as gases, molecular liquids or solids, and biological cells), energetic electrons generated by ionizing radiation play a central role because they are numerous, and deliver to atoms and molecules a large fraction of the total energy of radiation. What follows is a resume of our current understanding.

92.3.2 Degradation Spectra and Yields of Products

The prototype H_2 problem discussed in Sect. 92.2.1 may be generalized as follows. Consider the total number N_j of a particular molecular species j produced as a result of complete slowing down of electrons in a chemically pure medium consisting of n molecules per unit volume. The product species j could be ions or excited states specified by a set of quantum numbers. Let $\sigma_j(T)$ be the cross section for the production of j in a collision of an electron of kinetic energy $\mathcal{T}$ with a molecule. During its passage over an infinitesimal path length dx, an electron of kinetic energy $\mathcal{T}$ contributes the amount $dN_j = n\sigma_j(\mathcal{T})\,dx$ to N_j. Therefore, one may write

$$N_j = n \int \sigma_j(\mathcal{T})\,dx \ . \tag{92.1}$$

To carry out this integration, one must have a relation between $\mathcal{T}$ and x. To the extent that one regards x and $\mathcal{T}$ as related through an analytic function, one may write

$$dx = (d\mathcal{T}/dx)^{-1}\,d\mathcal{T} \ , \tag{92.2}$$

where $d\mathcal{T}/dx$ is the mean energy loss per unit path length traversed, or the stopping power as defined in Chapt. 91. This treatment, called the continuous-slowing-down approximation (CSDA), is justified if $\mathcal{T}$ greatly exceeds the majority of energy losses upon individual collisions.

However, the CSDA is inadequate for electrons in general because the energy loss of an electron upon an individual collision is not always small compared with the current kinetic energy, and because the CSDA does not account for secondary electrons, which are abundantly produced. An appropriate formulation, introduced by *Spencer* and *Fano* [92.14], is obtained by writing

$$dx = y(\mathcal{T})\,d\mathcal{T} \tag{92.3}$$

in place of (92.2) and determining the function $y(\mathcal{T})$ through full analysis of electron transport, production,

and slowing down. This function, called the degradation spectrum, has been an object of extensive studies [92.6, 15]. Once $y(\mathcal{T})$ is determined, the yield N_j of product species j is evaluated as

$$N_j = n \int_{E_{1,j}}^{\mathcal{T}_{\max}} \sigma_j(\mathcal{T})y(\mathcal{T})\,d\mathcal{T} \ , \tag{92.4}$$

where $E_{1,j}$ is the threshold energy for the production of j, and $\mathcal{T}_{\max}$ is the highest kinetic energy of electrons in the medium.

Three basic properties of $y(\mathcal{T})$ are as follows [92.15]. First, $y(\mathcal{T})$ is proportional to the electron energy distribution (as treated by the Boltzmann equation) multiplied by electron speed v, or $(2\mathcal{T}/m)^{1/2}$ in the nonrelativistic case.

Second, $y(\mathcal{T})$ obeys an integral equation called the Spencer–Fano equation. This equation expresses the balance of the number of electrons arriving at kinetic energy $\mathcal{T}$ with the number of electrons departing from it. One may write the cross section for a collision process in which an electron of kinetic energy $\mathcal{T}$ collides with an atom or molecule and an electron of kinetic energy $\mathcal{T}'$ emerges as $\sigma(\mathcal{T} \to \mathcal{T}')$. Then, the expression $\int \sigma(\mathcal{T}' \to \mathcal{T})y(\mathcal{T}')\,d\mathcal{T}' - \int \sigma(\mathcal{T} \to \mathcal{T}')\,d\mathcal{T}'y(\mathcal{T})$ represents the change in the number of electrons at kinetic energy $\mathcal{T}$ due to all collisions in a medium of unit density. For convenience, one may write the above expression as $K_{\mathcal{T}}y(\mathcal{T})$ using a linear operator $K_{\mathcal{T}}$ called the collision operator. In the simple case where a source steadily generates $u(\mathcal{T})\,d\mathcal{T}$ electrons having kinetic energies between $\mathcal{T}$ and $\mathcal{T} + d\mathcal{T}$ in a medium consisting of n atoms or molecules of a single species, the Spencer–Fano equation takes the form

$$nK_{\mathcal{T}}y(\mathcal{T}) + u(\mathcal{T}) = 0 \ . \tag{92.5}$$

Third, in the domain $E_1 < \mathcal{T} < \mathcal{T}_{\max}$, where E_1 is the lowest electronic-excitation threshold energy of the medium, $y(\mathcal{T})$ is invariably bimodal, as exemplified by Fig. 92.2. The behavior at high $\mathcal{T}$ is largely understandable from the CSDA (92.2), which approximately holds at $\mathcal{T} \gg E_1$; then, $y(\mathcal{T})$ is the reciprocal of the stopping power, which is given by the Bethe theory and corrections as explained in Chapt. 91. For example, for electrons with $\mathcal{T}$ between 1 keV and 10 keV, the stopping power of molecular hydrogen is a monotonically decreasing function of $\mathcal{T}$, and therefore $y(\mathcal{T})$ is a monotonically increasing function of $\mathcal{T}$, as seen in Fig. 92.2. In contrast, the steep rise of $y(\mathcal{T})$ at low

$\mathcal{T}$ occurs because most of the secondary electrons produced in an ionizing collision of any energetic charged particle (including an energetic electron) have low kinetic energies, corresponding to a few multiples of the ionization threshold energy, as fully documented by *Rudd* et al. [92.9–11].

As $\mathcal{T}$ varies, the principal contribution to the yield expression (92.4) comes from ranges where both $\sigma_j(\mathcal{T})$ and $y(\mathcal{T})$ are large. A large $y(\mathcal{T})$ means a long path length of electrons at that $\mathcal{T}$, and hence a modest energy loss per unit path length. From (92.2), the time interval $\mathrm{d}t$ during which electrons stay in the energy interval $\mathrm{d}\mathcal{T}$ is

$$\mathrm{d}t = (\mathrm{d}t/\mathrm{d}x)^{-1}\,\mathrm{d}x = v^{-1}y(\mathcal{T})\,\mathrm{d}\mathcal{T} \; . \qquad (92.6)$$

The quantity $v^{-1}y(\mathcal{T})\,\mathrm{d}\mathcal{T}$ represents the sojourn time of electrons at energy $\mathcal{T}$. Equation (92.4) expresses how N_j is determined by the competition between electron degradation, and the cross section $\sigma_j(\mathcal{T})$ for production of j upon individual collisions. The product $\sigma_j(\mathcal{T})y(\mathcal{T})$, called the yield spectrum for production of j, plays a central role in the theory.

Since $\mathcal{T}$ ranges from a few eV up to keV or MeV, it is convenient to rescale the yield spectrum to $\ln\mathcal{T}$. In fact, $\ln\mathcal{T}$ is more meaningful as a variable because it represents, in effect, the mean number of elastic collisions required to reduce $\mathcal{T}$ by a given amount. (In the neutron slowing down theory [92.16], $\ln\mathcal{T}$ is called lethargy by Fermi.) Equation (92.4) then becomes

$$N_j = n \int \mathcal{T}\sigma_j(\mathcal{T})y(\mathcal{T})\,\mathrm{d}(\ln\mathcal{T}) \; , \qquad (92.7)$$
with $\mathcal{T}\sigma_j(\mathcal{T})y(\mathcal{T})$ regarded as a function of $\ln\mathcal{T}$. The product $\mathcal{T}\sigma_j(\mathcal{T})$ is proportional to the collision strength in the theory of atomic collisions, as treated in Chapt. 47. It is also a key quantity in the Bethe theory [92.17].

Figure 92.3 is an example of a yield spectrum for ionization in molecular hydrogen. The area under the curve over any given interval of $\ln\mathcal{T}$ represents the number of ions produced in collisions of electrons in that interval. One sees a sizable contribution from high energies (between 1 keV and 10 keV). Below 1 keV, where the spectrum is roughly constant, each decade of $\mathcal{T}$ contributes roughly the same amount to the total ionization yield. This observation applies to any product j that results from dipole-allowed transitions.

In contrast, the yield spectrum for a product j resulting from forbidden transitions is dominated by values at low $\mathcal{T}$, where $\sigma_j(\mathcal{T})$ is appreciable, as Fig. 92.4 illustrates. An example is the production of two ground-state hydrogen atoms from a hydrogen molecule, which occurs solely from the lowest triplet repulsive state.

Finally, once electrons fall below E_1, they moderate much less rapidly than they do above E_1. These subexcitation electrons [92.18], lose energy through momentum transfer upon elastic collisions with molecules, rotational excitation, and vibrational excitation, as discussed in Chapt. 47. The behavior of the subexcitation
Fig. 92.3 The yield spectrum for ionization in molecular hydrogen. Source electrons are the same as for Fig. 92.2. The vertical axis represents $ny(\mathcal{T}_{max}, \mathcal{T})\mathcal{T}\sigma_i(\mathcal{T})/\mathcal{T}_{max}$, where n is the number density of molecules, $\mathcal{T}_{max} = 10$ keV is the source-electron energy, and $\sigma_i(\mathcal{T})$ is the ionization cross section of H_2 for electrons of energy $\mathcal{T}$. Data are taken from *Douthat* [92.8]

Fig. 92.2 Electron degradation spectrum in molecular hydrogen. Source electrons of kinetic energy $\mathcal{T}_{max} = 10$ keV steadily enter the hydrogen gas at $0\,^\circ$C and 1 atmosphere at the rate of 1 electron^{-1}cm^{-3}. Data are taken from *Douthat* [92.8]

electrons is treated by an extension of the Spencer–Fano equation [92.15], until they reach kinetic energies comparable with the thermal energy of the medium molecules. Then, the transport, moderation, and eventual energy gain from medium molecules become important, as well as the energy loss to them. The three main energy domains of electronic excitation, subexcitation, and thermal [92.19] are illustrated in Fig. 92.5. Because of the great disparity in the modes of interactions with the medium, electrons in each of the domains need different treatments.

Together with ions, molecular fragments, and other products of electron degradation, electrons in the thermal domain are important as precursors to subsequent chemical reactions, and therefore have been the subject of extensive study [92.4, 20, 21].

92.3.3 Quantities Expressing the Yields of Products

The total ionization yield is often expressed in terms of the quantity W, defined to be the mean energy required to produce an ion pair, or equivalently,

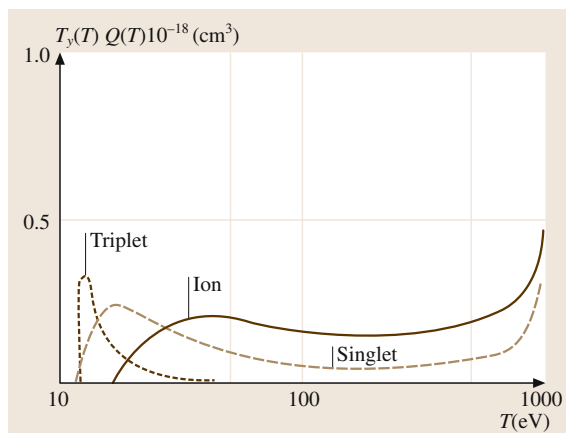
$$W = \mathcal{T}_{abs}/N_i , \qquad (92.8)$$


Fig. 92.4 The yield spectra for three product species in molecular hydrogen. Source electrons of kinetic energy $\mathcal{T}_{max} = 1000$ eV steadily enter the hydrogen gas at $0°C$ and 1 atmosphere at the rate of 1 electron^{-1}cm^{-3}. The *solid curve* labeled "ION" represents ionization, the *long-broken curve* labeled "SINGLET" represents the production of the $B^1\Sigma_u^+$ state, and the *short-broken curve* labeled "TRIPLET" represents the production of the $a^3\Sigma_g^+$ state, which dissociates into two hydrogen atoms in the ground state (Courtesy: Mineo Kimura)

where $\mathcal{T}_{abs}$ is the mean enery absorbed and N_i is the mean number of ions observed over many events. $\mathcal{T}_{abs}$ is simply the initial injection energy if all the resulting electrons are degraded to kinetic energies below the ionization threshold. Since each event is stochastic, $\mathcal{T}_{abs}$ and N_i in general fluctuate from one event to the next.

A simple index for the statistical fluctuations in N_I is the variance V of N_I from its mean. The ratio $F = V/N_i$, called the Fano factor [92.22].

Both measurements and theory indicate that W and F are approximately the same for different kinds of ionizing radiations of sufficiently high energy, and that they depend primarily on the material of the medium [92.15, 23, 24]. This fact is important as a basis for radiation dosimetry through ionization measurements. The ratio W/I ranges from 1.7 to 3.2 depending on the nature of materials, where I is the ionization threshold energy. The ratio always exceeds unity because a fraction of radiation energy absorbed is expended to generate products other than ionization, such as discrete excited states, neutral molecular fragments, and subexcitation electrons.
Fig. 92.5 A schematic diagram for showing three distinct domains of electron transport in a molecular substance. The horizontal axis represents the kinetic energy $\mathcal{T}$ of an electron. The vertical axis represents the energy loss E upon a single collision with a molecule. The vertical broken line indicates the first electronic excitation threshold E_1. The shade and fade schematically represent the magnitudes of cross sections

The Fano factor F is restricted to $0 < F < 1$ on general theoretical grounds. The maximum value $F = 1$ would occur if the ionization process were characterized by the Poisson statistics. In reality, the ionization process is subject to the constraints that it must compete with nonionizing events, and that the available total energy is fixed; therefore the fluctuations in the ionization yield must be smaller than those given by the Poisson statistics, viz., $F < 1$. Both theory and experimental data indicate that F and W tend to vary together from one material to another; more precisely, *Krajcar–Bronić* [92.24] found an approximate empirical relation

$$F = a(W/I) + b , \tag{92.9}$$

where a and b are constant. This relation is valid for electrons of sufficiently high energies.

For molecular products other than ions, it is customary to use G_j defined by

$$G_j = N_j / \mathcal{T}_{abs} , \tag{92.10}$$

where N_j is the mean number of molecular products of type j (see pp. 241–242 of *Kimura* et al. [92.15] for fuller discussion). Like W, G_j is often approximately the same for different kinds of ionizing radiations of sufficiently high energy, provided that the material, either liquid or solid, is homogeneous and that the absorbed energy is not extremely great. A counter example is the ferrous sulphate equeous solution, which is often used for dosimetry and in which the G value for the ferrous-ferric conversion depends appriciably on the kind of radiation (Chapt. 91). In the more general case of a heterogeneous material having complex molecular structure and aggregation, such as a biological cell, the yield of a product is not even approximately proportional to the absorbed energy, and the idea of a G value is useful only at the limit of vanishing absorbed energy.

In SI units, the G value has units of $mol J^{-1}$. This is related to the older unit, molecules $(100 \, eV^{-1})$, by

$$1 \, mol \, J^{-1} = 9.6485 \times 10^{-6} molecules (100 \, eV)^{-1} . \tag{92.11}$$

The meaning of the yield of a product depends on the process. The molecular species produced as a result of electron degradation (e.g., those given in Table 92.1) may be called initial products. Subsequently, they react with neighboring molecules or among themselves to form other species, which may be called secondary products, such as H_3^+, through the ion-molecule reaction

$$H_2^+ + H_2 \rightarrow H_3^+ + H . \tag{92.12}$$

The yield of an initial product is seldom measured and is accessible by theory only. Most yield measurements

concern a secondary product. To keep the distinction in mind, *Platzman* recommended [92.25] use of the symbol g for an initial product and the symbol G for a secondary product.

For data on G values, see *Tabata* et al. [92.4] and references cited therein.

92.3.4 Track Structures

The spatial distributions of initial products such as ions and excited states influence the kinetics of their subsequent chemical reactions, which lead to radiation effects. Spatial distribution is generally expected to have a role in a heterogeneous material; this role should be especially prominent when the scale characteristic of the distribution is comparable to the scale of the material inhomogeneity.

The simplest index of the distribution is the stopping power, which gives the linear density of energy lost from a particle along its path. From the point of view of radiation effects, or Class II problems, the linear density of energy imparted locally to matter is of greater interest. The distinction between the energy lost from a particle and the energy imparted locally to matter arises when one considers a volume having a linear scale less than the ranges of the majority of secondary electrons produced in the volume; sufficiently energetic secondary electrons will escape the volume and impart much of their kinetic energies elsewhere. This recognition led to the idea of the linear energy transfer (often abbreviated as LET), which is defined as the mean energy loss, excluding contributions from the production of secondary electrons having kinetic energies above a fixed value, such as $100 \, eV$ [92.26]. The LET, like the stopping power, depends on the particle charge and speed, as well as on the material, and is often used in radiation chemistry and biology to consider the role of the spatial distribution of initial products.

However, a given value of LET from particles of different charges and speeds does not necessarily lead to the same radiation effect. The aim of microdosimetry [92.27] is to provide a more detailed description of the energy imparted locally to a small volume of matter. For a fuller discussion see Chapt. 91.

The full representation of the spatial pattern of the initial products resulting from individual incident and secondary particles is called the track structure, because the pattern was first recognized in particle tracks visualized in cloud chambers, photographic emulsions, and other radiation detectors. Treatments of track structures and their consequences for the subsequent

chemical reactions by Monte Carlo simulations are certainly informative and flexible for application to a wider range of problems, as exemplified by [92.28–33]. Such treatments are in principle sound, because they are independent of an assumption that the yield of a product is proportional or otherwise simply related to the energy lost or imparted.

The spatial distribution of the initial products and other consequences of radiation interactions with matter can be also studied by analytic methods using transport equations. An excellent exposition of the recent status of this approach is given in the NCRP Report No. 108 [92.34]. By solving relatively simple problems, the analytic methods are effective in elucidating principles and providing insights into the physics involved, while the Monte Carlo simulations are powerful in providing answers to complicated problems. In summary, the two approaches are complementary, rather than competitive.

Meaningful results from these treatments require a large volume of accurate cross section and other data as input. Various surveys of atomic and molecular cross section data are available to present recommended values and to identify needs for further studies, such as the report [92.35] sponsored by the International Atomic Energy Agency. A broader review of the current status of cross section determination, dissemination, and related topics is in [92.36].

92.3.5 Condensed Matter Effects

Beyond the interactions of ionizing particles with individual atoms and molecules in a gas or beam, the atomic or molecular aggregation in condensed matter has fur-

ther important influences. A prelude to condensed matter effects is seen in studies of high-pressure gases [92.37] and in Chapt. 39.

Many phenomena are related to the complex dipole-response function $\epsilon(E)$, which is the electric displacement generated in matter by a spatially uniform electric field of unit strength oscillating at angular frequency $\omega = E/\hbar$ (see, e.g., *Landau* and *Lifshitz* [92.38]). For light at this frequency, the real part $\epsilon_1(E)$ describes the dispersion, and the imaginary part $\epsilon_2(E)$ describes the absorption. The probability that a glancing collision of a fast charged particle transfers energy E to matter is proportional to

$$\Pi(E) = \text{Im}[-1/\epsilon(E)] = \frac{\epsilon_2}{\epsilon_1^2(E) + \epsilon_2^2(E)} \ . \quad (92.13)$$

In a low-density material, such as a dilute gas, $\epsilon_1(E)$ is close to unity, and $\epsilon_2(E)$ is much smaller than unity for all E. Then, $\Pi(E)$ is practically the same as $\epsilon_2(E)$; in other words, the spectrum of energy transfer in a glancing collision of a fast charged particle is effectively the same as the spectrum of photoabsortion. In a high-density material, $\Pi(E)$ differs appreciably from $\epsilon_2(E)$ at some E. An extreme case occurs at E at which $\epsilon_1(E)$ changes its sign; there $\Pi(E)$ has a peak. This is the well-known plasma excitation in metals.

A general criterion for determining the effect of atomic or molecular aggregation on the dipole oscillator strength spectrum, and hence on $\Pi(E)$, was given by *Fano* [92.39]. One may qualitatively summarize his criterion as follows: If the density of the dipole oscillator strength of an atom or molecule in both space and

Table 92.2 Condensed matter effects

Classification	Example	Remarks on characteristics
Shift of oscillator strength toward higher energies	Water, hydrocarbons, and organics	Occurs over wide ranges of exitation energies.
Excitation of special modes of motion	Plasmons in metals	Occurs at specific energies and carries considerable strength.
	Excitons in molecular crystals and ionic crystals	Occurs at specific energies and at minor strengths.
Interaction of fast ejected electrons with other atoms and molecules	EXAFS (extended X-ray absorption fine structure)	Occurs at energies above 100 eV, slightly above the pertinent threshold, and at weak strengths, chiefly due to interference of electrons emerging from different atoms.
Resonances in electron interactions	N_2, C_2H_4, C_2H_2, and other unsaturated hydrocarbons	Occurs at energies slightly above the excitation threshold or even lower; leads to inelasticity.
Diffraction of the electron de Broglie wave	Materials with periodic structure	Leads to band structure effects, such as transmission without energy loss at certain electron kinetic energies.

energy (or frequency) is sufficiently high, the effects of atomic or molecular aggregation will be appreciable. In other words, the effect will be seen in a sufficiently dense material and in a generally limited spectral region where the oscillator strength spectrum of an isolated atom or molecule is especially intense. With the use of the Fano criterion, one understands the occurrence of collective excitation (electronic excitation involving more than one atom or molecule), such as excitons, plasmons, and other elementary modes of excitation in condensed matter. For a fuller and more recent discussion of this topic, see *Fano* [92.40].

Many manifestations of condensed matter effects on the absorption of radiation energy have been identified, as discussed, for instance, in [92.7] and [92.41]. Table 92.2 presents a summary of these effects.

92.4 Connections with Related Fields of Research

92.4.1 Astrophysics and Space Physics

Some of the ideas and methods sketched in Sect. 92.3.1 and Sect. 92.3.2 are readily applicable to studies on terrestrial and planetary auroras [92.42–46] and on effects of cosmic rays or X-rays on interstellar clouds and other astronomical objects [92.47–53]. These studies treat consequences of the interactions of energetic charged particles or high-energy photons on voluminous gases, at low densities and often partially ionized. Often the presence of electric and magnetic fields influence radiation degradation phenomena.

92.4.2 Material Science

As fully discussed earlier, radiation effects on gases, liquids, and molecular substances, including the biological cell, result mainly from electronic excitation. Radiation effects on insulators, including crystalline solids, are also initiated by electronic excitation [92.54, 55] and are therefore closely related to atomic, molecular, and optical physics.

In metals, electronic excitation per se is of little consequence, because most of the electronic excitation energy is rapidly converted into phonons (thermal energy). Generally, a small fraction of electronic excitation energy causes appreciable atomic displacement. Radiation effects on these materials occur predominantly via direct energy transfer to atoms from neutrons, protons, and heavier charged particles, causing atomic displacement from a regular crystalline site [92.56–58].

More generally, the role of atoms and ions having kinetic energies far exceeding the thermal energy is important in chemistry. This topic, known as hot-atom chemistry [92.59, 60], represents another application of the knowledge of atomic, molecular, and optical physics as discussed in Chapts. 64 and 65, 66 and 67.

Radiation effects on the surface of a solid are a subject of extensive study, because of their importance as means for material-structure probing and also for material processing (for example, the ion implantation in the manufacture of semiconductors and other devices). A major phenomenon of interest is sputtering, which is the ejection of atoms and molecules from the surface by the action of ionizing radiation [92.61–64].

92.5 Supplement

A supplement to the foregoing sketch is provided by an essay [92.65] on the role of physics written in commemoration of the fiftieth anniversary of the Radiation Research Society, an organ devoted to physical, chemical, biological, and medical studies on the action of radiation. According to the essay, contributions by physicists have been steady, and show no sign of decline in the total volume only changing emphasis over years. Topics of the contributions concern radiation sources, dosimetry, instrumentation for measurements of radiation effects, fundamentals of radiation physics, mechanisms of radiation actions, and applications. The role of physics is most certain and decisive in the development of instrumentation in a broad sense, ranging from radiation sources to probes of radiation effects.

Finally, Ugo Fano was a giant in atomic, molecular, and optical physics and also a pioneer of radiation physics. After his death in 2001 many articles about his work and life naturally appeared in print. A special issue of *Physics Essays* in his

honor [92.66] contains biographic materials, forty papers by his associates and friends, as well as his own memoir. A recent article [92.67] summarizes

Fano's contributions to atomic, molecular, and optical physics, and includes the most accurate list of his publications.

Acknowledgements

A.2 Angular Momentum Theory
by James D. Louck

This contribution on angular momentum theory is dedicated to Lawrence C. Biedenharn, whose tireless and continuing efforts in bringing understanding and structure to this complex subject is everywhere imprinted.

We also wish to acknowledge the many contributions of H. W. Galbraith and W. Y. C. Chen in sorting out the significance of results found in *Schwinger* [2.20]. The Supplement is dedicated to the memory of Brian G. Wybourne, whose contributions to symmetry techniques and angular momentum theory, both abstract and applied to physical systems, was monumental.

The author expresses his gratitude to Debi Erpenbeck, whose artful mastery of TEX and scrupulous attention to detail allowed the numerous complex relations to be displayed in two-column format.

Thanks are also given to Professors Brian Judd and Gordon Drake for the opportunity to make this contribution.

Author's note. It is quite impossible to attribute credits fairly in this subject because of its diverse origins across all areas of physics, chemistry, and mathematics. Any attempt to do so would likely be as misleading as it is informative. Most of the material is rooted in the very foundations of quantum theory itself, and the physical problems it addresses, making it still more difficult to assess unambiguous credit of ideas. Pragmatically, there is also the problem of confidence in the detailed correctness of complicated relationships, which prejudices one to cite those relationships personally checked. This accounts for the heavy use of formulas from [2.1], which is, by far, the most often used source. But most of that material itself is derived from other primary sources, and an inadequate attempt was made there to indicate the broad base of origins. While one might expect to find in a reference book a comprehensive list of credits for most of the formulas, it has been necessary to weigh the relative merits of presenting a mature subject from a viewpoint of conceptual unity versus credits for individual contributions. The first position was adopted. Nonetheless, there is an obligation to indicate the origins of a subject, noting those works that have been most influential in its developments. The list of textbooks and seminal articles given in the references is intended to serve this purpose, however inadequately.

Excerpts and Fig. 2.1 are reprinted from *Biedenharn* and *Louck* [2.1] with permission of Cambridge University Press. Tables 2.2–2.4 have been adapted from *Edmonds* [2.18] by permission of Princeton University Press. Thanks are given for this cooperation.

About the Authors

Miron Ya. Amusia

The Hebrew University
Racah Institute of Physics
Jerusalem, Israel
amusia@vms.huji.ac.il

Chapter B.23

Dr. Miron Amusia is a Professor of Physics at the Hebrew University of Jerusalem, Israel, and Principal Scientist of the Ioffe Physical-Technical Institute, St-Petersburg, Russia. He is author and co-author of more than 400 referred papers and 9 books. His research is in many-body theory of atoms, nuclei, molecules, clusters, and condensed matter, but primarily in atomic physics. He is Fellow of American Physical Society and a member of several professional societies and editorial boards. He received the Humboldt research award and is a member of the Russian Academy of Natural Sciences.

Nils Andersen

University of Copenhagen
Niels Bohr Institute
Copenhagen, Denmark
noa@fys.ku.dk

Chapter D.46

Nils Andersen is Professor of Physics at the Niels Bohr Institute of the University of Copenhagen. His main activities include experimental and theoretical studies of atomic collisions involving optically prepared states. Recent research interests include cold and ultracold collisions.

Thomas Bartsch

Georgia Institute of Technology
School of Physics
Atlanta, GA, USA
bartsch@cns.physics.gatech.edu

Chapter B.15

Thomas Bartsch received his PhD from the University of Stuttgart, Germany, in 2002. He is currently a postdoctoral fellow at the Georgia Institute of Technology. His research is centred on applications of nonlinear dynamics to atomic and molecular physics.

Klaus Bartschat

Drake University
Department of Physics and Astronomy
Des Moines, IA, USA
klaus.bartschat@drake.edu

Chapter A.7

Dr. Bartschat is the Ellis & Nelle Levitt distinguished Professor of Physics at the Department of Physics and Astronomy at Drake University. His research in theoretical and computational atomic physics focuses on combining the general theory of measurement with highly accurate numerical calculations. He is a fellow of the american physical society and has published 2 books, 30 book chapters, 10 review articles, and more than 200 papers on electron and photon collisions with atoms and ions.

William E. Baylis

University of Windsor
Department of Physics
Windsor, ON, Canada
baylis@uwindsor.ca

Chapters 1, B.12

Professor Baylis earned degrees in physics from Duke (B.Sc.), the University of Illinois (M.Sc.), and the Technical University of Munich (D.Sc.). He has authored two books, edited or co-edited four more, contributed 28 chapters to other volumes, and published over a hundred journal articles. His publications are in theoretical physics and emphasize atomic and molecular structure, atomic collisions, and interactions with radiation. His most recent work concerns relativistic dynamics, the photon position operator and wave function, and applications of Clifford algebra, especially to the quantum - classical interface. He is a fellow of the American Physical Society, past chair of the Divisions of Atomic and Molecular Physics and of Theoretical Physics of the Canadian Association of Physicists, a member of the international editorial boards of the Springer Series of Atomic, Optical, and Plasma Physics and of the journal Advances in Applied Clifford Algebras. He is currently a University Professor at the University of Windsor.

Authors

Anand K. Bhatia   Chapter B.25

NASA Goddard Space Flight Center
Laboratory for Astronomy & Solar Physics
Greenbelt, MD, USA
anand.k.bhatia@nasa.gov

Dr. Bhatia received his Ph.D. in theoretical physics from the University of Maryland in 1963. Since then he has been at Goddard Space Flight Center. He has published a large number of papers in refereed journals on various topics in atomic and astrophysics: scattering of electrons and positrons from atoms, muonic fusion, polarizabilities of two-electron systems, Lamb shift, Rydberg states, excitation of ions etc. He is a Fellow of the American Physical Society.

Hans Bichsel   Chapter G.91

University of Washington
Center for Experimental Nuclear Physics
and Astrophysics (CENPA)
Seattle, WA, USA
bichsel@npl.washington.edu

Professor Hans Bichsel has worked on the interactions of fast charged particles with matter for over 50 years. Some of his measurements are the most accurate of their type. At present he is studying the methods of particle identification for the time projection chambers at STAR and ALICE. Earlier he worked in nuclear physics and developed neutron radiation therapy in Seattle.

John M. Brown   Chapter C.41

University of Oxford
Physical and Theoretical Chemistry
Laboratory
Oxford, England
john.m.brown@chem.ox.ac.uk

Professor Brown obtained his Ph.D. degree from the University of Cambridge in 1966. Before moving to Oxford in 1983, he was a Lecturer in the Department of Chemistry at Southampton University. He is a high-resolution, gas-phase spectroscopist with a special interest in free radical species. In addition to experimental studies at all wavelengths from microwave to the ultraviolet, he is interested in the development of theoretical models to describe the experimental results.

Henry Buijs   Chapter C.40

ABB Bomem Inc.
Québec, Canada
henry.l.buijs@ca.abb.com

Henry Buijs founded ABB Bomem Inc. in 1973 to bring to market state of the art Fourier Transform spectrometers. He received his Ph.D. from the University of British Columbia. He has interest in spectroscopic measurement in the atmosphere for Ozone chemistry, meteorological sounding and climate change assessment. ABB Bomem Inc. is leader in FT spectrometers for satellite based sensors and industrial process monitoring solutions.

Philip Burke   Chapter D.47

The Queen's University of Belfast
Department of Applied Mathematics and
Theoretical Physics
Belfast, Northern Ireland, UK
p.burke@qub.ac.uk

Phil Burke is Emeritus Professor of Mathematical Physics at the Queen's University of Belfast, having been Professor at Queen's from 1967 until 1998. His research interests are the theory of atomic, molecular, and optical physics and their applications. He was awarded the Guthrie Medal and Prize in 1994 and the David Bates Prize in 2000. He is a Fellow of the Royal Society.

Denise Caldwell   Chapter E.61

National Science Foundation
Physics Division
Arlington, VA, USA
dcaldwel@nsf.gov

Dr. Caldwell is the Program Director for the Atomic, Molecular, Optical, and Plasma Physics program at the National Science Foundation. She was awarded her Ph.D. by Columbia University in 1976. She then held a postdoc at the University of Bielefeld and a junior faculty position at Yale University. In 1985 she joined the faculty at the University of Central Florida, where she maintained a research program on atomic photoionization using synchrotron radiation. In 1998 she left full-time academia to become a permanent staff member of the NSF. She is a Fellow of the American Physical Society.

Mark M. Cassar

University of Windsor
Department of Physics
Windsor, ON, Canada
cassar@uwindsor.ca

Chapter B.13

Mark M. Cassar received his Ph.D. from the University of Windsor, Canada in 2003. His research focuses on high-precision theoretical calculations for the energy level structure of three-body atomic and molecular systems.

Kelly Chance

Harvard–Smithsonian Center for Astrophysics
Cambridge, MA, USA
kchance@cfa.harvard.edu

Chapter G.85

Dr. Chance heads the Atomic and Molecular Physics Division of the Harvard-Smithsonian Center for Astrophysics. His current research applies molecular spectroscopy, structure and dynamics to studies of planetary atmospheres, with emphasis on satellite-based measurements of Earth's ozone layer composition and lower atmospheric pollution. Recent accomplishments include global measurements of tropospheric ozone, volatile organic compounds, and nitrogen oxides.

Raymond Y. Chiao

366 Leconte Hall
U.C. Berkeley
Berkeley, CA, USA
chiao@physics.berkeley.edu

Chapter F.80

Professor Chiao was awarded his Ph.D. by MIT in 1965. He has been Professor of Physics at Berkeley since 1977. His research interests are: Nonlinear and quantum optics; low temperature physics as applied to astrophysics; the relationship between general relativity and macroscopic quantum matter. He is writing a book with J. C. Garrison on Quantum Optics.

James S. Cohen

Los Alamos National Laboratory
Atomic and Optical Theory
Los Alamos, NM, USA
cohen@lanl.gov

Chapter G.90

Dr. Cohen is Group Leader of the Atomic and Optical Theory Group in the Theoretical Division of Los Alamos National Laboratory and a Fellow of the American Physical Society. He received a Ph.D. in Physics from Rice University in 1973. His general area of research is theoretical atomic and molecular physics, with special interest in exotic muonic and antiprotonic species.

Bernd Crasemann

University of Oregon
Department of Physics
Eugene, OR, USA
berndc@uoregon.edu

Chapter E.62

Bernd Crasemann is Professor Emeritus of Physics in the University of Oregon and Editor of Physical Review, Atomic, Molecular, and Optical Physics since 1993. He received his early education in Chile and a Ph.D. from the University of California at Berkeley. His work is in experimental and theoretical atomic inner-shell physics, particularly as explored with synchrotron radiation.

David R. Crosley

SRI International
Molecular Physics Laboratory
Menlo Park, CA, USA
david.crosley@sri.com

Chapter G.88

For most of his career, David R. Crosley has developed and used laser-induced fluorescence to study small free radicals. This research includes fundamental spectroscopic and energy transfer studies, as well as applications to combustion, atmospheric chemistry,and environmental monitoring. Notable among these are studies of OH, NH, and CH. He is a Fellow of the APS and AAAS.

Derrick Crothers

Queen's University Belfast
Department of Applied Mathematics and Theoretical Physics
Belfast, Northern Ireland, UK
d.crothers@qub.ac.uk

Chapter D.52

Derrick Crothers is Professor of Theoretical Physics (Personal chair). He researches in atomic, molecular, optical, and condensed matter physics. Topics include heavy-particle collisions, threshold phenomena, dielectrics and ferromagnetics. He was awarded an Honorary Professorship in Physics by St Petersburg State University in 2003.

Authors

Lorenzo J. Curtis

University of Toledo
Department of Physics and Astronomy
Toledo, OH, USA
ljc@physics.utoledo.edu

Chapter B.17

Lorenzo J. Curtis is a Distinguished University Professor of Physics at the University of Toledo. He received his Ph.D. from the University of Michigan in 1963 and was awarded the degree Philosophiae Doctorem Honoris Causa by the University of Lund in 1999. His research involves time-resolved atomic spectroscopy and the structure of highly ionized atoms. He is the author of over 200 scientific articles and a textbook on atomic structure,. He is an editor of Physica Scripta and a Member of the Editorial Board of Physical Review A.

Gordon W. F. Drake

University of Windsor
Department of Physics
Windsor, ON, Canada
gdrake@uwindsor.ca

Chapters 1, B.11

Dr. Gordon W.F. Drake is a Professor of Physics and Department Head at the University of Windsor, Canada. He received his Ph.D. degree from York University in Toronto. His research on high precision calculations and QED theory for helium and other few-body atomic systems has resulted in over 150 refereed journal articles, and numerous other review articles and book chapters. He is a Fellow of the American Physical Society and the Royal Society of Canada, and has been awarded numerous prizes and distinctions for his research. He is currently the Editor of the Canadian Journal of Physics, and an Associate Editor for Physical Review A, as well as Editor of the current volume, and Co-Editor-in-Chief of the Springer Series on Atomic, Optical, and Plasma Physics. He has served as President of the Canadian Association of Physicists, and as Chair of the Division of Atomic, Molecular, and Optical Physics of the American Physical Society.

Joseph H. Eberly

University of Rochester
Department of Physics and Astronomy
and Institute of Optics
Rochester, NY, USA
eberly@pas.rochester.edu

Chapter F.73

Joseph H. Eberly is Andrew Carnegie Professor of Physics and Professor of Optics at the University of Rochester. He earned his Ph.D. from Stanford University. He held the APS Chair of the Division of Laser Science from 1996–97 and was Divisional Councilor from 2003–2005. Eberly is OSA Vice President and its President in 2007. He is Foreign Member of the Academy of Science of Poland and received numerous awards such as the Charles Hard Townes Award in 1994, the Smoluchowski Medal in 1987, and the Humboldt Preis in 1984. He has published more than 300 research and review papers and several books in the areas of quantum optics, cavity QED and photon–atom interactions, evolution of coherence and quantum entanglement, high-field atomic physics, and nonlinear propagation of short optical pulses.

Guy T. Emery

Bowdoin College
Department of Physics
Brunswick, ME, USA
gemery@bowdoin.edu

Chapter B.16

Guy Emery was on the Brookhaven National Laboratory Staff, and taught physics at Indiana University and later Bowdoin College (Brunswick, ME). He was a visiting scientist at the Universities of Groningen and Osaka. His research has been in nuclear structure and reactions, the intersections of nuclear physics with atomic physics and particle physics, and in the history of physics.

Volker Engel

Universität Würzburg
Institut für Physikalische Chemie
Würzburg, Germany
voen@phys–chemie.uni–wuerzburg.de

Chapter C.35

Volker Engel studied Physics at the University of Göttingen and worked as a post-doctoral associate at the University of California, Santa Barbara. After his Habilitation in Physics (1993, University of Freiburg) he was appointed Professor in 1994 at the University of Würzburg. His research interests are in the time-dependent quantum theory of atomic and molecular dynamics in laser fields.

James M. Farrar   Chapter E.67

University of Rochester
Department of Chemistry
Rochester, NY, USA
farrar@chem.rochester.edu

James M. Farrar received his Ph.D. degree at the University of Chicago in 1974 working under the direction of Professor Yuan-Tseh Lee. Prior to joining the faculty at the University of Rochester, he was a postdoctoral fellow in the laboratory of Professor Bruce H. Mahan at the University of California at Berkeley. He has had a long-term interest in molecular beam studies of the dynamics of chemical reactions, and his current interests include low energy ion-molecule collisions and electronic spectroscopy of size-selected clusters ions. He is a Fellow of the American Physical Society.

Paul D. Feldman   Chapter G.83

The Johns Hopkins University
Department of Physics and Astronomy
Baltimore, MD, USA
pdf@pha.jhu.edu
Dr. Feldman is Professor of Physics and Astronomy at the Johns Hopkins University where he has been since 1967. He received his Ph.D. in physics from Columbia University in 1964. His recent work has been in space ultraviolet astronomy and spectroscopy with a focus on the study of the atmospheres of comets and planets and of the Earth's upper atmosphere.

Victor Flambaum   Chapter B.30

University of New South Wales
Department of Physics
Sydney, Australia
v.flambaum@unsw.edu.au

Dr. Victor Flambaum is a Professor of Physics and holds a Chair of Theoretical Physics. Ph.D., DSc. from the Institute of Nuclear Physics, Novosibirsk, Russia. He has about 200 publications in atomic, nuclear, particle, solid state, statistical physics, and astrophysics including works on violation of fundamental symmetries (parity, time reversal), test of unification theories, temporal and spatial variation of fundamental constants from Big Bang to present, many-body theory and high-precision atomic calculations, as well as statistical theory of finite chaotic Fermi systems and enhancement of weak interactions, high-temperature superconductivity, and conductance quantization.

David R. Flower   Chapter C.36

University of Durham
Department of Physics
Durham, United Kingdom
david.flower@durham.ac.uk

Professor Flower teaches at the University of Durham (UK). He was awarded his Ph.D. by the University of London in 1969. After working at the Observatoire de Paris (Meudon, France) and at the ETH (Zuerich, Switzerland), he joined the Physics Department of the University of Durham in 1978. He has been Professor of Physics since 1994. His research interests are in atomic and molecular physics related to astrophysics. He is currently preparing the second edition of his book on "Molecular Collisions in the Interstellar Medium".

A. Lewis Ford   Chapter D.50

Texas A&M University
Department of Physics
College Station, TX, USA
ford@physics.tamu.edu

Dr. Ford's research interests lie in theoretical atomic and molecular physics: inner-shell excitation, ionization, charge transfer, and electronic properties of diatomic molecules. Professor Ford joined the Texas A&M faculty in 1973. After receiving his B.A. degree from Rice University, he completed his Ph.D. at the University of Texas at Austin in 1972 and did post-doctoral work at Harvard. Professor Ford is a member of the American Physical Society, Division of Electron, Atomic, and Optical Physics.

Authors

Jane L. Fox   Chapter G.84

Wright State University
Department of Physics
Dayton, OH, USA
jane.fox@wright.edu

Jane Fox received her Ph.D. from Harvard University in Chemical Physics and has held positions at the State University of New York at Stony Brook, and the Harvard/Smithsonian Astrophysical Observatory. She has been elected a Fellow of the American Geophysical Union. Her research has focused on the chemistry, luminosity, heating of the thermospheres/ionospheres of the planets, and their evolution.

Matthias Freyberger   Chapter F.78

Universität Ulm
Abteilung für Quantenphysik
Ulm, Germany
matthias.freyberger@uni-ulm.de

Dr. Matthias Freyberger is extraordinary Professor at the Department of Quantum Physics at the University of Ulm, Germany. His research interests are in quantum optics, atom optics, quantum estimation theory, and the foundations of quantum mechanics.

Thomas F. Gallagher   Chapter B.14

University of Virginia
Department of Physics
Charlottesville, VA, USA
tfg@virginia.edu

Thomas F. Gallagher received his Ph.D. in physics in 1971 from Harvard University and is now the Jesse W. Beams Professor of Physics at the University of Virginia. His research is focused on the use of Rydberg atoms to realize novel physical systems.

Muriel Gargaud   Chapter D.51

Observatoire Aquitain des Sciences de l'Univers
Floirac, France
gargaud@obs.u-bordeaux1.fr

Muriel Gargaud is an astrophysicist at the "Observatoire Aquitain des Sciences de l'Univers" in Bordeaux, France. She studied for 2O years the physico-chemistry of the interstellar medium, her current research is now astrobiology. Astrobiolgy is an interdisciplinary research field (astronomy, geology, chemistry, biology) looking for the origins of life, its evolution and its development on Earth but also in and beyond the Solar System. She is the main scientific editor of "Lectures in Astrobiology" by Springer, Heidelberg 2005.

Alan Garscadden   Chapter G.87

Airforce Research Laboratory
Area B
Wright Patterson Air Force Base, OH, USA
alan.garscadden@wpafb.af.mil

Alan Garscadden received his B.Sc. and Ph.D. from Queen's University, Belfast, Northern Ireland. He is the chief Scientist, Propulsion Directorate, Air Force Research Laboratory. Wright-Patterson AFB, Ohio and Edwards AFB, California. Alan also performs basic and applied research in non-equilibrium plasmas and energized gas flows, lasers, mass spectroscopy measurements, and electron collision cross sections. He is a Fellow of the APS, IEEE, AIAA and of the UK Institute of Physics.

John Glass   Chapter D.52

British Telecommunications
Solution Design
Belfast, Northern Ireland, UK
john.glass@bt.com

John Glass earned his Ph.D. on Relativistic Ion-Atom Collisions from The Queen's University of Belfast in 1995. His Ph.D. focussed on distorted wave approximations in electron capture, in particular, the first fully symmetrical CDW solution via the Sommerfeld-Maue approximation. Dr. Glass now works in large-scale Business Support Systems, Solutions Design for British Telecommunications plc.

S. Pedro Goldman

The University of Western Ontario
Department of Physics & Astronomy
London, ON, Canada
goldman@uwo.ca

Chapter B.13

Professor Pedro Goldman completed a Ph.D. in Relativistic Atomic Physics at the University of Windsor. His work in atomic physics includes pioneering work on relativistic variational basis sets, relativistic calculations for many-electron atoms and diatomic molecules, accurate calculations for atoms in strong magnetic fields and accurate calculations of QED energy corrections and of the energy levels of Helium. Presently his research is directed to the optimization of the radiation therapy of tumours. He has as well received numerous teaching awards.

Ian P. Grant

University of Oxford
Mathematical Institute
Oxford, UK
ipg@maths.ox.ac.uk

Chapter B.22

Ian Grant is Emeritus Professor of Mathematical Physics, University of Oxford and a Fellow of the Royal Society. He graduated from Oxford with a degree in Mathematics and obtained his D. Phil. in Theoretical Physics in 1954. His interest in relativistic electronic structure of atoms arose whilst he was working for the UK Atomic Energy Authority at Aldermaston from 1957 to 1964 and the field has been a major component of his research ever since. He returned to Oxford to a research post in 1964 and was a full-time member of academic staff from 1969 until his retirement in 1998. He is the author of more than 220 research papers, many of them on relativistic quantum theory applied to atomic and molecular structure and processes.

William G. Harter
University of Arkansas
Department of Physics
Fayetteville, AR, USA
wharter@uark.edu

Chapter C.32

Professor Harter's research centers on theory of spectroscopy and what it reveals about quantum phenomena and symmetry principles of structure and dynamics. Current study focuses on how wave mechanics of light relates to matter waves and their relativistic symmetry ranging from intrinsic frames of floppy molecules to manifold dynamics of astrophysical objects. A strong educational effort is being developed to make modern theory more accessible. He is a Fellow of American Physical Society (DAMOP).

Carsten Henkel

Universität Potsdam
Institut für Physik
Potsdam, Germany
*carsten.henkel
@quantum.physik.uni-potsdam.de*

Chapter F.77

Carsten Henkel is Docteur en Sciences from the Université Paris-Sud Orsay. He habilitated in 2004 at Potsdam University where he is currently a Privatdozent. His research interests are in atom optics and nano optics. He is involved in several European projects on physical implementations of quantum information processing.

Eric Herbst

The Ohio State University
Departments of Physics
Columbus, OH, USA
herbst@mps.ohio-state.edu

Chapter C.37

Dr. Eric Herbst is Distinguished University Professor of Physics, Astronomy, and Chemistry at The Ohio State University. Herbst is a Fellow of both the American Physical Society and the Royal Society of Chemistry (UK). His specialty is the chemistry of molecules in interstellar clouds, which are large accumulations of gas and dust particles in our Galaxy and others in which star and planetary formation occur.

Robert N. Hill

Saint Paul, MN, USA
rnhill@fishnet.com

Chapter A.9

Professor Robert Nyden Hill received his Ph.D. from Yale University in 1962. In 1964, after postdoctoral fellowships at Princeton and Yale, he joined the faculty of the University of Delaware Physics Department. He retired in 1997, and moved to Saint Paul, Minnesota. He has published papers in relativistic dynamics, statistical mechanics, mathematical physics, and atomic and molecular physics.

Authors

David L. Huestis Chapter C.33

SRI International
Molecular Physics Laboratory
Menlo Park, CA, USA
david.huestis@sri.com

David L. Huestis received his Ph.D. in Chemistry from the California Institute of Technology in 1973. He is a Fellow of the American Physical Society. His research activities include a wide range of experimental and theoretical investigations of fundamental kinetic and optical processes involving atoms, small molecules, liquids, and solids. Two major application areas have been chemical kinetics and optical physics of high-power visible and ultraviolet gas lasers and the optical emissions of terrestrial and planetary atmospheres.

Mitio Inokuti Chapter G.92

Argonne National Laboratory
Physics Division
Argonne, IL, USA
inokuti@anl.gov

Dr. Mitio Inokuti earned his Ph.D. in Applied Physics from the University of Tokyo in 1962. From 1973–1995 he was Senior Physicist at Argonne National Laboratory. He is a Fellow of the American Physical Society and a member of the Radiation Research Society. Since 1985 he is a member of the International Commission on Radiation Units and Measurements, and since 1988 a member of the Editorial Board for Advances in Atomic, Molecular, and Optical Physics. He also is Associate Editor of the Journal of Applied Physics. His research interests focus on theoretical research in radiation physics and chemistry, and in atomic and molecular physics.

Juha Javanainen Chapters F.75, F.76

University of Connecticut
Department of Physics Unit 3046
Storrs, CT, USA
jj@phys.uconn.edu

Juha Javanainen is Professor of Physics at the University of Connecticut. He has worked on a number of topics in theoretical quantum optics, and currently concentrates on quantum degenerate gases.

Erik T. Jensen Chapter G.89

University of Northern British Columbia
Department of Physics
Prince George, BC, Canada
ejensen@unbc.ca

Erik Jensen is an Associate Professor of Physics at the University of Northern British Columbia (Canada). He obtained his Ph.D. in the Surface Physics Group at Cambridge University in 1990 and did post-Doctoral work with Prof. John Polanyi at the University of Toronto. His research interests are in low-energy electron and photon initiated dynamics for molecules at surfaces.

Brian R. Judd Chapters A.3, A.6

The Johns Hopkins University
Department of Physics and Astronomy
Baltimore, MD, USA
juddbr@pha.jhu.edu

Brian Judd has had a life-long interest in applying group theory to the spectroscopic properties of the rare earths. He held appointments at Oxford, Chicago, Paris and Berkeley before joining the Physics Department of the Johns Hopkins University in 1966. He received the Spedding Award for Rare-Earth Research in 1988 and is an Honorary Fellow of Brasenose College, Oxford.

Alexander A. Kachanov Chapter C.43

Research and Development
Picarro, Inc.
Sunnyvale, CA, USA
akachanov@picarro.com

Alexander Kachanov received the M.Sc. degree in physics from Moscow Institute of Physics and Technology in 1976, and the Ph.D. degree in physics from the Institute of Spectroscopy of the Russian Academy of Sciences in 1987. In 2001 he joined Picarro, Inc., where his research interests focus on ultra-sensitive gas detection and development of novel laser sources.

Savely G. Karshenboim

Chapter B.30

D.I.Mendeleev Institute for Metrology (VNIIM)
Quantum Metrology Department
St. Petersburg, Russia
sek@mpq.mpg.de

Dr. Savely G.Karshenboim was graduated in 1983 from St. Petersburg (then Leningrad) State University, Russia where he also received his Ph.D. in 1992 and habilitatetd in 1999. He has been a member of D.I. Mendeleev Institute for Metrology since 1983 and is at present a head of Laboratory for Precision Physics and Metrology of simple atomic systems. Since 1994 until now he has enjoyed numerous visiting opportunities at Max-Planck-Institut für Quantenoptik. He is a member of the CODATA task group on fundamental constants and SUNAMCO commission of IUPAP. SUNAMCO is a commission on Symbols, Units, Nomenclature, Atomic Masses and Fundamental Constants. Dr. Karshenboim's scientific interests include precision physics of simple atoms, quantum electrodynamics (QED), determination of fundamental constants and search for their variations.

Kate P. Kirby

Chapter G.85

Harvard–Smithsonian Center for Astrophysics
Cambridge, MA, USA
kkirby@cfa.havard.edu

Kate Kirby has a Ph.D. in Chemical Physics from the University of Chicago, and is currently director of the Institute for Theoretical Atomic, Molecular, and Optical Physics. Her research interests center on theoretical studies of ultracold molecule formation and atomic and molecular structure and processes which are of interest to astronomy and atmospheric physics. Such processes include: photoionization, photodissociation, radiative association, charge transfer, and line-broadening.

Sir Peter L. Knight

Chapter F.81

Imperial College London
Department of Physics Blackett Laboratory
London, UK
p.knight@imperial.ac.uk

Sir Peter Knight is Head of Physics at Imperial College. He is Chief Scientific Advisor to the National Physical Laboratory and past President of the Optical Society of America. He is a Fellow of the Royal Society and was knighted in 2005. He researches in strong field physics and quantum information and edits the Journal of Modern optics and contemporary physics.

Manfred O. Krause

Chapter E.61

Oak Ridge National Laboratory
Oak Ridge, TN, USA
mok@ornl.gov

Dr. Krause was a Senior Scientist at the Oak Ridge National Laboratory working primarily in the field of photoelectron spectrometry of atoms with the use of synchrotron radiation. He received his Dr. rer. nat. in physics at the Technische Universität and the Max Planck Institut für Metallforschung in Stuttgart in 1954. He joined the Oak Ridge National Laboratory in 1963 and retired in 1995. He is a Fellow of the American Physical Society, and was a Professeur d'Echange at the University of Paris in 1975 and an Alexander von Humboldt awardee at the University of Freiburg in 1976.

Paul G. Kwiat

Chapter F.80

University of Illinois at Urbana–Champaign
Department of Physics
Urbana, IL, USA
kwiat@uiuc.edu

Paul G. Kwiat is the Bardeen Chair in Physics, at the University of Illinois, in Urbana-Champaign. A Fellow of the American Physical Society and the Optical Society of America, he studies the phenomena of entanglement, quantum interrogation, quantum erasure, and optical implementations of quantum information protocols. He can't resist a good swing dance.

Authors

Maciej Lewenstein   Chapter F.74

ICFO−Institut de Ciéncies Fotóniques
Barcelona, Spain
maciej.lewenstein@icfo.es

Born in Warsaw Poland, Dr. Maciej Lewenstein worked for many years in the Center for Theoretical Physics in Warsaw. He graduated from the University of Essen, worked for several years at CEA, and the University of Hannover. Currently he leads the theoretical quantum optics group at ICFO, Barcelona, Spain. His interests include physics of ultracold gases, quantum information, and the physics of matter in strong fields. He is a Fellow of APS.

James D. Louck   Chapter A.2

Los Alamos National Laboratory
Retired Laboratory Fellow
Los Alamos, NM, USA
jimlouck@aol.com

James Louck is a Los Alamos National Laboratory Retired Fellow. He earned his Ph.D. in molecular physics from The Ohio State University in 1958, and is the co-author of three books. Except for the years 1960 - 1963 at Auburn University, his career was in the Theoretical Division at Los Alamos developing symmetry methods for physical systems. His current research is in the inter-relations between symmetry and combinatorics.

Joseph H. Macek   Chapter D.53

University of Tennessee and Oak Ridge National Laboratory
Department of Physics and Astronomy
Knoxville, TN, USA
jmacek@utk.edu

Dr. Joseph Macek is a Distinguished Professor at the University of Tennessee and a Distinguished Scientist at Oak Ridge National Laboratory. His currrent research concentrates on thetheory of atomic collisions. He has been assigned Co-Chair of the local committee for the annual meeting of the Division of Atomic and Molecular Physics of the American Physical Society, Knoxville, TN 2006.

Mary L. Mandich   Chapter C.39

Lucent Technologies Inc.
Bell Laboratories
Murray Hill, NJ, USA
mandich@lucent.com

Mary Mandich is a Technical Manager and Distinguished Member of Technical Staff at Bell Laboratories and currently leads research in high speed backplanes and optical remoting for next generation telecommunication networks. She obtained her Ph.D. degree in Physical Chemistry at Columbia University. She holds 6 U.S. Patents and has authored 2 book chapters and more than 55 scientific publications in chemistry, physics, and materials science.

Steven T. Manson   Chapter D.53

Georgia State University
Department of Physics and Astronomy
Atlanta, GA, USA
smanson@gsu.edu

Professor Manson is on the faculty at Georgia State University. He received the Ph.D. from Columbia University in 1966, and did a two-year post-doc at the NBS (now NIST) working with Ugo Fano and John Cooper. He started as a faculty member at Georgia State University in 1968 and has been Regents Professor since 1984. His research has been primarily in the area of theoretical studies of ionization of atoms and ions by charged particles and photons. He is a Fellow of the American Physical Society.

William C. Martin   Chapter B.10

National Institute of Standards and Technology
Atomic Physics Division
Gaithersburg, MD, USA
wmartin@nist.gov

Dr. Martin's research has included the measurement and energy-level analysis of atomic spectra. He has also published a number of critical compilations of atomic spectroscopic data, including a large volume for the rare-earth elements. In his current position as Scientist Emeritus at NIST, Dr. Martin is continuing work on internet-accessible atomic spectra databases.

Jim F. McCann

Queen's University Belfast
Dept. of Applied Mathematics and
Theoretical Physics
Belfast, Northern Ireland, UK
j.f.mccann@qub.ac.uk

Chapter D.52

Jim McCann was a Ph.D. student of Prof. Derrick Crothers at Queen's University, Belfast. He is currently a Reader in Theoretical Physics at Queen's and works in the field of Quantum Optics and Quantum Information Processing.

Ronald McCarroll

Université Pierre et Marie Curie
Laboratoire de Chimie Physique
Paris Cedex 05, France
mccarrol@ccr.jussieu.fr

Chapter D.51

Ronald McCarroll is a Professor of Physics at the Université Pierre et Marie Curie in Paris. He obtained his Ph.D. degree in Theoretical Physics at Queen's University, Belfast. After a post-doctoral fellowship at the National Physics Laboratory, Teddington and a Lectureship at Queen's University, Belfast he was appointed as a Directeur de Recherche au CNRS at the Observatoire de Pari, Meudon. Later, he moved to the Université de Bordeaux I as Professor in Astrophysics and finally to Paris as Professor in Physics at the Univerité Pierre et Marie Curie. He has worked in the field atomic and molecular photodynamics, particularly in view of their application to astrophysics and the physics of fusion plasmas. He is the author of more then 130 papers in refereed journals and contributed more than 20 specialised reviews to books and other specialised publications.

Fiona McCausland

Northern Ireland Civil Service
Department of Enterprise Trade and
Investment
Belfast, Northern Ireland, UK
fiona.mccausland@detini.gov.uk

Chapter D.52

Dr. Fiona McCausland gained her Ph.D. in Theoretical Physics in 1995 from the Queen's University of Belfast. Following a year spent as a Post Doctoral Research Assistant at the University, she joined the Northern Ireland Civil Service in September 1996. She currently holds the position of Project Manager in the Department of Enterprise, Trade and Investment.

William J. McConkey

University of Windsor
Department of Physics
Windsor, ON, Canada
mcconk@uwindsor.ca

Chapter E.63

Dr. Bill McConkey is a physicist with an extensive background in the measurement of absolute cross section data for the atomic, molecular, and optical physics community. His laboratory is recognised as a world leader in electron collisions research. He has been awarded the Gold Medal of the Canadian Association of Physicists (1999) and the Allis Prize of the American Physical Society (2004) for his work.

Robert P. McEachran

Australian National University
Atomic and Molecular Physics
Laboratories Research School of Physical
Sciences and Engineering
Canberra, Australia
robert.mceachran@anu.edu.au

Chapter D.48

Professor McEachran received his Ph.D. from the University of Western Ontario, Canada and then spent two years at the University College London (England) before joining York University in Toronto in 1964. In 1997 he accepted an Adjunct Professorship at the Australian National University. His current research interests are the theoretical treatment of electron/positron scattering from heavy atoms within a relativistic framework.

James H. McGuire

Tulane University
Department of Physics
New Orleans, LA, USA
mcguire@tulane.edu

Chapter D.57

Dr. McGuire is Murchison Mallory Chair and department chair at Tulane University. He is a past Chair of the Division of Atomic, Molecular and Optical Physics (DAMOP) of the American Physical Society. His research interests are in electron correlation dynamics. entanglement, complexity and correlation, and quantum time.

Authors

Authors

Dieter Meschede   Chapter F.79

Rheinische
Friedrich–Wilhelms–Universität Bonn
Institut für Angewandte Physik
Bonn, Germany
meschede@iap.uni-bonn.de

Professor Dieter Meschede teaches at the Institute for Applied Physics in Bonn. After his studies in Hanover and Cologne and having been awarded his Dr. rer. nat in Munich in 1984, he first worked at Yale University. Then he became senior scientist at the MPI for Quantum Optics, Garching. He has been Professor of Physics since 1990, first in Hanover, since 1994 in Bonn. Professor Meschede is author of "Optics, Light, and Laser", some 90 refereed articles, and, since 2001, editor of the "Gerthsen"textbook.

Pierre Meystre   Chapter F.68

University of Arizona
Department of Physics
Tucson, AZ, USA
meystre@physics.arizona

Pierre Meystre's research ranges from laser theory to cavity QED and to the physics of quantum-degenerate atomic and molecular systems. With Murray Sargent, he coauthored the textbook "Elements of Quantum Optics,"and he recently published the monograph "Atom Optics", both with Springer-erlag. He has been awarded the Senior Scientist Research Prize of the Humboldt Foundation and the R.W. Wood Prize of the Optical Society of America. He is currently a Regents Professor and the Head of the Physics Department at The University of Arizona.

Peter W. Milonni   Chapter F.70

Los Alamos, NM, USA
pwm@lanl.gov

Peter Milonni is a Laboratory Fellow (retired) at Los Alamos National Laboratory. His main interests are in theoretical physics, especially quantum optics and electrodynamics. He is an author of several books including Lasers (with J. H. Eberly), The Quantum Vacuum, and Fast Light, Slow Light, and Left-Handed Light. Previously he held positions with the U. S. Air Force, the Perkin-Elmer Corporation, and the University of Arkansas.

Peter J. Mohr   Chapter B.28

National Institute of Standards and
Technology
Atomic Physics Division
Gaithersburg, MD, USA
mohr@nist.gov

Dr. Peter Mohr received his Ph.D. from the University of California at Berkeley in 1973 and spent some years at the Lawrence Berkeley Laboratory (1973–1978), at Yale University (1978–1985), at the National Science Foundation (1985–1987), and at the National Bureau of Standards/ National Institute of Standards and Technology from 1987 until now. He is a Fellow of the American Physical Society, and received the Alexander von Humboldt Senior Research Award in 1995. He held the Chair of the CODATA Task Group on Fundamental Constants from 1999 to 2006 and was Chair of the Precision Measurement and Fundamental Constants Topical Group of the American Physical Society from 2000–2001.

John D. Morgan III   Chapters B.20, G.90

University of Delaware
Department of Physics and Astronomy
Newark, DE, USA
jdmorgan@udel.edu

Dr. Morgan is Associate Professor and obtained his B.S. from The George Washington University, his M.Sc. in Theoretical Chemistry from Oxford University, and his Ph.D. in Chemistry from Berkeley. He has served on the editorial boards of the Journal of Mathematical Physics and the International Journal of Quantum Chemistry. His wide-ranging interests include the application of sophisticated mathematical techniques to assist the accurate calculation of properties of atoms and molecules.

Michael S. Murillo

Los Alamos National Laboratory
Theoretical Division
Los Alamos, NM, USA
murillo@lanl.gov

Chapter G.86

Dr. Murillo received his Ph.D. in theoretical atomic and plasma physics from Rice University. He then received a Director's Postdoctoral Felloship at Los Alamos, where he has remained since. His current research interests lie in the areas of dense and strongly coupled plasmas, including laser-produced plasmas, dusty plasmas, astrophysical plasmas, and ultracold plasmas. He applies both analytical and molecular dynamics methods to these systems.

Evgueni E. Nikitin

Technion–Israel Institute of Technology
Department of Chemistry
Haifa, Israel
nikitin@techunix.technion.ac.il

Chapter D.49

Professor, Nikitin Evgueni is a researcher, head of the research group, and Professor of Chemical Physics at the Institute of Chemical Physics, Moscow, since 1958. He is also Professor of Physical Chemistry, Technion, Haifa, since 1991. He is a member of the Deutsche Akademie der Naturforscher Leopoldina, the European Academy of Arts, Sciences and Humanities, and the International Academy of Quantum Molecular Sciences. His research concentrates on the theory of inelastic and reactive scattering, theory of nonadiabatic processes, statistical theory of chemical reactions, and atom-molecule processes at low energies. He authored 15 books and about 300 papers. Research awards: Alexander von Humboldt Award, Gauss Professorship, and Barecha Fellowship

Robert F. O'Connell

Louisiana State University
Department of Physics and Astronomy
Baton Rouge, LA, USA
oconnell@phys.lsu.edu

Chapter F.78

Professor O'Connell earned his Ph.D. in 1962 from the University of Notre Dame, Indiana. For many years , in collaboration with G. W. Ford , he has been studying dissipative and fluctuation phenomena in quantum mechanics and related applications. In addition, he is using the generalized quantum Langevin equation to explore recent topical questions in non-equilibrium statistical mechanics (particularly claims that the fundamental laws of thermodynamics may be violated in the quantum regime).

Francesca O'Rourke

Queen's University Belfast
Department of Applied Mathematics and
Theoretical Physics
Belfast, UK
s.orourke@qub.ac.uk

Chapter D.52

Dr. O'Rourke obtained her Ph.D. in Ion-Atom Collisions from Queens University, Belfast, in 1991. She now lectures in Applied Mathematics and Theoretical Physics at Queens University, Belfast. Her current research interests include heavy particle collisions in atomic and molecular physics and more recently mathematical modelling in Biomedicine.

Ronald E. Olson

University of Missouri–Rolla
Physics Department
Rolla, MO, USA
olson@umr.edu

Chapter D.58

Ronald E. Olson, Curators' Professor of Physics earned his Ph.D. from Purdue University in 1967. He is a Fellow of the American Physics Society and a Fulbright Fellow to France. He was received the Humboldt Senior Prize Award, the University of Missouri system-wide Presidential Award for Research and Creativity. His research interests concentrate on theory of elastic and inelastic total and differential scattering cross sections: atom–atom, ion–atom, and ion–ion. Studies of multiply charged ion–atom collisions, Rydberg atom collisions, negative ion detachment mechanisms, and Penning and associative ionization.

Barbara A. Paldus   Chapter C.43

Skymoon Ventures
Palo Alto, CA, USA
bpaldus@skymoonventures.com

Dr. Barbara Paldus received her Ph.D. in electrical engineering from Stanford University. She is a partner at Skymoon Ventures, where she works with early stage photonics companies. Previously, she was CTO at Picarro, which she founded in 1998. She has received numerous research awards, most recently the Adolph Lomb Prize (2001) by the OSA for her work in cavity ring-down spectroscopy.

Josef Paldus   Chapters A.4, A.5

University of Waterloo
Department of Applied Mathematics
Waterloo, ON, Canada
paldus@scienide.uwaterloo.ca

Josef Paldus, FRSC, is a Distinguished Professor Emeritus in the Department of Applied Mathematics, Department of Chemistry, and Guelph-Waterloo Center for Graduate Work in Chemistry – Waterloo Campus, at the University of Waterloo, Waterloo, ON Canada. He is also an Adjunct Professor in the Department of Chemistry of the University of Florida in Gainesville, FL, USA. He received his Ph.D. degree from the Czechoslovak Academy of Sciences and his RNDr. and Dr.Sc. degrees from the Faculty of Mathematics and Physics of the Charles University in Prague, Czech Republic. His research interests are in the methodology of quantum chemistry, the many-electron correlation problem, and the electronic structure of molecular systems in general. On these topics he published about 300 papers, reviews, and monograph chapters. He is a member of several professional societies and editorial boards, and received various awards and international fellowships, notably a Killam Fellowship, Institute for Advanced Study in Berlin Fellowship, Alexander von Humboldt Senior Scientist Award, and most recently a Gold Medal of the Charles University. He is also a Fellow of the Royal Society of Canada and of the Fields Institute for Research in Mathematical Sciences.

Ruth T. Pedlow   Chapter D.52

Queen's University Belfast
Department of Applied Mathematics
and Theoretical Physics
Belfast, UK
r.pedlow@qub.ac.uk

Ruth Pedlow is working towards completion of her Ph.D. in heavy particle collisions in atomic and molecular physics at Queens University of Belfast.

David J. Pegg   Chapter E.60

University of Tennessee
Department of Physics
Knoxville, TN, USA
djpegg@utk.edu

Currently I am investigating the structure and dynamics of atomic and molecular negative ions by studying how they interact with photons and electrons. The threshold behaviour and resonance structure in detachment cross sections are used to measure correlation-sensitive parameters. Experiments on photo detachment involve the use of lasers or synchrotron radiation. Such measurements, for example, lead to information on the process of multiple electron detachment induced by the absorption of a single photon. Electron-impact detachment and dissociation processes are studied using a magnetic storage ring. These studies, for example, yield information on the production and decay of doubly negative charged molecular and cluster negative ions.

Ekkehard Peik   Chapter B.30

Physikalisch–Technische Bundesanstalt
Braunschweig, Germany
ekkehard.peik@ptb.de

Dr. Ekkehard Peik received his doctorate and the habilitation in physics at the University of Munich. His research interests are in the fields of laser-cooling and trapping of atoms and ions, precision laser spectroscopy and the application to optical time and frequency metrology and tests of fundamental physics. He is now head of the group 'Optical Clocks' at PTB and also a lecturer at the University of Hannover.

Ronald Phaneuf

University of Nevada
Department of Physics
Reno, NV, USA
phaneuf@unr.edu

Chapter E.64

Professor Phaneuf received a Ph.D. in atomic physics from the University of Windsor in 1973 and has since been engaged in experimental research on interactions of ions with electrons, atoms, molecules and photons using merged-beams and crossed-beams techniques. He was formerly at JILA and Oak Ridge National Laboratory. His current research emphasis is photon–ion interactions using synchrotron radiation.

Eric H. Pinnington

University of Alberta
Department of Physics
Edmonton, AB, Canada
pinning@phys.ualberta.ca

Chapter B.18

Eric Pinnington obtained his Ph.D. in Physics at Imperial College in 1962. Prior to joining the University of Alberta in 1965, he held an NRC postdoctoral fellowship at McMaster University in Hamilton, Ontario, and an Alexander von Humboldt Fellowship at the Max Planck Institute for Astrophysics in Munich. He was elected Fellow of the American Physical Society in 1995. He became Professor Emeritus of Physics in 1997.

Richard C. Powell

University of Arizona
Optical Sciences Center
Tuscon, AZ, USA
rcpowell@email.arizona.edu

Chapter F.71

Powell was educated in physics at the United States Naval Academy and Arizona State University. He has been a research scientist and professor at Air Force Cambridge Research Laboratories, Sandia National Laboratory, and Lawrence Livermore National Laboratory, Oklahoma State University and the University of Arizona. He has authored two textbooks and over 260 scientific papers in laser spectroscopy and solid-state laser development. Powell is an elected Fellow of both the American Physical Society and the Optical Society of America and has served a President of OSA. He has been elected to the Russian Academy of Engineering Science.

John F. Reading

Texas A&M University
Department of Physics
College Station, TX, USA
reading@physics.tamu.edu

Chapter D.50

Professor Reading earned his Ph.D. from the University of Birmingham, UK, in 1964. His current research interests are in theoretical calculations of cross sections for excitation and ionization following fast ion–atom collisions, the role of Pauli correlation in inner-shell vacancy production, and the role of dynamic electronic correlation. The latter especially in comparision of proton and anti-proton-induced single and double ionization of helium. He was named The Distinguished Texas Scientist of 1995 by the Texas Academy of Sciences and is Editor of the proceedings of several conferences on ion–atom collisions.

Jonathan R. Sapirstein

University of Notre Dame
Department of Physics
Notre Dame, IN, USA
jsapirst@nd.edu
Chapters B.27, B.29

Dr. Sapirstein earned his Ph.D. from Stanford University in 1979. He did postdoctoral work at UCLA and Cornell, and is at the University of Notre Dame, Indiana, since 1984. Current research interest in parity non-conservation in atoms, QED effects in highly charged many-electron ions, QED calculations in hydrogen, positronium, muonium, and helium. Dr. Sapirstein is a Fellow of the American Physical Society.

Stefan Scheel

Imperial College London
Blackett Laboratory
London, UK
s.scheel@imperial.ac.uk

Chapter F.81

Stefan Scheel received his Ph.D. (Dr. rer. nat.) from the Friedrich-Schiller-University Jena in 2001. He is an EPSRC Advanced Research Fellow in the Quantum Optics and Laser Science group in the Department of Physics at Imperial College London. His main research areas include QED in dielectric materials, quantum information processing using linear optics, and decoherence processes in atom chip experiments.

Authors

Axel Schenzle

Ludwig–Maximilians–Universität
Department für Physik
München, Germany
axel.schenzle@physik.uni-muenchen.de

Chapter F.79

Professor Schenzle has been working on various aspects of Theoretical Quantum Optics, the description of classical and quantummechanical noise in microscopic and mesoscopic systems, Bose–Einstein-Condensation, Quantum Information Theory, qunatum computing and decoherence. He has been Deputy Rector of the University of Munich and Dean for many years.

Reinhard Schinke

Max–Planck–Institut für Dynamik &
Selbstorganisation
Göttingen, Germany
rschink@gwdg.de

Chapter C.34

Dr. Reinhard Schinke received his Ph.D. from the Physics department of the University of Kaiserslautern in 1976. His main area of research is molecular dynamics, in particular energy transfer in atomic collisions, chemical reactions, and photodissociation. He is author of the book Photodissociation Dynamics. In recent years his interest shifted to dynamical investigations of recombination processes with particular emphasis on the ozone isotope effect.

Wolfgang P. Schleich

Universität Ulm
Abteilung für Quantenphysik
Ulm, Germany
wolfgang.schleich@uni-ulm.de

Chapter F.78

Prof. Schleich studied physics and mathematics at the Ludwig-Maximilians-Universität München where he obtained his Diplom, Doktor, and Habilitation. He worked at the University of New Mexico (Albuquerque) and University of Texas (Austin) and the Max-Planck Institut für Quantenoptik in Garching. Since 1991 he has held a chair of theoretical physics at the Universität Ulm. He has more than 200 publications, is a Fellow of APS, IOP and OSA and an elected member of the Heidelberger Akademie der Wissenschaften and the Leopoldina, and has received numerous awards including the Leibniz Prize and the Max-Planck Prize.

Michael Schulz

University of Missouri–Rolla
Physics Department
Rolla, MO, USA
schulz@umr.edu

Chapter E.65

Professor Dr. Michael Schulz received his Ph.D. in Physics from the University of Heidelberg in 1987 to become a Teaching Assistant from 1981–1987. After positions at Oak Ridge National Laboratory and Kansas State University he joined the University of Missouri-Rolla as Assistant Professor in 1990. Since 2002 he is Professor of Physics and since 2003 Director of the Laboratory for Atomic, Molecular, and Optical Research. His scientific concentrate on experimental atomic physics, dynamics of many-body problem, correlation effects, and three-dimensional imaging of atomic break-up processes. He is a Fellow of the American Physical Society and was Mercator Scholar 2004–2005.

Peter L. Smith

Harvard University
Harvard–Smithsonian Center for
Astrophysics
Cambridge, MA, USA
plsmith@cfa.havard.edu

Chapter C.44

Peter L. Smith received his Ph.D. degree in Physics from Caltech in 1972 and, after a year of teaching, came to and stayed at the Harvard-Smithsonian Center for Astrophysics. He is involved in measurements of fundamental atomic and molecular parameters at ultraviolet wavelengths for analysis of astronomical spectra, and design and calibration of instruments for ultraviolet spectroscopic and/or radiometric measurements, especially of the Sun, from earth-orbiting satellites.

Anthony F. Starace

The University of Nebraska
Department of Physics and Astronomy
Lincoln, NE, USA
astarace1@unl.edu

Chapter B.24

Dr. Starace earned his Ph.D. from the University of Chicago in 1971 and is George Holmes University Professor of Physics at the University of Nebraska since 2001. His primary research interests concern the interaction of intense laser light with atoms, especially single and multiphoton detachment and ionization processes. He is a Fellow of the American Physical Society and the American Association for the Advancement of Science, and is currently an Associate Editor of Reviews of Modern Physics.

Glenn Stark

Wellesley College
Department of Physics
Wellesley, MA, USA
gstark@wellesley.edu

Chapter C.44

Professor Stark's research interest is in the field of experimental molecular spectroscopy. His laboratory programs emphasize molecular transitions of interest to the astrophysics and aeronomy communities, primarily involving the measurement and interpretation of high-resolution absorption spectra of vacuum ultraviolet and extreme ultraviolet transitions. Related activities include Fourier transform spectroscopy of diatomic molecules, and laser spectroscopies of diatomics.

Allan Stauffer

Department of Physics and Astronomy
York University
Toronto, ON, Canada
stauffer@yorku.ca

Chapter D.48

Allan Stauffer has published numerous papers in the field of electron and positron scattering from atoms and simple molecules. In collaboration with numerous colleagues, he has been involved with extensive scattering calculations and developed methods to carry out these investigations and has worked closely with groups involved in measuring these processes.

Aephraim M. Steinberg

University of Toronto
Department of Physics
Toronto, ON, Canada
steinberg@physics.utoronto.ca

Chapter F.80

Aephraim Steinberg works on experimental quantum optics and laser cooling, with specific emphasis on foundational questions in quantum mechanics (esp. quantum measurement) and on quantum information. His obssession is with tunneling times; in 1994, he demonstrated (with Kwiat and Chiao) the superluminal tunneling of photons, and in 2005, he is starting an experiment to probe tunneling times for Bose-condensed atoms through optical barriers.

Stig Stenholm

Royal Institute of Technology
Physics Department
Stockholm, Sweden
stenholm@atom.kth.se

Chapter F.69

Stig Stenholm was Pprofessor of Laser Physics and Quantum Optics at the Royal Institute of Technology, Stockholm. He studied Technical Physics at the Helsinki Institute of Technology and Mathematics at the University of Helsinki. He worked at the Research Institute for Theoretical Physics in Helsinki until 1997, when moving to Stockholm. Theoretical research fields include spectroscopy, quantum optics, and informatics

Jack C. Straton

Portland State University
University Studies
Portland, OR, USA

Chapter D.57

Jack Straton earned a doctorate in quantum theory from the University of Oregon and served as both a volunteer and professional diversity trainer over the past 18 years. He is an Assistant Professor in Portland State University's interdisciplinary University Studies program, where his teaching blends science, art, diversity, and social responsibility. His research ranges from Quantum Scattering Theory to Anti-racist Pedagogy.

Carlos R. Stroud Jr.

University of Rochester
Institute of Optics
Rochester, NY, USA
stroud@optics.rochester.edu

Chapter F.73

Professor Stroud is Professor of Optics, Professor of Physics and Director of the Center for Quantum Information at the University of Rochester where he works in a variety of areas of experimental and theoretical quantum optics and atomic physics. His group pioneered the area of Rydberg electron wave packet physics observing localization, decays, revivals and interferometry with a single electron.

Barry N. Taylor

National Institute of Standards and Technology
Atom Physics Division
Gaithersburg, MD, USA
barry.taylor@nist.gov

Chapter B.28

Barry N. Taylor received his Ph.D. in Physics from the University of Pennsylvania in 1963. He remained at Penn as a faculty member until he joined RCA Laboratories in Princeton, NJ in 1966. He joined the National Bureau of Standards (now NIST) in 1970 as a Section Chief in the Electricity Division, becoming its Chief in 1974. In 1988 he became manager of the NIST Fundamental Constants Data Center, retiring from NIST and that position in 2001. Since then he has been a NIST Scientist Emeritus in the Data Center. Dr. Taylor has authored or co-authored over 100 publications, is a fellow of the APS and IEEE, and has received a number of awards. His current research focuses on the evaluation of data related to the fundamental constants and improving the International System of Units (SI).

Aaron Temkin

NASA Goddard Space Flight Center
Laboratory for Solar and Space Physics
Greenbelt, MD, USA
aaron.temkin–1@nasa.gov

Chapter B.25

Dr. Temkin is a research physicist (emeritus) at NASA/GSFC. He has specialized (primarily) in scattering problems of electrons from atoms and molecules, and associated processes (autoionization, in particular). He received his Ph.D. degree from the Massachusetts Institute of Technology in 1956, and has been at his present institution since 1960.

Sandor Trajmar

California Institute of Technology
Jet Propulsion Laboratory
Redwood City, USA
strajmar@comcast.net

Chapter E.63

Dr. Sandor Trajmar received his Ph.D. in physical chemistry from the University of California at Berkeley, California,. He was Head of the Electron collision Physics Group, Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California. He retired in January 1997.

Elmar Träbert

Ruhr–Universität Bochum
Experimentalphysik III/NB3
Bochum, Germany
traebert@ep3.rub.de

Chapter B.18

Professor Elmar Träbert obtained his doctorate and professorial title at Ruhr-Universität Bochum. He has extensive experience in time-resolved spectroscopy and atomic lifetime measurements mainly from working with beam-foil spectroscopic techniques, a heavy-ion storage ring, as well as radio-frequency and electron beam ion traps in more than a dozen laboratories.

Turgay Uzer

Georgia Institute of Technology
School of Physics
Atlanta, GA, USA
turgay.uzer@physics.gatech.edu

Chapter B.15

Professor Turgay Uzer obtained his doctorate at Harvard and was a postdoctoral fellow at Caltech. Currently he is Regents' Professor in the School of Physics, Georgia Institute of Technology. His research interests include: Rydberg atoms and molecules, semiclassical theories, nonlinear dynamics/chaos, intramolecular energy transfer, and chemical reactivity.

Karl Vogel

Universität Ulm
Abteilung für Quantenphysik
Ulm, Germany
karl.vogel@uni-ulm.de

Chapter F.78

Dr. Vogel received his PhD from the Universität Ulm in 1989. His research area is theoretical quantum optics. In particular, he investigated how quantum states of the radiation field can be prepared and how they can be measured.

Jon C. Weisheit

Washington State University
Institute for Shock Physics
Pullman, WA, USA
weisheit@wsu.edu

Chapter G.86

Jon Weisheit recently joined Washington State Universtity's Intstitute for Shock Physics, where he holds appointments as Research Professor and Associate Director, and conducts research focused on understanding quantum phenomena in high energy density matter. He is a Fellow of the American Physical Society, and is a frequent advisor in government agencies on issues pertaining both to basic science and to national defense programs. Her received his graduate degrees in space science and in physics from Rice University.

Wolfgang L. Wiese

National Institute of Standards and Technology
Gaithersburg, MD, USA
wiese@nist.gov

Chapter B.10

Dr. Wolfgang Wiese is a physicist with extensive research background in atomic spectroscopy and in the critical tabulation of atomic reference data. He has worked at the National Institute of Standards and Technology for more than 40 years and has led the Atomic Physics Division from 1978 to 2004. He has authored 6 data volumes on Atomic Transition Probabilities, 15 book chapters and about 225 shorter research papers.

Martin Wilkens

Universität Potsdam
Institut für Physik
Potsdam, Germany
martin.wilkens@physik.uni-potsdam.de

Chapter F.77

Dr. Martin Wilkens received a Ph.D. In Physics from Essen University. He spent his post-doctoral years in Warsaw, Tucson, and Konstanz and has been appointed Professor for Theoretical Physics / Quantum Optics at Potsdam University in 1997. His current research areas are Bose-Einstein condensation, degenerate quantum gases, and quantum information processing and communication.

Detailed Contents

7 Density Matrices

8 Computational Techniques

Part B Atoms

Part C Molecules

31 Molecular Structure

Detailed Cont.

55 Dielectronic Recombination

56 Rydberg Collisions: Binary Encounter, Born and Impulse Approximations

61 Photon–Atom Interactions: Low Energy

62 Photon–Atom Interactions: Intermediate Energies

Detailed Cont.

Detailed Cont.

74 Multiphoton and Strong–Field Processes

75 Cooling and Trapping

78 Quantized Field Effects

79 Entangled Atoms and Fields: Cavity QED

Part G Applications

82 Applications of Atomic and Molecular Physics to Astrophysics

83 Comets

84 Aeronomy

85 Applications of Atomic and Molecular Physics to Global Change

86 Atoms in Dense Plasmas

87 Conduction of Electricity in Gases

Detailed Cont.
