Handbook *of*
Atomic, Molecular, and Optical Physics

CD-ROM

Drake
Editor

Springer

Springer Handbooks
of Atomic, Molecular, and Optical Physics

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physics and engineering. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of physical and technical information.

The volumes will be designed to be useful as readable desk reference books to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook

of Atomic, Molecular, and Optical Physics

Foreword by Herbert Walther

The Handbook of Atomic, Molecular and Optical (AMO) Physics gives an in-depth survey of the present status of this field of physics. It is an extended version of the first issue to which new and emerging fields have been added. The selection of topics thus traces the recent historic development of AMO physics. The book gives students, scientists, engineers, and other interested people a comprehensive introduction and overview. It combines introductory explanations with descriptions of phenomena, discussions of results achieved, and gives a useful selection of references to allow more detailed studies, making the handbook very suitable as a desktop reference.

AMO physics is an important and basic field of physics. It provided the essential impulse leading to the development of modern physics at the beginning of the last century. We have to remember that at that time not every physicist believed in the existence of atoms and molecules. It was due to Albert Einstein, whose work we commemorate this year with the world year of physics, that this view changed. It was Einstein's microscopic view of molecular motion that led to a way of calculating Avogadro's number and the size of molecules by studying their motion. This work was the basis of his PhD thesis submitted to the University of Zurich in July 1905 and after publication became Einstein's most quoted paper. Furthermore, combining kinetic theory and classical thermodynamics led him to the conclusion that the displacement of a microparticle in Brownian motion varies as the square root of time. The experimental demonstration of this law by Jean Perrin three years later finally afforded striking proof that atoms and molecules are a reality. The energy quantum postulated by Einstein in order to explain the photoelectric effect was the basis for the subsequently initiated development of quantum physics, leading to a revolution in physics and many new applications in science and technology.

The results of AMO physics initiated the development of quantum mechanics and quantum electro-dynamics and as a consequence led to a better understanding of the structure of atoms and molecules and their respective interaction with radiation and to the attainment of unprecedented accuracy. AMO physics also influenced the development in other fields of physics, chemistry, astronomy, and biology. It is an astonishing fact that AMO physics constantly went through periods where new phenomena were found, giving rise to an enormous revival of this area. Examples are the maser and laser and their many applications, leading to a better understanding of the basics and the detection of new phenomena, and new possibilities such as laser cooling of atoms, squeezing, and other nonlinear behaviour. Recently, coherent interference effects allowed slow or fast light to be produced. Finally, the achievement of Bose–Einstein condensation in dilute media has opened up a wide range of new phenomena for study. Special quantum phenomena are leading to new applications for transmission of information and for computing. Control of photon emission through specially designed cavities allows controlled and deterministic generation of photons opening the way for a secure information transfer.

Further new possibilities are emerging, such as the techniques for producing attosecond laser pulses and laser pulses with known and controlled phase relation between the envelope and carrier wave, allowing synthesis of even shorter pulses in a controlled manner. Furthermore, laser pulses may soon be available that are sufficiently intense to allow polarization of the vacuum field. Another interesting development is the generation of artificial atoms, e.g., quantum dots, opening a field where nanotechnology meets atomic physics. It is thus evident that AMO physics is still going strong and will also provide new and interesting opportunities and results in the future.

Prof. Dr. Herbert Walther

Preface

The year 2005 has been officially declared by the United Nations to be the International Year of Physics to commemorate the three famous papers of Einstein published in 1905. It is a fitting tribute to the impact of his work that the *Springer Handbook of Atomic, Molecular, and Optical Physics* should be published in coincidence with this event. Virtually all of AMO Physics rests on the foundations established by Einstein in 1905 (including a fourth paper on relativity and his thesis) and his subsequent work. In addition to the theory of relativity, for which he is best known, Einstein ushered in the era of quantum mechanics with his explanation of the photoelectric effect, and he demonstrated the influence of molecular collisions with his explanation of Brownian motion. He also laid the theoretical foundations for all of laser physics with his discovery (in 1917) of the necessity of the process of stimulated emission, and his discussions of the Einstein–Podolsky–Rosen Gedanken experiment (in 1935) led, through Bell's inequalities, to current work on entangled states and quantum information. The past century has been a Golden Age for physics in every sense of the term.

Despite this history of unparalleled progress, the field of AMO Physics continues to advance more rapidly than ever. At the time of publication of an earlier Handbook published by AIP Press in 1996 I wrote "The ever increasing power and versatility of lasers continues to open up new areas for study." Since then, two Nobel Prizes have been awarded for the cooling and trapping of atoms with lasers (Steven Chu, Claude Cohen-Tannoudji, William D. Phillips in 1997), and for the subsequent achievement of Bose–Einstein condensation in a dilute gas of trapped atoms (Eric A. Cornell, Wolfgang Ketterle, Carl E. Wieman in 2001). Although the topic of cooling and trapping was covered in the AIP Handbook, Bose–Einstein condensation was barely mentioned. Since then, the literature has exploded to nearly 2500 papers on Bose–Einstein condensation alone. Similarly, the topics of quantum information and quantum computing barely existed in 1995, and have since become rapidly growing segments of the physics literature. Entirely new topics such as "fast light" and "slow light" have emerged. Techniques for both

high precision theory and measurement are opening the possibility to detect a cosmological variation of the fundamental constants with time. All of these topics hold the promise of important engineering and technological applications that come with advances in fundamental science. The more established areas of AMO Physics continue to provide the basic

Prof. Gordon W. F. Drake

data and broad understanding of a great wealth of underlying processes needed for studies of the environment, and for astrophysics and plasma physics.

These changes and advances provide more than sufficient justification to prepare a thoroughly revised and updated *Atomic, Molecular and Optical Physics Handbook* for the Springer Handbook Program. The aim is to present the basic ideas, methods, techniques and results of the field at a level that is accessible to graduate students and other researchers new to the field. References are meant to be a guide to the literature, rather than a comprehensive bibliography. Entirely new chapters have been added on Bose–Einstein condensation, quantum information, variations of the fundamental constants, and cavity ring-down spectroscopy. Other chapters have been substantially expanded to include new topics such as fast light and slow light. The intent is to provide a book that will continue to be a valuable resource and source of inspiration for both students and established researchers.

I would like to acknowledge the important role played by the members of the Advisory Board in their continuing support of this project, and I would especially like to acknowledge the talents of Mark Cassar as Assistant Editor. In addition to keeping track of the submissions and corresponding with authors, he read and edited the new material for every chapter to ensure uniformity in style and scientific content, and he composed new material to be added to some of the chapters, as noted in the text.
February 2005   Gordon W. F. Drake

Springer Handbook of Atomic, Molecular, and Optical Physics
Organization of the Handbook

Part A gathers together the mathematical methods applicable to a wide class of problems in atomic, molecular, and optical physics. The application of angular momentum theory to quantum mechanics is presented. The basic tenet that isolated physical systems are invariant to rotations of the system is thereby implemented into physical theory. The powerful methods of group theory and second quantization show how simplifications arise if the atomic shell is treated as a basic structural unit. The well established symmetry groups of quantum mechanical Hamiltonians are extended to the larger compact and noncompact dynamical groups. Perturbation theory is introduced as a bridge between an exactly solvable problem and a corresponding real one, allowing approximate solutions of various systems of differential equations. The consistent manner in which the density matrix formalism deals with pure and mixed states is developed, showing how the preparation of an initial state as well as the details regarding the observation of the final state can be treated in a systematic way. The basic computational techniques necessary for accurate and efficient numerical calculations essential to all fields of physics are outlined and a summary of relevant software packages is given. The ever present one-electron solutions of the nonrelativistic Schrödinger equation and the relativistic Dirac equation for the Coulomb potential are then summarized.

Part B presents the main concepts in the theoretical and experimental knowledge of atomic systems, including atomic structure and radiation. Ionization energies for neutral atoms and transition probabilities of selected neutral atoms are tabulated. The computational methods needed for very high precision approximations for helium are summarized. The physical and geometrical significance of simple multipoles is examined. The basic nonrelativistic and relativistic theory of electrons and atoms in external magnetic fields is given. Various properties of Rydberg atoms in external fields and in collisions are investigated. The sources of hyperfine structure in atomic and molecular spectra are outlined, and the resulting energy splittings and isotope shifts given. Precision oscillator strength and lifetime measurements, which provide stringent experimental tests of fundamental atomic structure calculations, are discussed. Ion beam spectroscopy is introduced, and individual applications of ion beam techniques are detailed A basic description of neutral collisional line shapes is given, along with a discussion of radiation transfer in a confined atomic vapor. Many qualitative features of the Thomas–Fermi model are studied and its later outgrowth into general density functional theory delineated. The Hartree–Fock and multiconfiguration Hartree–Fock theories, along with configuration interaction methods, are discussed in detail, and their application to the calculation of various atomic properties presented. Relativistic methods for the calculation of atomic structure for general many-electron atoms are described. A consistent diagrammatic method for calculating the structure of atoms and the characteristics of different atomic

processes is given. An outline of the theory of atomic photoionization and the dynamics of the photon–atom collision process is presented. Those kinds of electron correlation that are most important in photoionization are emphasized. The process of autoionization is treated as a quasibound state imbedded in the scattering continuum, and a brief description of the main elements of the theory is given. Green's function techniques are applied to the calculation of higher order corrections to atomic energy levels, and also of transition amplitudes for radiative transitions of atoms. Basic quantum electrodynamic calculations, which are needed to explain small deviations from the solution to the Schrödinger equation in simple systems, are presented. Comparisons of precise measurements and theoretical predictions that provide tests of our knowledge of fundamental physics are made, focussing on several quantitative tests of quantum electrodynamics. Precise measurements of parity nonconserving effects in atoms could lead to possible modifications of the Standard Model, and thus uncover new physics. An approach to this fundamental problem is described. The problem of the possible variation of the fundamental constants with time is discussed in relation to atomic clocks and precision frequency measurements. The most advanced atomic clocks are described, and the current laboratory constraints on these variations are listed.

Part C begins with a discussion of molecular structure from a theoretical/computational perspective using the Born–Oppenheimer approximation as the point of departure. The key role that symmetry considerations play in organizing and simplifying our knowledge of molecular dynamics and spectra is described. The theory of radiative transition probabilities, which determine the intensities of spectral lines, for the rotationally-resolved spectra of certain model molecular systems is summarized. The ways in which molecular photodissociation is studied in the gas phase are outlined. The results presented are particularly relevant to the investigation of combustion and atmospheric reactions. Modern experimental techniques allow the detailed motions of the atomic constituents of a molecule to be resolved as a function of time. A brief description of the basic ideas behind these techniques is given, with an emphasis on gas phase molecules in collision-free conditions. The semiclassical and quantal approaches to nonreactive scattering are outlined. Various quantitative approaches toward a description of the rates of gas phase chemical reactions are presented and then evaluated for their reliability and range of application. Ionic reactions in the gas phase are also considered. Clusters, which are important in many atmospheric and industrial processes, are arranged into six general categories, and then the physics and chemistry common to each category is described. The most important spectroscopic techniques used to study the properties of molecules are presented in detail.

Part D collects together the topics and approaches used in scattering theory. A handy compendium of equations, formulae, and expressions for the classical, quantal, and semiclassical approaches to elastic scattering is given; reactive systems and model potentials are also considered. The dependence of scattering processes on the angular orientation of the reactants and products is discussed through the analysis of scattering experiments which probe atomic collision theories at a fundamental level.

The detailed quantum mechanical techniques available to perform accurate calculations of scattering cross sections from first principles are presented. The theory of elastic, inelastic, and ionizing collisions of electrons with atoms and atomic ions is covered and then extended to include collisions with molecules. The standard scattering theory for electrons is extended to include positron collisions with atomic and molecular systems. Slow collisions of atoms or molecules within the adiabatic approximation are discussed; important deviations from this model are presented in some detail for the low energy case. The main methods in the theoretical treatment of ion-atom and atom–atom collisions are summarized with a focus on intermediate and high collision velocities. The molecular structure and collision dynamics involved in ion–atom charge exchange reactions is studied. Both the perturbative and variational capture theories of the continuum distorted wave model are presented. The Wannier theory for threshold ionization is then developed. Studies of the energy and angular distribution of electrons ejected by the impact of high-velocity atomic or ionic projectiles on atomic targets are overviewed. A useful collection of formulae, expressions, and specific equations that cover the various approaches to electron-ion and ion-ion recombination processes is given. A basic theoretical formulation of dielectronic recombination is described, and its importance in the interpretation of plasma spectral emission is presented. Many of the equations used to study theoretically the collisional properties of both charged and neutral particles with atoms and molecules in Rydberg states are collected together; the primary approximations considered are the impulse approximation, the binary encounter approximation, and the Born approximation. The Thomas mass-transfer process is considered from both a classical and a quantal perspective. Additional features of this process are also discussed. The theoretical background, region of validity, and applications of the classical trajectory Monte Carlo method are then delineated. One-photon processes are discussed and aspects of line broadening directly related to collisions between an emitting, or absorbing, atom and an electron, a neutral atom or an atomic ion are considered.

Part E focuses on the experimental aspects of scattering processes. Recent developments in the field of photodetachment are reviewed, with an emphasis on accelerator-based investigations of the photodetachment of atomic negative ions. The theoretical concepts and experimental methods for the scattering of low-energy photons, proceeding primarily through the photoelectric effect, are given. The main photon–atom interaction processes in the intermediate energy range are outlined. The atomic response to inelastic photon scattering is discussed; essential aspects of radiative and radiationless transitions are described in the two-step approximation. Advances such as cold-target recoil-ion momentum spectroscopy are also touched upon. Electron–atom and electron–molecule collision processes, which play a prominent role in a variety of systems, are presented. The discussion is limited to electron collisions with gaseous targets, where single collision conditions prevail, and to low-energy impact processes. The physical principles and experimental methods used to investigate low energy ion–atom collisions are outlined. Inelastic processes which occur in collisions between fast, often highly charged, ions and atoms, are described. A summary of the methods commonly employed in scattering experiments

involving neutral molecules at chemical energies is presented. Applications of single-collision scattering methods to the study of reactive collision dynamics of ionic species with neutral partners are discussed.

Part F presents a coherent collection of the main topics and issues found in quantum optics. Optical physics, which is concerned with the dynamical interactions of atoms and molecules with electromagnetic fields, is first discussed within the context of semiclassical theories, and then extended to a fully quantized version. The theoretical techniques used to describe absorption and emission spectra using density matrix methods are developed. Applications of the dark state in laser physics is briefly mentioned. The basic concepts common to all lasers, such as gain, threshold, and electromagnetic modes of oscillation are described. Recent developments in laser physics, including single-atom lasers, two-photon lasers, and the generation of attosecond pulses are also introduced. The current status of the development of different types of lasers – including nanocavity, quantum-cascade and free-electron lasers – are summarized. The important operational characteristics, such as frequency range and output power, are given for each of the types of lasers described. Nonlinear processes arising from the modifications of the optical properties of a medium due to the passage of intense light beams are discussed. Additional processes that are enabled by the use of ultrashort or ultra-intense laser pulses are presented. The concept of coherent optical transients in atomic and molecular systems reviewed; homogeneous and inhomogeneous relaxation in the theory are properly distinguished. Multiphoton and strong-field processes are given a theoretical description. A discussion of the generation of sub-femtosecond pulses is also included. General and specific theories for the control of atomic motion by light are presented. Various traps used for the cooling and trapping of charged and neutral particles and their applications are discussed. The fundamental physics of dilute quantum degenerate gases is outlined, especially in connection with Bose–Einstein condensation. de Broglie optics, which concerns the propagation of matter waves, is presented with a concentration on the underlying principles and the illustration of these principles. The fundamentals of the quantized electromagnetic field and applications to the broad area of quantum optics are discussed. A detailed description of the changes in the atom–field interaction that take place when the radiation field is modified by the presence of a cavity is given. The basic concepts needed to understand current research, such as the EPR experiment, Bell's inequalities, squeezed states of light, the properties of electromagnetic waves in cavities, and other topics depending on the nonlocality of light are reviewed. Applications to cryptography, tunneling times, and gravity wave detectors are included, along with recent work on "fast light" and "slow light." Correlations and quantum superpositions which can be exploited in quantum information processing and secure communication are delineated. Their link to quantum computing and quantum cryptography is given explicitly.

Part G is concerned with the various applications of atomic, molecular, and optical physics. A summary of the processes that take place in photoionized gases, collisionally ionized gases, the diffuse interstellar medium, molecular clouds, circumstellar shells, supernova ejecta, shocked regions, and the early

Universe are presented. The principal atomic and molecular processes that lead to the observed cometary spectra, as well as the needs for basic atomic and molecular data in the interpretation of these spectra, are focused on. The basic methods used to understand planetary atmospheres are given. The structure of atmospheres and their interaction with solar radiation are detailed, with an emphasis on ionospheres. Atmospheric global change is then studied in terms of the applicable atomic and molecular processes responsible for these changes. A summary of the well-known prescriptions for atomic structure and ionization balance, and a discussion of the modified transition rates for ions in dense plasmas are given. A review of current simulations being used to address a wide array of issues needed to accurately describe atoms in dense plasmas is also presented. The main concepts and processes of the physics and chemistry of the conduction of electricity in ionized gases are described. The physical models and laser diagnostics used to understand combustion systems are presented. Various applications of atomic and molecular physics to phenomena that occur at surfaces are reviewed; particular attention is placed on the application of electron- and photon-atom scattering processes to obtain surface specific structural and spectroscopic information. The effect of finite nuclear size on the electronic energy levels of atoms is also detailed; and conversely, the electronic structure effects in nuclear physics are discussed. A discussion of the concepts needed in the operation of charged particle detectors and in describing radiation effects is introduced. The description is restricted to fast charged particles. The key topics in basic radiation physics are then treated, and illustrative examples are given.

Contents

Part B Atoms

10 Atomic Spectroscopy

11 High Precision Calculations for Helium

12 Atomic Multipoles

List of Tables

21 Atomic Structure: Multiconfiguration Hartree−Fock Theories

22 Relativistic Atomic Structure

25 Autoionization

27 Quantum Electrodynamics

28 Tests of Fundamental Physics

30 Atomic Clocks and Constraints on Variations of Fundamental Constants

Part C Molecules

44 Spectroscopic Techniques: Ultraviolet

Part D Scattering Theory

Part E Scattering Experiments

Part F Quantum Optics

92 Radiation Physics

List of Abbreviations

2P/2H	two-particle/two-hole

A

AA	average atom
ACT	activated complex theory
ADDS	angular distribution by Doppler spectroscopy
ADO	average dipole orientation
AES	Auger electron spectroscopy
AI	adiabatic ionization
AL	absorption loss
ALS	advanced light source
AMO	atomic, molecular, and optical
ANDC	arbitrarily normalized decay curve
AO	atomic orbital
AOM	acoustooptic modulator
AS	active space
ASD	atomic spectra database
ASF	atomic state functions
ATI	above threshold ionization
AU	absorbance units

B

BEA	binary encounter approximation
BEC	Bose–Einstein condensate (or condensation)
BF	body-fixed
BI	Bell's inequality
BL	Bethe log
BO	Born–Oppenheimer
BS	Bethe–Salpeter
BW	Brillouin–Wigner

C

CARS	coherent anti-Stokes Raman scattering
CAS	complete active space
CASPT	complete active space perturbation theory
CAUGA	Clifford algebra unitary group approach
CC	coupled cluster
CCA	coupled cluster approximation
CCC	convergent close coupling
CCD	coupled cluster doubles
CCO	coupled-channels optical
CDW	continuum distorted wave
CEAS	cavity enhanced absorption spectroscopy
CES	cavity enhanced spectroscopy
CES	constant energy surface

CETS	cavity enhanced transmission spectroscopy
CFCP	free–free molecular Franck–Condon
CG	Clebsch–Gordan
CH	Clauser–Horne
CI	configuration interaction
CIS	constant ionic state
CL	constant log
CM	center-of-mass
CMA	cylindrical mirror analyzer
COA	classical oscillator approximation
CODATA	Committee on Data for Science and Technology
COIL	chemical-oxygen-iodine
COLTRIMS	cold-target recoil-ion momentum spectroscopy
CP	central potential
CPA	chirped-pulsed-amplification
CQC	classical-quantal coupling
CRDS	cavity ring-down spectroscopy
CSDA	continuous slowing down approximation
CSF	configurational state functions
CTF	common translation factor
CTMC	classical trajectory Monte Carlo
CW	continuous wave
CW-CRDS	continuous-Wave Cavity Ring-Down Spectroscopy
CX	charge exchange
CXO	Chandra X-ray Observatory

D

DB	detailed balance
DCS	differential cross sections
DDCS	doubly differential cross sections
DF	Dirac–Fock
DFB	distributed feedback
DFS	decoherence free subspace
DFT	discrete Fourier transform
DFWM	degenerate four wave mixing
DLR	dielectronic recombination
DODS	different orbitals for different spins
DR	dielectronic recombination
DSPB	distorted wave strong potential Born approximation

E

EA	excitation-autoionization
EBIT	electron beam ion traps
EBS	eikonal Born series

ECP	effective core potential
ECS	exterior complex scaling
EEDF	electron energy distribution functions
EOM	equation of motion
EPR	Einstein–Podolsky–Rosen
ESM	elastic scattering model
ESR	experimental storage ring
EUV	extreme ultraviolet
EW-CRDS	evanescent-wave CRDS
EXAFS	extended X-ray absorption fine structure

F

FBA	first Born approximation
FCPC	full-core plus correlation
FEL	free-electron lasers
FFT	fast Fourier transform
FID	free induction decay
FIR	far-infrared
FM	frequency modulation
FOTOS	first-order theory for oscillator strengths
FS	fine-structure
FT	Fourier transform
FTIR	Fourier transform infrared spectroscopy
FTMS	Fourier transform mass spectrometry
FTS	Fourier transform spectroscopy
FUSE	far ultraviolet spectroscopic explorer
FUV	far ultraviolet
FVP	Fermi virtual photon
FWHM	full width at half maximum

G

GBT	generalized Brillouin's Theorem
GFA	Green's function approach
GGA	generalized gradient approximation
GHZ	Greenberger, Horne, Zeilinger
GI	gauge invariant
GIB	guided ion beam
GOME	global ozone monitoring experiment
GOS	generalized oscillator strength
GPE	Gross–Pitaevskii equation
GRPAE	generalized random phase approximationwith exchange

H

HEDP	high energy-density physics
HF	Hartree–Fock equations
HF	Hellman–Feynman
HG	harmonic generation
HOM	Hong–Ou–Mandel
HREELS	high resolution electron energy loss spectroscopy
HRTOF	H-atom Rydberg time-of-flight
HUM	Hylleraas–Undheim–MacDonald theorem

I

IC	intermediate coupling
ICF	inertial confinement fusion
ICOS	integrated cavity output spectroscopy
ICSLS	international conference on spectral line shapes
IERM	intermediate energy R-matrix
IPCC	intergovernmental panel on climate change
IPES	inverse photoemission spectroscopy
IPIR	independent-processes and isolated-resonance
IPM	independent particle model
IPP	impact parameter picture
IR	irreducible representations
IR	infrared
IRI	international reference ionosphere
IRREP	irreducable representation
ISO	infrared space observatory

J

JB	Jeffrey–Born

K

KS	Kohn–Sham
KTA	potassium titanyl arsenate
KTP	potassium titanyl phosphate

L

LieA	Lie algebras
LA	linear algebraic
L-CETS	locked cavity enhanced transmission spectroscopy
LDA	local density approximation
LEED	low energy electron diffraction
LER	laser electric resonance
LG	Lie groups
LHC	left-hand circular
LHV	local hidden variable
LIF	laser-induced-fluorescence
LIGO	laser interferometer gravitational-wave observatory
LISA	laser interferometer space antenna
LL	Landau–Lifshitz
LM	Levenberg–Marquardt
LMR	laser magnetic resonance
LPT	laser photodetachment threshold
LRL	Laplace–Runge–Lenz
LTE	local thermodynamic equilibrium
LYP	Lee, Yang, and Parr
LZ	Landau–Zener

M

MBE	molecular beam epitaxy
MCP	microchannel plate
MDAL	minimum detectable absorption loss
MBPT	many-body perturbation theory
MCDHF	multiconfigurational Dirac–Hartree–Fock
MCHF	multiconfiguration Hartree–Fock
MCSCF	multiconfigurational self-consistent field
MEMS	microelectromechanical systems
MFP	mean free path
MIGO	matter–wave interferometric gravitational-wave observatory
MIM	metal-insulator-metal
MKSA	meters, kilograms, seconds, and amperes
MM	Massey–Mohr
MMCDF	multichannel multiconfiguration Dirac–Fock
MO	molecular orbital
MOPA	master oscillator power amplifier
MOT	magneto-optical trap
MOX	molecular orbital X-radiation
MP2	second order Møller–Plesset perturbation theory
MP3	third order Møller–Plesset perturbation theory
MPI	multiphoton ionization
MQDT	multichannel quantum defect theory
MR	multireference
MR-SDCI	multireference singles/doubles configuration interaction
MUV	middle ultraviolet

N

NAR	nonadiabatic region
NEP	noise-equivalent power
NEXAFS	near-edge X-ray absorption fine structure
NDIR	non-dispersive infrared
NFS	nonfine-structure
NICE-OHMS	noise-immune, cavity-enhanced optical heterodyne molecular spectroscopy
NIM	normal incidence monochromator
NIST	National Institute of Standards and Technology
NMR	nuclear magnetic resonance systems
NNS	nearest-neighbor energy level spacings
NR	nonrelativistic
NRQED	NR quantum electrodynamics

O

OAO-2	orbiting astronomical observatory
OB	ordinary Bremsstrahlung
OBE	optical Bloch equations
OBK	Oppenheimer–Brinkman–Kramers

OCP	one-component plasma
OHCE	one-and-a-half centered expansion
OMI	ozone monitoring instrument
OPO	optical parametric oscillator

P

P-CRDS	pulsed-cavity ringdown spectroscopy
PADDS	angular distribution by Doppler spectroscopy
PAH	polycyclic aromatic hydrocarbon
PBS	polarizing beam splitters
PCDW	projectile continuum distorted wave approximation
PDM	phase diffusion model
PEC	potential energy curves
PES	photoelectron spectroscopy
PES	potential energy surface
PH/HP	particle–hole/hole–particle
PI	photoionization
PID	particle identification
PIMC	path-integral Monte Carlo
PMT	photomultiplier tubes
PNC	parity nonconservation
PPT	positive partial transposes
PR	polarization radiation
PSD	postion senitive detectors
PSS	perturbed stationary state
PT	perturbation theory
PWBA	plane wave Born approximation
PZT	piezo-electric transducer

Q

QCD	quantum chromodynamics
QED	quantum electrodynamics
QIP	quantum information processing
QKD	quantum key distribution
QMC	quantum Monte Carlo
QND	quantum nondemolition
QS	quasistatic
QSS	quasi-steady state

R

RATIP	relativistic atomic transition and ionization properties
RDC	ring-down cavity
READI	resonant excitation auto-double ionization
REC	radiative electron capture
REDA	resonant excitation double autoionization
REMPI	resonance-enhanced multiphoton ionization
RES	rotational energy surface
RHC	right-hand circular
RHIC	relativistic heavy ion collider

RIMS	recoil-ion momentum spectroscopy
RMI	relativistic mass increase
RMPS	*R*-matrix with pseudostates
RNA	Raman–Nath approximation
RPA	random-phase approximation
RPA	retarding potential analyzer
RPAE	random phase approximation with exchange
RR	radiative recombination
RRKM	Rampsberger–Rice–Karplus–Marcus
RSE	radial Schrödinger equation
RSPT	Rayleigh–Schrödinger perturbation theory
RT	Ramsauer–Townsend
RTE	resonant transfer and excitation
RWA	rotating wave approximation

S

SA-MCSCF	state averaged multiconfiguration self-consistent field
SACM	statistical adiabatic channel model
SBS	stimulated Brillouin scattering
SCA	semiclassical approximation
SCF	self-consistent field
SCIAMACHY	scanning imaging absorption spectrometer for atmospheric chartography
SD	spin-dependent
SD	single and double
SDS	singly differential cross section
SDTQ	single, double, triple, quadruple
SE	Schrödinger equation
SEP	stimulated emission pump
SEPE	simultaneous electron photon excitation
SEXAFS	surface extended X-ray absorption fine structure
SF	space-fixed
SI	spin-independent
SIAM	Society for Industrial and Applied Mathematics
SM	submillimeter
SM-FIR	submillimeter far-infrared
SMS	specific mass shift
SOHO	solar and heliospheric observatory
SP	stationary phase
SPA	stationary phase approximations
SQL	standard quantum limit
SQUID	superconducting quantum interference detector
SR	synchrotron radiation
SRS	stimulated Raman scattering
SS	strong-short

STIRAP	stimulated Raman adiabatic passage
STO	Slater type orbital
STP	standard temperature and pressure

T

TCDW	target continuum distorted wave
TDCS	triply differential cross section
TDHF	time-dependent Hartree–Fock
TDS	thermal desorption spectroscopy
TDSE	time dependent Schrödinger equation
TEA	transverse-excitation-atmospheric-pressure
TF	toroidal field
TOF	time-of-flight
TOP	time orbiting potential
TPA	two-photon absorption
TSR	test storage ring
TuFIR	tunable far-infrared

U

UGA	unitary group approach
UHF	unrestricted Hartree–Fock
UPS	ultraviolet photoelectron spectroscopy
UV	ultraviolet
UV-VIS	ultraviolet-visible

V

VASP	Vienna ab-initio simulation package
VCSEL	vertical-cavity surface-emitting laser
VECSEL	vertical external cavity surface-emitting laser
VES	vibrational energy surfaces
VUV	vacuum ultraviolet

W

WCG	Wigner–Clebsch–Gordan
WDM	warm dense matter
WKB	Wentzel, Kramers, Brillouin
WL	weak-long
WMAP	Wilkinson microwave anisotropy probe
WPMD	wavepacket molecular dynamics

X

XPS	X-ray photoelectron spectroscopy

Y

YAG	Yttrium Aluminum Garnet

Units and Co

1. Units and Constants

The currently accepted values for the physical constants are listed in Table 1.1, based on the 2002 CODATA (Committee on Data for Science and Technology) recommendations [1.1]. The quoted values are based on all data available through 31 December 2002, and replace the earlier 1998 CODATA set. Because the uncertainties are correlated, the correlation matrix, given in Table 1.2, must be used in calculating

uncertainties for any quantities derived from those tabulated [1.1].

1.1 Electromagnetic Units

The standard electromagnetic units adopted by most scientific journals and elementary texts belong to the *système international* (SI) or rationalized MKSA (meters, kilograms, seconds, and amperes) units. However, many authors working with microscopic phenomena prefer *Gaussian* units, and theoretical physicists often use *Heaviside–Lorentz* (H–L) units. In this Handbook, SI units are used together with *atomic units*. The current section is meant as a reference relating these different systems.

The relations among different sets of units are not simple conversions since the same symbol in different systems can have different physical dimensions. To clarify the meanings of the units, we summarize basic electromagnetic relations for SI, Gaussian, and H–L systems below.

The Coulomb law for the magnitude F of the force acting on each of two static charges q and Q separated by a distance r in a homogeneous medium of permittivity ϵ can be written as

$$F = \frac{1}{4\pi\epsilon}\frac{qQ}{r^2} \, , \tag{1.1}$$

where in a vacuum, ϵ is

$$\epsilon_0 = \begin{cases} \left(\mu_0 c^2\right)^{-1} \, , & \text{SI} \\ (4\pi)^{-1} \, , & \text{Gaussian} \\ 1, & \text{H–L} \end{cases} \, , \tag{1.2}$$

with the closely related permeability of vacuum given by

$$\mu_0 = \begin{cases} 4\pi \times 10^{-7}\,\text{N/A}^2 \, , & \text{SI} \\ 4\pi \, , & \text{Gaussian} \\ 1, & \text{H–L} \end{cases} \cdot \tag{1.3}$$

(We deviate here from *Jackson* [1.2] who takes $\epsilon_0 = \mu_0 = 1$ in Gaussian units and must introduce additional constants to relate the units. The physically important quantities are the *relative values* $\epsilon_\mathrm{r} \equiv \epsilon/\epsilon_0$ and $\mu_\mathrm{r} \equiv \mu/\mu_0$, which in traditional Gaussian-unit notation are written without the r subscript.)

Note that ϵ_0 and μ_0 are dimensionless in H–L and Gaussian units, but not in the SI units. Current or electric charge is an independent quantity in the MKSA system but can be expressed in purely mechanical dimensions in the H–L and Gaussian systems. Thus, in Gaussian units, 1 statcoulomb = 1 dyne$^{(1/2)}$ cm, but in SI, even though the ampere is *defined* in terms of the attractive force between thin parallel wires carrying equal currents, there is no mechanical equivalent for the ampere or the coulomb. To establish such an equivalence, one can supplement the SI units by assigning a dimensionless number to ϵ_0 or to μ_0. Gaussian and H–L units arise from two different assignments. The result of assigning a number to ϵ_0 is analogous to the relation $1\,\text{s} = 3 \times 10^8\,\text{m}$ established between time and distance units if one sets the speed of light $c = 1$, a convention often used in conjunction with H–L units. (Note that for simplicity, the pure number

2.997 924 58, equal numerically to the defined speed of light in vacuum in units of 10^8 m/s, is represented by $\dot{3}$.) Thus, although within the Gaussian system, where the assignment $4\pi\epsilon_0 = 1$ is made, it is justified to assert that 1 coulomb *equals* $\dot{3} \times 10^9$ statcoulombs, this is not true in pure SI, where there is no equivalent mechanical unit for charge.

Maxwell's macroscopic equations can be written as

$$\lambda \nabla \cdot \boldsymbol{D} = \rho \,,$$

$$\lambda c' \nabla \times \boldsymbol{H} - \lambda \frac{\partial \boldsymbol{D}}{\partial t} = \boldsymbol{j} \,,$$

$$c' \nabla \times \boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} = 0 \,,$$

$$\nabla \cdot \boldsymbol{B} = 0 \,, \tag{1.4}$$

with the macroscopic field variables related to the polarizations $\boldsymbol{P}$ and $\boldsymbol{M}$ by

$$\lambda \boldsymbol{D} = \epsilon_0 \boldsymbol{E} + \boldsymbol{P} = \epsilon \boldsymbol{E}$$

$$\lambda \boldsymbol{H} = \mu_0^{-1} \boldsymbol{B} - \boldsymbol{M} = \boldsymbol{B}/\mu \tag{1.5}$$

(the last equalities for $\boldsymbol{D}$ and $\boldsymbol{H}$ hold only for homogeneous media) and

$$\lambda = \begin{cases} 1, \text{ SI} \\ \epsilon_0 = \mu_0^{-1}, \text{ Gaussian or H–L} \,, \end{cases} \tag{1.6}$$

$$c' = \begin{cases} 1, \text{ SI} \\ c, \text{ Gaussian or H–L} \,. \end{cases} \tag{1.7}$$

In Gaussian or H–L units, the fields $\boldsymbol{E}$, $\boldsymbol{B}$, $\boldsymbol{D}$, $\boldsymbol{H}$, and polarizations (dipole moments per unit volume) $\boldsymbol{P}$, $\boldsymbol{M}$ all have the same dimensions, whereas in SI units the microscopic fields $\boldsymbol{E}$ and $\boldsymbol{B}$ have dimensions that are generally distinct from each other as well as from $\boldsymbol{P}$ (or $\boldsymbol{D}$) and $\boldsymbol{M}$ (or $\boldsymbol{H}$), respectively. In all three unit systems, the dimensionless ratio ϵ/ϵ_0 is called the dielectric constant (or relative permittivity) of the medium, and the (dimensionless) fine-structure constant is

$$\alpha = \frac{1}{4\pi\epsilon_0} \frac{e^2}{\hbar c} \,, \tag{1.8}$$

with a numerical value $\alpha^{-1} = 137.035\,999\,11\,(46)$.

In atomic units (Sect. 1.3), the factor $e^2/(4\pi\epsilon_0)$, the electron mass m_e, and $\hbar$, Planck's constant divided by 2π, are all equal to 1. In Gaussian and H–L systems, these conditions determine a numerical value for all electro-mechanical units. Thus in Gaussian units, the electronic charge is $e = 1$, whereas in H–L atomic units $e = \sqrt{4\pi}$. In the SI system, on the other hand, the three conditions $e^2/(4\pi\epsilon_0) = m_e = \hbar = 1$ determine numerical values for mechanical units but not for electromagnetic ones. A complete determination of values requires that ϵ_0 also be assigned a value. The choice most consistent with previous work is to take $e = 1 = 4\pi\epsilon_0$. This choice is made here.

Since a volt is a joule/coulomb and a statvolt is an erg/statcoulomb, 1 volt corresponds to (but is not generally *equal* to, since the physical dimensions may

Table 1.3 Conversion factors for various physical quantities

Quantity	SI units	Gaussian units	Natural H–L units: $\hbar = c = \epsilon_0 = 1$
Length	1 m	$= 10^2$ cm	$= 1$ m

Action	1 J s	$= 10^7$ erg s	$\leftrightarrow 0.948\,252\,28(16) \times 10^{34}$
Force	$1\,\text{N} = 1\,\text{J}\,\text{m}^{-1}$	$= 10^5$ dyne	$\leftrightarrow 3.163\,029\,14(54) \times 10^{25}$ m^{-2}
Power	$1\,\text{W} = 1\,\text{J}\,\text{s}^{-1}$	$= 10^7$ erg s^{-1}	$\leftrightarrow 1.055\,072\,95(18) \times 10^{17}$ m^{-2}
Intensity	$1\,\text{W}\,\text{m}^{-2}$	$= 10^3$ erg cm^{-2}	$\leftrightarrow 1.055\,072\,95(18) \times 10^{17}$ m^{-4}
Charge	$1\,\text{C} = 1\,\text{A}\,\text{s}$	$\leftrightarrow \dot{3} \times 10^9$ statcoul	$\leftrightarrow 1.890\,067\,14(16) \times 10^{18}$
Potential	$1\,\text{V} = 1\,\text{J}\,\text{C}^{-1}$	$\leftrightarrow (\dot{3} \times 10^2)^{-1}$ statvolt	$\leftrightarrow 1.673\,500\,94(14) \times 10^7$ m^{-1}
Electric field	$1\,\text{V}\,\text{m}^{-1} = 1\,\text{N}\,\text{C}^{-1}$	$\leftrightarrow (\dot{3} \times 10^4)^{-1}$ statvolt cm^{-1}	$\leftrightarrow 1.673\,500\,94(14) \times 10^7$ m^{-2}
Magnetic field	$1\,\text{T} = 1\,\text{N}\,\text{A}^{-1}\,\text{m}^{-1}$	$\leftrightarrow 10^4$ gauss	$\leftrightarrow 5.017\,029\,61(43) \times 10^{15}$ m^{-2}

differ)

$$\frac{10^7 \text{ erg}}{\dot{3} \times 10^9 \text{ statcoulomb}} = \frac{1}{\dot{3} \times 10^2} \text{ statvolt} . \tag{1.9}$$

In Gaussian units, the unit of magnetic field, namely the Gauss (**B**) or Oersted (**H**) has the same physical size and dimension as the unit of electric field, namely the statvolt/cm, which in turn corresponds to an SI field of $\dot{3} \times 10^4$ V/m. However, the tesla (1 T = 1 weber/m^2), the SI unit of magnetic field **B** (older texts refer to **B** as the *magnetic induction*), has the physical dimensions of V s/m^2. To find the correspondence to Gaussian units, one must multiply by the speed of light c:

$$1\,\text{T}\,c = \dot{3} \times 10^8 \text{ V/m} , \tag{1.10}$$

which corresponds to 10^4 statvolt/cm and hence to 10^4 gauss.

Tables 1.3 and 1.4 related basic mechanical and electromagnetic quantities in the different unit systems. Caution is required both because the same symbol often stands for quantities of different physical dimensions in different systems of units, and because factors of 2π sometimes enter frequencies, depending on whether the units are cycles/s (Hz) or radians/s. The double-headed arrows ($\leftrightarrow$) indicate a correspondence between quantities whose dimensions are not necessarily equal. Thus for example, the force on an electron due to a Gaussian electric field of 1 statvolt/cm is the same as due to an SI electric field of $\dot{3} \times 10^4$ V/m. The correspondences between Gaussian and SI electrostatic quantities become equalities if and only if $4\pi\epsilon_0 = 1$. Thus they are equalities

within the Gaussian system but not within the less constrained SI scheme. The SI and Gaussian units of magnetic field have different dimensions unless both ϵ_0 and c are set equal to dimensionless numbers. *Natural H–L units* can be considered SI units supplemented by the conditions $\epsilon_0 = c = \hbar = 1$. They are listed here in units of meters, although eV are also often used: $1\,\text{eV} = 5.067\,731\,04(43) \times 10^6$ m$^{-1} \times \hbar c$. The correspondences may be considered equalities within the natural H–L system but not within SI. Note that the electronic charge in the natural H–L system has the magnitude $e = \sqrt{4\pi\alpha}$. More electromagnetic conversions can be found in *Jackson* [1.2]. The data here are based on the 2002 adjustment by *Mohr* and *Taylor* [1.1].

A few additional energy conversion factors are

$$\begin{aligned}
1\,\text{eV} &= 1.602\,176\,53\,(14) \times 10^{-19} \text{ J} \\
&= 2.417\,989\,40\,(21) \times 10^{14} \text{ Hz} \times h \\
&= 8065.544\,45\,(69) \text{ cm}^{-1} \times hc \\
&= 3.674\,932\,45\,(31) \times 10^{-2} E_\text{h} \\
&= 1.160\,4505\,(20) \times 10^4 \text{ K} \times k_\text{B} \\
&= 96.485\,3383\,(83) \text{ kJ mol}^{-1}
\end{aligned}$$

The basic unit of temperature, the kelvin, is equivalent to about $0.7\,\text{cm}^{-1}$, i. e., the value of the Boltzmann constant k_B expressed in wavenumber units per kelvin is $0.695\,0356(12)\,\text{cm}^{-1}\text{K}^{-1}$. Since K is the internationally accepted symbol for the Kelvin [1.3], this suggests that the use of the letter K as a symbol for $1\,\text{cm}^{-1}$ (1 Kayser) should be discontinued.

1.2 Atomic Units

Atomic and molecular calculations based on the Schrödinger equation are most conveniently done in atomic units (a.u.), and then the final result converted to the correct SI units as listed in Table 1.4. In atomic units, $\hbar = m_e = e = 4\pi\epsilon_0 = 1$. The atomic units of length, velocity, time, and energy are then

$$\text{length: } a_0 = \frac{4\pi\epsilon_0\hbar^2}{m_e e^2} = \frac{\hbar}{\alpha m_e c} ,$$

$$\text{velocity: } v_B = \frac{e^2}{4\pi\epsilon_0\hbar} = \alpha c ,$$

$$\text{time: } \tau_0 = \frac{16\pi^2\epsilon_0^2\hbar^3}{m_e e^4} = \frac{\hbar}{\alpha^2 m_e c^2} ,$$

$$\text{energy: } E_h = \frac{e^2}{4\pi\epsilon_0 a_0} = \alpha^2 m_e c^2 ,$$

where, from the definition (1.8), the numerical value of c is $\alpha^{-1} = 137.035\,999\,11(46)$ a.u. For the lowest 1s state of hydrogen (with infinite nuclear mass), a_0 is the Bohr radius, v_B is the Bohr velocity, $2\pi\tau_0$ is the time to complete a Bohr orbit, and E_h (the Hartree energy) is twice the ionization energy. To include the effects of a finite nuclear mass M, one must replace the electron mass m_e by the reduced electron mass $\mu = m_e M/(M + m_e)$.

Atomic energies are often expressed in units of the Rydberg (Ry). The Rydberg for an atom having nuclear mass M is

$$1 \text{ Ry} = R_M = \frac{\mu}{m_e} R_\infty = M(M + m_e)^{-1} R_\infty , \tag{1.11}$$

Table 1.4 Physical quantities in atomic units with $\hbar = e = m_e = 4\pi\epsilon_0 = 1$, and $\alpha^{-1} = 137.035\,999\,11(46)$

Quantity	Unit	Value
Length	a_0	$0.529\,177\,2108(18) \times 10^{-10}$ m
Mass	m_e	$0.910\,938\,26(16) \times 10^{-30}$ kg
Time	$\hbar/E_h$	$2.418\,884\,326\,505(16) \times 10^{-17}$ s
Velocity	$v_B \equiv \alpha c$	$2.187\,691\,2633(73) \times 10^6$ m s^{-1}
Energy	E_h	$4.359\,744\,17(75) \times 10^{-18}$ J
Action	$\hbar$	$1.054\,571\,68(18) \times 10^{-34}$ J s
Force	E_h/a_0	$0.823\,872\,25(14) \times 10^{-7}$ N
Power	$E_h^2/\hbar$	$0.180\,237\,811(31)$ W
Intensity	$E_h^2/\hbar a_0^2$	$64.364\,091(11) \times 10^{18}$ W m^{-2}
Charge	e	$1.602\,176\,53(14) \times 10^{-19}$ C
Electric potential	E_h/e	$27.211\,3845(23)$ V
Electric field	$E_h/ea_0 = \alpha\hbar c/ea_0^2$	$0.514\,220\,642(44) \times 10^{12}$ V m^{-1}
Magnetic flux density	$E_h/ea_0\alpha c$	$2.350\,517\,42(20) \times 10^5$ T

with

$$R_\infty = \frac{m_e c\alpha^2}{2h} = 10\,973\,731.568\,525\,(73) \text{ m}^{-1} . \tag{1.12}$$

The Rydberg constant R_∞ is thus the limiting value of R_M for infinite nuclear mass, and hcR_∞ is $\frac{1}{2}$ a.u., which is equivalent to $13.605\,6923(12)$ eV.

The energy equivalent of the electron mass, $m_e c^2$, is $0.510\,998\,918(44)$ MeV. This energy is a natural unit for relativistic atomic theory. For example, for inner-shell energies in the heaviest elements, the binding energy of the 1s electron in hydrogenic Lr ($Z = 103$) is $0.338\,42\,m_e c^2$.

1.3 Mathematical Constants

A selection of the most important mathematical constants is listed in Table 1.5. More extensive tabulations and formulas can be found in the standard mathematical works [1.4, 5]

1.3.1 Series Summation Formula

The Riemann zeta function defined by $\zeta(n) = \sum_{i=1}^{\infty} i^{-n}$ (Table 1.5) is particularly useful in summing slowly convergent series of the form

$$S = \sum_{i=1}^{\infty} T_i . \tag{1.13}$$

For example, suppose that the series

$$T_i = t_2 i^{-2} + t_3 i^{-3} + \cdots \tag{1.14}$$

for the individual terms in S is rapidly convergent for $i > N$, where N is some suitably large integer.

Then

$$S = \sum_{i=1}^{N} T_i + t_2 \zeta^N(2) + t_3 \zeta^N(3) + \cdots , \quad (1.15)$$

where $\zeta^N(n) = \zeta(n) - \sum_{i=1}^{N} i^{-n}$ is the zeta function with the first N terms subtracted. For N sufficiently large, only the first few t_j coefficients need be known, and they can be adequately estimated by solving the system of equations

$$T_N = t_2 N^{-2} + t_3 N^{-3} + \cdots$$
$$\qquad + t_{k+2} N^{-k-2} , \quad (1.16a)$$
$$T_{N-1} = t_2 (N-1)^{-2} + t_3 (N-1)^{-3} + \cdots$$
$$\qquad + t_{k+2} (N-1)^{-k-2} , \quad (1.16b)$$
$$\vdots$$
$$T_{N-k} = t_2 (N-k)^{-2} + t_3 (N-k)^{-3} + \cdots$$
$$\qquad + t_{k+2} (N-k)^{-k-2} , \quad (1.16c)$$

where $k + 1 \leq N$ is the number of terms retained in (1.14).

Table 1.5 Values of e, π, Euler's constant γ, and the Riemann zeta function $\zeta(n)$

Constant	Value

Part A Mathematical Methods

2. Angular Momentum Theory

Angular momentum theory is presented from the viewpoint of the group $SU(1)$ of unimodular unitary matrices of order two. This is the basic quantum mechanical rotation group for implementing the consequences of rotational symmetry into isolated complex physical systems, and gives the structure of the angular momentum multiplets of such systems. This entails the study of representation functions of $SU(2)$, the Lie algebra of $SU(2)$ and copies thereof, and the associated Wigner–Clebsch–Gordan coefficients, Racah coefficients, and $1n-j$ coefficients, with an almost boundless set of inter-relations, and presentations of the associated conceptual framework. The relationship to the rotation group in physical 3-space is given in detail. Formulas are often given in a compendium format with brief introductions on their physical and mathematical content. A special effort is made to inter-relate the material to the special functions of mathematics and to the combinatorial foundations of the subject.

Angular momentum theory in its quantum mechanical applications, which is the subject of this section, is the study of the group of 2×2 unitary unimodular matrices and its irreducible representations. It is the mathematics of implementing into physical theory the basic tenet that isolated physical systems are invariant to rotations of the system in physical 3-space, denoted $\mathbf{R}^3$, or, equivalently, to the orientation of a Cartesian reference system used to describe the system. That it is the group of 2×2 unimodular matrices that is basic in quantum theory in place of the more obvious group of 3×3 real, orthogonal matrices representing transformations of the coordinates of the constituent particles of the system, or of the reference frame, is a consequence of the Hilbert space structure of the state space of quantum systems and the impossibility of assigning overall phase factors to such states because measurements depend only on the absolute value of transition amplitudes.

The exact relationship between the group $SU(2)$ of 2×2 unimodular unitary matrices and the group $SO(3, \mathbf{R})$ of 3×3 real, proper, orthogonal matrices is an important one for keeping the quantum theory of angular momentum, with its numerous conventions and widespread applications across all fields of quantum

physics, free of ambiguities. These notations and relations are fixed at the outset.
Presentation of a point in $\mathbf{R}^3$:

$$\mathbf{x} = \mathrm{col}\,(x_1, x_2, x_3) \qquad \text{column matrix ,}$$
$$\mathbf{x}^T = (x_1, x_2, x_3) \qquad \text{row matrix ,}$$
$$X = \begin{pmatrix} x_3 & x_1 - \mathrm{i}x_2 \\ x_1 + \mathrm{i}x_2 & -x_3 \end{pmatrix}$$
$$2 \times 2 \text{ traceless Hermitian matrix ;}$$
$$\text{Cartan's representation .}$$

A one-to-one correspondence between the set $\mathbf{R}^3$ of points in 3-space and the set $\mathbf{H}^2$ of 2×2 traceless Hermitian matrices is obtained from $x_i = \frac{1}{2}\,\mathrm{Tr}\,(\sigma_i X)$, where the σ_i denote the matrices (Pauli matrices)

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{2.1}$$

Mappings of $\mathbf{R}^3$ onto itself:

$$\mathbf{x} \to \mathbf{x}' = R\mathbf{x} ,$$
$$X \to X' = UXU^\dagger ,$$

where † denotes Hermitian conjugation of a matrix or an operator.

Two-to-one homomorphism of $SU(2)$ onto $SO(3, \boldsymbol{R})$:

$$R_{ij} = R_{ij}(U) = \frac{1}{2}\mathrm{Tr}\left(\sigma_i U \sigma_j U^\dagger\right),\qquad(2.2)$$

$$\begin{pmatrix}\xi \\ \boldsymbol{x}'\end{pmatrix} = \begin{pmatrix}1 & 0 & 0 & 0 \\ 0 & & & \\ 0 & & R(U) & \\ 0 & & & \end{pmatrix} = \begin{pmatrix}\xi \\ \boldsymbol{x}\end{pmatrix}$$

$$= A^\dagger(U \times U^*)A\begin{pmatrix}\xi \\ \boldsymbol{x}\end{pmatrix},\qquad(2.3)$$

where ξ is an indeterminate, A is the unitary matrix given by

$$A = \frac{1}{\sqrt{2}}\begin{pmatrix}1 & 0 & 0 & 1 \\ 0 & 1 & -\mathrm{i} & 0 \\ 0 & 1 & \mathrm{i} & 0 \\ 1 & 0 & 0 & -1\end{pmatrix},$$

$U \times U^*$ denotes the matrix direct product, and $*$ denotes complex conjugation. There is a simple unifying theme in almost all the applications. The basic mathematical notions that are implemented over and over again in various contexts are: group action on the underlying coordinates and momenta of the physical system and the corresponding group action in the associated Hilbert space of states; the determination of those subspaces that are mapped irreducibly onto themselves by the group action; the Lie algebra and its actions as derived from the group actions, and conversely; the construction of composite objects from elementary constituents, using the notion of tensor product space and Kronecker products of representations, which are the basic precepts in quantum theory for building complex systems from simpler ones; the reduction of the Kronecker product of irreducible representations into irreducibles with the associated Wigner–Clebsch–Gordan and Racah coefficients determining not only this reduction, but also having a dual role in the construction of the irreducible state spaces themselves; and, finally, the repetition of this process for many-particle systems with the attendant theory of $3n - j$ coefficients. The universality of this methodology may be attributed to being able, in favorable situations, to separate the particular consequences of physical law (e.g., the Coulomb force) from the implications of symmetry imposed on the system by our underlying conceptions of space and time. Empirical models based on symmetry that attempt to identify the more important ingredients underlying observed physical phenomena are also of great importance.

The group actions in complex systems are often modeled after the following examples for the actions of the groups $SO(3, \boldsymbol{R})$ and $SU(2)$ on functions defined over the 2-sphere $\boldsymbol{S}^2 \subset \boldsymbol{R}^3$:

Hilbert space:

$$\boldsymbol{V} = \{f \mid f \text{ is a polynomial satisfying } \nabla^2 f(\boldsymbol{x}) = 0\}\,.$$

Inner or scalar product:

$$\left(f, f'\right) = \int\limits_{\text{unit sphere}} f^*(\boldsymbol{x}) f'(\boldsymbol{x})\,\mathrm{d}S\,,$$

where $f(\boldsymbol{x}) = f(X)$ for $\boldsymbol{x}$ presented in the Cartan matrix form X.

Group actions:

$$(O_R f)(\boldsymbol{x}) = f\left(R^{-1}\boldsymbol{x}\right),\qquad \text{each } f \in \boldsymbol{V}\,,$$
$$\text{each } \boldsymbol{x} \in \boldsymbol{R}^3\,,$$
$$(T_U f)(X) = f\left(U^\dagger X U\right),\qquad \text{each } f \in \boldsymbol{V}\,,$$
$$\text{each } X \in \boldsymbol{H}^2\,.$$

Operator properties:

- O_R is a unitary operator on $\boldsymbol{V}$; that is, $(O_R f, O_R f') = (f, f')$.
- T_U is a unitary operator on $\boldsymbol{V}$; that is, $(T_U f, T_U f') = (f, f')$.
- $R \to O_R$ is a unitary representation of $SO(3, \boldsymbol{R})$; that is, $O_{R_1} O_{R_2} = O_{R_1 R_2}$.
- $U \to T_U$ is a unitary representation of $SU(2)$; that is, $T_{U_1} T_{U_2} = T_{U_1 U_2}$.
- $O_{R(U)} = T_U = T_{-U}$ is an operator identity on the space $\boldsymbol{V}$.

One parameter subgroups:

$$U_j(t) = \exp(-\mathrm{i}t\sigma_j/2)\,,\quad t \in \boldsymbol{R}\,,\quad j = 1, 2, 3\,;$$
$$R_j(t) = R(U_j(t)) = \exp(-\mathrm{i}tM_j)\,,$$
$$t \in \boldsymbol{R}\,,\quad j = 1, 2, 3\,;$$

where

$$M_1 = \mathrm{i}\begin{pmatrix}0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0\end{pmatrix}\,,\quad M_2 = \mathrm{i}\begin{pmatrix}0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0\end{pmatrix}\,,$$

$$M_3 = \mathrm{i}\begin{pmatrix}0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0\end{pmatrix}\,.\qquad(2.4)$$

Infinitesimal generators:

$$L_j = \mathrm{i}(\mathrm{d}O_{R_j(t)}/\mathrm{d}t)_{t=0} ,$$
$$L_j = \mathrm{i}(\mathrm{d}T_{U_j(t)}/\mathrm{d}t)_{t=0} ,$$
$$(L_j f)(\boldsymbol{x}) = -\mathrm{i}\left(x_k \frac{\partial}{\partial x_l} - x_l \frac{\partial}{\partial x_k} \right) f(\boldsymbol{x}) ,$$
$$j, k, l \text{ cyclic in } 1, 2, 3 . \tag{2.5}$$

Historically, the algebra of angular momentum came about through the quantum rule of replacing the linear momentum $\boldsymbol{p}$ of a classical point particle, which is located at position $\boldsymbol{r}$, by $\boldsymbol{p} \rightarrow -\mathrm{i}\hbar\nabla$, thus replacing the classical angular momentum $\boldsymbol{r} \times \boldsymbol{p}$ about the origin of a chosen Cartesian inertial system by the angular

momentum operator:

$$\boldsymbol{L} = -\mathrm{i}\boldsymbol{r} \times \nabla \quad \text{(in units of } \hbar\text{) .} \tag{2.6}$$

The quantal angular momentum properties of this simple one-particle system are then to be inferred from the properties of these operators and their actions in the associated Hilbert space. This remains the method of introducing angular momentum theory in most textbooks because of its simplicity and historical roots. It also leads to focusing the developments of the theory on the algebra of operators in contrast to emphasizing the associated group transformations of the Hilbert space, although the two viewpoints are intimately linked, as illustrated above. Both perspectives will be presented here.

2.1 Orbital Angular Momentum

The model provided by orbital angular momentum operators is the paradigm for standardizing many of the conventions and relations used in more abstract and general treatments. These basic results for the orbital angular momentum operator $\boldsymbol{L} = -\mathrm{i}\boldsymbol{r} \times \nabla$ acting in the vector space $\boldsymbol{V}$ are given in this section both in Cartesian coordinates $\boldsymbol{x} = \mathrm{col}\,(x_1, x_2, x_3)$ and spherical polar coordinates:

$$\boldsymbol{x} = (r \sin\theta \cos\phi, r \sin\theta \sin\phi, r \cos\theta) ,$$
$$0 \le r < \infty , \quad 0 \le \phi < 2\pi , \quad 0 \le \theta \le \pi .$$

2.1.1 Cartesian Representation

Commutation relations:
Cartesian form:

$$[L_1, L_2] = \mathrm{i}L_3 , \quad [L_2, L_3] = \mathrm{i}L_1 ,$$
$$[L_3, L_1] = \mathrm{i}L_2 .$$

Cartan form:

$$[L_3, L_+] = L_+ , \quad [L_3, L_-] = -L_- ,$$
$$[L_+, L_-] = 2L_3 .$$

Squared orbital angular momentum:

$$\boldsymbol{L}^2 = L_1^2 + L_2^2 + L_3^2 = L_- L_+ + L_3(L_3 + 1)$$
$$= L_+ L_- + L_3(L_3 - 1)$$
$$= -r^2 \nabla^2 + (\boldsymbol{x} \cdot \nabla)^2 + (\boldsymbol{x} \cdot \nabla) .$$

$\boldsymbol{L}^2$, L_3 form a complete set of commuting Hermitian operators in $\boldsymbol{V}$ with eigenfunctions

$$\mathcal{Y}_{lm}(\boldsymbol{x}) = \left[\frac{2l+1}{4\pi}(l+m)!(l-m)! \right]^{\frac{1}{2}}$$
$$\times \sum_k \frac{(-x_1 - \mathrm{i}x_2)^{k+m}(x_1 - \mathrm{i}x_2)^k x_3^{l-m-2k}}{2^{2k+m}(k+m)!k!(l-m-2k)!} ,$$

where $l = 0, 1, 2, \ldots ,$; $m = l, l-1, \ldots, -l$.
Homogeneous polynomial solutions of Laplace's equation:

$$\mathcal{Y}_{lm}(\lambda\boldsymbol{x}) = \lambda^l \mathcal{Y}_{lm}(\boldsymbol{x}) ,$$
$$(\boldsymbol{x} \cdot \nabla)\mathcal{Y}_{lm}(\boldsymbol{x}) = l\mathcal{Y}_{lm}(\boldsymbol{x}) ,$$
$$\nabla^2 \mathcal{Y}_{lm}(\boldsymbol{x}) = 0 .$$

Complex conjugate:

$$\mathcal{Y}_{lm}^*(\boldsymbol{x}) = (-1)^m \mathcal{Y}_{l,-m}(\boldsymbol{x}) .$$

Action of angular momentum operators:

$$L_\pm \mathcal{Y}_{lm}(\boldsymbol{x}) = [(l \mp m)(l \pm m + 1)]^{\frac{1}{2}} \mathcal{Y}_{l,m\pm 1}(\boldsymbol{x}) ,$$
$$L_3 \mathcal{Y}_{lm}(\boldsymbol{x}) = m\mathcal{Y}_{lm}(\boldsymbol{x}) ,$$
$$\boldsymbol{L}^2 \mathcal{Y}_{lm}(\boldsymbol{x}) = l(l+1)\mathcal{Y}_{lm} .$$

Highest weight eigenfunction:

$$L_+ \mathcal{Y}_{ll}(\boldsymbol{x}) = 0 , \quad L_3 \mathcal{Y}_{ll}(\boldsymbol{x}) = l\mathcal{Y}_{ll}(\boldsymbol{x}) ,$$
$$\mathcal{Y}_{ll}(\boldsymbol{x}) = \frac{1}{2^l l!} \left(\frac{(2l+1)!}{4\pi} \right)^{\frac{1}{2}} (-x_1 - \mathrm{i}x_2)^l .$$

Generation from highest weight:

$$\mathcal{Y}_{lm}(\boldsymbol{x}) = \left(\frac{(l+m)}{(2l)!(l-m)!}\right)^{\frac{1}{2}} L_-^{l-m} Y_{ll}(\boldsymbol{x}) .$$

Relation to Gegenbauer and Jacobi polynomials:

$$\mathcal{Y}_{lm}(\boldsymbol{x}) = r^{l-|m|} \mathcal{Y}_m(x_1, x_2)$$
$$\times [(2l+1)(l+m)!(l-m)!/2]^{\frac{1}{2}}$$
$$\times H_{l,|m|}(x_3/r) ,$$
$$H_{l\lambda}(z) = \frac{(2\lambda)!}{2^\lambda \lambda!} C_{l-\lambda}^{\lambda+\frac{1}{2}}(z) = \frac{(l+\lambda)!}{2^\lambda l!} P_{l-\lambda}^{(\lambda,\lambda)}(z) ,$$
$$0 \le \lambda \le l = 0, 1, 2, \dots ,$$

where the $\mathcal{Y}_m(x_1, x_2)$ are homogeneous polynomial solutions of degree $|m|$ of Laplace's equation in 2-space, $\boldsymbol{R}^2$:

$$\mathcal{Y}_m(x_1, x_2) = \begin{cases} (-x_1 - \mathrm{i}x_2)^m/\sqrt{2\pi} , & m \ge 0 , \\ (x_1 - \mathrm{i}x_2)^{-m}/\sqrt{2\pi} , & m \le 0 . \end{cases}$$

(Section 2.1.2 for the definition of Gegenbauer and Jacobi polynomials.)
Orthogonal group action:

$$(O_R \mathcal{Y}_{lm})(\boldsymbol{x}) = \mathcal{Y}_{lm}(R^{-1}\boldsymbol{x}) = \sum_{m'} \mathcal{D}_{m'm}^l(R) \mathcal{Y}_{lm'}(\boldsymbol{x}) ,$$

where the functions $\mathcal{D}_{m'm}^l(R) = D_{m'm}^l(U(R))$ are defined in Sect. 2.3 for various parametrizations of R.
Unitary group action:

$$(T_U \mathcal{Y}_{lm})(X) = \mathcal{Y}_{lm}(U^\dagger X U)$$
$$= \sum_{m'} D_{m'm}^l(U) \mathcal{Y}_{lm'}(X) ,$$

where the functions $D_{m'm}^l(U)$ are defined in Sects. 2.2 and 2.3.
Orthogonality on the unit sphere:

$$\int_{\text{unit sphere}} \mathcal{Y}_{l'm'}^*(\boldsymbol{x}) \mathcal{Y}_{lm}(\boldsymbol{x}) \, \mathrm{d}S = \delta_{l'l}\delta_{m'm} .$$

Product of solid harmonics:

$$\mathcal{Y}_{k\mu}(\boldsymbol{x})\mathcal{Y}_{lm}(\boldsymbol{x}) = \sum_{l'} \langle l' || \mathcal{Y}_k || l \rangle C_{m,\mu,m+\mu}^{lkl'} \mathcal{Y}_{l',m+\mu}(\boldsymbol{x})$$
$$= \sum_{l'} (l' || \mathcal{Y}_k || l) \begin{pmatrix} l & k & l' \\ m & \mu & -m-\mu \end{pmatrix}$$
$$\times (-1)^{l'+m+\mu} \mathcal{Y}_{l',m+\mu}(\boldsymbol{x}) ,$$
$$\langle l' || \mathcal{Y}_k || l \rangle = r^{l+k-l'}\left(\frac{(2l+1)(2k+1)}{4\pi(2l'+1)}\right)^{\frac{1}{2}} C_{000}^{lkl'} ,$$
$$(l' || \mathcal{Y}_k || l) = r^{l+k-l'}\left(\frac{(2l+1)(2k+1)(2l'+1)}{4\pi}\right)^{\frac{1}{2}}$$
$$\times (-1)^l \begin{pmatrix} l & k & l' \\ 0 & 0 & 0 \end{pmatrix} ,$$

where $C_{m_1 m_2 m}^{l_1 l_2 l}$ and

$$\begin{pmatrix} l_1 & l_2 & l \\ m_1 & m_2 & -m \end{pmatrix} = \frac{(-1)^{l_1-l_2+m}}{\sqrt{2l+1}} C_{m_1 m_2 m}^{l_1 l_2 l}$$

denote Wigner–Clebsch–Gordan coefficients and 3–j coefficients, respectively (Sect. 2.7).
Vector addition theorem for solid harmonics:

$$\mathcal{Y}_{lm}(\boldsymbol{z} + \boldsymbol{z}') =$$
$$\sum_{k\mu} \left(\frac{4\pi(2l+1)!}{(2l-2k+1)!(2k+1)!}\right)^{\frac{1}{2}} C_{m-\mu,\mu,m}^{l-k,k,l}$$
$$\times \mathcal{Y}_{l-k,m-\mu}(\boldsymbol{z})\mathcal{Y}_{k\mu}(\boldsymbol{z}') , \quad \boldsymbol{z}, \boldsymbol{z}' \in \boldsymbol{C}^3 ,$$
$$C_{m-\mu,\mu,m}^{j-k,k,l} = \left[\begin{pmatrix} l+m \\ k+\mu \end{pmatrix}\begin{pmatrix} l-m \\ k-\mu \end{pmatrix} \Big/ \begin{pmatrix} 2l \\ 2k \end{pmatrix}\right]^{\frac{1}{2}} .$$

Rotational invariant in two vectors:

$$I_l(\boldsymbol{x}, \boldsymbol{y}) = \frac{1}{2^l}\sum_k (-1)^k \begin{pmatrix} l \\ k \end{pmatrix}\begin{pmatrix} 2l-2k \\ l \end{pmatrix}$$
$$\times (\boldsymbol{x}\cdot\boldsymbol{y})^{l-2k}(\boldsymbol{x}\cdot\boldsymbol{x})^k(\boldsymbol{y}\cdot\boldsymbol{y})^k$$
$$= (\boldsymbol{x}\cdot\boldsymbol{x})^{l/2}(\boldsymbol{y}\cdot\boldsymbol{y})^{l/2} C_l^{(1/2)}(\hat{\boldsymbol{x}}\cdot\hat{\boldsymbol{y}})$$
$$= \frac{4\pi}{2l+1}\sum_m (-1)^m \mathcal{Y}_{lm}(\boldsymbol{x})\mathcal{Y}_{l,-m}(\boldsymbol{y}) ,$$

where $C_l^{(1/2)}(z)$ is a Gegenbauer polynomial (Sect. 2.1.2) and

$$\hat{\boldsymbol{x}} = \boldsymbol{x}/|\boldsymbol{x}| , \quad \hat{\boldsymbol{y}} = \boldsymbol{y}/|\boldsymbol{y}| , \quad \cos\theta = \hat{\boldsymbol{x}}\cdot\hat{\boldsymbol{y}} .$$

Legendre polynomials:

$$P_l(\cos\theta) = \frac{4\pi}{2l+1}\sum_m (-1)^m \mathcal{Y}_{l,-m}(\hat{\boldsymbol{y}})\mathcal{Y}_{lm}(\hat{\boldsymbol{x}}) ,$$

$$\left(\frac{4\pi}{2l+1}\right)^{\frac{1}{2}}\mathcal{Y}_{l0}(\boldsymbol{x})$$

$$= \frac{1}{2^l}\sum_k (-1)^k \binom{l}{k}\binom{2l-2k}{l} x_3^{l-2k}(\boldsymbol{x}\cdot\boldsymbol{x})^k$$

$$= r^l P_l(x_3/r) .$$

Rayleigh plane wave expansion:

$$\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}} = 4\pi\sum_{l=0}^{\infty}\sum_{m=-l}^{l} \mathrm{i}^l j_l(kr)\mathcal{Y}_{lm}^*(\hat{\boldsymbol{k}})\mathcal{Y}_{lm}(\hat{\boldsymbol{x}}) ,$$

$$j_l(kr) = \left(\frac{\pi}{2kr}\right)^{\frac{1}{2}} J_{l+1/2}(kr) .$$

Relations in potential theory:

$$\mathcal{Y}_{lm}(\nabla)\left(\frac{1}{r}\right) = \frac{(-1)^l(2l)!}{2^l l!}\frac{\mathcal{Y}_{lm}(\boldsymbol{x})}{r^{2l+1}} ,$$

$$1/R = \sum_{l=0}^{\infty} I_l(\boldsymbol{x},\boldsymbol{y})/r^{2l+1} ,$$

$$I_l(\boldsymbol{x},\boldsymbol{y})/r^{2l+1} = \frac{(-1)^l}{l!}(\boldsymbol{y}\cdot\nabla)^l\left(\frac{1}{r}\right) .$$

For $\boldsymbol{R} = \boldsymbol{x}-\boldsymbol{y}$, $\quad r = (\boldsymbol{x}\cdot\boldsymbol{x})^{\frac{1}{2}}$, $\quad s = (\boldsymbol{y}\cdot\boldsymbol{y})^{\frac{1}{2}}$,

$$1/R = \sum_l P_l(\cos\theta)\frac{s^l}{r^{l+1}} , \quad s\le r, \cos\theta = \hat{\boldsymbol{x}}\cdot\hat{\boldsymbol{y}} .$$

Rotational invariants in three vectors:

$$I_{(l_1 l_2 l_3)}(\boldsymbol{x}^1,\boldsymbol{x}^2,\boldsymbol{x}^3)$$

$$= \frac{(4\pi)^{3/2}}{[(2l_1+1)(2l_2+1)(2l_3+1)]^{\frac{1}{2}}}$$

$$\times \sum_{m_1 m_2 m_3}\begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix}$$

$$\times \mathcal{Y}_{l_1 m_1}(\boldsymbol{x}^1)\mathcal{Y}_{l_2 m_2}(\boldsymbol{x}^2)\mathcal{Y}_{l_3 m_3}(\boldsymbol{x}^3) ,$$

where $\begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix}$ is a 3–j coefficient (Sect. 2.7).

$$I_{(l_1 l_2 l_3)}(\boldsymbol{x}^1,\boldsymbol{x}^2,0)$$

$$= \delta_{l_1 l_2}\delta_{l_3 0}(-1)^{l_1} I_{l_1}(\boldsymbol{x}^1,\boldsymbol{x}^2)/(2l_1+1)^{\frac{1}{2}} .$$

Product law:

$$I_{(l)}(\boldsymbol{x})I_{(k)}(\boldsymbol{x})$$

$$= \sum_{(j)}\left[\prod_{\alpha=1}^{3}(-1)^{j_\alpha}(2j_\alpha+1)\begin{pmatrix} l_\alpha & k_\alpha & j_\alpha \\ 0 & 0 & 0 \end{pmatrix}\right.$$

$$\left.\times(\boldsymbol{x}^\alpha\cdot\boldsymbol{x}^\alpha)^{(l_\alpha+k_\alpha-j_\alpha)/2}\right]\begin{Bmatrix} l_1 & l_2 & l_3 \\ k_1 & k_2 & k_3 \\ j_1 & j_2 & j_3 \end{Bmatrix} I_{(j)}(\boldsymbol{x}) ,$$

where $l = (l_1, l_2, l_3)$, etc., $\boldsymbol{x} = (\boldsymbol{x}^1, \boldsymbol{x}^2, \boldsymbol{x}^3)$.
Coplanar vectors:

$$I_{(l)}(\boldsymbol{x}^1,\boldsymbol{x}^2,\alpha\boldsymbol{x}^1+\beta\boldsymbol{x}^2)$$

$$= \sum_{kl}\left(\frac{(2l_3+1)!}{(2l_3-2k)!(2k)!}\right)^{\frac{1}{2}}$$

$$\times\alpha^{l_3-k}\beta^k(-1)^{l_1+l_3+k}(2l+1)$$

$$\times\begin{pmatrix} l_3-k & l_1 & l \\ 0 & 0 & 0 \end{pmatrix}\begin{pmatrix} k & l_2 & l \\ 0 & 0 & 0 \end{pmatrix}\begin{Bmatrix} l_3-k & l_3 & k \\ l_2 & l & l_1 \end{Bmatrix}$$

$$\times(\boldsymbol{x}^1\cdot\boldsymbol{x}^1)^{(l_1+l_3-l-k)/2}(\boldsymbol{x}^2\cdot\boldsymbol{x}^2)^{(l_2+k-l)/2}$$

$$\times I_l(\boldsymbol{x}^1,\boldsymbol{x}^2) .$$

The bracket symbols in these relations are 6–j and 9–j coefficients (Sects. 2.9, 2.10).
Cartan's vectors of zero length:

$$\boldsymbol{\alpha} = \left(-z_1^2+z_2^2, -\mathrm{i}(z_1^2+z_2^2), 2z_1 z_2\right) ,$$

$$\boldsymbol{\alpha}\cdot\boldsymbol{\alpha} = \alpha_1^2+\alpha_2^2+\alpha_3^2 = 0 ,$$

$$\boldsymbol{z} = (z_1, z_2) \in \boldsymbol{C}^2 .$$

Solutions of Laplace's equation using vectors of zero length:

$$\nabla^2(\boldsymbol{\alpha}\cdot\boldsymbol{x})^l = 0 , \quad l = 0, 1, \ldots .$$

Solid harmonics for vectors of zero length:

$$(-1)^m Y_{l,-m}(\boldsymbol{\alpha}) = \frac{(2l)!}{l!}\left(\frac{2l+1}{4\pi}\right)^{\frac{1}{2}} P_{lm}(z_1, z_2) ,$$

$$P_{lm}(z_1, z_2) = \frac{z_1^{l+m} z_2^{l-m}}{\sqrt{(l+m)!(l-m)!}} .$$

Orbital angular momentum operators for vectors of zero length:

$$\boldsymbol{J} = -\mathrm{i}(\boldsymbol{\alpha}\times\nabla_\alpha) ,$$

$$J_+ = z_1\frac{\partial}{\partial z_2} , \quad J_- = z_2\frac{\partial}{\partial z_1} ,$$

$$J_3 = \frac{1}{2}\left(z_1\frac{\partial}{\partial z_1} - z_2\frac{\partial}{\partial z_2}\right) .$$

Rotational invariant for vectors of zero length:

$$(\boldsymbol{\alpha} \cdot \boldsymbol{x})^l = \left(\frac{4\pi}{2l+1}\right)^{\frac{1}{2}} 2^l l! \sum_m P_{lm}(z)\, \mathcal{Y}_{lm}(\boldsymbol{x}) .$$

Spinorial invariant under $z^i \to Uz^i$ $(i = 1, 2, 3)$:

$$\sum_{m_1 m_2 m_3} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} P_{j_1 m_1}(z^1) P_{j_2 m_2}(z^2) P_{j_3 m_3}(z^3)$$

$$= [(j_1 + j_2 + j_3 + 1)!]^{-1/2}$$

$$\times \frac{(z_{12}^{12})^{j_1+j_2-j_3} (z_{12}^{31})^{j_3+j_1-j_2} (z_{12}^{23})^{j_2+j_3-j_1}}{[(j_1 + j_2 - j_3)!(j_3 + j_1 - j_2)!(j_2 + j_3 - j_1)!]^{\frac{1}{2}}} ,$$

$$z_{12}^{ij} = z_1^i z_2^j - z_1^j z_2^i .$$

This relation is invariant under the transformation

$$z \to Uz = \big((Uz)_1, (Uz)_2\big)$$
$$= (u_{11}z_1 + u_{12}z_2, u_{21}z_1 + u_{22}z_2) ,$$

where $U \in SU(2)$. Transformation properties of vectors of zero length:

$$\boldsymbol{\alpha} \to R\boldsymbol{\alpha} , \quad \boldsymbol{\alpha} = \mathrm{col}(\alpha_1, \alpha_2, \alpha_3) ,$$

where $z \to Uz$ and R is given in terms of U in the beginning of this chapter. Simultaneous eigenvectors of $\boldsymbol{L}^2$ and $\boldsymbol{J}^2$:

$$\boldsymbol{L}^2 (\boldsymbol{\alpha} \cdot \boldsymbol{x})^l = l(l+1)(\boldsymbol{\alpha} \cdot \boldsymbol{x})^l , \quad l = 0, 1, \ldots ,$$

$$\boldsymbol{J}^2 (\boldsymbol{\alpha} \cdot \boldsymbol{x})^l = l(l+1)(\boldsymbol{\alpha} \cdot \boldsymbol{x})^l , \quad l = 0, 1, \ldots .$$

2.1.2 Spherical Polar Coordinate Representation

The results given in Sect. 2.1.1 may be presented in any system of coordinates well-defined in terms of Cartesian coordinates. The principal relations for spherical polar coordinates are given in this section, where a vector in $\boldsymbol{R}^3$ is now given in the form

$$\boldsymbol{x} = r\hat{\boldsymbol{x}} = r(\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta) ,$$
$$0 \le \theta \le \pi, \quad 0 \le \phi < 2\pi .$$

Orbital angular momentum operators:

$$L_1 = \mathrm{i}\cos\phi\cot\theta\frac{\partial}{\partial\phi} + \mathrm{i}\sin\phi\frac{\partial}{\partial\theta} ,$$

$$L_2 = \mathrm{i}\sin\phi\cot\theta\frac{\partial}{\partial\phi} - \mathrm{i}\cos\phi\frac{\partial}{\partial\theta} ,$$

$$L_3 = -\mathrm{i}\frac{\partial}{\partial\phi} ,$$

$$L_\pm = \mathrm{e}^{\pm\mathrm{i}\phi}\left(\pm\frac{\partial}{\partial\theta} + \mathrm{i}\cot\theta\frac{\partial}{\partial\phi}\right) ,$$

$$\boldsymbol{L}^2 = -\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}\right) - \frac{1}{\sin^2\theta}\frac{\partial^2}{\partial\phi^2} .$$

Laplacian:

$$\boldsymbol{x}\cdot\nabla = r\frac{\partial}{\partial r} ,$$

$$\nabla^2 = \frac{1}{r^2}\left[\left(r\frac{\partial}{\partial r}\right)^2 + r\frac{\partial}{\partial r} - \boldsymbol{L}^2\right] .$$

Spherical harmonics (solid harmonics on the unit sphere $\boldsymbol{S}^2$):

$$Y_{lm}(\theta, \phi) = (-1)^m \left(\frac{2l+1}{4\pi}(l+m)!(l-m)!\right)^{\frac{1}{2}} \mathrm{e}^{\mathrm{i}m\phi}$$

$$\times \sum_k \frac{(-1)^k (\sin\theta)^{2k+m}(\cos\theta)^{l-2k-m}}{2^{2k+m}(k+m)!k!(l-2k-m)!} .$$

Orthogonality on the unit sphere:

$$\int\limits_0^{2\pi} \mathrm{d}\phi \int\limits_0^{\pi} \mathrm{d}\theta \sin\theta\, Y_{l'm'}^*(\theta, \phi)\, Y_{lm}(\theta, \phi) = \delta_{l'l}\delta_{m'm} .$$

Relation to Legendre, Jacobi, and Gegenbauer polynomials:

$$Y_{lm}(\theta, \phi) = (-1)^m \left(\frac{(2l+1)(l-m)!}{4\pi(l+m)!}\right)^{\frac{1}{2}}$$

$$\times P_l^m(\cos\theta)\, \mathrm{e}^{\mathrm{i}m\phi} ,$$

$$P_l^m(\cos\theta) = \frac{(l+m)!}{l!}\left(\frac{\sin\theta}{2}\right)^m P_{l-m}^{(m,m)}(\cos\theta) .$$

Jacobi polynomials:

$$P_n^{(\alpha,\beta)}(x) = \sum_s \binom{n+\alpha}{s}\binom{n+\beta}{n-s}$$

$$\times \left(\frac{x-1}{2}\right)^{n-s}\left(\frac{x+1}{2}\right)^s ,$$

$$n = 0, 1, \ldots ,$$

where α, β are arbitrary parameters and

$$
\binom{z}{k} = \begin{cases} z(z-1)\cdots(z-k+1)/k! \\ \qquad\qquad\qquad \text{for } k = 1, 2, \dots \\ 1 \qquad\qquad\quad \text{for } k = 0 \\ 0 \qquad\qquad\quad \text{for } k = -1, -2, \dots \end{cases}
$$

Relations between Jacobi polynomials for $n+\alpha$, $n+\beta$, $n+\alpha+\beta$ nonnegative integers:

$$
P_n^{\alpha,\beta}(x) = \frac{(n+\alpha)!(n+\beta)!}{n!(n+\alpha+\beta)!}\left(\frac{x+1}{2}\right)^{-\beta} P_{n+\beta}^{(\alpha,-\beta)}(x) ,
$$

$$
P_n^{\alpha,\beta}(x) = \frac{(n+\alpha)!(n+\beta)!}{n!(n+\alpha+\beta)!}\left(\frac{x-1}{2}\right)^{-\alpha} P_{n+\alpha}^{(-\alpha,\beta)}(x) ,
$$

$$
P_n^{\alpha,\beta}(x) = \left(\frac{x-1}{2}\right)^{-\alpha}\left(\frac{x+1}{2}\right)^{-\beta} P_{n+\alpha+\beta}^{(-\alpha,-\beta)}(x) .
$$

Nonstandard form (α arbitrary):

$$
P_n^{(\alpha,\alpha)}(x) = \sum_s \frac{(-1)^s(\alpha+s+1)_{n-s}\left(1-x^2\right)^s x^{n-2s}}{2^{2s}s!(n-2s)!} ,
$$

$$
(z)_k = z(z+1)\cdots(z+k-1) , \quad k = 1, 2, \dots ;
$$

$$
(z)_0 = 1 .
$$

Gegenbauer polynomials ($\alpha > -1/2$):

$$
C_n^{(\alpha)}(x) = \frac{(2\alpha)_n}{(\alpha+1/2)_n} P_n^{\left(\alpha-\frac{1}{2},\alpha-\frac{1}{2}\right)}(x)
$$

$$
= \sum_s \frac{(-1)^s(\alpha)_{n-s}(2x)^{n-2s}}{s!(n-2s)!} .
$$

2.2 Abstract Angular Momentum

Abstract angular momentum theory addresses the problem of constructing all finite Hermitian matrices, up to equivalence, that satisfy the same commutation relations

$$
[J_1, J_2] = \mathrm{i}J_3 , \quad [J_2, J_3] = \mathrm{i}J_1 , \quad [J_3, J_1] = \mathrm{i}J_2 \tag{2.7}
$$

as some set of Hermitian operators J_1, J_2, J_3 appropriately defined in some Hilbert space; that is, of constructing all finite Hermitian matrices M_i such that under the correspondence $J_i \to M_i (i = 1, 2, 3)$ the commutation relations are still obeyed. If M_1, M_2, M_3 is such a set of Hermitian matrices, then AM_1A^{-1}, AM_2A^{-1}, AM_3A^{-1}, is another such set, where A is an arbitrary unitary matrix. This defines what is meant by equivalence. The commutation relations (2.7) may also be formulated as:

$$
[J_3, J_\pm] = \pm J_\pm , \qquad [J_+, J_-] = 2J_3 ,
$$

$$
J_\pm = J_1 \pm \mathrm{i}J_2 , \qquad J_+^\dagger = J_- . \tag{2.8}
$$

The squared angular momentum

$$
\boldsymbol{J}^2 = J_1^2 + J_2^2 + J_3^2 = J_-J_+ + J_3(J_3+1)
$$
$$
= J_+J_- + J_3(J_3-1) \tag{2.9}
$$

commutes with each J_i, and J_3 is, by convention, taken with $\boldsymbol{J}^2$ as a pair of commuting Hermitian operators to be diagonalized.

Examples of matrices satisfying relations (2.7) are provided by $J_i \to \sigma_i/2$ [the 2×2 Hermitian Pauli matrices defined in (2.1)] and $J_i \to M_i$ [the 3×3 matrices defined in (2.4)], these latter matrices being equivalent to those obtained from the matrices of the orbital angular momentum operators for $l = 1$.

One could determine all Hermitian matrices solving (2.7) and (2.8) by using only matrix theory, but it is customary in quantum mechanics to formulate the problem using Hilbert space concepts appropriate to that theory. Thus, one takes the viewpoint that the J_i are linear Hermitian operators with an action defined in a separable Hilbert space $\mathcal{H}$ such that $J_i : \mathcal{H} \to \mathcal{H}$.

One then seeks to decompose the Hilbert space into a direct sum of subspaces that are irreducible with respect to this action; that is, subspaces that cannot be further decomposed as a direct sum of subspaces that all the J_i leave invariant (map vectors in the space into vectors in the space). In this section, the solution of this fundamental problem for angular momentum theory is given. These results set the notation and phase conventions for all of angular momentum theory, in all of its varied realizations, and the relations are therefore sometimes referred to as standard. The method most often used to solve the posed problem is called the method of highest weights.

The solution of this problem is among the most important in quantum theory because of its generality and applicability to a wide range of problems. The space $\mathcal{H}$ can be written as a direct sum

$$
\mathcal{H} = \sum_{j=0,\frac{1}{2},1,\dots} \oplus\, n_j\mathcal{H}_j ,
$$
$$
\text{each } \mathcal{H}_j \perp \mathcal{H}_{j'} , \quad j \neq j' , \tag{2.10}
$$

in which $\mathcal{H}_j$ denotes a vector space of dimension $2j+1$ that is invariant and irreducible under the action of the set of operators J_i, $i = 1, 2, 3$, and where the direct sum is over all half integers $j = 0, \frac{1}{2}, 1, \ldots$. There may be multiple occurrences, n_j in number, of the same space $\mathcal{H}_j$ for given j, or no such space, $n_j = 0$, in the direct sum. Abstractly, in so far as angular momentum properties are concerned, each repeated space $\mathcal{H}_j$ is *identical*. Such spaces may, however, be distinguished by their properties with respect to other physical observables, but not by the angular action of momentum operators themselves. The result, (2.10), applies to any physical system, no matter how complex, in which rotational symmetry, hence $SU(2)$ symmetry, is present, even in situations of higher symmetry where $SU(2)$ is a subgroup. Indeed, the resolution of the terms in (2.10) for various physical systems constitutes "spectroscopy" in the broadest sense.

The characterization of the space $\mathcal{H}_j$ with respect to angular momentum properties is given by the following results, where basis vectors are denoted in the Dirac braket notation.

Orthonormal basis:

$$\{|jm\rangle\, |\, m = -j, -j+1, \ldots, j\}\,. \tag{2.11}$$

$$\langle jm'|\, jm \rangle = \delta_{m',m}\,. \tag{2.12}$$

Simultaneous eigenvectors:

$$\boldsymbol{J}^2|\, jm\rangle = j(j+1)|\, jm\rangle\,, \quad J_3|\, jm\rangle = m|\, jm\rangle\,. \tag{2.13}$$

Action of angular momentum operators:

$$J_+|\, jm\rangle = [(j-m)(j+m+1)]^{1/2}|\, jm+1\rangle\,,$$
$$J_-|\, jm\rangle = [(j+m)(j-m+1)]^{1/2}|\, jm-1\rangle\,. \tag{2.14}$$

Defining properties of highest weight vector:

$$J_+|\, jj\rangle = 0\,, \quad J_3|\, jj\rangle = j|\, jj\rangle\,.$$

Generation of general vector from highest weight:

$$|\, jm\rangle = \left(\frac{(j+m)!}{(2j)!(j-m)!} \right)^{1/2} J_-^{j-m}|\, jj\rangle\,.$$

Necessary property of lowest weight vector:

$$J_-|\, j, -j\rangle = 0\,, \quad J_3|\, j, -j\rangle = -j|\, j, -j\rangle\,.$$

Operator in $\mathcal{H}$ corresponding to a rotation by angle ψ about direction $\hat{\boldsymbol{n}}$ in $\boldsymbol{R}^3$:

$$T_{U(\psi, \hat{\boldsymbol{n}})} = \exp(-\mathrm{i}\psi\hat{\boldsymbol{n}}\cdot \boldsymbol{J})\,,$$
$$\hat{\boldsymbol{n}}\cdot\hat{\boldsymbol{n}} = n_1^2 + n_2^2 + n_3^2 = 1\,,$$
$$\hat{\boldsymbol{n}}\cdot\boldsymbol{J} = n_1 J_1 + n_2 J_2 + n_3 J_3\,,$$
$$U(\psi, \hat{\boldsymbol{n}}) = \exp(-\mathrm{i}\psi\hat{\boldsymbol{n}}\cdot\boldsymbol{\sigma}/2)$$
$$= \sigma_0 \cos\left(\tfrac{1}{2}\psi\right) - \mathrm{i}(\hat{\boldsymbol{n}}\cdot\boldsymbol{\sigma})\sin\left(\tfrac{1}{2}\psi\right)$$
$$= \begin{pmatrix} \cos\left(\tfrac{1}{2}\psi\right) - \mathrm{i}n_3\sin\left(\tfrac{1}{2}\psi\right) & (-\mathrm{i}n_1 - n_2)\sin\left(\tfrac{1}{2}\psi\right) \\ (-\mathrm{i}n_1 + n_2)\sin\left(\tfrac{1}{2}\psi\right) & \cos\left(\tfrac{1}{2}\psi\right) + \mathrm{i}n_3\sin\left(\tfrac{1}{2}\psi\right) \end{pmatrix}\,,$$
$$0 \le \psi \le 2\pi, \tag{2.15}$$

where σ_0 denotes the 2×2 unit matrix.

Action of $T_{U(\psi, \hat{\boldsymbol{n}})}$ on $\mathcal{H}_j$:

$$T_U|\, jm\rangle = \sum_{m'} D^j_{m'm}(U)|\, jm'\rangle\,, \tag{2.16}$$

in which $U = U(\psi, \hat{\boldsymbol{n}})$ and $D^j_{m'm}(U)$ denotes a homogeneous polynomial of degree $2j$ defined on the elements $u_{ij} = U_{ij}(\psi, \hat{\boldsymbol{n}})$ in row i and column j of the matrix $U(\psi, \hat{\boldsymbol{n}})$ given by (2.15). The explicit form of this polynomial is

$$D^j_{m'm}(U)$$
$$= [(j+m)!(j-m)!(j+m')!(j-m')!]^{\frac{1}{2}}$$
$$\times \sum_{\boxed{\alpha}} \frac{(u_{11})^{\alpha_{11}}(u_{12})^{\alpha_{12}}(u_{21})^{\alpha_{21}}(u_{22})^{\alpha_{22}}}{\alpha_{11}!\alpha_{12}!\alpha_{21}!\alpha_{22}!}\,. \tag{2.17}$$

The notation $\boxed{\alpha}$ symbolizes a 2×2 array of nonnegative integers with certain constraints:

$$\begin{array}{|cc|c} \alpha_{11} & \alpha_{12} & j+m' \\ \alpha_{21} & \alpha_{22} & j-m' \\ \hline j+m & j-m \end{array}\,.$$

In this array the α_{ij} are nonnegative integers subject to the row and column constraints (sums) indicated by the (nonnegative) integers $j\pm m$, $j\pm m'$. Explicitly,

$$\alpha_{11} + \alpha_{12} = j+m'\,, \qquad \alpha_{21} + \alpha_{22} = j-m'\,,$$
$$\alpha_{11} + \alpha_{21} = j+m\,, \qquad \alpha_{12} + \alpha_{22} = j-m\,.$$

The summation is over all such arrays. Any one of the α_{ij} may serve as a single summation index if one wishes to

eliminate the redundancy inherent in the square-array notation. The form (2.17) is very useful for obtaining symmetry relations for these polynomials (Sect. 2.3.6). Unitary property on $\mathcal{H}$:

$$\langle T_U \Psi | T_U \Psi \rangle = \langle \Psi | \Psi \rangle , \qquad \text{each } \Psi \in \mathcal{H} .$$

Irreducible unitary matrix representation of $SU(2)$:

$$(D^j(U))_{j-m'+1, j-m+1} = D^j_{m'm}(U) ,$$
$$m' = j, j-1, \dots, -j ; \quad m = j, j-1, \dots, -j , \tag{2.18}$$

denotes the element in row $j - m' + 1$ and column $j - m + 1$. Then, dimension of $D^j(U) = 2j + 1$ and

$$D^j(U) D^j(U') = D^j(UU') ,$$
$$U \in SU(2) , \quad U' \in SU(2) ,$$
$$(D^j(U))^\dagger = (D^j(U))^{-1} = D^j(U^\dagger) .$$

Kronecker (direct) product representation:

$$D^{j_1}(U) \times D^{j_2}(U)$$

is a $(2j_1 + 1)(2j_2 + 1)$ dimensional reducible representation of $SU(2)$. One can also effect the reduction of this representation into irreducible ones by abstract methods. The results are given in Sect. 2.7.

2.3 Representation Functions

2.3.1 Parametrizations of the Groups SU(2) and SO(3,R)

The irreducible representations of the quantal rotation group, $SU(2)$, are among the most important quantities in all of angular momentum theory: These are the unitary matrices of dimension $2j + 1$, denoted by $D^j(U)$, where this notation is used to signify that the elements of this matrix, denoted $D^j_{m'm}(U)$, are functions of the elements u_{ij} of the 2×2 unitary unimodular matrix $U \in SU(2)$. It has become standard to enumerate the rows and columns of these matrices in the order $j, j-1, \dots, -j$ as read from top to bottom down the rows and from left to right across the columns [see also (2.18)]. These matrices may be presented in a variety of parametrizations, all of which are useful. In order to make comparisons between the group $SO(3, \mathbf{R})$ and the group $SU(2)$, it is most useful to parametrize these groups so that they are related according to the two-to-one homomorphism given by (2.2).

The general parametrization of the group $SU(2)$ is given in terms of the Euler–Rodrigues parameters corresponding to points belonging to the surface of the unit sphere $\mathbf{S}^3$ in $\mathbf{R}^4$,

$$\alpha_0^2 + \alpha_1^2 + \alpha_2^2 + \alpha_3^2 = 1 . \tag{2.19}$$

Each $U \in SU(2)$ can be written in the form:

$$U(\alpha_0, \boldsymbol{\alpha}) = \begin{pmatrix} \alpha_0 - \mathrm{i}\alpha_3 & -\mathrm{i}\alpha_1 - \alpha_2 \\ -\mathrm{i}\alpha_1 + \alpha_2 & \alpha_0 + \mathrm{i}\alpha_3 \end{pmatrix}$$
$$= \alpha_0 \sigma_0 - \mathrm{i}\boldsymbol{\alpha} \cdot \boldsymbol{\sigma} . \tag{2.20}$$

The $R \in SO(3, \mathbf{R})$ corresponding to this U in the two-to-one homomorphism given by (2.2) is:

$$R(\alpha_0, \boldsymbol{\alpha}) =$$
$$\begin{pmatrix} \alpha_0^2 + \alpha_1^2 - \alpha_2^2 - \alpha_3^2 & 2\alpha_1\alpha_2 - 2\alpha_0\alpha_3 & 2\alpha_1\alpha_3 + 2\alpha_0\alpha_2 \\ 2\alpha_1\alpha_2 + 2\alpha_0\alpha_3 & \alpha_0^2 + \alpha_2^2 - \alpha_3^2 - \alpha_1^2 & 2\alpha_2\alpha_3 - 2\alpha_0\alpha_1 \\ 2\alpha_1\alpha_3 - 2\alpha_0\alpha_2 & 2\alpha_2\alpha_3 + 2\alpha_0\alpha_1 & \alpha_0^2 + \alpha_3^2 - \alpha_1^2 - \alpha_2^2 \end{pmatrix} . \tag{2.21}$$

The procedure of parametrization is implemented uniformly by first parametrizing the points on the unit sphere $\mathbf{S}^3$ so as to cover the points in $\mathbf{S}^3$ exactly once, thus obtaining a parametrization of each $U \in SU(2)$. Equation (2.21) is then used to obtain the corresponding parametrization of each $R \in SO(3, \mathbf{R})$, where one notes that $R(-\alpha_0, -\boldsymbol{\alpha}) = R(\alpha_0, \boldsymbol{\alpha})$. Because of this two-to-one correspondence $\pm U \to R$, the domain of the parameters that cover the unit sphere $\mathbf{S}^3$ exactly once will cover the group $SO(3, \mathbf{R})$ exactly twice. This is taken into account uniformly by redefining the domain for $SO(3, \mathbf{R})$ so as to cover only the upper hemisphere ($\alpha_0 \geq 0$) of $\mathbf{S}^3$.

In the active viewpoint (reference frame fixed with points being transformed into new points), an arbitrary vector $\mathbf{x} = \mathrm{col}(x_1, x_2, x_3) \in \mathbf{R}^3$ is transformed to the new vector $\mathbf{x}' = \mathrm{col}(x_1', x_2', x_3')$ by the rule $\mathbf{x}' = R\mathbf{x}$, or, equivalently, in terms of the Cartan matrix: $X' = UXU^\dagger$. In the passive viewpoint, the basic inertial reference system, which is taken to be a right-handed triad of unit vectors $(\hat{\mathbf{e}}_1, \hat{\mathbf{e}}_2, \hat{\mathbf{e}}_3)$, is transformed by R to a new right-handed triad $(\hat{\mathbf{f}}_1, \hat{\mathbf{f}}_2, \hat{\mathbf{f}}_3)$ by the

rule

$$\hat{f}_j = \sum_i R_{ij}\hat{e}_i, \quad i = 1, 2, 3,$$

so that $\hat{e}_i \cdot \hat{f}_j = R_{ij}$. In this viewpoint, the coordinates of one and the same point P undergo a redescription under the change of frame. If the coordinates of P are (x_1, x_2, x_3) relative to the frame $(\hat{e}_1, \hat{e}_2, \hat{e}_3)$ and (x_1', x_2', x_3') relative to the frame $(\hat{f}_1, \hat{f}_2, \hat{f}_3)$, then

$$x_1\hat{e}_1 + x_2\hat{e}_2 + x_3\hat{e}_3 = x_1'\hat{f}_1 + x_2'\hat{f}_2 + x_3'\hat{f}_3,$$

so that $x' = R^T x$.

Rotation about direction $\hat{n} \in S^2$ by positive angle ψ (right-hand rule):

$$(\alpha_0, \boldsymbol{\alpha}) = \left(\cos\frac{1}{2}\psi, \, \hat{n}\sin\frac{1}{2}\psi\right), \quad 0 \le \psi \le 2\pi,$$

$$U(\psi, \hat{n}) = \exp\left(-\mathrm{i}\frac{1}{2}\psi\hat{n}\cdot\boldsymbol{\sigma}\right) =$$

$$\begin{pmatrix} \cos\frac{1}{2}\psi - \mathrm{i}n_3\sin\frac{1}{2}\psi & (-\mathrm{i}n_1 - n_2)\sin\frac{1}{2}\psi \\ (-\mathrm{i}n_1 + n_2)\sin\frac{1}{2}\psi & \cos\frac{1}{2}\psi + \mathrm{i}n_3\sin\frac{1}{2}\psi \end{pmatrix},$$

$$R(\psi, \hat{n}) = \exp(-\mathrm{i}\psi\hat{n}\cdot\boldsymbol{M}), \quad 0 \le \psi \le \pi$$

$$= I_3 - \mathrm{i}\sin\psi(\hat{n}\cdot\boldsymbol{M}) - (\hat{n}\cdot\boldsymbol{M})^2(1 - \cos\psi)$$

$$= \begin{pmatrix} R_{11} & R_{12} & R_{13} \\ R_{21} & R_{22} & R_{23} \\ R_{31} & R_{32} & R_{33} \end{pmatrix},$$

$$R_{11} = n_1^2 + (1 - n_1^2)\cos\psi,$$
$$R_{21} = n_1n_2(1 - \cos\psi) + n_3\sin\psi,$$
$$R_{31} = n_1n_3(1 - \cos\psi) - n_2\sin\psi,$$
$$R_{12} = n_1n_2(1 - \cos\psi) - n_3\sin\psi,$$
$$R_{22} = n_2^2 + (1 - n_2^2)\cos\psi,$$
$$R_{32} = n_2n_3(1 - \cos\psi) + n_1\sin\psi,$$
$$R_{13} = n_1n_3(1 - \cos\psi) + n_2\sin\psi,$$
$$R_{23} = n_2n_3(1 - \cos\psi) - n_1\sin\psi,$$
$$R_{33} = n_3^2 + (1 - n_3^2)\cos\psi.$$

The unit vector $\hat{n} \in S^2$ can be further parametrized in terms of the usual spherical polar coordinates:

$$\hat{n} = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta),$$
$$0 \le \theta \le \pi, \quad 0 \le \phi < 2\pi.$$

Euler angle parametrization:

$$U(\alpha\beta\gamma) = \mathrm{e}^{-\mathrm{i}\alpha\sigma_3/2}\,\mathrm{e}^{-\mathrm{i}\beta\sigma_2/2}\,\mathrm{e}^{-\mathrm{i}\gamma\sigma_3/2}$$

$$= \begin{pmatrix} \mathrm{e}^{-\mathrm{i}\alpha/2}\cos\left(\frac{1}{2}\beta\right)\mathrm{e}^{-\mathrm{i}\gamma/2} & -\mathrm{e}^{-\mathrm{i}\alpha/2}\sin\left(\frac{1}{2}\beta\right)\mathrm{e}^{\mathrm{i}\gamma/2} \\ \mathrm{e}^{\mathrm{i}\alpha/2}\sin\left(\frac{1}{2}\beta\right)\mathrm{e}^{-\mathrm{i}\gamma/2} & \mathrm{e}^{\mathrm{i}\alpha/2}\cos\left(\frac{1}{2}\beta\right)\mathrm{e}^{\mathrm{i}\gamma/2} \end{pmatrix},$$

$$0 \le \alpha < 2\pi, \quad 0 \le \beta \le \pi \quad \text{or } 2\pi \le \beta \le 3\pi,$$

$$0 \le \gamma < 2\pi,$$

$$U(\alpha, \beta + 2\pi, \gamma) = -U(\alpha\beta\gamma);$$

$$R(\alpha\beta\gamma) = \mathrm{e}^{-\mathrm{i}\alpha M_3}\,\mathrm{e}^{-\mathrm{i}\beta M_2}\,\mathrm{e}^{-\mathrm{i}\gamma M_3}$$

$$= \begin{pmatrix} \cos\alpha & -\sin\alpha & 0 \\ \sin\alpha & \cos\alpha & 0 \\ 0 & 0 & 1 \end{pmatrix}\begin{pmatrix} \cos\beta & 0 & \sin\beta \\ 0 & 1 & 0 \\ -\sin\beta & 0 & \cos\beta \end{pmatrix}$$

$$\times \begin{pmatrix} \cos\gamma & -\sin\gamma & 0 \\ \sin\gamma & \cos\gamma & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

$$= \begin{pmatrix} \cos\alpha\cos\beta\cos\gamma & -\cos\alpha\cos\beta\sin\gamma & \cos\alpha\sin\beta \\ -\sin\alpha\sin\gamma & -\sin\alpha\cos\gamma & \\ \sin\alpha\cos\beta\cos\gamma & -\sin\alpha\cos\beta\sin\gamma & \sin\alpha\sin\beta \\ +\cos\alpha\sin\gamma & +\cos\alpha\cos\gamma & \\ -\sin\beta\cos\gamma & \sin\beta\sin\gamma & \cos\beta \end{pmatrix}$$

$$0 \le \alpha < 2\pi, \quad 0 \le \beta \le \pi, \quad 0 \le \gamma < 2\pi.$$

This matrix corresponds to the sequence of frame rotations given by

> rotate by γ about $\hat{e}_3 = (0, 0, 1)$,
> rotate by β about $\hat{e}_2 = (0, 1, 0)$,
> rotate by α about $\hat{e}_3 = (0, 0, 1)$.

Equivalently, it corresponds to the sequence of frame rotations given by

> rotate by α about $\hat{n}_1 = (0, 0, 1)$,
> rotate by β about $\hat{n}_2 = (-\sin\alpha, \cos\alpha, 0)$,
> rotate by γ about $\hat{n}_3 =$
> $\qquad (\cos\alpha\sin\beta, \sin\alpha\sin\beta, \cos\beta)$.

This latter sequence of rotations is depicted in Fig. 2.1 in obtaining the frame $(\hat{f}_1, \hat{f}_2, \hat{f}_3)$ from $(\hat{e}_1, \hat{e}_2, \hat{e}_3)$.

The four complex numbers

$$(a, b, c, d)$$
$$= (\alpha_0 + \mathrm{i}\alpha_3, \mathrm{i}\alpha_1 - \alpha_2, \mathrm{i}\alpha_1 + \alpha_2, \alpha_0 - \mathrm{i}\alpha_3)$$
Fig. 2.1 Euler angles. The three Euler angles $(\alpha\beta\gamma)$ are defined by a sequence of three rotations. Reprinted with the permission of Cambridge University Press, after [2.1]

are called the Cayley–Klein parameters, whereas the four real numbers $(\alpha_0, \boldsymbol{\alpha})$ defining a point on the surface of the unit sphere in four-space, $\boldsymbol{S}^3$, are known as the Euler–Rodrigues parameters. The three ratios α_i/α_0 form the homogeneous or symmetric Euler parameters.

2.3.2 Explicit Forms of Representation Functions

The general form of the representation functions is given in its most basic and symmetric form in (2.17). This form applies to every parametrization, it being necessary only to introduce the explicit parametrizations of $U \in SU(2)$ or $R \in SO(3, \boldsymbol{R})$ given in Sect. 2.3.1 to obtain the explicit results given in this section. A choice is also made for the single independent summation parameter in the α-array. The notation for functions is abused by writing

$$D^j(\omega) = D^j(U(\omega)) \,,$$
$$\omega = \text{ set of parameters of } U \in SU(2) \,.$$

Euler–Rodrigues representation $\big[(\alpha_0, \boldsymbol{\alpha}) \in \boldsymbol{S}^3\big]$:

$$D^j_{m'm}(\alpha_0, \boldsymbol{\alpha})$$
$$= [(j+m')!(j-m')!(j+m)!(j-m)!]^{\frac{1}{2}}$$
$$\times \sum_s \frac{(\alpha_0 - i\alpha_3)^{j+m-s}(-i\alpha_1 - \alpha_2)^{m'-m+s}}{(j+m-s)!(m'-m+s)!}$$
$$\times \frac{(-i\alpha_1 + \alpha_2)^s(\alpha_0 + i\alpha_3)^{j-m'-s}}{s!(j-m'-s)!} \,. \tag{2.22}$$

Quaternionic multiplication rule for points on the sphere $\boldsymbol{S}^3$:

$$(\alpha_0', \boldsymbol{\alpha}')(\alpha_0, \boldsymbol{\alpha}) = (\alpha_0'', \boldsymbol{\alpha}'') \,,$$
$$\alpha_0'' = \alpha_0'\alpha_0 - \boldsymbol{\alpha}' \cdot \boldsymbol{\alpha} \,,$$
$$\boldsymbol{\alpha}'' = \alpha_0'\boldsymbol{\alpha} + \alpha_0\boldsymbol{\alpha}' + \boldsymbol{\alpha}' \times \boldsymbol{\alpha} \,;$$
$$D^j(\alpha_0', \boldsymbol{\alpha}') D^j(\alpha_0, \boldsymbol{\alpha}) = D^j(\alpha_0'', \boldsymbol{\alpha}'') \,.$$

The $(\psi, \hat{\boldsymbol{n}})$ parameters:

$$\alpha_0 = \cos\frac{1}{2}\psi \,, \quad \boldsymbol{\alpha} = \hat{\boldsymbol{n}}\sin\frac{1}{2}\psi \,.$$

Euler angle parametrization:

$$D^j_{m'm}(\alpha\beta\gamma) = e^{-im'\alpha} d^j_{m'm}(\beta) e^{-im\gamma} \,,$$
$$d^j_{m'm}(\beta) = \langle jm'|e^{-i\beta J_2}|jm\rangle$$
$$= [(j+m')!(j-m')!(j+m)!(j-m)!]^{\frac{1}{2}}$$
$$\times \sum_s \frac{(-1)^{m'-m+s}\left(\cos\frac{1}{2}\beta\right)^{2j+m-m'-2s}}{(j+m-s)!s!(m'-m+s)!}$$
$$\times \frac{\left(\sin\frac{1}{2}\beta\right)^{m'-m+2s}}{(j-m'-s)!} \,. \tag{2.23}$$

Explicit matrices:

$$d^{\frac{1}{2}}(\beta) = \begin{pmatrix} \cos\frac{1}{2}\beta & -\sin\frac{1}{2}\beta \\ \sin\frac{1}{2}\beta & \cos\frac{1}{2}\beta \end{pmatrix} \,,$$

$$d^1(\beta) = \begin{pmatrix} \dfrac{1+\cos\beta}{2} & \dfrac{-\sin\beta}{\sqrt{2}} & \dfrac{1-\cos\beta}{2} \\[2mm] \dfrac{\sin\beta}{\sqrt{2}} & \cos\beta & \dfrac{-\sin\beta}{\sqrt{2}} \\[2mm] \dfrac{1-\cos\beta}{2} & \dfrac{\sin\beta}{\sqrt{2}} & \dfrac{1+\cos\beta}{2} \end{pmatrix} \,.$$

Formal polynomial form (z_{ij} are indeterminates):

$$D^j_{m'm}(Z) = [(j+m')!(j-m')!(j+m)!(j-m)!]^{\frac{1}{2}}$$
$$\times \sum_{\boxed{\alpha}} \prod_{i,j=1}^{2} (z_{ij})^{\alpha_{ij}}/(\alpha_{ij})! \,, \tag{2.24}$$

$$D^j(Z') D^j(Z) = D^j(Z'Z) \,.$$

Boson operator form:

Put $a_i^j = z_{ij}$ ($i, j = 1, 2$) in (2.24). Let $\bar{a}_i^j$ denote the Hermitian conjugate boson so that

$$\left[a_l^k, a_i^j\right] = 0 \,, \quad \left[\bar{a}_l^k, \bar{a}_i^j\right] = 0 \,, \quad \left[\bar{a}_l^k, a_i^j\right] = \delta^{kj}\delta_{li} \,.$$

Then the boson polynomials are orthogonal in the boson inner product:

$$\langle 0 \mid D^{j'}_{\mu'\mu}(\bar{A}) D^{j}_{m'm}(A) \mid 0 \rangle = (2j)! \delta_{j'j} \delta_{\mu'm'} \delta_{\mu m} .$$

2.3.3 Relations to Special Functions

Jacobi polynomials (see Sect. 2.1.2):

$$d^{j}_{m'm}(\beta) = \left(\frac{(j+m)!(j-m)!}{(j+m')!(j-m')!} \right)^{\frac{1}{2}} \left(\sin \frac{1}{2}\beta \right)^{m-m'}$$
$$\times \left(\cos \frac{1}{2}\beta \right)^{m'+m} P^{(m-m', m+m')}_{j-m}(\cos \beta) ,$$
$$d^{j}_{m'm}(\beta) = (-1)^{m'-m} d^{j}_{-m', -m}(\beta)$$
$$= (-1)^{m'-m} d^{j}_{mm'}(\beta) = d^{j}_{mm'}(-\beta) .$$

Legendre polynomials:

$$D^{l}_{m0}(\beta) = (-1)^m \left(\frac{(l-m)!}{(l+m)!} \right)^{\frac{1}{2}} P^{m}_{l}(\cos \beta)$$
$$= \left(\frac{(l+m)!}{(l-m)!} \right)^{\frac{1}{2}} P^{-m}_{l}(\cos \beta) .$$

Spherical harmonics:

$$Y_{lm}(\beta\alpha) = \left(\frac{2l+1}{4\pi} \right)^{\frac{1}{2}} e^{im\alpha} d^{l}_{m0}(\beta)$$
$$= \left(\frac{2l+1}{4\pi} \right)^{\frac{1}{2}} D^{l*}_{m0}(\alpha\beta\gamma) ,$$
$$Y^{*}_{lm}(\beta\alpha) = (-1)^m Y_{l,-m}(\beta\alpha) .$$

Gegenbauer polynomials:

$$d^{l}_{m0}(\beta) = (-1)^m [(l+m)!(l-m)!]^{\frac{1}{2}}$$
$$\times \frac{(2m)!}{m!} \left[\frac{\sin \beta}{2} \right]^m C^{(m+1/2)}_{l-m}(\cos \beta) ,$$
$$m \geq 0 .$$

Solutions of Laplace's equation in $\boldsymbol{R}^4$ (Sect. 2.5):

$$\nabla^2_4 D^{j}_{m'm}(x_0, \boldsymbol{x}) = 0 , \quad (x_0, \boldsymbol{x}) \in \boldsymbol{R}^4 ,$$
$$\nabla^2_4 = \sum_{\mu=0}^{3} \frac{\partial^2}{\partial x^2_\mu} .$$

Replace the Euler–Rodrigues parameters $(\alpha_0, \boldsymbol{\alpha})$ in (2.22) by an arbitrary point $(x_0, \boldsymbol{x}) \in \boldsymbol{R}^4$.

2.3.4 Orthogonality Properties

Inner (scalar) product:

$$(\Psi, \Phi) = \int d\Omega \, \Psi^*(\boldsymbol{x}) \Phi(\boldsymbol{x}) ,$$

$$d\Omega = \text{invariant surface measure for } \boldsymbol{S}^3 ,$$

$$\int_{\boldsymbol{S}^3} d\Omega = 2\pi^2 .$$

Spherical polar coordinate for $\boldsymbol{S}^3$:

$$(\alpha_0, \boldsymbol{\alpha}) =$$
$$(\cos \chi, \cos \phi \sin \theta \sin \chi, \sin \phi \sin \theta \sin \chi, \cos \theta \sin \chi) ,$$
$$0 \leq \theta \leq \pi , \quad 0 \leq \phi < 2\pi , \quad 0 \leq \chi \leq \pi ,$$
$$d\Omega = d\omega \sin^2 \chi \, d\chi ,$$
$$d\omega = d\phi \sin \theta ,$$
$$d\theta = \text{ invariant surface measure for } \boldsymbol{S}^2 ;$$

$$\int_0^{2\pi} d\phi \int_0^\pi d\theta \sin \theta$$
$$\times \int_0^\pi d\chi \sin^2 \chi \, D^{j*}_{m'm}(\alpha_0, \boldsymbol{\alpha}) D^{j'}_{\mu'\mu}(\alpha_0, \boldsymbol{\alpha})$$
$$= \frac{2\pi^2}{2j+1} \delta_{jj'} \delta_{m'\mu'} \delta_{m\mu} .$$

Coordinates $(\psi, \hat{\boldsymbol{n}})$ for $\boldsymbol{S}^3$:

$$(\alpha_0, \boldsymbol{\alpha}) = \left(\cos \frac{\psi}{2}, \hat{\boldsymbol{n}} \sin \frac{\psi}{2} \right) ,$$
$$0 \leq \psi \leq 2\pi , \quad \hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{n}} = 1 ,$$
$$d\Omega = dS(\hat{\boldsymbol{n}}) \sin^2 \frac{\psi}{2} \frac{d\psi}{2} ,$$
$$dS(\hat{\boldsymbol{n}}) = d\omega$$
$$\text{for } \hat{\boldsymbol{n}} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta) ,$$

$$\int dS(\hat{\boldsymbol{n}}) \int_0^{2\pi} \frac{d\psi}{2} \left(\sin \frac{\psi}{2} \right)^2 D^{j*}_{m'm}(\psi, \hat{\boldsymbol{n}}) D^{j'}_{\mu'\mu}(\psi, \hat{\boldsymbol{n}})$$
$$= \frac{2\pi^2}{2j+1} \delta_{jj'} \delta_{m'\mu'} \delta_{m\mu} ,$$

Euler angles for S^3 ($SU(2)$):

$$(\alpha_0, \boldsymbol{\alpha}) = \left(\cos\frac{\beta}{2}\cos\frac{1}{2}(\gamma+\alpha), \sin\frac{\beta}{2}\sin\frac{1}{2}(\gamma-\alpha), \right.$$
$$\left. \sin\frac{\beta}{2}\cos\frac{1}{2}(\gamma-\alpha), \cos\frac{\beta}{2}\sin\frac{1}{2}(\gamma+\alpha) \right),$$

$$d\Omega = \frac{1}{8}\,d\alpha\,d\gamma\,\sin\beta\,d\beta\,, \tag{2.25}$$

$$\frac{1}{8}\int_0^{2\pi} d\alpha \int_0^{2\pi} d\gamma \int_0^{\pi} d\beta\,\sin\beta\, D^{j*}_{m'm}(\alpha\beta\gamma) D^{j'}_{\mu'\mu}(\alpha\beta\gamma)$$
$$+ \frac{1}{8}\int_0^{2\pi} d\alpha \int_0^{2\pi} d\gamma \int_{2\pi}^{3\pi} d\beta\,\sin\beta\, D^{j*}_{m'm}(\alpha\beta\gamma) D^{j'}_{\mu'\mu}(\alpha\beta\gamma)$$
$$= \frac{2\pi^2}{2j+1}\delta_{jj'}\delta_{m'\mu'}\delta_{m\mu}\,. \tag{2.26}$$

Euler angles for hemisphere of S^3 ($SO(3, \boldsymbol{R})$; j' and j both integral):

$$\int_0^{2\pi} d\alpha \int_0^{2\pi} d\gamma \int_0^{\pi} d\beta\,\sin\beta\, D^{j*}_{m'm}(\alpha\beta\gamma) D^{j'}_{\mu'\mu}(\alpha\beta\gamma)$$
$$= \frac{8\pi^2}{2j+1}\delta_{jj'}\delta_{m'\mu'}\delta_{m\mu}\,. \tag{2.27}$$

Formal polynomials (2.24):

$$\left(D^j_{m'm}, D^{j'}_{\mu'\mu} \right) = (2j)!\,\delta_{jj'}\delta_{m'\mu'}\delta_{m\mu}\,,$$

with inner product

$$(P, P') = P^*\left(\frac{\partial}{\partial Z}\right)P'(Z)|_{Z=0}\,,$$

where $P^*\left(\frac{\partial}{\partial Z}\right)$ is the complex conjugate polynomial P^* of P in which each z_{ij} is replaced by $\frac{\partial}{\partial z_{ij}}$.
Boson polynomials:

$$\left\langle D^j_{m'm} \middle| D^{j'}_{\mu'\mu} \right\rangle = (2j)!\,\delta_{jj'}\delta_{m'\mu'}\delta_{m\mu}\,,$$

with inner product $\langle P|P'\rangle = \langle 0| P^*(\bar{A}) P'(A)|0\rangle$.

2.3.5 Recurrence Relations

Many useful relations between the representation functions may be derived as special cases of general relations between these functions and the WCG-coefficients given in Sect. 2.7.1. The simplest of these are obtained from the Kronecker reduction

$$D^j \times D^{\frac{1}{2}} = D^{j+1/2} \oplus D^{j-1/2}\,.$$

Such relations are usually presented in terms of the Euler angle realization of U, leading to the following relations between the functions $d^j_{m',m}(\beta)$:

$$(j-m+1)^{\frac{1}{2}} \cos\left(\frac{1}{2}\beta\right) d^{j+1/2}_{m'-1/2,m-1/2}(\beta)$$
$$+ (j+m+1)^{\frac{1}{2}} \sin\left(\frac{1}{2}\beta\right) d^{j+1/2}_{m'-1/2,m+1/2}(\beta)$$
$$= (j-m'+1)^{\frac{1}{2}} d^j_{m'm}(\beta)\,,$$
$$- (j-m+1)^{\frac{1}{2}} \sin\left(\frac{1}{2}\beta\right) d^{j+1/2}_{m'+1/2,m-1/2}(\beta)$$
$$+ (j+m+1)^{\frac{1}{2}} \cos\left(\frac{1}{2}\beta\right) d^{j+1/2}_{m'+1/2,m+1/2}(\beta)$$
$$= (j+m'+1)^{\frac{1}{2}} d^j_{m'm}(\beta)\,,$$
$$(j+m)^{\frac{1}{2}} \cos\left(\frac{1}{2}\beta\right) d^{j-1/2}_{m'-1/2,m-1/2}(\beta)$$
$$- (j-m)^{\frac{1}{2}} \sin\left(\frac{1}{2}\beta\right) d^{j-1/2}_{m'-1/2,m+1/2}(\beta)$$
$$= (j+m')^{\frac{1}{2}} d^j_{m'm}(\beta)\,,$$
$$(j+m)^{\frac{1}{2}} \sin\left(\frac{1}{2}\beta\right) d^{j-1/2}_{m'+1/2,m-1/2}(\beta)$$
$$+ (j-m)^{\frac{1}{2}} \cos\left(\frac{1}{2}\beta\right) d^{j-1/2}_{m'+1/2,m+1/2}(\beta)$$
$$= (j-m')^{\frac{1}{2}} d^j_{m'm}(\beta)\,.$$

Two useful relations implied by the above are:

$$[(j-m)(j+m+1)]^{\frac{1}{2}} \sin\beta\, d^j_{m',m+1}(\beta)$$
$$+ [(j+m)(j-m+1)]^{\frac{1}{2}} \sin\beta\, d^j_{m',m-1}(\beta)$$
$$= 2(m\cos\beta - m') d^j_{m'm}(\beta)\,,$$
$$[(j+m)(j-m+1)]^{\frac{1}{2}} d^j_{m',m-1}(\beta)$$
$$+ [(j+m')(j-m'+1)]^{\frac{1}{2}} d^j_{m'-1,m}(\beta)$$
$$= (m-m') \cot\left(\frac{1}{2}\beta\right) d^j_{m'm}(\beta)\,.$$

By considering

$$D^j \times D^1 = D^{j+1} \oplus D^j \oplus D^{j-1}\,,$$

one can also readily derive the matrix elements of the direction cosines specifying the orientation of the body-fixed frame $(\hat{f}_1, \hat{f}_2, \hat{f}_3)$ of a symmetric rotor relative to

the inertial frame $(\hat{e}_1, \hat{e}_2, \hat{e}_3)$:

$$\lambda_{\mu,\nu}\Psi^j_{m,m'} = \sum_{j'}\left(\frac{2j+1}{2j'+1}\right)^{\frac{1}{2}}$$
$$\times C^{j1j'}_{m\mu m+\mu} C^{j1j'}_{m'\nu m'+\nu} \Psi^{j'}_{m+\mu,m'+\nu},$$

where the wave functions are those defined for integral j by (2.37), for half-integral j by (2.36), and

$$\lambda_{\mu,\nu} = \hat{e}_\mu \cdot \hat{f}^*_\nu = \left(D^1_{\mu,\nu}\right)^*, \quad \mu, \nu = -1, 0, +1;$$
$$\hat{e}_{+1} = -(\hat{e}_1 + \mathrm{i}\hat{e}_2)/\sqrt{2}, \qquad \hat{e}_0 = \hat{e}_3,$$
$$\hat{e}_{-1} = (\hat{e}_1 - \mathrm{i}\hat{e}_2)/\sqrt{2},$$
$$\hat{f}_{+1} = -(\hat{f}_1 + \mathrm{i}\hat{f}_2)/\sqrt{2}, \qquad \hat{f}_0 = \hat{f}_3,$$
$$\hat{f}_{-1} = (\hat{f}_1 - \mathrm{i}\hat{f}_2)/\sqrt{2}.$$

2.3.6 Symmetry Relations

Symmetry relations for the representation functions $D^j_{m'm}(Z)$ defined by (2.24) are associated with the action of a finite group G on the set $M(2,2)$ of complex 2×2 matrices: $g : M(2,2) \to M(2,2)$, $g \in G$. Equivalently, if $Z \in M(2,2)$ is parametrized by a set Ω of parameters $\omega \in \Omega$ (parameter space), then g may be taken to act directly in the parameter space $g : \Omega \to \Omega$. The action, denoted $\square$, of a group $G = \{e, g, g', \dots\}$ (e = identity) on a set $X = \{x, x', \dots\}$ must satisfy the rules

$$g : X \to X \quad e\,\square\,x = x, \text{ all } x \in X,$$
$$g'\,\square\,(g\,\square\,x) = (g'g)\,\square\,x, \text{ all } g', g \in G, \text{ all } x \in X. \tag{2.28}$$

Using $\cdot$ to denote the action of G on $M(2,2)$ and $\square$ to denote the action of G on Ω, one has the relation:

$$(g \cdot Z)(\omega) = Z(g^{-1}\,\square\,\omega).$$

Only finite subgroups G of the unitary group $U(2)$ (group of 2×2 unitary matrices) are considered here: $G \subset U(2)$.

Generally, when G acts on $M(2,2)$, it effects a unitary linear transformation of the set of functions $\{D^j_{m'm}\}$ (j fixed) defined over $Z \in M(2,2)$. For certain groups G, or for some elements of G, a single function $D^j_{\mu'\mu} \in \{D^j_{m'm}\}$ occurs in the transformation, so that

$$\left(g \cdot D^j_{m'm}\right)(Z) = D^j_{m'm}(g^{-1}\,\square\,Z)$$
$$= g_{m'm}D^j_{\mu'\mu}(Z), \tag{2.29}$$
$$(\mu'\mu)$$
$$\in \{(\lambda'm', \lambda m), (\lambda m, \lambda'm')|\lambda' = \pm1, \lambda = \pm1\},$$

where $g_{m'm}$ is a complex number of unit modulus. Relation (2.29) is called a symmetry relation of $D^j_{m'm}$ with respect to g. Usually not all elements in G correspond to symmetry relations. In a symmetry relation, the action of the group is effectively transferred to the discrete quantum labels themselves:

$$g : m' \to \mu' = m'(g),$$
$$m \to \mu = m(g). \tag{2.30}$$

In terms of a parametrization Ω of $M(2,2)$, relation (2.29) is written

$$\left(gD^j_{m'm}\right)(\omega) = D^j_{m'm}(g^{-1}\,\square\,\omega)$$
$$= g_{m'm}D^j_{\mu'\mu}(\omega). \tag{2.31}$$

In practice, action symbols such as $\cdot$ and $\square$ are often dropped in favor of juxtaposition, when the context is clear. Moreover the set of complex matrices $M(2,2)$ may be replaced by $U(2)$ or $SU(2)$ whenever the action conditions (2.28) are satisfied. Relations (2.29–2.31) are illustrated below by examples.

There are several finite subgroups of interest with various group-subgroup relations between them:

1. Pauli group:

$$P = \{\sigma_\mu, -\sigma_\mu, \mathrm{i}\sigma_\mu, -\mathrm{i}\sigma_\mu|\mu = 0, 1, 2, 3\},$$
$$|P| = 16.$$

Each element of this group is an element of $U(2)$. The action of the group P may therefore be defined on the group $U(2)$ by left and right actions as discussed in Sect. 2.4.1.

2. Symmetric group S_4:

$S_4 = \{p|p$ is a permutation of the four Euler–Rodrigues parameters $(\alpha_0, \alpha_1, \alpha_2, \sigma_3)\}$, $\left| S_4 \right| = 24$. Points in S^3 are mapped to distinct points in S^3; hence, one can take $Z \in SU(2)$, and define the group action directly from $U(\alpha_0, \boldsymbol{\alpha})$ in (2.20). It is simpler, however, to define the action of the group directly on the representation functions (2.22). Not all elements of this group define a symmetry in the sense defined by (2.29) (see below).

3. Abelian group T:

$$T = \{(t_0, t_1, t_2, t_3)| \text{ each } t_\mu = \pm1\},$$
$$|T| = 16.$$

Group multiplication is component-wise multiplication and the identity is (1,1,1,1). The action of an element of T is defined directly on the

Euler–Rodrigues parameters by component-wise multiplication, thus mapping points in S^3 to points in S^3; hence, one can take $Z \in SU(2)$. This group is isomorphic to the direct product group $S_2 \times S_2 \times S_2 \times S_2$, $S_2 =$ symmetric group on two distinct objects.

4. Group G:

$$G = \langle \mathcal{R}, \mathcal{C}, \mathcal{T}, \mathcal{K} \rangle, \quad |G| = 32,$$

where $\mathcal{R}, \mathcal{C}, \mathcal{T}, \mathcal{K}$ denote the operations of row interchange, column interchange, transposition, and conjugation (see below) of an arbitrary matrix.

$$Z = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$$

The notation $\langle\ \rangle$ designates that the enclosed elements generate G.

It is impossible to give here all the interrelationships among the groups defined in (1)–(4). Instead, some relations are listed as obtained directly from either $D^j_{m'm}(Z)$ defined by (2.24) or $D^j_{m'm}(\alpha_0, \boldsymbol{\alpha})$ defined by (2.22). The actions of the groups T and G defined in (3) and (4) are fully given.

Abelian group T of order 16:

Generators:

$$T = \langle t_0, t_1, t_2, t_3 \rangle, \quad t_0 = (-1, 1, 1, 1),$$

$$t_1 = (1, -1, 1, 1), \quad t_2 = (1, 1, -1, 1),$$

$$t_3 = (1, 1, 1, -1).$$

Group action:

$$t \cdot a = (t_0 \alpha_0, t_1 \alpha_1, t_2 \alpha_2, t_3 \alpha_3),$$

$$\text{each } t = (t_0, t_1, t_2, t_3) \in T,$$

$$\text{each } a = (\alpha_0, \alpha_1, \alpha_2, \alpha_3) \in S^3,$$

$$(tF)(a) = F(t \cdot a),$$

$$t_0 D^j_{m'm} = (-1)^{m'-m} D^j_{-m-m'},$$

$$t_1 D^j_{m'm} = (-1)^{m'-m} D^j_{mm'},$$

$$t_2 D^j_{m'm} = D^j_{mm'},$$

$$t_3 D^j_{m'm} = D^j_{-m-m'}.$$

Group G of order 32:

Generators:

$$G = \langle \mathcal{R}, \mathcal{C}, \mathcal{T}, \mathcal{K} \rangle,$$

Generator actions:

$$(\mathcal{R}F)\begin{pmatrix} a & b \\ c & d \end{pmatrix} = F\begin{pmatrix} c & d \\ a & b \end{pmatrix}, \qquad \begin{array}{l}\text{row}\\ \text{interchange}\end{array}$$

$$(\mathcal{C}F)\begin{pmatrix} a & b \\ c & d \end{pmatrix} = F\begin{pmatrix} b & a \\ d & c \end{pmatrix}, \qquad \begin{array}{l}\text{column}\\ \text{interchange}\end{array}$$

$$(\mathcal{T}F)\begin{pmatrix} a & b \\ c & d \end{pmatrix} = F\begin{pmatrix} a & c \\ b & d \end{pmatrix}, \qquad \text{transposition}$$

$$(\mathcal{K}F)\begin{pmatrix} a & b \\ c & d \end{pmatrix} = F\begin{pmatrix} d & -c \\ -b & a \end{pmatrix}, \qquad \text{conjugation}$$

Subgroup H:

$$\begin{aligned} H &= \langle \mathcal{R}, \mathcal{C}, \mathcal{T} \rangle \\ &= \{1, \mathcal{R}, \mathcal{C}, \mathcal{T}, \mathcal{RC} = \mathcal{CR}, \mathcal{TR} = \mathcal{CT}, \mathcal{TC} \\ &= \text{RT}, \mathcal{RCT}\} \end{aligned}$$

with relations in H given by

$$\mathcal{R}^2 = \mathcal{C}^2 = \mathcal{T}^2 = 1,$$

$$\mathcal{TRC} = \mathcal{TCR} = \mathcal{RCT} = \mathcal{CRT},$$

$$\mathcal{RTC} = \mathcal{CTR} = \mathcal{T}.$$

Adjoining the idempotent element $\mathcal{K}$ to H gives the group G of order 32:

$$G = \{H, H\mathcal{K}, H\mathcal{K}\mathcal{R}, H\mathcal{K}\mathcal{R}\mathcal{K}\}.$$

Symmetry relations:

$$\begin{aligned} \mathcal{R}D^j_{m'm} &= D^j_{-m'm}, \\ \mathcal{C}D^j_{m'm} &= D^j_{m'-m}, \\ \mathcal{T}D^j_{m'm} &= D^j_{mm'}, \\ \mathcal{K}D^j_{m'm} &= (-1)^{m'-m} D^j_{-m'-m}. \end{aligned} \qquad (2.32)$$

These function relations are valid for $D^j_{m'm}$ defined over the arbitrary matrix Z defined by (2.24). They are also true for $Z = U \in SU(2)$, but now the operations $\mathcal{R}$ and $\mathcal{C}$ change the sign of the determinant of the matrix Z so that the transformed matrix no longer belongs to $SU(2)$. It does, however, belong to $U(2)$, the group of all 2×2 unitary matrices. The special irreducible representation functions of $U(2)$ defined by (2.24),

$$D^j_{m'm}(U), \quad U \in U(2),$$

possess each of the 32 symmetries corresponding to the operations in the group G. [There exist other irreducible representations of U(2), involving $\det U$.] The operation $\mathcal{K}$ is closely related to complex conjugation, since for each $U \in$ U(2), $U = (u_{ij})$, one can write

$$U^* = (\det U)^{-1} \begin{pmatrix} u_{22} & -u_{21} \\ -u_{12} & u_{11} \end{pmatrix} ,$$

$$\left(\mathcal{K} D^j_{m'm} \right)(U) = (\det U)^{2j} D^j_{m'm}(U^*)$$

$$= (\det U)^{2j} D^{j*}_{m'm}(U)$$

$$= (-1)^{m'-m} D^j_{-m'-m}(U) . \qquad (2.33)$$

Relations (2.32) and (2.33) are valid in an arbitrary parametrization of $U \in$ U(2). In terms of the parametrization

$$U(\chi, \alpha_0, \boldsymbol{\alpha}) = \mathrm{e}^{\mathrm{i}\chi/2} U(\alpha_0, \boldsymbol{\alpha}) , \quad 0 \leq \chi \leq 2\pi ,$$

where $U(\alpha_0, \boldsymbol{\alpha}) \in SU(2)$ is the Euler–Rodrigues parametrization, the actions of $\mathcal{R}$, $\mathcal{C}$, $\mathcal{T}$, and $\mathcal{K}$ correspond to the following transformations in parameter space:

$$\mathcal{R} : \ \chi \to \chi + \pi, (\alpha_0, \alpha_1, \alpha_2, \alpha_3)$$
$$\to (-\alpha_1, \alpha_0, -\alpha_3, \alpha_2) ,$$

$$\mathcal{C} : \ \chi \to \chi + \pi, (\alpha_0, \alpha_1, \alpha_2, \alpha_3)$$
$$\to (-\alpha_1, \alpha_0, \alpha_3, -\alpha_2) ,$$

$$\mathcal{T} : \ \chi \to \chi, (\alpha_0, \alpha_1, \alpha_2, \alpha_3) \to (\alpha_0, \alpha_1, -\alpha_2, \alpha_3) ,$$

$$\mathcal{C} : \ \chi \to \chi, (\alpha_0, \alpha_1, \alpha_2, \alpha_3)$$
$$\to (\alpha_0, -\alpha_1, \alpha_2, -\alpha_3) .$$

The new angle $\chi' = \chi + \pi$ is to be identified with the corresponding point on the unit circle so that these mappings are always in the parameter space, which is the sphere S^3 together with the unit circle for χ. Observe that the following identities hold for functions over $SU(2)$; hence, over U(2):

$$\mathcal{C} = T_{t_1} T_{t_3} , \quad \mathcal{T} = T_{t_2} .$$

Abelian subgroup of S_4:

Generators:

$K = \langle (0, 3), (1, 2) \rangle$, where $(0, 3)$ and $(1, 2)$ denote transpositions in S_4, $|K| = 4$.

Group action in parameter space:

$$(0, 3)(\alpha_0, \alpha_1, \alpha_2, \alpha_3) = (\alpha_3, \alpha_1, \alpha_2, \alpha_0) ,$$

$$(1, 2)(\alpha_0, \alpha_1, \alpha_2, \alpha_3) = (\alpha_0, \alpha_2, \alpha_1, \alpha_3) .$$

Symmetry relations:

$$(0, 3) D^j_{m'm} = (-\mathrm{i})^{m'+m} D^j_{-m-m'} ,$$

$$(1, 2) D^j_{m'm} = (-\mathrm{i})^{m'-m} D^j_{mm'} .$$

Diagonal subgroup Σ of the direct product group $P \times P$ ($P =$ Pauli group):

Group elements:

$$\Sigma = \{ (\sigma, \sigma) | \sigma \in P \}, \quad |\Sigma| = 16 .$$

Group action:

$$(\sigma, \sigma) : U \to \sigma U \sigma^{\mathrm{T}} , \quad \text{each } \sigma \in P ,$$

$$[(\sigma, \sigma) F](U) = F(\sigma^{\mathrm{T}} U \sigma) .$$

Example: $\sigma = \mathrm{i}\sigma_2$:

$$(\sigma, \sigma) : (\alpha_0, \alpha_1, \alpha_2, \alpha_3) \to (\alpha_0, -\alpha_1, \alpha_2, -\alpha_3) ,$$

$$[(\sigma, \sigma) F](\alpha_0, \alpha_1, \alpha_2, \alpha_3) = F(\alpha_0, -\alpha_1, \alpha_2, -\alpha_3) ,$$

$$(\sigma, \sigma) = t_1 t_2 \text{ on functions over U(2)} .$$

The relations presented above barely touch on the interrelations among the finite groups introduced in (1)–(4). Symmetry relations (2.32) and (2.33), however, give the symmetries of the $d^j_{m'm}(\beta)$ given in Sect. 2.3.3 in the Euler angle parametrization. In general, it is quite tedious to present the above symmetries in terms of Euler angles, with χ adjoined when necessary, because the Euler angles are not uniquely determined by the points of S^3.

2.4 Group and Lie Algebra Actions

The concept of a group acting on a set is fundamental to applications of group theory to physical problems. Because of the unity that this notion brings to angular momentum theory, it is well worth a brief review in a setting in which a matrix group acts on the set of complex matrices. Thus, let $G \subseteq GL(n, \boldsymbol{C})$ and $H \subseteq GL(m, \boldsymbol{C})$ denote arbitrary subgroups, respectively, of the general linear groups of $n \times n$ and $m \times m$ nonsingular complex matrices, and let $M(n, m)$ denote the set of $n \times m$ complex matrices. A matrix $Z \in M(n, m)$ has row and column entries (z_i^α), $i = 1, 2, \ldots, n$; $\alpha = 1, 2, \ldots, m$.

2.4.1 Matrix Group Actions

Left and right translations of $Z \in M(n, m)$:

$$L_g Z = gZ, \quad \text{each } g \in G, \quad \text{each } Z \in M(n, m),$$
$$R_h Z = Zh^{\mathrm{T}}, \quad \text{each } h \in H, \quad \text{each } Z \in M(n, m).$$

(T denotes matrix transposition.)
Left and right translations commute:

$$Z' = L_g(R_h Z) = R_h(L_g Z), \quad \text{each } g \in G, h \in H,$$
$$Z \in M(n, m).$$

Equivalent form as a transformation on $z \in C^{nm}$:

$$z' = (g \times h)z,$$

where $\times$ denotes the direct product of g and h; the column matrix z (resp., z') is obtained from the columns of Z (resp., Z'), $z^\alpha, \alpha = 1, 2, \dots, m$, of the $n \times m$ matrix Z as successive entries in a single column vector $z \in C^{nm}$. Left and right translations in function space:

$$(\mathcal{L}_g f)(Z) = f(g^{\mathrm{T}} Z), \quad \text{each } g \in G,$$
$$(\mathcal{R}_h f)(Z) = f(Zh), \quad \text{each } h \in H,$$

where $f(Z) = f(z_i^\alpha)$, and the commuting property holds for all well-defined functions f:

$$\mathcal{L}_g(\mathcal{R}_h f) = \mathcal{R}_h(\mathcal{L}_g f).$$

2.4.2 Lie Algebra Actions

Lie algebra of left and right translations:

$$(D_X f)(Z) = \mathrm{i}\frac{\mathrm{d}}{\mathrm{d}t} f\left(\mathrm{e}^{-\mathrm{i}tX^T} Z\right)|_{t=0},$$
$$(D^Y f)(Z) = \mathrm{i}\frac{\mathrm{d}}{\mathrm{d}t} f\left(Z\mathrm{e}^{-\mathrm{i}tY}\right)|_{t=0};$$
$$D_X = \mathrm{Tr}(Z^{\mathrm{T}} X \partial/\partial Z), \quad \text{each } X \in L(G),$$
$$D^Y = \mathrm{Tr}(Y^{\mathrm{T}} Z^{\mathrm{T}} \partial/\partial Z), \quad \text{each } Y \in L(H),$$
$$L(G) = \text{Lie algebra of } G,$$
$$L(H) = \text{Lie algebra of } H.$$

Linear derivations:

$$D_{\alpha X + \beta X'} = \alpha D_X + \beta D_{X'}, \quad \alpha, \beta \in C,$$
$$[D_X, D_{X'}] = D_{[X, X']},$$

D^Y obeys these same rules.
Commuting property of left and right derivations:

$$[D_X, D^Y] = 0, \quad X \in L(G), \quad Y \in L(H).$$

Basis set:

$$D_X = \sum_{i,j=1}^n x_{ij} D_{ij}, \quad X = (x_{ij}),$$
$$D^Y = \sum_{\alpha,\beta=1}^m y^{\alpha\beta} D^{\alpha\beta}, \quad Y = (y^{\alpha\beta}),$$
$$D_{ij} = \sum_{\alpha=1}^m z_i^\alpha \frac{\partial}{\partial z_j^\alpha},$$
$$D^{\alpha\beta} = \sum_{i=1}^n z_i^\alpha \frac{\partial}{\partial z_i^\beta}.$$

Commutation rules:

$$[D_{ij}, D_{kl}] = \delta_{jk} D_{il} - \delta_{il} D_{kj},$$
$$[D^{\alpha\beta}, D^{\gamma\epsilon}] = \delta^{\beta\gamma} D^{\alpha\epsilon} - \delta^{\alpha\epsilon} D^{\gamma\beta},$$
$$[D_{ij}, D^{\alpha\beta}] = 0,$$

where $i, j, k, l = 1, 2, \dots, n$ and $\alpha, \beta, \gamma, \epsilon = 1, 2, \dots, m$. The operator sets $\{D_{ij}\}$ and $\{D^{\alpha\beta}\}$ are realizations of the Weyl generators of $GL(n, C)$ and $GL(m, C)$, respectively.

2.4.3 Hilbert Spaces

Space of polynomials with inner product:

$$(P, P') = P^*(\partial/\partial Z) P'(Z)|_{Z=0}.$$

Bargmann space of entire functions with inner product:

$$\langle F, F' \rangle = \int F^*(Z) F'(Z) \, \mathrm{d}\mu(Z),$$
$$\mathrm{d}\mu(Z) = \pi^{-nm} \exp\left(-\sum_{i,\alpha} z_i^{\alpha*} z_i^\alpha\right) \prod_{i,\alpha} \mathrm{d}x_i^\alpha \, \mathrm{d}y_i^\alpha,$$
$$z_i^\alpha = x_i^\alpha + \mathrm{i}y_i^\alpha, i = 1, 2, \dots, n; \ \alpha = 1, 2, \dots, m.$$

Numerical equality of inner products:

$$(P, P') = \langle P, P' \rangle.$$

2.4.4 Relation to Angular Momentum Theory

Spinorial Realization of Sects. 2.4.2 and 2.4.3:

$$G = SU(2), \quad H = (1), \quad Z \in M(2, 1),$$
$$z = \mathrm{col}(z_1, z_2),$$
$$X = \text{set of } 2 \times 2 \text{ traceless, Hermitian matrices},$$
$$(\mathcal{R}_U f)(z) = f(U^{\mathrm{T}} z),$$
$$D_{\sigma_i/2} = (z^{\mathrm{T}} \sigma_i \partial/\partial z)/2,$$

$$J_\pm = D_{\sigma_1/2} \pm i D_{\sigma_2/2} \,, \quad J_3 = D_{\sigma_3/2} \,,$$
$$J_+ = z_1 \partial/\partial z_2 \,, \quad J_- = z_2 \partial/\partial z_1 \,,$$
$$J_3 = (1/2)(z_1 \partial/\partial z_1 - z_2 \partial/\partial z_2) \,,$$
$$(P, P') = P^*(\partial/\partial z_1, \partial/\partial z_2) P(z_1, z_2)|_{z_1=z_2=0} \,.$$

Orthonormal basis:

$$P_{jm}(z_1, z_2) = z_1^{j+m} z_2^{j-m} / [(j+m)!(j-m)!]^{\frac{1}{2}} \,,$$
$$j = 0, 1/2, 1, 3/2, \dots; \quad m = j, j-1, \dots, -j \,.$$

Standard action:

$$\boldsymbol{J}^2 P_{jm}(z) = j(j+1) P_{jm}(z) \,,$$
$$J_3 P_{jm}(z) = m P_{jm}(z) \,,$$
$$J_\pm P_{jm}(z) = [(j \mp m)(j \pm m + 1)]^{\frac{1}{2}} P_{j,m\pm 1}(z) \,.$$

Group transformation:

$$(\mathcal{R}_U P_{jm})(z) = \sum_{m'} D^j_{m'm}(U) P_{jm'}(z) \,,$$

where the representation functions are given by (2.17).

The 2-Spinorial Realization of Sects. 2.4.2 and 2.4.3:

$$G = H = SU(2) \,, \qquad Z \in M(2, 2) \,,$$
$$Z = [z^1 z^2] \,, \qquad z^\alpha = \mathrm{col}(z_1^\alpha z_2^\alpha) \,,$$

$X = Y =$ set of 2×2 traceless, Hermitian matrices ,

$$(\mathcal{R}_U f)(Z) = f(U^\mathrm{T} Z) \,, \quad (\mathcal{L}_V f)(Z) = f(ZV) \,,$$
$$U, V \in SU(2) \,,$$
$$D_{\sigma_i/2} = \mathrm{Tr}(Z^\mathrm{T} \sigma_i \partial/\partial Z)/2 \,,$$
$$D^{\sigma_i/2} = \mathrm{Tr}(\sigma_i Z^\mathrm{T} \partial/\partial Z)/2 \,.$$

$$M_\pm = D_{\sigma_1/2} \pm i D_{\sigma_2/2} \,, \qquad M_3 = D_{\sigma_3/2} \,,$$
$$K_\pm = D^{\sigma_1/2} \pm i D^{\sigma_2/2} \,, \qquad K_3 = D^{\sigma_3/2} \,,$$
$$M_+ = \sum_{\alpha=1}^2 z_1^\alpha \partial/\partial z_2^\alpha \,, \quad M_- = \sum_{\alpha=1}^2 z_2^\alpha \partial/\partial z_1^\alpha \,,$$
$$M_3 = \frac{1}{2} \sum_{\alpha=1}^2 (z_1^\alpha \partial/\partial z_1^\alpha - z_2^\alpha \partial/\partial z_2^\alpha) \,,$$
$$K_+ = \sum_{i=1}^2 z_i^1 \partial/\partial z_i^2 \,, \quad K_- = \sum_{i=1}^2 z_i^2 \partial/\partial z_i^1 \,,$$
$$K_3 = \frac{1}{2} \sum_{i=1}^2 (z_i^1 \partial/\partial z_i^1 - z_i^2 \partial/\partial z_i^2) \,.$$

Mutual commutativity of Lie algebras:

$$[M_i, K_j] = 0 \,, \quad i, j = 1, 2, 3 \,.$$

Inner product:

$$(P, P') = P^*(Z) P'(\partial/\partial Z)|_{Z=0} \,,$$

Orthogonal basis (2.24):

$$D^j_{mm'}(Z) \,, \quad j = 0, 1/2, 1, 3/2, \dots \,,$$
$$m = j, j-1, \dots, -j \,;$$
$$m' = j, j-1, \dots, -j \,;$$
$$\left(D^j_{mm'}, D^{j'}_{\mu\mu'}\right) = (2j)! \delta_{jj'} \delta_{m\mu} \delta_{m'\mu'} \,.$$

Equality of Casimir operators:

$$\boldsymbol{M}^2 = \boldsymbol{K}^2 = M_1^2 + M_2^2 + M_3^2 = K_1^2 + K_2^2 + K_3^2 \,.$$

Standard actions:

$$\boldsymbol{M}^2 D^j_{mm'}(Z) = \boldsymbol{K}^2 D^j_{mm'}(Z) = j(j+1) D^j_{mm'}(Z) \,,$$
$$M_3 D^j_{mm'}(Z) = m D^j_{mm'}(Z) \,,$$
$$K_3 D^j_{mm'}(Z) = m' D^j_{mm'}(Z) \,,$$
$$M_\pm D^j_{mm'}(Z) = [(j \mp m)(j \pm m + 1)]^{\frac{1}{2}} D^j_{m\pm 1,m'}(Z) \,,$$
$$K_\pm D^j_{mm'}(Z) = [(j \mp m')(j \pm m' + 1)]^{\frac{1}{2}}$$
$$\times D^j_{m,m'\pm 1}(Z) \,.$$

Special values:

$$D^j \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} = I_{2j+1} = \text{ unit matrix} \,,$$
$$D^j_{mm'} \begin{pmatrix} z_1 & 0 \\ z_2 & 0 \end{pmatrix} = \delta_{jm'} P_{jm}(z_1, z_2) \,,$$
$$D^j_{mm'} \begin{pmatrix} 0 & z_1 \\ 0 & z_2 \end{pmatrix} = \delta_{jm} P_{jm'}(z_1, z_2) \,,$$
$$D^j_{mm'} \begin{pmatrix} z_1 & 0 \\ 0 & z_2 \end{pmatrix} = \delta_{mm'} z_1^{j+m} z_2^{j-m} \,,$$
$$D^j_{jj}(Z) = \left(z_1^1\right)^{2j} \,.$$

Symmetry relation:

$$\left[D^j(Z) \right]^{\mathrm{T}} = D^j\left(Z^{\mathrm{T}}\right) .$$

Generation from highest weight:

$$D^j_{mm'}(Z) = \left(\frac{(j+m)!}{(2j)!(j-m)!} \times \frac{(j+m')!}{(2j)!(j-m')!} \right)^{\frac{1}{2}}$$
$$\times M_-^{j-m} K_-^{j-m'} D^j_{jj}(Z) .$$

Generating functions:

$$(\mathbf{x}^{\mathrm{T}} Z \mathbf{y})^{2j} / (2j)! = \sum_{mm'} P_{jm}(\mathbf{x}) D^j_{mm'}(Z) P_{jm'}(\mathbf{y}) ,$$

$$\exp(t\mathbf{x}^{\mathrm{T}} Z \mathbf{y}) = \sum_j t^{2j} \sum_{mm'} P_{jm}(\mathbf{x}) D^j_{mm'}(Z) P_{jm'}(\mathbf{y}) ,$$

$$\mathbf{x} = \mathrm{col}(x_1 x_2) , \quad \mathbf{y} = \mathrm{col}(y_1 y_2) ,$$
$$Z = \left(z_i^\alpha\right) , \quad i, \alpha = 1, 2 ; \quad \text{all indeterminates} .$$

2.5 Differential Operator Realizations of Angular Momentum

Differential operators realizing the standard commutation relations (2.7) and (2.8) can be obtained from the 2-spinorial realizations given in Sect. 2.4.4 by specializing the matrix Z to the appropriate unitary unimodular matrix $U \in SU(2)$ and using the chain rule of elementary calculus. Similarly, one obtains the explicit functions $D^j_{mm'}$ simply by substituting for Z the parametrized U in (2.24). This procedure is used in this section to obtain all the realizations listed. The notations $\mathbf{M} = (M_1, M_2, M_3)$ and $\mathbf{K} = (K_1, K_2, K_3)$ and the associated $M_\pm$ and $K_\pm$ refer to the differential operators given by the 2-spinorial realization now transformed to the parameters in question.

Euler angles with $Z = U(\alpha\beta\gamma)$ (Sect. 2.3.1):

$$M_3 = \mathrm{i}\partial/\partial\alpha , \quad K_3 = \mathrm{i}\partial/\partial\gamma ,$$

$$\frac{1}{2}\left(\mathrm{e}^{\mathrm{i}\alpha} M_+ - \mathrm{e}^{-\mathrm{i}\alpha} M_- \right)$$
$$= \frac{1}{2}\left(\mathrm{e}^{-\mathrm{i}\gamma} K_- - \mathrm{e}^{\mathrm{i}\gamma} K_+ \right) = \frac{\partial}{\partial\beta} ,$$

$$\frac{1}{2}\left(\mathrm{e}^{\mathrm{i}\alpha} M_+ + \mathrm{e}^{-\mathrm{i}\alpha} M_- \right)$$
$$= -(\cot\beta) M_3 + (\sin\beta)^{-1} K_3 ,$$

$$\frac{1}{2}\left(\mathrm{e}^{-\mathrm{i}\gamma} K_- + \mathrm{e}^{\mathrm{i}\gamma} K_+ \right) = (\cot\beta) K_3 - (\sin\beta)^{-1} M_3 ,$$

$$M_+ = \mathrm{e}^{-\mathrm{i}a}[\partial/\partial\beta - (\cot\beta) M_3 + (\sin\beta)^{-1} K_3] ,$$
$$M_- = \mathrm{e}^{\mathrm{i}\alpha}[-\partial/\partial\beta - (\cot\beta) M_3 + (\sin\beta)^{-1} K_3] ,$$
$$K_+ = \mathrm{e}^{-\mathrm{i}\gamma}[-\partial/\partial\beta + (\cot\beta) K_3 - (\sin\beta)^{-1} M_3] ,$$
$$K_- = \mathrm{e}^{\mathrm{i}\gamma}[\partial/\partial\beta + (\cot\beta) K_3 - (\sin\beta)^{-1} M_3] .$$

Euler angles with $Z = U^*(\alpha\beta\gamma)$ [replace i by $-$i in the above relations]:

$$M_3 = -\mathrm{i}\partial/\partial\alpha , \quad K_3 = -\mathrm{i}\partial/\partial\gamma , \tag{2.34}$$
$$M_\pm = \mathrm{e}^{\pm\mathrm{i}\alpha}\left[\pm\partial/\partial\beta - (\cot\beta) M_3 + (\sin\beta)^{-1} K_3 \right] ,$$
$$K_\pm = \mathrm{e}^{\pm\mathrm{i}\gamma}\left[\mp\partial/\partial\beta + (\cot\beta) K_3 - (\sin\beta)^{-1} M_3 \right] .$$

Since $D^j(U^*) = (D^j(U))^*$, which is denoted $D^{j*}(U)$, these operators have the standard action on the complex conjugate functions $D^{j*}_{mm'}(U)$. Quaternionic variables. $(x_0, \mathbf{x}) \in \mathbf{R}^4$:

$$\left(x_0', \mathbf{x}'\right)(x_0, \mathbf{x}) = \left(x_0' x_0 - \mathbf{x}' \cdot \mathbf{x}, \, x_0' \mathbf{x} + x_0 \mathbf{x}' + \mathbf{x}' \times \mathbf{x}\right) ;$$

$$Z = \begin{pmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{pmatrix} = \begin{pmatrix} x_0 - \mathrm{i}x_3 & -\mathrm{i}x_1 - x_2 \\ -\mathrm{i}x_1 + x_2 & x_0 + \mathrm{i}x_3 \end{pmatrix} ;$$

$$\frac{\partial}{\partial Z} = \begin{pmatrix} \partial/\partial z_{11} & \partial/\partial z_{12} \\ \partial/\partial z_{21} & \partial/\partial z_{22} \end{pmatrix}$$
$$= \frac{1}{2} \begin{pmatrix} \partial/\partial x_0 + \mathrm{i}\partial/\partial x_3 & \mathrm{i}\partial/\partial x_1 - \partial/\partial x_2 \\ \mathrm{i}\partial/\partial x_1 + \partial/\partial x_2 & \partial/\partial x_0 - \mathrm{i}\partial/\partial x_3 \end{pmatrix} ;$$

$$M_{\mathrm{i}} = \frac{1}{2}\mathrm{Tr}\left(Z^{\mathrm{T}} \sigma_i \partial/\partial Z\right) , \quad K_i = \frac{1}{2}\mathrm{Tr}\left(\sigma_i Z^{\mathrm{T}} \partial/\partial Z\right) .$$

(The form of $\partial/\partial Z$ is determined by the requirement $(\partial/\partial z_{ij}) z_{lk} = \delta_{il}\delta_{jk}$; for example, $\frac{1}{2}(\partial/\partial x_0 + \mathrm{i}\partial/\partial x_3)(x_0 - \mathrm{i}x_3) = 1$).

Define the six orbital angular momentum operators in $\mathbf{R}^4$ by

$$L_{jk} = -\mathrm{i}(x_j \partial/\partial x_k - x_k \partial/\partial x_j) , \quad j < k = 0, 1, 2, 3 ,$$

which may be written as the orbital angular momentum $\mathbf{L}$ in $\mathbf{R}^3$ together with the three operators $\mathbf{A}$ given by

$$\mathbf{L} = -\mathrm{i}\mathbf{x} \times \nabla , \quad L_1 = L_{23} ,$$
$$L_2 = L_{31} , \quad L_3 = L_{12} ,$$
$$\mathbf{A} = (A_1, A_2, A_3) = (L_{01}, L_{02}, L_{03}) .$$

Then, we have the following relations:

$$K_1 = (L_1 - A_1)/2 , \quad K_2 = (L_2 - A_2)/2 ,$$
$$K_3 = (L_3 - A_3)/2 ;$$
$$M_1 = -(L_1 + A_1)/2 , \quad M_2 = (L_2 + A_2)/2 ,$$
$$M_3 = -(L_3 + A_3)/2 .$$

Commutation rules:

$$[M_j, K_k] = 0 , \quad j, k = 1, 2, 3 ,$$
$$\boldsymbol{M} \times \boldsymbol{M} = \mathrm{i}\boldsymbol{M} , \quad \boldsymbol{K} \times \boldsymbol{K} = \mathrm{i}\boldsymbol{K} ,$$
$$\boldsymbol{L} \times \boldsymbol{L} = \mathrm{i}\boldsymbol{L} , \quad \boldsymbol{A} \times \boldsymbol{A} = \mathrm{i}\boldsymbol{L} ,$$
$$[L_j, A_k] = \mathrm{i}e_{jkl}A_l ,$$

where $e_{jkl} = 1$ for j, k, l an even permutation of 1, 2, 3; $e_{jkl} = -1$ for an odd permutation of 1, 2, 3; $e_{jkl} = 0$, otherwise.

The $\boldsymbol{M} = (M_1, M_2, M_3)$ and $\boldsymbol{K} = (K_1, K_2, K_3)$ operators have the standard action given in Sect. 2.2 on the functions $D^j_{mm'}(x_0, \boldsymbol{x})$ defined by (2.22) (Replace α_0 by x_0 and $\boldsymbol{\alpha}$ by $\boldsymbol{x}$). Additional relations:

$$\boldsymbol{K}^2 = \boldsymbol{M}^2 = -\frac{1}{4}R^2\nabla_4^2 + K_0^2 + K_0 ,$$
$$R^2 = x_0^2 + \boldsymbol{x} \cdot \boldsymbol{x} ,$$
$$\nabla_4^2 = \frac{\partial^2}{\partial x_0^2} + \nabla^2 = \sum_\mu \frac{\partial^2}{\partial x_\mu^2} ,$$
$$K_0 = \frac{1}{2}\mathrm{Tr}\left(z^\mathrm{T}\frac{\partial}{\partial Z}\right) = \frac{1}{2}\sum_{\mu=0}^{3} x_\mu \frac{\partial}{\partial x_\mu} ;$$
$$K_0 D^j_{mm'}(x_0, \boldsymbol{x}) = j D^j_{mm'}(x_0, \boldsymbol{x}) ,$$
$$\nabla_4^2 D^j_{mm'}(x_0, \boldsymbol{x}) = 0 ;$$

$$(M_1, -M_2, M_3) =$$
$$\left(\sum_i R_{i1}K_i, \sum_i R_{i2}K_i, \sum_i R_{i3}K_i\right) ,$$
$$R_{ij} = \frac{(x_0^2 - \boldsymbol{x} \cdot \boldsymbol{x})\delta_{ij} - 2e_{ijk}x_0 x_k + 2x_i x_j}{x_0^2 + \boldsymbol{x} \cdot \boldsymbol{x}} ,$$
$$\text{each } (x_0, \boldsymbol{x}) \in \boldsymbol{R}^4 .$$

The relation $R_{ij} = R_{ij}(x_0, \boldsymbol{x})$ is a mapping of all points of four-space $\boldsymbol{R}^4$ (except the origin) onto the group of proper, orthogonal matrices; for $x_0^2 + \boldsymbol{x} \cdot \boldsymbol{x} = 1$, it is just the Euler–Rodrigues parametrization, (2.21).

The operators $\boldsymbol{R} = (-M_1, M_2, -M_3)$ and $\boldsymbol{K} = (K_1, K_2, K_3)$ have the standard action on $(-1)^{j+m} D^j_{-m,m'}(x_0, \boldsymbol{x})$, so that the orbital angular momentum in $\boldsymbol{R}^3$ is given by the addition $\boldsymbol{L} = \boldsymbol{R} + \boldsymbol{K}$. Thus, one finds:

$$\sum_{mm'} C^{jjL}_{mm'M}(-1)^{j+m} D^j_{-mm'}(x_0, \boldsymbol{x})$$
$$= A_{2j,L} R^{2j-L} \mathcal{Y}_{LM}(\boldsymbol{x}) C^{(L+1)}_{2j-L}(x_0/R) ,$$
$$A_{2j,L} = (2\mathrm{i})^L (-1)^{2j} L! \left(\frac{4\pi(2j-L)!}{(2j+L+1)!}\right)^{\frac{1}{2}} .$$

2.6 The Symmetric Rotor and Representation Functions

The rigid rotor is an important physical object and its quantum description enters into many physical theories. This description is an application of angular momentum theory with subtleties that need to be made explicit. It is customary to describe the classical rotor in terms of a right-handed triad of unit vectors $(\hat{\boldsymbol{f}}_1, \hat{\boldsymbol{f}}_2, \hat{\boldsymbol{f}}_3)$ fixed in the rotor and constituting a principal axes system located at the center of mass. The instantaneous orientation of this body-fixed frame relative to a right-handed triad of unit vector $(\hat{\boldsymbol{e}}_1, \hat{\boldsymbol{e}}_2, \hat{\boldsymbol{e}}_3)$ specifying an inertial frame, also located at the center of mass, is then given, say, in terms of Euler angles (one could use for this purpose any parametrization of a proper, orthogonal matrix). For Euler angles, the relationship is

$$\hat{\boldsymbol{f}}_j = \sum_i R_{ij}(\alpha\beta\gamma)\hat{\boldsymbol{e}}_i . \tag{2.35}$$

The Hamiltonian for the rigid rotor is then of the form

$$H = A\mathcal{P}_1^2 + B\mathcal{P}_2^2 + C\mathcal{P}_3^2 ,$$

where A, B, and C are physical constants related to the reciprocals of the principal moments of inertia, and the angular momenta $\mathcal{P}_j$ ($j = 1, 2, 3$) are the components of the total angular momentum $\mathcal{J}$ referred to the body-fixed frame:

$$\mathcal{P}_j = \hat{\boldsymbol{f}}_j \cdot \mathcal{J} = \sum_i R_{ij}(\alpha\beta\gamma)\mathcal{J}_i ,$$
$$\mathcal{J} = \hat{\boldsymbol{e}}_1\mathcal{J}_1 + \hat{\boldsymbol{e}}_2\mathcal{J}_2 + \hat{\boldsymbol{e}}_3\mathcal{J}_3 .$$

For the symmetric rotor (taking $A = B$), the Hamiltonian can be written in the form

$$H = a\mathcal{P}^2 + b\mathcal{P}_3^2 .$$

It is in the interpretation of this Hamiltonian for quantum mechanics that the subtleties already enter, since the nature of angular momentum components referred to a moving reference system must be treated correctly. Relation (2.35) shows that the body-fixed axes cannot commute with the components of the total angular momentum $\mathcal{J}$ referred to the frame $(\hat{\boldsymbol{e}}_1, \hat{\boldsymbol{e}}_2, \hat{\boldsymbol{e}}_3)$. A position

vector x and the orbital angular momentum L, with components both referred to an inertial frame, satisfy the commutation relations $[L_j, x_k] = i e_{jkl} x_l$, and for a rigid body thought of as a collection of point particles rotating together, the same conditions are to be enforced. Relative to the body-fixed frame, the vector x is expressed as

$$\sum_k x_k \hat{e}_k = \sum_h a_h \hat{f}_h , \quad \text{each } a_h = \text{constant} ,$$

$$x_k = \sum_h a_h R_{kh}(\alpha\beta\gamma) .$$

The direction cosines $R_{kh} = R_{kh}(\alpha\beta\gamma) = \hat{e}_k \cdot \hat{f}_h$ and the physical total angular momentum components referred to an inertial frame must satisfy

$$\left[\mathcal{J}_j, R_{kh} \right] = i e_{jkl} R_{lh} , \quad \text{each } h = 1, 2, 3 ,$$

in complete analogy to $[L_j, x_k] = i e_{jkl} x_l$.

The description of the angular momentum associated with a symmetric rigid rotor and the angular momentum states is summarized as follows [compare (2.35)]: Physical total angular momentum $\mathcal{J}$ with components referred to $(\hat{e}_1, \hat{e}_2, \hat{e}_3)$:

$$\mathcal{J}_1 = i \cos \alpha \cot \beta \frac{\partial}{\partial \alpha} + i \sin \alpha \frac{\partial}{\partial \beta} - i \frac{\cos \alpha}{\sin \beta} \frac{\partial}{\partial \gamma} ,$$

$$\mathcal{J}_2 = i \sin \alpha \cot \beta \frac{\partial}{\partial \alpha} - i \cos \alpha \frac{\partial}{\partial \beta} - i \frac{\sin \alpha}{\sin \beta} \frac{\partial}{\partial \gamma} ,$$

$$\mathcal{J}_3 = -i \frac{\partial}{\partial \alpha} .$$

Physical angular momentum $\mathcal{J}$ with components referred to $(\hat{f}_1, \hat{f}_2, \hat{f}_3)$:

$$\mathcal{P}_1 = -i \cos \gamma \cot \beta \frac{\partial}{\partial \gamma} - i \sin \gamma \frac{\partial}{\partial \beta} + i \frac{\cos \gamma}{\sin \beta} \frac{\partial}{\partial \alpha} ,$$

$$\mathcal{P}_2 = i \sin \gamma \cot \beta \frac{\partial}{\partial \gamma} - i \cos \gamma \frac{\partial}{\partial \beta} - i \frac{\sin \gamma}{\sin \beta} \frac{\partial}{\partial \alpha} ,$$

$$\mathcal{P}_3 = -i \frac{\partial}{\partial \gamma} .$$

Standard commutation of the $\mathcal{J}_i$:

$$[\mathcal{J}_i, \mathcal{J}_j] = i \mathcal{J}_k , \quad i, j, k \text{ cyclic} .$$

$\mathcal{J}_i$ can stand to either side:

$$\mathcal{P}_j = \sum_i R_{ij}(\alpha\beta\gamma) \mathcal{J}_i , \quad \mathcal{J}_i = \sum_i \mathcal{J}_i R_{ij}(\alpha\beta\gamma) .$$

The famous Van Vleck factor of $-i$ in the commutation of the $\mathcal{P}_i$:

$$[\mathcal{P}_i, \mathcal{P}_j] = -i \mathcal{P}_k , \quad i, j, k \text{ cyclic} .$$

Mutual commutativity of the $\mathcal{J}_j$ and $\mathcal{P}_i$:

$$[\mathcal{P}_i, \mathcal{J}_j] = 0 , \quad i, j = 1, 2, 3 .$$

Same invariant (squared) total angular momentum:

$$\mathcal{P}_1^2 + \mathcal{P}_2^2 + \mathcal{P}_3^2 = \mathcal{J}_1^2 + \mathcal{J}_2^2 + \mathcal{J}_3^2 = \mathcal{J}^2$$

$$= - \csc^2 \beta \left(\frac{\partial^2}{\partial \alpha^2} + \frac{\partial^2}{\partial \gamma^2} - 2 \cos \beta \frac{\partial^2}{\partial \alpha \partial \gamma} \right)$$

$$- \frac{\partial^2}{\partial \beta^2} - \cot \beta \frac{\partial}{\partial \beta} .$$

Standard actions:

$$\mathcal{J}^2 D_{mm'}^{j*}(\alpha\beta\gamma) = j(j+1) D_{mm'}^{j*}(\alpha\beta\gamma) ,$$

$$\mathcal{J}_3 D_{mm'}^{j*}(\alpha\beta\gamma) = m D_{mm'}^{j*}(\alpha\beta\gamma) ,$$

$$\mathcal{P}_3 D_{mm'}^{j*}(\alpha\beta\gamma) = m' D_{mm'}^{j*}(\alpha\beta\gamma) ;$$

$$\mathcal{J}_\pm D_{mm'}^{j*}(\alpha\beta\gamma) = [(j \mp m)(j \pm m + 1)]^{\frac{1}{2}}$$
$$\times D_{m \pm 1, m'}^{j*}(\alpha\beta\gamma) ,$$

$$(\mathcal{P}_1 - i \mathcal{P}_2) D_{mm'}^{j*}(\alpha\beta\gamma) = [(j - m')(j + m' + 1)]^{\frac{1}{2}}$$
$$\times D_{m, m'+1}^{j*}(\alpha\beta\gamma) ,$$

$$(\mathcal{P}_1 + i \mathcal{P}_2) D_{mm'}^{j*}(\alpha\beta\gamma) = [(j + m')(j - m' + 1)]^{\frac{1}{2}}$$
$$\times D_{m, m'-1}^{j*}(\alpha\beta\gamma) .$$

Normalized wave functions:

Integral or half-integral j ($SU(2)$ solid body):

$$\left\langle \alpha\beta\gamma \left| \begin{matrix} j \\ mm' \end{matrix} \right. \right\rangle = \sqrt{\frac{2j+1}{2\pi^2}} D_{mm'}^{j*}(\alpha\beta\gamma) , \tag{2.36}$$

with inner product

$$\langle F | F' \rangle = \int d\Omega \, \langle \alpha\beta\gamma | F \rangle^* \langle \alpha\beta\gamma | F' \rangle ,$$

where $d\Omega$ is defined by (2.25) and the integration extends over all α, β, γ given by (2.26).

Integral j (collection of "rigid" point particles):

$$\Psi_{mm'}^j(\alpha\beta\gamma) = \sqrt{\frac{2j+1}{8\pi^2}} D_{mm'}^{j*}(\alpha\beta\gamma) , \tag{2.37}$$

with inner product

$$(\Psi, \Psi') = \int_0^{2\pi} d\alpha \int_0^\pi d\beta \sin \beta \int_0^{2\pi} d\gamma \, F^*(\alpha\beta\gamma) F'(\alpha\beta\gamma) .$$

The concept of a solid (impenetrable) body is conceptually distinct from that of a collection of point particles moving collectively together in translation and rotation.

2.7 Wigner–Clebsch–Gordan and 3–j Coefficients

Wigner–Clebsch–Gordan (WCG) coefficients (also called vector coupling coefficients) enter the theory of angular momentum in several ways: (1) as the coefficients in the real, orthogonal matrix that reduces the Kronecker product of two irreducible representations of the quantal rotation group into a direct sum of irreducibles; (2) as the coupling coefficients for constructing basis states of sharp angular momentum in the tensor product space from basis states of sharp angular momentum spanning the two constituent spaces; (3) as purely combinatorial objects in the expansion of a power of a 3×3 determinant; and (4) as coupling coefficients in the algebra of tensor operators. These perspectives are intimately connected, but have a different focus: the first considers the group itself to be primary and views the Lie algebra as the secondary or derived concept; the second considers the Lie algebra and the construction of the vector spaces that carry irreducible representations as primary, and views the representations carried by these spaces as derived quantities; the third is a mathematical construction, at first seeming almost empty of angular momentum concepts, yet the most revealing in showing the symmetry and other properties of the WCG-coefficients; and the fourth is the natural extension of (2) to operators, recognizing that the set of mappings of a vector space into itself is also a vector space. The subject of tensor operator algebra is considered in the next section because of its special importance for physical applications. This section summarizes formulas relating to the first three viewpoints, giving also the explicit mathematical expression of the coefficients in their several forms.

Either viewpoint, (1) or (2), may be taken as an interpretation of the Clebsch–Gordan series, which expresses abstractly the reduction of a Kronecker product of matrices (denoted $\times$) into a direct sum (denoted $\oplus$) of matrices:

$$[j_1] \times [j_2] = \sum_{j=|j_1-j_2|}^{j_1+j_2} \oplus [j]$$
$$= [|j_1 - j_2|] \oplus [|j_1 - j_2| + 1] \oplus \cdots \oplus [j_1 + j_2] .$$

(2.38)

Given two angular momenta $j_1 \in \{0, \frac{1}{2}, 1, \ldots\}$ and $j_2 \in \{0, \frac{1}{2}, 1, \ldots\}$, the Clebsch–Gordan (CG) series also expresses the rule of addition of two angular momenta:

$$j = j_1 + j_2, \ j_1 + j_2 - 1, \ \ldots, \ |j_1 - j_2| .$$

The integers $\epsilon_{j_1 j_2 j}$ defined by

$$\epsilon_{j_1 j_2 j} = \begin{cases} 1 , & \text{for } j_1, j_2, j \text{ satisfying} \\ & \text{the CG-series rule} \\ 0 , & \text{otherwise} \end{cases} , \qquad (2.39)$$

are useful in many relations between angular momentum quantities. The notation $(j_1 j_2 j)$ is used to symbolize the CG-series relation between three angular momentum quantum numbers.

The representation function and Lie algebra interpretations of the CG-series (2.38) are, respectively:

$$C(D^{j_1} \times D^{j_2})C^{\mathrm{T}} = \sum_j \oplus \epsilon_{j_1 j_2 j} D^j ,$$

$$C\left(J_i^{(j_1)} \times J_i^{(j_2)}\right) C^{\mathrm{T}} = \sum_j \oplus \epsilon_{j_1 j_2 j} J_i^{(j)} ,$$

$$i = 1, 2, 3 .$$

The notation $J_i^{(j)}$ denotes the $(2j+1) \times (2j+1)$ matrix with elements

$$J_{m',m}^{(j)} = \langle jm' \mid J_i \mid jm \rangle ,$$
$$m', m = j, j-1, \ldots, -j .$$

The elements of the real, orthogonal matrix C of dimension $(2j_1 + 1)(2j_2 + 1)$ that effects these reductions are the WCG-coefficients:

$$(C)_{jm;m_1 m_2} = C_{m_1 m_2 m}^{j_1 j_2 j} .$$

The pairs, (jm) and $(m_1 m_2)$, index rows and columns, respectively, of the matrix C:

$$(jm) : j = j_1 + j_2, \ldots, |j_1 - j_2| ,$$
$$m = j, \ldots, -j ;$$
$$(m_1 m_2) : m_1 = j_1, \ldots, -j_1 ;$$
$$m_2 = j_2, \ldots, -j_2 .$$

Sum rule on projection quantum numbers:

$$C_{m_1 m_2 m}^{j_1 j_2 j} = 0 , \quad \text{for } m_1 + m_2 \neq m . \qquad (2.40)$$

Clebsch–Gordan series rule on angular momentum quantum numbers:

$$C_{m_1 m_2 m}^{j_1 j_2 j} = 0 , \text{ for } \epsilon_{j_1 j_2 j} = 0 . \qquad (2.41)$$

In presenting formulas that express relations relating to the conceptual framework described above, it is best to use a notation for a WCG-coefficient giving it as an element of an orthogonal matrix. For the expression of symmetry relations, the $3-j$ coefficient or $3-j$ symbol notation is most convenient. The following notations are used here:

WCG-coefficient notation:

$$|(j_1 j_2) jm\rangle = \sum_{m_1, m_2} C^{j_1 j_2 j}_{m_1 m_2 m} |j_1 m_1\rangle \otimes |j_2 m_2\rangle ,$$

$$|j_1 m_1; j_2 m_2\rangle = |j_1 m_1\rangle \otimes |j_2 m_2\rangle ,$$

$$C^{j_1 j_2 j}_{m_1 m_2 m} = \langle j_1 m_1; j_2 m_2 | (j_1 j_2) jm\rangle ,$$

$$\langle (j_1 j_2) j' m' | (j_1 j_2) jm\rangle = \delta_{j' j} \delta_{m' m} .$$

The $3-j$ coefficient notation:

$$\begin{pmatrix} j_1 & j_2 & j \\ m_1 & m_2 & -m \end{pmatrix}$$
$$= (-1)^{j_1 - j_2 + m} (2j+1)^{-1/2} C^{j_1 j_2 j}_{m_1 m_2 m} . \qquad (2.42)$$

Orthogonality of WCG-coefficients:
  Orthogonality of rows:

$$\sum_{m_1 m_2} C^{j_1 j_2 j}_{m_1 m_2 m} C^{j_1 j_2 j'}_{m_1 m_2 m'} = \delta_{jj'} \delta_{mm'} . \qquad (2.43)$$

Orthogonality of columns (three forms):

$$\sum_{jm} C^{j_1 j_2 j}_{m_1 m_2 m} C^{j_1 j_2 j}_{m'_1 m'_2 m} = \delta_{m_1 m'_1} \delta_{m_2 m'_2} ,$$

$$\sum_{j} C^{j_1 j_2 j}_{m_1 m - m_1, m} C^{j_1 j_2 j}_{m'_1, m - m'_1, m} = \delta_{m_1 m'_1} ,$$

$$\sum_{j} C^{j_1 j_2 j}_{m - m_2, m_2, m} C^{j_1 j_2 j}_{m - m'_2, m'_2, m} = \delta_{m_2 m'_2} . \qquad (2.44)$$

Orthogonality of $3-j$ coefficients (symbols):

$$\sum_{m_1 m_2} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \begin{pmatrix} j_1 & j_2 & j'_3 \\ m_1 & m_2 & m'_3 \end{pmatrix}$$
$$= \delta_{j_3 j'_3} \delta_{m_3 m'_3} / (2j_3 + 1) , \qquad (2.45)$$

$$\sum_{j_3 m_3} (2j_3 + 1) \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \begin{pmatrix} j_1 & j_2 & j_3 \\ m'_1 & m'_2 & m_3 \end{pmatrix}$$
$$= \delta_{m_1 m'_1} \delta_{m_2 m'_2} . \qquad (2.46)$$

The integers $\epsilon_{j_1 j_2 j}$ $(j_3 = j)$ are sometimes included in the orthogonality relations (2.43) and (2.45) to incorporate the extended definition (2.41) of the WCG-coefficients.

2.7.1 Kronecker Product Reduction

Product form:

$$D^{j_1}_{m'_1 m_1}(U) D^{j_2}_{m'_2 m_2}(U)$$
$$= \sum_{j} C^{j_1 j_2 j}_{m'_1, m'_2, m'_1 + m'_2} C^{j_1 j_2 j}_{m_1, m_2, m_1 + m_2}$$
$$\times D^{j}_{m'_1 + m'_2, m_1 + m_2}(U) .$$

Singly coupled form:

$$\sum_{m_1 + m_2 = m} C^{j_1 j_2 j}_{m_1 m_2 m} D^{j_1}_{m'_1 m_1}(U) D^{j_2}_{m'_2 m_2}(U)$$
$$= C^{j_1 j_2 j}_{m'_1, m'_2, m'_1 + m'_2} D^{j}_{m'_1 + m'_2, m}(U) .$$

Doubly coupled (reduction) form:

$$\sum_{\substack{m'_1 + m'_2 = m' \\ m_1 + m_2 = m}} C^{j_1 j_2 j}_{m'_1 m'_2 m'} C^{j_1 j_2 j}_{m_1 m_2 m} D^{j_1}_{m'_1 m_1}(U) D^{j_2}_{m'_2 m_2}(U)$$
$$= \delta_{j' j} D^{j}_{m' m}(U) .$$

Integral relation:

$$\int d\Omega D^{j_1}_{m'_1 m_1}(U) D^{j_2}_{m'_2 m_2}(U) D^{j*}_{m' m_1}(U)$$
$$= \frac{2\pi^2}{2j+1} C^{j_1 j_2 j}_{m'_1 m'_2 m'} C^{j_1 j_2 j}_{m_1 m_2 m} ,$$

in any parametrization of $U \in SU(2)$ that covers S^3 exactly once.

Gaunt's integral:

$$\int_0^{2\pi} d\alpha \int_0^{\pi} \sin \beta \, d\beta Y^*_{lm}(\beta\alpha) Y_{l_1 m_1}(\beta\alpha) Y_{l_2 m_2}(\beta\alpha)$$
$$= \left(\frac{(2l_1 + 1)(2l_2 + 1)}{4\pi(2l + 1)} \right)^{1/2} C^{l_1 l_2 l}_{000} C^{l_1 l_2 l}_{m_1 m_2 m'} .$$

Integral over three Legendre functions:

$$\int\limits_0^\pi \sin\beta\, d\beta\, P_l(\cos\beta)\, P_{l_1}(\cos\beta)\, P_{l_2}(\cos\beta)$$

$$= \frac{2\left(C_{000}^{l_1 l_2 l}\right)^2}{2l+1}\,.$$

$$C_{000}^{l_1 l_2 l}$$

$$= \left(\frac{(2l+1)(l_1+l_2-l)!(l_1-l_2+l)!(-l_1+l_2+l)!}{(l_1+l_2+l+1)!}\right)^{\frac{1}{2}}$$

$$\times \frac{(-1)^{L-1}L!}{(L-l_1)!(L-l_2)!(L-l)!}\,,$$

$$L = \frac{1}{2}(l_1+l_2+l)\,,$$

for l_1+l_2+l even

$$C_{000}^{l_1 l_2 l} = 0\,, \quad \text{for } l_1+l_2+l \text{ odd}\,.$$

2.7.2 Tensor Product Space Construction

Orthonormal basis of H_{j_1}:

$$\left\{|j_1 m_1\rangle \,\middle|\, m_1 = j_1, j_1-1, \dots, -j_1\right\}\,.$$

Orthonormal basis of H_{j_2}:

$$\left\{|j_2 m_2\rangle \,\middle|\, m_2 = j_2, j_2-1, \dots, -j_2\right\}\,.$$

Uncoupled basis of $H_{j_1} \otimes H_{j_2}$:

$$\left\{|j_1 m_1\rangle \otimes |j_2 m_2\rangle \,\middle|\, m_1 = j_1, j_1-1, \dots, -j_1;\right.$$
$$\left. m_2 = j_2, j_2-1, \dots, -j_2\right\}\,.$$

Coupled basis of $H_{j_1} \otimes H_{j_2}$:

$$\left\{|(j_1 j_2) jm\rangle \,\middle|\, j = j_1+j_2, j_1+j_2-1, \dots, |j_1-j_2|;\right.$$
$$m = j, j-1, \dots, -j\Big\}\,,$$

$$|(j_1 j_2) jm\rangle = \sum_{m_1 m_2} C_{m_1 m_2 m}^{j_1 j_2 j} |j_1 m_1\rangle \otimes |j_2 m_2\rangle\,.$$

Unitary transformations of spaces:

$$T_U |j_1 m_1\rangle = \sum_{m_1'} D_{m_1' m_1}^{j_1}(U) |j_1 m_1'\rangle\,,$$

$$m_1 = j_1, j_1-1, \dots, -j_1\,, \quad \text{each } U \in SU(2)\,;$$

$$T_V |j_2 m_2\rangle = \sum_{m_2'} D_{m_2' m_2}^{j}(V) |j_2 m_2'\rangle\,,$$

$$m_2 = j_2, j_2-1, \dots, -j_2\,, \quad \text{each } V \in SU(2)\,;$$

$$T_{(U,V)} |j_1 m_1\rangle \otimes |j_2 m_2\rangle = T_U |j_1 m_1\rangle \otimes T_V |j_2 m_2\rangle$$

$$= \sum_{m_1' m_2'} D_{m_1' m_1}^{j_1}(U) D_{m_2' m_2}^{j_2}(V) |j_1 m_1'\rangle \otimes |j_2 m_2'\rangle\,,$$

$$\text{each } U \in SU(2)\,, \quad \text{each } V \in SU(2)\,;$$

$$T_{(U,U)} |(j_1 j_2) jm\rangle = \sum_{m'} D_{m'm}^{j}(U) |(j_1 j_2) jm'\rangle\,,$$

$$m = j, j-1, \dots, -j;\ \text{each } U \in SU(2)\,.$$

Representation of direct product group $SU(2) \times SU(2)$:

$$T_{(U,V)} T_{(U',V')} = T_{(UU',VV')}\,.$$

Representation of $SU(2)$ as diagonal subgroup of $SU(2) \times SU(2)$:

$$T_{(U,U)} T_{(U',U')} = T_{(UU',UU')}\,,$$
$$T_U = T_{(U,U)}\,.$$

2.7.3 Explicit Forms of WCG-Coefficients

Wigner's form:

$$C_{m_1 m_2 m}^{j_1 j_2 j}$$

$$= \delta(m_1+m_2, m)(2j+1)^{\frac{1}{2}}$$

$$\times \left(\frac{(j+j_1-j_2)!(j-j_1+j_2)!(j_1+j_2-j)!}{(j+j_1+j_2+1)!}\right)^{\frac{1}{2}}$$

$$\times \left(\frac{(j+m)!(j-m)!}{(j_1+m_1)!(j_1-m_1)!(j_2+m_2)!(j_2-m_2)!}\right)^{\frac{1}{2}}$$

$$\times \sum_s \frac{(-1)^{j_2+m_2+s}(j_2+j+m_1-s)!(j_1-m_1+s)!}{s!(j-j_1+j_2-s)!(j+m-s)!(j_1-j_2-m+s)!}\,.$$

Racah's form:

$$C_{m_1 m_2 m}^{j_1 j_2 j} =$$
$$\delta(m_1+m_2, m)$$

$$\times \left(\frac{(2j+1)(j_1+j_2-j)!}{(j_1+j_2+j+1)!(j+j_1-j_2)!(j+j_2-j_1)!}\right)^{\frac{1}{2}}$$

$$\times \left(\frac{(j_1-m_1)!(j_2-m_2)!(j-m)!(j+m)!}{(j_1+m_1)!(j_2+m_2)!}\right)^{\frac{1}{2}}$$

$$\times \sum_t \frac{(-1)^{j_1-m_1+t}(j_1+m_1+t)!(j+j_2-m_1-t)!}{t!(j-m-t)!(j_1-m_1-t)!(j_2-j+m_1+t)!}\,.$$

Van der Waerden's form:

$$C^{j_1 j_2 j}_{m_1 m_2 m}$$

$$= \delta(m_1 + m_2, m)$$

$$\times \left(\frac{(2j+1)(j_1 + j_2 - j)!(j + j_1 - j_2)!(j + j_2 - j_1)!}{(j_1 + j_2 + j + 1)!} \right)^{\frac{1}{2}}$$

$$\times \left[(j_1 + m_1)!(j_1 - m_1)!(j_2 + m_2)!(j_2 - m_2)! \right]^{\frac{1}{2}}$$

$$\times \left[(j + m)!(j - m)! \right]^{\frac{1}{2}}$$

$$\times \sum_k (-1)^k \left[k!(j_1 + j_2 - j - k)!(j_1 - m_1 - k)! \right.$$

$$\times (j_2 + m_2 - k)!(j - j_2 + m_1 + k)!$$

$$\times (j - j_1 - m_2 + k)! \right]^{-1}$$

Regge's formula and its combinatoric structure:

$$(\det A)^k = \sum_{\boxed{\alpha}} A(\alpha) \prod_{i,j=1}^{3} (a_{ij})^{\alpha_{ij}}, \quad A = (a_{ij}),$$

$$(2.47)$$

where the summation is over all nonnegative integers α_{ij} that satisfy the row and column sum constraints (2.17) given by

$$\alpha = \begin{array}{|ccc|c} \hline \alpha_{11} & \alpha_{12} & \alpha_{13} & k \\ \alpha_{21} & \alpha_{22} & \alpha_{23} & k \\ \alpha_{31} & \alpha_{32} & \alpha_{33} & k \\ \hline k & k & k \end{array}$$

$$(2.48)$$

The coefficients $A(\alpha)$ are constrained sums over multinomial coefficients:

$$A(\alpha) = \sum (-1)^{\phi(K)}$$

$$\times \binom{k}{k_{123}, k_{132}, k_{231}, k_{213}, k_{312}, k_{321}},$$

where the summation is carried out over all nonnegative integers $k_{i_1 i_2 i_3}$ such that

$$\alpha_{11} = k_{123} + k_{132}, \quad \alpha_{12} = k_{231} + k_{213},$$

$$\alpha_{13} = k_{312} + k_{321},$$

$$\alpha_{21} = k_{312} + k_{213}, \quad \alpha_{22} = k_{123} + k_{321},$$

$$\alpha_{23} = k_{231} + k_{132},$$

$$\alpha_{31} = k_{231} + k_{321}, \quad \alpha_{32} = k_{312} + k_{132},$$

$$\alpha_{33} = k_{123} + k_{213},$$

$$\phi(K) = \sum_{\pi \in A_3} k_\pi = k_{132} + k_{213} + k_{321}.$$

The general multinomial coefficient is the integer defined by

$$\binom{k}{k_1, k_2, \ldots, k_s} = k!/k_1! k_2! \cdots k_s!, \quad k = \sum_i k_i.$$

Relation (2.47) generalizes in the obvious way to an $n \times n$ determinant, using the symmetric group S_n and its S_{n-1} subgroups $S^{(j)}_{n-1}$, where j denotes that this is the permutation group on the integers $1, 2, \ldots, n$ with j deleted [2.2].

Regge's formula for the 3–j coefficient is:

$$\begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix}$$

$$= \delta(m_1 + m_2 + m_3, 0) \left[\prod_{i,j=1}^{3} (\alpha_{ij})! \right]^{\frac{1}{2}}$$

$$\times \frac{A(\alpha)}{k![(k+1)!]^{\frac{1}{2}}},$$

$$k = j_1 + j_2 + j_3, \qquad (2.49)$$

$$\alpha_{11} = j_1 + m_1, \quad \alpha_{12} = j_2 + m_2, \quad \alpha_{13} = j_3 + m_3,$$

$$\alpha_{21} = j_1 - m_1, \quad \alpha_{22} = j_2 - m_2, \quad \alpha_{23} = j_3 - m_3,$$

$$\alpha_{31} = j_2 + j_3 - j_1, \quad \alpha_{32} = j_3 + j_1 - j_2,$$

$$\alpha_{33} = j_1 + j_2 - j_3.$$

Equation (2.49) shows that WCG-coefficients and 3–j coefficients are sums over integers, except for a multiplicative normalization factor.

Schwinger's generating function:

$$\exp(t \det A) = \sum_k \frac{t^k}{k!} \sum_{\boxed{\alpha}} A(\alpha) \prod_{i,j} (a_{ij})^{\alpha_{ij}}.$$

The general definition of the $_pF_q$ hypergeometric function depending on p numerator parameters, q denominator parameters, and a single variable z is:

$$_pF_q \begin{pmatrix} a_1 \ldots, a_p \\ b_1 \ldots, b_q \end{pmatrix}; z = \sum_{n=0}^{\infty} \frac{(a_1)_n \cdots (a_p)_n}{(b_1)_n \cdots (b_q)_n} \frac{z^n}{n!},$$

$$(a)_n = a(a+1) \cdots (a+n-1), \quad (a)_0 = 1.$$

Such a series is terminating if at least one of the numerator parameters is a negative integer (and all other factors are well-defined). Both WCG-coefficients and Racah 6–j coefficients relate to special series of this type, evaluated at $z = 1$. For WCG-coefficients, we have for $\alpha + \beta = \gamma$:

$$
\begin{aligned}
&C^{abc}_{\alpha\beta\gamma} \\
&= [(2c+1)(a+\alpha)!(a-\alpha)!(b+\beta)!(b-\beta)!(c+\gamma)! \\
&\times (c-\gamma)!]^{\frac{1}{2}} (-1)^{a+b+\gamma+\delta_1} \Delta(abc) \\
&\times \frac{{}_3F_2\left(\begin{array}{c} \epsilon_1 - \delta_1, \epsilon_2 - \delta_1, \epsilon_3 - \delta_1 \\ \delta_2 - \delta_1 + 1, \delta_3 - \delta_1 + 1 \end{array}; 1\right)}{(\delta_2-\delta_1)!(\delta_3-\delta_1)!(\delta_1-\epsilon_1)!(\delta_1-\epsilon_2)!(\delta_1-\epsilon_3)!},
\end{aligned}
$$

$\delta_1 = \min(a+\alpha+b+\beta, b-\beta+c+\gamma, a+\alpha+c+\gamma)$, $(\delta_1, \delta_2, \delta_3) =$ any permutation of $(a+\alpha+b+\beta, b-\beta +c+\gamma, a+\alpha+c+\gamma)$, after δ_1 is fixed, $(\epsilon_1, \epsilon_2, \epsilon_3) =$ any permutation of $(a+\alpha, b+\alpha+\gamma, c+\gamma)$. A somewhat better form can be found in [2.2].
The quantity

$$
\Delta(abc) = \left(\frac{(a+b-c)!(a-b+c)!(-a+b+c)!}{(a+b+c+1)!}\right)^{\frac{1}{2}}.
$$

is called a triangle coefficient.

All 72 Regge symmetries are consequences of known properties of the ${}_3F_2$ hypergeometric series.

2.7.4 Symmetries of WCG–Coefficients in 3–j Symbol Form

There are 72 known symmetries (up to sign changes) of the 3–j coefficient. There are at least four ways of verifying these symmetries: (1) directly from the van der Waerden form of the coefficients; (2) directly from Regge's generating function; (3) from the known symmetries of the ${}_3F_2$ hypergeometric series; and (4) directly from the symmetries of the representation functions $D^j_{mm'}(U)$. The set of 72 symmetries is succinctly expressed in terms of the coefficient $A(\alpha)$ defined in Sect. 2.8.3 with α_{ij} entries given by (2.48) and (2.49) in which $m_1 + m_2 + m_3 = 0$:

$$
A\begin{pmatrix} j_1+m_1 & j_2+m_2 & j_3+m_3 \\ j_1-m_1 & j_2-m_2 & j_3-m_3 \\ j_2+j_3-j_1 & j_3+j_1-j_2 & j_1+j_2-j_3 \end{pmatrix}.
$$

This coefficient has determinantal symmetry; that is, it is invariant under even permutations of its rows or columns and under transposition, and is multiplied by the factor $(-1)^{j_1+j_2+j_3}$ under odd permutations of its rows or columns. These 72 determinantal operations may be generated from the three operations C_{12}, C_{13}, T consisting of interchange of columns 1 and 2, interchange of columns 1 and 3, and transposition, since the first two operations generate the symmetric group S_3 of permutations of columns, and the symmetric group S'_3 of permutations of rows is then given by TS_3T. The transposition T itself generates a group $\{e, T\}$ isomorphic to the symmetric group S_2. Thus, the 72 element determinantal group is the direct product group $S_3 \times S'_3 \times \{e, T\}$. The three relations between 3–j coefficients corresponding to the generators C_{12}, C_{13}, T are

$$
\begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} = (-1)^{j_1+j_2+j_3} \begin{pmatrix} j_2 & j_1 & j_3 \\ m_2 & m_1 & m_3 \end{pmatrix},
$$

$$
\begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} = (-1)^{j_1+j_2+j_3} \begin{pmatrix} j_3 & j_2 & j_1 \\ m_3 & m_2 & m_1 \end{pmatrix},
$$

$$
\begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix}
$$

$$
= \begin{pmatrix} \frac{j_1+j_2+m_1+m_2}{2} & \frac{j_1+j_2-m_1-m_2}{2} & j_3 \\ \frac{j_1-j_2+m_1-m_2}{2} & \frac{j_1-j_2-m_1+m_2}{2} & j_2-j_1 \end{pmatrix}.
$$

All 72 relations among 3–j coefficients can be obtained from these 3. The 12 "classical" symmetries of the 3–j symbol

$$
\begin{pmatrix} a & b & c \\ \alpha & \beta & \gamma \end{pmatrix}
$$

are expressed by:

1. even permutations of the columns leave the coefficient invariant;
2. odd permutations of the columns change the sign by the factor $(-1)^{a+b+c}$;
3. simultaneous sign reversal of the projection quantum numbers changes the sign by $(-1)^{a+b+c}$.

The 72 corresponding symmetries of the WCG-coefficients (up to sign changes and dimensional factors) are best obtained from those of the 3j-coefficients by using (2.42).

2.7.5 Recurrence Relations

Three-term:

$$[(J+1)(J-2j_1)]^{\frac{1}{2}} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix}$$

$$= [(j_2+m_2)(j_3-m_3)]^{\frac{1}{2}} \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3-\frac{1}{2} \\ m_1 & m_2-\frac{1}{2} & m_3+\frac{1}{2} \end{pmatrix}$$

$$- [(j_2-m_2)(j_3+m_3)]^{\frac{1}{2}} \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3-\frac{1}{2} \\ m_1 & m_2+\frac{1}{2} & m_3-\frac{1}{2} \end{pmatrix} ;$$

$$[(J-2j_2)(J+1-2j_3)]^{\frac{1}{2}} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix}$$

$$+ [(j_2+m_2+1)(j_3+m_3)]^{\frac{1}{2}}$$

$$\times \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3+\frac{1}{2} \\ m_1 & m_2-\frac{1}{2} & m_3+\frac{1}{2} \end{pmatrix}$$

$$+ [(j_2-m_2+1)(j_3-m_3)]^{\frac{1}{2}}$$

$$\times \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3+\frac{1}{2} \\ m_1 & m_2+\frac{1}{2} & m_3-\frac{1}{2} \end{pmatrix} = 0 ;$$

$$(j_2+m_2)^{\frac{1}{2}} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m & m_3 \end{pmatrix}$$

$$= [(j_3-j_1+j_2)(J+1)(j_3-m_3)]^{\frac{1}{2}}$$

$$\times \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3-\frac{1}{2} \\ m_1 & m_2-\frac{1}{2} & m_3-\frac{1}{2} \end{pmatrix}$$

$$- [(j_1-j_3+j_2)(J-2j_2+1)(j_3+m_3+1)]^{\frac{1}{2}}$$

$$\times \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3+\frac{1}{2} \\ m_1 & m_2-\frac{1}{2} & m_3+\frac{1}{2} \end{pmatrix} ;$$

$$\begin{pmatrix} j_1 & j_2 & j_3 \\ j_2-m_3 & -j_2 & m_3 \end{pmatrix}$$

$$= - \left(\frac{2j_2(j_3+m_3)}{(j_3-j_1+j_2)(J+1)} \right)^{\frac{1}{2}}$$

$$\times \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3-\frac{1}{2} \\ j_2-m_3 & -j_2+\frac{1}{2} & m_3-\frac{1}{2} \end{pmatrix} ,$$

$$j_3 = j_1+j_2, \, j_1+j_2-1, \ldots, j_1-j_2+1$$

$$\text{for } j_1 \geq j_2 ;$$

$$\begin{pmatrix} j_1 & j_2 & j_3 \\ j_2-m_3 & -j_2 & m_3 \end{pmatrix}$$

$$= - \left(\frac{2j_2(j_3-m_3+1)}{(j_1-j_3+j_2)(J-2j_2+1)} \right)^{\frac{1}{2}}$$

$$\times \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3+\frac{1}{2} \\ j_2-m_3 & -j_2+\frac{1}{2} & m_3-\frac{1}{2} \end{pmatrix} ,$$

$$j_3 = j_1+j_2-1, \, j_1+j_2-2, \ldots, j_1-j_2$$

$$\text{for } j_1 \geq j_2 .$$

Four-term:

$$[(J+1)(J-2j_1)(J-2j_2)(J-2j_3+1)]^{\frac{1}{2}}$$

$$\times \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} = [(j_2-m_2)(j_2+m_2+1)$$

$$\times (j_3+m_3)(j_3+m_3-1)]^{\frac{1}{2}}$$

$$\times \begin{pmatrix} j_1 & j_2 & j_3-1 \\ m_1 & m_2+1 & m_3-1 \end{pmatrix}$$

$$- 2m_2[(j_3+m_3)(j_3-m_3)]^{\frac{1}{2}} \begin{pmatrix} j_1 & j_2 & j_3-1 \\ m_1 & m_2 & m_3 \end{pmatrix}$$

$$- [(j_2+m_2)(j_2-m_2+1)(j_3-m_3)(j_3-m_3-1)]^{\frac{1}{2}}$$

$$\times \begin{pmatrix} j_1 & j_2 & j_3-1 \\ m_1 & m_2-1 & m_3+1 \end{pmatrix} .$$

Five-term:

$$C^{bdf}_{\beta,\delta,\beta+\delta}$$

$$= \left(\frac{(b+d-f)(b+f-d+1)(d-\delta)(f+\beta+\delta+1)}{(2d)(2f+1)(2d)(2f+2)} \right)^{\frac{1}{2}}$$

$$\times C^{bd-1/2\,f+1/2}_{\beta,\delta+1/2,\beta+\delta+1/2}$$

$$- \left(\frac{(b+d-f)(b+f-d+1)(d+\delta)(f-\beta-\delta+1)}{(2d)(2f+1)(2d)(2f+2)} \right)^{\frac{1}{2}}$$

$$\times C^{bd-1/2\,f+1/2}_{\beta,\delta-1/2,\beta+\delta-1/2}$$

$$+ \left(\frac{(d+f-b)(b+d+f+1)(d+\delta)(f+\beta+\delta)}{(2d)(2f+1)(2d)(2f)} \right)^{\frac{1}{2}}$$

$$\times C^{bd-1/2\,f-1/2}_{\beta,\delta-1/2,\beta+\delta-1/2}$$

$$+ \left(\frac{(d+f-b)(b+d+f+1)(d-\delta)(f-\beta-\delta)}{(2d)(2f+1)(2d)(2f)} \right)^{\frac{1}{2}}$$

$$\times C^{bd-1/2\,f-1/2}_{\beta,\delta+1/2,\beta+\delta+1/2} .$$

This relation may be used to prove the limit relation (2.50) from the similar recurrence relation (2.84c) for the Racah coefficients.

2.7.6 Limiting Properties and Asymptotic Forms

$$\lim_{a\to\infty} C^{aba+\rho}_{a-\alpha,\beta,a-\alpha+\beta} = \delta_{\rho\beta} \,,$$

$$\lim_{j\to\infty} (-1)^{a+b+2j-\tau}[(2c+1)(2j-2\sigma+1)]^{\frac{1}{2}}$$

$$\times \begin{Bmatrix} j-\tau & a & j-\sigma \\ b & j & c \end{Bmatrix} = C^{abc}_{\rho\sigma\tau} \,, \qquad (2.50)$$

where the brace symbol is a $6-j$ coefficient (Sect. 2.9).

$$C^{jkj+\Delta}_{m,\mu,m+\mu} \approx (-1)^{\Delta-\mu} D^{k}_{\mu\Delta} \begin{pmatrix} \cos\frac{1}{2}\beta & \sin\frac{1}{2}\beta \\ -\sin\frac{1}{2}\beta & \cos\frac{1}{2}\beta \end{pmatrix}$$

$$= d^{k}_{\mu\Delta}(\beta) \,, \qquad \text{for large } j \,;$$

$$\cos\frac{1}{2}\beta = \sqrt{\frac{j+m}{2j}} \,, \qquad \sin\frac{1}{2}\beta = \sqrt{\frac{j-m}{2j}} \,,$$

$$C^{jkj}_{m0m} \approx P_k(\cos\beta) \,, \qquad \text{for large } j \,;$$
$$(-1)^k[(2j+1)(2J+1)]^{\frac{1}{2}} W(j,k,J+m,J;j,J)$$
$$\sim P_k(\cos\beta),$$
first for large J, then large j (Sect. 2.9).

2.7.7 WCG–Coefficients as Discretized Representation Functions

$$C^{j_1 j_2 j}_{m_1 m_2 m}$$
$$= \delta_{m_1+m_2,m}(-1)^{j_1-m_1}$$

$$\times \left(\frac{(2j+1)(j_1+j_2-j)!}{(j_1+j_2+j+1)!} \right)^{\frac{1}{2}}$$

$$\times D^{j}_{m,j_1-j_2} \begin{pmatrix} \sqrt{j_1+m_1} & \sqrt{j_2+m_2} \\ -\sqrt{j_1-m_1} & \sqrt{j_2-m_2} \end{pmatrix} \underset{\text{powers}}{\text{symbolic}} \,,$$

$$\qquad (2.51)$$

where in evaluating this result one first substitutes

$$u_{11} = \sqrt{j_1+m_1} \,,$$
$$u_{12} = \sqrt{j_2+m_2} \,,$$
$$u_{21} = -\sqrt{j_1-m_1} \,,$$
$$u_{22} = \sqrt{j_2-m_2}$$

into the form (2.17), followed by the replacement of ordinary powers by generalized powers:

$$(\pm\sqrt{k})^s \to (\pm 1)^s \left(\frac{k!}{(k-s)!} \right)^{\frac{1}{2}} \,.$$

2.8 Tensor Operator Algebra

2.8.1 Conceptual Framework

A tensor operator can be characterized in terms of its algebraic properties with respect to the angular momentum $\mathbf{J}$ or in terms of its transformation properties under unitary transformations generated by $\mathbf{J}$. Both viewpoints are essential.

A tensor operator $\mathbf{T}$ with respect to the group $SU(2)$ is a set of linear operators

$$\mathbf{T} = \{T_1, T_2, \dots, T_n\} \,,$$

where each operator in the set acts in the space $\mathcal{H}$ defined by (2.10) and maps this space into itself $T_i : \mathcal{H} \to \mathcal{H}$, $i = 1, 2, \dots, n$, and where this set of operators has the following properties with respect to the angular momentum $\mathbf{J}$, which acts in the same space $\mathcal{H}$ in the standard way:

1. Commutation relations with respect to the angular momentum $\mathbf{J}$:

$$[J_i, T_j] = \sum_{k=1}^{n} t^{(i)}_{kj} T_k \,,$$

where the $t^{(i)}_{kj}$ are scalars (invariants) with respect to $\mathbf{J}$.

2. Unitary transformation with respect to $SU(2)$ rotations:

$$e^{-i\psi\hat{\mathbf{n}}\cdot\mathbf{J}} T_i \, e^{i\psi\hat{\mathbf{n}}\cdot\mathbf{J}} = \sum_{j=1}^{n} D_{ji}(U) T_j \,,$$
$$U = U(\psi, \hat{\mathbf{n}}) \,,$$

where the matrix $D(U)$ is an $n \times n$ unitary matrix representation of $SU(2)$. Reduction of this representation into its irreducible constituents gives the notion of an ir-

reducible tensor operator $\boldsymbol{T}^J$ of rank J. An irreducible tensor operator $\boldsymbol{T}^J$ of rank J is a set of $2J+1$ operators

$$\boldsymbol{T}^J = \left\{ T_M^J \mid M = J, J-1, \dots, -J \right\}$$

with the following properties with respect to $SU(2)$:

1. Commutation relations with respect to the angular momentum $\boldsymbol{J}$:

$$\left[J_+, T_M^J \right] = \left[(J-M)(J+M+1) \right]^{\frac{1}{2}} T_{M+1}^J ,$$
$$\left[J_-, T_M^J \right] = \left[(J+M)(J-M+1) \right]^{\frac{1}{2}} T_{M-1}^J ,$$
$$\left[J_3, T_M^J \right] = M T_M^J ,$$
$$\sum_i \left[J_i, \left[J_i, T_M^J \right] \right] = J(J+1) T_M^J . \qquad (2.52)$$

2. Generation from highest "weight":

$$T_M^J = \left(\frac{(J+M)!}{(2J)!(J-M)!} \right)^{\frac{1}{2}} \left[J_-, T_J^J \right]_{(J-M)} ,$$

where $[A, B]_{(k)} = [A, [A, B]_{(k-1)}], k = 1, 2, \dots$, with $[A, B]_{(0)} = B$, denotes the k-fold commutator of A with B.

3. Unitary transformation with respect to $SU(2)$ rotations:

$$e^{-i\psi\hat{\boldsymbol{n}}\cdot\boldsymbol{J}} T_M^J e^{i\psi\hat{\boldsymbol{n}}\cdot\boldsymbol{J}} =$$
$$\sum_{M'} D_{M'M}^J(U) T_{M'}^J, \quad U = U(\psi, \hat{\boldsymbol{n}}) . \qquad (2.53)$$

Angular momentum operators act in Hilbert spaces by acting linearly on the vectors in such spaces. The concept of a tensor operator generalizes this by replacing the irreducible space H_J by the irreducible tensor $\boldsymbol{T}^J$, and angular momentum operator action on H_J by commutator action on $\boldsymbol{T}^J$, as symbolized, respectively, by

$$\boldsymbol{J} : \{\text{ states }\} \to \{\text{ states }\},$$
$$\{ \text{ commutator action of } \boldsymbol{J} \} : \{ \text{ tensor operators }\}$$
$$\to \{\text{tensor operators }\} .$$

Just as exponentiation of the standard generator action (2.13) and (2.14) gives relation (2.16), so does the exponentiation of the commutator action (2.52) give relation (2.53), when one uses the Baker–Campell–Hausdorff identity:

$$e^{tA} B e^{-tA} = \sum_k \frac{t^k}{k!} [A, B]_{(k)} .$$

Thus, the linear vector space of states is replaced by the linear vector space of operators. Abstractly, relations (2.13) and (2.52) are identical: only the rule of action and the object of that action has changed.

An example of an irreducible tensor of rank 1 is the angular momentum $\boldsymbol{J}$ itself, which has the special property $\boldsymbol{J} : \mathcal{H}_j \to \mathcal{H}_j$. Thus, relations (2.52) and (2.53) are realized as:

$$T_1^1 = J_{+1} = -(J_1 + iJ_2)/\sqrt{2} ,$$
$$T_0^1 = J_0 = J_3 ,$$
$$T_{-1}^1 = J_{-1} = (J_1 - iJ_2)/\sqrt{2} ;$$
$$\left[J_+, T_\mu^1 \right] = \left[(1-\mu)(2+\mu) \right]^{\frac{1}{2}} T_{\mu+1}^1 ,$$
$$\left[J_-, T_\mu^1 \right] = \left[(1+\mu)(2-\mu) \right]^{\frac{1}{2}} T_{\mu-1}^1 ,$$
$$\left[J_3, T_\mu^1 \right] = \mu T_\mu^1 , \quad \mu = 1, 0, -1 ;$$
$$e^{-i\psi\hat{\boldsymbol{n}}\cdot\boldsymbol{J}} \boldsymbol{J} e^{i\psi\hat{\boldsymbol{n}}\cdot\boldsymbol{J}} = \boldsymbol{J}\cos\psi + \hat{\boldsymbol{n}}(\hat{\boldsymbol{n}}\cdot\boldsymbol{J})(1-\cos\psi)$$
$$- (\hat{\boldsymbol{n}} \times \boldsymbol{J}) \sin\psi ,$$
$$e^{-i\psi\hat{\boldsymbol{n}}\cdot\boldsymbol{J}} T_\mu^1 e^{i\psi\hat{\boldsymbol{n}}\cdot\boldsymbol{J}} = \sum_\nu D_{\nu\mu}^1(\psi, \hat{\boldsymbol{n}}) T_\nu^1 .$$

2.8.2 Universal Enveloping Algebra of J

The universal enveloping algebra $A(\boldsymbol{J})$ of $\boldsymbol{J}$ is the set of all complex polynomial operators in the components J_i of $\boldsymbol{J}$, or equivalently in (J_+, J_3, J_-). The irreducible tensor operators spanning this algebra are the analogues of the solid harmonics $\mathcal{Y}_{lm}(\boldsymbol{x})$ and are characterized by the following properties: Basis set:

$$\mathcal{T}_k^k = a_k J_+^k , \quad a_k \text{ arbitrary constant} ,$$
$$\mathcal{T}_\mu^k = a_k \left(\frac{(k+\mu)!}{(2k)!(k-\mu)!} \right) \left[J_-, J_+^k \right]_{(k-\mu)} ,$$
$$\mu = k, k-1, \dots, -k ; \quad k = 0, 1, 2, \dots .$$

Standard action with respect to $\boldsymbol{J}$:

$$\left[J_\pm, \mathcal{T}_\mu^k \right] = \left[(k \mp \mu)(k \pm \mu + 1) \right]^{\frac{1}{2}} \mathcal{T}_{\mu\pm1}^k ,$$
$$\left[J_3, \mathcal{T}_\mu^k \right] = \mu \mathcal{T}_\mu^k ,$$
$$\sum_{i=1}^3 \left[J_i, \left[J_i, \mathcal{T}_\mu^k \right] \right] = k(k+1) \mathcal{T}_\mu^k .$$

Unitary transformation:

$$e^{-i\psi\hat{\boldsymbol{n}}\cdot\boldsymbol{J}} \mathcal{T}_\mu^k e^{i\psi\hat{\boldsymbol{n}}\cdot\boldsymbol{J}} = \sum_\nu D_{\nu\mu}^k(\psi, \hat{\boldsymbol{n}}) \mathcal{T}_\nu^k .$$

2.8.3 Algebra of Irreducible Tensor Operators

Irreducible tensor operators possess, as linear operators acting in the same space, properties 1., 2., and 3. below, and an additional multiplication property 4., which constructs new irreducible tensor operators out of two given ones and is called coupling of irreducible tensor operators. Property 4. extends also to tensor operators acting in the tensor product space associated with kinematically independent systems. It is important that associativity extends to the product (2.54), as well as to the product (2.55). Commutativity in these products is generally invalid. The coupling properties given in 4. and 5. are analogous to the coupling of basis state vectors. The operation of Hermitian conjugation of operators, which is the analogue of complex conjugation of states, is also important, and has the properties presented under 5.

1. Multiplication of an irreducible tensor operator of rank k by a complex number or an invariant with respect to angular momentum J gives an irreducible tensor operator of the same rank.
2. Addition of two irreducible tensor operator of the same rank gives an irreducible tensor of that rank.
3. Ordinary multiplication (juxtaposition) of three irreducible tensor operators is associative, but the multiplication of two is noncommutative, in general.
4. Two irreducible tensor operators S^{k_1} and T^{k_2} of different or the same ranks acting in the same space may be multiplied to obtain new irreducible tensor operators of ranks given by the angular momentum addition rule (Clebsch–Gordan series):

$$\left[S^{k_1} \times T^{k_2}\right]^k_\mu = \sum_{\mu_1,\mu_2} C^{k_1 k_2 k}_{\mu_1 \mu_2 \mu} S^{k_1}_{\mu_1} T^{k_2}_{\mu_2}, \qquad (2.54)$$
$$\mu = k, k-1, \ldots, -k;$$
$$\text{rank} =$$
$$k \in \{k_1 + k_2, k_1 + k_2 - 1, \ldots, |k_1 - k_2|\}.$$

The following symbol denotes the irreducible tensor operator with the μ-components (2.54):

$$\left[S^{k_1} \times T^{k_2}\right]^k.$$

5. Two irreducible tensor operators S^{k_1} and T^{k_2} of different or the same ranks acting in different Hilbert spaces, say $\mathcal{H}$ and $\mathcal{K}$, may first be multiplied by the tensor product rule so as to act in the tensor product space $\mathcal{H} \otimes \mathcal{K}$, that is,

$$S^{k_1}_{\mu_1} \otimes T^{k_2}_{\mu_2} : \mathcal{H} \otimes \mathcal{K} \to \mathcal{H} \otimes \mathcal{K},$$

and then coupled to obtain new irreducible tensor operators, acting in the same tensor product space $\mathcal{H} \otimes \mathcal{K}$:

$$\left[S^{k_1} \otimes T^{k_2}\right]^k_\mu = \sum_{\mu,\mu_2} C^{k_1 k_2 k}_{\mu_1 \mu_2 \mu} S^{k_1}_{\mu_1} \otimes T^{k_2}_{\mu_2},$$
$$\mu = k, k-1, \ldots, -k. \qquad (2.55)$$

The following symbol denotes the tensor operator with the μ-components (2.55):

$$\left[S^{k_1} \otimes T^{k_2}\right]^k,$$
$$k \in \{k_1 + k_2, k_1 + k_2 - 1, \ldots, |k_1 - k_2|\}.$$

6. The conjugate tensor operator to T^J, denoted by $T^{J\dagger}$, is the set of operators with components $T^{J\dagger}_M$ defined by

$$\left\langle j'm' \left| T^{J\dagger}_M \right| jm \right\rangle = \left\langle jm \left| T^J_M \right| j'm' \right\rangle^*.$$

These components satisfy the following relations:

$$\left[J_\pm, T^{J\dagger}_M\right] = -[(J \pm M)(J \mp M + 1)]^{\frac{1}{2}} T^{J\dagger}_{M \mp 1}$$
$$\left[J_3, T^{J\dagger}_M\right] = -M T^{J\dagger}_M,$$
$$\sum_i \left[J_i, \left[J_i, T^{J\dagger}_M\right]\right] = J(J+1) T^{J\dagger}_M;$$
$$e^{-i\psi \hat{n} \cdot J} T^{J\dagger}_M e^{i\psi \hat{n} \cdot J} = \sum_{M'} D^{J*}_{M'M}(\psi, \hat{n}) T^{J\dagger}_{M'};$$
$$I^J = \sum_M T^J_M T^{J\dagger}_M = \begin{pmatrix} \text{invariant operator to} \\ SU(2) \text{ rotations} \end{pmatrix},$$
$$e^{-i\psi \hat{n} \cdot J} I^J e^{i\psi \hat{n} \cdot J} = I^J.$$

An important invariant operator is

$$I^{k_1 k_2 k} = \sum_{\mu_1 \mu_2 \mu} C^{k_1 k_2 k}_{\mu_1 \mu_2 \mu} T^{k_1}_{\mu_1} T^{k_2}_{\mu_2} T^{k\dagger}_\mu.$$

7. Other definitions of conjugation:

$$T^T_M \to (-1)^{J-M} T^J_{-M}, \qquad T^J_M \to (-1)^{J+M} T^J_{-M}.$$

2.8.4 Wigner–Eckart Theorem

The Wigner–Eckart theorem establishes the form of the matrix elements of an arbitrary irreducible tensor operator:

$$\left\langle j'm' \left| T^J_M \right| jm \right\rangle = \left\langle j' \| T^J \| j \right\rangle C^{jJj'}_{mMm'}$$
$$= \left(j' \| T^J \| j \right)(-1)^{j+J+m'} \begin{pmatrix} j & J & j' \\ m & M & -m' \end{pmatrix}.$$

Reduced matrix elements with respect to WCG-coefficients:

$$\langle j'\|\boldsymbol{T}^J\|j\rangle = \sum_{\mu M} C^{jJj'}_{\mu M\mu'}\langle j'\mu'|T^J_M|j\mu\rangle ,$$

each $\mu' = j', j'-1, \ldots, -j'$ (the reduced matrix element is independent of μ').

Reduced matrix elements with respect to $3-j$ coefficients:

$$\big(j'\|\boldsymbol{T}^J\|j\big) = (-1)^{2J}\sqrt{2j'+1}\langle j'\|\boldsymbol{T}^J\|j\rangle .$$

Examples of irreducible tensor operators include:

1. The solid harmonics with respect to the orbital angular momentum $\boldsymbol{L}$:

$$\boldsymbol{\mathcal{Y}}^k(\boldsymbol{x}) = \{\mathcal{Y}_{k\mu}(\boldsymbol{x}) : \mu = k, \ldots, -k\} ,$$

$$\mathcal{Y}_{k\mu}|lm\rangle = \sum_{l'}\langle l'\|\boldsymbol{\mathcal{Y}}^k\|l\rangle C^{lkl'}_{m,\mu,m+\mu}|l', m+\mu\rangle ,$$

where

$$\langle \boldsymbol{x}\mid lm\rangle = \mathcal{Y}_{lm}(\boldsymbol{x}) ,$$

$$\langle l'\|\boldsymbol{\mathcal{Y}}^k\|l\rangle = r^{l+k-l'}\left(\frac{(2l+1)(2k+1)}{4\pi(2l'+1)}\right)^{\frac{1}{2}}C^{lkl'}_{000} ,$$

$$\mathcal{Y}_{k\mu}(\boldsymbol{x})\mathcal{Y}_{lm}(\boldsymbol{x})$$
$$= \sum_{l'}\langle l'\|\boldsymbol{\mathcal{Y}}^k\|l\rangle C^{lkl'}_{m,\mu,m+\mu}\mathcal{Y}_{l',m+\mu}(\boldsymbol{x}) ,$$

$$\big[\boldsymbol{\mathcal{Y}}^{k_1}(\boldsymbol{x})\otimes\boldsymbol{\mathcal{Y}}^{k_2}(\boldsymbol{x})\big]^k_\mu$$
$$= \sum_{\mu_1\mu_2} C^{k_1k_2k}_{\mu_1\mu_2\mu}\mathcal{Y}_{k_1\mu_1}(\boldsymbol{x})\mathcal{Y}_{k_2\mu_2}(\boldsymbol{x}) ,$$

$$\big[\boldsymbol{\mathcal{Y}}^{k_1}(\boldsymbol{x})\otimes\boldsymbol{\mathcal{Y}}^{k_2}(\boldsymbol{x})\big]^k_\mu = \langle k\|\boldsymbol{\mathcal{Y}}^{k_1}\|k_2\rangle\mathcal{Y}_{k\mu}(\boldsymbol{x}) .$$

2. The polynomial operator $\boldsymbol{\mathcal{T}}^k$ in the components of $\boldsymbol{J}$ (Sect. 2.8.2):

$$\langle j'm'|\boldsymbol{\mathcal{T}}^k_\mu|jm\rangle = \delta_{j'j}\langle j\|\boldsymbol{\mathcal{T}}^k\|j\rangle C^{jkj}_{m\mu m'} ,$$

$$\langle j\|\boldsymbol{\mathcal{T}}^k\|j\rangle$$
$$= a_k(-1)^k\left(\frac{(2j+k+1)!k!k!}{(2j+1)(2j-k)!(2k)!}\right)^{\frac{1}{2}} .$$

3. Polynomials in the components of an arbitrary vector operator $\boldsymbol{V}$, which has the defining relations:

$$\big[J_i, V_j\big] = \mathrm{i}e_{ijk}V_k ,$$

$$\big[J_\pm, V_\mu\big] = [(1\mp\mu)(2\pm\mu)]^{\frac{1}{2}}V_{\mu\pm 1} ,$$

$$\big[J_3, V_\mu\big] = \mu V_\mu ,$$

$$V_{+1} = -(V_1+\mathrm{i}V_2)/\sqrt{2}, \; V_0 = V_3 ,$$

$$V_{-1} = (V_1-\mathrm{i}V_2)/\sqrt{2} .$$

This construction parallels exactly that given in Sect. 2.8.2 upon replacing $\boldsymbol{J}$ by $\boldsymbol{V}$. The explicit form of the resulting polynomials may be quite different since no assumptions are made concerning commutation relations between the components V_i of $\boldsymbol{V}$. The solid harmonics in the gradient operator ∇ constitute an irreducible tensor operator with respect to the orbital angular momentum $\boldsymbol{L}$.

2.8.5 Unit Tensor Operators or Wigner Operators

A unit tensor operator is an irreducible tensor operator $\hat{\boldsymbol{T}}^{J,\Delta}$, indexed not only by the angular momentum quantum number J, but also by an additional label Δ, which specifies that this irreducible tensor operator has reduced matrix elements given by

$$\langle j'\|\hat{\boldsymbol{T}}^{J,\Delta}\|j\rangle = \delta_{j', j+\Delta} .$$

This condition is to be true for all $j = 0, 1/2, 1, \ldots$. There is a unit tensor operator defined for each

$$\Delta = J, J-1, \ldots, -J .$$

The special symbol

$$\left\langle\begin{matrix} & J+\Delta & \\ 2J & & 0 \\ & \bullet & \end{matrix}\right\rangle$$

denotes a unit tensor operator, replacing the boldface symbol $\hat{\boldsymbol{T}}^{J,\Delta}$, while the symbol

$$\left\langle\begin{matrix} & J+\Delta & \\ 2J & & 0 \\ & J+M & \end{matrix}\right\rangle , \quad M = J, J-1, \ldots, -J$$

denotes the components. In the same way that abstract angular momentum $\boldsymbol{J}$ and state vectors $\{|jm\rangle\}$ extract the intrinsic structure of all realizations of angular momentum theory, as given in Sect. 2.2, so does the notion of a unit tensor operator extract the intrinsic structure of the concept of irreducible tensor operator by disregarding the physical content of the theory, which is carried in the structure of the reduced matrix elements. Physical theory is regained from the fact that the unit tensor operators are the basis for arbitrary tensor operators, which is the structural content of the Wigner–Eckart theorem. The concept of a unit tensor operator was introduced by Racah, but it was Biedenharn who recognized the full significance of this concept not only for $SU(2)$, but for all the unitary groups.

All of the content of physical tensor operator theory can be regained from the properties of unit tensor operators or Wigner operators as summarized below:

Notation (double Gel'fand patterns):

$$\left\langle 2J \begin{array}{cc} J+\Delta & \\ & 0 \\ J+M & \end{array} \right\rangle, \quad \begin{array}{c} M, \Delta = J, J-1, \ldots, -J \\ 2J = 0, 1, 2, \ldots. \end{array}$$

Definition (shift action):

$$\left\langle 2J \begin{array}{cc} J+\Delta & \\ & 0 \\ J+M & \end{array} \right\rangle |jm\rangle = C^{jJj+\Delta}_{m,M,m+M} |j+\Delta, m+M\rangle$$

(2.56)

for all $j = 0, \frac{1}{2}, \ldots$; $m = j, j-1, \ldots, -j$.

Conjugation:

$$\left\langle 2J \begin{array}{cc} J+\Delta & \\ & 0 \\ J+M & \end{array} \right\rangle^{\dagger} |jm\rangle$$
$$= C^{j-\Delta Jj}_{m-M,M,m} |j-\Delta, m-M\rangle.$$

(2.57)

Orthogonality:

$$\sum_M \left\langle 2J \begin{array}{cc} J+\Delta' & \\ & 0 \\ J+M & \end{array} \right\rangle \left\langle 2J \begin{array}{cc} J+\Delta & \\ & 0 \\ J+M & \end{array} \right\rangle^{\dagger} = \delta_{\Delta'\Delta} I^J_\Delta,$$

(2.58)

$$\sum_\Delta \left\langle 2J \begin{array}{cc} J+\Delta & \\ & 0 \\ J+M' & \end{array} \right\rangle^{\dagger} \left\langle 2J \begin{array}{cc} J+\Delta & \\ & 0 \\ J+M & \end{array} \right\rangle = \delta_{M'M},$$

(2.59)

$$\sum_m \langle jm| \left\langle 2J' \begin{array}{cc} J'+\Delta' & \\ & 0 \\ J'+M' & \end{array} \right\rangle \left\langle 2J \begin{array}{cc} J+\Delta & \\ & 0 \\ J+M & \end{array} \right\rangle^{\dagger} |jm\rangle$$
$$= \frac{2j+1}{2J+1} \delta_{J'J} \delta_{M'M} \delta_{\Delta'\Delta}.$$

(2.60)

The invariant operator I^J_Δ is defined by its action on an arbitrary vector $\psi_j \in \mathcal{H}_j$:

$$I^J_\Delta \psi_j = \epsilon_{j-\Delta,J,j} \psi_j.$$

Tensor operator property:

$$e^{-i\psi\hat{\boldsymbol{n}}\cdot\boldsymbol{J}} \left\langle 2J \begin{array}{cc} J+\Delta & \\ & 0 \\ J+M & \end{array} \right\rangle e^{i\psi\hat{\boldsymbol{n}}\cdot\boldsymbol{J}}$$
$$= \sum_{M'} D^J_{M'M}(\psi, \hat{\boldsymbol{n}}) \left\langle 2J \begin{array}{cc} J+\Delta & \\ & 0 \\ J+M' & \end{array} \right\rangle.$$

(2.61)

Basis property (Wigner–Eckart theorem):

$$T^J_M |jm\rangle$$
$$= \left(\sum_\Delta \langle j+\Delta \| \boldsymbol{T}^J \| j\rangle \left\langle 2J \begin{array}{cc} J+\Delta & \\ & 0 \\ J+M & \end{array} \right\rangle \right) |jm\rangle.$$

(2.62)

Characteristic null space:

The characteristic null space of the Wigner operator defined by (2.56) is the set of irreducible subspaces $\mathcal{H}_j \subset \mathcal{H}$ given be

$$\{\mathcal{H}_j : 2j = 0, 1, \ldots, J - \Delta - 1\}.$$

Coupling law:

$$\sum_{\alpha\beta} C^{abc}_{\alpha\beta\gamma} \left\langle 2b \begin{array}{cc} b+\sigma & \\ & 0 \\ b+\beta & \end{array} \right\rangle \left\langle 2a \begin{array}{cc} a+\rho & \\ & 0 \\ a+\alpha & \end{array} \right\rangle$$
$$= W^{abc}_{\rho,\sigma,\rho+\sigma} \left\langle 2c \begin{array}{cc} c+\rho+\sigma & \\ & 0 \\ c+\gamma & \end{array} \right\rangle,$$

(2.63)

where $W^{abc}_{\rho\sigma\tau}$ is an invariant operator (commutes with $\boldsymbol{J}$) and is called a Racah invariant. Its relationship to Racah coefficients and 6–j coefficients is given in Sect. 2.9.

Product law:

$$\left\langle 2b \begin{array}{cc} b+\sigma & \\ & 0 \\ b+\beta & \end{array} \right\rangle \left\langle 2a \begin{array}{cc} a+\rho & \\ & 0 \\ a+\alpha & \end{array} \right\rangle$$
$$= \sum_c W^{abc}_{\rho,\sigma,\rho+\sigma} C^{abc}_{\alpha,\beta,\alpha+\beta} \left\langle 2c \begin{array}{cc} c+\rho+\sigma & \\ & 0 \\ c+\alpha+\beta & \end{array} \right\rangle.$$

(2.64)

Racah invariant:

$$W^{abc}_{\rho\sigma\tau} = \sum_{\alpha\beta\gamma} C^{abc}_{\alpha\beta\gamma}$$
$$\times \left\langle 2b \begin{array}{cc} b+\sigma & \\ & 0 \\ b+\beta & \end{array} \right\rangle \left\langle 2a \begin{array}{cc} a+\rho & \\ & 0 \\ a+\alpha & \end{array} \right\rangle \left\langle 2c \begin{array}{cc} c+\tau & \\ & 0 \\ c+\gamma & \end{array} \right\rangle^{\dagger}.$$

(2.65)

The notation $W^{abc}_{\rho\sigma\tau}$ for a Racah invariant is designed to "match" that of the WCG-coefficient on the left, the latter being associated with the lower group theoretical labels, for example,

$$\left(2a \begin{array}{cc} & 0 \\ a+\alpha & \end{array} \right) \to |a\alpha\rangle,$$

the state vector having a group transformation law under the action of $SU(2)$, and the former with the shift labels of a unit tensor operator,

$$\left(\begin{matrix} & \alpha+\rho & \\ 2\alpha & & 0 \end{matrix} \right) ,$$

and having no associated group transformation law. The invariant operator defined by (2.65) has real eigenvalues, hence, is a Hermitian operator,

$$W^{abc\dagger}_{\rho\sigma\tau} = W^{abc}_{\rho\sigma\tau} , \tag{2.66}$$

which is diagonal on an arbitrary state vector in $\mathcal{H}_j$ (Sect. 2.9).

The Racah invariant operator does not commute with a unit tensor operator, and it makes a difference whether it is written to the left or to the right of such a unit tensor operator. The convention here writes it to the left.

Relation (2.65) is taken as the definition of $W^{abc}_{\rho\sigma\tau}$ and the following properties all follow from this expression:

Domain of definition:

$$W^{abc}_{\rho\sigma\tau} : a, b, c \in \{0, 1/2, 1, 3/2, \dots\} ;$$
$$\rho = a, a-1, \dots, -a$$
$$\sigma = b, b-1, \dots, -b$$
$$\tau = c, c-1, \dots, -c ;$$
$$W^{abc}_{\rho\sigma\tau} = 0, \text{ if } \rho+\sigma \neq \tau; \text{ if } \epsilon_{abc} = 0 .$$

Orthogonality relations:

$$\sum_{\rho\sigma} W^{abc}_{\rho\sigma\tau} W^{abd}_{\rho\sigma\tau'} = \delta_{cd}\delta_{\tau\tau'}\epsilon_{abc} I^c_\tau , \tag{2.67}$$

$$\sum_{c\tau} W^{abc}_{\rho\sigma\tau} W^{abc}_{\rho'\sigma'\tau} = \delta_{\rho\rho'}\delta_{\sigma\sigma'} I^{ab}_{\rho\sigma} , \tag{2.68}$$

where the I invariant operators in these expressions have the following eigenvalues on an arbitrary vector $\psi_j \in \mathcal{H}_j$:

$$I^c_\tau \psi_j = \epsilon_{j-\tau,c,j}\psi_j ,$$
$$I^{ab}_{\rho\sigma}\psi_j = \epsilon_{j-\sigma-\rho,a,j-\sigma}\epsilon_{j-\sigma,b,j}\psi_j .$$

The orthogonality relations for Racah invariants parallel exactly those of WCG-coefficients.

Using the orthogonality relations (2.67) for Racah invariants, the following two relations now follow from (2.63) and (2.64), respectively:

WCG and Racah operator coupling:

$$\sum_{\rho\sigma} \sum_{\alpha\beta} W^{abd}_{\rho,\sigma,\rho+\sigma} C^{abc}_{\alpha,\beta,\alpha+\beta}$$
$$\times \left\langle 2b \begin{matrix} b+\sigma & \\ & 0 \\ b+\beta & \end{matrix} \right\rangle \left\langle 2a \begin{matrix} a+\rho & \\ & 0 \\ a+\alpha & \end{matrix} \right\rangle$$
$$= \delta_{cd}\epsilon_{abc} I^d_\tau \left\langle 2c \begin{matrix} c+\tau & \\ & 0 \\ c+\gamma & \end{matrix} \right\rangle . \tag{2.69}$$

Racah operator coupling of shift patterns:

$$\sum_{\rho\sigma} W^{abc}_{\rho\sigma\tau} \left\langle 2b \begin{matrix} b+\sigma & \\ & 0 \\ b+\beta & \end{matrix} \right\rangle \left\langle 2a \begin{matrix} a+\rho & \\ & 0 \\ a+\alpha & \end{matrix} \right\rangle$$
$$= C^{abc}_{\alpha,\beta,\alpha+\beta} \left\langle 2c \begin{matrix} c+\tau & \\ & 0 \\ c+\alpha+\beta & \end{matrix} \right\rangle . \tag{2.70}$$

Relations (2.56–2.70) capture the full content of irreducible tensor operator algebra through the concept of unit tensor operators that have only 0 or 1 for their reduced matrix elements. Using the Wigner–Eckart theorem (2.62), the relations between general tensor operators can be reconstructed. Unit tensor operators were invented to exhibit in the most elementary way possible the abstract and intrinsic structure of the irreducible tensor operator algebra, stripping away the details of particular physical applications, thus giving the theory universal application. It accomplishes the same goal for tensor operator theory that the abstract multiplet theory in Sect. 2.2 accomplishes for representation theory.

Physical theory is regained through the concept of reduced matrix element. The coupling rule (2.54) is now transformed to a rule empty of WCG-coefficient content and becomes a rule for coupling of reduced matrix elements using the invariant Racah operators:

$$\left\langle (\alpha') j' \| \left[S^{k_1} \times T^{k_2} \right]^k \| (\alpha) j \right\rangle$$
$$= (-1)^{k_1+k_2-k} \sum_{(\alpha'')j''} W^{k_2 k_1 k}_{j''-j, j'-j'', j'-j}(j')$$
$$\times \left\langle (\alpha') j' \| S^{k_1} \| (\alpha'') j'' \right\rangle \left\langle (\alpha'') j'' \| T^{k_2} \| (\alpha) j \right\rangle . \tag{2.71}$$

This coupling rule is invariant to all $SU(2)$ rotations, and reveals the true role of the Racah coefficients and reduced matrix elements in physical theory as invariant objects under $SU(2)$ rotations. It now becomes imperative to understand Racah coefficients as objects free of their original definition in terms of WCG-coefficients.

2.9 Racah Coefficients

Relation (2.65) is taken, initially, as the definition of the Racah coefficient with appropriate adjustments of notations to conform to Racah's W-notation and to Wigner's $6-j$ notation. Corresponding to each of (2.63–2.65), (2.69, 2.70), there is a corresponding numerical relationship between WCG-coefficients and Racah coefficients. Despite the present day popularity of expressing all such relations in terms of the $3-j$ and $6-j$ notation, this temptation is resisted here for this particular set of relations because of their fundamental origins. The relation between the Racah invariant notation and Racah's original W-notation is

$$
\begin{aligned}
&W^{abc}_{\rho\sigma\tau} \mid jm\rangle = W^{abc}_{\rho\sigma\tau}(j) \mid jm\rangle , \\
&W^{abc}_{\rho\sigma\tau}(j) = 0 \quad \text{if } \tau \neq \rho+\sigma , \quad \text{or } \epsilon_{abc} = 0 , \\
&W^{abc}_{\rho\sigma\tau}(j) = [(2c+1)(2j-2\sigma+1)]^{1/2} \\
&\qquad\qquad \times W(j-\tau, a, j, b; j-\sigma, c) , \\
&[(2e+1)(2f+1)]^{1/2} W(abcd; ef) \\
&\qquad = W^{bdf}_{e-a, c-e, c-a}(c) ,
\end{aligned}
$$

$W(abcd; ef) = 0$ unless the triples of nonnegative integers and half-integers (abe), (cde), (acf), (bdf) satisfy the triangle conditions.

2.9.1 Basic Relations Between WCG and Racah Coefficients

$$
\begin{aligned}
&\sum_{\beta\delta} C^{bdf}_{\beta\delta\gamma} C^{edc}_{\alpha+\beta,\delta,\alpha+\gamma} C^{abe}_{\alpha,\beta,\alpha+\beta} \\
&= [(2e+1)(2f+1)]^{1/2} W(abcd; ef) C^{afc}_{\alpha,\gamma,\alpha+\gamma} , \\
&\sum_f [(2e+1)(2f+1)]^{1/2} W(abcd; ef) \\
&\qquad \times C^{bdf}_{\beta,\delta,\beta+\delta} C^{afc}_{\alpha,\beta+\delta,\alpha+\beta+\delta} \\
&= C^{edc}_{\alpha+\beta,\delta,\alpha+\beta+\delta} C^{abe}_{\alpha,\beta,\alpha+\beta} , \\
&\delta_{cc'} [(2e+1)(2f+1)]^{1/2} W(abcd; ef) \\
&= \sum_{\beta\delta} C^{bdf}_{\beta,\delta,\beta+\delta} C^{edc}_{\gamma-\delta,\delta,\gamma} C^{abe}_{\gamma-\beta-\delta,\beta,\gamma-\delta} \\
&\qquad \times C^{abc'}_{\gamma-\beta-\delta,\beta+\delta,\gamma} , \\
&\sum_{\beta\delta e} [(2e+1)(2f+1)]^{1/2} W(abcd; ef) \\
&\qquad \times C^{bdf'}_{\beta\delta\gamma} C^{edc}_{\alpha+\beta,\delta,\alpha+\gamma} C^{abe}_{\alpha,\beta,\alpha+\beta} \\
&= \delta_{ff'} C^{afc}_{\alpha,\gamma,\alpha+\gamma} , \\
&\sum_e [(2e+1)(2f+1)]^{1/2} W(abcd; ef) \\
&\qquad \times C^{edc}_{\alpha+\beta,\delta,\alpha+\beta+\delta} C^{abe}_{\alpha,\beta,\alpha+\beta} \\
&= C^{bdf}_{\beta,\delta,\beta+\delta} C^{afc}_{\alpha,\beta+\delta,\alpha+\beta+\delta} .
\end{aligned}
$$

2.9.2 Orthogonality and Explicit Form

Orthogonality relations for Racah coefficients:

$$
\begin{aligned}
&\sum_e (2e+1)(2f+1) W(abcd; ef) W(abcd; ef') \\
&= \delta_{ff'} \epsilon_{acf} \epsilon_{bdf} ,
\end{aligned}
\tag{2.72}
$$

$$
\begin{aligned}
&\sum_f (2e+1)(2f+1) W(abcd; ef) W(abcd; e'f) \\
&= \delta_{ee'} \epsilon_{abe} \epsilon_{cde} .
\end{aligned}
\tag{2.73}
$$

Definition of $6-j$ coefficients:

$$
\begin{Bmatrix} a & b & e \\ d & c & f \end{Bmatrix} = (-1)^{a+b+c+d} W(abcd; ef) .
\tag{2.74}
$$

Orthogonality of $6-j$ coefficients:

$$
\begin{aligned}
&\sum_e (2e+1)(2f+1) \begin{Bmatrix} a & b & e \\ d & c & f \end{Bmatrix} \begin{Bmatrix} a & b & e \\ d & c & f' \end{Bmatrix} \\
&= \delta_{ff'} \epsilon_{acf} \epsilon_{bdf} ,
\end{aligned}
\tag{2.75}
$$

$$
\begin{aligned}
&\sum_f [(2e+1)(2f+1)] \begin{Bmatrix} a & b & e \\ d & c & f \end{Bmatrix} \begin{Bmatrix} a & b & e' \\ d & c & f \end{Bmatrix} \\
&= \delta_{ee'} \epsilon_{abe} \epsilon_{cde} .
\end{aligned}
\tag{2.76}
$$

Explicit form of Racah coefficients:

$$
\begin{aligned}
W(abcd; ef) &= \Delta(abe) \Delta(cde) \Delta(acf) \Delta(bdf) \\
&\times \sum_k \frac{(-1)^{a+b+c+d+k}(k+1)!}{(k-a-b-e)!(k-c-d-e)!} \\
&\times \frac{1}{(k-a-c-f)!(k-b-d-f)!} \\
&\times \frac{1}{(a+b+c+d-k)!} \\
&\times \frac{1}{(a+d+e+f-k)!(b+c+e+f-k)!} ,
\end{aligned}
\tag{2.77}
$$

where $\Delta(abc)$ denotes the triangle coefficient, defined for every triple a, b, c of integers and half-odd integers satisfying the triangle conditions by:

$$
\begin{aligned}
&\Delta(abc) \\
&= \left(\frac{(a+b-c)!(a-b+c)!(-a+b+c)!}{(a+b+c+1)!} \right)^{\frac{1}{2}} .
\end{aligned}
\tag{2.78}
$$

2.9.3 The Fundamental Identities Between Racah Coefficients

Each of the three relations given in this section is between Racah coefficients alone. Each expresses a fundamental mathematical property. The Biedenharn–Elliott identity is a consequence of the associativity rule for the open product of three irreducible tensor operators; the Racah sum rule is a consequence of the commutativity of a mapping diagram associated with the coupling of three angular momenta; and the triangle coupling rule is a consequence of the associativity of the open product of three symplection polynomials [2.1]. As such, these three relations between Racah coefficients, together with the orthogonality relations, are the building blocks on which is constructed a theory of these coefficients that stands on its own, independent of the WCG-coefficient origins. Indeed, the latter is recovered through the limit relation (2.50).

Biedenharn–Elliott identity:

$$W(a'ab'b; c'e)W(a'ed'd; b'c)$$
$$= \sum_f (2f+1)W(abcd; ef)W(c'bd'd; b'f)$$
$$\times W(a'ad'f; c'c), \tag{2.79a}$$

$$\begin{Bmatrix} a' & a & c' \\ b & b' & e \end{Bmatrix} \begin{Bmatrix} a' & e & b' \\ d & d' & c \end{Bmatrix}$$
$$= \sum_f (-1)^\phi (2f+1) \begin{Bmatrix} a & b & e \\ d & c & f \end{Bmatrix} \begin{Bmatrix} c' & b & b' \\ d & d' & f \end{Bmatrix}$$
$$\times \begin{Bmatrix} a' & a & c' \\ f & d' & c \end{Bmatrix},$$
$$\phi = f - e + a' + a + b' + b + c' - c + d' - d. \tag{2.79b}$$

Racah sum rule:

$$\sum_f (-1)^{b+d-f}(2f+1)W(abcd; ef)W(adcb; gf)$$
$$= (-1)^{e+g-a-c}W(bacd; eg), \tag{2.80a}$$

$$\sum_f (-1)^{e+g+f}(2f+1) \begin{Bmatrix} a & b & e \\ d & c & f \end{Bmatrix} \begin{Bmatrix} a & d & g \\ b & c & f \end{Bmatrix}$$
$$= \begin{Bmatrix} b & a & e \\ d & c & g \end{Bmatrix}. \tag{2.80b}$$

Triangle sum rule:

$$[\Delta(acf)\Delta(bdf)]^{-1}$$
$$= (2f+1)\sum_e [\Delta(abe)\Delta(cde)]^{-1}W(abcd; ef), \tag{2.81a}$$

$$(-1)^{a+b+c+d}[\Delta(acf)\Delta(bdf)]^{-1}$$
$$= (2f+1)\sum_e [\Delta(abe)\Delta(cde)]^{-1} \begin{Bmatrix} abe \\ dcf \end{Bmatrix}. \tag{2.81b}$$

2.9.4 Schwinger–Bargmann Generating Function and its Combinatorics

Triangles associated with the $6-j$ symbol $\begin{Bmatrix} j_1 & j_2 & j_3 \\ j_4 & j_5 & j_6 \end{Bmatrix}$:

$$(j_1 j_2 j_3), (j_3 j_4 j_5), (j_1 j_5 j_6), (j_2 j_4 j_6).$$

Points in $\mathbf{R}^3$ associated with the triangles:

$$(j_1 j_2 j_3) \to (x_1, x_2, x_3), (j_3 j_4 j_5) \to (y_3, x_4, x_5),$$
$$(j_1 j_5 j_6) \to (y_1, y_5, x_6), (j_2 j_4 j_6) \to (y_2, y_4, y_6).$$

Tetrahedron associated with the points:
    The points define the vertices of a general tetrahedron with lines joining each pair of points that share a common subscript, and the lines are labeled by the product of the common coordinates (Fig. 2.2).

Monomial term:
    Define the triangle monomial associated with a triangle $(j_a j_b j_c)$ and its associated point (z_a, z_b, z_c) in $\mathbf{R}^3$ by

$$(z_a, z_b, z_c)^{(j_a j_b j_c)} = z_a^{j_b + j_c - j_a} z_b^{j_c + j_a - j_b} z_c^{j_a + j_b - j_c}. \tag{2.82}$$

Cubic graph (tetrahedral $\mathbf{T}_4$) functions:
    Interchange the symbols x and y in the coordinates of the vertices of the tetrahedron and define the following polynomials on the vertices and edges of the tetrahedron with this modified labeling.

Vertex function: multiply together the coordinates of each vertex and sum over all such vertices to obtain

$$V_3 = y_1 y_2 y_3 + x_3 y_4 y_5 + x_1 x_5 y_6 + x_2 x_4 x_6;$$

Edge function: multiply together the coordinates of a given edge and the opposite edge and sum over all such pairs to obtain

$$E_4 = x_1 y_1 x_4 y_4 + x_2 y_2 x_5 y_5 + x_3 y_3 x_6 y_6.$$
Fig. 2.2 Labeled cubic graph (tetrahedron) associated with $6-j$ coefficients

Generating function:

$$(1 + V_3 + E_4)^{-2} = \sum_{\Delta} T(\Delta) Z^{\Delta} , \qquad (2.83a)$$

$$Z^{\Delta} = (x_1, x_2, x_3)^{(j_1 j_2 j_3)} (y_3, x_4, x_5)^{(j_3 j_4 j_5)}$$
$$\times (y_1, y_5, x_6)^{(j_1 j_5 j_6)} (y_2, y_4, y_6)^{(j_2 j_4 j_6)} , \qquad (2.83b)$$

$$\Delta = \begin{bmatrix} (j_1 j_2 j_3) \\ (j_3 j_4 j_5) \\ (j_1 j_5 j_6) \\ (j_2 j_4 j_6) \end{bmatrix} ;$$

$$T(\Delta) = \sum_{k} (-1)^k (k+1)$$
$$\times \binom{k}{k_1, k_2, k_3, k_4, k_5, k_6, k_7} , \qquad (2.83c)$$

$k_i = k - t_i , \quad i = 1, 2, 3, 4 ,$

$k_j = e_{j-4} - k , \quad j = 5, 6, 7 ;$

$t_i = $ triangle sum = vertex sum,

$e_j = $ opposite edge sum, in pairs,

$t_1 = j_1 + j_2 + j_3 , \quad t_2 = j_3 + j_4 + j_5 ,$

$t_3 = j_1 + j_5 + j_6 , \quad t_4 = j_2 + j_4 + j_6 ,$

$e_1 = (j_2 + j_5) + (j_3 + j_6) ,$

$e_2 = (j_1 + j_4) + (j_3 + j_6) ,$

$e_3 = (j_1 + j_4) + (j_2 + j_5) .$

The summation in (2.83b) is over the infinite set of all tetrahedra; that is, over the infinite set of arrays Δ having nonnegative integral entries. The $6-j$ coefficients is then given by

$$\begin{Bmatrix} j_1 & j_2 & j_3 \\ j_4 & j_5 & j_6 \end{Bmatrix}$$
$$= \frac{T(\Delta)}{\Delta(j_1 j_2 j_3) \Delta(j_1 j_5 j_6) \Delta(j_2 j_4 j_6) \Delta(j_3 j_4 j_5)} .$$

Since the factor $T(\Delta)$ is an integer in the expansion (2.83a), this result shows that the $6-j$ coefficient is an integer, up to the multiplicative triangle coefficient factors.

2.9.5 Symmetries of $6-j$ Coefficients

There are 144 symmetry relations among the Racah $6-j$ coefficients. The 24 classical ones, given already by Racah, and corresponding to the tetrahedral point group T_d of rotations-inversions (isomorphic to the symmetric group S_4) mapping the regular tetrahedron onto itself, are realized in the $6-j$ symbol

$$\begin{Bmatrix} a & b & e \\ d & c & f \end{Bmatrix}$$

as permutations of its columns and the exchange of any pair of letters in the top row with the corresponding pair in the bottom row. Regge discovered the 6-fold increase in symmetry by noting that each term in the summation in (2.77) is invariant not only to the classical 24 symmetries, but also under certain linear transformations of the quantum labels. These symmetries are also implicit in Schwinger's generating function.

The full set, including the original 24 substitutions, of linear transformations of the letters a, b, c, d, e, f thus yields a group of linear transformation isomorphic to $S_4 \times S_3$. The column permutations and row-pair interchanges described above applied to each of the six symbols in the equalities below yield the set of 144 relationships:

$$\begin{Bmatrix} a & b & e \\ d & c & f \end{Bmatrix} = \begin{Bmatrix} a & \dfrac{b+c+e-f}{2} & \dfrac{b+e+f-c}{2} \\ d & \dfrac{b+c+f-e}{2} & \dfrac{c+e+f-b}{2} \end{Bmatrix}$$

$$= \begin{Bmatrix} \dfrac{a+d+e-f}{2} & b & \dfrac{a+e+f-d}{2} \\ \dfrac{a+d+f-e}{2} & c & \dfrac{d+e+f-a}{2} \end{Bmatrix}$$

$$= \left\{ \begin{matrix} \frac{a+b+d-c}{2} & \frac{a+b+c-d}{2} & e \\ \frac{a+c+d-b}{2} & \frac{b+c+d-a}{2} & f \end{matrix} \right\}$$

$$= \left\{ \begin{matrix} \frac{a+b+d-c}{2} & \frac{b+c+e-f}{2} & \frac{a+e+f-d}{2} \\ \frac{a+c+d-b}{2} & \frac{b+c+f-e}{2} & \frac{d+e+f-a}{2} \end{matrix} \right\}$$

$$= \left\{ \begin{matrix} \frac{a+d+e-f}{2} & \frac{a+b+c-d}{2} & \frac{b+e+f-c}{2} \\ \frac{a+d+f-e}{2} & \frac{b+c+d-a}{2} & \frac{c+e+f-b}{2} \end{matrix} \right\} .$$

2.9.6 Further Properties

Recurrence relations:
Three-term:

$$[(a+b+e+1)(b+e-a)$$
$$\times (c+d+e+1)(d+e-c)]^{1/2} \left\{ \begin{matrix} a & b & e \\ d & c & f \end{matrix} \right\}$$
$$= -2e[(b+d+f+1)(b+d-f)]^{1/2}$$
$$\times \left\{ \begin{matrix} a & b-\frac{1}{2} & e-\frac{1}{2} \\ d-\frac{1}{2} & c & f \end{matrix} \right\}$$
$$+ [(a+b-e+1)(a+e-b)(c+d-e+1)$$
$$\times (c+e-d)]^{1/2} \left\{ \begin{matrix} a & b & e-1 \\ d & c & f \end{matrix} \right\} , \qquad (2.84a)$$

$$[(a+c+f+1)(c+e-d)$$
$$\times (d+e-c+1)(b+d-f+1)]^{1/2} \left\{ \begin{matrix} a & b & e \\ d & c & f \end{matrix} \right\}$$
$$= [(a+c-f)(a+e-b)$$
$$\times (b+f+d+2)(b+e-a+1)]^{1/2}$$
$$\times \left\{ \begin{matrix} a+\frac{1}{2} & b+\frac{1}{2} & e \\ d+\frac{1}{2} & c-\frac{1}{2} & f \end{matrix} \right\} .$$
$$+ [(c+f-a)(c+e-d)(b-a-c+d+1)]^{1/2}$$
$$\times \left\{ \begin{matrix} a & b & e \\ d+\frac{1}{2} & c-\frac{1}{2} & f-\frac{1}{2} \end{matrix} \right\} . \qquad (2.84b)$$

Five-term:

$$(2c+1)(2d)(2f+1) \left\{ \begin{matrix} a & b & e \\ d & c & f \end{matrix} \right\}$$
$$= [(b+d-f)(b+f-d+1)(d+e-c)$$
$$\times (c+e-d+1)(c+f-a+1)(a+c+f+2)]^{\frac{1}{2}}$$

$$\times \left\{ \begin{matrix} a & b & e \\ d-\frac{1}{2} & c+\frac{1}{2} & f+\frac{1}{2} \end{matrix} \right\} + [(b+d-f)$$
$$\times (b+f-d+1)(c+d-e)(c+d+e+1)$$
$$\times (a+c-f)(a+f-c+1)]^{\frac{1}{2}}$$
$$\times \left\{ \begin{matrix} a & b & e \\ d-\frac{1}{2} & c-\frac{1}{2} & f+\frac{1}{2} \end{matrix} \right\} - [(d+f-b)$$
$$\times (b+d+f+1)(c+d-e)(c+d+e+1)$$
$$\times (c+f-a)(a+c+f+1)]^{\frac{1}{2}}$$
$$\times \left\{ \begin{matrix} a & b & e \\ d-\frac{1}{2} & c-\frac{1}{2} & f-\frac{1}{2} \end{matrix} \right\} + [(d+f-b)$$
$$\times (b+d+f+1)(d+e-c)(c+e-d+1)$$
$$\times (a+f-c)(a+c-f+1)]^{\frac{1}{2}}$$
$$\times \left\{ \begin{matrix} a & b & e \\ d-\frac{1}{2} & c+\frac{1}{2} & f-\frac{1}{2} \end{matrix} \right\} . \qquad (2.84c)$$

Relation to hypergeometric series:

$$\left\{ \begin{matrix} a & b & e \\ d & c & f \end{matrix} \right\} = (-1)^{a+b+c+d} W(abcd; ef)$$

$$= \Delta(abe)\Delta(cde)\Delta(acf)\Delta(bdf)$$

$$\times \frac{(-1)^{\beta_1}(\beta_1+1)!}{(\beta_2-\beta_1)!(\beta_3-\beta_1)!}$$

$$\times \frac{{}_4F_3 \left(\begin{matrix} \alpha_1-\beta_1, & \alpha_2-\beta_1, & \alpha_3-\beta_1, & \alpha_4-\beta_1 \\ -\beta_1-1, & \beta_2-\beta_1+1, & \beta_3-\beta_1+1, & \end{matrix} ; 1 \right)}{(\beta_1-\alpha_1)!(\beta_1-\alpha_2)!(\beta_1-\alpha_3)!(\beta_1-\alpha_4)!} ,$$

$$\beta_1 = \min(a+b+c+d, a+d+e+f, b+c+e+f) ,$$

The parameters β_2 and β_3 are identified in either way with the pair remaining in the 3-tuple

$$(a+b+c+d, a+d+e+f, b+c+e+f)$$

after deleting β_1. The $(\alpha_1, \alpha_2, \alpha_3, \alpha_4)$ may be identified with any permutation of the 4-tuple

$$(a+b+e, c+d+e, a+c+f, b+d+f) .$$

The ${}_4F_3$ series is Saalschützian:

$$1 + \sum(\text{numerator parameters})$$
$$= \sum(\text{denominator parameters}) .$$

2.10 The 9−*j* Coefficients

2.10.1 Hilbert Space and Tensor Operator Actions

Let $T^a(1)$ and $T^b(2)$ denote irreducible tensor operators of ranks a and b with respect to kinematically independent angular momentum operators $J(1)$ and $J(2)$ that act, respectively, in separable Hilbert spaces $\mathcal{H}(1)$ and $\mathcal{H}(2)$. Let $\mathcal{H}(1)$ and $\mathcal{H}(2)$ be reduced, respectively, into a direct sum of spaces $\mathcal{H}_{j_1}(1)$ and $\mathcal{H}_{j_2}(2)$. The angular momentum $J(1)$ has the standard action on the orthonormal basis $\left\{|\,j_1 m_1\rangle \,\middle|\, m_1 = j_1, j_1 - 1, \ldots, -j_1\right\}$ of $\mathcal{H}_{j_1}(1)$, and $J(2)$ has the standard action on the orthonormal basis $\left\{|\,j_2 m_2\rangle \,\middle|\, m_2 = j_2, j_2 - 1, \ldots, -j_2\right\}$ of $\mathcal{H}_{j_2}(2)$. The irreducible tensor operators $T^a(1)$ and $T^b(2)$ also have the standard actions in their respective Hilbert spaces $\mathcal{H}(1)$ and $\mathcal{H}(2)$, as given by the Wigner–Eckart theorem. The total angular momentum J has the standard action on the coupled orthonormal basis of the tensor product space $\mathcal{H}_{j_1} \otimes \mathcal{H}_{j_2}$:

$$|(j_1 j_2)\, jm\rangle = \sum_{m_1 m_2} C^{j_1 j_2 j}_{m_1 m_2 m} |j_1 m_1\rangle \otimes |j_2 m_2\rangle \,.$$

$$(2.85)$$

The tensor product operator $T^a(1) \otimes T^b(2)$ acts in the tensor product space $\mathcal{H}(1) \otimes \mathcal{H}(2)$ according to the rule:

$$\left(T^a(1) \otimes T^b(2)\right)\left(|j_1 m_1\rangle \otimes |j_2 m_2\rangle\right)$$
$$= T^a(1)|j_1 m_1\rangle \otimes T^b(2)|j_2 m_2\rangle \,,$$

so that

$$\left(T^a(1) \otimes T^b(2)\right)|(j_1 j_2)\, jm\rangle$$
$$= \sum_{m_1 m_2} C^{j_1 j_2 j}_{m_1 m_2 m} T^a(1)|j_1 m_1\rangle \otimes T^b(2)|j_2 m_2\rangle \,.$$

$$(2.86a)$$

The angular momentum quantities called 9−j coefficients arise when the coupled tensor operators $T^{(ab)c}$ with components γ defined by

$$T^{(ab)c}_{\;\;\gamma} = \sum_{\alpha\beta} C^{abc}_{\alpha\beta\gamma} T^a_\alpha(1) \otimes T^b_\beta(2) \,,$$

$$\gamma = c, c-1, \ldots, -c \,,$$

$$(2.86b)$$

are considered. The quantity $T^{(ab)c}$ is an irreducible tensor operator of rank c with respect to the total angular momentum J for all a, b that yield c under the rule of addition of angular momentum.

2.10.2 9−j Invariant Operators

The entire angular momentum content of relation (2.86b) is captured by taking the irreducible tensor operators $T^a(1)$ and $T^b(2)$ to be unit tensor operators acting in the respective spaces $\mathcal{H}(1)$ and $\mathcal{H}(2)$:

$$T^{(ab)c}_{(\rho\sigma)\gamma}$$
$$= \sum_{\alpha\beta} C^{abc}_{\alpha\beta\gamma} \left\langle 2a \begin{array}{c} \alpha+\rho \\ a+\alpha \end{array} 0 \right\rangle_{\!1} \otimes \left\langle 2b \begin{array}{c} b+\sigma \\ b+\beta \end{array} 0 \right\rangle_{\!2} .$$

$$(2.87)$$

The placement of the unit tensor operators shows in which space they act, so that the additional identification by indices 1 and 2 could be eliminated. For each given $c \in \{0, 1/2, 1, 3/2, 2, \ldots\}$ and all a, b such that the triangle relation (abc) is satisfied, and, for each such pair a, b, all ρ, σ with $\rho \in \{a, a-1, \ldots, -a\}, \sigma \in \{b, b-1, \ldots, -b\}$, an irreducible tensor operator of rank c with respect to the total angular momentum J with components γ is defined by (2.87). By the Wigner–Eckart theorem, it must be possible to write

$$\sum_{\alpha\beta} C^{abc}_{\alpha\beta\gamma} \left\langle 2a \begin{array}{c} \alpha+\rho \\ a+\alpha \end{array} 0 \right\rangle_{\!1} \otimes \left\langle 2b \begin{array}{c} b+\sigma \\ b+\beta \end{array} 0 \right\rangle_{\!2}$$
$$= \sum_\tau \begin{bmatrix} abc \\ \rho\sigma\tau \end{bmatrix} \left\langle 2c \begin{array}{c} c+\tau \\ c+\gamma \end{array} 0 \right\rangle .$$

$$(2.88)$$

where: (i) The unit tensor operator on the right-hand side is a irreducible tensor operator with respect to J; that is, has the action on the coupled states given by

$$\left\langle 2c \begin{array}{c} c+\tau \\ c+\gamma \end{array} 0 \right\rangle |(j_1 j_2)\, jm\rangle$$
$$= C^{j\,c\;j+\tau}_{m,\gamma,m+\gamma} |(j_1 j_2)\, j+\tau, m+\gamma\rangle \,;$$

$$(2.89)$$

and (ii) the symbol $\begin{bmatrix} abc \\ \rho\sigma\tau \end{bmatrix}$ denotes an invariant operator with respect to the total angular momentum J. Using the orthogonality of unit tensor operators, we can also write relation (2.88) in the

form:

$$\begin{bmatrix} abc \\ \rho\sigma\tau \end{bmatrix} = \sum_{\alpha\beta\gamma} C^{abc}_{\alpha\beta\gamma} \left\langle 2a \begin{matrix} a+\rho \\ a+\alpha \end{matrix} 0 \right\rangle_1$$

$$\otimes \left\langle 2b \begin{matrix} b+\sigma \\ b+\beta \end{matrix} 0 \right\rangle_2 \left\langle 2c \begin{matrix} c+\tau \\ c+\gamma \end{matrix} 0 \right\rangle^\dagger . \qquad (2.90)$$

This form is taken as the definition of the $9-j$ invariant operator. Its eigenvalues in the coupled basis define the $9-j$ coefficient:

$$\begin{bmatrix} abc \\ \rho\sigma\tau \end{bmatrix} |(j_1 j_2) jm\rangle$$

$$= \langle (j_1+\rho, \, j_2+\sigma)j+\tau| \left\| \begin{bmatrix} abc \\ \rho\sigma\tau \end{bmatrix} \right\| |(j_1 j_2)j\rangle$$

$$\times |(j_1 j_2) jm\rangle$$

$$= [(2j+1)(2c+1)(2j_1+2\rho+1)(2j_2+2\sigma+1)]^{\frac{1}{2}}$$

$$\times \begin{Bmatrix} j_1 & j_2 & j \\ a & b & c \\ j_1+\rho & j_2+\sigma & j+\tau \end{Bmatrix} |(j_1 j_2) jm\rangle . \qquad (2.91)$$

The $9-j$ invariant operators play exactly the same role in the tensor product space of two irreducible angular momentum spaces as do the Racah invariants in one such irreducible angular momentum space.

The full content of the coupling law (2.86b) for physical irreducible tensor operators is regained in the coupling law for reduced matrix elements:

$$\langle (\alpha_1'\alpha_2' j_1' j_2')j' \| [\boldsymbol{T}^a(1) \times \boldsymbol{T}^b(2)]^c \| (\alpha_1\alpha_2 j_1 j_2)j\rangle$$

$$= \begin{bmatrix} j_1 & j_2 & j \\ a & b & c \\ j_1' & j_2' & j' \end{bmatrix} \langle (\alpha_1')j_1' \| \boldsymbol{T}^a(1) \| (\alpha_1)j_1\rangle$$

$$\times \langle (\alpha_2')j_2' \| \boldsymbol{T}^b(2) \| (\alpha_2)j_2\rangle ; \qquad (2.92a)$$

$$\begin{bmatrix} j_1 & j_2 & j \\ a & b & c \\ j_1' & j_2' & j' \end{bmatrix}$$

$$= [(2j_1'+1)(2j_2'+1)(2j+1)(2c+1)]^{\frac{1}{2}}$$

$$\times \begin{Bmatrix} j_1 & j_2 & j \\ a & b & c \\ j_1' & j_2' & j' \end{Bmatrix} . \qquad (2.92b)$$

2.10.3 Basic Relations Between 9−j Coefficients and 6−j Coefficients

Orthogonality of $9-j$ coefficients:

$$\sum_{hi} (2c+1)(2f+1)(2h+1)(2i+1)$$

$$\times \begin{Bmatrix} a & b & c \\ d & e & f \\ h & i & j \end{Bmatrix} \begin{Bmatrix} a & b & c' \\ d & e & f' \\ h & i & j \end{Bmatrix} = \delta_{cc'}\delta_{ff'} ,$$

where this relation is to be applied only to triples (abc), (def), (cfj), (abc'), (def'), $(c'f'j)$ for which the triangle conditions hold.

$9-j$ coefficients in terms of $3-j$ coefficients:

$$\delta_{j_{33}j_{33}'}(2j_{33}+1)^{-1} \begin{Bmatrix} j_{11} & j_{12} & j_{13} \\ j_{21} & j_{22} & j_{23} \\ j_{31} & j_{32} & j_{33} \end{Bmatrix}$$

$$= \sum_{\substack{\text{all } m_{ij} \\ \text{except } m_{33}}} \begin{pmatrix} j_{11} & j_{12} & j_{13} \\ m_{11} & m_{12} & m_{13} \end{pmatrix} \begin{pmatrix} j_{21} & j_{22} & j_{23} \\ m_{21} & m_{22} & m_{23} \end{pmatrix}$$

$$\times \begin{pmatrix} j_{31} & j_{32} & j_{33} \\ m_{31} & m_{32} & m_{33} \end{pmatrix} \begin{pmatrix} j_{11} & j_{21} & j_{31} \\ m_{11} & m_{21} & m_{31} \end{pmatrix}$$

$$\times \begin{pmatrix} j_{12} & j_{22} & j_{32} \\ m_{12} & m_{22} & m_{32} \end{pmatrix} \begin{pmatrix} j_{13} & j_{23} & j_{33}' \\ m_{13} & m_{23} & m_{33} \end{pmatrix} . \qquad (2.93)$$

$9-j$ coefficients in terms of $6-j$ coefficients:

$$\begin{Bmatrix} j_{11} & j_{12} & j_{13} \\ j_{21} & j_{22} & j_{23} \\ j_{31} & j_{32} & j_{33} \end{Bmatrix} = \sum_k (-1)^{2k}(2k+1)$$

$$\times \begin{Bmatrix} j_{11} & j_{21} & j_{31} \\ j_{32} & j_{33} & k \end{Bmatrix} \begin{Bmatrix} j_{12} & j_{22} & j_{32} \\ j_{21} & k & j_{23} \end{Bmatrix}$$

$$\times \begin{Bmatrix} j_{13} & j_{23} & j_{33} \\ k & j_{11} & j_{12} \end{Bmatrix} . \qquad (2.94)$$

Basic defining relation for $9-j$ coefficient from (2.88):

$$(-1)^\phi \begin{Bmatrix} j_{12} & j_{22} & j_{32} \\ j_{11} & j_{21} & j_{31} \\ j_{13} & j_{23} & j_{33} \end{Bmatrix} \begin{pmatrix} j_{31} & j_{32} & j_{33} \\ m_{31} & m_{32} & m_{33} \end{pmatrix}$$

$$= \sum_{\text{all } m_{(1i)}m_{(2i)}} \begin{pmatrix} j_{11} & j_{21} & j_{31} \\ m_{11} & m_{21} & m_{31} \end{pmatrix}$$

$$\times \begin{pmatrix} j_{12} & j_{22} & j_{32} \\ m_{12} & m_{22} & m_{32} \end{pmatrix} \begin{pmatrix} j_{13} & j_{23} & j_{33} \\ m_{13} & m_{23} & m_{33} \end{pmatrix}$$

$$\times \begin{pmatrix} j_{11} & j_{12} & j_{13} \\ m_{11} & m_{12} & m_{13} \end{pmatrix} \begin{pmatrix} j_{21} & j_{22} & j_{23} \\ m_{21} & m_{22} & m_{23} \end{pmatrix},$$

$$\phi = \sum_{kl} j_{kl} . \tag{2.95}$$

Additional relations:

$$\sum_{kl} (-1)^{2b+l+h-f} (2k+1)(2l+1)$$

$$\times \begin{Bmatrix} a & b & c \\ e & d & f \\ k & l & i \end{Bmatrix} \begin{Bmatrix} a & e & k \\ d & b & l \\ g & h & i \end{Bmatrix} = \begin{Bmatrix} a & b & c \\ d & e & f \\ g & h & i \end{Bmatrix},$$

$$\sum_{c} (2c+1) \begin{Bmatrix} a & b & c \\ d & e & f \\ g & h & i \end{Bmatrix} \begin{Bmatrix} a & b & c \\ f & i & j \end{Bmatrix}$$

$$= (-1)^{2j} \begin{Bmatrix} d & e & f \\ b & j & h \end{Bmatrix} \begin{Bmatrix} g & h & i \\ j & a & d \end{Bmatrix},$$

$$\sum_{klm} (2k+1)(2l+1)(2m+1)$$

$$\times \begin{Bmatrix} a & b & c \\ d & e & f \\ k & l & m \end{Bmatrix} \begin{Bmatrix} k & l & m \\ a' & b' & c' \\ d' & e' & f' \end{Bmatrix}$$

$$\times \begin{Bmatrix} a & d & k \\ a' & d' & k' \end{Bmatrix} \begin{Bmatrix} b & e & l \\ b' & e' & l' \end{Bmatrix} \begin{Bmatrix} c & f & m \\ c' & f' & m' \end{Bmatrix}$$

$$= \begin{Bmatrix} a & b & c \\ d' & e' & f' \\ k' & l' & m' \end{Bmatrix} \begin{Bmatrix} k' & l' & m' \\ a' & b' & c' \\ d & e & f \end{Bmatrix} .$$

2.10.4 Symmetry Relations for 9−*j* Coefficients and Reduction 6−*j* Coefficients

The 9−*j* coefficient

$$\begin{Bmatrix} j_{11} & j_{12} & j_{13} \\ j_{21} & j_{22} & j_{23} \\ j_{31} & j_{32} & j_{33} \end{Bmatrix}$$

is invariant under even permutation of its rows, even permutation of its columns, and under the interchange of rows and columns (matrix transposition). It is multiplied by the factor $(-1)^\phi$ (2.95) under odd permutations of its rows or columns. These 72 symmetries are all consequences of the 72 symmetries of the 3−*j* coefficient in relation (2.93).

Reduction to 6−*j* coefficients:

$$\begin{Bmatrix} a & b & e \\ c & d & e \\ f & f & 0 \end{Bmatrix} = \begin{Bmatrix} 0 & e & e \\ f & d & b \\ f & c & a \end{Bmatrix} = \begin{Bmatrix} e & 0 & e \\ c & f & a \\ d & f & b \end{Bmatrix}$$

$$= \begin{Bmatrix} f & f & 0 \\ d & c & e \\ b & a & e \end{Bmatrix} = \begin{Bmatrix} f & b & d \\ 0 & e & e \\ f & a & c \end{Bmatrix} = \begin{Bmatrix} a & f & c \\ e & 0 & e \\ b & f & d \end{Bmatrix}$$

$$= \begin{Bmatrix} b & a & e \\ f & f & 0 \\ d & c & e \end{Bmatrix} = \begin{Bmatrix} e & d & c \\ e & b & a \\ 0 & f & f \end{Bmatrix} = \begin{Bmatrix} c & e & d \\ a & e & b \\ f & 0 & f \end{Bmatrix}$$

$$= \frac{(-1)^{b+c+e+f}}{[(2e+1)(2f+1)]^{\frac{1}{2}}} \begin{Bmatrix} abe \\ dcf \end{Bmatrix} .$$

2.10.5 Explicit Algebraic Form of 9−*j* Coefficients

$$\begin{Bmatrix} a & b & c \\ d & e & f \\ h & i & j \end{Bmatrix} = (1)^{c+f-j} \frac{(dah)(bei)(jhi)}{(def)(bac)(jcf)}$$

$$\times \sum_{xyz} \frac{(-1)^{x+y+z}}{x!y!z!}$$

$$\times \frac{(2f-x)!(2a-z)!}{(2i+1+y)!(a+d+h+1-z)!}$$

$$\times \frac{(d+e-f+x)!(c+j-f+x)!}{(e+f-d-x)!(c+f-j-x)!}$$

$$\times \frac{(e+i-b+y)!(h+i-j+y)!}{(b+e-i-y)!(h+j-i-y)!}$$

$$\times \frac{(b+c-a+z)!}{(a+d-h-z)!(a+c-b-z)!}$$

$$\times \frac{(a+d+j-i-y-z)!}{(d+i-b-f+x+y)!(b+j-a-f+x+z)!} ,$$

$$(abc)$$

$$= \left(\frac{(a-b+c)!(a+b-c)!(a+b+c+1)!}{(b+c-a)!} \right)^{\frac{1}{2}} .$$

2.10.6 Racah Operators

A Racah operator is denoted

$$
\left\{\begin{matrix} & a+\rho & \\ 2a & & 0 \\ & a+\sigma & \end{matrix}\right\} \qquad \begin{matrix} \rho, \sigma = a, a-1, \ldots, -a, \\ 2a = 0, 1, 2, \ldots, \end{matrix}
$$

and is a special case of the operator defined by (2.87):

$$
\left\{\begin{matrix} & a+\rho & \\ 2a & & 0 \\ & a+\sigma & \end{matrix}\right\} |(j_1 j_2)\, jm\rangle
$$

$$
= \left(\frac{(2a+1)(2j_2+1)}{(2j_2+2\sigma+1)}\right)^{\frac{1}{2}} T^{(aa)0}_{(\rho\sigma)0} |(j_1 j_2)\, jm\rangle \, . \quad (2.96)
$$

Thus, a Racah operator is an invariant operator with respect to the total angular momentum $\boldsymbol{J}$. Alternative definitions are:

$$
\left\{\begin{matrix} & a+\rho & \\ 2a & & 0 \\ & a+\sigma & \end{matrix}\right\}
$$

$$
= (-1)^{a+\sigma} \sum_a \left\langle 2a \begin{matrix} a+\rho \\ \\ a+\alpha \end{matrix} 0 \right\rangle \otimes \left\langle 2a \begin{matrix} a-\sigma \\ \\ a+\alpha \end{matrix} 0 \right\rangle^{\dagger} ,
$$

$$
\left\{\begin{matrix} & a+\rho & \\ 2a & & 0 \\ & a+\sigma & \end{matrix}\right\} |(j_1 j_2)\, jm\rangle
$$

$$
= [(2j_1+2\rho+1)(2j_2+1)]^{\frac{1}{2}}
$$
$$
\times W(j, j_1, j_2+\sigma, a; j_2, j_1+\rho)
$$
$$
\times |(j_1+\rho, j_2+\sigma)\, jm\rangle
$$

with conjugate

$$
\left\{\begin{matrix} & a+\rho & \\ 2a & & 0 \\ & a+\sigma & \end{matrix}\right\}^{\dagger} |(j_1 j_2)\, jm\rangle
$$

$$
= [(2j_1+1)(2j_2-2\sigma+1)]^{\frac{1}{2}}
$$
$$
\times W(j, j_1-\rho, j_2, a; j_2-\sigma, j_1)
$$
$$
\times |(j_1-\rho, j_2-\sigma)\, jm\rangle \, .
$$

Racah operators satisfy orthogonality relations similar in form to Wigner operators. The open product rule

is:

$$
\left\{\begin{matrix} & b+\sigma & \\ 2b & & 0 \\ & b+\beta & \end{matrix}\right\} \left\{\begin{matrix} & a+\rho & \\ 2a & & 0 \\ & a+\alpha & \end{matrix}\right\}
$$

$$
= \sum_c \overline{\boldsymbol{W}}^{abc}_{\rho,\sigma,\rho+\sigma} \underline{\boldsymbol{W}}^{abc}_{\alpha,\beta,\alpha+\beta} \left\{\begin{matrix} & c+\rho+\sigma & \\ 2c & & 0 \\ & c+\alpha+\beta & \end{matrix}\right\} . \tag{2.97}
$$

In this result $\overline{\boldsymbol{W}}^{abc}_{\rho\sigma\tau}$ and $\underline{\boldsymbol{W}}^{abc}_{\alpha,\beta,\alpha+\beta}$ denote Racah invariants with respect to the angular momenta $\boldsymbol{J}(1)$ and $\boldsymbol{J}(2)$, respectively, so that

$$
\overline{\boldsymbol{W}}^{abc}_{\rho\sigma\tau} |(j_1 j_2)\, jm\rangle = W^{abc}_{\rho\sigma\tau}(j_1) |(j_1 j_2)\, jm\rangle \, ,
$$
$$
\underline{\boldsymbol{W}}^{abc}_{\alpha\beta\gamma} |(j_1 j_2)\, jm\rangle = W^{abc}_{\alpha\beta\gamma}(j_2) |(j_1 j_2)\, jm\rangle \, .
$$

The matrix elements of relation (2.97) lead to the Biedenharn–Elliott identity. There are five versions of this relationship in complete analogy to relations (2.63–2.65) and (2.69–2.70) for Wigner operators.

Racah operators are a basis for all invariant operators acting in the tensor product space spanned by the coupled basis vectors (2.85) and are the natural way of formulating interactions in that space. Their algebra is a fascinating study, initiated already in a different guise in the work of *Schwinger* [2.3]. Little use has been made of this concept in physical applications.

Additional relations between Racah coefficients or $6-j$ coefficients may be derived from the various versions of the rule (2.97) or directly from relation (2.79b) by using the orthogonality relations (2.75). Two of these are:

$$
\sum_e (-1)^{a+b+e}(2e+1)
$$

$$
\times \left\{\begin{matrix} a & b & e \\ d & c & g \end{matrix}\right\} \left\{\begin{matrix} a' & a & c' \\ b & b' & e \end{matrix}\right\} \left\{\begin{matrix} a' & e & b' \\ d & d' & c \end{matrix}\right\}
$$

$$
= (-1)^{\phi_1} \left\{\begin{matrix} c' & b & b' \\ d & d' & g \end{matrix}\right\} \left\{\begin{matrix} a' & a & c' \\ g & d' & c \end{matrix}\right\} ,
$$

$$
\phi_1 = g + a' + b' + c' + c + d' + d \, ;
$$

$$
\sum_{e,e'} (-1)^{a-c'+e-e'}(2e+1)(2e'+1)(2f+1)
$$

$$
\times \left\{\begin{matrix} c' & b & e' \\ d & d' & f \end{matrix}\right\} \left\{\begin{matrix} a & b & e \\ d & c & g \end{matrix}\right\} \left\{\begin{matrix} a' & a & c' \\ b & e' & e \end{matrix}\right\} \left\{\begin{matrix} a' & e & e' \\ d & d' & c \end{matrix}\right\}
$$

$$
= \delta_{fg}(-1)^{\phi_2} \left\{\begin{matrix} a' & a & c' \\ g & d' & c \end{matrix}\right\} ,
$$

$$
\phi_2 = g + a' - b + c + d' + d \, .
$$

The W-coefficient form of these relations is obtained by deleting all phase factors and making the substitution (2.74), ignoring the phase factor. There are no phase factors in the corresponding W-coefficient relations.

2.10.7 Schwinger–Wu Generating Function and its Combinatorics

Triangles associated with the 9−j coefficient $\left\{ \begin{matrix} j_1 j_2 j_3 \\ j_4 j_5 j_6 \\ j_7 j_8 j_9 \end{matrix} \right\}$:

$(j_1 j_2 j_3)$, $(j_4 j_5 j_6)$, $(j_7 j_8 j_9)$, $(j_1 j_4 j_7)$, $(j_2 j_5 j_8)$, $(j_3 j_6 j_9)$.

Points in $\mathbf{R}^3$ associated with the triangles:

$(j_1 j_2 j_3) \rightarrow (x_1, x_2, x_3)$, $(j_4 j_5 j_6) \rightarrow (x_4, x_5, x_6)$,
$(j_7 j_8 j_9) \rightarrow (x_7, x_8, x_9)$, $(j_1 j_4 j_7) \rightarrow (y_1, y_4, y_7)$,
$(j_2 j_5 j_8) \rightarrow (y_2, y_5, y_8)$, $(j_3 j_6 j_9) \rightarrow (y_3, y_6, y_9)$.

Cubic graph $\mathbf{C}_6$ in $\mathbf{R}^3$ associated with the points:

The points define the vertices of a cubic graph $\mathbf{C}_6$ on six points with lines joining each pair of points that share a common subscript, and the lines are labeled by the products $x_i y_i$, where i is the common subscript (Fig. 2.3).

Cubic graph $\mathbf{C}_6$ functions:

Interchange the symbols x and y in the coordinates of the vertices of the cubic graph $\mathbf{C}_6$, and define the following polynomials on the vertices and edges of the $\mathbf{C}_6$ with this modified labeling:

Vertex function: multiply together the coordinates of each pair of adjacent vertices, divide out the coordinates with a common subscript, and sum over all pairs of
Fig. 2.3 Labeled cubic graph associated with the 9−j coefficient

vertices to obtain

$$V_4 = y_1 y_2 x_6 x_9 + y_1 y_3 x_5 x_8 + y_2 y_3 x_4 x_7$$
$$+ y_4 y_5 x_3 x_9 + y_4 y_6 x_2 x_8 + y_5 y_6 x_1 x_7$$
$$+ y_7 y_8 x_3 x_6 + y_7 y_9 x_2 x_5 + y_8 y_9 x_1 x_4 .$$

Edge function:

$$E_6 = \det \begin{bmatrix} x_1 y_1 & x_2 y_2 & x_3 y_3 \\ x_4 y_4 & x_5 y_5 & x_6 y_6 \\ x_7 y_7 & x_8 y_8 & x_9 y_9 \end{bmatrix} .$$

Generating function [2.4–6]:

$$(1 - V_4 + E_6)^{-2} = \sum_{\Delta} C(\Delta) Z^{\Delta} ,$$

$$Z^{\Delta} = \prod_{\text{all vertices}} (z_a, z_b, z_c)^{(j_a j_b j_c)} \quad [\text{see } (2.82,)] ,$$

$$\Delta = \begin{bmatrix} (j_1 j_2 j_3) \\ (j_4 j_5 j_6) \\ (j_7 j_8 j_9) \\ (j_1 j_4 j_7) \\ (j_2 j_5 j_8) \\ (j_3 j_6 j_9) \end{bmatrix} ,$$

$$C(\Delta) = \sum_k \sum_{\square} \sum_a (-1)^{k_{10}+k_{11}+k_{12}} (k+1)$$
$$\times \binom{k}{k_1, \ldots, k_9, k_{10}, \ldots, k_{15}} ,$$

where summation $\sum_{\square}$ is over all 3×3 square arrays of nonnegative integers $k_j (j = 1, 2, \ldots, 9)$ with fixed row and column sums given by

$$\begin{bmatrix} k_1 & k_2 & k_3 \\ k_4 & k_5 & k_6 \\ k_7 & k_8 & k_9 \end{bmatrix} \begin{matrix} k - t_1 \\ k - t_2 \\ k - t_3 \end{matrix}$$
$$k - t_4 \quad k - t_5 \quad k - t_6$$

and for each such array the summation $\sum_a$ is over all nonnegative integers a such that the following quantities are nonnegative integers:

$$k_{10} = -a + k_1 - k + j_2 + j_3 + j_4 + j_7 ,$$
$$k_{11} = -a + k_6 - k + j_3 + j_4 + j_5 + j_9 ,$$
$$k_{12} = -a + k_8 - k + j_2 + j_5 + j_7 + j_9 ,$$
$$k_{13} = a + k_5 - k_1 - j_3 + j_6 - j_7 + j_8 ,$$
$$k_{14} = a + k_2 - k_6 + j_1 - j_4 + j_8 - j_9 ,$$
$$k_{15} = a .$$

Note that

$$\sum_{i=10}^{15} k_i = -2k + \sum_{i=1}^{9} j_i .$$

The t_i are the following triangle sums:

$$t_1 = j_1 + j_2 + j_3, t_2 = j_4 + j_5 + j_6 ,$$
$$t_3 = j_7 + j_8 + j_9 ,$$
$$t_4 = j_1 + j_4 + j_7, t_5 = j_2 + j_5 + j_8 ,$$
$$t_6 = j_3 + j_6 + j_9 .$$

The $9-j$ coefficient is given by

$$\begin{Bmatrix} j_1 j_2 j_3 \\ j_4 j_5 j_6 \\ j_7 j_8 j_9 \end{Bmatrix} = \Delta(j_1 j_2 j_3)\Delta(j_4 j_5 j_6)\Delta(j_7 j_8 j_9)$$
$$\times \Delta(j_1 j_4 j_7)\Delta(j_2 j_5 j_8)\Delta(j_3 j_6 j_9)C(\Delta) .$$

The coefficient $C(\Delta)$ is an integer associated with each cubic graph C_6 that counts the number of occurrences of the monomial term Z^Δ in the expansion of $(1 - V_4 + E_6)^{-2}$.

2.11 Tensor Spherical Harmonics

Tensor spherical or tensor solid harmonics are special cases of the coupling of two irreducible tensor operators in the tensor product space given in Sect. 2.7.2. They are defined by

$$\mathcal{Y}^{(ls)jm} = \sum_{\nu} C^{l\,s\,j}_{m-\nu,\nu,m} \mathcal{Y}_{l,m-\nu} \otimes \xi_\nu$$

and belong to the tensor product space $\mathcal{H}_l \otimes \mathcal{H}'_s$, where the orthonormal bases of the spaces $\mathcal{H}_l$ and $\mathcal{H}'_s$ are:

$$\{\mathcal{Y}_{l\mu} : \mu = l, l-1, \ldots, -l\} ,$$
$$\{\xi_\nu : \nu = s, s-1, \ldots, -s\} .$$

The orbital angular momentum L has the standard action on the solid harmonics, and a second set of kinematically independent angular momentum operators S has the standard action on the basis set of $\mathcal{H}'_s$.
The total angular momentum is:

$$J = L \otimes 1' + 1 \otimes S ,$$

The set of vectors

$$\{ \mathcal{Y}^{(ls)jm} : m = j, j-1, \ldots, -j; (lsj)$$
$$\text{obey the triangle conditions} \}$$

has the following following properties:
Orthogonality:

$$\left\langle \mathcal{Y}^{(l's)j'm'}, \mathcal{Y}^{(ls)jm} \right\rangle$$
$$= \sum_{\nu\nu'} C^{l'\,s\,j'}_{m'-\nu',\nu',m'} C^{l\,s\,j}_{m-\nu,\nu,m} (\mathcal{Y}_{l',m'-\nu'}, \mathcal{Y}_{l,m-\nu})$$
$$\times (\xi_{\nu'}, \xi_\nu)' = \delta_{j'j}\delta_{l'l}\delta_{m'm} ,$$

where $\langle\,,\,\rangle$ denotes the inner product in the space $\mathcal{H}_l \otimes \mathcal{H}'_s$, $(\,,\,)$ the inner product in $\mathcal{H}_l$, and $(\,,\,)'$ the inner product in $\mathcal{H}'_s$.
Operator actions:

$$J^2 \mathcal{Y}^{(ls)jm} = j(j+1)\mathcal{Y}^{(ls)jm} ,$$
$$J_3 \mathcal{Y}^{(ls)jm} = m\mathcal{Y}^{(ls)jm} ,$$
$$(L^2 \otimes 1')\mathcal{Y}^{(ls)jm} = l(l+1)\mathcal{Y}^{(ls)jm} ,$$
$$(1 \otimes S^2)\mathcal{Y}^{(ls)jm} = s(s+1)\mathcal{Y}^{(ls)jm} ,$$
$$J^2 = L^2 \otimes 1' + 1 \otimes S^2 + 2\sum_i L_i \otimes S_i ,$$

$$J_\pm \mathcal{Y}^{(ls)jm} = [(j\mp m)(j\pm m+1)]^{\frac{1}{2}} \mathcal{Y}^{(ls)j,m\pm 1} .$$

Transformation property under unitary rotations:

$$\exp(-i\psi\hat{n}\cdot J)\mathcal{Y}^{(ls)jm} = \sum_{m'} D^j_{m'm}(\psi,\hat{n})\mathcal{Y}^{(ls)jm'} .$$

Special realization:
The eigenvectors ξ_ν are often replaced by column matrices:

$$\xi_\nu = \text{col}(0\cdots 010\cdots 0) ,$$
$$\text{1 in position } s-\nu+1, \quad \nu = s, s-1, \ldots, -s .$$

The operators $S = (S_1, S_2, S_3)$ are correspondingly replaced by their standard $(2s+1)\times(2s+1)$ matrix representations $S_i^{(s)}$. The tensor product of operators becomes a $(2s+1)\times(2s+1)$ matrix containing both operators and numerical matrix elements, e.g.,

$$J_i = L_i I_{2s+1} + S_i^{(s)} ,$$

in which L_i is a differential operator multiplying the unit matrix, that is, L_i is repeated $2s+1$ times along the diagonal.

2.11.1 Spinor Spherical Harmonics as Matrix Functions

Choose $\xi_{+1/2} = \text{col}(1, 0)$, $\xi_{-1/2} = \text{col}(0, 1)$, and $\boldsymbol{S} = \boldsymbol{\sigma}/2$. The spinor spherical harmonics or Pauli central field spinors are the following, where $j \in \{1/2, 3/2, \dots\}$:

$$\boldsymbol{\mathcal{Y}}^{\left(j-\frac{1}{2},\frac{1}{2}\right)jm} = \begin{pmatrix} \sqrt{\frac{j+m}{2j}} \; \mathcal{Y}_{j-\frac{1}{2},m-\frac{1}{2}} \\[6pt] \sqrt{\frac{j-m}{2j}} \; \mathcal{Y}_{j-\frac{1}{2},m+\frac{1}{2}} \end{pmatrix},$$

$$\boldsymbol{\mathcal{Y}}^{\left(j+\frac{1}{2},\frac{1}{2}\right)jm} = \begin{pmatrix} -\sqrt{\frac{j-m+1}{2j+2}} \; \mathcal{Y}_{j+\frac{1}{2},m-\frac{1}{2}} \\[6pt] \sqrt{\frac{j+m+1}{2j+2}} \; \mathcal{Y}_{j+\frac{1}{2},m+\frac{1}{2}} \end{pmatrix}.$$

2.11.2 Vector Spherical Harmonics as Matrix Functions

Choose $\xi_{+1} = \text{col}(1, 0, 0)$, $\xi_0 = \text{col}(0, 1, 0)$, $\xi_{-1} = \text{col}(0, 0, 1)$, and $\boldsymbol{S}$ the 3×3 angular momentum matrices given by

$$S_+ = \begin{pmatrix} 0 & \sqrt{2} & 0 \\ 0 & 0 & \sqrt{2} \\ 0 & 0 & 0 \end{pmatrix}, \quad S_- = \begin{pmatrix} 0 & 0 & 0 \\ \sqrt{2} & 0 & 0 \\ 0 & \sqrt{2} & 0 \end{pmatrix},$$

$$S_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}.$$

The vector spherical harmonics are the following, where $j \in \{0, 1, 2, \dots\}$:

$$\boldsymbol{\mathcal{Y}}^{(j-1,1)jm} = \begin{pmatrix} \sqrt{\frac{(j+m-1)(j+m)}{2j(2j-1)}} \mathcal{Y}_{j-1,m-1} \\[8pt] \sqrt{\frac{(j-m)(j+m)}{j(2j-1)}} \mathcal{Y}_{j-1,m} \\[8pt] \sqrt{\frac{(j-m-1)(j-m)}{2j(2j-1)}} \mathcal{Y}_{j-1,m+1} \end{pmatrix},$$

$$\boldsymbol{\mathcal{Y}}^{(j1)jm} = \begin{pmatrix} -\sqrt{\frac{(j+m)(j-m+1)}{2j(j+1)}} \mathcal{Y}_{j,m-1} \\[8pt] \frac{m}{\sqrt{j(j+1)}} \mathcal{Y}_{j,m} \\[8pt] \sqrt{\frac{(j-m)(j+m+1)}{2j(j+1)}} \mathcal{Y}_{j,m+1} \end{pmatrix},$$

$$\boldsymbol{\mathcal{Y}}^{(j+1,1)jm} = \begin{pmatrix} \sqrt{\frac{(j-m+1)(j-m+2)}{2(j+1)(2j+3)}} \mathcal{Y}_{j+1,m-1} \\[8pt] -\sqrt{\frac{(j-m+1)(j+m+1)}{(j+1)(2j+3)}} \mathcal{Y}_{j+1,m} \\[8pt] \sqrt{\frac{(j+m+2)(j+m+1)}{2(j+1)(2j+3)}} \mathcal{Y}_{j+1,m+1} \end{pmatrix}.$$

Eigenvalue properties:

$$\nabla^2 \boldsymbol{\mathcal{Y}}^{(l1)jm} = 0,$$
$$\boldsymbol{J}^2 \boldsymbol{\mathcal{Y}}^{(l1)jm} = j(j+1) \boldsymbol{\mathcal{Y}}^{(l1)jm},$$
$$J_3 \boldsymbol{\mathcal{Y}}^{(l1)jm} = m \boldsymbol{\mathcal{Y}}^{(l1)jm},$$
$$\boldsymbol{L}^2 \boldsymbol{\mathcal{Y}}^{(l1)jm} = l(l+1) \boldsymbol{\mathcal{Y}}^{(l1)jm},$$
$$\boldsymbol{S}^2 \boldsymbol{\mathcal{Y}}^{(l1)jm} = 2 \boldsymbol{\mathcal{Y}}^{(l1)jm}.$$

2.11.3 Vector Solid Harmonics as Vector Functions

Vector spherical and solid harmonics can also be defined and their properties presented in terms of the ordinary solid harmonics, using the vectors $\boldsymbol{x}$, ∇, and $\boldsymbol{L}$, and the operations of divergence and curl:
Defining equations:

$$\boldsymbol{\mathcal{Y}}^{(l+1,1)lm} = -[(l+1)(2l+1)]^{-\frac{1}{2}}[(l+1)\boldsymbol{x} + i\boldsymbol{x} \times \boldsymbol{L}]\mathcal{Y}_{lm},$$
$$\boldsymbol{\mathcal{Y}}^{(l1)lm} = [l(l+1)]^{-1/2} \boldsymbol{L} \mathcal{Y}_{lm},$$
$$r^2 \boldsymbol{\mathcal{Y}}^{(l-1,1)lm} = -[l(2l+1)]^{-\frac{1}{2}} \times (-l\boldsymbol{x} + i\boldsymbol{x} \times \boldsymbol{L})\mathcal{Y}_{lm}.$$

Eigenvalue properties:

$$\boldsymbol{J}^2 \boldsymbol{\mathcal{Y}}^{(l1)jm} = j(j+1) \boldsymbol{\mathcal{Y}}^{(l1)jm},$$
$$\boldsymbol{L}^2 \boldsymbol{\mathcal{Y}}^{(l1)jm} = l(l+1) \boldsymbol{\mathcal{Y}}^{(l1)jm},$$
$$\boldsymbol{S}^2 \boldsymbol{\mathcal{Y}}^{(l1)jm} = 2 \boldsymbol{\mathcal{Y}}^{(l1)jm},$$
$$J_3 \boldsymbol{\mathcal{Y}}^{(l1)jm} = m \boldsymbol{\mathcal{Y}}^{(l1)jm},$$
$$\nabla^2 \boldsymbol{\mathcal{Y}}^{(l1)jm} = \boldsymbol{0},$$
$$2i\boldsymbol{L} \times \boldsymbol{\mathcal{Y}}^{(l1)jm} = [j(j+1) - l(l+1) - 2]\boldsymbol{\mathcal{Y}}^{(l1)jm}.$$

Orthogonality:

$$\int dS_{\hat{\boldsymbol{x}}} \boldsymbol{\mathcal{Y}}^{(l'1)j'm'*}(\boldsymbol{x}) \cdot \boldsymbol{\mathcal{Y}}^{(l1)jm}(\boldsymbol{x}) = \delta_{l'l}\delta_{j'j}\delta_{m'm} r^{l'+l},$$

where the integration is over the unit sphere in $\boldsymbol{R}^3$.
Complex conjugation:

$$\boldsymbol{\mathcal{Y}}^{(l1)jm*} = (-1)^{l+1-j}(-1)^m \boldsymbol{\mathcal{Y}}^{(l1)j,-m}.$$

Vector and gradient formulas:

$$x\mathcal{Y}_{lm} = -\left(\frac{l+1}{2l+1}\right)^{\frac{1}{2}} \mathbf{y}^{(l+1,1)lm}$$

$$+ \left(\frac{l}{2l+1}\right)^{\frac{1}{2}} r^2 \mathbf{y}^{(l-1,1)lm} \,,$$

$$[(l+1)\nabla + \mathrm{i}\nabla \times \mathbf{L}](F\mathcal{Y}_{lm})$$
$$= -[(l+1)(2l+1)]^{\frac{1}{2}} \left(\frac{1}{r}\frac{\mathrm{d}F}{\mathrm{d}r}\right) \mathbf{y}^{(l+1,1)lm} \,,$$

$$[-l\nabla + \mathrm{i}\nabla \times \mathbf{L}](F\mathcal{Y}_{lm})$$
$$= -[l(2l+1)]^{\frac{1}{2}} \left[r\frac{\mathrm{d}F}{\mathrm{d}r} + (2l+1)F\right] \mathbf{y}^{(l-1,1)lm} \,,$$

$$\nabla(F\mathcal{Y}_{lm}) = -\left(\frac{l+1}{2l+1}\right)^{\frac{1}{2}} \left(\frac{1}{r}\frac{\mathrm{d}F}{\mathrm{d}r}\right) \mathbf{y}^{(l+1,1)lm}$$

$$+ \left(\frac{l}{2l+1}\right)^{\frac{1}{2}} \left[r\frac{\mathrm{d}F}{\mathrm{d}r} + (2l+1)F\right] \mathbf{y}^{(l-1,1)lm} \,,$$

$$\mathrm{i}\nabla \times \mathbf{L}(F\mathcal{Y}_{lm}) = -l\left(\frac{l+1}{2l+1}\right)^{\frac{1}{2}} \left(\frac{1}{r}\frac{\mathrm{d}F}{\mathrm{d}r}\right) \mathbf{y}^{(l+1,1)lm}$$

$$- (l+1)\left(\frac{l}{2l+1}\right)^{\frac{1}{2}}$$

$$\times \left[r\frac{\mathrm{d}F}{\mathrm{d}r} + (2l+1)F\right] \mathbf{y}^{(l-1,1)lm} \,.$$

Curl equations:

$$\mathrm{i}\nabla \times (F\mathbf{y}^{(l+1,1)lm}) = -\left(\frac{l}{2l+1}\right)^{\frac{1}{2}}$$

$$\times \left[r\frac{\mathrm{d}F}{\mathrm{d}r} + (2l+3)F\right] \mathbf{y}^{(l1)lm} \,,$$

$$\mathrm{i}\nabla \times (F\mathbf{y}^{(l1)lm}) = -\left(\frac{l}{2l+1}\right)^{\frac{1}{2}}$$

$$\times \left(\frac{1}{r}\frac{\mathrm{d}F}{\mathrm{d}r}\right) \mathbf{y}^{(l+1,1)lm} - \left(\frac{l+1}{2l+1}\right)^{\frac{1}{2}}$$

$$\times \left[r\frac{\mathrm{d}F}{\mathrm{d}r} + (2l+1)F\right] \mathbf{y}^{(l-1,1)lm} \,,$$

$$\mathrm{i}\nabla \times (F\mathbf{y}^{(l-1,1)lm}) = -\left(\frac{l+1}{2l+1}\right)^{\frac{1}{2}} \left(\frac{1}{r}\frac{\mathrm{d}F}{\mathrm{d}r}\right) \mathbf{y}^{(l1)lm} \,.$$

Divergence equations:

$$\nabla \cdot (F\mathbf{y}^{(l+1,1)lm}) =$$
$$-\left(\frac{l+1}{2l+1}\right)^{\frac{1}{2}} \left[r\frac{\mathrm{d}F}{\mathrm{d}r} + (2l+3)F\right] \mathcal{Y}_{lm} \,,$$

$$\nabla \cdot (F\mathbf{y}^{(l1)lm}) = 0 \,,$$

$$\nabla \cdot (F\mathbf{y}^{(l-1,1)lm}) = \left(\frac{l}{2l+1}\right)^{\frac{1}{2}} \left(\frac{1}{r}\frac{\mathrm{d}F}{\mathrm{d}r}\right) \mathcal{Y}_{lm} \,.$$

Parity property:

$$\mathbf{y}^{(l+\delta,1)lm}(-x) = (-1)^{l+\delta} \mathbf{y}^{(l+\delta,1)lm}(x) \,.$$

Scalar product:

$$\mathbf{y}^{(l'1)j'm'} \cdot \mathbf{y}^{(l1)jm} =$$

$$\sum_{l''} r^{l+l'-l''} \left(\frac{(2j+1)(2j'+1)(2l+1)(2l'+1)}{4\pi(2l''+1)}\right)^{\frac{1}{2}}$$

$$\times (-1)^{l+j'+l''} C^{ll'l''}_{000} C^{jj'l''}_{m,m',m+m'}$$

$$\times \begin{Bmatrix} l' & j' & 1 \\ j & l & l'' \end{Bmatrix} \mathcal{Y}_{l'',m+m'} \,.$$

Cross product:

$$\mathbf{y}^{(l'1)j'm'} \times \mathbf{y}^{(l1)jm} = \left(-\mathrm{i}\sqrt{2}\right) \sum_{l''j''} r^{l+l'-l''}$$

$$\times \left(\frac{(2j+1)(2j'+1)(3)(2l+1)(2l'+1)}{4\pi}\right)^{\frac{1}{2}}$$

$$\times C^{ll'l''}_{000} C^{jj'j''}_{m,m',m+m'} \begin{Bmatrix} l & 1 & j \\ l' & 1 & j' \\ l'' & 1 & j'' \end{Bmatrix} \mathbf{y}^{(l''1)j'',m+m'} \,.$$

Conversion to spherical harmonic form:

$$\mathbf{y}^{(l+\delta,1)lm}(x) = r^{l+\delta} \mathbf{y}^{(l+\delta,1)lm}(\hat{x}) \,,$$

with appropriate modification of F to account for the factor $r^{l+\delta}$.

2.12 Coupling and Recoupling Theory and $3n-j$ Coefficients

2.12.1 Composite Angular Momentum Systems

An "elementary" angular momentum system is one whose state space can be written as a direct sum of vector spaces $\mathcal{H}_j$ with orthonormal basis

$$\{|\,jm\rangle \,|\, m = j, j-1, \ldots, -j\}$$

on which the angular momentum $\mathbf{J}$ has the standard action, and which under unitary transformation by

$\exp(-\mathrm{i}\psi\hat{\boldsymbol{n}}\cdot\boldsymbol{J})$ undergoes the standard unitary transformation. A composite angular momentum system is one whose state space is a direct sum of the tensor product spaces $\mathcal{H}_{j_1 j_2 \cdots j_n}$ of dimension $\prod_{\alpha=1}^{n}(2j_\alpha+1)$ with orthonormal basis in the tensor product space of the elementary systems given by

$$|\,j_1 m_1\rangle \otimes |\,j_2 m_2\rangle \otimes \cdots \otimes |\,j_n m_n\rangle \,, \qquad (2.98)$$

each $m_\alpha = j_\alpha, j_\alpha - 1, \ldots, -j_\alpha$.

The following properties then hold for the composite system:

Independent rotations of the elementary parts:

$$
\begin{aligned}
&\left\{ \exp\left[-\mathrm{i}\psi_1\hat{\boldsymbol{n}}_1\cdot\boldsymbol{J}(1)\right] \otimes \cdots \otimes \exp\left[-\mathrm{i}\psi_n\hat{\boldsymbol{n}}_n\cdot\boldsymbol{J}(n)\right] \right\} \\
&\quad \times |\,j_1 m_1\rangle \otimes \cdots \otimes j_n m_n\rangle \\
&= \exp\left[-\mathrm{i}\psi_1\hat{\boldsymbol{n}}_1\cdot\boldsymbol{J}(1)\right] |\,j_1 m_1\rangle \otimes \cdots \\
&\qquad \otimes \exp\left[-\mathrm{i}\psi_n\hat{\boldsymbol{n}}_n\cdot\boldsymbol{J}(n)\right] |\,j_n m_n\rangle \\
&= \sum_{m_1'\cdots m_n'} \left[D^{j_1}(U_1) \times \cdots \times D^{j_n}(U_n) \right]_{m_1'\cdots m_n'; m_1\cdots m_n} \\
&\quad \times \left|\,j_1 m_1'\right\rangle \otimes \cdots \otimes \left|\,j_n m_n'\right\rangle \,,
\end{aligned} \qquad (2.99)
$$

$$
\begin{aligned}
&\left[D^{j_1}(U_1) \times \cdots \times D^{j_n}(U_n) \right]_{m_1'\cdots m_n'; m_1\cdots m_n} \\
&= D^{j_1}_{m_1' m_1}(U_1) \cdots D^{j_n}_{m_n' m_n}(U_n) \,, \\
&U_\alpha = U(\psi_\alpha, \hat{\boldsymbol{n}}_\alpha) \in SU(2) \,, \quad \alpha = 1, 2, \ldots, n \,.
\end{aligned}
$$

Multiple Kronecker (direct) product group $SU(2)\times\cdots\times SU(2)$:

Group elements:

$$(U_1, \ldots, U_n) \,, \quad \text{each } U_\alpha \in SU(2) \,.$$

Multiplication rule:

$$\left(U_1', \ldots, U_n'\right)(U_1, \ldots, U_n) = \left(U_1' U_1, \ldots, U_n' U_n\right) \,.$$

Irreducible representations:

$$D^{j_1}(U_1) \times \cdots \times D^{j_n}(U_n) \,. \qquad (2.100)$$

Rotation of the composite system as a unit:

Common rotation:

$$U_1 = U_2 = \cdots = U_n = U \in SU(2) \,.$$

Diagonal subgroup $SU(2) \subset SU(2) \times \cdots \times SU(2)$:

$$(U, U, \ldots, U), \qquad \text{each } U \in SU(2) \,.$$

Reducible representation of $SU(2)$:

$$D^{j_1}(U) \times \cdots \times D^{j_n}(U) \,. \qquad (2.101)$$

Total angular momentum of the composite system:

$$\boldsymbol{J} = \boldsymbol{J}(1) + \boldsymbol{J}(2) + \cdots + \boldsymbol{J}(n) \,,$$

in which the k-th term in the sum is to be interpreted as the tensor product operator:

$$\boldsymbol{I}_1 \otimes \cdots \otimes \boldsymbol{J}(k) \otimes \cdots \otimes \boldsymbol{I}_n, \ \boldsymbol{I}_\alpha = \text{ unit operator in } \mathcal{H}_{j_\alpha} \,.$$

The basic problem for composite systems:

The basic problem is to reduce the n-fold direct product representation (2.101) of $SU(2)$ into a direct sum of irreducible representations, or equivalently, to find all subspaces $\mathcal{H}_j \subset \mathcal{H}_{j_1 j_2 \cdots j_n}$, $j \in \{0, 1/2, 1, \ldots\}$, with orthonormal bases sets $\{|\,jm\rangle\,|\,m = j, j-1, \ldots, -j\}$ on which the total angular momentum $\boldsymbol{J}$ has the standard action.

Form of the solution:

$$
\begin{aligned}
|\,(j_1 j_2 \cdots j_n)(k)\,jm\rangle &= \sum_{\substack{\text{all } m_\alpha \\ \sum m_\alpha = m}} C^{j_1 j_2 \cdots j_n j}_{m_1 m_2 \cdots m_n m}(k) \\
&\quad \times |\,j_1 m_1\rangle \otimes |\,j_2 m_2\rangle \otimes \cdots \otimes |\,j_n m_n\rangle \,,
\end{aligned} \qquad (2.102)
$$

$m = j, j-1, \ldots, -j$; index set (k) unspecified.

Diagonal operators:

$$
\begin{aligned}
&\boldsymbol{J}^2(\alpha) = J_1^2(\alpha) + J_2^2(\alpha) + J_3^2(\alpha), \\
&\boldsymbol{J}^2(\alpha) |\,(j_1 j_2 \cdots j_n)(k)\,jm\rangle \\
&\quad = j_\alpha(j_\alpha + 1) |\,(j_1 j_2 \cdots j_n)(k)\,jm\rangle \,, \\
&\quad \alpha = 1, 2, \ldots, n \,.
\end{aligned} \qquad (2.103)
$$

Total angular momentum properties imposed:

$$
\begin{aligned}
&\boldsymbol{J}^2 |\,(j_1 j_2 \cdots j_n)(k)\,jm\rangle \\
&\quad = j(j+1) |\,(j_1 j_2 \cdots j_n)(k)\,jm\rangle \,, \\
&J_3 |\,(j_1 j_2 \cdots j_n)(k)\,jm\rangle \\
&\quad = m |\,(j_1 j_2 \cdots j_n)(k)\,jm\rangle \,, \\
&J_\pm |\,(j_1 j_2 \cdots j_n)(k)\,jm\rangle \\
&\quad = [(j \mp m)(j \pm m + 1)]^{\frac{1}{2}} \\
&\qquad \times |\,(j_1 j_2 \cdots j_n)(k)\,jm \pm 1\rangle \,.
\end{aligned} \qquad (2.104)
$$

Properties of the index set (k):

Reduction of Kronecker product (2.101):

$$D^{j_1} \times D^{j_2} \times \cdots \times D^{j_n} = \sum_j \oplus n_j D^j \,,$$

$$\prod_\alpha (2j_\alpha + 1) = \sum_j n_j (2j + 1) \,. \qquad (2.105)$$

For fixed $j_1, j_2, \ldots, j_n$, and j, the index set (k) must enumerate exactly n_j perpendicular spaces $\mathcal{H}_j$.

Incompleteness of set of operators:

There are $2n$ commuting Hermitian operators diagonal on the basis (2.98):

$$\left\{ \mathbf{J}^2(\alpha), J_3(\alpha) \mid \alpha = 1, 2, \ldots, n \right\} . \qquad (2.106a)$$

There are $n + 2$ commuting Hermitian operators diagonal on the basis (2.102):

$$\left\{ \mathbf{J}^2, J_3; \mathbf{J}^2(\alpha) \mid \alpha = 1, 2, \ldots, n \right\} . \qquad (2.106b)$$

There are $n - 2$ additional commuting Hermitian operators, or other rules, required to complete set (2.106b) and determine the indexing set (k).

Basic content of coupling and recoupling theory:

Coupling theory is the study of completing the operator set (2.106b), or the specification of other rules, that uniquely determine the irreducible representation spaces $\mathcal{H}_j$ occurring in the Kronecker product reduction (2.105). Recoupling theory is the study of the inter-relations between different methods of effecting this reduction; it is a study of relations between the different ways of spanning the multiplicity space

$$\mathcal{H}_j \oplus \mathcal{H}_j \oplus \cdots \oplus \mathcal{H}_j \ (n_j \text{ terms}) .$$

2.12.2 Binary Coupling Theory: Combinatorics

Binary coupling of angular momenta refers to the selecting any pair of angular momentum operators from the set of individual system angular momenta

$$\{ \mathbf{J}(1), \mathbf{J}(2), \ldots, \mathbf{J}(n) \} ,$$

and carrying out the "addition of angular momenta" for that pair by coupling the corresponding states in the tensor product space by the standard use of $SU(2)$ WCG-coefficients; this is followed by addition of a new pair, which may be a pair distinct from the first pair, or the addition of one new angular momentum to the sum of the first pair, etc. If the order $1, 2, \ldots, n$ of the angular momenta is kept fixed in

$$\mathbf{J}_1 + \mathbf{J}_2 + \cdots + \mathbf{J}_n , \qquad (2.107)$$

one is led to the problem of parentheses. (To avoid misleading parentheses, the notation $\mathbf{J}_\alpha = \mathbf{J}(\alpha)$ is used in this section.) This is the problem of introducing pairs of parentheses into expression (2.107) that specify the coupling procedure that is to be implemented.

The procedure is clear from the following cases for $n = 2, 3$, and 4:

$$n = 2 : \ \mathbf{J}_1 + \mathbf{J}_2 ;$$

$$n = 3 : \ (\mathbf{J}_1 + \mathbf{J}_2) + \mathbf{J}_3 ,$$
$$\mathbf{J}_1 + (\mathbf{J}_2 + \mathbf{J}_3) ;$$

$$n = 4 : \ (\mathbf{J}_1 + \mathbf{J}_2) + (\mathbf{J}_3 + \mathbf{J}_4) ,$$
$$[(\mathbf{J}_1 + \mathbf{J}_2) + \mathbf{J}_3] + \mathbf{J}_4 ,$$
$$[\mathbf{J}_1 + (\mathbf{J}_2 + \mathbf{J}_3)] + \mathbf{J}_4 ,$$
$$\mathbf{J}_1 + [(\mathbf{J}_2 + \mathbf{J}_3) + \mathbf{J}_4] ,$$
$$\mathbf{J}_1 + [\mathbf{J}_2 + (\mathbf{J}_3 + \mathbf{J}_4)] .$$

It is customary to use the ordered sequence

$$j_1 j_2 \cdots j_n \qquad (2.108)$$

of angular momentum quantum numbers in place of the angular momentum operators in (2.107). Thus, the five placement of parentheses for $n = 4$ becomes:

$$(j_1 j_2)(j_3 j_4) , \ [(j_1 j_2) j_3] j_4 , \ [j_1 (j_2 j_3)] j_4 ,$$
$$j_1 [(j_2 j_3) j_4] , \ j_1 [j_2 (j_3 j_4)] .$$

(It is also customary to omit the last parentheses pair, which encloses the whole sequence.) A sequence (2.108) into which pairwise insertions of parentheses has been completed is called a binary bracketing of the sequence, and denoted by $(j_1 j_2 \cdots j_n)^B$. This symbol may also be called a coupling symbol. The total number of coupling symbols, that is, the total number of elements a_n in the set

$$\{ (j_1 j_2 \cdots j_n)^B \mid B \text{ is a binary bracketing} \}$$

is given by the Catalan numbers:

$$a_n = \frac{1}{n} \binom{2n-2}{n-1} , \quad n = 2, 3, \ldots .$$

Effect of permuting the angular momenta:

Since the position of an individual vector space in the tensor product $\mathcal{H}_{j_1} \otimes \cdots \otimes \mathcal{H}_{j_n}$ is kept fixed, the meaning of a permutation of the j_α in the sequence (2.108) corresponding to a given binary bracketing is to permute the positions of the terms in the summation for the total angular momentum, e.g., $(j_1 j_2) j_3 \to (j_3 j_1) j_2$ corresponds to

$$(\mathbf{J}_1 \otimes \mathbf{I}_2 \otimes \mathbf{I}_3 + \mathbf{I}_1 \otimes \mathbf{J}_2 \otimes \mathbf{I}_3) + \mathbf{I}_1 \otimes \mathbf{I}_2 \otimes \mathbf{J}_3$$
$$= (\mathbf{I}_1 \otimes \mathbf{I}_2 \otimes \mathbf{J}_3 + \mathbf{J}_1 \otimes \mathbf{I}_2 \otimes \mathbf{I}_3) + \mathbf{I}_1 \otimes \mathbf{J}_2 \otimes \mathbf{I}_3 .$$

Total number of binary bracketing schemes including permutations:

The number of symbols in the set

$$\left\{ (j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B \;\middle|\; \begin{array}{l} B \text{ is a binary bracketing and} \\ \alpha_1 \alpha_2 \cdots \alpha_n \text{ is a permutation} \\ \text{of } 1, 2, \ldots, n \end{array} \right\}$$

(2.109)

is $c_n = n! a_n = (n)_{n-1} = n(n+1) \cdots (2n-2)$.

Caution: One should not assign numbers to the symbols j_α, since these symbols serve as noncommuting, nonassociative distinct objects in a counting process.

Binary subproducts:

A binary subproduct in the coupling symbol $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B$ is the subset of symbols between a given parentheses pair, say, $\{xy\}$. The symbols x and y may themselves contain binary subproducts. Commutation of a binary subproduct is the operation $\{xy\} \to \{yx\}$. For example, the coupling symbol $\{[(j_1 j_2) j_3] j_4\}$ contains three binary subproducts, $\{xy\}$, $[xy]$, (xy).

Equivalence relation:

Two coupling symbols are defined to be equivalent

$$(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B \sim (j_{\alpha'_1} j_{\alpha'_2} \cdots j_{\alpha'_n})^B$$

if one can be obtained from the other by commutation of the symbols in the binary subproducts. Such commutations change the overall phase of the state vector (2.102) corresponding to a particular coupling symbol, and such states are counted as being the same (equivalent).

Number of inequivalent coupling schemes:

The equivalence relation under commutation of binary subproducts partitions the set (2.109) into equivalence classes, each containing 2^{n-1} elements. There are $d_n = c_n/2^{n-1} = (2n-3)!!$ inequivalent coupling schemes in binary coupling theory. Thus, for $n = 4$, there are $5!! = 5 \times 3 \times 1 = 15$ inequivalent binary coupling schemes.

Type of a coupling symbol:

The type of the coupling symbol $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B$ is defined to be the symbol obtained by setting all the j_α equal to a common symbol, say, x. Thus, the type of the coupling symbol $\{[(j_1 j_2) j_3] j_4\}$ is $\{[(x^2)x]x\}$.

The Wedderburn–Etherington number b_n gives the number of coupling symbols of distinct types, counting two symbols as equivalent if they are related by commutation of binary subproducts. A closed form of these numbers is not known, although generating functions exist. The first few numbers are:

n	1	2	3	4	5	6	7	8	9	10
b_n	1	1	1	2	3	6	11	23	46	98

There are 15 nontrivial coupling schemes for 4 angular momenta, and they are classified into 2 types, allowing commutation of binary subproducts:

Type $[(x^2)x]x$

$[(j_1 j_2) j_3] j_4$, $[(j_2 j_3) j_1] j_4$, $[(j_3 j_1) j_2] j_4$

$[(j_1 j_2) j_4] j_3$, $[(j_2 j_4) j_1] j_3$, $[(j_4 j_1) j_2] j_3$

$[(j_1 j_3) j_4] j_2$, $[(j_3 j_4) j_1] j_2$, $[(j_4 j_1) j_3] j_2$

$[(j_2 j_3) j_4] j_1$, $[(j_3 j_4) j_2] j_1$, $[(j_4 j_2) j_3] j_1$

Type $(x^2)(x^2)$

$(j_1 j_2)(j_3 j_4)$, $(j_1 j_3)(j_2 j_4)$, $(j_2 j_3)(j_1 j_4)$

2.12.3 Implementation of Binary Couplings

Each binary coupling scheme specifies uniquely a set of intermediate angular momentum operators. For example, the intermediate angular momenta associated with the coupling symbol $[(j_1 j_2) j_3] j_4$ are

$$\boldsymbol{J}(1) + \boldsymbol{J}(2) = \boldsymbol{J}(12), \quad \boldsymbol{J}(12) + \boldsymbol{J}(3) = \boldsymbol{J}(123),$$
$$\boldsymbol{J}(123) + \boldsymbol{J}(4) = \boldsymbol{J},$$

where $\boldsymbol{J}$ is the total angular momentum. Each coupling symbol $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B$, defines exactly $n-2$ intermediate angular momentum operators $\boldsymbol{K}(\lambda), \lambda = 1, 2, \ldots, n-2$. The squares of these operators completes the set of operators (2.106b) for each coupling symbol; that is, the states vectors satisfying (2.103–2.104) and the following equations are unique, up to an overall choice of phase factor:

$$\boldsymbol{K}^2(\lambda) \,\big|\, (j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B (k_1 k_2 \cdots k_{n-2}) jm\rangle$$
$$= k_\lambda(k_\lambda + 1)|(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B (k_1 k_2 \cdots k_{n-2}) jm\rangle,$$
$$\lambda = 1, 2, \ldots, n-2, \quad n > 2. \quad (2.110)$$

The intermediate angular momentum operators $\boldsymbol{K}^2(\lambda)$ depend, of course, on the choice of binary couplings implicit in the symbol $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B$. The vectors have the following properties:

Orthonormal basis of $\mathcal{H}_{j_1}(1) \otimes \cdots \otimes \mathcal{H}_{j_n}(n)$:

$$\langle (j_\alpha)^B (k') jm | (j_\alpha)^B (k) jm \rangle = \prod_\lambda \delta_{k'_\lambda k_\lambda},$$

$$(j_\alpha) = (j_{\alpha_1}, j_{\alpha_2}, \ldots, j_{\alpha_n}),$$
$$(k) = (k_1, k_2, \ldots, k_{n-2}),$$
$$(k') = (k'_1, k'_2, \ldots, k'_{n-2}).$$

The range of each k_λ is uniquely determined by the Clebsch–Gordan series and the binary couplings in the

coupling symbol. Together these ranges enumerate exactly the multiplicity n_j of $\mathcal{H}_j$ occurring in the reduction of the multiple Kronecker product.

Uniqueness of state vectors:

$$| (j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B (k_1 k_2 \cdots k_{n-2}) jm \rangle$$

$$= \sum_{\sum m_\alpha = m} C \left[\begin{pmatrix} j_{\alpha_1} \cdots j_{\alpha_n} \\ m_{\alpha_1} \cdots m_{\alpha_n} \end{pmatrix}^B \begin{matrix} j \\ m \end{matrix} \right] (k_1, \ldots, k_{n-2})$$

$$\times | j_1 m_1 \rangle \otimes \cdots \otimes | j_n m_n \rangle \,.$$

In the C-coefficient, the $\begin{pmatrix} j_\alpha \\ m_\alpha \end{pmatrix}$ are paired in the binary bracketing. Each such C-coefficient is a summation over a unique product of $n-1$ $SU(2)$ WCG-coefficients.

Equivalent basis vectors:

$$| (j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B (k_1 k_2 \cdots k_{n-2}) jm \rangle$$

$$= \pm | (j_{\alpha'_1} j_{\alpha'_2} \cdots j_{\alpha'_n})^B (k_1 k_2 \cdots k_{n-2}) jm \rangle \,,$$

if and only if $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B \sim (j_{\alpha'_1} j_{\alpha'_2} \cdots j_{\alpha'_n})^B$. Inequivalent basis vector are orthonormal in all quantum numbers labeling the state vector.

Recoupling coefficients:

A recoupling coefficient is a transformation coefficient

$$\left\langle (j_\beta)^{B'} \,\middle|\, (l) jm \,\middle|\, (j_\alpha)^B (k) jm \right\rangle$$

relating any two orthonormal bases of the space $\mathcal{H}_{j_1} \otimes \cdots \otimes \mathcal{H}_{j_n}$, say, the one defined by (2.103, 2.104), and (2.110) for a prescribed coupling scheme corresponding to a bracketing B, and a second one, again defined by these relations but for a different coupling scheme corresponding to a bracketing B'. For example, for $n = 3$, there are 3 inequivalent coupling symbols and $\binom{3}{2} = 3$ recoupling coefficients; for $n = 4$, there are 15 inequivalent coupling symbols and $\binom{15}{2} = 105$ recoupling coefficients. Each coefficient is, of course, expressible as a sum over products of $2(n-1)$ WCG-coefficients, obtained simply by taking the inner product:

$$\left\langle (j_\beta)^{B'} (l) jm \,\middle|\, (j_\alpha)^B (k) jm \right\rangle$$

$$= \sum_{\sum m_\alpha = m} C \left[\begin{pmatrix} j_{\beta_1} \cdots j_{\beta_n} \\ m_{\beta_1} \cdots m_{\beta_n} \end{pmatrix}^{B'} \begin{matrix} j \\ m \end{matrix} \right] (l)$$

$$\times C \left[\begin{pmatrix} j_{\alpha_1} \cdots j_{\alpha_n} \\ m_{\alpha_1} \cdots m_{\alpha_n} \end{pmatrix}^B \begin{matrix} j \\ m \end{matrix} \right] (k) \,.$$

$$\tag{2.111}$$

The fundamental theorem of binary coupling theory states for inequivalent coupling schemes is:

Each recoupling coefficient is expressible as a sum over products of Racah coefficients, the only other quantities occurring in the summation being phase and dimension factors.

In every instance, the summation over projection quantum numbers in the right-hand side of (2.111) is re-expressible as a sum over Racah coefficients.

2.12.4 Construction of all Transformation Coefficients in Binary Coupling Theory

Augmented notation:

The coupling symbol $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B$ contains all information as to how n angular momenta are to be coupled, but is not specific in how the intermediate angular momentum quantum numbers $(k_1 k_2 \cdots k_{n-2})$, are to be matched with the binary couplings implicit in the coupling symbol. For explicit calculations, it is necessary to remedy this deficiency in notation. This may be done by attaching the $n-2$ intermediate angular momentum quantum numbers and the total angular momentum j as subscripts to the $n-1$ parentheses pairs in the coupling symbol. For example, for $(j_1 j_2 j_3 j_4 j_5)^B = \{[(j_1 j_2)(j_3 j_4)] j_5\}$, this results in the replacement

$$\{[(j_1 j_2)(j_3 j_4)] j_5\} (k_1 k_2 k_3)$$

$$\rightarrow \{[(j_1 j_2)_{k_1} (j_3 j_4)_{k_2}]_{k_3} j_5\}_j \,.$$

The basic coupling symbol structure is regained simply by ignoring all inferior letters.

Basic rules for commutation and association:

Let x, y, z denote arbitrary disjoint contiguous subcoupling symbols $\{[(x)(y)](z)\}$ contained in the coupling symbol $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B$. Let a, b, c denote the intermediate angular momenta associated with addition of the angular momenta represented in x, y, z, respectively, d the angular momentum representing the sum of a and b, and k the sum of d and c. Symbolically, this subcoupling may be presented as

$$\sum \boldsymbol{J}(x) = \boldsymbol{J}(a) \,, \quad \sum \boldsymbol{J}(y) = \boldsymbol{J}(b) \,,$$

$$\sum \boldsymbol{J}(z) = \boldsymbol{J}(c) \,,$$

$$\boldsymbol{J} = \cdots \{[\boldsymbol{J}(a) + \boldsymbol{J}(b)] + \boldsymbol{J}(c)\} \cdots ;$$

$$\boldsymbol{J}(a) + \boldsymbol{J}(b) = \boldsymbol{J}(d); \quad \boldsymbol{J}(d) + \boldsymbol{J}(c) = \boldsymbol{J}(k)$$

with augmented coupling symbol

$$(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B = \cdots \{[(x)_a (y)_b]_d (z)_c\}_k \cdots \,.$$

There are only two basic operations in constructing the recoupling coefficient between any two coupling schemes:

commutation of symbols:

$$(x)_a(y)_b \rightarrow (y)_b(x)_a$$

with the transformation of state vector given by

$$| \cdots [(x)_a(y)_b]_d \cdots \rangle$$
$$\rightarrow (-1)^{a+b-d} | \cdots [(y)_b(x)_a]_d \cdots \rangle$$
$$= | \cdots [(x)_a(y)_b]_d \cdots \rangle .$$

Association of symbols:

$$[(x)_a(y)_b](z)_c \rightarrow (x)_a[(y)_b(z)_c]$$

with the transformation of state vector given by

$$| \cdots \{[(x)_a(y)_b]_d(z)_c\}_k \cdots \rangle$$
$$\rightarrow \sum_e [(2d+1)(2e+1)]^{1/2} W(abkc; de)$$
$$\times | \cdots \{(x)_a[(y)_b(z)_c]_e\}_k \cdots \rangle$$
$$= | \cdots \{[(x)_a(y)_b]_d(z)_c\}_k \cdots \rangle .$$

The basic result for the calculation of all recoupling coefficients is:

Each pair of coupling schemes for n angular momenta can be brought into coincidence by a series of commutations and associations performed on either of the set of coupling symbols defining the coupling scheme.

In principle, this result gives a method for the construction of all recoupling transformation coefficients and sets the stage for the formulation of still deeper questions arising in recoupling theory, as summarized in Sect. 2.12.5. The following examples illustrate the content of the preceding abstract constructions.

Examples:

WCG-coefficient form:

$$\langle \{[(ab)_e c]_f d\}_g \, | \, [(ac)_h (bd)_k]_g \rangle$$
$$= \sum_{\alpha+\beta+\gamma+\delta=m} C^{a b e}_{\alpha,\beta,\alpha+\beta} C^{e c f}_{\alpha+\beta,\gamma,\alpha+\beta+\gamma} C^{f d g}_{\alpha+\beta+\gamma,\delta,m}$$
$$\times C^{a c h}_{\alpha,\gamma,\alpha+\gamma} C^{b d k}_{\beta,\delta,\beta+\delta} C^{h k g}_{\alpha+\gamma,\beta+\delta,m} .$$

$6-j$ coefficient as recoupling coefficient:

$$(ac)(bd) \xrightarrow{\text{R}} [(ac)b]d \xrightarrow{\phi} [b(ac)]d \xrightarrow{\text{R}} [(ba)c]d$$
$$\xrightarrow{\phi} [(ab)c]d ,$$

where ϕ denotes that the communication of symbols effects a phase factor transformation, and R denotes that

the associative of symbol effects a Racah coefficient transformation:

$$\langle \{[(ab)_e c]_f d\}_g \, | \, [(ac)_h (bd)_k]_g \rangle$$
$$= (-1)^{e+h-a-f} [(2f+1)(2k+1)]^{1/2} W(hbgd; fk)$$
$$\times [(2e+1)(2h+1)]^{1/2} W(bafc; eh) .$$

$9-j$ coefficient as recoupling coefficient:

$$(ac)(bd) \xrightarrow{\text{R}} [(ac)b]d \xrightarrow{\phi} [b(ac)]d \xrightarrow{\text{R}} [(ba)c]d$$
$$\xrightarrow{\phi} [(ab)c]d \xrightarrow{\text{R}} (ab)(cd) ,$$
$$\langle [(ab)_e (cd)_f]_g \, | \, [(ac)_h (bd)_k]_g \rangle$$
$$= [(2e+1)(2f+1)(2h+1)(2k+1)]^{\frac{1}{2}}$$
$$\times \sum_l (-1)^{2l}(2l+1) \begin{Bmatrix} a c h \\ l b e \end{Bmatrix} \begin{Bmatrix} b d k \\ g h l \end{Bmatrix} \begin{Bmatrix} e f g \\ d l c \end{Bmatrix}$$
$$= [(2e+1)(2f+1)(2h+1)(2k+1)]^{\frac{1}{2}} \begin{Bmatrix} a b e \\ c d f \\ h k g \end{Bmatrix} .$$

2.12.5 Unsolved Problems in Recoupling Theory

1. Define a route between two coupling symbols for n angular momenta to be any sequence of transpositions and associations that carries one symbol into the other. Each such route then gives rise to a unique expression for the corresponding recoupling coefficient in terms of $6-j$ coefficients. In general, there are several routes between the same pair of coupling symbols, leading therefore to identities between $6-j$ coefficients. How many nontrivial routes are there between two given coupling symbols, leading to nontrivial relations between $6-j$ coefficients (trivial means related by a phase factor)?

2. Only $6-j$ coefficients arise in all possible couplings of three angular momenta; only $6-j$ and $9-j$ coefficients arise in all possible couplings of four angular momenta; in addition to $6-j$ and $9-j$ coefficients, two new "classes" of coefficients, called $12-j$ coefficients of the first and second kind, arise in the coupling of five angular momenta; in addition to $6-j$, $9-j$, and the two classes of $12-j$ coefficients, five new classes of $15-j$ coefficients arise in the coupling of six angular momenta, $\cdots$. What are the classes of $3n-j$ coefficients? The nonconstructive answer is that a summation over $6-j$ coefficients arising in the coupling of n angular momenta is of a new class if it cannot be expressed in terms

of previously defined coefficients occurring in the recoupling of $n-1$ or fewer angular momenta.

3. Toward answering the question of classes of $3n-j$ coefficients, one is lead into the classification problem of planar cubic graphs. It is known that every $3n-j$ coefficient corresponds to a planar cubic graph, but the converse is not true. For small n, the relation between the coupling of n angular momenta, the number of new classes of $3(n-1)-j$ coefficients, and the number of nonisomorphic planar cubic graphs on $2(n-1)$ points is:

n	Classes of $3(n-1)-j$ coefficients	Cubic graphs on $2(n-1)$ points
3	1	1
4	1	2
5	2	5
6	5	19
7	18	87
8	84	?
9	576	?

The geometrical object for $n=3$ is a planar graph isomorphic to the tetrahedron in 3-space. The classification of all nonisomorphic cubic graphs on $2(n-1)$ points is an unsolved problem in mathematics, as is the classification of classes for $3(n-1)-j$ coefficients.

Fig. 2.4 The fundamental triangle $[(ab)c]$ can be realized by lines or points

4. There are (at least) two methods of realizing the basic triangles of angular momentum theory in terms of graphs. The fundamental structural element $[(ab)c]$ is represented either in terms of its points or in terms of its lines (Fig. 2.4):
The right representation leads to the interpretation of recoupling coefficients as functions defined on pairs of labeled binary trees [2.1]; the left to the diagrams of the Jucys school [2.7, 8]. Either method leads to the relationship of recoupling coefficients to cubic graphs.

5. The approach of classifying $3n-j$ coefficients through the use of unit tensor operator couplings, Racah operators, $9-j$ invariant operators, and general invariant operators is undeveloped.

2.13 Supplement on Combinatorial Foundations

The quantum theory of angular momentum can be worked out using the abstract postulates of the properties of angular momenta operators and the abstract Hilbert space in which they act. The underlying mathematical apparatus is the Lie algebra of the group $SU(2)$ and multiple copies thereof. An alternative approach is to use special Hilbert spaces that realize all the properties of the abstract postulates and perform calculations within that framework. The framework must be sufficiently rich in structure so as to apply to a manifold of physical situations. This approach has been used often in our treatment; it is an approach that is particularly useful for revealing the combinatorial foundations of quantum angular momentum theory. We illustrate this concretely in this supplementary section. The basic objects are the polynomials defined by (2.24), which we now call $SU(2)$ solid harmonics, where we change the notation slightly by interchanging the role of m and m'.

2.13.1 $SU(2)$ Solid Harmonics

The $SU(2)$ solid harmonics are defined to be the homogeneous polynomials of degree $2j$ in four commuting indeterminates given by

$$D_{m\,m'}^{j}(Z) = \sqrt{\alpha!\beta!} \sum_{(\alpha:A:\beta)} \frac{Z^A}{A!} , \qquad (2.112)$$

in which the indeterminates Z and the nonnegative exponents A are encoded in the matrix arrays

$$Z = \begin{pmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{pmatrix} , \qquad A = \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} ,$$

$$X^A = \prod_{i,j=1}^{2} z_{ij}^{a_{ij}} , \qquad A! = \prod_{i,j=1}^{2} (a_{ij})! ,$$

$$\alpha! = \alpha_1!\alpha_2! , \qquad \beta! = \beta_1!\beta_2! .$$

The symbol $(\alpha : A : \beta)$ in (2.112) denotes that the matrix array A of nonnegative integer entries has row and column sums of its a_{ij} entries given in terms of the quantum numbers j, m, m' by

$$a_{11} + a_{12} = \alpha_1 = j + m, \; a_{21} + a_{22} = \alpha_2 = j - m \,,$$
$$a_{11} + a_{21} = \beta_1 = j + m', \; a_{12} + a_{22} = \beta_2 = j - m' \,.$$

These $SU(2)$ solid harmonics are among the most important functions in angular momentum theory. Not only do they unify the irreducible representations of $SU(2)$ in any parametrization by the appropriate definition of the indeterminates in terms of generalized coordinates, they also include the popular boson calculus realization of state vectors for quantum mechanical systems, as well as the state vectors for the symmetric rigid rotator.

The realization of the inner product is essential. Physical theory demands an inner product that is given in terms of integrations of wave functions over the variables of the theory, as required by the probabilistic interpretation of wave functions. It is the requirement that realizations of angular momentum operators be Hermitian with respect to the inner product for the spaces being used that assures the orthogonality of functions, so that one is able to take results from one realization of the inner product to another with compatibility of relations. Often, in combinatorial arguments, the inner product plays no direct role.

The nomenclature $SU(2)$ solid harmonics for the polynomials defined by (2.112) is by analogy with the term $SO(3, \mathbf{R})$ solid harmonics for the polynomials described in Sect. 2.1.

The polynomials $\mathcal{Y}_{lm}(\mathbf{x}), \mathbf{x} = (x_1, x_2, x_3) \in \mathbf{R}^3$ are homogeneous of degree l. The angular momentum operator $\mathbf{L}^2$ is given by

$$\mathbf{L}^2 = -r^2 \nabla^2 + (\mathbf{x} \cdot \nabla)^2 + (\mathbf{x} \cdot \nabla) \,,$$

which is a sum of two commuting operators $-r^2 \nabla^2$ and $(\mathbf{x} \cdot \nabla)^2 + \mathbf{x} \cdot \nabla$, each of which is invariant under orthogonal transformations. The $SO(3, \mathbf{R})$ solid harmonics are homogeneous polynomials of degree l that solve $\nabla^2 \mathcal{Y}_{lm}(\mathbf{x}) = 0$, so that $\mathbf{L}^2 \mathcal{Y}_{lm}(\mathbf{x}) = l(l+1) \mathcal{Y}_{lm}(\mathbf{x})$. The component angular momentum operators L_i then have the standard action on these polynomials, and under real, proper, orthogonal transformations give the irreducible representations of the group $SO(3, \mathbf{R})$.

The polynomials $D_{m m'}^j(Z), \mathbf{z} = (z_{11}, z_{21}, z_{12}, z_{22}) \in \mathbf{C}^4$ are homogeneous of degree $2j$. The angular momentum operator $\mathbf{J}^2$, with $\mathbf{J} = (J_1, J_2, J_3)$, is given

by

$$\mathbf{J}^2 = -(\det Z) \left(\det \frac{\partial}{\partial Z} \right) + J_0(J_0 + 1) \,,$$

$$J_0 = \frac{1}{2} z \cdot \boldsymbol{\partial} \,,$$

$$\boldsymbol{\partial} = \left(\frac{\partial}{\partial z_{11}}, \frac{\partial}{\partial z_{21}}, \frac{\partial}{\partial z_{12}}, \frac{\partial}{\partial z_{22}} \right) \,, \qquad (2.113)$$

which is a sum of two commuting operators $-(\det Z)\left(\det \frac{\partial}{\partial Z} \right)$ and $J_0(J_0 + 1)$, each of which is invariant under $SU(2)$ transformations. The $SU(2)$ solid harmonics are homogeneous polynomials of degree $2j$ such that

$$\det \frac{\partial}{\partial Z} D_{m m'}^j(Z) = 0 \,,$$

$$\mathbf{J}^2 D_{mm'}^j(Z) = j(j+1) D_{mm'}^j(Z) \,.$$

The components of the angular momentum operators $\mathbf{J} = (J_1, J_2, J_3) = (M_1, M_2, M_3)$ and $\mathbf{K} = (K_1, K_2, K_3)$ then have the standard action on these polynomials as given in Sect. 2.4.4, and under either left or right $SU(2)$ transformations these polynomials give the irreducible representations of the group $SU(2)$.

2.13.2 Combinatorial Definition of Wigner–Clebsch–Gordan Coefficients

The $SU(2)$ solid harmonics have a basic role in the interpretation of WCG-coefficients in combinatorial terms. We recall from Sect. 2.7.2 that the basic abstract Hilbert space coupling rule for compounding two kinematically independent angular momenta with components $\mathbf{J}_1 = (J_1(1), J_2(1), J_3(1))$ and $\mathbf{J}_2 = (J_1(2), J_2(2), J_3(2))$ to a total angular momentum $\mathbf{J} = (J_1, J_2, J_3) = \mathbf{J}_1 + \mathbf{J}_2$ is

$$|(j_1 \, j_2) \, j \, m\rangle$$

$$= \sum_{m_1 + m_2 = m} C \begin{matrix} j_1 & j_2 & j \\ m_1 & m_2 & m \end{matrix} |j_1 \, m_1\rangle \otimes |j_2 \, m_2\rangle \,. \quad (2.114)$$

This relation in abstract Hilbert space is realized explicitly by spinorial polynomials as follows:

$$\psi_{(j_1 \, j_2) \, jm}(Z) = \sum_{m_1 + m_2 = m} C \begin{matrix} j_1 & j_2 & j \\ m_1 & m_2 & m \end{matrix}$$
$$\times \psi_{j_1 \, m_1}(z_{11}, z_{21}) \psi_{j_2 \, m_2}(z_{12}, z_{22}) \,, \quad (2.115)$$

$$\psi_{(j_1 j_2) jm}(Z) = \sqrt{\frac{2j+1}{(j_1 + j_2 - j)!(j_1 + j_2 + j + 1)!}}$$
$$\times (\det Z)^{j_1 + j_2 - j} D^j_{m, j_1 - j_2}(Z) ,$$

(2.116)

$$\psi_{jm}(x, y) = \frac{x^{j+m} y^{j-m}}{\sqrt{(j+m)!(j-m)!}} . \qquad (2.117)$$

Explicit knowledge of the WCG-coefficients is not needed to prove these relationships. The angular momentum operators

$$J_+(1) = z_{11} \frac{\partial}{\partial z_{21}} , \qquad J_-(1) = z_{21} \frac{\partial}{\partial z_{11}} ,$$
$$J_3(1) = \frac{1}{2} \left(z_{11} \frac{\partial}{\partial z_{11}} - z_{21} \frac{\partial}{\partial z_{21}} \right) ;$$
$$J_+(2) = z_{12} \frac{\partial}{\partial z_{22}} , \qquad J_-(2) = z_{22} \frac{\partial}{\partial z_{12}} ,$$
$$J_3(2) = \frac{1}{2} \left(z_{12} \frac{\partial}{\partial z_{12}} - z_{22} \frac{\partial}{\partial z_{22}} \right)$$

are Hermitian in the polynomial inner product defined in Sect. 2.4.3, and have the standard action on the polynomials $\psi_{j_1 m_1}(z_{11}, z_{21})$ and $\psi_{j_2 m_2}(z_{12}, z_{22})$, respectively, which are normalized in the inner product (,). The components of total angular momentum operator $\boldsymbol{J} = \boldsymbol{M} = \boldsymbol{J}_1 + \boldsymbol{J}_2$ have the standard action on the polynomials $\psi_{(j_1 j_2) jm}(Z)$, since they have the standard action on the factor $D^j_{m, j_1 - j_2}(Z)$, as given in Sect. 2.4.4, and $[\boldsymbol{J}, \det X] = \left[\boldsymbol{J}, \det \frac{d}{dZ} \right] = 0$. Thus, we have

$$\boldsymbol{J}^2 \psi_{(j_1 j_2) jm}(Z) = j(j+1) \psi_{(j_1 j_2) jm}(Z),$$
$$J_\pm \psi_{(j_1 j_2) jm}(Z) = \sqrt{(j \mp m)(j \pm m + 1)}$$
$$\times \psi_{(j_1 j_2) jm \pm 1}(Z) .$$

We also note that the two commuting parts of $\boldsymbol{J}^2$ are diagonal on these functions:

$$J_0(J_0 + 1) \psi_{(j_1 j_2) jm}(Z)$$
$$= (j_1 + j_2)(j_1 + j_2 + 1) \psi_{(j_1 j_2) jm}(Z) ,$$
$$(\det Z) \left(\det \frac{\partial}{\partial X} \right) \psi_{(j_1 j_2) jm}(Z)$$
$$= (j_1 + j_2 - j)(j_1 + j_2 + j + 1) \psi_{(j_1 j_2) jm}(Z) .$$

It is necessary only to verify these properties for the highest weight function $D^j_{j j}(Z) = z_{11}^{2j} / \sqrt{(2j)!}$, for which they are seen to hold.

The angular momentum operators $\boldsymbol{K} = (K_1, K_2, K_3)$ defined in Sect. 2.4.4 with components that commute with those of $\boldsymbol{J} = (M_1, M_2, M_3)$ and having $\boldsymbol{K}^2 = \boldsymbol{J}^2$ also have a well-defined action on the functions $\psi_{(j_1 j_2) jm}(Z)$. The action of K_+, K_-, and K_3 on the quantum numbers (j_1, j_2) is to effect the shifts to $\left(j_1 + \frac{1}{2}, j_2 - \frac{1}{2} \right)$, $\left(j_1 - \frac{1}{2}, j_2 + \frac{1}{2} \right)$, and (j_1, j_2), respectively. These actions of Hermitian angular momentum operators satisfying the standard commutation relations $\boldsymbol{K} \times \boldsymbol{K} = i\boldsymbol{K}$ are quite unusual in that they depend only on the angular momentum quantum numbers j_1, j_2, j themselves, which satisfy the triangle rule, and give further interesting properties of the modified $SU(2)$ solid harmonics $\psi_{(j_1 j_2) jm}(Z)$. We note these properties in full:

$$\boldsymbol{K}^2 \psi_{(j_1 j_2) jm}(Z) = j(j+1) \psi_{(j_1 j_2) jm}(Z) ,$$
$$K_3 \psi_{(j_1 j_2) jm}(Z) = (j_1 - j_2) \psi_{(j_1 j_2) jm}(Z) ,$$
$$K_+ \psi_{(j_1 j_2) jm}(Z) =$$
$$\sqrt{(j - j_1 + j_2)(j + j_1 - j_2 + 1)} \psi_{\left(j_1 + \frac{1}{2} j_2 - \frac{1}{2} \right) jm}(Z) ,$$
$$K_- \psi_{(j_1 j_2) jm}(Z) =$$
$$\sqrt{(j + j_1 - j_2)(j - j_1 + j_2 + 1)} \psi_{\left(j_1 - \frac{1}{2} j_2 + \frac{1}{2} \right) jm}(Z) .$$

These relations play no direct role in our continuing considerations of (2.116) and the determination of the WCG-coefficients, and we do not interpret them further.

The explicit WCG-coefficients are obtained by expanding the 2×2 determinant in (2.116), multiplying this expansion into the D-polynomial, and changing the order of the summation. These operations are most succinctly expressed in terms of the umbral calculus of *Roman* and *Rota* [2.6], using his evaluation operation. The evaluation at y of a divided power $x^k / k!$ of a single indeterminate x to a nonnegative integral power k is defined by

$$\text{eval}_y \frac{x^k}{k!} = \frac{(y)_k}{k!} = \frac{y(y-1) \cdots (y-k+1)}{k!} = \binom{y}{k} ,$$

where $(y)_k$ is the falling factorial. This definition is extended to products by

$$\text{eval}_{(y_1, y_2, \dots, y_n)} \prod_{i=1}^{n} \frac{x^{k_i}}{k_i!} = \prod_{i=1}^{n} \text{eval}_{y_i} \frac{x^{k_i}}{k_i!} = \prod_{i=1}^{n} \binom{y_i}{k_i} .$$

It is also extended by linearity to sums of such divided powers, multiplied by arbitrary numbers.

The application of these rules to our problem involving four indeterminates gives

$$\frac{(\det X)^n}{n!} \sum_{(\alpha:A:\alpha')} \frac{X^A}{A!}$$

$$= \sum_{(\beta:B:\beta')} \mathrm{eval}_B \left(\frac{(\det X)^n}{n!} \right) \frac{X^B}{B!}, \qquad (2.118)$$

$$\beta = (\alpha_1+n, \alpha_2+n), \ \beta' = (\alpha'_1+n, \alpha'_2+n),$$

$$\mathrm{eval}_B \frac{(\det X)^n}{n!}$$

$$= \sum_{k_1+k_2=n} (-1)^{k_2} k_1! k_2! \binom{b_{11}}{k_1}\binom{b_{12}}{k_2}\binom{b_{21}}{k_2}\binom{b_{22}}{k_1}. \qquad (2.119)$$

In this result, we do not identify the labels with angular momentum quantum numbers. Relation (2.119) is a purely combinatorial, algebraic identity for arbitrary indeterminates and arbitrary row and column sum constraints on the array A as specified by $\alpha = (\alpha_1, \alpha_2)$ and $\alpha' = (\alpha'_1, \alpha'_2)$. There are no square roots involved.

We now apply relations (2.118–2.119) to the case at hand: $n = j_1 + j_2 - j$, $\alpha = (j+m, j-m)$, $\alpha' = (j+j_1-j_2, j-j_1+j_2)$, $\beta = (j_1+j_2+m, j_1+j_2-m)$, $\beta' = (2j_1, 2j_2)$. This gives the following result for the WCG-coefficients:

$$C^{j_1 j_2 j}_{m_1 m_2 m}$$

$$= \sqrt{\frac{(j_1+j_2-j)!(j_1-j_2+j)!(-j_1+j_2+j)!}{(j_1+j_2+j+1)!}}$$

$$\times \sqrt{\frac{(2j+1)(j+m)!(j-m)!}{(j_1+m_1)!(j_1-m_1)!(j_2+m_2)!(j_2-m_2)!}}$$

$$\times \mathrm{eval}_A \frac{(\det X)^{j_1+j_2-j}}{(j_1+j_2-j)!}, \qquad (2.120)$$

$$\mathrm{eval}_A \frac{(\det X)^{j_1+j_2-j}}{(j_1+j_2-j)!}$$

$$= \sum_{k_1+k_2=j_1+j_2-j} (-1)^{k_2} k_1! k_2! \binom{j_1+m_1}{k_1}\binom{j_2+m_2}{k_2}$$

$$\times \binom{j_1-m_1}{k_2}\binom{j_2-m_2}{k_1}. \qquad (2.121)$$

In summary, we have the following:

Up to multiplicative square-root factors, the WCG-coefficient is the evaluation at the point

$$B = \begin{pmatrix} j_1+m_1 & j_2+m_2 \\ j_1-m_1 & j_2-m_2 \end{pmatrix}$$

of the divided power

$$\frac{(\det X)^{j_1+j_2-j}}{(j_1+j_2-j)!}$$

of a determinant, which is an integer. The abstract umbral calculus of Rota thus finds its way, at a basic level, into angular momentum theory. Relation (2.120) is but a rewriting in terms of evaluations of the well-known Van der Waerden form of the WCG-coefficients.

2.13.3 Magic Square Realization of the Addition of Two Angular Momenta

The origin of (2.114), giving the states of total angular momentum by compounding two angular momenta, is usually attributed to properties of the direct sum of two copies of the Lie algebra of the unitary unimodular group $SU(2)$, and to the use of differential operators to realize the Lie algebras and state vectors, as done above. It is an interesting combinatorial result that this structure for adding angular momentum is fully encoded within the properties of magic squares of order 3, and no operators whatsoever are needed, only the condition of being a magic square. We have already noted in Sect. 2.7.4 that Regge observed that the restrictions on the domains of the quantum numbers j_1, m_1, j_2, m_2, j, m are encoded in terms of a magic square A with line-sum $J = j_1 + j_2 + j$:

$$A = \begin{pmatrix} j_1+m_1 & j_2+m_2 & j-m \\ j_1-m_1 & j_2-m_2 & j+m \\ j_2-j_1+j & j_1-j_2+j & j_1+j_2-j \end{pmatrix}. \qquad (2.122)$$

The angular momentum quantum numbers are given in terms of the elements of $A = (a_{ij})_{1 \leq i,j \leq 3}$ by the invertible relations

$$j_1 = \frac{1}{2}(a_{11}+a_{21}), \quad j_2 = \frac{1}{2}(a_{12}+a_{22}),$$

$$j = \frac{1}{2}(a_{13}+a_{23}),$$

$$m_1 = \frac{1}{2}(a_{11}-a_{21}), \quad m_2 = \frac{1}{2}(a_{12}-a_{22}),$$

$$m = \frac{1}{2}(a_{23}-a_{13}).$$

It follows from these definitions and the fact that A is a magic square of line-sum J, that the sum rule $m_1 + m_2 = m$ and the triangle condition are fulfilled.

We use the symbol $\langle j_1, j_2, j \rangle$ to denote any triple j_1, j_2, j of angular momentum quantum numbers that satisfy the triangle conditions, where we note that, if a given triple satisfies the triangle conditions, then all permutations of the triple also satisfy the triangle conditions. The number of magic squares for fixed line-sum J is obtained as follows: Define $\Delta_J = \{$all triangles $\langle j_1, j_2, j \rangle \mid j_1 + j_2 + j = J\}$ and $M(j_1, j_2, j) = \{(m_1, m_2) \mid -j_1 \le m_1 \le j_1;\ -j_2 \le m_2 \le j_2;\ -j \le m_1 + m_2 \le j\}$. Then we have the following identity, which gives the number of angular momentum magic squares with line-sum J:

$$\sum_{\langle j_1, j_2, j \rangle \in \Delta_J} |M(j_1, j_2, j)| = \binom{J+5}{5} - \binom{J+2}{5}.$$
(2.123)

It is nontrivial to effect the summation on the left-hand side of this relation to obtain the right-hand side, but this expression is known from the theory of magic squares *Stanley* [2.9, 10].

Not only can the addition of two angular momenta in quantum theory, with its triangle rule for three angular momentum quantum numbers and its sum rule on the corresponding projection quantum numbers, be codified in magic squares of order 3 and arbitrary line-sum, but also the content of the abstract state vector of (2.114) itself can be so expressed:

$$\left| \frac{1}{2}(a_{11} + a_{21}),\ \frac{1}{2}(a_{12} + a_{22});\ \frac{1}{2}(a_{13} + a_{23}),\ \right.$$

$$\left. \frac{1}{2}(a_{23} - a_{13}) \right\rangle =$$

$$\sum_{\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix}} C(A) \left| \frac{1}{2}(a_{11} + a_{21}),\ \frac{1}{2}(a_{11} - a_{21}) \right\rangle$$

$$\otimes \left| \frac{1}{2}(a_{12} + a_{22}),\ \frac{1}{2}(a_{12} - a_{22}) \right\rangle,$$

where the summation is over all subsets

$$\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix}$$

of the magic square of order 3 such that row 3 and column 3 are held fixed. The coefficients $C(A)$ themselves are the WCG-coefficients, which may be regarded as a function whose domain of definition is the set of all magic squares of order 3. The triangle rule $\langle j_1, j_2, j \rangle$ and the sum rule on (m_1, m_2, m) are implied by the structure of

magic squares of order 3. These rich combinatorial footings of angular momentum theory are completed by the observation that the Clebsch–Gordan coefficients themselves are obtained by the Schwinger–Regge generating function given in Sect. 2.7.3 (see [2.2] for the relation to $_3F_2$ hypergeometric functions).

2.13.4 MacMahon's and Schwinger's Master Theorems

Generating functions codify the content of many mathematical entities in a unifying, comprehensive way. These functions are very popular in combinatorics, and Schwinger used them extensively in his treatment of angular momentum theory. In this subsection, we present a natural generalization of the $SU(2)$ solid harmonics to a class of polynomials that are homogeneous in n^2 indeterminates. While these polynomials are of interest in their own right, it is their fundamental role in the addition of n kinematically independent angular momenta that motivates their introduction here. They bring an unexpected unity and coherence to angular momentum coupling and recoupling theory [2.11].

We list in compendium format some of the principal results:

Special $U(n)$ solid harmonics:

$$D_{\alpha,\beta}^k(Z) = \sqrt{\alpha!\beta!} \sum_{A \in M(\alpha,\beta)} \frac{Z^A}{A!},$$
(2.124)

$A = (a_{ij})_{1 \le i, j \le n}$: matrix of order n in nonnegative integers;

$$A! = \prod_{i,j=1}^{n} a_{ij}!,\quad Z^A = \prod_{i,j=1}^{n} z_{ij}^{a_{ij}};$$

where we employ the notations:
$\alpha = (\alpha_1, \alpha_2, \dots, \alpha_n)$: sequence (composition) of nonnegative integers having the sum k, denoted $\alpha \vdash k$;
$x^\alpha = x_1^{\alpha_1} x_2^{\alpha_2} \cdots x_n^{\alpha_n}$, $\alpha! = \alpha_1! \alpha_2! \cdots \alpha_n!$;
$\beta = (\beta_1, \beta_2, \dots, \beta_n)$: second composition $\beta \vdash k$;
$M(\alpha, \beta)$, set of all matrices A such that the entries in row i sums to α_i and those in column j to β_j.
The significance of the row-sum vector α is that α_i is the degree of the polynomial in the variables $(z_{i1}, z_{i2}, \dots, z_{in})$ in row i of Z, with a similar interpretation for β in terms of columns.
Matrix of the $D_{\alpha,\beta}^k(Z)$ polynomials:
The number of compositions of the integer k into n nonnegative parts is given by $\binom{n+k-1}{k}$. The compositions in this set may be linearly ordered by the lexicographical rule $\alpha > \beta$, if the first nonzero part of $\alpha - \beta$ is

positive. The polynomial $D_{\alpha,\beta}^k(Z)$ is then the entry in row α and column β in the matrix $D^k(Z)$ of dimension $\dim D^k(Z) = \binom{n+k-1}{k}$, where, following the convention for $SU(2)$, the rows are labelled from top to bottom by the greatest to the least sequence, and the columns are labelled in the same manner as read from left to right. There is a combinatorial proof by *Chen* and *Louck* [2.12] that these polynomials satisfy the following multiplication rule for arbitrary matrices X and Y:

$$D^k(XY) = D^k(X)D^k(Y) . \qquad (2.125)$$

Orthogonality in the inner product (,) defined in Sect. 2.4.3:

$$\left\langle D_{\alpha,\beta}^k, D_{\alpha',\beta'}^k \right\rangle = \delta_{\alpha,\alpha'}\delta_{\beta,\beta'}k! .$$

Value on $Z = \mathrm{diag}(z_1, z_2, \ldots, z_n)$:

$$D_{\alpha,\beta}^k\big[\mathrm{diag}(z_1, z_2, \ldots, z_n)\big] = \delta_{\alpha,\beta}z^\alpha, \qquad (2.126)$$
$$D^k(I_n) = I_{\binom{n+k-1}{k}} .$$

Transposition property:

$$D^k(Z^{\mathrm{T}}) = \big[D^k(Z)\big]^{\mathrm{T}} .$$

Special irreducible unitary representations of $U(n)$:

$$D^k(U)D^k(V) = D^k(UV) , \quad \text{all } U, V \in U(n) .$$

Schwinger's Master Theorem: For any two matrices X and Y of order n, the following identities hold:

$$\mathrm{e}^{(\partial_x : X : \partial_y)}\, \mathrm{e}^{(x : Y : y)}\Big|_{x=y=0}$$
$$= \sum_{k=0}^{\infty} \sum_{\alpha,\beta \vdash k} D_{\alpha,\beta}^k(X) D_{\beta,\alpha}^k(Y)$$
$$= \frac{1}{\det(I - XY)} , \qquad (2.127)$$
$$(x : Z : y) = xZy^{\mathrm{T}} = \sum_{i,j=1}^{n} z_{ij}x_i y_j .$$

MacMahon's Master Theorem: Let X be the diagonal matrix $X = \mathrm{diag}(x_1, x_2, \ldots, x_n)$ and Y a matrix of order n. Then the coefficient of x^α in the expansion of $\frac{1}{\det(I-XY)}$ equals the coefficient of x^α in the product y^α, $y_i = \sum_{j=1}^{n} y_{ij}x_j$, that is,

$$\frac{1}{\det(I - XY)} = \sum_{k=0}^{\infty} \sum_{\alpha \vdash k} D_{\alpha,\alpha}^k(Y) x^\alpha . \qquad (2.128)$$

Basic Master Theorem: Let Z be a matrix of order n. Then

$$\frac{1}{\det(I - tZ)} = \sum_{k=0}^{\infty} t^k \sum_{\alpha \vdash k} D_{\alpha,\alpha}^k(Z) . \qquad (2.129)$$

Schwinger's relation (2.127) follows from the basic relation (2.129) by setting $Z = XY$ and using the multiplication property (2.125); MacMahon's relation then follows from Schwinger's result by setting $X = \mathrm{diag}(x_1, x_2, \ldots, x_n)$ and using property (2.126). Of course, MacMahon's Master Theorem preceded Schwinger's result by many years (see *MacMahon* [2.13]). The unification into the single form by using properties of the $D_{\alpha,\beta}^k(Z)$ polynomials was pointed out in [2.14]. More surprisingly, relation (2.129) was already discovered for the general linear group in 1897 by *Molien* [2.15]; its properties are developed extensively in *Michel* and *Zhilinski* [2.16] in the context of group theory.

For many purposes, it is better in combinatorics to avoid all square roots by using the polynomials

$$L_{\alpha,\beta}(Z) = \sum_{A \in M(\alpha,\beta)} \frac{Z^A}{A!}$$

in place of the $D_{\alpha,\beta}^k(Z)$ defined in (2.124).

2.13.5 The Pfaffian and Double Pfaffian

Schwinger observed that the calculation of $3n - j$ coefficients involves taking the square root $\sqrt{(I - AB)}$, where A and B are skew symmetric (antisymmetric) matrices of order n, but the procedure is rather obscure. The appropriate concepts for taking the square root is that of a Pfaffian and a double Pfaffian, denoted, respectively, by $\mathrm{Pf}(A)$ and $\mathrm{Pf}(A, B)$. The definitions require the concept of a matching of the set of integers $\{1, 2, \ldots, n\}$. A matching of $\{1, 2, \ldots, n\}$ is an unordered set of disjoint subsets $\{i, j\}$ containing two elements. For example, the matchings of $1, 2, 3$ are $\{1, 2\}$, $\{1, 3\}$, and $\{2, 3\}$. We then have the following constructs:

Pfaffian and double Pfaffian of skew symmetric matrices $A = (a_{ij})$ and $B = (b_{ij})$ of order n :

$$\mathrm{Pf}(A) = \sum_{\{i_1,i_2\},\{i_3,i_4\},\ldots,\{i_{n-1},i_n\}} \varepsilon(i_1 i_2 \cdots i_n)$$
$$\times a_{i_1,i_2}a_{i_3,i_4}\cdots a_{i_{n-1},i_n} , \qquad (2.130)$$

$$\mathrm{Pf}(A, B) = 1 + \sum_{k \geq 1} \sum_{\substack{\{i_1, i_2\}, \{i_3, i_4\}, \ldots, \{i_{2k-1}, i_{2k}\} \\ \{j_1, j_2\}, \{j_3, j_4\}, \ldots, \{j_{2k-1}, j_{2k}\}}}$$
$$\varepsilon(i_1 i_2 \cdot i_{2k}) \varepsilon(j_1 j_2 \cdots j_{2k})$$
$$\times a_{i_1, i_2} a_{i_3, i_4} \cdots a_{i_{2k-1}, i_{2k}}$$
$$\times b_{j_1, j_2} b_{j_3, j_4} \cdots b_{j_{2k-1}, j_{2k}} \quad (2.131)$$

where $\{i_1, i_2\}, \{i_3, i_4\}, \ldots, \{i_{n-1}, i_n\}$ is a matching of $\{1, 2, \ldots, n\}$, and $\varepsilon(i_1 i_2 \cdots i_n)$ is the sign of the permutation (number of inversions). Similarly, in the double Pfaffian, the 2-subsets are matchings of a subset of $\{1, 2, \ldots, n\}$ of even length.
Relations of skew symmetric matrices A, B to Pfaffians:

$$\sqrt{\det A} = \mathrm{Pf}(A) ; \quad \sqrt{\det(I - AB)} = \mathrm{Pf}(A, B) . \quad (2.132)$$

2.13.6 Generating Functions for Coupled Wave Functions and Recoupling Coefficients

This section is a reformulation, nontrivial extension, and interpretation of results found in *Schwinger* [2.3]. We first refine the notation used in Sect. 2.12.3.
Set of triangles in the coupling scheme:
Each coupling scheme, as determined by the bracketing B, has associated with it a unique ordered set of $n - 1$ triangles

$$\mathbf{T}_B(\mathbf{j}, \mathbf{k}, j) = \{\langle a_i, b_i, k_i \rangle | i = 1, 2, \ldots, n-1\} ,$$
$$\mathbf{j} = (j_1, j_2, \ldots, j_n) ,$$
$$\mathbf{k} = (k_1, k_2, \ldots, k_{n-2}) ,$$
$$k_{n-1} = j .$$

The third part k_i of $\langle a_i, b_i, k_i \rangle$ can always be chosen, without loss of generality, as an intermediate angular momentum ($k_{n-1} = j$), and the triangles in the set can be ordered by $\langle a_i, b_i, k_i \rangle < \langle a_{i+1}, b_{i+1}, k_{i+1} \rangle$. The remaining pair of angular momentum labels in the triangle $\langle a_i, b_i, k_i \rangle$ then fall, in general, into four classes: $\langle a_i, b_i, k_i \rangle$ in which a_i can be either a j_r or a k_s, and b_i can be either a $j_{r'}$ or $k_{s'}$. The distribution of the $j's$ and $k's$ among the a_i and b_i is uniquely determined by the bracketing B that defines the coupling scheme.
Clebsch–Gordan coefficients for a given coupling scheme:

$$\begin{pmatrix} \mathbf{j} & \mathbf{k} & j \\ \mathbf{m} & \mathbf{q} & m \end{pmatrix}^B = \prod_{\langle a_i, b_i, k_i \rangle \in \mathbf{T}_B(\mathbf{j}, \mathbf{k}, j)} C^{a_i b_i k_i}_{\alpha_i \beta_i q_i} , \quad (2.133)$$

in which the projection quantum numbers α_i and β_i are $m's$ and $q's$ that match the a_i and b_i. In the given coupling scheme determined by the bracketing B, only (j_i, m_i), $i = 1, 2 \ldots, n$; (k_i, q_i), $i = 1, 2, \ldots, n-2$, and (j, m) appear in the Clebsch–Gordan coefficients. In fact, if one explicitly implements the sum rule on the projection quantum numbers, it is always possible to express the q_i as sums over the m_i and m.
Coupled angular momentum function for n angular momenta:

$$\Psi^B_{(\mathbf{j} \mathbf{k}) j m}(\mathbf{x}, \mathbf{y}) = \sum_{\mathbf{m}} \begin{pmatrix} \mathbf{j} & \mathbf{k} & j \\ \mathbf{m} & \mathbf{q} & m \end{pmatrix}^B \prod_{i=1}^n \psi_{j_i m_i}(x_i, y_i) . \quad (2.134)$$

$$\begin{pmatrix} \mathbf{j} \\ \mathbf{m} \end{pmatrix} = \begin{pmatrix} j_1 & j_2 & \cdots & j_n \\ m_1 & m_2 & \cdots & m_n \end{pmatrix} ,$$
$$\begin{pmatrix} \mathbf{k} \\ \mathbf{q} \end{pmatrix} = \begin{pmatrix} k_1 & k_2 & \cdots & k_{n-2} \\ q_1 & q_2 & \cdots & q_{n-2} \end{pmatrix} . \quad (2.135)$$

$$Z = (z_1 z_2 \ldots z_{n+1}) = \begin{pmatrix} x_1 & x_2 & \ldots & x_{n+1} \\ y_1 & y_2 & \ldots & y_{n+1} \end{pmatrix} . \quad (2.136)$$

Only the first n columns of Z enter into (2.136), but the last column occurs below.
The skew symmetric matrix of a coupling scheme:
    The set of triangles $\mathbf{T}_B(\mathbf{j}, \mathbf{k}, j) = \{\langle a_i, b_i, k_i \rangle | i = 1, 2, \ldots, n-1\}$, which is uniquely defined by the bracketing B, can be mapped to a unique skew symmetric matrix of order $n + 1$. This mapping is one of the most important results for obtaining generating functions for the coupled wave functions (2.134) and the recoupling coefficients given below. The skew symmetric matrix depends on the bracketing B and the detailed manner in which the $j's$ and $k's$ are distributed among the triangles in $\mathbf{T}_B(\mathbf{j}, \mathbf{k}, j)$. The rule for constructing the skew symmetric matrix is quite intricate. First, we define a $3 \times (n - 1)$ matrix T of indeterminates by

$$T = \begin{pmatrix} t_{11} & t_{12} & \cdots & t_{1,n-1} \\ t_{21} & t_{22} & \cdots & t_{2,n-1} \\ t_{31} & t_{32} & \cdots & t_{3,n-1} \end{pmatrix} . \quad (2.137)$$

Second, we associate with each $\langle a_i, b_i, k_i \rangle \in \mathbf{T}_B(\mathbf{j}, \mathbf{k}, j)$, a triple of indeterminates (u_i, v_i, w_i) as

given by

$$\langle a_1, b_1, k_1 \rangle \mapsto (u_1, v_1, w_1), \text{ with } w_1 = t_{21}u_1 + t_{11}v_1,$$

$$\langle a_2, b_2, k_2 \rangle \mapsto (u_2, v_2, w_2), \text{ with } w_2 = t_{22}u_2 + t_{12}v_2,$$

$$\vdots \qquad\qquad \vdots$$

$$\langle a_{n-1}, b_{n-1}, k_{n-1} \rangle \mapsto (u_{n-1}, v_{n-1}, w_{n-1}),$$
$$\text{with } w_{n-1} = t_{2,n-1}u_{n-2} + t_{1,n-1}v_{n-1} . \tag{2.138}$$

The indeterminates u_i and v_i are identified as a column $z_i = (x_i, y_i)$ of the $2 \times (n+1)$ matrix Z defined by (2.136), or as one of the w's occurring higher in the display (2.138). The distribution rule is in one-to-one correspondence with the distribution of j's and k's in the corresponding triangle. Thus, we have

$$u_i = z_r , \text{ if } a_i = j_r ; \ v_i = z_s , \text{ if } b_i = j_s ;$$
$$u_i = z_r , \text{ if } a_i = j_r ; \ v_i = w_s , \text{ if } b_i = k_s ;$$
$$u_i = w_r , \text{ if } a_i = k_r ; \ v_i = z_s , \text{ if } b_i = j_s ;$$
$$u_i = w_r , \text{ if } a_i = k_r ; \ v_i = w_s , \text{ if } b_i = k_s .$$

The explicit identification of all j's and k's is uniquely determined by the bracketing B. Once this identification has been made, the elements a_{ij}, $i < j$ of the skew symmetric matrix A of order $n+1$ are uniquely determined in terms of the elements of T by equating coefficients of $\det(z_i, z_j) = x_i y_j - x_j y_i$ on the two sides of the form

$$\sum_{1 \le i < j \le n+1} a_{ij} \det(z_i, z_j)$$
$$= \sum_{i=1}^{n-1} t_{3i} \det(u_i, v_i) + \det(w_{n-1}, z_{n+1}) , \tag{2.139}$$

where (t_{1i}, t_{2i}, t_{3i}) is the i-th column of the $3 \times (n-1)$ matrix T of indeterminates. This relation can be inferred from results given by Schwinger. Since the elements of A are determined as monomials in the elements of T, we sometimes denote A by $A(T)$.

It is useful to illustrate the rule for determining A for $n = 2, 3, 4$:

$n = 2$: Triangle: $\langle j_1, j_2, k_1 \rangle$:
$$w_1 = t_{21}z_1 + t_{11}z_2$$

$$a_{12} \det(z_1, z_2) + a_{13} \det(z_1, z_3) + a_{23} \det(z_2, z_3)$$
$$= t_{31} \det(u_1, v_1) + \det(w_1, z_3)$$
$$= t_{31} \det(z_1, z_2) + t_{21} \det(z_1, z_3)$$
$$\quad + t_{11} \det(z_2, z_3) ;$$
$$a_{12} = t_{31} , \quad a_{13} = t_{21} , \quad a_{23} = t_{11} .$$

$n = 3$: Ordered triangles: $\langle j_1, j_2, k_1 \rangle$, $\langle k_1, j_3, k_2 \rangle$:

$$w_1 = t_{21}u_1 + t_{11}v_1 , \quad u_1 = z_1, \ v_1 = z_2 ;$$
$$w_2 = t_{22}u_2 + t_{12}v_2 , \quad u_2 = w_1, \ v_2 = z_3 .$$
$$\sum_{1 \le i < j \le 4} a_{ij} \det(z_i, z_j)$$
$$= t_{31} \det(u_1, v_1) + t_{32} \det(u_2, v_2) + \det(w_2, z_4) ;$$

$$a_{12} = t_{31}, \ a_{13} = t_{21}t_{32}, \ a_{14} = t_{21}t_{22}$$
$$a_{23} = t_{11}t_{32}, \ a_{24} = t_{11}t_{22}$$
$$a_{34} = t_{12}$$

$n = 4$: Ordered triangles: $\langle j_3, j_1, k_1 \rangle$, $\langle j_4, j_2, k_2 \rangle$, $\langle k_1, k_2, k_3 \rangle$:

$$w_1 = t_{21}u_1 + t_{11}v_1 , \quad u_1 = z_3 , \quad v_1 = z_1 ,$$
$$w_2 = t_{22}u_2 + t_{12}v_2 , \quad u_2 = z_4 , \quad v_2 = z_2 ,$$
$$w_3 = t_{23}u_3 + t_{13}v_3 , \quad u_3 = w_1 , \quad v_3 = w_2 ;$$
$$w_3 = t_{11}t_{23}z_1 + t_{12}t_{13}z_2 + t_{21}t_{23}z_3 + t_{22}t_{13}z_4 ,$$
$$\sum_{1 \le i < j \le 5} a_{ij} \det(z_i, z_j) = t_{31} \det(u_1, v_1) + t_{32}$$
$$\times \det(u_2, v_2) + t_{33} \det(u_3, v_3) + \det(w_3, z_5) ;$$

$$a_{12} = t_{11}t_{12}t_{33}, \ a_{13} = -t_{31}, \qquad a_{14} = t_{11}t_{22}t_{33},$$
$$a_{23} = -t_{12}t_{21}t_{33}, \ a_{24} = -t_{32},$$
$$a_{34} = t_{21}t_{22}t_{33},$$

$$a_{15} = t_{11}t_{23}$$
$$a_{25} = t_{12}t_{13}$$
$$a_{35} = t_{21}t_{23}$$
$$a_{45} = t_{22}t_{13}$$

Triangle monomials:

Let $\langle a, b, c \rangle$ be a triangle of quantum numbers (a, b, c), let (x, y, z) be three indeterminates, and let B denote a binary coupling scheme with the set of triangles $T_B(\boldsymbol{j}, \boldsymbol{k}, j)$:

Elementary triangle monomial:

$$\Phi_{\langle a,b,c \rangle}(x, y, z) = \{abc\}^{-1} x^{b+c-a} y^{a+c-b} z^{a+b-c} , \tag{2.140}$$

$$\{abc\}$$
$$= \left(\frac{(2c+1)(b+c-a)(a+c-b)!(a+b-c)!}{(a+b+c+1)!} \right)^{\frac{1}{2}} .$$

Triangle monomial associated with a given coupling scheme B :

$$\Phi^B_{\boldsymbol{j},\boldsymbol{k},j}(T) = \prod_{\langle a_i, b_i, k_i \rangle \in T_B(\boldsymbol{j},\boldsymbol{k},j)} \Phi_{\langle a_i,b_i,k_i \rangle}(t_{1i}, t_{2i}, t_{3i}) . \tag{2.141}$$

Using the definitions introduced above, we can now give the generating functions for the coupled wave functions and the recoupling coefficients for each coupling scheme as determined by the bracketing B.

Generating function for coupled wave functions:

$$e^{xA(T)y^T} = e^{\sum_{1 \le i < j \le n+1} a_{i,j} \det(z_i, z_j)}$$
$$= \sum_{jk} \Phi_{j,k,j}^B(T) \sum_m (-1)^{j-m} \psi_{j,-m}(x_{n+1}, y_{n+1})$$
$$\times \Psi_{(jk)jm}^B(x, y), \tag{2.142}$$

$$x = (x_1, x_2, \ldots, x_{n+1}), \quad y = (y_1, y_2, \ldots, y_{n+1}).$$

Relation to $U(n+1)$ solid harmonics:

$$e^{xA(T)y^T} = \sum_{k=0}^{\infty} \sum_{\alpha, \beta \vdash k} \frac{x^\alpha}{\sqrt{\alpha!}} D_{\alpha,\beta}^k(A(T)) \frac{y^\beta}{\sqrt{\beta!}}. \tag{2.143}$$

Relation of $U(n+1)$ solid harmonics to triangle monomials:

$$D_{\alpha,\beta}^k[A(T)] = (-1)^{j-m} \sum_k \begin{pmatrix} j & k & j \\ m & q & m \end{pmatrix}^B \Phi_{j,k,j}^B(T) \tag{2.144}$$

$$\alpha_i = j_i + m_i, \quad \beta_i = j_i - m_i \quad i = 1, 2, \ldots, n;$$
$$\alpha_{n+1} = j - m, \quad \beta_{n+1} = j + m;$$
$$\sum_i \alpha_i = \sum_i \beta_i = j_1 + j_2 + \cdots + j_n + j.$$

The relation between the skew symmetric matrix $A(T)$ of order $n+1$ and the elements of the $3 \times (n-1)$ matrix T is that described in relations (2.138).

Generating function for all recoupling coefficients:

$$\frac{1}{[\text{Pf}(A(T), A'(T'))]^2} \tag{2.145}$$
$$= \sum_{j,k,k',j} \Phi_{j,k,j}^B(T) \Phi_{j',k',j}^{B'}(T') \langle j, k, j || j', k', j \rangle,$$

where $\langle j, k, j || j', k', j \rangle$ denotes the recoupling coefficient that effects the transformation between the coupling schemes corresponding to the bracketing B and the bracketing B', and where the sequence j' is a permutation of j in accordance with the bracketing B'. We also note that

$$\frac{1}{\text{Pf}(A, A')} = \frac{1}{\sqrt{\det(I - AA')}}$$
$$= \left[1 + \sum_{k \ge 1} \sum_{\alpha, \beta \vdash k} D_{\alpha,\beta}^k(A) D_{\beta,\alpha}^k(A') \right]^{\frac{1}{2}}, \tag{2.146}$$

for arbitrary skew symmetric matrices of order n.

Relation (2.145) generates all recoupling coefficients, the trivial ones (those differing by signs) and all the complicated ones, that is, those corresponding to $3n - j$ coefficients. It will also be observed that the expansion of the reciprocal of the double Pfaffian effects an infinite sum in which no radicals occur, which in turn implies that the every recoupling coefficient has the form

$$\langle j, k, j || j', k', j \rangle$$
$$= \prod_{\langle a_i, b_i, k_i \rangle \in T_B(j,k,j)} \{a_i, b_i, k_i\}$$
$$\times \prod_{\langle a_i', b_i', k_i' \rangle \in T_{B'}(j',k',j)} \{a_i', b_i', k_i'\}$$
$$\times I(j, k, j || j', k', j),$$

where $I(j, k, j || j', k', j)$ is an integer:
Each recoupling coefficient is an integer multiplied by square-root factors that depend on the triangles associated with the coupling scheme.

Such features can be very useful in the development of algorithms for the calculation of $3n - j$ coefficients, including WCG-coefficients [2.17]. Relation (2.145) should be useful for the classification of $3n - j$ coefficients.

Table 2.3 The $3-j$ coefficients for $J_3 = 1, \frac{3}{2}, 2$

$$\begin{pmatrix} J+1 & J & 1 \\ M & -M-1 & 1 \end{pmatrix} = (-1)^{J-M-1}\left(\frac{(J-M)(J-M+1)}{(2J+3)(2J+2)(2J+1)}\right)^{\frac{1}{2}}$$

$$\begin{pmatrix} J+1 & J & 1 \\ M & -M & 0 \end{pmatrix} = (-1)^{J-M-1}\left(\frac{2(J+M+1)(J-M+1)}{(2J+3)(2J+2)(2J+1)}\right)^{\frac{1}{2}}$$

$$\begin{pmatrix} J & J & 1 \\ M & -M-1 & 1 \end{pmatrix} = (-1)^{J-M}\left(\frac{2(J-M)(J+M+1)}{(2J+2)(2J+1)(2J)}\right)^{\frac{1}{2}}$$

$$\begin{pmatrix} J & J & 1 \\ M & -M & 0 \end{pmatrix} = (-1)^{J-M}\frac{M}{[(2J+1)(J+1)J]^{\frac{1}{2}}}$$

$$\begin{pmatrix} J+\frac{3}{2} & J & \frac{3}{2} \\ M & -M-\frac{3}{2} & \frac{3}{2} \end{pmatrix} = (-1)^{J-M+\frac{1}{2}}\left(\frac{\left(J-M-\frac{1}{2}\right)\left(J-M+\frac{1}{2}\right)\left(J-M+\frac{3}{2}\right)}{(2J+4)(2J+3)(2J+2)(2J+1)}\right)^{\frac{1}{2}}$$

$$\begin{pmatrix} J+\frac{3}{2} & J & \frac{3}{2} \\ M & -M-\frac{1}{2} & \frac{1}{2} \end{pmatrix} = (-1)^{J-M+\frac{1}{2}}\left(\frac{3\left(J-M+\frac{1}{2}\right)\left(J-M+\frac{3}{2}\right)\left(J+M+\frac{3}{2}\right)}{(2J+4)(2J+3)(2J+2)(2J+1)}\right)^{\frac{1}{2}}$$

3. Group Theory for Atomic Shells

The basic elements of the theory of Lie groups and their irreducible representations (IRs) are described. The IRs are used to label the states of an atomic shell and also the components of operators of physical interest. Applications of the generalized Wigner–Eckart theorem lead to relations between matrix elements appearing in different electronic configurations. This is particularly useful in the f shell, where transformations among the seven orbital states of an f electron can be described by the unitary group U(7) and its sequential subgroups SO(7), G$_2$, and SO(3) with respective IRs [λ], W, U, and L. Extensions to groups that involve electron spin S (like Sp(14)) are described, as are groups that do not conserve electron number. The most useful of the latter is the quasispin group whose generators $\boldsymbol{Q}$ connect states of identical W, U, L and seniority v in the f shell. The symmetries of products of objects (states or operators) that themselves possess symmetries are described by the technique of plethysms.

Part A | 3

3.1 Generators

3.1.1 Group Elements

An element S_a of a Lie group $\mathcal{G}$, corresponding to an infinitesimal transformation can be written in the form

$$S_a = 1 + \delta a^{\sigma} X_{\sigma} \,, \tag{3.1}$$

where the δa^{σ} are the infinitesimal parameters and the X_{σ} are the generators [3.1]. Summation over the repeated Greek index is implied. Transformations corresponding to finite parameters can be found by exponentiation:

$$S_a \rightarrow \exp\left(a^1 X_1\right) \exp\left(a^2 X_2\right) \cdots \exp\left(a^r X_r\right) \,. \tag{3.2}$$

The generators necessarily form a Lie algebra, that is, they close under commutation:

$$\left[X_{\rho}, X_{\sigma}\right] = c_{\rho\sigma}^{\tau} X_{\tau} \,. \tag{3.3}$$

In terms of the structure constants $c^\tau_{\rho\sigma}$, the metric tensor is defined as

$$g_{\rho\sigma} = c^\mu_{\rho\lambda}\, c^\lambda_{\sigma\mu}\,. \tag{3.4}$$

3.1.2 Conditions on the Structure Constants

For an Abelian group, all the generators commute with one another:

$$c^\tau_{\rho\sigma} = 0\,. \tag{3.5}$$

The operators X_σ, $(\sigma = 1, 2, \ldots, p < r)$ form the generators of a subgroup if [3.2]

$$c^\tau_{\rho\sigma} = 0\,, \quad (\rho, \sigma \leq p,\ \tau > p)\,. \tag{3.6}$$

The subgroup is invariant if the stronger condition

$$c^\tau_{\rho\sigma} = 0\,, \quad (\rho \leq p,\ \tau > p) \tag{3.7}$$

is satisfied. A group is *simple* if it contains no invariant subgroup (besides the unit element). A group is *semisimple* if it contains no Abelian invariant subgroup (besides the unit element). A necessary and sufficient condition that a group be semisimple is that

$$\det |\, g_{\rho\tau}\,| \neq 0\,. \tag{3.8}$$

All simple groups are semisimple. For semisimple groups, the inverse tensor $g^{\mu\nu}$ can be formed, thus permitting suffixes to be raised. The quadratic operator

$$C = g^{\rho\sigma} X_\rho X_\sigma \tag{3.9}$$

commutes with all generators of the group and is called Casimir's operator [3.1]. If the generators of a group $\mathcal{G}$ can be broken up into two sets such that each member of one set commutes with all the members of the other, that is, if

$$c^\tau_{\rho\sigma} = 0\,, \quad (\rho \leq p, \sigma > p)\,, \tag{3.10}$$

then the two sets form the generators of two invariant subgroups, $\mathcal{H}$ and $\mathcal{K}$. The group $\mathcal{G}$ is the direct product of $\mathcal{H}$ and $\mathcal{K}$ and is written as $\mathcal{H} \times \mathcal{K}$.

3.1.3 Cartan–Weyl Form

By taking suitable linear combinations H_i and E_α of the generators X_σ, the basic commutation relations (3.3) can be thrown into the so-called Cartan–Weyl form [3.1]

$$[H_i, H_j] = 0\,, \tag{3.11}$$

$$[H_i, E_\alpha] = \alpha_i E_\alpha\,, \tag{3.12}$$

$$[E_\alpha, E_{-\alpha}] = \alpha^i H_i\,, \tag{3.13}$$

$$[E_\alpha, E_\beta] = N_{\alpha\beta} E_{\alpha+\beta}\,. \tag{3.14}$$

The Roman symbols $i, j, \ldots$ run over an l-dimensional space (the *weight* space of *rank l*) in which the numbers α_i can be visualized as the components of the vectors (called *roots*). The E_α are shift operators, the displacements being specified by the components of $\boldsymbol{\alpha}$. The operator $E_{\alpha+\beta}$ in (3.17) is to be interpreted as 0 if $\boldsymbol{\alpha} + \boldsymbol{\beta}$ is not a root. The coefficient $N_{\alpha\beta}$ depends on the choice of normalization.

3.1.4 Atomic Operators as Generators

The pairs $a^\dagger_\xi a_\eta$ of creation and annihilation operators for either bosons or fermions, as defined in Sect. 6.1.1 close under commutation and form a Lie algebra. The coupled forms $\boldsymbol{W}^{(\kappa k)}$, defined in Sect. 6.2.2, are often used to play the role of the generators for electrons in an atomic shell.

3.2 Classification of Lie Algebras

3.2.1 Introduction

The semisimple Lie algebras have been classified by *Cartan* [3.3]. They consist of four main classes A_l, B_l, C_l, D_l, and five exceptions G_2, F_4, E_6, E_7, E_8. Each algebra is characterized by an array of roots in the l-dimensional weight space; they are conveniently specified by a set of mutually orthogonal unit vectors $\boldsymbol{e}_i$. The total number of generators (those of type E_α plus the l generators of type H_i) gives the *order* of the algebra.

3.2.2 The Semisimple Lie Algebras

A_l. The roots are conveniently represented by the vectors $\boldsymbol{e}_i - \boldsymbol{e}_j$ $(i, j = 1, 2, \ldots, l+1)$. They are all perpendicular to $\Sigma \boldsymbol{e}_k$ and do not extend beyond the l-dimensional weight space. The order of the algebra is $l(l+2)$. The group for which this algebra can serve as a basis is the special unitary group $\mathrm{SU}(l+1)$.

B_l. The roots are $\pm \boldsymbol{e}_i$ and $\pm \boldsymbol{e}_i \pm \boldsymbol{e}_j$ $(i, j = 1, 2, \ldots, l;\ i \neq j)$. The order of the algebra is $l(2l+1)$. A cor-

Table 3.1 Generators of the Lie groups for the atomic l shell. The subscripts i and j run over all $4l + 2$ states of a single electron

Group	Generators
SO$(8l+5)$[a]	$a_i^\dagger a_j^\dagger, a_i^\dagger a_j, a_i a_j, a_i^\dagger, a_j$
SO$(8l+4)$[a]	$a_i^\dagger a_j^\dagger, a_i^\dagger a_j, a_i a_j$
U$(4l+2)$[b]	$W^{(\kappa k)}$ ($\kappa = 0, 1$; $k = 0, 1, \ldots, 2l$)
SU$(4l+2)$[b]	$W^{(\kappa k)}$ (As above, with $\kappa = k = 0$ excluded)
Sp$(4l+2)$[c]	$W^{(\kappa k)}$ (As above, with $\kappa + k$ odd)
U$(2l+1)$[d]	$W^{(0k)}$ ($k = 0, 1, \ldots, 2l$)
SU$(2l+1)$[d]	$W^{(0k)}$ ($k = 1, 2, \ldots, 2l$)
SO$(2l+1)$[d]	$W^{(0k)}$ ($k = 1, 3, 5, \ldots, 2l-1$)
G$_2^{\text{d}}$	$W^{(01)}, W^{(05)}$ (for $l = 3$)
SO$_L(3)$[e]	$W^{(01)}$ (or $\boldsymbol{L}$)
SO$_S(3)$[e]	$W^{(10)}$ (or $\boldsymbol{S}$)
U$_A(2l+1) \times$ U$_B(2l+1)$[f]	$W_{0q}^{(0k)} + W_{0q}^{(1k)}, W_{0q}^{(0k)} - W_{0q}^{(1k)}$ ($k = 0, 1, \ldots, 2l$)
SO$_\lambda(2l+1) \times$ SO$_\mu(2l+1) \times$ SO$_\nu(2l+1) \times$ SO$_\xi(2l+1)$[g]	$(\boldsymbol{\theta}^\dagger \boldsymbol{\theta})^{(k)}$ (k odd, $\boldsymbol{\theta} \equiv \boldsymbol{\lambda}, \boldsymbol{\mu}, \boldsymbol{\nu}, \boldsymbol{\xi}$)
U$_\lambda(2^l) \times$ U$_\mu(2^l) \times$ U$_\nu(2^l) \times$ U$_\xi(2^l)$[h]	$\boldsymbol{q}_\theta^\dagger \boldsymbol{q}_\theta$ (all components, $\theta \equiv \lambda, \mu, \nu, \xi$)

[a] [3.4,5]   [b] [3.1,6]   [c] [3.6,7]   [d] [3.6]   [e] [3.8]   [f] [3.9]   [g] [3.10] and (6.69)–(6.72)   [h] [3.11]

responding group is the special orthogonal (or rotation) group in $2l + 1$ dimensions, SO$(2l+1)$.

C_l. The roots are $\pm 2\boldsymbol{e}_i$ and $\pm \boldsymbol{e}_i \pm \boldsymbol{e}_j$ ($i, j = 1, 2, \ldots, l$; $i \neq j$). The order of the algebra is $l(2l+1)$. A corresponding group is the symplectic group in $2l$ dimensions, Sp$(2l)$. A rotation of the roots yields $C_2 = B_2$.

D_l. The roots are $\pm \boldsymbol{e}_i \pm \boldsymbol{e}_j$ ($i, j = 1, 2, \ldots, l$; $i \neq j$). The order of the algebra is $l(2l-1)$. A corresponding group is the special orthogonal (or rotation) group SO$(2l)$. A rotation of the roots yields $D_3 = A_3$. Also, $D_2 = A_1 \times A_1$.

E_6, E_7, E_8. The roots are given by *Racah* [3.1]. The respective orders are 78, 133, and 248.

F_4. The roots consist of the roots of B_4 together with the 16 vectors $\frac{1}{2}(\pm \boldsymbol{e}_1 \pm \boldsymbol{e}_2 \pm \boldsymbol{e}_3 \pm \boldsymbol{e}_4)$. The order of the algebra is 52.

G_2. The roots consist of the roots of A_2 together with the six vectors $\pm (2\boldsymbol{e}_i - \boldsymbol{e}_j - \boldsymbol{e}_k)$ ($i \neq j \neq k = 1, 2, 3$). The order of the algebra is 14.

Examples of Lie groups used in atomic shell theory, together with their generators, are given in Table 3.1.

3.3 Irreducible Representations

3.3.1 Labels

If n atomic states of a collection transform among themselves under an arbitrary action of the generators of a group $\mathcal{G}$, then the states form a *representation* of $\mathcal{G}$. The representation is *irreducible* if n' linear combinations of the states cannot be found that also exhibit that property, where $n' < n$. The commuting generators H_i of $\mathcal{G}$ can be simultaneously diagonalized within the n states: their eigenvalues $(m_1, m_2, \ldots, m_l)$ for an eigenstate ψ specify the *weight* of the eigenstate. The weight above is said to be *higher* than $(m_1', m_2', \ldots, m_l')$ if the first non-vanishing term in the sequence $m_1 - m_1', m_2 - m_2', \ldots$ is positive. An irre-

ducible representation (IR) of a semisimple group is uniquely specified (to within an equivalence) by its highest weight [3.1], which can therefore be used as a defining label.

3.3.2 Dimensions

The dimensions of the IRs of various groups are expressed in terms of the highest weights and set out in Table 3.2. General algebraic expressions have been given by *Wybourne* [3.12, pp. 137]. Numerical tabulations have been made by Butler in the appendix to another book by *Wybourne* [3.13], and also by *McKay* and *Patera* [3.14]. The latter defines the IRs by speci-

fying the coordinates of the weights with respect to the simple roots of *Dynkin* [3.15].

3.3.3 Casimir's Operator

The eigenvalues of Casimir's operator C, defined in (3.9), can be expressed in terms of the highest weights of an IR [3.1]. A complete algebraic listing for all the semisimple Lie groups has been given by *Wybourne* [3.12, p. 140]. Sometimes Casimir's operator is given in terms of the spherical tensors $W^{(\kappa k)}$, or of their special cases $V^{(k)}\left(= 2^{\frac{1}{2}}W^{(0k)}\right)$ for which the single-electron reduced matrix element satisfies

$$(nl\|v^{(k)}\|nl) = (2k+1)^{\frac{1}{2}} . \tag{3.15}$$

The eigenvalues of several operators of that form are given in Table 3.3.

Table 3.2 Dimensions D of the irreducible representations (IR's) of various Lie groups

Group	IR	D
SO(2)	M	1
SO(3)	D_J	$2J+1$
SO(4) = SO$_A$(3)×SO$_B$(3)	$D_J \times D_K$	$(2J+1)(2K+1)$
SO(5)	$(w_1 w_2)$	$(w_1 + w_2 + 2)(w_1 - w_2 + 1)(2w_1 + 3)(2w_2 + 1)/6$
SO(6)	$(w_1 w_2 w_3)$	$(w_1 - w_2 + 1)(w_1 - w_3 + 2)(w_2 - w_3 + 1)$ $\times (w_1 + w_2 + 3)(w_1 + w_3 + 2)(w_2 + w_3 + 1)/12$
SO(7)	$(w_1 w_2 w_3)$	$(w_1 + w_2 + 4)(w_1 + w_3 + 3)(w_2 + w_3 + 2)$ $\times (w_1 - w_2 + 1)(w_1 - w_3 + 2)(w_2 - w_3 + 1)$ $\times (2w_1 + 5)(2w_2 + 3)(2w_3 + 1)/720$
G$_2$	$(u_1 u_2)$	$(u_1 + u_2 + 3)(u_1 + 2)(2u_1 + u_2 + 5)(u_1 + 2u_2 + 4)$ $\times (u_1 - u_2 + 1)(u_2 + 1)/120$
SU(3) or U(3)	$[\lambda_1 \lambda_2 \lambda_3]$	$(\lambda_1 - \lambda_2 + 1)(\lambda_1 - \lambda_3 + 2)(\lambda_2 - \lambda_3 + 1)/2$
SU(4) or U(4)	$[\lambda_1 \lambda_2 \lambda_3 \lambda_4]$	As for $(w_1 w_2 w_3)$ of SO(6)[a]
Sp(4)	$\langle \sigma_1 \sigma_2 \rangle$	As for $(w_1 w_2)$ of SO(5)[b]
Sp(6)	$\langle \sigma_1 \sigma_2 \sigma_3 \rangle$	$(\sigma_1 - \sigma_2 + 1)(\sigma_1 - \sigma_3 + 2)(\sigma_1 + \sigma_2 + 5)$ $\times (\sigma_1 + \sigma_3 + 4)(\sigma_2 + \sigma_3 + 3)(\sigma_2 - \sigma_3 + 1)$ $\times (\sigma_1 + 3)(\sigma_2 + 2)(\sigma_3 + 1)/720$

[a] Subject to the conditions $w_1 = (\lambda_1 + \lambda_2 - \lambda_3 - \lambda_4)/2$, $w_2 = (\lambda_1 - \lambda_2 + \lambda_3 - \lambda_4)/2$, $w_3 = (\lambda_1 - \lambda_2 - \lambda_3 + \lambda_4)/2$
[b] Subject to the conditions $w_1 = (\sigma_1 + \sigma_2)/2$, $w_2 = (\sigma_1 - \sigma_2)/2$

3.4 Branching Rules

3.4.1 Introduction

If a group $\mathcal{H}$ shares some of its generators with a group $\mathcal{G}$, the first can be considered a subgroup of the second. That is, $\mathcal{G} \supset \mathcal{H}$. Many of the groups in Table 3.1 can be put in extended group–subgroup sequences. The IRs of a subgroup that together span an IR of the group constitute a *branching* rule.

3.4.2 U(n) ⊃ SU(n)

The group U(n) differs from SU(n) in that the former contains among its generators a scalar $\left(\text{such as } W^{(00)}\right)$ that, by itself, forms an invariant subgroup. Thus U(n)

is not semisimple. The scalar in question commutes with all the generators of the group and so is of type H_i. Its presence enlarges the dimension, l, of the weight space by 1, an extension that can be accommodated by the unit vectors e_i of A_l given in Sect. 3.2.2. The reduction U(n) ⊃ SU(n) leads to the branching rule

$$[\lambda_1 \lambda_2 \cdots \lambda_n] \to [\lambda_1 - a, \lambda_2 - a, \cdots, \lambda_n - a] , \tag{3.16}$$

where, in the IR of SU(n) on the right,

$$a = (\lambda_1 + \lambda_2 + \cdots + \lambda_n)/n . \tag{3.17}$$

Table 3.3 Eigenvalues of Casimir's operator C for groups used in the atomic l shell

Group	IR	Operator	Eigenvalue
SU$(2l+1)$	$[\lambda]^a$	$\sum_{k>0}\left(V^{(k)}\right)^2$	$3N + 2Nl - \frac{1}{2}N^2 - 2S(S+1) - N^2/(2l+1)$
SO$(2l+1)$	W^b	$\sum_{k_{\text{odd}}}\left(V^{(k)}\right)^2$	$\frac{1}{2}\sum_{i=1}^{l} w_i(w_i + 1 + 2l - 2i)$
G$_2$	$(u_1 u_2)$	$\frac{1}{4}\left[\left(V^{(1)}\right)^2 + \left(V^{(5)}\right)^2\right]$	$\left(u_1^2 + u_2^2 + u_1 u_2 + 5u_1 + 4u_2\right)/12$

^{a} Appropriate for terms of l^N with total spin S [3.7], p. 125
^{b} Defined by the l weights $(w_1 w_2 \cdots w_l)$

To avoid fractional weights, the IRs of SU(n) are frequently replaced by those of U(n) for which the λ_i are integers. The weights $\lambda_1, \lambda_2, \ldots$ can be interpreted as the number of cells in successive rows of a *Young Tableau*. When the n states of a single particle are taken as a basis for the IR [10 ... 0] of U(n), thus corresponding to a tableau comprising a single cell, the tableaux comprising N cells can be interpreted in two ways, namely, (1) as an IR of U(n) for a system of N particles, and (2) as an IR of S_N, the finite group of permutations on N objects. A given tableau corresponds to as many permutations as there are ways of entering the numbers 1, 2, ... , N in the cells such that the numbers increase going from left to right along the rows, and from top to bottom down the columns. A tableau possessing cells numbered in this way is called *standard*; it defines a permutation corresponding to a symmetrization with respect to the numbers in the rows, followed by an antisymmetrization with respect to the numbers in the columns [3.16].

3.4.3 Canonical Reductions

A group–subgroup sequence of the type

$$U(n) \supset U(n-1) \supset U(n-2) \supset \cdots \supset U(1) \quad (3.18)$$

is called *canonical* [3.17]. The branching rules for those IRs $\left[\lambda_1' \lambda_2' \cdots \lambda_{n-1}'\right]$ of U$(n-1)$ contained in $[\lambda_1 \lambda_2 \cdots \lambda_n]$ of U(n) have been given by *Weyl* [3.18]

in terms of the "betweenness" conditions

$$\lambda_1 \geq \lambda_1' \geq \lambda_2 \geq \lambda_2' \cdots \geq \lambda_{n-1}' \geq \lambda_n . \quad (3.19)$$

The possibility of using the scheme of (3.18) in the theory of complex atomic spectra has been explored by *Harter* and *Patterson* [3.19–21], and by *Drake* and *Schlesinger* [3.22, 23] (see also Sect. 4.3.1).

3.4.4 Other Reductions

The algebraic formulae for U$(n) \supset$ SO(n) and U$(n) \supset$ Sp(n) have been given by *Littlewood* [3.24] and in a rather more accessible form by *Wybourne* [3.13]. Special cases have been tabulated by *Butler* (in Tables C-1 through C-15 in [3.13]). Another set of tables, in which Dynkin's labeling scheme is used, has been given by *McKay* and *Patera* [3.14]. Descriptions of how to apply the mechanics of the mathematics to the Young tableaux that describe the IRs of U(n) can be found in the articles of *Jahn* [3.25] [with particular reference to SO(5)] and *Flowers* [3.26] [for Sp$(2j+1)$]. For the atomic l shell, the reductions SO$(2l+1) \supset$ SO(3) and (for f electrons) SO(7) $\supset$ G$_2$ and G$_2 \supset$ SO(3) are important. The sources cited in the previous Section are useful here. It is important to recognize that the embedding of one group in another can often be performed in inequivalent ways, depending on which generators are discarded in the reduction process. Thus the use of SO(5) $\supset$ SO(3) in the atomic d shell involves a different SO(3) group from that derived from the canonical sequence SO(5) $\supset$ SO(4) $\supset$ SO(3).

3.5 Kronecker Products

3.5.1 Outer Products of Tableaux

Consider the tableau $[\lambda_1 \lambda_2 \cdots \lambda_n]$, where the total number of cells is N. A preliminary definition is required.

If among the first r terms of any permutation of the N factors of the product, $x_1^{\lambda_1} x_2^{\lambda_2} \cdots x_n^{\lambda_n}$, the number of times x_1 occurs is $\geq$ the number of times x_2 occurs $\geq$ the number of times x_3 occurs, etc. for all values of r,

this permutation is called a *lattice* permutation. The prescription of *Littlewood* [3.24] for finding the tableaux appearing in the Kronecker product of $[\lambda_1 \lambda_2 \cdots \lambda_n]$ with $[\mu_1 \mu_2 \cdots \mu_m]$ is as follows. The acceptable tableaux are those that can be built by adding to the tableau $[\lambda_1 \lambda_2 \cdots \lambda_n]$, μ_1 cells containing the same symbol α, then μ_2 cells containing the same symbol β, etc., subject to two conditions:

1. After the addition of each set of cells labeled by a common symbol we must have a permissible tableau with no two identical symbols in the same column;
2. If the total set of added symbols is read from right to left in the consecutive rows of the final tableau, we obtain a lattice permutation of $\alpha^{\mu_1} \beta^{\mu_2} \gamma^{\mu_3} \cdots$.

Examples of this procedure have been given ([3.24, p. 96], [3.7, p. 136], [3.13, p. 24]). An extensive tabulation involving tableaux with $N < 8$ has been calculated by *Butler* and given by *Wybourne* [3.13, Table B-1].

3.5.2 Other Outer Products

The rules for constructing the Kronecker products for U(n) follow by interpreting the Young tableaux of the previous section as IRs of U(n). The known branching rules for reductions to subgroups enable the Kronecker products for the subgroups to be found. Many examples for SO(n), Sp(n), and G$_2$ can be found in the book by *Wybourne* ([3.13, Tables D-1 through D-15, and E-4].

3.5.3 Plethysms

Sometimes a particle can be thought of as being composite [as when the six orbital states s + d of a single electron are taken to span the IR [200] of SU(3)]. When the n' component states of a particle form a basis for

an IR $[\lambda']$ of U(n) other than [10 ... 0], the process of finding which IRs of U(n) occur for N-particle states whose permutation symmetries are determined by a given Young tableau $[\lambda]$ with N cells is called a *plethysm* [3.24, p. 289] and written as $[\lambda'] \otimes [\lambda]$. The special techniques for doing this have been described by *Wybourne* [3.13]. An elementary method, which is often adequate in many cases, runs as follows:

1. Expand $[\lambda']^N$ by repeated use of Table B-1 from [3.13]. The resulting tableaux $[\lambda'']$ are independent of n.
2. Choose a small value of n, and strike out all tableaux from the set $[\lambda'']$ that possess more than n rows [since they are unacceptable as IRs of U(n)].
3. Interpret the remaining tableaux $[\lambda'']$ as IRs of U(n) and find their dimensions from Tables A-2 through A-17 of [3.13]. Check that the sum of the dimensions is $(\dim[\lambda'])^N$.
4. Interpret the various tableaux $[\lambda]$ possessing the same number N of cells as IRs of U$(\dim[\lambda'])$, and find their dimensions from [3.13].
5. Match the dimensions of parts (3) and (4), remembering that each tableau $[\lambda]$ occurs as often as the number of its standard forms. This determines the possible ways of assigning the IRs $[\lambda'']$ of U(n) to each $[\lambda]$.
6. Proceed to higher n to remove ambiguities and to include the tableaux struck out in step 2.

This procedure can be extended to calculate the plethysms for other groups. Examples of the type $W \otimes [\lambda]$ and $U \otimes [\lambda]$, where W and U are IRs of SO(7) and G$_2$, have been given for $[\lambda] \equiv [2]$ and [11] corresponding to the separation of W^2 and U^2 into their symmetric and antisymmetric parts [3.27]. The technique of plethysm is also useful for mixed atomic configurations (Sect. 3.6.1).

3.6 Atomic States

3.6.1 Shell Structure

The 2^{4l+2} states of the l shell span the elementary spinor IR $\left(\frac{1}{2}\frac{1}{2}\cdots\frac{1}{2}\right)$ of SO($8l+5$), which decomposes into the two IRs $\left(\frac{1}{2}\frac{1}{2}\cdots\pm\frac{1}{2}\right)$ of SO($8l+4$), corresponding to an even and an odd number N of electrons [3.4]. The states of l^N span the IR $\left[1^N 0^{4l+2-N}\right]$ of U($4l+2$), corresponding to the antisymmetric Young tableau comprising a single column of N cells. The separation of spin and orbit through the subgroup

U(2) × U($2l+1$) yields the tableau products $[\lambda] \times [\tilde{\lambda}]$, where $[\tilde{\lambda}]$ is the tableau obtained by reflecting $[\lambda]$ in a diagonal line [3.1]. The IRs of the subgroup U(2) × SO($2l+1$) are denoted by S and W [3.6]. An alternative way of reaching this subgroup from U($4l+2$) involves the intermediary Sp($4l+2$), whose IRs $\left\langle 1^v 0^{2l+1-v}\right\rangle$ possess as a basis the states with seniority v [3.7]. A subgroup of SO($2l+1$) is the SO(3) group whose IRs specify L, the total orbital angular momentum.

Alternatives to this classic sequence are provided by the last three groups listed in Table 3.1, together with their respective subgroups. For $U_A(2l+1) \times U_B(2l+1)$, the shell is factored by considering spin-up and spin-down electrons as distinct (and statistically independent) particles [3.28]. A further factorization by means of the quasiparticles, θ, leads to four independent spaces. The 2^l states in each space span the elementary spinor $\left(\frac{1}{2}^l\right)$ of $SO_\theta(2l+1)$, which can be regarded as a fictitious particle (or quark), q_θ [3.29].

The standard classification of the states of the d-shell is given in Table 3.4. The component M_Q of the quasispin Q (defined in (6.33–6.35)) is listed, as well as the seniority, $v = 2l+1-2Q$, the IRs W of $SO(5)$, and the value of L (as a spectroscopic symbol). Only states in the first half of the shell appear; the classification for the second half is the same as the first except that the signs of M_Q are reversed. A general rule for arbitrary l is exemplified by noting that every W [the IR of $SO(2l+1)$] occurs with two spins (S_1 and S_2) and two quasispins (Q_1 and Q_2) such that $S_1 = Q_2$ and $S_2 = Q_1$. No duplicated spectroscopic terms appear in Table 3.4. The generators of $SO(5)$ do not commute with the inter-electronic Coulomb interaction; thus the separations effected by $SO(5)$ merely define (to within a phase) a basis. The analog of Table 3.4 has been given

Table 3.4 The states of the d shell

d^N	M_Q	$^{2S+1}[\lambda]$	v	W	L
d^0	$-\frac{5}{2}$	$^1[0]$	0	(00)	S

by *Wybourne* [3.30] for the f shell. As *Racah* [3.6] showed, the group G_2 can be used to help distinguish repeated terms, but a few duplications remain. They are distinguished by *Nielson* and *Koster* [3.31] in their tables of spectroscopic coefficients by the letters A and B. The scope for applications of group theory becomes enlarged when the states of a single electron embrace more than one l value. Extensions of the standard model have been made by *Feneuille* [3.32] with particular reference to the configurations $(d+s)^N$, for which quasiparticles have also been considered [3.33]. The group $SU(3)$ has been used for $(d+s)^N p^M$ [3.34]. The mixed configurations $(s+f)^4$ have found a use in the quark model of the atomic f shell [3.29]. A brief description of this model has been given by *Fano* and *Rao* [3.35].

3.6.2 Automorphisms of SO(8)

The quark structure $s+f$ derives from the $SO(3)$ structure of the elementary spinor $\left(\frac{1}{2}\frac{1}{2}\frac{1}{2}\right)$ of $SO(7)$. Its eight components span the IR (1000) of $SO(8)$, a group that admits automorphisms [3.36]. This property is exhibited by the existence of the three distinct subgroups $SO(7)$ (Racah's group), $SO(7)'$, and $SO(7)''$, all of which possess the same G_2 and $SO(3)$ as subgoups. A reversal of the relative phase of the s and f quarks takes $SO(7)$ into $SO(7)''$ and vice versa [3.37]. The generators of $SO(7)'$ are the sums of the corresponding generators of $SO(7)$ and $SO(7)''$. The phase reversal between the s and f quarks, when interpreted in terms of electronic states, explains the unexpected simplifications found by *Racah* [3.6] in his equation (87) [3.38], which goes beyond what the Wigner–Eckart theorem for G_2 would predict. Similarly, explanations can be found for some (but not all) proportionalities between blocks of matrix elements of components of the spin–other-orbit interaction for f electrons [3.39]. *Hansen* and *Ven* have given some examples of still unexplained proportionalities [3.40]. The group $SO(7)'$ has proved useful in analyses of the effective three-electron operators used to represent weak configuration interaction in the f shell [3.37].

3.6.3 Hydrogen and Hydrogen-Like Atoms

The nonrelativistic hydrogen atom possesses an $SO(4)$ symmetry associated with the invariance of the Runge–Lenz vector, which indicates the direction of the major axis of the classical elliptic orbit [3.5]. The

quantum-mechanical form of this vector can be written in dimensionless units as

$$\boldsymbol{a} = [(\boldsymbol{l} \times \boldsymbol{p}) - (\boldsymbol{p} \times \boldsymbol{l}) + 2Z\boldsymbol{r}/ra_0]/2p_0 \,, \qquad (3.20)$$

where $a_0 = \hbar^2/me^2$ is the Bohr radius, Ze is the nuclear charge, p_0 is related to the principal quantum number n by $p_0 = Z/na_0$, and where the momentum $\boldsymbol{p}$ and angular momentum $\boldsymbol{l}$ of the electron in its orbit are measured in units of $\hbar$. The analysis is best carried out in momentum space [3.41]. The four coordinates to which SO(4) refers can be taken from (9.43–9.46) or directly as kp_x, kp_y, kp_z, and $kp_0(1 - p^2/p_0^2)/2$, where $k = 2p_0/(p^2 + p_0^2)$. The generators of SO(4) are provided by the 6 components of the two mutually commuting vectors $(\boldsymbol{l} + \boldsymbol{a})/2$ and $(\boldsymbol{l} - \boldsymbol{a})/2$, each of which behaves as an angular momentum vector. The equivalence $SO(4) = SO(3) \times SO(3)$ corresponds to the isomorphism $D_2 = A_1 \times A_1$ of Sect. 3.2.2.

Hydrogenic eigenfunctions belonging to various energies can be selected to form bases for a number of groups. The inclusion of all the levels up to a given n yields the IR $(n - 1, 0)$ of SO(5). Levels of a given l and all n form an infinite basis for an IR of the noncompact group SO(2, 1) [3.42]. All the bound hydrogenic states span an IR of SO(4, 2), as do the states in the continuum [3.43]. Subgroups of SO(4, 2) and their generators have been listed by *Wybourne* [3.12] in his Table 21.2.

To the extent that the central potential of a complex atom resembles the r^{-1} dependence for a bare nucleus, the group SO(4) can be used to label the states [3.44].

3.7 The Generalized Wigner–Eckart Theorem

3.7.1 Operators

All atomic operators involving only the electrons can be built from their creation and annihilation operators. The appropriate group labels for an atomic operator acting on N electrons, each with n relevant component states, reduces to working out the various parts of the Kronecker products $[10\ldots0]^N \times [0\ldots0-1]^N$ of U(n). Subgroups of U(n) can further define these parts, which may be limited by Hermiticity constraints. The group labels for the Coulomb interaction for f electrons were first given by *Racah* [3.6]. Interactions involving electron spin were classified later [3.45–47]. Operators that represent the effects of configuration interaction on the d and f shells have also been studied [3.27, 48–52].

3.7.2 The Theorem

Let the ket, operator T, and bra of a matrix element be labeled by an IR (R_a, R_c, R_b) of a group $\mathcal{G}$, each with a component (i_a, i_c, i_b). Suppose the supplementary labels γ_k are also required to complete the definitions. The generalized Wigner–Eckart theorem is

$$\langle \gamma_a R_a i_a | T(\gamma_c R_c i_c) | \gamma_b R_b i_b \rangle =$$
$$\sum_\beta A_\beta (\beta R_a i_a | R_b i_b, R_c i_c) \,, \qquad (3.21)$$

where β distinguishes the IRs R_a should they appear more than once in the reduction of the Kronecker product $R_b \times R_c$. The *reduced* matrix element A_β is independent of the i_k [3.6, 8]. The second factor on the right-hand side of (3.21) is a Clebsch–Gordan (CG) coefficient for the group $\mathcal{G}$.

If the specification Ri can be replaced by $R\tau ri$, where r denotes an IR of a subgroup $\mathcal{H}$ of $\mathcal{G}$, and τ is an additional symbol that may be necessary to make the classification unambiguous, the CG coefficient for $\mathcal{G}$ factorizes according to the Racah lemma [3.6]

$$(\beta R_a \tau_a r_a i_a | R_b \tau_b r_b i_b, \, R_c \tau_c r_c i_c)$$
$$= \sum_\alpha (\alpha r_a i_a | r_b i_b, r_c i_c)(\beta R_a \tau_a r_a | R_b \tau_b r_b + R_c \tau_c r_c)_\alpha \,.$$
$$(3.22)$$

The first factor on the right is a CG coefficient for the group $\mathcal{H}$; the second factor is an *isoscalar* factor [3.53].

3.7.3 Calculation of the Isoscalar Factors

The group $\mathcal{H}$ above is often SO(3), whose Clebsch–Gordan coefficients (and their related 3–j symbols) are well-known (Chapt. 2). The principal difficulty in establishing comparable formulae for the isoscalar factors lies in giving algebraic meaning to β. Several methods are available for obtaining numerical results as follows.

Extraction from Tabulated Quantities
If R_b or R_c correspond to the IRs labeling a single electron, the factorization of the known [3.31] coefficients of fractional parentage (cfp) according to formulae of

the type [3.6]

$$\left(\mathrm{d}^N S L v \{| \mathrm{d}^{N-1} S' L' v'\right) =$$
$$\left(\mathrm{d}^N S v \{| \mathrm{d}^{N-1} S' v'\right)\left(W' L' + (10)\mathrm{d} | WL\right) \qquad (3.23)$$

yields some isoscalar factors. In this example, W and W' are the IRs of SO(5) defined by the triples NSv and $N'S'v'$ (with $N' = N - 1$) as in Table 3.4. This approach can be applied to the f shell to give isoscalar factors for SO(7) and G_2. The many-electron cfp of *Donlan* [3.54] and the multielectron cfp of *Velkov* [3.55] further extend the range to IRs R_b and R_c describing many-electron systems. Isoscalar factors found in this way have the advantage that their relative phases as well as the significance of the indices β and τ coincide with current usage.

Evaluation Using Casimir's Operator

Two commuting copies (b and c) are made of the generators of the group $\mathcal{G}$ to form the generators of the direct product $\mathcal{G}_b \times \mathcal{G}_c$ [3.56]. Corresponding generators of $\mathcal{G}_b$ and $\mathcal{G}_c$ are added to give the generators of $\mathcal{G}_a$. Each quadratic operator $(\boldsymbol{T}_a)^2$ appearing in the expression for Casimir's operator C_a for $\mathcal{G}_a$ (as listed in Table 3.3) is written as $(\boldsymbol{T}_b + \boldsymbol{T}_c)^2$. On expanding the expressions of this type, the terms $(\boldsymbol{T}_b)^2$ and $(\boldsymbol{T}_c)^2$ yield Casimir's operators C_b and C_c for $\mathcal{G}_b$ and $\mathcal{G}_c$. Their eigenvalues can be written down in terms of the highest weights of the IRs appearing in the isoscalar factor of (3.22). If the cross products of the type $(\boldsymbol{T}_b \cdot \boldsymbol{T}_c)$ can be evaluated within the uncoupled states $|R_b \tau_b r_b, R_c \tau_c r_c\rangle$, then our knowledge of the eigenvalues of C_a for the coupled states $|\beta R_a \tau_a r_a\rangle$ provides the equations for determining (to within the freedom implied by β) the isoscalar factors relating the uncoupled to the coupled states. The evaluation of the cross products is straightforward when $\mathcal{H} = \mathrm{SO}(3)$, since the relevant $6-j$ symbols are readily available [3.57]. Examples of this method can be found in the literature [3.48].

3.7.4 Generalizations of Angular Momentum Theory

CG coefficients, $n-j$ symbols, reduced matrix elements, and the entire apparatus of angular momentum theory all have their generalizations to groups other than SO(3). An interchange of two columns of a $3-j$ symbol has its analog in the interchange of two parts of an isoscalar factor. For IRs W and L of SO($2l+1$) and SO(3), there are two possibilities:
(1) The interchange of the two parts separated by the plus sign, namely,

$$(W_a \tau_a L_a | W_b \tau_b L_b + W_c \tau_c L_c) =$$
$$(-1)^t (W_a \tau_a L_a | W_c \tau_c L_c + W_b \tau_b L_b), \qquad (3.24)$$

where $t = L_a - L_b - L_c + x$, with x dependent on the IRs W only; or,
(2) The *reciprocity* relation of *Racah* [3.6]:

$$(W_a \tau_a L_a | W_b \tau_b L_b + W_c \tau_c L_c) =$$
$$(-1)^{t'} [(2L_b + 1) \dim W_a / (2L_a + 1) \dim W_b]^{\frac{1}{2}}$$
$$\times (W_b \tau_b L_b | W_a \tau_a L_a + W_c \tau_c L_c), \qquad (3.25)$$

where $t' = L_a - L_b - L_c + x'$, with x' dependent on the IRs W, but taken to be l by Racah for $W_c = (10 \ldots 0)$.

Reduced matrix elements in SO(3) can be further reduced by the extraction of isoscalar factors. When W_a occurs once in the decomposition of $W \times W_b$ we have

$$\left(\gamma_a W_a \tau_a L_a \| T^{(\mathrm{WL})} \| \gamma_b W_b \tau_b L_b\right) =$$
$$[(2L_a + 1) / \dim W_a]^{\frac{1}{2}} \left(\gamma_a W_a \| | T^{(W)} | \| \gamma_b W_b\right)$$
$$\times (W_b \tau_b L_b + \mathrm{WL} | W_a \tau_a L_a). \qquad (3.26)$$

Analogs of the $n-j$ symbols are discussed by *Butler* [3.58].

3.8 Checks

The existence of numerical checks is useful when using group theory in atomic physics. The CG coefficients, isoscalar factors, and the various generalizations of the $n-j$ symbols are often calculated in ways that conceal the simplicity and structure of the answer. Practitioners are familiar with several empirical rules:

1. Numbers with different irrationalities, such as $\sqrt{2}$ and $\sqrt{3}$, are never added to one another.
2. The denominators of fractions seldom involve high primes.
3. High primes are uncommon, but when they appear, it is usually in diagonal matrix elements rather than off-diagonal ones.

4. A sum of a number of terms frequently factors in what appears to be an unexpected way, and similar sums often exhibit similar factors.

Guided by these rules, one will find that such errors as do arise occur with phases rather than with magnitudes.

4. Dynamical Groups

The well known *symmetry* (*invariance, degeneracy*) *groups* or *algebras* of quantum mechanical Hamiltonians provide quantum numbers (conservation laws, integrals of motion) for state labeling and the associated selection rules. In addition, it is often advantageous to employ much larger groups, referred to as the *dynamical groups* (*noninvariance groups, dynamical algebras, spectrum generating algebras*), which may or may not be the invariance groups of the studied system [4.1–7]. In all known cases, they are Lie groups (LGs), or rather corresponding Lie algebras (LAs), and one usually requires that all states of interest of a system be contained in a single irreducible representation (irrep). Likewise, one may require that the Hamiltonian be expressible in terms of the Casimir operators of the corresponding universal enveloping algebra [4.8, 9]. In a weaker sense, one regards any group (or corresponding algebra) as a dynamical group if the Hamiltonian can be expressed in terms of its generators [4.10–12]. In nuclear physics, one sometimes distinguishes *exact* (baryon number preserving), *almost exact* (e.g., total isospin), *approximate* (e.g., SU(3) of the "eightfold way") and *model* (e.g., nuclear shell model) *dynamical symmetries* [4.13]. The dynamical groups of interest in atomic and molecular physics can be conveniently classified by their topological characteristic of compactness. Noncompact LGs (LAs) generally arise in simple problems involving an infinite number of bound states, while those involving a finite number of bound states (e.g., molecular vibrations or ab

initio models of electronic structure) exploit compact LG's.

We follow the convention of designating Lie groups by capital letters and Lie algebras by lower case letters, e.g., the Lie algebra of the rotation group SO(3) is designated as so(3).

4.1 Noncompact Dynamical Groups

As an illustration we present basic facts concerning LAs that are useful for centrosymmetric Kepler-type problems, their realizations and typical applications. Recall that *a realization* of a LA is a homomorphism associating a concrete set of physically relevant operators with each abstract basis of the given LA. The physical operators we will use are general (intrinsic) position vectors $\boldsymbol{R} = (X_1, X_2, \ldots, X_N)$ in $\mathbb{R}^N$ and their corresponding momenta $\boldsymbol{P} = (P_1, P_2, \ldots, P_N)$, satisfying the basic

commutation relations ($\hbar = 1$)

$$\left[X_j, X_k\right] = \left[P_j, P_k\right] = 0, \quad \left[X_j, P_k\right] = \mathrm{i}\delta_{jk}I .$$

(4.1)

4.1.1 Realizations of so(2,1)

This important LA is a simple noncompact analogue of the well known rotation group LA so(3), (cf. Sects. 2.1 and 3.2). Designating its three generators by T_j ($j = 1, 2, 3$), its structure constants (Sect. 2.1.1 and Sect. 3.1.1) are defined by

$$[T_1, T_2] = \mathrm{i}\gamma T_3 ,$$
$$[T_2, T_3] = \mathrm{i}T_1 ,$$
$$[T_3, T_1] = \mathrm{i}T_2 ,$$

(4.2)

with $\gamma = -1$, while $\gamma = 1$ gives so(3). Defining the so-called ladder (raising and lowering) operators

$$T_\pm = T_1 \pm \mathrm{i}T_2 ,$$

(4.3)

we also have that

$$\left[T_+, T_-\right] = 2\gamma T_3 , \quad \left[T_3, T_\pm\right] = \pm T_3 .$$

(4.4)

The Casimir operator then has the form

$$T^2 = \gamma\left(T_1^2 + T_2^2\right) + T_3^2 = \gamma T_+ T_- + T_3^2 - T_3 .$$

(4.5)

With a Hermitian scalar product satisfying $T_j^\dagger = T_j$ ($j = 1, 2, 3$), so that $T_\pm^\dagger = T_\mp$, the unitary irreps (unirreps) carried by the simultaneous eigenstates of T^2 and T_3 have the form (cf. Sects. 2.1.1 and 2.2)

$$T^2|kq\rangle = k(k+1)|kq\rangle ,$$
$$T_3|kq\rangle = q|kq\rangle ,$$
$$T_\pm|kq\rangle = \sqrt{\gamma(k\mp q)(k\pm q+1)}|k, q\pm 1\rangle .$$

(4.6)

For so(3), ($\gamma = 1$), only finite dimensional irreps $\mathcal{D}^{(k)}$, $k = 0, 1, 2, \ldots$ with $|q| \leq k$ are possible (Sects. 2.2 and 2.3). In contrast, there are no nontrivial finite dimensional unirreps of so(2,1); (for classification, see e.g., [4.2, 14, 15]). The relevant class $\mathcal{D}^+(k)$ of so(2,1) unirreps for bound state problems has a T_3 eigenspectrum bounded from below and is given by $q = -k + \mu$; $\mu = 0, 1, 2, \ldots$, and $k < 0$ or, equivalently, $\mathcal{D}^+(-k-1)$ with $q = k+1+\mu$; $\mu = 0, 1, 2, \ldots$; $k > -1$, since $k_1 = -k - 1$ defines an equivalent unirrep and $k_1(k_1+1) = k(k+1)$. There exists a similar class of irreps with the T_3 spectrum bounded from above and two classes (principal and supplementary)

with unbounded T_3 spectra (which may be exploited in scattering problems).

For problems involving only central potentials, a useful realization is given in terms of the radial distance $R = |\boldsymbol{R}|$ and the radial momentum

$$P_\mathrm{R} = -\frac{\mathrm{i}}{R}\frac{\partial}{\partial R}R = -\mathrm{i}\left(\frac{\partial}{\partial R} + \frac{1}{R}\right)$$
$$= \frac{1}{R}\left(\boldsymbol{R}\cdot\boldsymbol{P} - \mathrm{i}I\right) ,$$

(4.7)

so that $[R, P_\mathrm{R}] = \mathrm{i}I$. Recall that

$$P^2 = P_\mathrm{R}^2 + \frac{L^2}{R^2} , \quad \boldsymbol{L} = \boldsymbol{R}\wedge\boldsymbol{P} .$$

(4.8)

The general form of the desired so(2,1) realization is [4.2, 14–17]

$$\left.\begin{array}{c}T_1\\T_3\end{array}\right\} = \frac{1}{2}R^{-\nu}\left(\nu^{-2}R^2 P_\mathrm{R}^2 + \xi \mp R^{2\nu}\right) ,$$
$$T_2 = \frac{1}{2}\left[2\nu^{-1}R P_\mathrm{R} - \mathrm{i}(1-\nu^{-1})I\right] ,$$

(4.9)

where ξ is either a c-number (scalar operator) or an operator which commutes with both R and P_R, and ν is an arbitrary real number.

To interrelate this realization with so(2,1) unirreps $\mathcal{D}^+(k)$ or $\mathcal{D}^+(-k-1)$, we have to establish the connection between the quantum numbers k, q and the parameters ξ and ν. Considering the Casimir operator T^2 in (4.5), we find that in our realization (4.9)

$$T^2 = \xi + \left(1 - \nu^2\right)/4\nu^2 ,$$

(4.10)

so that

$$k = \frac{1}{2}\left(-1 \pm \sqrt{4\xi + \nu^{-2}}\right)$$

(4.11)

and

$$q = q_0 + \mu , \quad \mu = 0, 1, 2, \ldots$$

(4.12)

where

$$q_0 = k + 1 = \frac{1}{2}\left(1 \pm \sqrt{4\xi + \nu^{-2}}\right) , \quad k > -1 .$$

(4.13)

4.1.2 Hydrogenic Realization of so(4,2)

To obtain suitable hydrogenic realizations of so(4,2) it is best to proceed from so(4) (the dynamical symmetry group for the bound states of the nonrelativistic Kepler problem), and merge it with so(2,1) [4.2, 14, 15].

The so(4) LA can be realized either as a direct sum so(4) = so(3) ⊕ so(3), or by supplementing so(3) with an appropriately scaled quantum mechanical analogue of the Laplace–Runge–Lenz (LRL) vector (cf. Sect. 3.6.2). In the first case, we use two commuting angular momentum vectors $\boldsymbol{M}$ and $\boldsymbol{N}$ (cf. Sect. 2.5),

$$
\begin{aligned}
&\left[M_j, M_k\right] = \mathrm{i}\varepsilon_{jk\ell} M_\ell \,, \quad \left[N_j, N_k\right] = \mathrm{i}\varepsilon_{jk\ell} N_\ell \,, \\
&\left[M_j, N_k\right] = 0 \,, \quad (j, k, \ell = 1, 2, 3)
\end{aligned} \tag{4.14}
$$

while in the second case we use the components of the total angular momentum vector $\boldsymbol{J}$ and LRL-like vector $\boldsymbol{V}$ with commutation relations

$$
\begin{aligned}
&\left[J_j, J_k\right] = \mathrm{i}\varepsilon_{jk\ell} J_\ell \,, \\
&\left[V_j, V_k\right] = \mathrm{i}\sigma\varepsilon_{jk\ell} J_\ell \,, \\
&\left[J_j, V_k\right] = \mathrm{i}\varepsilon_{jk\ell} V_\ell \,, \quad (j, k, \ell = 1, 2, 3) \,,
\end{aligned} \tag{4.15}
$$

with $\sigma = 1$. For $\sigma = -1$ we obtain so(3,1) (the LA of the homogeneous Lorentz group), which is relevant to the scattering problem of a particle in the Coulomb (or Kepler) potential (see below). For $\sigma = 0$ we get e(3) (the LA of the three-dimensional Euclidean group) [4.18–20]. Note that (4.14) and (4.15) are interrelated by

$$
\boldsymbol{M} = \frac{1}{2}(\boldsymbol{J} + \boldsymbol{V}) \,, \quad \boldsymbol{N} = \frac{1}{2}(\boldsymbol{J} - \boldsymbol{V}) \,, \tag{4.16}
$$

so that $\boldsymbol{J} = \boldsymbol{M} \oplus \boldsymbol{N}$ and $\boldsymbol{V} = 2\boldsymbol{M} - \boldsymbol{J}$. The two Casimir operators C_1 and C_2 are

$$
\begin{aligned}
C_1 &= \sigma J^2 + V^2 \\
&= \sigma J_+ J_- + V_+ V_- + V_3^2 + \sigma J_3 (J_3 - 2) \,, \\
C_2 &= (\boldsymbol{V} \cdot \boldsymbol{J}) = (\boldsymbol{J} \cdot \boldsymbol{V}) \\
&= \frac{1}{2}(V_+ J_- + V_- J_+) + V_3 J_3 \,,
\end{aligned} \tag{4.17}
$$

where again

$$
X_\pm = X_1 \pm \mathrm{i} X_2 \,, \quad X = J \text{ or } V \,. \tag{4.18}
$$

For so(3,1) and e(3), only infinite dimensional nontrivial irreps are possible, while for so(4), only finite dimensional ones arise. To get unirreps, we require $\boldsymbol{J}$ and $\boldsymbol{V}$ to be Hermitian. Using $\left\{J^2, J_3, C_1, C_2\right\}$ as a complete set of commuting operators for so(4), we label the basis vectors by the four quantum numbers as $|\gamma jm\rangle \equiv |(j_0, \eta) jm\rangle$, so that

$$
\begin{aligned}
J^2 |\gamma jm\rangle &= j(j+1)|\gamma jm\rangle \,, \\
J_3 |\gamma jm\rangle &= m|\gamma jm\rangle \,, \\
C_1 |\gamma jm\rangle &= \left(j_0^2 - \eta^2 - 1\right)|\gamma jm\rangle \,, \\
C_2 |\gamma jm\rangle &= j_0 \eta |\gamma jm\rangle \,,
\end{aligned} \tag{4.19}
$$

with $2|j_0|$ being a nonnegative integer and

$$
\begin{aligned}
&j = |j_0|, \ |j_0| + 1, \ldots, \eta - 1 \,; \\
&\eta = |j_0| + k \,, \quad k = 1, 2, \ldots
\end{aligned} \tag{4.20}
$$

(see, e.g., [4.17] for the action of $J_\pm$, V_3 and $V_\pm$).

To obtain the hydrogenic (or Kepler) realization of so(4), we consider the quantum mechanical analog of the classical LRL vector

$$
\begin{aligned}
\tilde{\boldsymbol{V}} &= \frac{1}{2}(\boldsymbol{p} \wedge \boldsymbol{L} - \boldsymbol{L} \wedge \boldsymbol{p}) - Z r^{-1}\boldsymbol{r} \\
&= \frac{1}{2}\boldsymbol{r} p^2 - \boldsymbol{p}(\boldsymbol{r} \cdot \boldsymbol{p}) + \boldsymbol{r} H \,, \\
\boldsymbol{L} &= \boldsymbol{r} \wedge \boldsymbol{p} \,,
\end{aligned} \tag{4.21}
$$

which commutes with the hydrogenic Hamiltonian

$$
H = \frac{1}{2}p^2 - Z r^{-1} \,. \tag{4.22}
$$

Note that

$$
\begin{aligned}
&[\boldsymbol{L}, H] = \left[\tilde{\boldsymbol{V}}, H\right] = 0 \,, \\
&\left(\boldsymbol{L} \cdot \tilde{\boldsymbol{V}}\right) = \left(\tilde{\boldsymbol{V}} \cdot \boldsymbol{L}\right) = 0 \,, \\
&\tilde{V}^2 = 2H\left(L^2 + 1\right) + Z^2 \,,
\end{aligned} \tag{4.23}
$$

while the components of $\boldsymbol{L}$ and $\tilde{\boldsymbol{V}}$ satisfy the commutation relations

$$
\begin{aligned}
&\left[L_j, L_k\right] = \mathrm{i}\epsilon_{jk\ell} L_\ell \,, \\
&\left[L_j, \tilde{V}_k\right] = \mathrm{i}\epsilon_{jk\ell} \tilde{V}_\ell \,, \\
&\left[\tilde{V}_j, \tilde{V}_k\right] = (-2H)\mathrm{i}\epsilon_{jk\ell} L_\ell \,.
\end{aligned} \tag{4.24}
$$

Thus, restricting ourselves to a specific bound state energy level E_n, we can replace H by E_n and define

$$
V_j = (-2E_n)^{-1/2}\tilde{V}_j \quad (j = 1, 2, 3) \,, \tag{4.25}
$$

obtaining the so(4) commutation relations (4.15) (with $\boldsymbol{J}$ replaced by $\boldsymbol{L}$). This is Pauli's hydrogenic realization of so(4) [4.21–23]. [In a similar way we can consider continuum states $E > 0$ and define $\boldsymbol{V} = (2E)^{-1/2}\tilde{\boldsymbol{V}}$, obtaining an so(3,1) realization.] The last identity of (4.23) now becomes

$$
V^2 = -\left(L^2 + 1\right) - Z^2/2E_n \,, \tag{4.26}
$$

which immediately implies Bohr's formula, since $V^2 + L^2 = 4M^2 = -1 - Z^2/2E_n$, so that

$$
E_n = -Z^2/2(2j_1 + 1)^2 = -Z^2/2n^2 \,, \tag{4.27}
$$

where $n = 2j_1 + 1$ and j_1 is the angular momentum quantum number for $\boldsymbol{M}$, (4.16). In terms of the ir-

rep labels (4.20), we have that $j_0 = 0$, $\eta = n$, so that $|\gamma \ell m\rangle = |(0, n)\ell m\rangle \equiv |n\ell m\rangle$, $\ell = 0, 1, \ldots, n - 1$.

Using the stepwise merging of so(4) and so(2,1) [adding first T_2 which leads to so(4,1) and subsequently T_1 and T_3], we arrive at the hydrogenic realization of so(4,2) having fifteen generators $\boldsymbol{L}$, $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{\Gamma}$, T_1, T_2, T_3, namely (cf. [4.2, 14, 15, 17])

$$\boldsymbol{L} = \boldsymbol{R} \wedge \boldsymbol{P} ,$$

$$\left.\begin{array}{c}\boldsymbol{A}\\\boldsymbol{B}\end{array}\right\} = \frac{1}{2}\boldsymbol{R}P^2 - \boldsymbol{P}(\boldsymbol{R} \cdot \boldsymbol{P}) \mp \boldsymbol{R} ,$$

$$\boldsymbol{\Gamma} = \boldsymbol{R}P ,$$

$$\left.\begin{array}{c}T_1\\T_3\end{array}\right\} = \frac{1}{2}\left(RP^2 \mp R\right) = \frac{1}{2}\left(RP_{\mathrm{R}}^2 + L^2 R^{-1} \mp R\right) ,$$

$$T_2 = \boldsymbol{R} \cdot \boldsymbol{P} - \mathrm{i}I = RP_{\mathrm{R}} . \qquad (4.28)$$

Relabeling these generators by the elements of an anti-symmetric 6×6 matrix according to the scheme

$$L_{jk} \leftrightarrow \begin{pmatrix} 0 & L_3 & -L_2 & A_1 & B_1 & \Gamma_1 \\ & 0 & L_1 & A_2 & B_2 & \Gamma_2 \\ & & 0 & A_3 & B_3 & \Gamma_3 \\ & & & 0 & T_2 & T_1 \\ & & & & 0 & T_3 \\ & & & & & 0 \end{pmatrix} \qquad (4.29)$$

we can write the commutation relations in the following standard form

$$\begin{aligned}\left[L_{jk}, L_{\ell m}\right] = \\ \mathrm{i}\left(g_{j\ell}L_{km} + g_{km}L_{j\ell} - g_{k\ell}L_{jm} - g_{jm}L_{k\ell}\right) ,\end{aligned}$$
$$(4.30)$$

with the diagonal metric tensor g_{jk} defined by the matrix $G = \mathrm{diag}[1, 1, 1, 1, -1, -1]$. The matrix form (4.29) also implies the subalgebra structure

$$\mathrm{so}(4, 2) \supset \mathrm{so}(4, 1) \supset \mathrm{so}(4) \supset \mathrm{so}(3) , \qquad (4.31)$$

with so(4,1) generated by $\boldsymbol{L}$, $\boldsymbol{A}$, $\boldsymbol{B}$ and T_2, and so(4) by $\boldsymbol{L}$, $\boldsymbol{A}$. [$\boldsymbol{L}$, $\boldsymbol{B}$ also generate so(3,1).]

The three independent Casimir operators (quadratic, cubic and quartic) are [4.24], (summation over all indices is implied)

$$\begin{aligned}Q_2 &= \frac{1}{2}L_{jk}L^{jk} \\ &= L^2 + A^2 - B^2 - \Gamma^2 + T_3^2 - T_1^2 - T_2^2 , \\ Q_3 &= \frac{1}{48}\varepsilon_{ijk\ell mn}L^{ij}L^{k\ell}L^{mn} \\ &= T_1(\boldsymbol{B} \cdot \boldsymbol{L}) + T_2(\boldsymbol{\Gamma} \cdot \boldsymbol{L}) + T_3(\boldsymbol{A} \cdot \boldsymbol{L}) \\ &\quad + \boldsymbol{A} \cdot (\boldsymbol{B} \wedge \boldsymbol{\Gamma}) , \\ Q_4 &= L_{jk}L^{k\ell}L_{\ell m}L^{mj} . \end{aligned} \qquad (4.32)$$

For our hydrogenic realization $Q_2 = -3$, $Q_3 = Q_4 = 0$. Thus, our hydrogenic realization implies a single unirrep of so(4,2) adapted to the chain (4.31).

4.2 Hamiltonian Transformation and Simple Applications

The basic idea is to transform the relevant Schrödinger equation into an eigenvalue problem for one of the operators from the complete set of commuting operators in our realizations, e.g., T_3 for so(2,1). Instead of using a rather involved "tilting" transformation ([4.1, p. 20], and [4.2, 14, 15]), we can rely on a simple scaling transformation [4.16, 25]

$$\boldsymbol{r} = \lambda \boldsymbol{R} , \quad \boldsymbol{p} = \lambda^{-1}\boldsymbol{P} , \quad r = \lambda R , \quad p_{\mathrm{r}} = \lambda^{-1}P_{\mathrm{R}} , \qquad (4.33)$$

where

$$r = \left(\sum_{j=1}^{N} x_j^2\right)^{1/2} , \qquad (4.34)$$

and

$$p^2 = p_{\mathrm{r}}^2 + r^{-2}\left[\frac{1}{4}(N-1)(N-3) + L^2\right] , \qquad (4.35)$$

with p_{r} defined analogously to P_{R} in (4.7); r and p are the physical operators in terms of which the Hamiltonian of the studied system is expressed. Recall that L^2 has eigenvalues [4.26]

$$\ell(\ell + N - 2) , \quad \ell = 0, 1, 2, \ldots \quad \text{for} \quad N \geq 2 , \qquad (4.36)$$

and we can set $\ell = 0$ for $N = 1$ (angular momentum term vanishes in one-dimensional case). The units in which $m = e = \hbar = 1$, $c \approx 137$ are used throughout.

4.2.1 *N*–Dimensional Isotropic Harmonic Oscillator

Considering the Hamiltonian

$$H = \frac{1}{2}p^2 + \frac{1}{2}\omega^2 r^2 , \qquad (4.37)$$

with p^2 in the form (4.35), transforming the corresponding Schrödinger equation using the scaling transformation (4.33) and multiplying by $\frac{1}{4}\lambda^2$, we get for the radial component

$$\frac{1}{2}\left(\frac{1}{4}P_R^2 + R^{-2}\xi + \frac{1}{4}\omega^2\lambda^4 R^2 - \frac{1}{2}\lambda^2 E\right)\psi_R(\lambda R) = 0, \tag{4.38}$$

with

$$\xi = \frac{1}{16}(N-1)(N-3) + \frac{1}{4}\ell(\ell+N-2). \tag{4.39}$$

Choosing λ such that $(\omega/2)^2\lambda^4 = 1$, we can rewrite (4.38) using the so(2,1) realization (4.9) with $\nu = 2$ as

$$\left(T_3 - \frac{1}{4}\lambda^2 E\right)\psi_R(\lambda R) = 0. \tag{4.40}$$

Thus, using the second equation of (4.6) we can interrelate $\psi_R(\lambda R)$ with $|kq\rangle$ and set $\frac{1}{4}\lambda^2 E = q$, so that

$$E = 4q/\lambda^2 = 2q\omega, \tag{4.41}$$

with q given by (4.12) and (4.13), i. e.,

$$q = q_0 + \mu, \quad \mu = 0, 1, 2, \ldots \tag{4.42}$$

and

$$q_0 = k + 1 = \frac{1}{2}\left[1 \pm \left(\ell + \frac{1}{2}N - 1\right)\right]. \tag{4.43}$$

Now, for $N = 1$ we set $\ell = 0$ so that $q_0 = \frac{1}{4}$ and $q_0 = \frac{3}{4}$, yielding for $E = 2q\omega$ the values $\left(\frac{1}{2} + 2\mu\right)\omega$ and $\left(\frac{1}{2} + 2\mu + 1\right)\omega$, $\mu = 0, 1, 2, \ldots$. Combining both sets we thus get for $N = 1$ the well known result

$$E \equiv E_n = \left(n + \frac{1}{2}\right)\omega, \quad n = 0, 1, 2, \ldots. \tag{4.44}$$

Similarly, for the general case $N \geq 2$ we choose the upper sign in (4.43) [so that $k > -1$] and get

$$E \equiv E_n = \left(n + \frac{1}{2}N\right)\omega, \quad n = 0, 1, 2, \ldots \tag{4.45}$$

where we identified $(\ell + 2\mu)$ with the principal quantum number n.

4.2.2 *N*–Dimensional Hydrogenic Atom

Applying the scaling transformation (4.33) to the hydrogenic Hamiltonian (4.22) in *N*-dimensions, we get for the radial component (after multiplying from the left by $\lambda^2 R$)

$$\left[\frac{1}{2}\left(RP_R^2 + R^{-1}\xi - 2\lambda^2 ER\right) - \lambda\mathcal{Z}\right]\psi_R(\lambda R) = 0, \tag{4.46}$$

where now

$$\xi = \frac{1}{4}(N-1)(N-3) + \ell(\ell+N-2). \tag{4.47}$$

In this case we must set $2\lambda^2 E = -1$ and use realization (4.9) with $\nu = 1$ to obtain

$$(T_3 - \lambda\mathcal{Z})\psi_R(\lambda R) = 0. \tag{4.48}$$

This immediately implies that

$$\lambda\mathcal{Z} = q \tag{4.49}$$

and

$$q_0 = k + 1 = \frac{1}{2}[1 \pm (2\ell + N - 2)]. \tag{4.50}$$

Choosing the upper sign [since $\ell \geq 0$ and $k > -1$], so that $q_0 = \ell + \frac{1}{2}(N-1)$, and identifying q with the principal quantum number n, we have finally that

$$E \equiv E_n = -\frac{1}{2\lambda^2} = -\frac{\mathcal{Z}^2}{2n^2}. \tag{4.51}$$

The *N*-dimensional relativistic hydrogenic atom can be treated in the same way, using either the Klein–Gordon or Dirac–Coulomb equations [4.2, 14–17].

4.2.3 **Perturbed Hydrogenic Systems**

The so(4,2) based Lie algebraic formalism can be conveniently exploited to carry out large order perturbation theory (see [4.27–29] and Chapt. 5) for hydrogenic systems described by the Schrödinger equation

$$[H_0 + \varepsilon V(r)]\psi(r) = (E_0 + \Delta E)\psi(r), \tag{4.52}$$

with H_0 given by (4.22) and E_0 by E of (4.51). Applying transformation (4.33), using (4.49), (4.51) and multiplying on the left by $\lambda^2 R$, we get

$$\left[\frac{1}{2}RP^2 - q + \frac{1}{2}R + \varepsilon\lambda^2 RV(\lambda R) - \lambda^2 R\Delta E\right]\Psi(R)$$
$$= 0, \tag{4.53}$$

where we set $\psi(\lambda R) \equiv \Psi(R)$. For the important case of a 3-dimensional hydrogenic atom [$N = 3$, $\xi = \ell(\ell + 1)$, $q \equiv n$] we get using the so(4,2) realization (4.28) [or so(2,1) realization (4.9) with $\nu = 1$]

$$(K + \varepsilon W - S\Delta E)\Psi(R) = 0, \tag{4.54}$$

with

$$K = T_3 - n \, ,$$
$$W = \lambda^2 R V(\lambda \boldsymbol{R}) \, ,$$
$$S = \lambda^2 R \, . \tag{4.55}$$

We also have that $\lambda = n/\mathcal{Z}$ and for the ground state case $n = q = 1$. Although (4.54) has the form of a generalized eigenvalue problem requiring perturbation theory formalism with a nonorthogonal basis (where S represents an overlap), T_3 is Hermitian with respect to a $(1/R)$ scalar product, and the required matrix elements can therefore be easily evaluated [4.2, 14, 15, 17, 27–29].

For central field perturbations, $V(\boldsymbol{r}) = V(r)$, the problem reduces to one dimension and since $R = T_3 - T_1$, the so(2,1) hydrogenic realization ($\nu = 1$) can be employed. For problems of a hydrogenic atom in a magnetic field (Zeeman effect) [4.27–30] or a one-electron diatomic ion [4.31], the so(4,2) formalism is required (note, however, that the LoSurdo–Stark effect can also be treated as a one-dimensional problem using parabolic coordinates [4.32]).

The main advantage of the LA approach stems from the fact that the spectrum of T_3 is discrete, so that no integration over continuum states is required. Moreover, the relevant perturbations are closely packed around the diagonal in this representation, so that infinite sums are replaced by small finite sums.

For example, for the LoSurdo–Stark problem when $V(\boldsymbol{r}) = \mathcal{F} z$, where $\mathcal{F}$ designates electric field strength in the z-direction, we get (4.54) with $\varepsilon = \mathcal{F}$ and $W = (n/\mathcal{Z})^3 R Z$, $S = (n/\mathcal{Z})^2 R$. Since both R and

Z are easily expressed in terms of so(4,2) generators,

$$Z = B_3 - A_3 \, , \quad R = T_3 - T_1 \, , \tag{4.56}$$

we can easily compute all the required matrix elements [4.2, 14, 15, 17].

Similarly, considering the Zeeman effect with

$$V(\boldsymbol{r}) = \frac{1}{2} \mathcal{B} L_3 + \frac{1}{8} \mathcal{B}^2 \left(r^2 - z^2 \right) \, , \tag{4.57}$$

where $\mathcal{B}$ designates magnetic field strength in the z-direction, we have for the ground state when $n = 1$, $\ell = m = 0$ that $\varepsilon = \frac{1}{8} \mathcal{B}^2$, $K = T_3 - 1$, $W = \mathcal{Z}^{-4} R(R^2 - Z^2)$ and $S = \mathcal{Z}^{-2} R$. Again, the matrix elements of W and S are obtained from those of Z and R, (4.56) by matrix multiplication (for tables and programs, see [4.17]).

One can treat one-electron diatomic ions [4.2, 14, 15, 31] and screened Coulomb potentials, including charmonium and harmonium [4.10–12, 17, 33, 34], in a similar way.

Note, finally, that we can also formulate the perturbed problem (4.54) in a standard form not involving the "overlap" by defining the scaling factor as $\lambda = (-2E)^{-1/2}$, where E is now the exact energy $E = E_0 + \Delta E$. Equation (4.54) then becomes

$$(T_3 + \varepsilon W - \lambda \mathcal{Z}) \Psi(\boldsymbol{R}) = 0 \, , \tag{4.58}$$

with the eigenvalue $\lambda \mathcal{Z}$. In this case any conventional perturbation formalism applies, but the desired energy has to be found from $\lambda \mathcal{Z}$ [4.35].

4.3 Compact Dynamical Groups

Unitary groups U(n) and their LAs often play the role of (compact) dynamical groups since

1. quantum mechanical observables are Hermitian and the LA of U(n) is comprised of Hermitian operators [under the exp(iA) mapping],
2. any compact Lie group is isomorphic to a subgroup of some U(n),
3. "nothing of algebraic import is lost by the unitary restriction" [4.36].

All U(n) irreps have finite dimension and are thus relevant to problems involving a finite number of bound states [4.3–6, 10–12, 36–43].

4.3.1 Unitary Group and Its Representations

The unitary group U(n) has n^2 generators E_{ij} spanning its LA and satisfying the commutation relations

$$\left[E_{ij}, E_{k\ell} \right] = \delta_{jk} E_{i\ell} - \delta_{i\ell} E_{kj} \tag{4.59}$$

and the Hermitian property

$$E_{ij}^\dagger = E_{ji} \, . \tag{4.60}$$

They are classified as *raising* ($i < j$), *lowering* ($i > j$) and *weight* ($i = j$) generators according to whether they

raise, lower and preserve the weight, respectively. The *weight vector* is a vector of the carrier space of an irrep which is a simultaneous eigenvector of all weight generators E_{ii} of U(n) (comprising its Cartan subalgebra), and the vector $\boldsymbol{m} = (m_1, m_2, \ldots, m_n)$ with integer components, consisting of corresponding eigenvalues, is called a *weight*. The *highest weight* $\boldsymbol{m}_n$ (in lexical ordering),

$$\boldsymbol{m}_n = (m_{1n}, m_{2n}, \ldots, m_{nn}) , \tag{4.61}$$

with

$$m_{1n} \geq m_{2n} \geq \cdots \geq m_{nn} , \tag{4.62}$$

uniquely labels U(n) irreps, $\Gamma(\boldsymbol{m}_n)$, and may be represented by a Young pattern. Subducing $\Gamma(\boldsymbol{m}_r)$ of U(r) to U($r-1$), embedded as U($r-1$) $\oplus$ 1 in U(r), gives [4.41]

$$\Gamma(\boldsymbol{m}_r) \downarrow \mathrm{U}(r-1) = \bigoplus \Gamma(\boldsymbol{m}_{r-1}) , \tag{4.63}$$

where the sum extends over all U($r-1$) weights $\boldsymbol{m}_{r-1} = (m_{1,r-1}, m_{2,r-1}, \ldots m_{r-1,r-1})$ satisfying the so-called "betweenness conditions" [4.38]

$$m_{ir} \geq m_{i,r-1} \geq m_{i+1,r} \qquad (i=1,\ldots,r-1) . \tag{4.64}$$

Two irreps $\Gamma(\boldsymbol{m}_n)$ and $\Gamma(\boldsymbol{m}'_n)$ of U(n) yield the same irrep when restricted to SU(n) if $m_i = m'_i + h$, $i = 1, \ldots, n$. The SU(n) irreps are thus labeled with highest weights with $m_{nn} = 0$. The dimension of $\Gamma(\boldsymbol{m}_n)$ of U(n) is given by the Weyl dimension formula [4.36]

$$\dim \Gamma(\boldsymbol{m}_n) =$$
$$\prod_{i<j} \left(m_{in} - m_{jn} + j - i \right) \Big/ 1!2!\cdots(n-1)! . \tag{4.65}$$

The U(n) Casimir operators have the form

$$C_k^{\mathrm{U}(n)} = \sum_{i_1,i_2,\ldots,i_k=1}^{n} E_{i_1 i_2} E_{i_2 i_3} \cdots E_{i_{k-1} i_k} E_{i_k i_1} . \tag{4.66}$$

The first order Casimir operator is given by the sum of weight generators and equals the sum of the highest weight components.

Since U(1) is Abelian, the *Gel'fand-Tsetlin* [4.42] canonical chain (Sect. 3.4.3)

$$\mathrm{U}(n) \supset \mathrm{U}(n-1) \supset \cdots \supset \mathrm{U}(1) \tag{4.67}$$

can be used to label uniquely the basis vectors of the carrier space of $\Gamma(\boldsymbol{m}_n)$ by triangular Gel'fand tableaux

[m] defined by

$$[m] = \begin{bmatrix} \boldsymbol{m}_n \\ \boldsymbol{m}_{n-1} \\ \cdots \\ \cdots \\ \boldsymbol{m}_2 \\ \boldsymbol{m}_1 \end{bmatrix} = \begin{bmatrix} m_{1n} & m_{2n} & \cdots\cdots & m_{nn} \\ & m_{1,n-1} \cdots\cdots m_{n-1,n-1} \\ & & \cdots \\ & & \cdots \\ & & m_{12} \, m_{22} \\ & & m_{11} \end{bmatrix} , \tag{4.68}$$

with entries satisfying betweenness conditions (4.64). Matrix representatives of weight generators are diagonal

$$\langle [m'] | E_{ii} | [m] \rangle = \delta_{[m],[m']} \left(\sum_{j=1}^{i} m_{ji} - \sum_{j=1}^{i-1} m_{j,i-1} \right) , \tag{4.69}$$

while those for other generators are rather involved [4.42, 43]. Note that only elementary ($E_{i,i+1}$) raising generators are required since

$$\langle [m'] | E_{ij} | [m] \rangle = \langle [m] | E_{ji} | [m'] \rangle \tag{4.70}$$

and

$$E_{ij} = \left[E_{i,i+1}, E_{i+1,j} \right] . \tag{4.71}$$

In special cases required in applications ([4.39, 40] and Sect. 4.3.4) efficient algorithms exist for the computation of explicit representations.

4.3.2 Orthogonal Group O(n) and Its Representations

Since O(n) is a proper subgroup of U(n), its representation theory has a similar structure. The suitable generators are

$$F_{ij} = E_{ij} - E_{ji} , \quad F_{ji} = -F_{ij} ,$$
$$F_{ii} = 0 , \qquad\qquad F_{ij}^{\dagger} = -F_{ji} \tag{4.72}$$

and satisfy the commutation relations

$$\left[F_{ij}, F_{k\ell} \right] = \delta_{jk} F_{i\ell} + \delta_{i\ell} F_{jk} - \delta_{ik} F_{j\ell} - \delta_{j\ell} F_{ik} . \tag{4.73}$$

The canonical chain has the form

$$\mathrm{O}(n) \supset \mathrm{O}(n-1) \supset \cdots \supset \mathrm{O}(2) . \tag{4.74}$$

The components of the highest weight $\boldsymbol{m}_n$,

$$\boldsymbol{m}_n = (m_{1n}, m_{2n}, \ldots, m_{kn}) , \tag{4.75}$$

satisfy the conditions

$$m_{1n} \geq m_{2n} \geq \cdots \geq m_{kn} \geq 0 \quad \text{for} \quad n = 2k + 1 ,$$
(4.76)

and

$$m_{1n} \geq m_{2n} \geq \cdots \geq |m_{kn}| \quad \text{for} \quad n = 2k , \qquad (4.77)$$

where m_{in} are simultaneously integers or half-odd integers. The former are referred to as *tensor representations* (since they arise as tensor products of fundamental irreps), while those with half-odd integer components are called *spinor representations*. Note that for $n = 2k$, we have two lowest (mirror-conjugated) spinor representations, namely $\boldsymbol{m}^{(+)} = (\frac{1}{2}, \frac{1}{2}, \dots, \frac{1}{2})$ and $\boldsymbol{m}^{(-)} = (\frac{1}{2}, \dots, \frac{1}{2}, -\frac{1}{2})$. Only tensor representations can be labeled by Young tableaux.

Subducing O(n) to O($n-1$), the betweenness conditions (branching rules) have the form

$$m_{in} \geq m_{i,n-1} \geq m_{i+1,n} \quad (i = 1, \dots, k-1) \quad (4.78)$$

together with

$$m_{k,2k+1} \geq |m_{k,2k}| \qquad (4.79)$$

when $n = 2k + 1$. The $m_{i,n-1}$ components are integral (half-odd integral) if the m_{in} are integral (half-odd integral). The U(n) ⊃ O(n) [or SU(n) ⊃ SO(n)] subduction rules are more involved [4.44].

4.3.3 Clifford Algebras and Spinor Representations

While all reps of U(n) or SL(n) arise as tensor powers of the standard rep, only half of the reps of SO(m) or O(m) arise this way, since SO(m) is not simply connected when $m > 2$. A double covering of SO(m) leads to *spin groups* Spin(m). The best way to proceed is, however, to construct the so-called *Clifford algebras* C_m, whose multiplicative group (consisting of invertible elements) contains a subgroup which provides a double cover of SO(m). The key fact is that C_{2k} is isomorphic with gl(2^k) and C_{2k+1} with gl(2^k) ⊕ gl(2^k). The reps of C_m thus provide the required *spinor reps*.

A Clifford algebra C_m is an associative algebra generated by *Clifford numbers* α_i satisfying the anticommutation relations

$$\{\alpha_i, \alpha_j\} = 2\delta_{ij} \quad (i, j = 1, \dots, m) . \qquad (4.80)$$

Since $\alpha_i^2 = 1$, dim $C_m = 2^m$ and a general element of C_m is a product of Clifford numbers $\alpha_1^{\nu_1} \alpha_2^{\nu_2} \cdots \alpha_m^{\nu_m}$ with $\nu_i = 0$ or 1.

To see the relation with so($m + 1$), note that

$$F_{0k} = -\frac{1}{2} \mathrm{i}\alpha_k , \quad F_{jk} = \frac{1}{4}[\alpha_j, \alpha_k] = \frac{1}{2}\alpha_j\alpha_k ,$$
$$(j \neq k)$$
(4.81)

satisfy the commutation relations (4.73).

As an example, C_2 can be realized by Pauli matrices by setting

$$\alpha_1 = \boldsymbol{\sigma}_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} , \quad \alpha_2 = \boldsymbol{\sigma}_2 = \begin{pmatrix} 0 & \mathrm{i} \\ -\mathrm{i} & 0 \end{pmatrix} .$$
(4.82)

Clearly, the four matrices $\mathbf{1}_2, \alpha_1, \alpha_2$ and $\alpha_1\alpha_2$ are linearly independent (note that $\boldsymbol{\sigma}_3 = \mathrm{i}\boldsymbol{\sigma}_1\boldsymbol{\sigma}_2$), so that C_2 is isomorphic to gl(2, $\mathbb{C}$).

Similarly, considering Dirac–Pauli matrices

$$\boldsymbol{\gamma}_0 = \begin{pmatrix} -\mathrm{i}\mathbf{1}_2 & \mathbf{0} \\ \mathbf{0} & -\mathrm{i}\mathbf{1}_2 \end{pmatrix} = \mathrm{i}\boldsymbol{\gamma}_4 ,$$

$$\boldsymbol{\gamma}_k = \begin{pmatrix} \mathbf{0} & \mathrm{i}\boldsymbol{\sigma}_k \\ -\mathrm{i}\boldsymbol{\sigma}_k & \mathbf{0} \end{pmatrix} , \quad (k = 1, 2, 3) \qquad (4.83)$$

we have that

$$\{\boldsymbol{\gamma}_i, \boldsymbol{\gamma}_j\} = 2\delta_{ij}, \quad (i, j = 1, \dots, 4) \qquad (4.84)$$

so that $\boldsymbol{\gamma}_i$ $(i = 1, \dots, 4)$ or $(i = 0, \dots, 3)$ represent Clifford numbers for C_4 and $\mathbf{1}_4, \boldsymbol{\gamma}_i, \boldsymbol{\gamma}_i\boldsymbol{\gamma}_j$ $(i < j), \boldsymbol{\gamma}_i\boldsymbol{\gamma}_j\boldsymbol{\gamma}_k$ $(i < j < k)$ and $\boldsymbol{\gamma}_5 \equiv \boldsymbol{\gamma}_1\boldsymbol{\gamma}_2\boldsymbol{\gamma}_3\boldsymbol{\gamma}_4 = \mathrm{i}\boldsymbol{\gamma}_0\boldsymbol{\gamma}_1\boldsymbol{\gamma}_2\boldsymbol{\gamma}_3$ form an additive basis for gl(4, $\mathbb{C}$) (the $\boldsymbol{\gamma}_i$ themselves are said to form a *multiplicative basis*). For general construction of C_m Clifford numbers in terms of direct products of Pauli matrices see [4.45, 46].

4.3.4 Bosonic and Fermionic Realizations of U(n)

Designating by $b_i^\dagger$ (b_i) the boson creation (annihilation) operators (Sect. 6.1.1) satisfying the commutation relations $[b_i, b_j] = [b_i^\dagger, b_j^\dagger] = 0$, $[b_i, b_j^\dagger] = \delta_{ij}$, we obtain a possible U(n) realization by defining its n^2 generators as follows

$$G_{ij} = b_i^\dagger b_j . \qquad (4.85)$$

The first order Casimir operator, (4.66) with $k = 1$, then represents the total number operator

$$\hat{N} \equiv C_1^{\mathrm{U}(n)} = \sum_{i=1}^n G_{ii} = \sum_{i=1}^n b_i^\dagger b_i , \qquad (4.86)$$

and the physically relevant states, being totally symmetric, carry single row irreps $\Gamma(N\dot{0}) \equiv \Gamma(N0\cdots 0)$.

Similarly for fermion creation (annihilation) operators $X_I^\dagger(X_I)$ that are associated with some orthonormal spin orbital set $\{|I\rangle\}$, $I = 1, 2, \ldots, 2n$, and satisfy the anticommutation relations $\{X_I, X_J\} = \{X_I^\dagger, X_J^\dagger\} = 0$, $\{X_I, X_J^\dagger\} = \delta_{IJ}$, the operators

$$e_{IJ} = X_I^\dagger X_J \tag{4.87}$$

again represent the U(2n) generators satisfying (4.59) and (4.60). The first-order Casimir then represents the total number operator $\hat{N} = \sum_I X_I^\dagger X_I$, while the possible physical states are characterized by totally antisymmetric single column irreps $\Gamma(1^N \dot{0}) \equiv \Gamma(11\cdots 1\,0\cdots 0)$.

4.3.5 Vibron Model

Similar to the unified description of nuclear collective rovibrational states using the interacting boson model [4.47–49], one can build an analogous model for molecular rotation-vibration spectra [4.8]. For diatomics, an appropriate dynamical group is U(4) [4.8, 50–52] and, generally, for rotation-vibration spectra in r-dimensions one requires U($r+1$). For triatomics, the U(4) generating algebra is generalized to U(4) ⊗ U(4), and for the $(k+1)$ atomic molecule to $U^{(1)}(4) \otimes \cdots \otimes U^{(k)}(4)$ [4.8, 50–52].

For the bosonic realization of U(4), we need four creation $(b_i^\dagger, i = 1, \ldots, 4)$ and four annihilation (b_i) operators (Sect. 4.3.4). The Hamiltonian may be generally expressed as a multilinear form in terms of boson number preserving products $(b_i^\dagger b_j)$, so that using (4.85) we can write

$$H = h^{(0)} + \sum_{ij} h_{ij}^{(1)} G_{ij} + \frac{1}{2} \sum_{ijk\ell} h_{ijk\ell}^{(2)} G_{ij} G_{k\ell} + \cdots.$$
$$\tag{4.88}$$

The energy levels (as a function of $0, 1, 2, \ldots$-body matrix elements h^0, $h_{ij}^{(1)}$, $h_{ijk\ell}^{(2)}$, etc.) are then determined by diagonalizing H in an appropriate space, which is conveniently provided by the carrier space of the totally symmetric irrep $\Gamma(N\,0\,0\,0) \equiv \Gamma(N\dot{0})$ of U(4).

The requirement that the resulting states be characterized by angular momentum J and parity P quantum numbers necessitates that the boson operators involved have definite transformation properties under rotations and reflections [4.8]. The boson operators are thus subdivided into the scalar operators $(\sigma^\dagger, \sigma)$, $J = 0$, and vector operators $(\pi_\mu^\dagger, \pi_\mu; \mu = 0, \pm 1)$, $J = 1$ with parity $P = (-)^J$. All commutators vanish except

for

$$[\sigma, \sigma^\dagger] = 1, \quad [\pi_\mu, \pi_{\mu'}^\dagger] = \delta_{\mu\mu'}. \tag{4.89}$$

Since H preserves the total number of vibrons $N = n_\sigma + n_\pi$, the second order Hamiltonian (4.88) within the irrep $\Gamma(N\dot{0})$ can be expressed in terms of four independent parameters (apart from an overall constant) as

$$H = e^{(0)} + e^{(1)} \left[\pi^\dagger \times \tilde{\pi}\right]_0^{(0)}$$
$$+ e_1^{(2)} \left[\left[\pi^\dagger \times \pi^\dagger\right]^{(0)} \times \left[\tilde{\pi} \times \tilde{\pi}\right]^{(0)}\right]_0^{(0)}$$
$$+ e_2^{(2)} \left[\left[\pi^\dagger \times \pi^\dagger\right]^{(2)} \times \left[\tilde{\pi} \times \tilde{\pi}\right]^{(2)}\right]_0^{(0)}$$
$$+ e_3^{(2)} \left[\left[\pi^\dagger \times \pi^\dagger\right]^{(0)} \times \left[\tilde{\sigma} \times \tilde{\sigma}\right]^{(0)}\right]$$
$$+ \left[\sigma^\dagger \times \sigma^\dagger\right]^{(0)} \times \left[\tilde{\pi} \times \tilde{\pi}\right]^{(0)}\Big]_0^{(0)} + \cdots, \tag{4.90}$$

where $\tilde{\sigma} = \sigma$, $\tilde{\pi}_\mu = (-)^{1-\mu}\pi_{-\mu}$ and square brackets indicate the SU(2) couplings.

In special cases the eigenvalue problem for H can be solved analytically, assuming that H can be expressed in terms of Casimir operators of a complete chain of subgroups of U(4) [referred to as dynamical symmetries]. Requiring that the chain contain the physical rotation group O(3), one has two possibilities

$$(I) \qquad U(4) \supset O(4) \supset O(3) \supset O(2),$$
$$(II) \qquad U(4) \supset U(3) \supset O(3) \supset O(2). \tag{4.91}$$

These imply labels (quantum numbers): N [total vibron number defining a totally symmetric irrep of U(4)], $\omega = N$, $N-2$, $N-4$, $\ldots$, 1 or 0 [defining a totally symmetric irrep of O(4)] and $n_\pi = N$, $N-1$, $\ldots$, 0 [defining the U(3) irrep], in addition to the O(3) ⊃ O(2) labels J, M; $|M| \le J$. In terms of these labels one finds for the respective Hamiltonians

$$H^{(I)} = F + A\,C_2^{O(4)} + B\,C_2^{O(3)},$$
$$H^{(II)} = F + \varepsilon C_1^{U(3)} + \alpha C_2^{U(3)} + \beta C_2^{O(3)}, \tag{4.92}$$

where F, A, B, ε, α, β are free parameters and $C_i^{U(k)}$, $C_i^{O(k)}$ are relevant Casimir operators, the following expressions [4.8, 50–52] for their eigenvalues

$$E^{(I)}(N, \omega, J, M) = F + A\omega(\omega + 2) + BJ(J+1),$$
$$E^{(II)}(N, n_\pi, J, M) = F + \epsilon n_\pi + \alpha n_\pi(n_\pi + 3)$$
$$+ \beta J(J+1). \tag{4.93}$$

The limit (I) is appropriate for rigid diatomics and limit (II) for nonrigid ones [4.8, 50–52].

In addition to handling di- and tri-atomic systems, the vibron model was also applied to the overtone spectrum of acetylene [4.53], intramolecular relaxation in benzene and its dimers [4.54, 55], octahedral molecules of the XF_6 type (X = S, W, and U) [4.56], and to linear polyatomics [4.57]. Most recently, the experimental (dispersed fluorescence and stimulated emission pumping) vibrational spectra of H_2O and SO_2 in their ground states, representing typical local-mode and normal-mode molecules, respectively, have been analyzed, including highly excited levels, by relying on the U(2) algebraic effective Hamiltonian approach [4.58–60]. The U(2) algebraic scheme [4.61] also enabled the treatment of Franck–Condon transition intensities [4.62, 63] in rovibronic spectra. The attempts at a similar heuristic phenomenological description of electronic spectra have met so-far with only a limited success [4.64].

4.3.6 Many–Electron Correlation Problem

In atomic and molecular electronic structure calculations one employs a spin-independent model Hamiltonian

$$H = \sum_{i,j} h_{ij} \sum_{\sigma=1}^{2} X_{i\sigma}^{\dagger} X_{j\sigma}$$
$$+ \frac{1}{2} \sum_{i,j,k,\ell} v_{ij,k\ell} \sum_{\sigma,\tau=1}^{2} X_{i\sigma}^{\dagger} X_{j\tau}^{\dagger} X_{\ell\tau} X_{k\sigma} , \quad (4.94)$$

where $X_I^{\dagger} \equiv X_{i\sigma}^{\dagger}$ (X_I) designate the creation (annihilation) operators associated with the orthonormal spin orbitals $|I\rangle \equiv |i\sigma\rangle = |i\rangle \otimes |\sigma\rangle$; $i = 1, \ldots, n$; $\sigma = 1, 2$ [$\sigma = 1, 2$ labeling the spin-up and spin-down eigenstates of S_z], and $h_{ij} = \langle i|\hat{h}|j\rangle$, $v_{ij,k\ell} = \langle i(1) j(2)|\hat{v}|k(1)\ell(2)\rangle$ are the one- and two-electron integrals in the orbital basis $\{|i\rangle\}$. As stated in Sect. 4.3.4, $e_{IJ} \equiv e_{i\sigma,j\tau} = X_{i\sigma}^{\dagger} X_{j\tau}$ may then be regarded as U(2n) generators, and the appropriate U(2n) irrep for N-electron states is $\Gamma(1^N\dot{0})$.

Similar to the nuclear many-body problem [4.65], one defines mutually commuting partial traces of spin orbital generators e_{IJ}, (4.87),

$$E_{ij} = \sum_{\sigma=1}^{2} e_{i\sigma,j\sigma} = \sum_{\sigma=1}^{2} X_{i\sigma}^{\dagger} X_{j\sigma} ,$$
$$\mathcal{E}_{\sigma\tau} = \sum_{i=1}^{n} e_{i\sigma,i\tau} = \sum_{i=1}^{n} X_{i\sigma}^{\dagger} X_{i\tau} , \quad (4.95)$$

which again satisfy the unitary group commutation relations (4.59) and property (4.60), and may thus be

considered as the generators of the orbital group U(n) and the spin group U(2). The Hamiltonian (4.94) is thus expressible in terms of orbital U(n) generators

$$H = \sum_{i,j} h_{ij} E_{ij} + \frac{1}{2} \sum_{i,j,k,\ell} v_{ij,k\ell} (E_{ik} E_{j\ell} - \delta_{jk} E_{i\ell}) . \quad (4.96)$$

We can thus achieve an automatic spin adaptation by exploiting the chain

$$U(2n) \supset U(n) \otimes U(2) \quad (4.97)$$

and diagonalize H within the carrier space of two-column U(n) irreps $\Gamma(2^a 1^b 0^c) \equiv \Gamma(a, b, c)$ with [4.39, 66]

$$a = \frac{1}{2} N - S , \quad b = 2S ,$$
$$c = n - a - b = n - \frac{1}{2} N - S , \quad (4.98)$$

considering the states of multiplicity $(2S + 1)$ involving n orbitals and N electrons. The dimension of each spin-adapted subproblem equals [4.39, 66]

$$\dim \Gamma(2^a 1^b 0^c) = \frac{b+1}{n+1} \binom{n+1}{a} \binom{n+1}{c} , \quad (4.99)$$

where $\binom{m}{n}$ designate binomial coefficients.

Exploiting simplified irrep labeling by triples of integers (a, b, c), (4.98), at each level of the canonical chain (4.67), one achieves more efficient state labeling by replacing Gel'fand tableaux (4.68) by $n \times 3$ *ABC* [4.66] or *Paldus or Gel'fand–Paldus tableaux* [4.40, 67–75]

$$[P] = [a_i b_i c_i] , \quad (4.100)$$

where $a_i + b_i + c_i = i$. Another convenient labeling uses the ternary *step numbers* d_i, $0 \le d_i \le 3$ [4.66–68, 76, 77]

$$d_i = 1 + 2(a_i - a_{i-1}) - (c_i - c_{i-1}) . \quad (4.101)$$

An efficient and transparent representation of this basis can be achieved in terms of *Shavitt graphs* and *distinct row tables* ([4.67, 68], cf. also [4.10–12, 39, 69]). An efficient evaluation of generator matrix representatives, as well as of their products, is formulated in terms of products of *segment values*, whose explicit form has been derived in several different ways [4.10–12, 66–69, 73–75, 77, 78]. Since the dimension (4.99) rapidly increases with n and N, various truncated schemes (limited CI) are often employed. The unitary group formalism

that is based either on U(n) or on the universal enveloping algebra of U(n) proved to be of great usefulness in various post-Hartree–Fock approaches to molecular electronic structure [4.79], especially in large-scale CI calculations (in particular in the COLUMBUS Program System [4.80]; see also [24–31] in [4.12]) and in the spin-adapted UGA version of the coupled cluster (CC) method [4.81–83] (cf. Chapter 5; for applications, see [4.84–86]), as well as in various other investigations (e.g. quantum dots [4.87], charge migration in fragmentation of peptide ions [4.88, 89]; see also [4.10–12] for other references).

4.3.7 Clifford Algebra Unitary Group Approach

The Clifford algebra unitary group approach (CAUGA) exploits a realization of the spinor algebra of the rotation group SO($2n + 1$) in the covering algebra of U(2^n) to obtain explicit representation matrices for the U(n) [or SO($2n + 1$) or SO($2n$)] generators in the basis adapted to the chain [4.90–94]

$$U(2^n) \supset \text{Spin}(m) \supset SO(m) \supset U(n) ,$$
$$(m = 2n + 1 \text{ or } m = 2n) \tag{4.102}$$

supplemented, if desired, by the canonical chain (4.67) for U(n).

To realize the connection with the fermionic Grassmann algebra generated by the creation $\left(X_I^\dagger\right)$ and annihilation (X_I) operators, $I = 1, \dots , 2n$, note that it is isomorphic with the Clifford algebra C_{4n} when we define [4.12, 25]

$$\alpha_I = X_I + X_I^\dagger , \quad \alpha_{I+2n} = \text{i}\left(X_I - X_I^\dagger\right) ,$$
$$(I = 1, \dots , 2n) . \tag{4.103}$$

For practical applications, the most important is the final imbedding U(2^n) $\supset$ U(n), (for the role of intermediate groups, see [4.90–92]). All states of an n-orbital model, regardless the electron number N and the total spin S, are contained in a single two-box totally symmetric irrep $\langle 2\dot{0} \rangle$ of U(2^n) [4.93, 94]. To simplify the notation, one employs the one-to-one correspondence between the Clifford algebra monomials, labeled by the occupation numbers $m_i = 0$ or $m_i = 1$ ($i = 1, \dots , n$), and "multiparticle" single-column U(n) states labeled by

$$p \equiv p\{m_i\} = 2^n - (m_1 \, m_2 \cdots m_n)_2 , \tag{4.104}$$

where the occupation number array ($m_1 \cdots m_n$) is interpreted as a binary integer, which we then regard as

one-box states $|p\rangle$ of U(2^n). The orbital U(n) generators Λ_{ij} may then be expressed as simple linear combinations of U(2^n) generators $E_{pq} = |p\rangle\langle q|$ with coefficients equal to ± 1 [4.93, 94].

Generally, any p-column U(n) irrep is contained at least once in the totally symmetric p-box irrep of U(2^n). For many-electron problems, one thus requires a two-box irrep $\langle 2\dot{0} \rangle$. Any state arising in the U(n) irrep $\Gamma(a, b, c)$ can then be represented as a linear combination of two-box states, labeled by the Weyl tableaux $[i|j] \equiv \boxed{i}\boxed{j}$. In particular, the highest weight state of $\Gamma(a, b, c)$ is represented by $\left[2^c|2^{b+c}\right]$. Once this representation is available, it is straightforward to compute explicit representations of U(n) generators, since E_{pq} act trivially on $[i|j]$ [4.94]. Defining unnormalized states $(i|j)$ as

$$(i|j) = \sqrt{1 + \delta_{ij}} \quad [i|j] , \tag{4.105}$$

we have

$$E_{pq}(i|j) = \delta_{qi}(p|j) + \delta_{qj}(i|p) . \tag{4.106}$$

The main features of CAUGA may thus be summarized as follows: CAUGA

1. effectively reduces an N-electron problem to a number of two-boson problems;
2. enables an exploitation of an arbitrary coupling scheme (being particularly suited for the valence bond method);
3. can be applied to particle-number nonconserving operators;
4. easily extends to fermions with an arbitrary spin;
5. drastically simplifies evaluation of explicit representations of U(n) generators and of their products;
6. can be exploited in other than shell-model approaches [4.95–101].

4.3.8 Spin–Dependent Operators

The spin-adapted U(n)-based UGA is entirely satisfactory in most investigations of molecular electronic structure. However, when exploring the fine structure in high-resolution spectra, the intersystem crossings, phosphorescent lifetimes, molecular predissociation, spin–orbit interactions in transition metals, and like phenomena, the *explicitly* spin-dependent terms must be included in the Hamiltonian. Since in most cases the total spin S represents a good approximate quantum number, so that the spin-adapted N-electron states render an excellent point of departure, it is necessary to consider the

corresponding matrix elements of general spin-orbital U(2n) generators in terms of which the relevant spin-dependent terms may be expressed. This was first done in the context of the symmetric group and Racah algebra by *Drake* and *Schlesinger* [4.78] and later on in terms of the *Gel'fand–Paldus tableaux* [4.102–106].

In general, the U(2n) generators $e_{i\sigma, j\tau} \equiv e_{IJ}$ may be resolved into the spin-shift components $e(\pm)_{IJ}$ that increase (+) or decrease (−) the total spin S by one unit and the zero-spin component $e(0)_{IJ}$ that preserves S. The relevant matrix elements can then be expressed in terms of the matrix elements of a single U(n) adjoint tensor operator Δ, which is given by the following second degree polynomial in U(n) generators,

$$\Delta = \boldsymbol{E}(\boldsymbol{E} + N/2 - n - 2), \quad \boldsymbol{E} = \|E_{ij}\| \quad (4.107)$$

and by the well-known matrix elements of U(2) or SU(2) generators in terms of the pure spin states [4.102, 103] (see also [4.107, 108]). The operator (4.107), referred to as the *Gould–Paldus operator* [4.109], also plays a key role in the determination of reduced density matrices [4.110, 111], and has been recently exploited in the multireference spin-adapted variant of the *density functional theory* [4.109].

5. Perturbation Theory

Perturbation theory (PT) represents one of the bridges that takes us from a simpler, exactly solvable (unperturbed) problem to a corresponding real (perturbed) problem by expressing its solutions as a series expansion in a suitably chosen "small" parameter ε in such a way that the problem reduces to the unperturbed problem when $\varepsilon = 0$. It originated in classical mechanics and eventually developed into an important branch of applied mathematics enabling physicists and engineers to obtain approximate solutions of various systems of differential equations [5.1–4]. For the problems of atomic and molecular structure and dynamics, the perturbed problem is usually given by the time-independent or time-dependent Schrödinger equation [5.5–8].

5.1 Matrix Perturbation Theory (PT)

A prototype of a time-independent PT considers an eigenvalue problem for the Hamiltonian H of the form

$$H = H_0 + V , \quad V = \sum_{i=1}^{\infty} \varepsilon^i V_i , \tag{5.1}$$

acting in a (finite-dimensional) Hilbert space $\mathcal{V}_n$, assuming that the spectral resolution of the unperturbed operator H_0 is known; i. e.,

$$H_0 = \sum_i \omega_i P_i , \quad P_i P_j = \delta_{ij} P_j , \quad \sum_i P_i = I , \tag{5.2}$$

where ω_i are distinct eigenvalues of H_0, the P_i form a complete orthonormal set of Hermitian idempotents

and I is the identity operator on $\mathcal{V}_n$. The PT problem for H can then be formulated within the Lie algebra $\mathcal{A}$ (see Sect. 3.2) generated by H_0 and V [5.9, 10].

5.1.1 Basic Concepts

Define the diagonal part $\langle X \rangle$ of a general operator $X \in \mathcal{A}$ by

$$\langle X \rangle = \sum_i P_i X P_i , \tag{5.3}$$

and recall that the adjoint action of $X \in \mathcal{A}$, $\text{ad} X : \mathcal{A} \to \mathcal{A}$, is defined by

$$\text{ad}\, X(Y) = [X, Y] , \quad (\forall\, Y \in \mathcal{A}) , \tag{5.4}$$

where the square bracket denotes the commutator. The key problem of PT is the 'inversion' of this operation, i. e., the solution of the equation [5.9–11]

$$\mathrm{ad}H_0(X) \equiv [H_0, X] = Y \ . \tag{5.5}$$

Assuming that $\langle Y \rangle = 0$, then

$$X = R(Y) + \langle A \rangle \ , \tag{5.6}$$

where $A \in \mathcal{A}$ is arbitrary and

$$R(Y) = \sum_{i \neq j} \Delta_{ij}^{-1} P_i Y P_j \ , \tag{5.7}$$

with $\Delta_{ij} = \omega_i - \omega_j$, represents the solution of (5.5) with the vanishing diagonal part $\langle R(Y) \rangle = 0$.

5.1.2 Level–Shift Operators

To solve the PT problem for H, (5.1), we search for a unitary level-shift transformation U [5.9, 10], $U^\dagger U = UU^\dagger = I$,

$$UHU^\dagger = U(H_0 + V)U^\dagger = H_0 + E \ , \tag{5.8}$$

where the level-shift operator E satisfies the condition

$$E = \langle E \rangle \ . \tag{5.9}$$

To guarantee the unitarity of U, we express it in the form

$$U = \mathrm{e}^G \ , \quad G^\dagger = -G \ , \quad \langle G \rangle = 0 \ . \tag{5.10}$$

Using the Haussdorff formula

$$\mathrm{e}^A B \mathrm{e}^{-A} = \sum_{k=0}^{\infty} (k!)^{-1} (\,\mathrm{ad}A)^k B \ , \tag{5.11}$$

and defining the operator

$$F = [H_0, G] \ , \tag{5.12}$$

we find from (5.8) that

$$E + F = V + \frac{1}{2}[G, V + E]$$
$$+ \sum_{k=2}^{\infty} (k!)^{-1} B_k (\,\mathrm{ad}G)^k (V - E) \ , \tag{5.13}$$

where we used the identity [5.12]

$$\left(\sum_{k=0}^{\infty} \frac{B_k}{k!} X^k \right) \left(\sum_{k=0}^{\infty} \frac{1}{(k+1)!} X^k \right) = I \ , \tag{5.14}$$

and B_k designates the Bernoulli numbers [5.13]

$$B_0 = 1 \ , \quad B_1 = -\frac{1}{2} \ , \quad B_2 = \frac{1}{6} \ ,$$
$$B_{2k+1} = 0 \quad (k \geq 1) \ ,$$
$$B_4 = \frac{1}{30} \ , \quad B_6 = \frac{1}{42} \ , \quad \text{etc.} \tag{5.15}$$

5.1.3 General Formalism

Introducing the PT expansion for relevant operators,

$$X = \sum_{i=1}^{\infty} \varepsilon^i X_i \ , \quad X = E, F, G \ ; \quad F_i = [H_0, G_i] \ , \tag{5.16}$$

(5.13) leads to the following system of equations

$$E_1 + F_1 = V_1 \ ,$$
$$E_2 + F_2 = V_2 + \frac{1}{2}[G_1, V_1 + E_1] \ ,$$
$$E_3 + F_3 = V_3 + \frac{1}{2}[G_1, V_2 + E_2]$$
$$+ \frac{1}{2}[G_2, V_1 + E_1]$$
$$+ \frac{1}{12}[G_1, [G_1, V_1 - E_1]] \ ,$$
$$\text{etc.} \ , \tag{5.17}$$

which can be solved recursively for E_i and G_i by taking their diagonal part and applying operator R, (5.7), since

$$\langle E_i \rangle = E_i \ , \qquad \langle G_i \rangle = \langle F_i \rangle = 0 \ ,$$
$$R F_i = G_i \ , \qquad R E_i = 0 \ . \tag{5.18}$$

We thus get

$$E_1 = \langle V_1 \rangle \ ,$$
$$E_2 = \langle V_2 \rangle + \frac{1}{2} \langle [R V_1, V_1] \rangle \ ,$$
$$E_3 = \langle V_3 \rangle + \langle [R V_1, V_2] \rangle$$
$$+ \frac{1}{6} \langle [R V_1, [R V_1, 2V_1 + E_1]] \rangle \ , \quad \text{etc.} \ , \tag{5.19}$$

and

$$G_1 = R V_1 \ ,$$
$$G_2 = R V_2 + \frac{1}{2} R [R V_1, V_1 + E_1] \ , \quad \text{etc.} \tag{5.20}$$

Since

$$\langle R(X) \rangle = R \langle X \rangle = 0 \ , \qquad \langle R(X) Y \rangle = -\langle X R(Y) \rangle \ ,$$
$$R(X \langle Y \rangle) = R(X) \langle Y \rangle, \qquad R(\langle X \rangle Y) = \langle X \rangle R(Y) \ , \tag{5.21}$$

these relationships can be transformed to a more conventional form

$$E_2 = \langle V_2 \rangle - \langle V_1 R V_1 \rangle ,$$
$$E_3 = \langle V_3 \rangle - \langle V_1 R V_2 \rangle - \langle V_2 R V_1 \rangle$$
$$\quad + \frac{1}{6} \langle R(V_1) R(V_1) [2V_1 + \langle V_1 \rangle] \rangle$$
$$\quad - \frac{1}{3} \langle R(V_1) [2V_1 + \langle V_1 \rangle] R(V_1) \rangle$$
$$\quad + \frac{1}{6} \langle [2V_1 + \langle V_1 \rangle] R(V_1) R(V_1) \rangle , \quad \text{etc.}$$
(5.22)

However, in this way certain nonphysical terms arise that exactly cancel when the commutator form is employed (Sect. 5.3.7).

5.1.4 Nondegenerate Case

In the nondegenerate case, when $P_i = |i\rangle\langle i|$, with $|i\rangle$ representing the eigenvector of H_0 associated with the eigenvalue ω_i, the level-shift operator is diagonal and its explicit PT expansion (as well as that for the corresponding eigenvectors) is easily obtained from (5.19) and (5.20). Writing x_{ij} for the matrix element $\langle i|X|j\rangle$,

we get

$$(e_1)_{ii} = (v_1)_{ii} ,$$
$$(e_2)_{ii} = (v_2)_{ii} - \sum_j{}' \frac{(v_1)_{ij}(v_1)_{ji}}{\Delta_{ji}} ,$$
$$(e_3)_{ii} = (v_3)_{ii} - \sum_j{}' \frac{(v_1)_{ij}(v_2)_{ji} + (v_2)_{ij}(v_1)_{ji}}{\Delta_{ji}}$$
$$\quad + \sum_{j,k}{}' \frac{(v_1)_{ij}(v_1)_{jk}(v_1)_{ki}}{\Delta_{ji}\Delta_{ki}}$$
$$\quad - (v_1)_{ii} \sum_j{}' \frac{(v_1)_{ij}(v_1)_{ji}}{\Delta_{ji}^2} ,$$
etc., (5.23)

the prime on the summation symbols indicating that the terms with the vanishing denominator are to be deleted.

Note that in contrast to PT expansions which directly expand the level-shift transformation U, $U = 1 + \varepsilon U_1 + \varepsilon^2 U_2 + \cdots$, the above Lie algebraic formulation has the advantage that U stays unitary in every order of PT. This is particularly useful in spectroscopic applications, such as line broadening.

5.2 Time–Independent Perturbation Theory

For stationary problems, particularly those arising in atomic and molecular electronic structure studies relying on *ab initio* model Hamiltonians, the PT of Sect. 5.1 can be given a more explicit form which avoids a priori the nonphysical, size inextensive terms [5.6–8, 14, 15].

5.2.1 General Formulation

We wish to find the eigenvalues and eigenvectors of the full (perturbed) problem

$$K|\Psi_i\rangle \equiv (K_0 + W)|\Psi_i\rangle = k_i|\Psi_i\rangle , \quad (5.24)$$

assuming we know those of the unperturbed problem

$$K_0|\Phi_i\rangle = \kappa_i|\Phi_i\rangle, \quad \langle \Phi_i|\Phi_j\rangle = \delta_{ij} . \quad (5.25)$$

For simplicity, we restrict ourselves to the nondegenerate case ($\kappa_i \neq \kappa_j$ if $i \neq j$) and consider only the first order perturbation [see (5.1), $\varepsilon V_1 \equiv W$, $V_i = 0$ for $i \geq 2$]. Of course, K and K_0 are Hermitian operators acting in a Hilbert space which, in ab initio applications, is finite-dimensional.

Using the intermediate normalization for $|\Psi_i\rangle$,

$$\langle \Psi_i|\Phi_i\rangle = 1 , \quad (5.26)$$

the asymmetric energy formula gives

$$k_i = \kappa_i + \langle \Phi_i|W|\Psi_i\rangle . \quad (5.27)$$

The idempotent Hermitian projectors

$$P_i = |\Phi_i\rangle\langle \Phi_i|, \quad Q_i = P_i^\perp = 1 - P_i = \sum_{j(\neq i)} |\Phi_j\rangle\langle \Phi_j| , \quad (5.28)$$

commute with K_0, so that

$$(\lambda - K_0)Q_i|\Psi_i\rangle = Q_i(\lambda - k_i + W)|\Psi_i\rangle , \quad (5.29)$$

λ being an arbitrary scalar (note that we write λI simply as λ). Since the resolvent $(\lambda - K_0)^{-1}$ of K_0 is nonsingular on the orthogonal complement of the ith eigenspace, we get

$$Q_i|\Psi_i\rangle = |\Psi_i\rangle - |\Phi_i\rangle = R_i(\lambda)(\lambda - k_i + W)|\Psi_i\rangle , \quad (5.30)$$

where

$$R_i \equiv R_i(\lambda) = (\lambda - K_0)^{-1} Q_i$$
$$= Q_i(\lambda - K_0)^{-1} = \sum_{j(\neq i)} \frac{|\Phi_j\rangle\langle\Phi_j|}{\lambda - \kappa_j} ,$$

$$(5.31)$$

assuming $(\lambda \neq \kappa_j)$. Iterating this relationship, we get prototypes of the desired PT expansion for $|\Psi_i\rangle$,

$$|\Psi_i\rangle = \sum_{n=0}^{\infty} [R_i(\lambda - k_i + W)]^n |\Phi_i\rangle , \qquad (5.32)$$

and, from (5.27), for k_i,

$$k_i = \kappa_i + \sum_{n=0}^{\infty} \langle\Phi_i|W[R_i(\lambda - k_i + W)]^n|\Phi_i\rangle . \quad (5.33)$$

5.2.2 Brillouin–Wigner and Rayleigh–Schrödinger PT (RSPT)

So far, the parameter λ was arbitrary, as long as $\lambda \neq \kappa_j$ $(j \neq i)$. The following two choices lead to the two basic types of many-body perturbation theory (MBPT):

Brillouin–Wigner (BW) PT
Setting $\lambda = k_i$ gives

$$k_i = \kappa_i + \sum_{n=0}^{\infty} \langle\Phi_i|W\left(R_i^{(BW)}W\right)^n|\Phi_i\rangle , \qquad (5.34)$$

$$|\Psi_i\rangle = \sum_{n=0}^{\infty} \left(R_i^{(BW)}W\right)^n |\Phi_i\rangle , \qquad (5.35)$$

where

$$R_i^{(BW)} = \sum_{j(\neq i)} \frac{|\Phi_j\rangle\langle\Phi_j|}{k_i - \kappa_j} . \qquad (5.36)$$

Rayleigh–Schrödinger (RS) PT
Setting $\lambda = \kappa_i$ gives

$$k_i = \kappa_i + \sum_{n=0}^{\infty} \langle\Phi_i|W\left[R_i^{(RS)}(\kappa_i - k_i + W)\right]^n|\Phi_i\rangle , \qquad (5.37)$$

$$|\Psi_i\rangle = \sum_{n=0}^{\infty} \left[R_i^{(RS)}(\kappa_i - k_i + W)\right]^n |\Phi_i\rangle , \qquad (5.38)$$

where now

$$R_i \equiv R_i^{(RS)} = \sum_{j(\neq i)} \frac{|\Phi_j\rangle\langle\Phi_j|}{\kappa_i - \kappa_j} . \qquad (5.39)$$

The main distinction between these two PTs lies in the fact that the BW form has the exact eigenvalues appearing in the denominators, and thus leads to polynomial expressions for k_i. Although these are not difficult to solve numerically, since the eigenvalues are separated, the resulting energies are never size extensive and thus unusable for extended systems. They are also unsuitable for finite systems when the particle number changes, as in various dissociation processes. From now on, we thus investigate only the RSPT, which yields a fully size-extensive theory.

5.2.3 Bracketing Theorem and RSPT

Expressions (5.37) and (5.38) are not explicit, since they involve the exact eigenvalues k_i on the right-hand side. To achieve an order by order separation, set

$$k_i \equiv k = \sum_{j=0}^{\infty} k^{(j)} , \quad |\Psi_i\rangle \equiv |\Psi\rangle = \sum_{j=0}^{\infty} |\Psi^{(j)}\rangle , \qquad (5.40)$$

where the superscript (j) indicates the jth-order in the perturbation W. We only consider the eigenvalue expressions, since the corresponding eigenvectors are easily recovered from them by removing the bra state and the first interaction W [see (5.37) and (5.38)]. We also simplify the mean value notation writing for a general operator X,

$$\langle X\rangle \equiv \langle\Phi_i|X|\Phi_i\rangle . \qquad (5.41)$$

Substituting the first expansion (5.40) into (5.37) and collecting the terms of the same order in W, we get

$$k^{(0)} = \kappa_i ,$$
$$k^{(1)} = \langle W\rangle ,$$
$$k^{(2)} = \langle WRW\rangle ,$$
$$k^{(3)} = \langle W(RW)^2\rangle - \langle W\rangle\langle WR^2W\rangle ,$$
$$k^{(4)} = \langle W(RW)^3\rangle$$
$$\quad - \langle W\rangle\left(\langle WR(RW)^2\rangle + \langle(WR)^2RW\rangle\right)$$
$$\quad + \langle W\rangle^2\langle WR^3W\rangle - \langle WRW\rangle\langle WR^2W\rangle , \quad \text{etc.}$$

$$(5.42)$$

The general expression has the form

$$k^{(n)} = \langle W(RW)^{n-1}\rangle + \mathcal{R}^{(n)} , \qquad (5.43)$$

the first term on the right-hand side being referred to as the *principal n*th-order term, while $\mathcal{R}^{(n)}$ designates the so-called *renormalization* terms that are obtained by the *bracketing theorem* [5.14, 16] as follows:

1. Insert the bracketings $\langle \cdots \rangle$ around the W, WRW, $\ldots$, $WR \cdots RW$ operator strings of the principal term in all possible ways.

2. Bracketings involving the rightmost and/or the leftmost interaction vanish.
3. The sign of each bracketed term is given by $(-1)^{n_B}$, where n_B is the number of bracketings.
4. Bracketings within bracketings are allowed, e.g., $\langle WR\langle WR\langle W\rangle RW\rangle RW\rangle = \langle W\rangle\langle WR^2W\rangle^2$.
5. The total number of bracketings (including the principal term) is $(2n-2)!/[n!(n-1)!]$.

5.3 Fermionic Many–Body Perturbation Theory (MBPT)

5.3.1 Time Independent Wick's Theorem

The development of an explicit MBPT formalism is greatly facilitated by the exploitation of the time-independent version of Wick's theorem. This version of the theorem expresses an arbitrary product of creation ($a_\mu^\dagger$) and annihilation (a_μ) operators (see Chapt. 6) as a normal product (relative to $|\Phi_0\rangle$) and as normal products with all possible contractions of these operators [5.14, 15],

$$x_1 x_2 \cdots x_k = N[x_1 x_2 \cdots x_k] + \Sigma N[x_1 \overline{x_2 \cdots \cdots} x_k],$$
$$(x_i = a_{\mu_i}^\dagger \text{ or } x_i = a_{\mu_i}) \tag{5.44}$$

where

$$\overline{a_\mu^\dagger a_\nu^\dagger} = \overline{a_\mu a_\nu} = 0,$$
$$\overline{a_\mu^\dagger a_\nu} = h(\mu)\delta_{\mu\nu}, \quad \overline{a_\mu a_\nu^\dagger} = p(\mu)\delta_{\mu\nu}, \tag{5.45}$$

and

$h(\mu) = 1$, $p(\mu) = 0$ if $|\mu\rangle$ is occupied in $|\Phi_0\rangle$
(hole states),
$h(\mu) = 0$, $p(\mu) = 1$ if $|\mu\rangle$ is unoccupied in $|\Phi_0\rangle$
(particle states) . $\tag{5.46}$

The N-product with contractions is defined as a product of individual contractions times the N-product of uncontracted operators (defining $N[\emptyset] \equiv 1$ for an empty set) with the sign given by the parity of the permutation reordering the operators into their final order.

Note that the Fermi vacuum mean value of an N-product vanishes unless all operators are contracted. Thus, $\langle x_1 x_2 \cdots x_k \rangle$ is given by the sum over all possible fully contracted terms (vacuum terms). Similar rules follow for the expressions of the type $(x_1 x_2 \cdots x_k)|\Phi\rangle$. Moreover, if some operators on the left-hand side of (5.44) are already in the N-product form, all the terms involving contractions between these operators vanish.

5.3.2 Normal Product Form of PT

Consider the eigenvalue problem for a general *ab initio* or semi-empirical electronic Hamiltonian H with one- and two-body components Z and V, namely,

$$H|\Psi_i\rangle = E_i|\Psi_i\rangle,$$
$$H = Z + V = \sum_i z(i) + \sum_{i<j} v(i,j), \tag{5.47}$$

and a corresponding unperturbed problem

$$H_0|\Phi_i\rangle = \varepsilon_i|\Phi_i\rangle, \tag{5.48}$$
$$H_0 = Z + U, \quad \langle \Phi_i|\Phi_j\rangle = \delta_{ij},$$

with U representing some approximation to V. In the case that U is also a one-electron operator, $U = \Sigma_i u(i)$, the unperturbed problem (5.48) is separable and reduces to a one-electron problem,

$$(z+u)|\mu\rangle = \omega_\mu|\mu\rangle, \tag{5.49}$$

which is assumed to be solved. Choosing the orthonormal spin orbitals $\{|\mu\rangle\}$ as a basis of the second quantization representation [Chapt. 6, (6.8)], the N-electron solutions of (5.48) can be represented as

$$|\Phi_i\rangle = a_{\mu_1}^\dagger a_{\mu_2}^\dagger \cdots a_{\mu_N}^\dagger |0\rangle, \tag{5.50}$$

$$\varepsilon_i = \sum_{j=1}^{N} \omega_{\mu_j}, \tag{5.51}$$

the state label i representing the occupied spin orbital set $\{\mu_1, \mu_2, \ldots, \mu_N\}$, while the one- and two-body operators take the form

$$X = \sum_{\mu,\nu} \langle \mu|x|\nu\rangle a_\mu^\dagger a_\nu, \quad X = Z, U; \ x = z, u,$$
$$\tag{5.52}$$

$$V = \frac{1}{2} \sum_{\mu,\nu,\sigma,\tau} \langle \mu\nu|v|\sigma\tau\rangle a_\mu^\dagger a_\nu^\dagger a_\tau a_\sigma. \tag{5.53}$$

Considering, for simplicity, a nondegenerate ground state $|\Phi\rangle \equiv |\Phi_0\rangle = a_1^\dagger a_2^\dagger \cdots a_N^\dagger |0\rangle$, referred to as a Fermi vacuum, we define the *normal product form* of these operators relative to $|\Phi\rangle$

$$X_N \equiv X - \langle X\rangle = \sum_{\mu,\nu}\langle\mu|x|\nu\rangle N\big[a_\mu^\dagger a_\nu\big] , \quad (5.54a)$$

$$(X = Z, U, G; \quad x = z, u, g)$$

$$\begin{aligned}
V_N &\equiv V - \langle V\rangle - G_N \\
&= \frac{1}{2}\sum_{\mu,\nu,\sigma,\tau}\langle\mu\nu|v|\sigma\tau\rangle N\big[a_\mu^\dagger a_\nu^\dagger a_\tau a_\sigma\big] \\
&= \frac{1}{4}\sum_{\mu,\nu,\sigma,\tau}\langle\mu\nu|v|\sigma\tau\rangle_A N\big[a_\mu^\dagger a_\nu^\dagger a_\tau a_\sigma\big] , \quad (5.54b)
\end{aligned}$$

where

$$\langle\mu|g|\nu\rangle = \sum_{\sigma=1}^{N}\langle\mu\sigma|v|\nu\sigma\rangle_A , \quad (5.55)$$

$$\langle\mu\nu|v|\sigma\tau\rangle_A = \langle\mu\nu|v|\sigma\tau\rangle - \langle\mu\nu|v|\tau\sigma\rangle , \quad (5.56)$$

$\langle X\rangle = \langle\Phi|X|\Phi\rangle$, and $N[\cdots]$ designates the normal product relative to $|\Phi\rangle$ [5.14, 15]. (Recall that $N[x_1 x_2 \cdots x_k] = \pm b_{\mu_1}^\dagger \cdots b_{\mu_i}^\dagger b_{\mu_{i+1}}\cdots b_{\mu_k}$, where $x_i = b_{\mu_i}$ or $b_{\mu_i}^\dagger$ are the annihilation and creation operators of the particle-hole formalism relative to $|\Phi\rangle$, i.e., $b_\mu = a_\mu^\dagger$ for $\mu \le N$ and $b_\mu = a_\mu$ for $\mu > N$, the sign being determined by the parity of the permutation $p : j \mapsto \mu_j$.)

Defining

$$K = H - \langle H\rangle , \quad K_0 = H_0 - \langle H_0\rangle = H_0 - \varepsilon_0 , \quad (5.57)$$

we can return to (5.24) and (5.25), where now

$$k_i = E_i - \langle H\rangle , \quad \kappa_i = \varepsilon_i - \varepsilon_0 ,$$

$$\varepsilon_0 = \sum_{\mu=1}^{N}\omega_\mu , \quad (5.58)$$

and

$$W = K - K_0 = V - U - \langle V - U\rangle . \quad (5.59)$$

With this choice, $\langle W\rangle = 0$, so that for the reference state $|\Phi\rangle$, (5.42) simplify to (we drop the subscript 0 for simplicity)

$$\begin{aligned}
k^{(0)} &= 0 , \quad k^{(1)} = 0 , \\
k^{(2)} &= \langle WRW\rangle , \\
k^{(3)} &= \langle WRWRW\rangle , \\
k^{(4)} &= \big\langle W(RW)^3\big\rangle - \langle WRW\rangle\big\langle WR^2W\big\rangle , \quad \text{etc.}
\end{aligned}$$
$$(5.60)$$

Note that W is also in the N-product form,

$$W = W_1 + W_2 , \quad W_1 = G_N - U_N , \quad W_2 = V_N . \quad (5.61)$$

5.3.3 Møller–Plesset and Epstein–Nesbet PT

Choosing $U = G$ we have

$$H_0 = Z + G \equiv F , \quad (5.62)$$

so that (5.49) represent Hartree–Fock (HF) equations, and ω_μ and $|\mu\rangle$ the canonical HF orbital energies and spin orbitals, respectively. Since $\langle H\rangle = \sum_{\mu=1}^{N}\big(\langle\mu|z|\mu\rangle + \frac{1}{2}\langle\mu|g|\mu\rangle\big)$ is the HF energy, $k = k_0$ gives directly the ground state correlation energy. (Note, however, that the N-product form of PT eliminates the first-order contribution $k^{(1)} = \langle W\rangle$ in any basis, even when F is not diagonal.) With this choice, $W_1 = 0$, $W = V_N$, and the denominators in (5.39) are given by the differences of HF orbital energies

$$\kappa_0 - \kappa_j = \sum_{i=1}^{\lambda}(\omega_{\mu_i} - \omega_{\nu_i}) \equiv \Delta\langle\{\mu_i\};\{\nu_j\}\rangle , \quad (5.63)$$

assuming that $|\Phi_j\rangle$ is a λ-times excited configuration relative to $|\Phi\rangle$ obtained through excitations $\mu_i \to \nu_i$, $i = 1, \ldots, \lambda$. Using the Slater rules (or the second quantization algebra), we can express the second-order contribution in terms of the two-electron integrals and HF orbital energies as

$$k^{(2)} = \frac{1}{2}\sum_{a,b,r,s}\frac{\langle ab|v|rs\rangle\big(\langle rs|v|ab\rangle - \langle rs|v|ba\rangle\big)}{\omega_a + \omega_b - \omega_r - \omega_s} , \quad (5.64)$$

where the summations over a, b (r, s) extend over all occupied (unoccupied) spin orbitals in $|\Phi\rangle$. Obtaining the corresponding higher-order corrections becomes more and more laborious and, beginning with the fourth-order, important cancellations arise between the principal and renormalization terms, even when the N-product form is employed. These will be addressed in Sect. 5.3.7.

The above outlined PT with H_0 given by the HF operator is often referred to as the *Møller–Plesset PT* [5.17] and, when truncated to the n-th order, is designated by the acronym MPn, $n = 2, 3, \ldots$. In this version, the two-electron integrals enter the denominators only through the HF orbital energies. In an alternative, less often employed variant, referred to as the *Epstein–Nesbet PT* [5.18, 19], the whole diagonal part of H is
Fig. 5.1a–d Diagrammatic representation of one- and two-electron operators

used as the unperturbed Hamiltonian, i. e.,

$$H_0 = \sum_i \langle \Phi_i | H | \Phi_i \rangle P_i \; . \tag{5.65}$$

With this choice, the denominators are given as differences of the diagonal elements of the configuration interaction matrix.

5.3.4 Diagrammatic MBPT

To facilitate the evaluation of higher order terms, and especially to derive the general properties and characteristics of the MBPT, it is useful to employ a diagrammatic representation [5.6–8, 14, 15]. Representing all the operators in (5.42) and (5.43) or (5.60) in the second quantized form, we have to deal with the reference state (i. e., the Fermi vacuum) mean values of the strings of annihilation and creation operators (or with these strings acting on the reference in the case of a wave function). This is efficiently done using Wick's theorem and its diagrammatic representation via a special form of Feynman diagrams. In this representation we associate with various operators suitable vertices with incident oriented lines representing the creation (outgoing lines) and annihilation (ingoing lines) operators that are involved in their second quantization form. A few typical diagrams representing operators $(-U)$, W_1 and V are shown in Fig. 5.1a, Fig. 5.1b and Fig. 5.1c, Fig. 5.1d, respectively. Using the N-product form of PT with HF orbitals (Sect. 5.3.3), we only need the two-electron operator V or V_N, which can be represented using either non-antisymmetrized vertices (Fig. 5.1c), leading to the *Goldstone diagrams* [5.20], or antisymmetrized vertices (Fig. 5.1d), associated with antisymmetrized two-electron integrals (5.56) and yielding the *Hugenholtz diagrams* [5.21].

5.3.5 Vacuum and Wave Function Diagrams

Applying Wick's theorem to the strings of operators involved, we represent the individual contractions, (5.45), by joining corresponding oriented lines. To obtain a non-
Fig. 5.2a–c The second-order Goldstone (**a**), (**b**) and Hugenholtz (**c**) diagrams

vanishing contribution, only contractions preserving the orientation need be considered [*cf.* (5.45)]. The resulting *internal* lines have either the left–right orientation (*hole* lines) or the right–left one (*particle* lines). Only fully contracted terms, represented by the so-called *vacuum diagrams* (having only internal lines), can contribute to the energy, while those representing wave function contributions have uncontracted or *free* lines extending to the left. When the operators involved are in the N-product form, no contractions of oriented lines issuing from the same vertex are allowed. The projection-like operators R, (5.39), or their powers, lead to the denominators, (5.63), given by the difference of hole and particle orbital energies associated with, respectively, hole and particle lines passing through the interval separating the corresponding two neighboring vertices. Clearly, there must always be at least one pair of such lines lest the denominator vanish. Thus, for example, the second-order contribution $\langle WRW \rangle$ is represented either by the two Goldstone diagrams [5.20] (Fig. 5.2a,b) or by the single Hugenholtz diagram [5.21] (Fig. 5.2c). The rules for the energy (vacuum) diagram evaluation are as follows:

1. Associate appropriate matrix elements with all vertices and form their product. The outgoing (ingoing) lines on each vertex define the bra (ket) states of a given matrix element, and for the Goldstone diagrams, the oriented lines attached to the same node are associated with the same electron number, (e.g., for the leftmost vertex in diagram (a) of Fig. 5.2 we have $\langle ab | \hat{v} | rs \rangle \equiv \langle a(1)b(2)|v|r(1)s(2) \rangle$).
2. Associate a denominator, (5.63), or its appropriate power, with every neighboring pair of vertices (and, for the wave function diagrams, also with the free lines extending to the left of the leftmost vertex; with each pair of such free lines associate also the corresponding pair of particle creation and hole annihilation operators).
3. Sum over all hole and particle labels.
4. Multiply each diagram contribution by the weight factor given by the reciprocal value of the order of
Fig. 5.3 Hugenholtz diagrams for the third-order energy contribution

the group of automorphisms of the diagram (stripped of summation labels) and by the sign $(-1)^{h+\ell}$, where h designates the number of internal hole lines and ℓ gives the number of closed loops of oriented lines (for Hugenholtz diagrams, use any of its Goldstone representatives to determine the correct phase).

Applying these rules to diagrams (a) and (b) of Fig. 5.2 we clearly recover (5.64) or, using the Hugenholtz diagram of Fig. 5.2, the equivalent expression

$$k^{(2)} = \frac{1}{4} \sum_{a,b,r,s} \langle ab|v|rs \rangle_A \langle rs|v|ab \rangle_A \Delta^{-1}(a, b; r, s) \ .$$

(5.66)

The possible third-order Hugenholtz diagrams are shown in Fig. 5.3 with the central vertex involving particle–particle, hole–hole, and particle–hole interaction [5.14, 15].

5.3.6 Hartree–Fock Diagrams

In the general case (non-HF orbitals and/or not normal product form of PT), the one-electron terms, as well as the contractions between operators associated with the same vertex, can occur (the latter are always the hole lines). Representing the W_1 and $(-U)$ operators as shown in Fig. 5.1, the one-body perturbation W_1 represents in fact the three diagrams as shown in Fig. 5.4. The second-order contribution of this type is then represented by the diagrams in Fig. 5.5, which in fact represents nine diagrams which result when each W_1 vertex is replaced by three vertices as shown in Fig. 5.4.

Using HF orbitals, all these terms mutually cancel out as seen above. For this reason, the diagrams involving contractions of lines issuing from the same vertex

Fig. 5.5 The second-order one-particle contribution

are referred to as *Hartree–Fock diagrams*. Note, however, that even when not employing the canonical HF orbitals, it is convenient to introduce W_1 vertices of the normal product form PT and replace all nine HF-type diagrams by a single diagram of Fig. 5.5 (clearly, this feature provides even greater efficiency in higher orders of PT).

5.3.7 Linked and Connected Cluster Theorems

Using the N-product form of PT, the first nonvanishing renormalization term occurs in the fourth-order [*cf.* (5.60)]. For a system consisting of N noninteracting species, the energy given by this nonphysical term is proportional to N^2, and thus violates the size extensivity of the theory. It was first shown by *Brueckner* [5.22] that in the fourth-order these terms are in fact exactly canceled by the corresponding contributions originating in the principal term. A general proof of this cancellation in an arbitrary order was then given by *Goldstone* [5.20] using the time-dependent PT formalism (Sect. 5.4).

To comprehend this cancellation, consider the fourth-order energy contribution arising from the so-called unlinked diagrams (no such contribution can arise in the second- or the third-order) shown in Fig. 5.6. An *unlinked diagram* is defined as a diagram containing a disconnected vacuum diagram (for the energy diagrams, the terms unlinked and disconnected are synonymous). The numerators associated with both diagrams being identical, we only consider the denominators. Designating the denominator associated with the

Fig. 5.4a–d Schematic representation of $W_1 = G_N - U_N$
Fig. 5.6 The fourth-order unlinked diagrams

top and the bottom part by A and B, respectively, we find for the overall contribution

$$\frac{1}{B} \cdot \frac{1}{A+B} \cdot \frac{1}{B} + \frac{1}{A} \cdot \frac{1}{A+B} \cdot \frac{1}{B}$$
$$= \left(\frac{1}{B} + \frac{1}{A} \right) \frac{1}{(A+B)B} = \frac{1}{AB^2} . \qquad (5.67)$$

Thus, the contribution from these terms exactly cancels that from the renormalization term $\langle WRW \rangle \langle WR^2 W \rangle$.

Generalizing (5.67), we obtain the *factorization lemma* of *Frantz* and *Mills* [5.23], which implies the cancellation of renormalization terms by the unlinked terms originating from the principal term. This result holds for the energy as well as for the wave function contributions in every order of PT, as ascertained by the *linked cluster theorem*, which states that

$$\Delta E = k = \sum_{n=0}^{\infty} \langle \Phi | W | \Psi^{(n)} \rangle = \sum_{n=0}^{\infty} \langle W(RW)^n \rangle_{\mathrm{L}} ,$$
$$(5.68)$$

$$|\Psi\rangle = \sum_{n=0}^{\infty} |\Psi^{(n)}\rangle = \sum_{n=0}^{\infty} \left\{ (RW)^n |\Phi\rangle \right\}_{\mathrm{L}} , \qquad (5.69)$$

where the subscript L indicates that only linked diagrams (or terms) are to be considered. This enables us to obtain general, explicit expressions for the nth-order PT contributions by first constructing all possible linked diagrams involving n vertices and by converting them into the explicit algebraic expressions using the rules of Sect. 5.3.5. Note that linked energy diagrams are always connected, but the linked wave function diagrams are either connected or disconnected, each disconnected component possessing at least one pair of particle–hole free lines extending to the left.

To reveal a deeper structure of the result (5.69), define the *cluster operator* T that generates all connected wave function diagrams,

$$T|\Phi\rangle = \sum_{n=1}^{\infty} \left\{ (RW)^n |\Phi\rangle \right\}_{\mathrm{C}} , \qquad (5.70)$$

the subscript C indicating that only contributions from *connected* diagrams are to be included. Since the general component with r disconnected parts can be shown to be represented by the term $(r!)^{-1} T^r |\Phi\rangle$, the general structure of the exact wave function $|\Psi\rangle$ is given by the *connected cluster theorem*, which states that

$$|\Psi\rangle = \mathrm{e}^T |\Phi\rangle . \qquad (5.71)$$

In other words, the wave operator $\mathcal{W}$ which transforms the unperturbed independent particle model wave function $|\Phi\rangle$ into the exact one according to

$$|\Psi\rangle = \mathcal{W}|\Phi\rangle , \qquad (5.72)$$

is given by the exponential of the cluster operator T,

$$\mathcal{W} = \mathrm{e}^T , \qquad (5.73)$$

which in turn is given by the connected wave function diagrams. This is in fact the basis of the coupled cluster methods [5.15, 24–28] (Sect. 5.3.8).

The contributions to T may be further classified by their excitation rank i,

$$T = \sum_{i=1}^{N} T_i , \qquad (5.74)$$

where T_i designates connected diagrams with i pairs of free particle–hole lines, producing i-times excited components of $|\Psi\rangle$ when acting on $|\Phi\rangle$.

5.3.8 Coupled Cluster Theory

Summing all HF diagrams (Sect. 5.3.6) is equivalent to solving the HF equations. Depending on the average electron density of the system, it may be essential to sum certain types of PT diagrams to infinite order at the post-HF level. A frequently used approach that is capable of recovering a large part of the electronic correlation energy is based on the connected cluster theorem (Sect. 5.3.7), referred to in this context as the exponential cluster Ansatz for the wave operator. Using this Ansatz, one derives a system of energy-independent nonlinear coupled cluster (CC) equations [5.15, 26–28] determining the cluster amplitudes of T. These CC equations can be regarded as recurrence relations generating the MBPT series [5.15], so that by solving these equations one in fact implicitly generates all the MBPT diagrams and sums them to infinite order. Since the solution of the full CC equations is equivalent to the exact solution of the Schrödinger equation, we must – in all practical applications – introduce a suitable truncation scheme, which implies that only diagrams of certain types are summed.

Generally, using the cluster expansion (5.71) in the N-product form of the Schrödinger equation,

$$H_{\mathrm{N}}|\Psi\rangle \equiv (H - \langle H \rangle)|\Psi\rangle = \Delta E |\Psi\rangle ,$$
$$\Delta E = E - E_0 , \qquad (5.75)$$

premultiplying with the inverse of the wave operator, and using the Hausdorff formula (5.11) yields

$$e^{-T} H_N e^T |\Phi\rangle = \sum_{n=0}^{\infty} \frac{[\mathrm{ad}(-T)]^n H_N}{n!} = \Delta E |\Phi\rangle \ . \tag{5.76}$$

In fact, this expansion terminates, so that using (5.74) and projecting onto $|\Phi\rangle$ we obtain the energy expression

$$\Delta E = \langle H_N T_2 \rangle + \frac{1}{2} \langle H_N T_1^2 \rangle \ , \tag{5.77}$$

while the projection onto the manifold of excited states $\{|\Phi_i\rangle\}$ relative to $|\Phi\rangle \equiv |\Phi_0\rangle$ gives the system of CC equations

$$\langle \Phi_i | H_N + [H_N, T] + \frac{1}{2} [[H_N, T], T] + \cdots |\Phi\rangle = 0 \ . \tag{5.78}$$

Approximating, e.g., T by the most important pair cluster component $T \approx T_2$ gives the so-called CCD (coupled clusters with doubles) approximation

$$\langle \Phi_i^{(2)} | H_N + [H_N, T_2] + \frac{1}{2} [[H_N, T_2], T_2] |\Phi\rangle = 0 \ , \tag{5.79}$$

the superscript (2) indicating pair excitations relative to $|\Phi\rangle$.

Equivalently, (5.77) and (5.78) can be written in the form

$$\Delta E = \langle H_N e^T \rangle_C \ , \tag{5.80}$$

$$\langle \Phi_i | (H_N e^T)_C |\Phi\rangle = 0 \ , \tag{5.81}$$

the subscript C again indicating that only connected diagrams are to be considered. The general form of CC equations is

$$a_i + \sum_j b_{ij} t_j + \sum_{j \leq k} c_{ijk} t_j t_k + \cdots = 0 \ , \tag{5.82}$$

where $a_i = \langle \Phi_i | H_N | \Phi_0 \rangle$, $b_{ij} = \langle \Phi_i | H_N | \Phi_j \rangle_C$, $c_{ijk} = \langle \Phi_i | H_N | \Phi_j \otimes \Phi_k \rangle_C$, etc. Writing the diagonal linear term b_{ii} in the form

$$b_{ii} = \Delta_i + b_{ii}' \ , \tag{5.83}$$

this system can be solved iteratively by rewriting it in the form

$$t_i^{(n+1)} = \Delta_i^{-1} \Big(a_i + b_{ii}' t_i^{(n)} + \sum_j{}' b_{ij} t_j^{(n)}$$
$$+ \sum_{j \leq k} c_{ijk} t_j^{(n)} t_k^{(n)} + \cdots \Big) \ . \tag{5.84}$$

Starting with the zeroth approximation $t_i^{(0)} = 0$, the first iteration is

$$t_i^{(1)} = \Delta_i^{-1} a_i \ , \tag{5.85}$$

which yields the second-order PT energy when used in (5.77). Clearly, the successive iterations generate higher and higher orders of the PT. At any truncation level, a size extensive result is obtained.

The CC methods belong to the most accurate and often used tools in computations of molecular electronic structure and several general-purpose codes are available for this purpose (for reviews see [5.29–32]). The standard approach truncates the cluster operator (5.74) at the singly (S) and doubly (D) excited level (the CCSD method [5.33]) and is often supplemented by a perturbative account of the triply-excited (T) cluster components [the CCSD(T) method] for greater accuracy [5.34]. To avoid the breakdown of the latter method in quasi-degenerate situations, one can employ one of the renormalized versions of CCSD(T) [5.35]. The CC ansatz (5.71) has also been exploited in the context of the *equation-of-motion* (EOM) and the *linear-response* formalisms, enabling the computation of the excitation energies and of properties other than the energy (dipole and quadrupole moments, polarizabilities, etc., [5.29–32].

At this stage it is important to recall that the above described MBPT and CC approaches pertain to nondegenerate, lowest-lying closed-shell states of a given symmetry species. Although the CC methods are often used even for open-shell states by relying on the unrestricted HF (UHF) reference [of the different-orbitals-for-different-spins (DODS) type], a proper description of such states requires a multi-reference (MR) generalization based on the *effective Hamiltonian* formalism [5.6, 31, 32, 36–38]. Unfortunately, such a generalization is not unambiguous. The two existing formulations, the so-called *valence universal* [5.6, 37] and *state universal* [5.38] methods, are computationally demanding and often plagued with the intruder state and other problems [5.15, 36]. For these reasons, no general-purpose codes have yet been developed and very few actual applications have been carried out [5.31, 32] (see, however, the recently formulated SU CC approach for general model spaces [5.39, 40]). Nonetheless, the MR CC formalism proved to be very useful in the formulation of the so-called *state selective* or *state specific* approaches (e.g., the reduced MR CCSD method [5.41–46]).

Most recently, the CC approach has been used to handle bosonic-type problems of the vibrational structure in molecular spectra and, generally, multimode dynamics [5.47].

5.4 Time–Dependent Perturbation Theory

5.4.1 Evolution Operator PT Expansion

By introducing the *evolution operator* $U(t, t_0)$

$$|\Psi(t)\rangle = U(t, t_0)|\Psi(t_0)\rangle , \qquad (5.86)$$

time-dependent Schrödinger equation

$$i\hbar \frac{\partial}{\partial t}|\Psi(t)\rangle = H|\Psi(t)\rangle \qquad (5.87)$$

becomes

$$i\hbar \frac{\partial}{\partial t}U(t, t_0) = HU(t, t_0) . \qquad (5.88)$$

Clearly,

$$\begin{aligned}
U(t_0, t_0) &= 1 , \\
U(t, t_0) &= U(t, t')U(t', t_0) , \\
U(t, t_0)^{-1} &= U(t_0, t) = U^\dagger(t, t_0) .
\end{aligned} \qquad (5.89)$$

If the Hamiltonian is time independent then

$$U(t, t_0) = \exp\left[-\frac{i}{\hbar}H(t - t_0)\right] . \qquad (5.90)$$

In the *interaction picture* (subscript I)

$$|\Psi(t)\rangle_I = \exp\left(\frac{i}{\hbar}H_0 t\right)|\Psi(t)\rangle , \qquad (5.91)$$

where now

$$H = H_0 + V , \qquad (5.92)$$

the Schrödinger equation becomes

$$i\hbar \frac{\partial}{\partial t}|\Psi(t)\rangle_I = V(t)_I|\Psi(t)\rangle_I , \qquad (5.93)$$

known as *Tomonaga-Schwinger equation* [5.48]. Analogously, the evolution operator in this picture (we drop the subscript I from now on) satisfies

$$i\hbar \frac{\partial}{\partial t}U(t, t_0) = V(t)U(t, t_0) , \qquad (5.94)$$

with the initial condition $U(t_0, t_0) = 1$. This differential equation is equivalent to an integral equation

$$U(t, t_0) = 1 - \frac{i}{\hbar}\int_{t_0}^{t} V(t_1)U(t_1, t_0)\,dt_1 . \qquad (5.95)$$

Iterating we get [5.49, 50]

$$\begin{aligned}
U(t, t_0) &= \sum_{n=0}^{\infty}\left(-\frac{i}{\hbar}\right)^n \\
&\times \int_{t_0}^{t}dt_1 \int_{t_0}^{t_1}dt_2 \cdots \int_{t_0}^{t_{n-1}}dt_n V(t_1)V(t_2)\cdots V(t_n) \\
&= \sum_{n=0}^{\infty}\frac{(-i/\hbar)^n}{n!} \\
&\times \int_{t_0}^{t}dt_1 \cdots \int_{t_0}^{t}dt_n T[V(t_1)\cdots V(t_n)] , \qquad (5.96)
\end{aligned}$$

where $T[\cdots]$ designates the time-ordering or chronological operator.

5.4.2 Gell–Mann and Low Formula

For a time-independent perturbation, one introduces the so-called *adiabatic switching* by writing

$$H_\alpha(t) = H_0 + \lambda\, e^{-\alpha|t|}V , \quad \alpha > 0 \qquad (5.97)$$

so that $H_\alpha(t \to \pm\infty) = H_0$ and $H_\alpha(t \to 0) = H = H_0 + \lambda V$. Then

$$|\Psi(t)\rangle_I = U_\alpha(t, -\infty|\lambda)|\Phi_0\rangle , \qquad (5.98)$$

with $U_\alpha(t, -\infty|\lambda)$ obtained with $V_\alpha(t) = \lambda\, e^{-\alpha|t|}V$ (all in the interaction picture). The desired energy is then given by the Gell–Mann and Low formula [5.51]

$$\Delta E = \lim_{\alpha \to 0+} i\hbar\alpha\lambda \frac{\partial}{\partial\lambda}\ln\langle\Phi_0|U_\alpha(0, -\infty|\lambda)|\Phi_0\rangle , \qquad (5.99a)$$

or

$$\Delta E = \frac{1}{2}\lim_{\alpha \to 0+} i\hbar\alpha\lambda \frac{\partial}{\partial\lambda}\ln\langle\Phi_0|U_\alpha(\infty, -\infty|\lambda)|\Phi_0\rangle , \qquad (5.99b)$$

which result from the asymmetric energy formula (5.27). One can similarly obtain the perturbation expansion for the one- or two-particle Green functions, e.g.,

$$G_{\mu\nu}(t, t') = \lim_{\alpha \to 0+} \frac{\langle T\{a_\mu(t)a_\nu^\dagger(t')U_\alpha(\infty, -\infty|\lambda)\}\rangle}{\langle U_\alpha(\infty, -\infty|\lambda)\rangle} , \qquad (5.100)$$

with the operators in the interaction representation and the expectation values in the noninteracting ground state $|\Phi_0\rangle$. Analogous expressions result for $G(\boldsymbol{r}t, \boldsymbol{r}'t')$, etc., when the creation and annihilation operators are replaced by the corresponding field operators.

5.4.3 Potential Scattering and Quantum Dynamics

The Schrödinger equation for a free particle of energy $E = \hbar^2 k^2/2m$, moving in the potential $V(\boldsymbol{r})$,

$$\left(\nabla^2 + k^2\right)\psi(k, \boldsymbol{r}) = v(\boldsymbol{r})\psi(k, \boldsymbol{r}) ,$$
$$v(\boldsymbol{r}) = \left(2m/\hbar^2\right)V(\boldsymbol{r}) , \qquad (5.101)$$

has the formal solution

$$\psi(k, \boldsymbol{r}) = \Phi(k, \boldsymbol{r}) + \int G_0(k, \boldsymbol{r}, \boldsymbol{r}')v(\boldsymbol{r}')\psi(k, \boldsymbol{r}')\,\mathrm{d}\boldsymbol{r}' , \qquad (5.102)$$

where $\Phi(k, \boldsymbol{r})$ is a solution of the homogeneous equation $[v(\boldsymbol{r}) \equiv 0]$ and $G_0(k, \boldsymbol{r}, \boldsymbol{r}')$ is a classical Green function

$$\left(\nabla^2 + k^2\right)G_0(k, \boldsymbol{r}, \boldsymbol{r}') = \delta(\boldsymbol{r} - \boldsymbol{r}') . \qquad (5.103)$$

For an in-going plane wave $\Phi(k, \boldsymbol{r}) \equiv \Phi_{\boldsymbol{k}_i}(\boldsymbol{r}) = (2\pi)^{3/2}\exp(\mathrm{i}\boldsymbol{k}_i \cdot \boldsymbol{r})$ with the initial wave vector $\boldsymbol{k}_i$ and appropriate asymptotic boundary conditions (outgoing spherical wave with positive phase velocity), when $G_0(k, \boldsymbol{r}, \boldsymbol{r}') \equiv G_0^{(+)}(|\boldsymbol{r} - \boldsymbol{r}'|) = -(4\pi|\boldsymbol{r} - \boldsymbol{r}'|)^{-1}\,\mathrm{e}^{\mathrm{i}k|\boldsymbol{r}-\boldsymbol{r}'|}$, (5.102) is referred to as the *Lippmann–Schwinger equation* [5.52]. It can be equivalently transformed into the integral equation for the Green function

$$G^{(+)}(\boldsymbol{r}, \boldsymbol{r}') = G_0^{(+)}(\boldsymbol{r}, \boldsymbol{r}') + \int G_0^{(+)}(\boldsymbol{r}, \boldsymbol{r}'')v(\boldsymbol{r}'') \times G^{(+)}(\boldsymbol{r}'', \boldsymbol{r}')\,\mathrm{d}\boldsymbol{r}'' , \qquad (5.104)$$

representing a special case of the Dyson equation.

In the time-dependent case, considering the scattering of a spinless massive particle by a time-dependent potential $V(\boldsymbol{r}, t)$, we get similarly

$$\psi(\boldsymbol{r}, t) = \Phi(\boldsymbol{r}, t) + \int G_0(\boldsymbol{r}, \boldsymbol{r}'; t, t')V(\boldsymbol{r}', t')\psi(\boldsymbol{r}', t')\,\mathrm{d}\boldsymbol{r}'\,\mathrm{d}t' , \qquad (5.105)$$

where the zero-order time-dependent Green function now satisfies the equation

$$\left(\mathrm{i}\hbar\frac{\partial}{\partial t} - H_0\right)G_0(\boldsymbol{r}, \boldsymbol{r}'; t, t') = \delta(\boldsymbol{r} - \boldsymbol{r}')\delta(t - t') . \qquad (5.106)$$

Again, for causal propagation one chooses the *time-retarded* or *causal* Green function or propagator $G_0^{(+)}(\boldsymbol{r}, \boldsymbol{r}'; t, t')$.

5.4.4 Born Series

Iteration of (5.105) gives the *Born sequence*

$$\psi_0(\boldsymbol{r}, t) = \Phi(\boldsymbol{r}, t) ,$$
$$\psi_1(\boldsymbol{r}, t) = \Phi(\boldsymbol{r}, t) + \int G_0^{(+)}(\boldsymbol{r}, \boldsymbol{r}'; t, t') \times V(\boldsymbol{r}', t')\Phi(\boldsymbol{r}', t')\,\mathrm{d}\boldsymbol{r}'\,\mathrm{d}t' , \qquad (5.107\mathrm{a})$$
$$\psi_2(\boldsymbol{r}, t) = \Phi(\boldsymbol{r}, t) + \int G_0^{(+)}(\boldsymbol{r}, \boldsymbol{r}'; t, t') \times V(\boldsymbol{r}', t')\psi_1(\boldsymbol{r}', t')\,\mathrm{d}\boldsymbol{r}'\,\mathrm{d}t' , \qquad (5.107\mathrm{b})$$

and, generally

$$\psi_n(\boldsymbol{r}, t) = \Phi(\boldsymbol{r}, t) + \int G_0^{(+)}(\boldsymbol{r}, \boldsymbol{r}'; t, t') \times V(\boldsymbol{r}', t')\psi_{n-1}(\boldsymbol{r}', t')\,\mathrm{d}\boldsymbol{r}'\,\mathrm{d}t' . \qquad (5.108)$$

Summing individual contributions gives the *Born series* for $\psi(\boldsymbol{r}, t) \equiv \psi^{(+)}(\boldsymbol{r}, t)$,

$$\psi(\boldsymbol{r}, t) = \sum_{n=0}^{\infty} \chi_n(\boldsymbol{r}, t) , \qquad (5.109)$$

where

$$\chi_0(\boldsymbol{r}, t) = \Phi(\boldsymbol{r}, t) ,$$
$$\chi_n(\boldsymbol{r}, t) = \int \mathcal{G}_n(\boldsymbol{r}, \boldsymbol{r}'; t, t')\Phi(\boldsymbol{r}', t')\,\mathrm{d}\boldsymbol{r}'\,\mathrm{d}t' , \qquad (5.110)$$

with

$$\mathcal{G}_n(\boldsymbol{r}, \boldsymbol{r}'; t, t') = \int \mathcal{G}_1(\boldsymbol{r}, \boldsymbol{r}''; t, t'') \times \mathcal{G}_{n-1}(\boldsymbol{r}'', \boldsymbol{r}'; t'', t')\,\mathrm{d}\boldsymbol{r}''\,\mathrm{d}t'' , \quad (n > 1)$$
$$\mathcal{G}_1(\boldsymbol{r}, \boldsymbol{r}'; t, t') = G_0^{(+)}(\boldsymbol{r}, \boldsymbol{r}'; t, t')V(\boldsymbol{r}', t') . \qquad (5.111)$$

In a similar way we obtain the Born series for the scattering amplitudes or transition matrix elements.

5.4.5 Variation of Constants Method

An alternative way of formulating the time-dependent PT is the method of variation of the constants [5.53, 54]. Start again with the time-dependent Schrödinger equation (5.87) with $H = H_0 + V$, and assume that H_0 is time-independent, while V is a time-dependent perturbation. Designating the eigenvalues and eigenstates of

H_0 by ε_i and $|\Phi_i\rangle$, respectively [cf. (5.48)], the general solution of the unperturbed time-dependent Schrödinger equation

$$i\hbar \frac{\partial}{\partial t}|\Psi_0\rangle = H_0|\Psi_0\rangle \qquad (5.112)$$

has the form

$$|\Psi_0\rangle = \sum_j c_j|\Phi_j\rangle \exp\left(-\frac{i}{\hbar}\varepsilon_j t\right), \qquad (5.113)$$

with c_j representing arbitrary constants, and the sum indicating both the summation over the discrete part and the integration over the continuum part of the spectrum of H_0.

In the spirit of the general variation of constants procedure, write the unknown perturbed wave function $|\Psi(t)\rangle$, (5.87), in the form

$$|\Psi(t)\rangle = \sum_j C_j(t)|\Phi_j\rangle \exp\left(-\frac{i}{\hbar}\varepsilon_j t\right), \qquad (5.114)$$

where the $C_j(t)$ are now functions of time. Substituting this Ansatz into the time-dependent Schrödinger equation (5.87) gives

$$\dot{C}_j(t) = (i\hbar)^{-1} \sum_k C_k(t) V_{jk} \exp[(i/\hbar)\Delta_{jk}t], \qquad (5.115)$$

where

$$\Delta_{jk} = \varepsilon_j - \varepsilon_k, \quad V_{jk} = \langle \Phi_j|V|\Phi_k\rangle. \qquad (5.116)$$

Introducing again the 'small' parameter λ by writing the Hamiltonian H in the form

$$H = H_0 + \lambda V(t), \qquad (5.117)$$

and expanding the 'coefficients' $C_j(t)$ in powers of λ,

$$C_j \equiv C_j(t) = \sum_{k=0}^{\infty} C_j^{(k)}(t)\lambda^k, \qquad (5.118)$$

gives the system of first order differential equations

$$\dot{C}_j^{(n+1)} = (i\hbar)^{-1} \sum_k C_k^{(n)} V_{jk} \exp\left[(i/\hbar)\Delta_{jk}t\right],$$
$$n = 0, 1, 2, \ldots, \qquad (5.119)$$

with the initial condition $\dot{C}_j^{(0)} = 0$, which implies that $C_j^{(0)}$ are time independent, so that $C_j^{(0)} = c_j$, obtaining (5.113) in the zeroth order. The system (5.119) can be integrated to any prescribed order. For example, if the system is initially in a stationary state $|\Phi_i\rangle$, then set

$$C_j^{(0)} = \begin{cases} \delta_{ji} & \text{for discrete states}, \\ \delta(j-i) & \text{for continuous states}, \end{cases} \qquad (5.120)$$

so that

$$C_{j(i)}^{(1)}(t) = (i\hbar)^{-1} \int_{-\infty}^{t} V_{ji} \exp\left[(i/\hbar)\Delta_{ji}t'\right] dt', \qquad (5.121)$$

assuming $C_{j(i)}^{(1)}(-\infty) = 0$. Clearly, $|C_{j(i)}^{(1)}(t)|^2$ gives the first order transition probability for the transition from the initial state $|\Phi_i\rangle$ to a particular state $|\Phi_j\rangle$. These in turn will yield the first order differential cross sections [5.55].

Second Quant

6. Second Quantization

In second quantization, the characteristic properties of eigenfunctions are transferred to operators. This approach has the advantage of treating the atomic shell as the basic unit, as opposed to the electron configuration. The creation and annihilation operators allow one to move from configuration to configuration, exposing an intrinsic shell structure. The introduction of coefficients of fractional parentage (cfp) then allows the calculation of the matrix elements of an operator in one configuration to be expressed in terms of those of the same operator in another configuration; hence the matrix elements of an operator in all configurations may be determined from the knowledge of its matrix elements in but one. This can be viewed as an extension of the usual Wigner–Eckart theorem. The basic concepts of quasispin and quasiparticle are also introduced within this context.

6.1 Basic Properties

6.1.1 Definitions

The creation operator $a_\xi^\dagger$ creates the quantum state ξ. The annihilation (or destruction) operator a_η annihilates the quantum state η. The vacuum (or reference) state $|0\rangle$ satisfies the equation

$$a_\eta |0\rangle = 0 . \tag{6.1}$$

Bosons satisfy the commutation relations

$$\left[a_\xi^\dagger, a_\eta^\dagger\right] = 0 , \tag{6.2}$$

$$[a_\xi, a_\eta] = 0 , \tag{6.3}$$

$$\left[a_\xi, a_\eta^\dagger\right] = \delta(\xi, \eta) , \tag{6.4}$$

where $[A, B] \equiv AB - BA$. Fermions satisfy the anti-commutation relations

$$\left[a_\xi^\dagger, a_\eta^\dagger\right]_+ = 0 , \tag{6.5}$$

$$[a_\xi, a_\eta]_+ = 0 , \tag{6.6}$$

$$\left[a_\xi, a_\eta^\dagger\right]_+ = \delta(\xi, \eta) , \tag{6.7}$$

where $[A, B]_+ \equiv AB + BA$.

6.1.2 Representation of States

For an electron in an atom, characterized by the quantum number quartet $(n \, \ell \, m_s \, m_\ell)$, the identification $\xi \equiv (n \, \ell \, m_s \, m_\ell)$ for fermions is made. For normalized Slater determinants $\{\alpha\beta \ldots \nu\}$ characterized by the electron states $\alpha, \beta, \ldots, \nu$, the equivalences

$$a_\alpha^\dagger a_\beta^\dagger \ldots a_\nu^\dagger |0\rangle \equiv \{\alpha\beta \ldots \nu\} , \tag{6.8}$$

$$\langle 0|a_\nu \ldots a_\beta a_\alpha \equiv \{\alpha\beta \ldots \nu\}^* \tag{6.9}$$

are valid, where the asterisk denotes the complex conjugate.

For a normalized boson state $\{ \cdots \}$ in which the label ξ appears N_ξ times, the additional factor

$$[N_\alpha! N_\beta! \ldots N_\nu!]^{-\frac{1}{2}} \tag{6.10}$$

must be included on the left-hand sides of the equivalences (6.8) and (6.9).

6.1.3 Representation of Operators

For an operator F, consisting of the sum of operators f_i acting on the single electron i,

$$F \equiv \sum_{\xi,\eta} a_\xi^\dagger \langle \xi | f | \eta \rangle a_\eta . \tag{6.11}$$

For an operator G, consisting of the sum of operators g_{ij} acting on the pair of electrons i and j,

$$G \equiv \frac{1}{2} \sum_{\xi,\eta,\zeta,\lambda} a_\xi^\dagger a_\eta^\dagger \langle \xi_1 \eta_2 | g_{12} | \zeta_1 \lambda_2 \rangle a_\lambda a_\zeta . \tag{6.12}$$

For an N-particle system $|\Psi\rangle$,

$$\sum_\xi a_\xi^\dagger a_\xi |\Psi\rangle = N|\Psi\rangle . \tag{6.13}$$

The representations of single-particle and two-particle operators for bosons are identical to those given above for fermions [6.1].

6.2 Tensors

6.2.1 Construction

If the description ξ for a single fermion or boson state includes an angular momentum quantum number t and the corresponding magnetic quantum number m_t, then the $2t + 1$ components of a creation operator $a_\sigma^\dagger$, where $\sigma \equiv (t, m_t)$ and $-t \le m_t \le t$, satisfy the commutation relations of *Racah* [6.2] for an irreducible spherical tensor of rank t with respect to the total angular momentum T, given by

$$T = \sum a_\xi^\dagger \langle \xi | t | \eta \rangle a_\eta . \tag{6.14}$$

That is, with the phase conventions of *Condon* and *Shortley* [6.3],

$$\left[T_z, a_\sigma^\dagger \right] = m_t a_\sigma^\dagger , \tag{6.15}$$

$$\left[T_x \pm \mathrm{i} T_y, a_\sigma^\dagger \right] = [t(t+1) - m_t(m_t \pm 1)]^{\frac{1}{2}} a_\tau^\dagger , \tag{6.16}$$

where $\tau \equiv (t, m_t \pm 1)$.

A spherical tensor a constructed from annihilation operators possesses the components $\tilde{a}_\sigma$, which satisfy

$$\tilde{a}_\sigma = (-1)^p a_\zeta , \tag{6.17}$$

with $p = t - m_t$ and $\zeta \equiv (t, -m_t)$.

The $4\ell + 2$ components of the creation operator for an electron in the atomic ℓ shell form a double tensor of rank $\frac{1}{2}$ with respect to the total spin S, and rank ℓ with respect to the total angular momentum L.

6.2.2 Coupled Forms

Tensors formed from annihilation and creation operators can be coupled by means of the usual rules of angular momentum theory [6.4]. The double tensor defined for electrons in the ℓ shell by

$$W^{(\kappa k)} = -\left(a^\dagger a \right)^{(\kappa k)} , \tag{6.18}$$

possesses a rank κ with respect to S, and rank k with respect to L. Its reduced matrix element, defined here as in (5.4.1) of *Edmonds* [6.4], for a single electron in both the spin and orbital spaces, is given by

$$\left(s \, \ell \, || \, W^{(\kappa k)} \, || \, s \, \ell \right) = [(2\kappa + 1)(2k + 1)]^{\frac{1}{2}} . \tag{6.19}$$

The connections to tensors whose matrix elements have been tabulated [6.5, 6] are

$$W^{(0k)} = [(2k+1)/2]^{\frac{1}{2}} U^{(k)} , \tag{6.20}$$

$$W^{(1k)} = [2(2k+1)]^{\frac{1}{2}} V^{(k1)} . \tag{6.21}$$

For terms with common spin S, say ψ and ψ',

$$\left(\psi || W^{(0k)} || \psi' \right) = \\ [(2S+1)(2k+1)/2]^{\frac{1}{2}} \left(\psi || U^{(k)} || \psi' \right) . \tag{6.22}$$

This result is obtained because the ranks assigned to the tensors imply that $W^{(0k)}$ is to be reduced with respect to both the spin S and the orbit L, while $U^{(k)}$ is to be reduced only with respect to L.

The following relations hold for electrons with azimuthal quantum numbers ℓ [6.7]:

$$S = [(2\ell+1)/2]^{\frac{1}{2}} W^{(10)} , \qquad (6.23)$$

$$L = [2\ell(\ell+1)(2\ell+1)/3]^{\frac{1}{2}} W^{(01)} , \qquad (6.24)$$

$$\sum_i \left(s_i C_i^{(2)}\right)^{(1)} = -\left(\frac{\ell(\ell+1)(2\ell+1)}{10(2\ell-1)(2\ell+3)}\right)^{\frac{1}{2}} W^{(12)1} , \qquad (6.25)$$

$$\sum_i (s_i \cdot \ell_i) = -[\ell(\ell+1)(2\ell+1)/2] W^{(11)0} , \qquad (6.26)$$

where the tensor C^k of *Racah* [6.2] is related to the spherical harmonics by

$$C_q^{(k)} = [4\pi/(2k+1)]^{\frac{1}{2}} Y_{kq} , \qquad (6.27)$$

and where the tensors of the type $W^{(\kappa k)K}$ indicate that the spin and orbital ranks are coupled to a resultant K.

6.2.3 Coefficients of Fractional Parentage

Let ψ and $\bar{\psi}$ denote terms of ℓ^N and ℓ^{N-1} characterized by (S, L) and $(\bar{S}, \bar{L})$. The coefficients of fractional parentage (cfp) $(\psi\{|\bar{\psi})$ of *Racah* [6.8] allow one to calculate an antisymmetrized function ψ by vector-coupling $\bar{\psi}$ to the spin and orbit of the Nth electron:

$$|\psi\rangle = \sum_{\bar{\psi}} |\bar{\psi}, {}^2\ell, SL\rangle \left(\bar{\psi}|\}\psi\right) , \qquad (6.28)$$

where the sum over $\bar{\psi}$ includes $\bar{S}, \bar{L}$, and any other quantum numbers necessary to define the spectroscopic terms of ℓ^{N-1}. The cfp's are given by

$$\left(\psi||a^\dagger||\bar{\psi}\right) = (-1)^N [N(2S+1)(2L+1)]^{\frac{1}{2}} \left(\psi\{|\bar{\psi}\right) , \qquad (6.29)$$

$$\left(\bar{\psi}||a||\psi\right) = (-1)^g [N(2S+1)(2L+1)]^{\frac{1}{2}} \left(\bar{\psi}|\}\psi\right) , \qquad (6.30)$$

where $g = N + \bar{S} + \bar{L} - s - S - \ell - L$. A tabulation for the p, d, and f shells has been given by *Nielson* and *Koster* [6.5].

Two-electron cfp are given by

$$\left(\psi||\left(a^\dagger a^\dagger\right)^{(\kappa k)}||\tilde{\psi}\right) = [N(N-1)(2S+1)(2L+1)]^{\frac{1}{2}}$$
$$\times \left(\psi\{|\tilde{\psi}, \ell^2(\kappa k)\right) , \qquad (6.31)$$

where $\tilde{\psi}$ denotes a term of ℓ^{N-2}, and the symbols κ and k stand for the S and the L of a term of ℓ^2. A tabulation for the p, d, and f shells has been given by *Donlan* [6.9]. An extension to all multielectron cfp has been carried out by *Velkov* [6.10].

If, through successive applications of the two-particle operators $(aa)^{(00)}$, a state of ℓ^N can be reduced to ℓ^v, but no further, then v is the seniority number of *Racah* [6.8].

If the ranks s and ℓ of $a^\dagger$ are coupled to $\bar{S}$ and $\bar{L}$ of $\bar{\psi}$, the term

$$\left(a^\dagger|\bar{\psi}\right)^{(SL)} \qquad (6.32)$$

either vanishes, or is a term of ℓ^N characterized by S and L. Such a term is said to possess the *godparent* $\bar{\psi}$. *Redmond* [6.11] has used the notion of godparents to generate an explicit formula for the single particle cfp [6.7].

6.3 Quasispin

6.3.1 Fermions

For electrons, the components $Q_\pm (\equiv Q_x \pm iQ_y)$ and Q_z of the quasispin Q are defined by [6.7, 12]

$$Q_+ = [(2\ell+1)/2]^{\frac{1}{2}} \left(a^\dagger a^\dagger\right)^{(00)} , \qquad (6.33)$$

$$Q_- = -[(2\ell+1)/2]^{\frac{1}{2}} (aa)^{(00)} , \qquad (6.34)$$

$$Q_z = -[(2\ell+1)/8]^{\frac{1}{2}} \left[\left(a^\dagger a\right)^{(00)} + \left(aa^\dagger\right)^{(00)}\right] . \qquad (6.35)$$

The term quasispin comes from the fact that the components of Q satisfy the commutation relations of an angular momentum vector. The eigenvalues M_Q of Q_z, for a state of ℓ^N, are given by

$$M_Q = -(2\ell+1-N)/2 . \qquad (6.36)$$

The shift operators Q_+ and Q_- connect states of the ℓ shell possessing the same value of the seniority v of *Racah* [6.8]. A string of such connected states defines the extrema of M_Q, from which it follows that

$$Q = (2\ell+1-v)/2 . \qquad (6.37)$$

Rudzikas has placed special emphasis on quasispin in his reworking of atomic shell theory, and he has also introduced isospin to embrace electrons differing in their principal quantum numbers n [6.13]. Concise tables of one-electron cfp with their quasispin dependence factored out have been given [6.14], as have the algebraic dependences on v and S of two-electron cfp [6.15].

6.3.2 Bosons

For real vibrational modes created by $a_v^\dagger$ ($v = 1, 2, \ldots, d$), the analogs of (6.33–6.35) are

$$P_+ = -\frac{1}{2}\sum_v a_v^\dagger a_v^\dagger \,, \tag{6.38}$$

$$P_- = \frac{1}{2}\sum_v a_v a_v \,, \tag{6.39}$$

$$P_z = \frac{1}{4}\sum_v \left(a_v^\dagger a_v + a_v a_v^\dagger\right) \,, \tag{6.40}$$

and P is an angular momentum vector [6.16]. The eigenvalues M_P for an n-boson state are given by

$$M_P = (2n + d)/4 \,, \tag{6.41}$$

and can therefore be quarter-integral. Successive application of the operator P_+ to a state $|n_0\rangle$, for which $P_-|n_0\rangle = 0$, generates an infinite ladder of states characterized by

$$P = (2n + d - 4)/4 \,. \tag{6.42}$$

6.3.3 Triple Tensors

The creation and annihilation operators $a_\xi^\dagger$ and a_ξ for a given state ξ can be regarded as the two components of a tensor of rank $\frac{1}{2}$ with respect to quasispin (either Q or P). For electrons, this leads to triple tensors $a^{(qs\ell)}$ (for which $q = s = \frac{1}{2}$) satisfying

$$a_\lambda^{(qs\ell)} a_\mu^{(qs\ell)} + a_\mu^{(qs\ell)} a_\lambda^{(qs\ell)} =$$
$$(-1)^{x+1}\delta\left(m_q, -m_q'\right)\delta\left(m_s, -m_s'\right)\delta\left(m_\ell, -m_\ell'\right) \,, \tag{6.43}$$

where $\lambda \equiv (m_q m_s m_\ell)$, $\mu \equiv (m_q' m_s' m_\ell')$, and $x = q + s + \ell + m_q + m_s + m_\ell$. In terms of the coupled tensor

$$X^{(K\kappa k)} = (a^{(qs\ell)} a^{(qs\ell)})^{(K\kappa k)} \,, \tag{6.44}$$

the angular momenta Q, S, and L are given by

$$Q = -[(2\ell + 1)/4]^{\frac{1}{2}} X^{(100)} \,, \tag{6.45}$$

$$S = -[(2\ell + 1)/4]^{\frac{1}{2}} X^{(010)} \,, \tag{6.46}$$

$$L = -[\ell(\ell + 1)(2\ell + 1)/3]^{\frac{1}{2}} X^{(001)} \,. \tag{6.47}$$

Furthermore, the components of $X^{(K\kappa k)}$ for which $M_K = 0$ are identical to the corresponding components of $2^{\frac{1}{2}}(a^\dagger a)^{(\kappa k)}$ when $K + \kappa + k$ is odd; and

$$X^{(K\kappa k)} = -(2\ell + 1)^{\frac{1}{2}}\delta(K, 0)\delta(\kappa, 0)\delta(k, 0) \tag{6.48}$$

when $K + \kappa + k$ is even.

6.3.4 Conjugation

Creation and annihilation operators can be interchanged by the operation of the conjugation operator C [6.7, 17]. For electrons in the atomic ℓ shell,

$$C a_\xi^{(qs\ell)} C^{-1} = (-1)^{q - m_q} a_\eta^{(qs\ell)} \,, \tag{6.49}$$

where $\xi \equiv (m_q m_s m_\ell)$ and $\eta \equiv ((-m_q) m_s m_\ell)$. In terms of the tensors $a^\dagger$ and a,

$$C a^\dagger C^{-1} = a \,, \quad C a C^{-1} = -a^\dagger \,. \tag{6.50}$$

Furthermore,

$$C X_\lambda^{(K\kappa k)} C^{-1} = (-1)^{K - M_K} X_\mu^{(K\kappa k)} \,, \tag{6.51}$$

where $\lambda \equiv (M_K M_\kappa M_k)$ and $\mu \equiv [(-M_K) M_\kappa M_k]$, and

$$C|Q M_Q\rangle = (-1)^{Q - M_Q}|Q - M_Q\rangle \,. \tag{6.52}$$

Thus, from (6.36), the action of C takes N into $4\ell + 2 - N$; that is, C interchanges electrons and holes. When the case $\kappa = k = 0$ is excluded, application of (6.51) and (6.52) yields

$$\left(\ell^N \psi \| W^{(\kappa k)} \| \ell^N \psi'\right) =$$
$$(-1)^y \left(\ell^{4\ell + 2 - N}\psi \| W^{(\kappa k)} \| \ell^{4\ell + 2 - N}\psi'\right) \,, \tag{6.53}$$

where $y = \kappa + k + \frac{1}{2}(v' - v) + 1$, and where the seniorities v and v' are implied by ψ and ψ'. A similar application to reduced matrix elements of $a^\dagger$ and a gives the following relation between cfp:

$$\left(\ell^{N+1}\psi\{|\ell^N \psi'\right) = (-1)^z \left(\ell^{4\ell + 1 - N}\psi\}|\ell^{4\ell + 2 - N}\psi'\right)$$
$$\times \left(\frac{(4\ell + 2 - N)(2S' + 1)(2L' + 1)}{(N + 1)(2S + 1)(2L + 1)}\right)^{\frac{1}{2}} \,, \tag{6.54}$$

where $z = S + S' - s + L + L' - \ell + \frac{1}{2}(v + v' - 1)$. The phases y and z stem from the conventions of angular momentum theory, which enter via quasispin. *Racah* [6.2, 8] did not use this concept, and his phase choices are slightly different from the ones above.

For a Cartesian component Q_u of the quasispin $\boldsymbol{Q}$,

$$CQ_uC^{-1} = -Q_u \, . \tag{6.55}$$

Thus, C is the analog of the time-reversal operator T, for which

$$TL_uT^{-1} = -L_u \, , \tag{6.56}$$

$$TS_uT^{-1} = -S_u \, . \tag{6.57}$$

Both C and T are antiunitary; thus,

$$CiC^{-1} = -\mathrm{i} \, . \tag{6.58}$$

6.3.5 Dependence on Electron Number

Application of the Wigner–Eckart theorem to matrix elements whose component parts have well-defined quasispin ranks yields the dependence of the matrix elements on the electron number N [6.18, 19]. For $\kappa + k$ even and nonzero, the quasispin rank of $\boldsymbol{W}^{(\kappa k)}$ is 1, and

$$\left(\ell^N \psi || W^{(\kappa k)} || \ell^N \psi'\right) = \tag{6.59}$$
$$\frac{(2\ell + 1 - N)}{(2\ell + 1 - v)}\left(\ell^v \psi || W^{(\kappa k)} || \ell^v \psi'\right) \, .$$

For $\kappa + k$ odd, $\boldsymbol{W}^{(\kappa k)}$ is necessarily a quasispin scalar, and the matrix elements are diagonal with respect to the seniority and independent of N. These properties were first stated in Eqs. (69) and (70) of [6.8].

Application of these ideas to single-electron cfp yields, for states ψ and $\bar{\psi}$ with seniorities v and $v + 1$, respectively,

$$\left(\ell^N \psi \{|\ell^{N-1}\bar{\psi}\right) =$$
$$[(N - v)(v + 2)/2N]^{\frac{1}{2}}\left(\ell^{v+2}\psi |\}\ell^{v+1}\bar{\psi}\right) \, . \tag{6.60}$$

6.3.6 The Half-filled Shell

Selection rules for operators of good quasispin rank K, taken between states of the half-filled shell (for which $M_Q = 0$), can be found by inspecting the $3-j$ symbol

$$\begin{pmatrix} Q & K & Q' \\ 0 & 0 & 0 \end{pmatrix} \, ,$$

which appears when the Wigner-Eckart theorem is applied in quasispin space. This $3-j$ symbol vanishes unless $Q + K + Q'$ is even. An equivalent result can be obtained for $\boldsymbol{W}^{(\kappa k)}$ by referring to (6.53) and insisting that y be even.

6.4 Complementarity

6.4.1 Spin–Quasispin Interchange

The operator R formally interchanges spin and quasispin. The result for the creation and annihilation operators for electrons can be expressed in terms of triple tensors:

$$Ra_\xi^{(qs\ell)}R^{-1} = a_\eta^{(qs\ell)} \, , \tag{6.61}$$

where $\xi \equiv (m_q m_s m_\ell)$ and $\eta \equiv (m_s m_q m_\ell)$. For the tensors $X^{(K\kappa k)}$ defined in (6.44), we get

$$RX_\lambda^{(K\kappa k)}R^{-1} = X_\mu^{(\kappa K k)} \, , \tag{6.62}$$

where $\lambda \equiv (M_K M_\kappa M_k)$ and $\mu \equiv (M_\kappa M_K M_k)$. For states of the ℓ shell,

$$R|\gamma Q M_Q S M_S\rangle = (-1)^t |\gamma S M_S Q M_Q\rangle \, , \tag{6.63}$$

where the quasispin of the ket on the right is S and the spin is Q. The phase factor t depends on S and Q and on phase choices made for the coefficients of fractional parentage. The symbol γ denotes the additional labels necessary to completely define the state in question, including L and M_L.

For every γ, *Racah* [6.20] observed that there are two possible pairs (v_1, S_1) and (v_2, S_2) satisfying

$$v_1 + 2S_2 = v_2 + 2S_1 = 2\ell + 1 \, . \tag{6.64}$$

From (6.37) it follows that

$$S_1 = Q_2 \, , \qquad S_2 = Q_1 \, . \tag{6.65}$$

6.4.2 Matrix Elements

Application of the complementarity operator R to the component parts of a matrix element leads to the equation

$$\langle \gamma Q M_Q S M_S | X_\lambda^{(K\kappa k)} | \gamma' Q' M'_Q S' M'_S \rangle = \tag{6.66}$$
$$(-1)^y \langle \gamma S M_S Q M_Q | X_\mu^{(\kappa K k)} | \gamma' S' M'_S Q' M'_Q \rangle \, ,$$

where λ and μ have the same significance as in (6.62), and where y, like t of (6.63), depends on the spins and quasispins but not on the associated magnetic quantum numbers. Equation (6.66) leads to a useful special case when $M_K = M_\kappa = 0$ and the tensors X are converted to

those of type W, defined in (6.18). The sum $K + \kappa + k$ is taken to be odd, with the scalars $\kappa = k = 0$ and $K = k = 0$ excluded. Application of the Wigner-Eckart theorem to the spin and orbital spaces yields

$$
\frac{\left(\gamma Q M_Q S || W^{(\kappa k)} || \gamma' Q' M'_Q S'\right)}{\left(\gamma S M_S Q || W^{(Kk)} || \gamma' S' M'_S Q'\right)} =
$$

$$
(-1)^z \frac{\begin{pmatrix} Q & K & Q' \\ -M_Q & 0 & M_Q \end{pmatrix}}{\begin{pmatrix} S & \kappa & S' \\ -M_S & 0 & M_S \end{pmatrix}} , \tag{6.67}
$$

where $z = y + Q - M_Q - S + M_S$. An equivalent form is

$$
\frac{\left(\ell^N \gamma v_1 S_1 || W^{(\kappa k)} || \ell^N \gamma' v'_1 S'_1\right)}{\left(\ell^{N'} \gamma v_2 S_2 || W^{(Kk)} || \ell^{N'} \gamma' v'_2 S'_2\right)} = \tag{6.68}
$$

$$
(-1)^z \frac{\begin{pmatrix} \frac{1}{2}(2\ell+1-v_1) & K & \frac{1}{2}(2\ell+1-v'_1) \\ \frac{1}{2}(2\ell+1-N) & 0 & \frac{1}{2}(N-2\ell-1) \end{pmatrix}}{\begin{pmatrix} \frac{1}{2}(2\ell+1-v_2) & \kappa & \frac{1}{2}(2\ell+1-v'_2) \\ \frac{1}{2}(2\ell+1-N') & 0 & \frac{1}{2}(N'-2\ell-1) \end{pmatrix}} ,
$$

where (6.64) is satisfied both for the unprimed and primed quantities.

6.5 Quasiparticles

Sets of linear combinations of the creation and annihilation operators for electrons in the ℓ shell can be constructed such that every member of one set anticommutes with a member of a different set. To preserve the tensorial character of these quasiparticle operators with respect to L, it is convenient to define [6.21]

$$
\lambda_q^\dagger = 2^{-\frac{1}{2}} \left[a_{\frac{1}{2},q}^\dagger + (-1)^{\ell-q} a_{\frac{1}{2},-q} \right] , \tag{6.69}
$$

$$
\mu_q^\dagger = 2^{-\frac{1}{2}} \left[a_{\frac{1}{2},q}^\dagger - (-1)^{\ell-q} a_{\frac{1}{2},-q} \right] , \tag{6.70}
$$

$$
v_q^\dagger = 2^{-\frac{1}{2}} \left[a_{-\frac{1}{2},q}^\dagger + (-1)^{\ell-q} a_{-\frac{1}{2},-q} \right] , \tag{6.71}
$$

$$
\xi_q^\dagger = 2^{-\frac{1}{2}} \left[a_{-\frac{1}{2},q}^\dagger - (-1)^{\ell-q} a_{-\frac{1}{2},-q} \right] . \tag{6.72}
$$

The four tensors $\theta^\dagger (\equiv \lambda^\dagger, \mu^\dagger, v^\dagger, \text{ or } \xi^\dagger)$ anticommute with each other; the first two act in the spin-up space, the second two in the spin-down space. The tensors θ, whose components $\tilde{\theta}_q$ are defined as in (6.17) with $t = \ell$ and $m_t = q$, are related to their adjoints by the equations

$$
\lambda^\dagger = \lambda , \qquad \mu^\dagger = -\mu , \tag{6.73}
$$

$$
v^\dagger = v , \qquad \xi^\dagger = -\xi . \tag{6.74}
$$

Under the action of the complementarity operator R (see (6.61)) [6.22],

$$
R \lambda R^{-1} = \lambda , \qquad R \mu R^{-1} = \mu , \tag{6.75}
$$

$$
R v R^{-1} = v , \qquad R \xi R^{-1} = -\xi . \tag{6.76}
$$

The tensors λ, μ, and v, for a given component q, form a vector with respect to $S + Q$. Every component of ξ is scalar with respect to $S + Q$ [6.23].

The compound quasiparticle operators defined by [6.21]

$$
\Theta_q^\dagger = 2^{-\frac{1}{2}} [\theta_q^\dagger, \theta_0^\dagger] , \tag{6.77}
$$

where $q > 0$ and $\theta \equiv \lambda$, μ, v, or ξ satisfy the anticommutation relations

$$
[\Theta_q^\dagger, \Theta_{q'}^\dagger]_+ = 0 , \tag{6.78}
$$

$$
[\Theta_q, \Theta_{q'}]_+ = 0 , \tag{6.79}
$$

$$
[\Theta_q^\dagger, \Theta_{q'}]_+ = \delta(q, q') , \tag{6.80}
$$

for $q, q' > 0$. The $\Theta_q^\dagger$ with $q > 0$ can thus be regarded as the creation operators for a fermion quasiparticle with ℓ components.

The connection between the creation and annihilation operators for quasiparticles and for quarks (appearing in the last two rows of Table 3.1) is

$$
\theta \rightarrow 2^{(\ell-1)/2} \epsilon_\theta \gamma_\theta \left(q_\theta^\dagger q_\theta \right)^{(10...0)} , \tag{6.81}
$$

where the γ_θ are Dirac matrices satisfying

$$
\gamma_\theta \gamma_\phi + \gamma_\phi \gamma_\theta = 2\delta(\theta, \phi) , \tag{6.82}
$$

and the ϵ_θ are phases, to some extent dependent on the definitions (6.69–6.72) [6.24]. The superscript $(10...0)$ indicates that $q_\theta^\dagger$ and q_θ each of which belongs to the elementary spinor $(\frac{1}{2}\frac{1}{2}...\frac{1}{2})$ of $SO_\theta(2\ell+1)$, are to be coupled to the resultant $(10...0)$, which matches the group label for θ. In the quark model, the $2^{4\ell+2}$ states of the atomic ℓ shell are given by

$$
q_\lambda^\dagger q_\mu^\dagger q_v^\dagger q_\xi^\dagger |0\rangle_{pp'} , \tag{6.83}
$$

where p and p' are parity labels that distinguish the four reference states $|0\rangle$ corresponding to the evenness and oddness of the number of spin-up and spin-down electrons. The scalar nature of ξ (and hence of $\boldsymbol{q}_\xi$) with respect to $\boldsymbol{S}+\boldsymbol{Q}$ can be used to derive relations between spin-orbit matrix elements that go beyond those expected from an application of the Wigner–Eckart theorem [6.25].

7. Density Matrices

The density operator was first introduced by J. von *Neumann* [7.1] in 1927 and has since been widely used in quantum statistics. Over the past decades, however, the application of density matrices has spread to many other fields of physics. Density matrices have been used to describe, for example, coherence and correlation phenomena, alignment and orientation and their effect on the polarization of emitted radiation, quantum beat spectroscopy, optical pumping, and scattering processes, particularly when spin–polarized projectiles and/or targets are involved. A thorough introduction to the theory of density matrices and their applications with emphasis on atomic physics can be found in the book by *Blum* [7.2] from which many equations have been extracted for use in this chapter.

The main advantage of the density matrix formalism is its ability to deal with pure and mixed states in the same consistent manner. The preparation of the initial state as well as the details regarding the observation of the final state can be treated in a systematic way. In particular, averages over quantum numbers of unpolarized beams in the initial state and incoherent sums over non-observed quantum numbers in the final state can be accounted for via the reduced density matrix. Furthermore, expansion of the density matrix in terms of irreducible tensor operators and the corresponding state multipoles allows for the use of advanced angular momentum techniques, as outlined in Chaps. 2, 3 and 12. More details can be found in two recent textbooks [7.3, 4].

7.1 Basic Formulae

7.1.1 Pure States

Consider a system in a quantum state that is represented by a single wave function $|\Psi\rangle$. The density operator for this situation is defined as

$$\rho = |\Psi\rangle\langle\Psi| \, . \tag{7.1}$$

If $|\Psi\rangle$ is normalized to unity, i.e., if

$$\langle\Psi|\Psi\rangle = 1 \, , \tag{7.2}$$

then

$$\rho^2 = \rho \, . \tag{7.3}$$

Equation (7.3) is the basic equation for identifying *pure* quantum mechanical states represented by a density operator.

Next, consider the expansion of $|\Psi\rangle$ in terms of a complete orthonormal set of basis functions $\{|\Phi_n\rangle\}$, i.e.,

$$|\Psi\rangle = \sum_n c_n |\Phi_n\rangle . \tag{7.4}$$

The density operator then becomes

$$\rho = \sum_{n,m} c_n c_m^* |\Phi_n\rangle\langle\Phi_m| = \rho_{nm} |\Phi_n\rangle\langle\Phi_m| , \tag{7.5}$$

where the star denotes the complex conjugate quantity. Note that the density matrix elements $\rho_{nm} = \langle\Phi_n|\,\rho\,|\Phi_m\rangle$ depend on the choice of the basis and that the density matrix is Hermitian, i.e.,

$$\rho_{mn}^* = \rho_{nm} . \tag{7.6}$$

Finally, if $|\Psi\rangle = |\Phi_i\rangle$ is one of the basis functions, then

$$\rho_{mn} = \delta_{ni}\delta_{mi} , \tag{7.7}$$

where δ_{ni} is the Kronecker δ. Hence, the density matrix is diagonal in this representation with only one nonvanishing element.

7.1.2 Mixed States

The above concepts can be extended to treat statistical ensembles of pure quantum states. In the simplest case, such *mixed* states can be represented by a diagonal density matrix of the form

$$\rho = \sum_n w_n |\Psi_n\rangle\langle\Psi_n| , \tag{7.8}$$

where the weight w_n is the fraction of systems in the pure quantum state $|\Psi_n\rangle$. The standard normalization for the trace of ρ is

$$\mathrm{Tr}\{\rho\} = \sum_n w_n = 1 . \tag{7.9}$$

Since the trace is invariant under unitary transformations of the basis functions, (7.9) also holds if the $|\Psi_n\rangle$ states themselves are expanded in terms of basis functions as in (7.4). For a pure state and the normalization (7.9), one finds in an arbitrary basis

$$\mathrm{Tr}\{\rho\} = \mathrm{Tr}\{\rho^2\} = 1 . \tag{7.10}$$

7.1.3 Expectation Values

The density operator contains the maximum available information about a physical system. Consequently, it can be used to calculate expectation values for any operator $\mathcal{A}$ that represents a physical observable. In general,

$$\langle\mathcal{A}\rangle = \mathrm{Tr}\{\mathcal{A}\rho\}/\mathrm{Tr}\{\rho\} , \tag{7.11}$$

where $\mathrm{Tr}\{\rho\}$ in the denominator of (7.11) ensures the correct result even for a normalization that is different from (7.9). The invariance of the trace operation ensures the same result – independent of the particular choice of the basis representation.

7.1.4 The Liouville Equation

Suppose (7.8) is valid for a time $t = 0$. If the functions $|\Psi_n(\mathbf{r}, t)\rangle$ obey the Schrödinger equation, i.e.

$$\mathrm{i}\frac{\partial}{\partial t}|\Psi_n(\mathbf{r}, t)\rangle = H(t)|\Psi_n(\mathbf{r}, t)\rangle , \tag{7.12}$$

the density operator at the time t can be written as

$$\rho(t) = U(t)\,\rho(0)\,U^\dagger(t) . \tag{7.13}$$

In (7.13), $U(t)$ is the time evolution operator which relates the wave functions at times $t = 0$ and t according to

$$|\Psi_n(\mathbf{r}, t)\rangle = U(t)|\Psi_n(\mathbf{r}, 0)\rangle , \tag{7.14}$$

and $U^\dagger(t)$ denotes its adjoint. Note that

$$U(t) = \mathrm{e}^{-\mathrm{i}Ht} , \tag{7.15}$$

if the Hamiltonian H is time-independent.

Differentiation of (7.13) with respect to time and inserting (7.14) into the Schrödinger equation (7.12) yields the equation of motion

$$\mathrm{i}\frac{\partial}{\partial t}\rho(t) = [H(t), \rho(t)] , \tag{7.16}$$

where $[\mathcal{A}, \mathcal{B}]$ denotes a commutator.

The Liouville equation (7.16) can be used to determine the density matrix and to treat transitions from nonequilibrium to equilibrium states in quantum mechanical systems. Especially for approximate solutions in the presence of small time-dependent perturbation terms in an otherwise time-independent Hamiltonian, i.e., for

$$H(t) = H_0 + V(t) , \tag{7.17}$$

the interaction picture is preferably used. The Liouville equation then becomes

$$\mathrm{i}\frac{\partial}{\partial t}\rho_\mathrm{I}(t) = \left[V_\mathrm{I}(t), \rho_\mathrm{I}(t)\right] , \tag{7.18}$$

where the subscript I denotes the operator in the interaction picture. In first-order perturbation theory, (7.18) can be integrated to yield

$$\rho_I(t) = \rho_I(0) - i \int_0^t [V_I(\tau), \rho_I(0)]\, d\tau \;, \qquad (7.19)$$

and higher-order terms can be obtained through subsequent iterations.

7.1.5 Systems in Thermal Equilibrium

According to quantum statistics, the density operator for a system which is in thermal equilibrium with a surrounding reservoir $\mathcal{R}$ at a temperature T (canonical ensemble), can be expressed as

$$\rho = \frac{\exp(-\beta H)}{Z} \;, \qquad (7.20)$$

where H is the Hamiltonian, and $\beta = 1/k_B T$ with k_B being the Boltzmann constant. The partition sum

$$Z = \text{Tr}\big\{ \exp(-\beta H) \big\} \;, \qquad (7.21)$$

ensures the normalization condition (7.9). Expectation values are calculated according to (7.11), and extensions to other types of ensembles are straightforward.

7.1.6 Relaxation Processes

Transitions from nonequilibrium to equilibrium states can also be described within the density matrix formalism. One of the basic problems is to account for irreversibility in the energy (and sometimes particle) exchange between the system of interest, $\mathcal{S}$, and the reservoir, $\mathcal{R}$. This is usually achieved by assuming that the interaction of the system with the reservoir is negligible and, therefore, the density matrix representation for the reservoir at any time t is the same as the representation for $t = 0$.

Another important assumption that is frequently made is the Markov approximation. In this approximation, one assumes that the system "forgets" all knowledge of the past, so that the density matrix elements at the time $t + \Delta t$ depend only on the values of these elements, and their first derivatives, at the time t. When (7.19) is put back into (7.18), the result in the Markov approximation can be rewritten as

$$\frac{\partial}{\partial t} \rho_{\mathcal{S}I}(t) = - i \,\text{Tr}_{\mathcal{R}}\big[V_I(t),\, \rho_{\mathcal{S}I}(0)\rho_{\mathcal{R}}(0)\big]$$
$$- \int_0^t d\tau \,\text{Tr}_{\mathcal{R}}\big[V_I(t),[V_I(\tau),\rho_{\mathcal{S}I}(t)\rho_{\mathcal{R}}(0)]\big] \;, \qquad (7.22)$$

where $\text{Tr}_{\mathcal{R}}$ denotes the trace with regard to all variables of the reservoir. Note that the integral over $d\tau$ contains the system density matrix in the interaction picture, $\rho_{\mathcal{S}I}$, at the time t, rather than at all times τ which are integrated over (the Markov approximation), and that the density matrix for the reservoir is taken as $\rho_{\mathcal{R}}(0)$ at all times. For more details, see Chapter 7 of *Blum* [7.2] and references therein.

Equations such as (7.22) are the basis for the master or rate equation approach used, for example, in quantum optics for the theory of lasers and the coupling of atoms to cavity modes. For more details, see Chapts. 68, 69, 70 and 78.

7.2 Spin and Light Polarizations

Density matrices are frequently used to describe the polarization state of spin-polarized particle beams as well as light. The latter can either be emitted from excited atomic or molecular ensembles or can be used, for example, for laser pumping purposes.

7.2.1 Spin–Polarized Electrons

The spin polarization of an electron beam with respect to a given quantization axis $\hat{n}$ is defined as [7.5]

$$P_{\hat{n}} = \frac{N_\uparrow - N_\downarrow}{N_\uparrow + N_\downarrow} \;, \qquad (7.23)$$

where $N_\uparrow (N_\downarrow)$ is the number of electrons with spin up (down) with regard to this axis. An arbitrary polarization state is described by the density matrix

$$\rho = \frac{1}{2} \begin{pmatrix} 1 + P_z & P_x - iP_y \\ P_x + iP_y & 1 - P_z \end{pmatrix} \;, \qquad (7.24)$$

where $P_{x,y,x}$ are the cartesian components of the spin polarization vector. The individual components can be obtained from the density matrix as

$$P_i = \text{Tr}\{\sigma_i\, \rho\} \;, \qquad (7.25)$$

where the σ_i $(i = x, y, z)$ are the standard Pauli spin matrices.

7.2.2 Light Polarization

Another important use of the density matrix formalism is the description of light polarization in terms of the so-called Stokes parameters [7.6]. For a given direction of observation, the general polarization state of light can be fully determined by the measurement of one circular and two independent linear polarizations. Using the notation of Born and Wolf [7.7], the density matrix is given by

$$\rho = \frac{I_{\text{tot}}}{2} \begin{pmatrix} 1 - P_3 & P_1 - iP_2 \\ P_1 + iP_2 & 1 + P_3 \end{pmatrix} , \tag{7.26}$$

where P_1 and P_2 are linear light polarizations while P_3 is the circular polarization (see also Sect. 7.6). In (7.26), the density matrix is normalized in such as way that

$$\text{Tr}\{\rho\} = I_{\text{tot}} , \tag{7.27}$$

where I_{tot} is the total light intensity. Other frequently used names for the various Stokes parameters are

$$P_1 = \quad \eta_3 \ = M , \tag{7.28}$$
$$P_2 = \quad \eta_1 \ = C , \tag{7.29}$$
$$P_3 = -\eta_2 \ = S . \tag{7.30}$$

The Stokes parameters of electric dipole radiation can be related directly to the charge distribution of the emitting atomic ensemble. As discussed in detail in Chapt. 46, one finds, for example,

$$L_\perp = -P_3 \tag{7.31}$$

for the angular momentum transfer perpendicular to the scattering plane in collisional (de-)excitation, and

$$\gamma = \frac{1}{2}\arg\{P_1 + iP_2\} \tag{7.32}$$

for the alignment angle.

7.3 Atomic Collisions

7.3.1 Scattering Amplitudes

Transitions from an initial state $|J_0 M_0; \boldsymbol{k}_0 m_0\rangle$ to a final state $|J_1 M_1; \boldsymbol{k}_1 m_1\rangle$ are described by scattering amplitudes

$$f(M_1 m_1; M_0 m_0) = \langle J_1 M_1; \boldsymbol{k}_1 m_1 | \mathcal{T} | J_0 M_0; \boldsymbol{k}_0 m_0\rangle , \tag{7.33}$$

where $\mathcal{T}$ is the transition operator. Furthermore, J_0 (J_1) is the total electronic angular momentum in the initial (final) state of the target and M_0 (M_1) its corresponding z-component, while $\boldsymbol{k}_0$ ($\boldsymbol{k}_1$) is the initial (final) momentum of the projectile and m_0 (m_1) its spin component.

7.3.2 Reduced Density Matrices

While the scattering amplitudes are the central elements in a theoretical description, some restrictions usually need to be taken into account in a practical experiment. The most important ones are: (i) there is no "pure" initial state, and (ii) not all possible quantum numbers are simultaneously determined in the final state. The solution to this problem can be found by using the density matrix formalism. First, the complete density operator after the collision process is given by [7.2]

$$\rho_{\text{out}} = \mathcal{T} \rho_{\text{in}} \mathcal{T}^\dagger , \tag{7.34}$$

where ρ_{in} is the density operator before the collision. The corresponding matrix elements are given by

$$(\rho_{\text{out}})^{\boldsymbol{k}_1, M_1' M_1}_{m_1' m_1} = \sum_{m_0' m_0 M_0' M_0} \rho_{m_0' m_0} \, \rho_{M_0' M_0}$$
$$\times f\left(M_1' m_1'; M_0' m_0'\right)$$
$$\times f^*\left(M_1 m_1; M_0 m_0\right) , \tag{7.35}$$

where the term $\rho_{m_0' m_0} \rho_{M_0' M_0}$ describes the preparation of the initial state (i). Secondly, "reduced" density matrices account for (ii). For example, if only the scattered projectiles are observed, the corresponding elements of the reduced density matrix are obtained by summing over the atomic quantum numbers as follows:

$$(\rho_{\text{out}})^{\boldsymbol{k}_1}_{m_1' m_1} = \sum_{M_1} (\rho_{\text{out}})^{\boldsymbol{k}_1, M_1 M_1}_{m_1' m_1} . \tag{7.36}$$

The differential cross section for unpolarized projectile and target beams is given by

$$\frac{d\sigma}{d\Omega} = C \sum_{m_1} (\rho_{\text{out}})^{\boldsymbol{k}_1}_{m_1 m_1} , \tag{7.37}$$

where C is a constant that depends on the normalization of the continuum waves in a numerical calculation.

On the other hand, if only the atoms are observed (for example, by analyzing the light emitted in optical transitions), the elements

$$(\rho_{\text{out}})_{M_1' M_1} = \int d^3 \boldsymbol{k}_1 \sum_{m_1} (\rho_{\text{out}})^{\boldsymbol{k}_1, M_1' M_1}_{m_1 m_1} \tag{7.38}$$

determine the integrated Stokes parameters [7.8, 9], i.e., the polarization of the emitted light. They contain information about the angular momentum distribution in the excited target ensemble.

Finally, for electron–photon coincidence experiments without spin analysis in the final state, the elements

$$(\rho_{\text{out}})^{k_1}_{M'_1 M_1} = \sum_{m_1} (\rho_{\text{out}})^{k_1, M'_1 M_1}_{m_1 m_1} \tag{7.39}$$

simultaneously contain information about the projectiles and the target. This information can be extracted

7.4 Irreducible Tensor Operators

The general density matrix theory can be formulated in a very elegant fashion by decomposing the density operator in terms of irreducible components whose matrix elements then become the state multipoles. In such a formulation, full advantage can be taken of the most sophisticated techniques developed in angular momentum algebra (see Chapt. 2). Many explicit examples can be found in [7.3, 4].

7.4.1 Definition

The density operator for an ensemble of particles in quantum states labeled as $|JM\rangle$ where J and M are the total angular momentum and its magnetic component, respectively, can be written as

$$\rho = \sum_{J'JM'M} \rho^{J'J}_{M'M} |J'M'\rangle\langle JM| , \tag{7.40}$$

where

$$\rho^{J'J}_{M'M} = \langle J'M'|\rho|JM\rangle \tag{7.41}$$

are the matrix elements. (For simplicity, interactions outside the single manifold of momentum states $|JM\rangle$ are neglected). Alternatively, one may write

$$\rho = \sum_{J'JKQ} \left\langle T(J'J)^{\dagger}_{KQ} \right\rangle T(J'J)_{KQ} , \tag{7.42}$$

where the irreducible tensor operators are defined in terms of 3–j symbols as

$$T(J'J)_{KQ} = \sum_{M'M} (-1)^{J'-M'}\sqrt{2K+1}$$
$$\times \begin{pmatrix} J' & J & K \\ M' & -M & -Q \end{pmatrix} |J'M'\rangle\langle JM| , \tag{7.43}$$

by measuring the angle-differential Stokes parameters. In particular, for unpolarized electrons and atoms, the "natural coordinate system", where the quantization axis coincides with the normal to the scattering plane, allows for a simple physical interpretation of the various parameters [7.10] (see Chapt. 46).

The density matrix formalism outlined above is very useful for obtaining a qualitative description of the geometrical and sometimes also of the dynamical symmetries of the collision process [7.11]. Two explicit examples are discussed in Sect. 7.6.

and the state multipoles or statistical tensors are given by

$$\left\langle T(J'J)^{\dagger}_{KQ} \right\rangle = \sum_{M'M} (-1)^{J'-M'}\sqrt{2K+1}$$
$$\times \begin{pmatrix} J' & J & K \\ M' & -M & -Q \end{pmatrix} \langle J'M'|\rho|JM\rangle . \tag{7.44}$$

Hence, the selection rules for the 3–j symbols imply that

$$|J-J'| \le K \le J+J' , \tag{7.45}$$
$$M'-M = Q . \tag{7.46}$$

Equation (7.44) can be inverted through the orthogonality condition of the 3–j symbols to give

$$\langle J'M'|\rho|JM\rangle = \sum_{KQ} (-1)^{J'-M'}\sqrt{2K+1}$$
$$\times \begin{pmatrix} J' & J & K \\ M' & -M & -Q \end{pmatrix} \left\langle T(J'J)^{\dagger}_{KQ} \right\rangle . \tag{7.47}$$

7.4.2 Transformation Properties

Suppose a coordinate system (X_2, Y_2, Z_2) is obtained from another coordinate system (X_1, Y_1, Z_1) through a rotation by a set of three Euler angles (γ, β, α) as defined in *Edmonds* [7.12]. The irreducible tensor operators (7.43) defined in the (X_1, Y_1, Z_1) system are then related to the operators $\langle T(J'J)^{\dagger}_{KQ}\rangle$ in the (X_2, Y_2, Z_2)

system by

$$T(J'J)_{KQ} = \sum_q T(J'J)_{Kq} \, D(\gamma, \, \beta, \, \alpha)^K_{qQ} \, , \quad (7.48)$$

where

$$D(\gamma, \, \beta, \, \alpha)^J_{M'M} = e^{iM'\gamma} \, d(\beta)^J_{M'M} \, e^{iM\alpha} \quad (7.49)$$

is a rotation matrix (see Chapt. 2). Note that the rank K of the tensor operator is invariant under such rotations. Similarly,

$$\left\langle T(J'J)^\dagger_{KQ} \right\rangle = \sum_q \left\langle T(J'J)^\dagger_{Kq} \right\rangle D(\gamma, \, \beta, \, \alpha)^{K\,*}_{qQ}$$

$$(7.50)$$

holds for the state multipoles.

The irreducible tensor operators fulfill the orthogonality condition

$$\mathrm{Tr}\left\{ T(J'J)_{KQ} \, T(J'J)^\dagger_{K'Q'} \right\} = \delta_{K'K} \, \delta_{Q'Q} \, , \quad (7.51)$$

with

$$T(J'J)_{00} = \frac{1}{\sqrt{2J+1}} \, \delta_{J'J} \, \mathbf{1} \quad (7.52)$$

being proportional to the unit operator $\mathbf{1}$, it follows that all tensor operators have vanishing trace, except for the monopole $T(J'J)_{00}$.

Reduced tensor operators fulfill the Wigner–Eckart theorem (see Sect. 2.8.4)

$$\left\langle J'M' | T(J'J)_{KQ} | JM \right\rangle$$

$$= (-1)^{J'-M'} \begin{pmatrix} J' & K & J \\ -M' & Q & M \end{pmatrix}$$

$$\times \left\langle J' \| T_K \| J \right\rangle , \quad (7.53)$$

where the reduced matrix element is simply given by

$$\left\langle J' \| T_K \| J \right\rangle = \frac{1}{\sqrt{2K+1}} \, . \quad (7.54)$$

7.4.3 Symmetry Properties of State Multipoles

The Hermiticity condition for the density matrix implies

$$\left\langle T(J'J)^\dagger_{KQ} \right\rangle^* = (-1)^{J'-J+Q} \left\langle T(JJ')^\dagger_{K-Q} \right\rangle , \quad (7.55)$$

which, for sharp angular momentum $J' = J$, yields

$$\left\langle T(J)^\dagger_{KQ} \right\rangle^* = (-1)^Q \left\langle T(J)^\dagger_{K-Q} \right\rangle . \quad (7.56)$$

Hence, the state multipoles $\left\langle T(J)^\dagger_{K0} \right\rangle$ are real numbers.

Furthermore, the transformation property (7.50) of the state multipoles imposes restrictions on nonvanishing state multipoles to describe systems with given symmetry properties. In detail, one finds:

1. For spherically symmetric systems,

$$\left\langle T(J'J)^\dagger_{KQ} \right\rangle = \left\langle T(J'J)^\dagger_{KQ} \right\rangle_{\mathrm{rot}} \quad (7.57)$$

for *all* sets of Euler angles. This implies that only the monopole term $\left\langle T(J)^\dagger_{00} \right\rangle$ can be different from zero.

2. For axially symmetric systems,

$$\left\langle T(J'J)^\dagger_{KQ} \right\rangle = \left\langle T(J'J)^\dagger_{KQ} \right\rangle_{\mathrm{rot}} \quad (7.58)$$

for *all* Euler angles ϕ that describe a rotation around the z-axis. Since this angle enters via a factor $\exp(-iQ\phi)$ into the general transformation formula (7.50), it follows that only state multipoles with $Q = 0$, i.e., $\left\langle T(J'J)^\dagger_{K0} \right\rangle$, can be different from zero in such a situation.

3. For planar symmetric systems with fixed $J' = J$,

$$\left\langle T(J)^\dagger_{KQ} \right\rangle = (-1)^K \left\langle T(J)^\dagger_{KQ} \right\rangle^* \quad (7.59)$$

if the system properties are invariant under reflection in the xz-plane. Hence, state multipoles with even rank K are real numbers, while those with odd rank are purely imaginary in this case.

The above results can be applied immediately to the description of atomic collisions where the incident beam axis is the quantization axis (the so-called "collision system"). For example, impact excitation of unpolarized targets by unpolarized projectiles without observation of the scattered projectiles is symmetric both with regard to rotation around the incident beam axis and with regard to reflection in any plane containing this axis. Consequently, the state multipoles $\left\langle T(J)^\dagger_{00} \right\rangle$, $\left\langle T(J)^\dagger_{20} \right\rangle$, $\left\langle T(J)^\dagger_{40} \right\rangle$, ... fully characterize the atomic ensemble of interest. Using (7.50), similar relationships can be derived for state multipoles defined with regard to other coordinate systems, such as the "natural system" where the quantization axis coincides with the normal vector to the scattering plane (see Chapt. 46).

7.4.4 Orientation and Alignment

From the above discussion, it is apparent that the description of systems that do not exhibit spherical symmetry requires the knowledge of state multipoles with rank $K \neq 0$. Frequently, the multipoles with $K = 1$ and $K = 2$ are determined via the angular correlation and the polarization of radiation emitted from

an ensemble of collisionally excited targets. The state multipoles with $K = 1$ are proportional to the spherical components of the angular momentum expectation value and, therefore, give rise to a nonvanishing circular light polarization (see also Sect. 7.6). This corresponds to a sense of rotation or an orientation in the ensemble which is therefore called oriented (see Sect. 46.1).

On the other hand, nonvanishing multipoles with rank $K = 2$ describe the alignment of the system. Some authors, however, use the terms "alignment" or "orientation" synonymously for all nonvanishing state multipoles with ranks $K \neq 0$, thereby describing any system with anisotropic occupation of magnetic sublevels as "aligned" or "oriented". For details on alignment and orientation, see Chapt. 46 and [7.3, 4].

7.4.5 Coupled Systems

Tensor operators and state multipoles for coupled systems are constructed as direct products ($\otimes$) of the operators for the individual systems. For example, the density operator for two subsystems in basis states $|L, M_L\rangle$ and $|S, M_S\rangle$ is constructed as [7.2]

$$\rho = \sum_{KQkq} \left\langle T(L)^\dagger_{KQ} \otimes T(S)^\dagger_{kq} \right\rangle \left[T(L)_{KQ} \otimes T(S)_{kq} \right] . \tag{7.60}$$

If the two systems are uncorrelated, the state multipoles factor as

$$\left\langle T(L)^\dagger_{KQ} \otimes T(S)^\dagger_{kq} \right\rangle = \left\langle T(L)^\dagger_{KQ} \right\rangle \left\langle T(S)^\dagger_{kq} \right\rangle ; \tag{7.61}$$

More generally, irreducible representations of coupled operators can be defined in terms of a 9–j symbol as

$$T(J', J)_{K'Q'} = \sum_{KQkq} \hat{K}\hat{k}\hat{J}\hat{J}' \, (KQ, kq|K'Q')$$
$$\times \left\{ \begin{matrix} K & k & K' \\ L & S & J' \\ L & S & J \end{matrix} \right\} T(L)_{KQ} \otimes T(S)_{kq} , \tag{7.62}$$

where $\hat{x} \equiv \sqrt{2x+1}$, and $(j_1 m_1, j_2 m_2 | j_3 m_3)$ is a standard Clebsch-Gordan coefficient.

7.5 Time Evolution of State Multipoles

7.5.1 Perturbation Coefficients

From the general expansions

$$\rho(t) = \sum_{j'jkq} \left\langle T(j'j; t)^\dagger_{kq} \right\rangle T(j'j)_{kq} \tag{7.63}$$

in terms of irreducible components, together with (7.42) for time $t = 0$ and (7.13) for the time development of the density operator, it follows that

$$\left\langle T(j'j; t)^\dagger_{kq} \right\rangle = \sum_{J'JKQ} \left\langle T(J'J; 0)^\dagger_{KQ} \right\rangle$$
$$\times G(J'J, j'j; t)^{Qq}_{Kk} , \tag{7.64}$$

where the perturbation coefficients are defined as

$$G(J'J, j'j; t)^{Qq}_{Kk}$$
$$= \mathrm{Tr} \left\{ U(t) T(J'J)_{KQ} U(t)^\dagger T(j'j)^\dagger_{kq} \right\} . \tag{7.65}$$

Hence, these coefficients relate the state multipoles at time t to those at $t = 0$.

7.5.2 Quantum Beats

An important application of the perturbation coefficients is the coherent excitation of several quantum states which subsequently decay by optical transitions. Such an excitation may be performed, for example, in beam-foil experiments or electron–atom collisions where the energy width of the electron beam is too large to resolve the fine structure (or hyperfine structure) of the target states.

Suppose, for instance, that explicitly relativistic effects, such as the spin–orbit interaction between the projectile and the target, can be neglected *during* a collision process between an incident electron and a target atom. In that case, the orbital angular momentum (L) system of the collisionally excited target states may be oriented, depending on the scattering angle of the projectile. On the other hand, the spin (S) system remains unaffected (unpolarized), provided that both the target and the projectile beams are unpolarized. During the lifetime of the excited target states, however, the spin–orbit interaction *within* the target produces an exchange of orientation between the L and the S systems, which results in a net loss of orientation in the L system.

This effect can be observed directly through the intensity and the polarization of the light emitted from the excited target ensemble. The perturbation coefficients for the fine structure interaction are found to be [7.2, 13]

$$G(L;t)_K = \frac{\exp(-\gamma t)}{2S+1} \sum_{J'J} (2J'+1)(2J+1)$$

$$\times \begin{Bmatrix} L & J' & S \\ J & L & K \end{Bmatrix}^2 \cos(\omega_{J'} - \omega_J)t,$$

(7.66)

where $\omega_{J'} - \omega_J$ corresponds to the (angular) frequency difference between the various multiplet states with total electronic angular momenta J' and J, respectively. Also, γ is the natural width of the spectral line; for simplicity, the same lifetime has been assumed in (7.66) for all states of the multiplet.

Note that the perturbation coefficients are independent of the multipole component Q in this case, and that there is no mixing between different multipole ranks K. Similar results can be derived [7.2, 13] for the hyperfine interaction and also to account for the combined effect of fine and hyperfine structure. The cosine terms represent correlation between the signal from different fine structure states, and they lead to oscillations in the intensity as well as the measured Stokes parameters in a time-resolved experiment.

Finally, generalized perturbation coefficients have been derived for the case where both the L and the S systems may be oriented and/or aligned during the collision process [7.14]. This can happen when spin-polarized projectiles and/or target beams are prepared.

7.5.3 Time Integration over Quantum Beats

If the excitation and decay times cannot be resolved in a given experimental setup, the perturbation coefficients need to be integrated over time. As a result, the quantum beats disappear, but a net effect may still be visible through a depolarization of the emitted radiation. For the case of atomic fine structure interaction discussed above, one finds [7.2, 13]

$$\bar{G}(L)_K = \int_0^\infty G(L;t)_K \, dt$$

$$= \frac{1}{2S+1} \sum_{J'J} (2J'+1)(2J+1)$$

$$\times \begin{Bmatrix} L & J' & S \\ J & L & K \end{Bmatrix}^2 \frac{\gamma}{\gamma^2 + \omega_{J'J}^2},$$

(7.67)

where $\omega_{J'J} = \omega_{J'} - \omega_J$. Note that the amount of depolarization depends on the relationship between the fine structure splitting and the natural line width. For $|\omega_{J'J}| \gg \gamma$ (if $J' \neq J$), the terms with $J' = J$ dominate and cause the maximum depolarization; for the opposite case $|\omega_{J'J}| \ll \gamma$, the sum rule for the 6–j symbols can be applied and no depolarization is observed.

Similar depolarizations can be caused through hyperfine structure effects, as well as through external fields. An important example of the latter case is the Hanle effect (see Sect. 17.2.1).

7.6 Examples

In this section, two examples of the reduced density formalism are discussed explicitly. These are: (i) the change of the spin polarization of initially polarized spin-$\frac{1}{2}$ projectiles after scattering from unpolarized targets, and (ii) the Stokes parameters describing the angular distribution and the polarization of light as detected in projectile-photon coincidence experiments after collisional excitation. The recent book by *Andersen* and *Bartschat* [7.4] provides a detailed introduction to these topics, together with a thorough discussion of benchmark studies in the field of electronic and atomic collisions, including extensions to ionization processes, as well as applications in plasma, surface, and nuclear physics.

Even more extensive compilations of such studies can be found in a review series dealing with unpolarized electrons colliding with unpolarized targets [7.10], heavy-particle collisions [7.15], and the special role of projectile and target spins in such collisions [7.16].

7.6.1 Generalized *STU*-parameters

For spin-polarized projectile scattering from unpolarized targets, the generalized *STU*-parameters [7.11] contain information about the projectile spin polarization after the collision. These parameters can be expressed in terms of the elements (7.36).

To analyze this problem explicitly, one defines the quantities

$$\langle m_1' m_0'; m_1 m_0 \rangle = \frac{1}{2J_0 + 1} \sum_{M_1 M_0} f(M_1 m_1'; M_0 m_0')$$
$$\times f^*(M_1 m_1; M_0 m_0) \qquad (7.68)$$

which contain the *maximum information* that can be obtained from the scattering process, if only the polarization of the projectiles is prepared before the collision and measured thereafter.

Next, the number of independent parameters that can be determined in such an experiment needs to be examined. For spin-$\frac{1}{2}$ particles, there are $2 \times 2 \times 2 \times 2 = 16$ possible combinations of $\{m_1' m_0'; m_1 m_0\}$ and, therefore, 16 complex or 32 real parameters (in the most general case of spin-S particles, there would be $(2S+1)^4$ combinations). However, from the definition (7.68) and the Hermiticity of the reduced density matrix contained therein, it follows that

$$\langle m_1' m_0'; m_1 m_0 \rangle = \langle m_1 m_0; m_1' m_0' \rangle^* . \qquad (7.69)$$

Furthermore, parity conservation of the interaction or the equivalent reflection invariance with regard to the scattering plane yields the additional relationship [7.11]

$$f(M_1 m_1; M_0 m_0) = (-1)^{J_1 - M_1 + \frac{1}{2} - m_1 + J_0 - M_0 + \frac{1}{2} - m_0}$$
$$\times \Pi_1 \Pi_0 f(-M_1 - m_1; -M_0 - m_0) , \qquad (7.70)$$

where Π_1 and Π_0 are ± 1, depending on the parities of the atomic states involved. Hence,

$$\langle m_1' m_0'; m_1 m_0 \rangle = (-1)^{m_1' - m_1 + m_0' - m_0}$$
$$\times \langle -m_1' - m_0'; -m_1 - m_0 \rangle . \qquad (7.71)$$

Note that (7.70, 71) hold for the collision frame where the quantization axis ($\hat{z}$) is taken as the incident beam axis and the scattering plane is the xz-plane. Similar formulas can be derived for the natural frame (see Sect. 7.3.2)

Consequently, *eight* independent parameters are sufficient to characterize the reduced spin density matrix of the scattered projectiles. These can be chosen as the *absolute* differential cross section

$$\sigma_u = \frac{1}{2} \sum_{m_1, m_0} \langle m_1 m_0; m_1 m_0 \rangle \qquad (7.72)$$

for the scattering of unpolarized projectiles from unpolarized targets and the seven *relative* parameters

$$S_A = -\frac{2}{\sigma_u} \operatorname{Im} \left\{ \left\langle \frac{1}{2} - \frac{1}{2}; \frac{1}{2} \frac{1}{2} \right\rangle \right\} , \qquad (7.73)$$

$$S_P = -\frac{2}{\sigma_u} \operatorname{Im} \left\{ \left\langle \frac{1}{2} \frac{1}{2}; -\frac{1}{2} \frac{1}{2} \right\rangle \right\} , \qquad (7.74)$$

$$T_y = \frac{1}{\sigma_u} \left\{ \left\langle -\frac{1}{2} - \frac{1}{2}; \frac{1}{2} \frac{1}{2} \right\rangle - \left\langle -\frac{1}{2} \frac{1}{2}; \frac{1}{2} - \frac{1}{2} \right\rangle \right\} , \qquad (7.75)$$

$$T_x = \frac{1}{\sigma_u} \left[\left\langle -\frac{1}{2} - \frac{1}{2}; \frac{1}{2} \frac{1}{2} \right\rangle + \left\langle -\frac{1}{2} \frac{1}{2}; \frac{1}{2} - \frac{1}{2} \right\rangle \right] , \qquad (7.76)$$

$$T_z = \frac{1}{\sigma_u} \left[\left\langle \frac{1}{2} \frac{1}{2}; \frac{1}{2} \frac{1}{2} \right\rangle - \left\langle \frac{1}{2} \frac{1}{2}; -\frac{1}{2} \frac{1}{2} \right\rangle \right] , \qquad (7.77)$$

$$U_{xz} = \frac{2}{\sigma_u} \operatorname{Re} \left\{ \left\langle \frac{1}{2} \frac{1}{2}; -\frac{1}{2} \frac{1}{2} \right\rangle \right\} , \qquad (7.78)$$

$$U_{zx} = -\frac{2}{\sigma_u} \operatorname{Re} \left\{ \left\langle \frac{1}{2} - \frac{1}{2}; \frac{1}{2} \frac{1}{2} \right\rangle \right\} , \qquad (7.79)$$

where $\operatorname{Re}\{x\}$ and $\operatorname{Im}\{x\}$ denote the real and imaginary parts of the complex quantity x, respectively. Note that normalization constants have been omitted in (7.72) to simplify the notation.

Therefore, the most general form for the polarization vector after scattering, $\boldsymbol{P}'$, for an initial polarization vector $\boldsymbol{P} = (P_x, P_y, P_z)$ is given by

$$\frac{(S_P + T_y P_y)\hat{\boldsymbol{y}} + (T_x P_x + U_{xz} P_z)\hat{\boldsymbol{x}} + (T_z P_z - U_{zx} P_x)\hat{\boldsymbol{z}}}{1 + S_A P_y} . \qquad (7.80)$$

The physical meaning of the above relation is illustrated in Fig. 7.1.

The following geometries are particularly suitable for the experimental determination of the individual parameters; σ_u and S_P can be measured with unpolarized incident projectiles. A transverse polarization component perpendicular to the scattering plane $(\boldsymbol{P} = P_y \hat{\boldsymbol{y}})$ is needed to obtain S_A and T_y. Finally, the measurement of T_x, U_{zx}, T_z, and U_{xz} requires both transverse $(P_x \hat{\boldsymbol{x}})$ and longitudinal $(P_z \hat{\boldsymbol{z}})$ projectile polarization components in the scattering plane.

7.6.2 Radiation from Excited States: Stokes Parameters

The state multipole description is also widely used for the parametrization of the Stokes parameters that describe the polarization of light emitted in optical decays of excited atomic ensembles. The general case of excitation by spin-polarized projectiles has been treated by
Fig. 7.1 Physical meaning of the generalized *STU*-parameters: the polarization function S_P gives the polarization of an initially unpolarized projectile beam after the collision while the asymmetry function S_A determines a left-right asymmetry in the differential cross section for scattering of a spin-polarized beam. Furthermore, the contraction parameters (T_x, T_y, T_z) describe the change of an initial polarization component along the three cartesian axes while the parameters U_{xz} and U_{zx} determine the rotation of a polarization component in the scattering plane

Bartschat and collaborators [7.8]. The basic experimental setup for electron-photon coincidence experiments and the definition of the Stokes parameters are illustrated in Figs. 7.2 and 7.3.

For impact excitation of an atomic state with total electronic angular momentum J and an electric dipole transition to a state with J_f, the photon intensity in a direction $\hat{n} = (\Theta_\gamma, \Phi_\gamma)$ is given by

$$
I(\Theta_\gamma, \Phi_\gamma) = C \left[\frac{2\,(-1)^{J-J_f}}{3\sqrt{2J+1}} \left\langle T(J)_{00}^\dagger \right\rangle \right.
$$
$$
- \begin{Bmatrix} 1 & 1 & 2 \\ J & J & J_f \end{Bmatrix}
$$
$$
\times \left(\mathrm{Re} \left\{ \left\langle T(J)_{22}^\dagger \right\rangle \right\} \sin^2 \Theta_\gamma \cos 2\Phi_\gamma \right.
$$
$$
- \mathrm{Re} \left\{ \left\langle T(J)_{21}^\dagger \right\rangle \right\} \sin 2\Theta_\gamma \cos \Phi_\gamma
$$
$$
+ \sqrt{\frac{1}{6}} \left\langle T(J)_{20}^\dagger \right\rangle (3\cos^2 \Theta_\gamma - 1)
$$
$$
- \mathrm{Im} \left\{ \left\langle T(J)_{22}^\dagger \right\rangle \right\} \sin^2 \Theta_\gamma \sin 2\Phi_\gamma
$$
$$
\left. \left. + \mathrm{Im} \left\{ \left\langle T(J)_{21}^\dagger \right\rangle \right\} \sin 2\Theta_\gamma \sin \Phi_\gamma \right) \right],
$$
(7.81)

where

$$
C = \frac{e^2 \omega^4}{2\pi c^3} \left| \langle J_f \| r \| J \rangle \right|^2 (-1)^{J-J_f}
$$
(7.82)
Fig. 7.2 Geometry of electron–photon coincidence experiments
Fig. 7.3 Definition of the Stokes parameters: Photons are observed in a direction $\hat{n}$ with polar angles $(\Theta_\gamma, \Phi_\gamma)$ in the collision system. The three unit vectors $(\hat{n}, \hat{e}_1, \hat{e}_2)$ define the helicity system of the photons, $\hat{e}_1 = (\Theta_\gamma + 90°, \Phi_\gamma)$ lies in the plane spanned by $\hat{n}$ and $\hat{z}$ and is perpendicular to $\hat{n}$ while $\hat{e}_2 = (\Theta_\gamma, \Phi_\gamma + 90°)$ is perpendicular to both $\hat{n}$ and $\hat{e}_1$. In addition to the circular polarization P_3, the linear polarizations P_1 and P_2 are defined with respect to axes in the plane spanned by $\hat{e}_1$ and $\hat{e}_2$. Counting from the direction of $\hat{e}_1$, the axes are located at $(0°, 90°)$ for P_1 and at $(45°, 135°)$ for P_2, respectively

is a constant containing the frequency ω of the transition as well as the reduced radial dipole matrix element.

Similarly, the product of the intensity I and the circular light polarization P_3 can be written in terms of

state multipoles as

$$(I \cdot P_3)(\Theta_\gamma, \Phi_\gamma) = -C \begin{Bmatrix} 1 & 1 & 1 \\ J & J & J_f \end{Bmatrix}$$
$$\times \left(\mathrm{Im} \left\{ \left\langle T(J)_{11}^\dagger \right\rangle \right\} 2 \sin \Theta_\gamma \sin \Phi_\gamma \right.$$
$$- \mathrm{Re} \left\{ \left\langle T(J)_{11}^\dagger \right\rangle \right\} 2 \sin \Theta_\gamma \cos \Phi_\gamma$$
$$\left. + \sqrt{2} \left\langle T(J)_{10}^\dagger \right\rangle \cos \Theta_\gamma \right),$$

$$(7.83)$$

so that P_3 can be calculated as

$$P_3(\Theta_\gamma, \Phi_\gamma) = (I \cdot P_3)(\Theta_\gamma, \Phi_\gamma) / I(\Theta_\gamma, \Phi_\gamma).$$

$$(7.84)$$

Note that each state multipole gives rise to a characteristic angular dependence in the formulas for the Stokes parameters, and that perturbation coefficients may need to be applied to deal, for example, with depolarization effects due to internal or external fields. General formulas for $P_1 = \eta_3$ and $P_2 = \eta_1$ can be found in [7.8] and, for both the natural and the collision systems, in [7.4].

As pointed out before, some of the state multipoles may vanish, depending on the experimental arrangement. A detailed analysis of the information contained in the state multipoles and the generalized Stokes parameters (which are defined for specific values of the projectile spin polarization) has been given by *Andersen* and *Bartschat* [7.4, 17, 18]. They re-analyzed the experiment performed by *Sohn* and *Hanne* [7.19] and showed how the density matrix of the excited atomic ensemble can be determined by a measurement of the generalized Stokes parameters. In some cases, this will allow for the extraction of a complete set of scattering amplitudes for the collision process. Such a "perfect scattering experiment" has been called for by *Bederson* many years ago [7.20] and is now within reach even for fairly complex excitation processes. The most promising cases have been discussed by *Andersen* and *Bartschat* [7.4, 17, 21].

7.7 Summary

The basic formulas dealing with density matrices in quantum mechanics, with particular emphasis on reduced matrix theory and its applications in atomic physics, have been summarized. More details are given in the introductory textbooks by *Blum* [7.2], *Balashov* et al. [7.3], *Andersen* and *Bartschat* [7.4], and the references listed below.

8. Computational Techniques

Essential to all fields of physics is the ability to perform numerical computations accurately and efficiently. Whether the specific approach involves perturbation theory, close coupling expansion, solution of classical equations of motion, or fitting and smoothing of data, basic computational techniques such as integration, differentiation, interpolation, matrix and eigenvalue manipulation, Monte Carlo sampling, and solution of differential equations must be among the standard tool kit.

This chapter outlines a portion of this tool kit with the aim of giving guidance and organization to a wide array of computational techniques. Having digested the present overview, the reader is then referred to detailed treatments given in many of the large number of texts existing on numerical analysis and computational techniques [8.1–5], and mathematical physics [8.6–10]. We also summarize, especially in the sections on differential equations and computational linear algebra, the role of software

packages readily available to aid in implementing practical solutions.

8.1 Representation of Functions

The ability to represent functions in terms of polynomials or other basic functions is the key to interpolating or fitting data, and to approximating numerically the operations of integration and differentiation. In addition, using methods such as Fourier analysis, knowledge of the properties of functions beyond even their intermediate values, derivatives, and antiderivatives may be determined (e.g., the "spectral" properties).

8.1.1 Interpolation

Given the value of a function $f(x)$ at a set of points $x_1, x_2, \ldots, x_n$, the function is often required at some other values between these abscissae. The process known as *interpolation* seeks to estimate these unknown values by adjusting the parameters of a known

function to approximate the local or global behavior of $f(x)$. One of the most useful representations of a function for these purposes utilizes the *algebraic polynomials*, $P_n(x) = a_0 + a_1 x + \cdots + a_n x^n$, where the coefficients are real constants and the exponents are nonnegative integers. The utility stems from the fact that given any continuous function defined on a closed interval, there exists an algebraic polynomial which is as close to that function as desired (Weierstrass Theorem).

One simple application of these polynomials is the power series expansion of the function $f(x)$ about some point, x_0, i.e.,

$$f(x) = \sum_{k=0}^{\infty} a_k (x - x_0)^k . \tag{8.1}$$

A familiar example is the *Taylor expansion* in which the coefficients are given by

$$a_k = \frac{f^{(k)}(x_0)}{k!} \, , \qquad (8.2)$$

where $f^{(k)}$ indicates the kth derivative of the function. This form, though quite useful in the derivation of formal techniques, is not very useful for interpolation since it assumes the function and its derivatives are known, and since it is guaranteed to be a good approximation only very near the point x_0 about which the expansion has been made.

Lagrange Interpolation

The polynomial of degree $n-1$ which passes through all n points $[x_1, f(x_1)], [x_2, f(x_2)], \dots, [x_n, f(x_n)]$ is given by

$$P(x) = \sum_{k=1}^{n} f(x_k) \prod_{i=1, i \neq k}^{n} \frac{x - x_i}{x_k - x_i} \qquad (8.3)$$

$$= \sum_{k=1}^{n} f(x_k) L_{nk}(x) \, , \qquad (8.4)$$

where $L_{nk}(x)$ are the *Lagrange interpolating polynomials*. Perhaps the most familiar example is that of linear interpolation between the points $[x_1, y_1 \equiv f(x_1)]$ and $[x_2, y_2 \equiv f(x_2)]$, namely,

$$P(x) = \frac{x - x_2}{x_1 - x_2} y_1 + \frac{x - x_1}{x_2 - x_1} y_2 \, . \qquad (8.5)$$

In practice, it is difficult to estimate the formal error bound for this method, since it depends on knowledge of the $(n+1)$th derivative. Alternatively, one uses *iterated interpolation* in which successively higher order approximations are tried until appropriate agreement is obtained. *Neville's algorithm* defines a recursive procedure to yield an arbitrary order interpolant from polynomials of lower order. This method, and subtle refinements of it, form the basis for most "recommended" polynomial interpolation schemes [8.3].

One important caution to bear in mind is that the more points that are used in constructing the interpolant, and therefore the higher the polynomial order, the greater will be the oscillation in the interpolating function. This highly oscillating polynomial most likely will not correspond more closely to the desired function than polynomials of lower order, and, as a general rule of thumb, fewer than six points should be used.

Cubic Splines

By dividing the interval of interest into a number of subintervals and in each using a polynomial of only modest order, one may avoid the oscillatory nature of high-order (many-point) interpolants. This approach utilizes *piecewise polynomial functions*, the simplest of which is just a linear segment. However, such a straight line approximation has a discontinuous derivative at the data points – a property that one may wish to avoid especially if the derivative of the function is also desired – and which clearly does not provide a smooth interpolant. The solution is therefore to choose the polynomial of lowest order that has enough free parameters (the constants $a_0, a_1, \dots$) to satisfy the constraints that the function and its derivative are continuous across the subintervals, as well as specifying the derivative at the endpoints x_0 and x_n.

Piecewise cubic polynomials satisfy these constraints, and have a continuous second derivative as well. *Cubic spline interpolation* does not, however, guarantee that the derivatives of the interpolant agree with those of the function at the data points, much less globally. The cubic polynomial in each interval has four undetermined coefficients,

$$P_i(x) = a_i + b_i(x - x_i) + c_i(x - x_i)^2 + d_i(x - x_i)^3 \qquad (8.6)$$

for $i = 0, 1, \dots, n-1$. Applying the constraints, a system of equations is found which may be solved once the endpoint derivatives are specified. If the second derivatives at the endpoints are set to zero, then the result is termed a *natural spline* and its shape is like that which a long flexible rod would take if forced to pass through all the data points. A *clamped spline* results if the first derivatives are specified at the endpoints, and is usually a better approximation since it incorporates more information about the function (if one has a reasonable way to determine or approximate these first derivatives).

The set of equations in the unknowns, along with the boundary conditions, constitute a *tridiagonal system* or *matrix*, and is therefore amenable to solution by algorithms designed for speed and efficiency for such systems (see Sect. 8.3; [8.1–3]). Other alternatives of potentially significant utility are schemes based on the use of rational functions and orthogonal polynomials.

Rational Function Interpolation

If the function which one seeks to interpolate has one or more poles for real x, then polynomial approximations are not good, and a better method is to use quotients of polynomials, so-called *rational functions*. This occurs

since the inverse powers of the dependent variable will fit the region near the pole better if the order is large enough. In fact, if the function is free of poles on the real axis but its analytic continuation in the complex plane has poles, the polynomial approximation may also be poor. It is this property that slows or prevents the convergence of power series. Numerical algorithms very similar to those used to generate iterated polynomial interpolants exist [8.1, 3] and can be useful for functions which are not amenable to polynomial interpolation. Rational function interpolation is related to the method of *Padé approximation* used to improve convergence of power series, and which is a rational function analog of Taylor expansion.

Orthogonal Function Interpolation

Interpolation using functions other than the algebraic polynomials can be defined and are often useful. Particularly worthy of mention are schemes based on *orthogonal polynomials* since they play a central role in numerical quadrature. A set of functions $\phi_1(x), \phi_2(x), \ldots, \phi_n(x)$ defined on the interval $[a, b]$ is said to be orthogonal with respect to a weight function $\mathcal{W}(x)$ if the inner product defined by

$$\langle \phi_i | \phi_j \rangle = \int_a^b \phi_i(x) \phi_j(x) \mathcal{W}(x) \, dx \tag{8.7}$$

is zero for $i \neq j$ and positive for $i = j$. In this case, for any polynomial $P(x)$ of degree at most n, there exists unique constants α_k such that

$$P(x) = \sum_{k=0}^{n} \alpha_k \phi_k(x) . \tag{8.8}$$

Among the more commonly used orthogonal polynomials are *Legendre, Laguerre*, and *Chebyshev* polynomials.

Chebyshev Interpolation

The significant advantages of employing a representation of a function in terms of Chebyshev polynomials, $T_k(x)$ [8.4, 6] for tabulations, recurrence formulas, orthogonality properties, etc. of these polynomials), i. e.,

$$f(x) = \sum_{k=0}^{\infty} a_k T_k(x) , \tag{8.9}$$

stems from the fact that (i) the expansion rapidly converges, (ii) the polynomials have a simple form, and (iii) the polynomial approximates very closely the solution

of the *minimax* problem. This latter property refers to the requirement that the expansion *mini*mizes the *max*imum magnitude of the error of the approximation. In particular, the Chebyshev series expansion can be truncated so that for a given n it yields the most accurate approximation to the function. Thus, Chebyshev polynomial interpolation is essentially as "good" as one can hope to do. Since these polynomials are defined on the interval $[-1, 1]$, if the endpoints of the interval in question are a and b, the change of variable

$$y = \frac{x - \frac{1}{2}(b+a)}{\frac{1}{2}(b-a)} \tag{8.10}$$

will effect the proper transformation. *Press* et al. [8.3], for example, give convenient and efficient routines for computing the Chebyshev expansion of a function.

8.1.2 Fitting

Fitting of data stands in distinction from interpolation in that the data may have some uncertainty, and therefore, simply determining a polynomial which passes through the points may not yield the best approximation of the underlying function. In fitting, one is concerned with minimizing the deviations of some model function from the data points in an optimal or best fit manner. For example, given a set of data points, even a low-order interpolating polynomial might have significant oscillation, when, in fact, if one accounts for the statistical uncertainties in the data, the best fit may be obtained simply by considering the points to lie on a line.

In addition, most of the traditional methods of assigning this quality of best fit to a particular set of parameters of the model function rely on the assumption that the random deviations are described by a Gaussian (normal) distribution. Results of physical measurements, for example the counting of events, is often closer to a Poisson distribution which tends (not necessarily uniformly) to a Gaussian in the limit of a large number of events, or may even contain "outliers" which lie far outside a Gaussian distribution. In these cases, fitting methods might significantly distort the parameters of the model function in trying to force these different distributions to the Gaussian form. Thus, the *least squares* and *chi-square* fitting procedures discussed below should be used with this caveat in mind. Other techniques, often termed "robust" [8.3, 11], should be used when the distribution is not Gaussian, or replete with outliers.

Least Squares

In this common approach to fitting, we wish to determine the m parameters a_l of some function $f(x; a_1, a_2, \ldots, a_m)$ depending in this example on one variable, x. In particular, we seek to minimize the sum of the squares of the deviations

$$\sum_{k=1}^{n} [y(x_k) - f(x_k; a_1, a_2, \ldots, a_m)]^2 \qquad (8.11)$$

by adjusting the parameters, where the $y(x_k)$ are the n data points. In the simplest case, the model function is just a straight line, $f(x; a_1, a_2) = a_1 x + a_2$. Elementary multivariate calculus implies that a minimum occurs if

$$a_1 \sum_{k=1}^{n} x_i^2 + a_2 \sum_{k=1}^{n} x_i = \sum_{k=1}^{n} x_i y_i , \qquad (8.12)$$

$$a_1 \sum_{k=1}^{n} x_i + a_2 n = \sum_{k=1}^{n} y_i , \qquad (8.13)$$

which are called the *normal equations*. Solution of these equations is straightforward, and an error estimate of the fit can be found [8.3]. In particular, variances may be computed for each parameter, as well as measures of the correlation between uncertainties and an overall estimate of the "goodness of fit" of the data.

Chi-square Fitting

If the data points each have associated with them a different standard deviation, σ_k, the least square principle is modified by minimizing the *chi-square*, defined as

$$\chi^2 \equiv \sum_{k=1}^{n} \left[\frac{y_k - f(x_k; a_1, a_2, \ldots, a_m)}{\sigma_k} \right]^2 . \qquad (8.14)$$

Assuming that the uncertainties in the data points are normally distributed, the chi-square value gives a measure of the goodness of fit. If there are n data points and m adjustable parameters, then the probability that χ^2 should exceed a particular value purely by chance is

$$Q = Q\left(\frac{n-m}{2}, \frac{\chi^2}{2}\right) , \qquad (8.15)$$

where $Q(a, x) = \Gamma(a, x)/\Gamma(a)$ is the incomplete gamma function. For small values of Q, the deviations of the fit from the data are unlikely to be by chance, and values close to one are indications of better fits. In terms of the chi-square, reasonable fits often have $\chi^2 \approx n - m$.

Other important applications of the chi-square method include simulation and estimating standard deviations. For example, if one has some idea of the actual (i.e., non-Gaussian) distribution of uncertainties of the data points, Monte Carlo simulation can be used to generate a set of test data points subject to this presumed distribution, and the fitting procedure performed on the simulated data set. This allows one to test the accuracy or applicability of the model function chosen. In other situations, if the uncertainties of the data points are unknown, one can assume that they are all equal to some value, say σ, fit using the chi-square procedure, and solve for the value of σ. Thus, some measure of the uncertainty from this statistical point of view can be provided.

General Least Squares

The least squares procedure can be generalized usually by allowing any linear combination of basis functions to determine the model function

$$f(x; a_1, a_2, \ldots, a_m) = \sum_{l=1}^{m} a_l \psi_l(x) . \qquad (8.16)$$

The basis functions need not be polynomials. Similarly, the formula for chi-square can be generalized, and normal equations determined through minimization. The equations may be written in compact form by defining a matrix A with elements

$$A_{i,j} = \frac{\psi_j(x_i)}{\sigma_i} , \qquad (8.17)$$

and a column vector B with elements

$$B_i = \frac{y_i}{\sigma_i} . \qquad (8.18)$$

Then the normal equations are [8.3]

$$\sum_{j=1}^{m} \alpha_{kj} a_j = \beta_k , \qquad (8.19)$$

where

$$[\alpha] = A^T A , \quad [\beta] = A^T B , \qquad (8.20)$$

and a_j are the adjustable parameters. These equations may be solved using standard methods of computational linear algebra such as Gauss–Jordan elimination. Difficulties involving sensitivity to round-off errors can be avoided by using carefully developed codes to perform this solution [8.3]. We note that elements of the inverse of the matrix α are related to the variances associated with the free parameters and to the covariances relating them.

Statistical Analysis of Data

Data generated by an experiment, or perhaps from a Monte Carlo simulation, have uncertainties due to the statistical, or random, character of the processes by which they are acquired. Therefore, one must be able to describe statistically certain features of the data such as their mean, variance and skewness, and the degree to which correlations exist, either between one portion of the data and another, or between the data and some other standard or model distribution. A very readable introduction to this type analysis has been given by *Young* [8.12], while more comprehensive treatments are also available [8.13].

8.1.3 Fourier Analysis

The *Fourier transform* takes, for example, a function of time, into a function of frequency, or vice versa, namely

$$\tilde{\varphi}(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \varphi(t) \, \mathrm{e}^{\mathrm{i}\omega t} \, \mathrm{d}t \, , \qquad (8.21)$$

$$\varphi(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \tilde{\varphi}(\omega) \, \mathrm{e}^{-\mathrm{i}\omega t} \, \mathrm{d}\omega \, . \qquad (8.22)$$

In this case, the time history of the function $\varphi(t)$ may be termed the "signal" and $\tilde{\varphi}(\omega)$ the "frequency spectrum". Also, if the frequency is related to the energy by $E = \hbar\omega$, one obtains an "energy spectrum" from a signal, and thus the name *spectral methods* for techniques based on the Fourier analysis of signals.

The Fourier transform also defines the relationship between the spatial and momentum representations of wave functions, i.e.,

$$\psi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \tilde{\psi}(p) \, \mathrm{e}^{\mathrm{i}px} \, \mathrm{d}p \, , \qquad (8.23)$$

$$\tilde{\psi}(p) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \psi(x) \, \mathrm{e}^{-\mathrm{i}px} \, \mathrm{d}x \, . \qquad (8.24)$$

Along with the closely related *sine*, *cosine*, and *Laplace transforms*, the Fourier transform is an extraordinarily powerful tool in the representation of functions, spectral analysis, convolution of functions, filtering, and analysis of correlation. Good introductions to these techniques with particular attention to applications in physics can be found in [8.6, 7, 14]. To implement the Fourier transform numerically, the integral tranform pair can be

converted to sums

$$\tilde{\varphi}(\omega_j) = \frac{1}{\sqrt{2N2\pi}} \sum_{k=0}^{2N-1} \varphi(t_k) \, \mathrm{e}^{\mathrm{i}\omega_j t_k} \, , \qquad (8.25)$$

$$\varphi(t_k) = \frac{1}{\sqrt{2N2\pi}} \sum_{j=0}^{2N-1} \tilde{\varphi}(\omega_j) \, \mathrm{e}^{-\mathrm{i}\omega_j t_k} \, , \qquad (8.26)$$

where the functions are "sampled" at $2N$ points. These equations define the *discrete Fourier transform* (DFT). Two cautions in using the DFT are as follows.

First, if a continuous function of time that is sampled at, for simplicity, uniformly spaced intervals, (i.e., $t_{i+1} = t_i + \Delta$), then there is a critical frequency $\omega_c = \pi/\Delta$, known as the *Nyquist frequency*, which limits the fidelity of the DFT of this function in that it is *aliased*. That is, components outside the frequency range $-\omega_c$ to ω_c are falsely transformed into this range due to the finite sampling. This effect can be remediated by filtering or windowing techniques. If, however, the function is *bandwidth limited* to frequencies smaller than ω_c, then the DFT does not suffer from this effect, and the signal is completely determined by its samples. Second, implementing the DFT directly from the above equations would require approximately N^2 multiplications to perform the Fourier transform of a function sampled at N points. A variety of *fast Fourier transform* (FFT) algorithms have been developed (e.g., the Danielson–Lanczos and Cooley–Tukey methods) which require only on the order of $(N/2)\log_2 N$ multiplications. Thus, for even moderately large sets of points, the FFT methods are indeed much faster than the direct implementation of the DFT. Issues involved in sampling, aliasing, and selection of algorithms for the FFT are discussed in great detail, for example, in [8.3, 15, 16].

8.1.4 Approximating Integrals

Polynomial Quadrature

Definite integrals may be approximated through a procedure known as numerical quadrature by replacing the integral by an appropriate sum, i.e.,

$$\int_a^b f(x) \, \mathrm{d}x \approx \sum_{k=0}^{n} a_k f(x_k) \, . \qquad (8.27)$$

Most formulas for such approximation are based on the interpolating polynomials described in Sect. 8.1.1, especially the Lagrange polynomials, in which case the

coefficients a_k are given by

$$a_k = \int_a^b L_{nk}(x_k)\,\mathrm{d}x \ . \tag{8.28}$$

If first or second degree Lagrange polynomials are used with a uniform spacing between the data points, one obtains the *trapezoidal* and *Simpson's rules*, i. e.,

$$\int_a^b f(x)\,\mathrm{d}x \approx \frac{\delta}{2}\left[f(a)+f(b)\right] + \mathcal{O}\left[\delta^3 f^{(2)}(\zeta)\right] , \tag{8.29}$$

$$\int_a^b f(x)\,\mathrm{d}x \approx \frac{\delta}{3}\left[f(a)+4f\left(\frac{\delta}{2}\right)+f(b)\right]$$
$$+ \mathcal{O}\left[\delta^5 f^{(4)}(\zeta)\right] , \tag{8.30}$$

respectively, with $\delta = b - a$, and for some ζ in $[a,b]$.

Other commonly used formulas based on low-order polynomials, and generally referred to as *Newton–Cotes* formulas, are described and discussed in detail in numerical analysis texts [8.1, 2]. Since potentially unwanted rapid oscillations in interpolants may arise, it is generally the case that increasing the order of the quadrature scheme too greatly does not generally improve the accuracy of the approximation. Dividing the interval $[a,b]$ into a number of subintervals and summing the result of application of a low-order formula in each subinterval is usually a much better approach. This procedure, referred to as *composite quadrature*, may be combined with choosing the data points at a nonuniform spacing, decreasing the spacing where the function varies rapidly, and increasing the spacing for economy where the function is smooth to construct an *adaptive quadrature*.

Gaussian Quadrature

If the function whose definite integral is to be approximated can be evaluated explicitly, then the data points (abscissas) can be chosen in a manner in which significantly greater accuracy may be obtained than using Newton–Cotes formulas of equal order. *Gaussian quadrature* is a procedure in which the error in the approximation is minimized owing to this freedom to choose both data points (abscissas) and coefficients. By utilizing orthogonal polynomials and choosing the abscissas at the roots of the polynomials in the interval under consideration, it can be shown that the coefficients may be optimally chosen by solving a simple set of linear equations. Thus, a Gaussian quadrature scheme

approximates the definite integral of a function multiplied by the weight function appropriate to the orthogonal polynomial being used as

$$\int_a^b \mathcal{W}(x) f(x)\,\mathrm{d}x \approx \sum_{k=1}^n a_k f(x_k) , \tag{8.31}$$

where the function is to be evaluated at the abscissas given by the roots of the orthogonal polynomial, x_k. In this case, the coefficients a_k are often referred to as "weights," but should not be confused with the weight function $\mathcal{W}(x)$ (Sect. 8.1.1). Since the Legendre polynomials are orthogonal over the interval $[-1, 1]$ with respect to the weight function $\mathcal{W}(x) \equiv 1$, this equation has a particularly simple form, leading immediately to the *Gauss–Legendre quadrature*. If $f(x)$ contains as a factor the weight function of another of the orthogonal polynomials, the corresponding *Gauss–Laguerre* or *Gauss–Chebyshev* quadrature should be used.

The roots and coefficients have been tabulated [8.4] for many common choices of the orthogonal polynomials (e.g., Legendre, Laguerre, Chebyshev) and for various orders. Simple computer subroutines are also available which conveniently compute them [8.3]. Since the various orthogonal polynomials are defined over different intervals, use of the change of variables such as that given in (8.10) may be required. So, for Gauss–Legendre quadrature we make use of the transformation

$$\int_a^b f(x)\,\mathrm{d}x \approx \frac{(b-a)}{2}\int_{-1}^1 f\left(\frac{(b-a)y+b+a}{2}\right)\,\mathrm{d}y \ . \tag{8.32}$$

Other Methods

Especially for multidimensional integrals which can not be reduced analytically to seperable or iterated integrals of lower dimension, *Monte Carlo* integration may provide the only means of finding a good approximation. This method is described in Sect. 8.4.3. Also, a convenient quadrature scheme can easily be devised based on the cubic spline interpolation described in Sect. 8.1.1. since in each subinterval, the definite integral of a cubic polynomial of known coefficients is evident.

8.1.5 Approximating Derivatives

Numerical Differentiation

The calculation of derivatives from a numerical representaion of a function is generally less stable than the

calculation of integrals because differentation tends to enhance fluctuations and worsen the convergence properties of power series. For example, if $f(x)$ is twice continuously differentiable on $[a, b]$, then differentiation of the linear Lagrange interpolation formula (8.5) yields

$$f^{(1)}(x_0) = \frac{f(x_0 + \delta) - f(x_0)}{\delta} + \mathcal{O}\left[\delta f^{(2)}(\zeta)\right]$$
(8.33)

for some x_0 and ζ in $[a, b]$, where $\delta = b - a$. In the limit $\delta \to 0$, (8.33) coincides with the definition of the derivative. However, in practical calculations with finite precision arithmetic, δ cannot be taken too small because of numerical cancellation in the calculation of $f(a + \delta) - f(a)$.

In practice, increasing the order of the polynomial used decreases the truncation error, but at the expense of increasing round-off error, the upshot being that three- and five-point approximations are usually most useful. Various three- and five-point formulas are given in standard texts [8.2, 4, 17]. Two common five-point formulas

(centered and forward/backward) are

$$\begin{aligned}
f^{(1)}(x_0) = \frac{1}{12\delta} & \left[f(x_0 - 2\delta) - 8 f(x_0 - \delta) \right. \\
& + 8 f(x_0 + \delta) - f(x_0 + 2\delta) \Big] \\
& + \mathcal{O}\left[\delta^4 f^{(5)}(\zeta) \right]
\end{aligned}$$
(8.34)

$$\begin{aligned}
f^{(1)}(x_0) = \frac{1}{12\delta} & \left[-25 f(x_0) + 48 f(x_0 + \delta) \right. \\
& - 36 f(x_0 + 2\delta) + 16 f(x_0 + 3\delta) \\
& - 3 f(x_0 + 4\delta) \Big] + \mathcal{O}\left[\delta^4 f^{(5)}(\zeta) \right] .
\end{aligned}$$
(8.35)

The second formula is useful for evaluating the derivative at the left or right endpoint of the interval, depending on whether δ is positive or negative, respectively.

Derivatives of Interpolated Functions

An interpolating function can be directly differentiated to obtain the derivative at any desired point. For example, if $f(x) \approx a_0 + a_1 x + a_2 x^2$, then $f^{(1)}(x) = a_1 + 2a_2 x$. However, this approach may fail to give the best approximation to $f^{(1)}(x)$ if the original interpolation was optimized to give the best possible representaion of $f(x)$.

8.2 Differential and Integral Equations

The subject of differential and integral equations is immense in both richness and scope. The discussion here focuses on techniques and algorithms, rather than the formal aspect of the theory. Further information can be found elsewhere under the broad catagories of finite element and finite difference methods. The *Numerov method*, which is particularly useful in integrating the Schrödinger equation, is described in great detail in [8.8].

8.2.1 Ordinary Differential Equations

An *ordinary differential equation* is an equation involving an unknown function and one or more of its derivatives that depends on only one independent variable [8.18]. The *order* of a differential equation is the order of the highest derivative appearing in the equation. A *solution* of a general differential equation of order n,

$$f\left(t, y, \dot{y}, \dots, y^{(n)}\right) = 0 ,$$
(8.36)

is a real-valued function $y(t)$ having the following properties: (1) $y(t)$ and its first n derivatives exist, so $y(t)$ and its first $n-1$ derivatives must be continuous, and (2) $y(t)$ satisfies the differential equation for all t. A unique

solution requires the specification of n conditions on $y(t)$ and its derivatives. The conditions may be specified as n initial conditions at a single t to give an *initial value problem*, or at the end points of an interval to give a *boundary value problem*.

Consider first solutions to the simple equation

$$\dot{y} = f(t, y) , \qquad y(a) = A .$$
(8.37)

The methods discussed below can easily be extended to systems of first-order differential equations and to higher-order differential equations. The methods are referred to as *discrete variable methods* and generate a sequence of approximate values for $y(t)$, $y_1, y_2, y_3, \dots$ at points $t_1, t_2, t_3, \dots$. For simplicity, the discussion assumes a constant spacing h between t points. We shall first describe a class of methods known as *one-step* methods [8.19]. They have no memory of the solutions at past times; given y_i, there is a recipe for y_{i+1} that depends only on information at t_i. Errors enter into numerical solutions from two sources. The first is *discretization error* and depends on the method being used. The second is *computational error* which includes such things as round off error.

For a solution on the interval $[a, b]$, let the t points be equally spaced; so for some positive integer n and $h = (b - a)/n$, $t_i = a + ih$, $i = 0, 1, \ldots, n$. If $a < b$, h is positive and the integration is forward; if $a > b$, h is negative and the integration is backward. The latter case could occur in solving for the initial point of a solution curve given the terminal point. A general one-step method can then be written in the form

$$y_{i+1} = y_i + h \Delta(t_i, y_i), \qquad y_0 = y(t_0), \qquad (8.38)$$

where Δ is a function that characterizes the method. Different Δ functions are displayed, giving rise to the Taylor series methods and the Runge–Kutta methods.

Taylor Series Algorithm

To obtain an approximate solution of order p on $[a, b]$, generate the sequence

$$y_{i+1} = y_i + h \left[f(t_i, y_i) + \cdots \right.$$
$$\left. + f^{(p-1)}(t_i, y_i) \frac{h^{p-1}}{p!} \right],$$
$$t_{i+1} = t_i + h, \quad i = 0, 1, \ldots, n - 1 \qquad (8.39)$$

where $t_0 = a$ and $y_0 = A$. The Taylor method of order $p = 1$ is known as *Euler's method*:

$$y_{i+1} = y_i + h f(t_i, y_i),$$
$$t_{i+1} = t_i + h. \qquad (8.40)$$

Taylor series methods can be quite effective if the total derivatives of f are not too difficult to evaluate. Software packages are available that perform exact differentiation, (ADIFOR, MAPLE, MATHEMATICA, etc.) facilitating the use of this approach.

Runge–Kutta Methods

Runge–Kutta methods are designed to approximate Taylor series methods [8.20], but have the advantage of not requiring explicit evaluations of the derivatives of $f(t, y)$. The basic idea is to use a linear combination of values of $f(t, y)$ to approximate $y(t)$. This linear combination is matched up as closely as possible with a Taylor series for $y(t)$ to obtain methods of the highest possible order p. Euler's method is an example using one function evaluation.

To obtain an approximate solution of order $p = 2$, let $h = (b - a)/n$ and generate the sequences

$$y_{i+1} = y_i + h \left[(1 - \gamma) f(t_i, y_i) \right.$$
$$\left. + \gamma f \left[t_i + \frac{h}{2\gamma}, y_i + \frac{h}{2\gamma} f(t_i, y_i) \right] \right],$$

$$t_{i+1} = t_i + h, \qquad i = 0, 1, \ldots, n - 1, \qquad (8.41)$$

where $\gamma \neq 0$, $t_0 = a$, $y_0 = A$.

Euler's method is the special case, $\gamma = 0$, and has order 1; the improved Euler method has $\gamma = 1/2$ and the Euler–Cauchy method has $\gamma = 1$.

The Adams–Bashforth and Adams–Moulton Formulas

These formulas furnish important and widely-used examples of multistep methods [8.21]. On reaching a mesh point t_i with approximate solution $y_i \cong y(t_i)$, there are (usually) available approximate solutions $y_{i+1-j} \cong y(t_{i+1-j})$ for $j = 2, 3, \ldots, p$. From the differential equation itself, approximations to the derivatives $\dot{y}(t_{i+1-j})$ can be obtained.

An attractive feature of the approach is the form of the underlying polynomial approximation, $P(t)$, to $\dot{y}(t)$ because it can be used to approximate $y(t)$ between mesh points

$$y(t) \cong y_i + \int_{t_i}^{t} P(t) \, dt. \qquad (8.42)$$

The lowest-order Adams–Bashforth formula arises from interpolating the single value $f_i = f(t_i, y_i)$ by $P(t)$. The interpolating polynomial is constant so its integration from t_i to t_{i+1} results in $h f(t_i, y_i)$ and the first order Adams–Bashforth formula:

$$y_{i+1} = y_i + h f(t_i, y_i). \qquad (8.43)$$

This is just the forward Euler formula. For constant step size h, the second-order Adams–Bashforth formula is

$$y_{i+1} = y_i + h \left[\left(\frac{3}{2} \right) f(t_i, y_i) - \left(\frac{1}{2} \right) f(t_{i-1}, y_{i-1}) \right]. \qquad (8.44)$$

The lowest-order Adams–Moulton formula involves interpolating the single value $f_{i+1} = f(x_{i+1}, y_{i+1})$ and leads to the backward Euler formula

$$y_{i+1} = y_i + h f(t_{i+1}, y_{i+1}), \qquad (8.45)$$

which defines y_{i+1} implicitly. From its definition it is clear that it has the same accuracy as the forward Euler method; its advantage is vastly superior stability. The second-order Adams–Moulton method also does not use previously computed solution values; it is called the trapezoidal rule because it generalizes the trapezoidal rule for integrals to differential equations:

$$y_{i+1} = y_i + \frac{h}{2} \left[f(t_{i+1}, y_{i+1}) + f(t_i, y_i) \right]. \qquad (8.46)$$

The Adams–Moulton formula of order p is more accurate than the Adams–Bashforth formula of the same order, so that it can use a larger step size; the Adams–Moulton formula is also more stable. A code based on such methods is more complex than a Runge–Kutta code because it must cope with the difficulties of starting the integration and changing the step size. Modern Adams codes attempt to select the most efficient formula at each step, as well as to choose an optimal step size h to achieve a specified accuracy.

8.2.2 Differencing Algorithms for Partial Differential Equations

The modern approach to evolve differencing schemes for most physical problems is based on flux conservation methods [8.22]. One begins by writing the balance equations for a single cell, and subsequently applying quadratures and interpolation formulas. Such approaches have been successful for the full spectrum of hyperbolic, elliptic, and parabolic equations. For simplicity, we begin by discussing systems involving only one space variable.

As a prototype, consider the parabolic equation

$$c \frac{\partial}{\partial t} u(x, t) = \sigma \frac{\partial^2}{\partial x^2} u(x, t) , \tag{8.47}$$

where c and σ are constants and $u(x, t)$ is the solution. We begin by establishing a grid of points on the xt-plane with step size h in the x direction and step size k in the t-direction. Let spatial grid points be denoted by $x_n = x_0 + nh$ and time grid points by $t_j = t_0 + jk$, where n and j are integers and (x_0, t_0) is the origin of the space–time grid. The points ξ_{n-1} and ξ_n are introduced to establish a "control interval". We begin with a conservation statement

$$\int_{\xi_{n-1}}^{\xi_n} \mathrm{d}x \left[r(x, t_{j+1}) - r(x, t_j) \right]$$

$$= \int_{t_j}^{t_{j+1}} \mathrm{d}t \left[q(\xi_{n-1}, t) - q(\xi_n, t) \right] . \tag{8.48}$$

This equation states that the change in the field density on the interval (ξ_{n-1}, ξ_n) from time $t = t_j$ to time $t = t_{j+1}$ is given by the flux into this interval at ξ_{n-1} minus the flux out of the interval at ξ_n from time t_j to time t_{j+1}. This expresses the conservation of material in the case that no sources or sinks are present. We relate the field variable u to the physical variables (the density r

and the flux q). We consider the case in which density is assumed to have the form

$$r(x, t) = cu(x, t) + b \tag{8.49}$$

with c and b constants, thus

$$c \int_{\xi_{n-1}}^{\xi_n} \mathrm{d}x \left[u(x, t_{j+1}) - u(x, t_j) \right]$$

$$\approx c[u(x_n, t_{j+1}) - u(x_n, t_j)]h . \tag{8.50}$$

When developing conservation law equations, there are two commonly used strategies for approximating the right-hand-side of (8.48): (i) left end-point quadrature

$$\int_{t_j}^{t_{j+1}} \mathrm{d}t \left[q(\xi_{n-1}, t) - q(\xi_n, t) \right]$$

$$\approx \left[q(\xi_{n-1}, t_j) - q(\xi_n, t_j) \right] k , \tag{8.51}$$

and (ii) right end-point quadrature

$$\int_{t_j}^{t_{j+1}} \mathrm{d}t \left[q(\xi_{n-1}, t) - q(\xi_n, t) \right]$$

$$\approx \left[q(\xi_{n-1}, t_{j+1}) - q(\xi_n, t_{j+1}) \right] k . \tag{8.52}$$

Combining (8.48) with the respective approximations yields: from (i) an explicit method

$$c \left[u(x_n, t_{j+1}) - u(x_n, t_j) \right] h$$

$$\approx \left[q(\xi_{n-1}, t_j) - q(\xi_n, t_j) \right] k , \tag{8.53}$$

and from (ii) an implicit method

$$c \left[u(x_n, t_{j+1}) - u(x_n, t_j) \right] h$$

$$\approx \left[q(\xi_{n-1}, t_{j+1}) - q(\xi_n, t_{j+1}) \right] k . \tag{8.54}$$

Using centered finite difference formulas to approximate the fluxes at the control points ξ_{n-1} and ξ_n yields

$$q(\xi_{n-1}, t_j) = -\sigma \frac{u(x_n, t_j) - u(x_{n-1}, t_j)}{h} , \tag{8.55}$$

and

$$q(\xi_n, t_j) = -\sigma \frac{u(x_{n+1}, t_j) - u(x_n, t_j)}{h} \tag{8.56}$$

where σ is a constant. We also obtain similar formulas for the fluxes at time t_{j+1}.

We have used a lower case u to denote the continuous field variable, $u = u(x, t)$. Note that all of the quadrature and difference formulas involving u are stated as approximate equalities. In each of these approximate equality statements, the amount by which the right side differs from the left side is called the truncation error. If u is a well-behaved function (has enough smooth derivatives), then it can be shown that these truncation errors approach zero as the grid spacings, h and k, approach zero.

If U_n^j denotes the exact solution on the grid, we have from (i) the result

$$c \left(U_n^{j+1} - U_n^j \right) h^2 = \sigma k \left(U_{n-1}^j + U_{n+1}^j - 2U_n^j \right) .$$
(8.57)

This is an explicit method since it provides the solution to the difference equation at time t_{j+1}, knowing the values at time t_j.

If we use the numerical approximations (ii) we obtain the result

$$c \left(U_n^{j+1} - U_n^j \right) h^2 = \sigma k \left(U_{n-1}^{j+1} + U_{n+1}^{j+1} - 2U_n^{j+1} \right) .$$
(8.58)

Note that this equation defines the solution at time t_{j+1} implicitly, since a system of algebraic equations is required to be satisfied.

8.2.3 Variational Methods

Perhaps the most widely used approximation procedures in AMO physics are the variational methods. We shall outline in detail the Rayleigh–Ritz method [8.23]. This method is limited to boundary value problems which can be formulated in terms of the minimization of a functional $J[u]$. For definiteness we consider the case of a differential operator defined by

$$Lu(\mathbf{x}) = f(\mathbf{x})$$
(8.59)

with $\mathbf{x} = x_i$, $i = 1, 2, 3$ in R, for example, and with $u = 0$ on the boundary of R. The function $f(x)$ is the source. It is assumed that L is always nonsingular and in addition, for the Ritz method L is Hermitian. The real-valued functions u are in the Hilbert space Ω of the operator L. We construct the functional $J[u]$ defined as

$$J[u] = \int_\Omega dx \left[u(x) Lu(x) - 2u(x) f(x) \right] .$$
(8.60)

The variational ansatz considers a subspace of Ω, Ω_n, spanned by a class of functions $\phi_n(x)$, and we construct the function $u^n \approx u$

$$u^n(x) = \sum_{i=1}^n c_i \phi_i(x) .$$
(8.61)

We solve for the coefficients c_i by minimizing $J[u^n]$

$$\partial_{c_i} J[u^n] = 0 , \quad i = 1, \ldots, n .$$
(8.62)

These equations are simply cast into a set of well-behaved algebraic equations

$$\sum_{j=1}^n A_{i,j} c_j = g_i , \quad i = 1, \ldots, n ,$$
(8.63)

with $A_{i,j} = \int_\Omega dx \phi_i(x) L\phi_j(x)$, and $g_i = \int_\Omega dx \phi_i(x) f(x)$. Under very general conditions, the functions u^n converge uniformly to u. The main drawback of the Ritz method is in the assumption of Hermiticity of the operator L. For the *Galerkin Method* we relax this assumption with no other changes. Thus we obtain an identical set of equations, as above with the exception that the function g is no longer symmetric. The convergence of the sequence of solutions u^n to u is no longer guaranteed, unless the operator can be separated into a symmetric part L_0, $L = L_0 + K$ so that $L_0^{-1} K$ is bounded.

8.2.4 Finite Elements

As discussed in Sect. 8.2.2, in the finite difference method for classical partial differential equations, the solution domain is approximated by a grid of uniformly spaced nodes. At each node, the governing differential equation is approximated by an algebraic expression which references adjacent grid points. A system of equations is obtained by evaluating the previous algebraic approximations for each node in the domain. Finally, the system is solved for each value of the dependent variable at each node.

In the finite element method [8.24], the solution domain can be discretized into a number of uniform or nonuniform finite elements that are connected via nodes. The change of the dependent variable with regard to location is approximated within each element by an interpolation function. The interpolation function is defined relative to the values of the variable at the nodes associated with each element. The original boundary value problem is then replaced with an equivalent in-

tegral formulation. The interpolation functions are then substituted into the integral equation, integrated, and combined with the results from all other elements in the solution domain.

The results of this procedure can be reformulated into a matrix equation of the form

$$\sum_{j=1}^{n} A_{i,j} c_j = g_i , \quad i = 1, \dots, n ,$$ (8.64)

with $A_{i,j} = \int_{\Omega} dx \phi_i(x) L \phi_j(x)$, and $g_i = \int_{\Omega} dx \phi_i(x) f(x)$ exactly as obtained in Sect. 8.2.3. The only difference arises in the definitions of the support functions $\phi_i(x)$. In general, if these functions are piecewise polynomials on some finite domain, they are called finite elements or splines. Finite elements make it possible to deal in a systematic fashion with regions having curved boundaries of an arbitrary shape. Also, one can systematically estimate the accuracy of the solution in terms of the parameters that label the finite element family, and the solutions are no more difficult to generate than more complex variational methods.

In one space dimension, the simplest finite element family begins with the set of step functions defined by

$$\phi_i(x) = \begin{cases} 1 & x_{i-1} \le x \le x_i \\ 0 & \text{otherwise} . \end{cases}$$ (8.65)

The use of these simple "hat" functions as a basis provides no advantage over the usual finite difference schemes. However, for certain problems in two or more dimensions, finite element methods have distinct advantages over other methods. Generally, the use of finite elements requires complex, sophisticated computer programs for implementation. The use of higher-order polynomials, commonly called splines, as a basis has been extensively used in atomic and molecular physics. An extensive literature is available [8.25, 26].

We illustrate the use of the finite element method by applying it to the Schrödinger equation. In this case, the linear operator L is $H - E$ where, as usual, E is the energy and the Hamiltonian H is the sum of the kinetic and potential energies, that is, $L = H - E = \mathcal{T} + V - E$ and $Lu(x) = 0$. We define the finite elements through support points, or knots, given by the sequence $\{x_1, x_2, x_3, \dots\}$ which are not necessarily spaced uniformly. Since the "hat" functions have vanishing derivatives, we employ the next more complex basis, i.e., "tent" functions, which are piecewise linear

functions given by

$$\phi_i(x) = \begin{cases} \dfrac{x - x_{i-1}}{x_i - x_{i-1}} & x_{i-1} \le x \le x_i \\[2mm] \dfrac{x_{i+1} - x}{x_{i+1} - x_i} & x_i \le x \le x_{i+1} \\[2mm] 0 & \text{otherwise} , \end{cases}$$ (8.66)

and for which the derivative is given by

$$\frac{d}{dx}\phi_i(x) = \begin{cases} \dfrac{1}{x_i - x_{i-1}} & x_{i-1} \le x \le x_i \\[2mm] \dfrac{-1}{x_{i+1} - x_i} & x_i \le x \le x_{i+1} \\[2mm] 0 & \text{otherwise} . \end{cases}$$ (8.67)

The functions have a maximum value of one at the midpoint of the interval $[x_{i-1}, x_{i+1}]$, with partially overlapping adjacent elements. In fact, the overlaps may be represented by a matrix $\mathbf{O}$ with elements

$$O_{ij} = \int_{-\infty}^{\infty} dx \, \phi_i(x) \phi_j(x) .$$ (8.68)

Thus, if $i = j$

$$O_{ii} = \int_{x_{i-1}}^{x_i} dx \, \frac{(x - x_{i-1})^2}{(x_i - x_{i-1})^2} + \int_{x_i}^{x_{i+1}} dx \, \frac{(x - x_i)^2}{(x_{i+1} - x_i)^2}$$

$$= \frac{1}{3}(x_{i+1} - x_{i-1}) ,$$ (8.69)

if $i = j - 1$

$$O_{ij} = \int_{x_i}^{x_{i+1}} dx \, \frac{(x - x_i)(x_{i+1} - x)}{(x_{i+1} - x_i)^2}$$

$$= \frac{1}{6}(x_{i+1} - x_i) ,$$ (8.70)

if $i = j + 1$

$$O_{ij} = \int_{x_{i-1}}^{x_i} dx \, \frac{(x - x_{i-1})(x_i - x)}{(x_i - x_{i-1})^2}$$

$$= \frac{1}{6}(x_i - x_{i-1}) ,$$ (8.71)

and $O_{ij} = 0$ otherwise.

The potential energy is represented by the matrix

$$V_{ij} = \int_{-\infty}^{\infty} dx \, \phi_i(x) V(x) \phi_j(x) ,$$ (8.72)

which may be well approximated by

$$V_{ij} \approx V(x_i) \int_{-\infty}^{\infty} dx \, \phi_i(x)\phi_j(x) \qquad (8.73)$$

$$= V(x_i) O_{ij}$$

if $x_j - x_i$ is small. The kinetic energy, $\mathcal{T} = -\frac{1}{2} d^2/dx^2$, is similarly given by

$$\mathcal{T}_{ij} = -\frac{1}{2} \int_{-\infty}^{\infty} dx \phi_i(x) \frac{d^2}{dx^2}\phi_j(x) , \qquad (8.74)$$

which we compute by integrating by parts since the tent functions have a singular second derivative

$$\mathcal{T}_{ij} = \frac{1}{2} \int_{-\infty}^{\infty} dx \left(\frac{d}{dx}\phi_i(x) \right)\left(\frac{d}{dx}\phi_j(x) \right) , \qquad (8.75)$$

which in turn is evalutated to yield

$$\mathcal{T}_{ij} = \begin{cases} \dfrac{x_{i+1} - x_{i-1}}{2(x_i - x_{i-1})(x_{i+1} - x_i)} & i = j \\[2ex] \dfrac{1}{2(x_i - x_{i+1})} & i = j - 1 \\[2ex] \dfrac{1}{2(x_{i-1} - x_i)} & i = j + 1 \\[2ex] 0 & \text{otherwise} . \end{cases} \qquad (8.76)$$

Finally, since the Hamiltonian matrix is $H_{ij} = \mathcal{T}_{ij} + V_{ij}$, the solution vector $u_i(x)$ may be found by solving the eigenvalue equation

$$[H_{ij} - EO_{ij}]u_i(x) = 0 . \qquad (8.77)$$

8.2.5 Integral Equations

Central to much of practical and formal scattering theory is the integral equation and techniques of its solution. For example, in atomic collision theory, the Schrödinger differential equation

$$[E - H_0(\boldsymbol{r})] \psi(\boldsymbol{r}) = V(\boldsymbol{r})\psi(\boldsymbol{r}) \qquad (8.78)$$

where the Hamiltonian $H_0 \equiv -(\hbar^2/2m)\nabla^2 + V_0$ may be solved by exploiting the solution for a delta function source, i.e.,

$$(E - H_0)G(\boldsymbol{r},\boldsymbol{r}') = \delta(\boldsymbol{r} - \boldsymbol{r}') . \qquad (8.79)$$

In terms of this *Green's function* $G(\boldsymbol{r},\boldsymbol{r}')$, and any solution $\chi(\boldsymbol{r})$ of the homogeneous equation [i.e. with $V(\boldsymbol{r}) = 0$], the general solution is

$$\psi(\boldsymbol{r}) = \chi(\boldsymbol{r}) + \int d\boldsymbol{r}' \, G(\boldsymbol{r},\boldsymbol{r}')V(\boldsymbol{r}')\psi(\boldsymbol{r}') \qquad (8.80)$$

for which, given a choice of the functions $G(\boldsymbol{r},\boldsymbol{r}')$ and $\chi(\boldsymbol{r})$, particular boundary conditions are determined. This integral equation is the Lippmann–Schwinger equation of potential scattering. Further topics on scattering theory are covered in other chapters (see especially Chaps. 47 to 58) and in standard texts such as those by *Joachain* [8.27], *Rodberg* and *Thaler* [8.28], and *Goldberger* and *Watson* [8.29]. Owing especially to the wide variety of specialized techniques for solving integral equations, we survey briefly only a few of the most widely applied methods.

Integral Transforms
Certain classes of integral equations may be solved using integral transforms such as the Fourier or Laplace transforms. These integral transforms typically have the form

$$f(x) = \int dx' \, K(x, x')g(x') , \qquad (8.81)$$

where $f(x)$ is the integral transform of $g(x')$ by the kernel $K(x, x')$. Such a pair of functions is the solution of the Schrödinger equation (spatial wave function) and its Fourier transform (momentum representation wave function). *Arfken* [8.6], *Morse* and *Feshbach* [8.9], and *Courant* and *Hilbert* [8.10] give other examples, as well as being excellent references for the application of integral equations and Green's functions in mathematical physics. In their analytic form, these transform methods provide a powerful method of solving integral equations for special cases, and, in addition, they may be implemented by performing the transform numerically.

Power Series Solution
For an equation of the form (in one dimension for simplicity)

$$\psi(r) = \chi(r) + \lambda \int dr' \, K(r, r')\psi(r') , \qquad (8.82)$$

a solution may be found by iteration. That is, as a first approximation, set $\psi_0(r) = \chi(r)$ so that

$$\psi_1(r) = \chi(r) + \lambda \int dr' \, K(r, r')\chi(r') . \qquad (8.83)$$

This may be repeated to form a power series solution, i. e.,

$$\psi_n(r) = \sum_{k=0}^{n} \lambda^k I_k(r) , \qquad (8.84)$$

where

$$I_0(r) = \chi(r) , \qquad (8.85)$$

$$I_1(r) = \int dr' \, K(r, r') \chi(r') , \qquad (8.86)$$

$$I_2(r) = \int dr'' \int dr' \, K(r, r') K(r', r'') \chi(r'') , \qquad (8.87)$$

$$I_n(r) = \int dr' \cdots \int dr^{(n)} \, K(r, r') K(r, r'') \\ \cdots K(r^{(n-1)}, r^{(n)}) . \quad (8.88)$$

If the series converges, then the solution $\psi(r)$ is approached by the expansion. When the Schrödinger equation is cast as an integral equation for scattering in a potential, this iteration scheme leads to the *Born series*, the first term of which is the incident, unperturbed wave, and the second term is usually referred to simply as the *Born approximation*.

Separable Kernels

If the kernel is separable, i. e.,

$$K(r, r') = \sum_{k=1}^{n} f_k(r) g_k(r') , \qquad (8.89)$$

where n is finite, then substitution into the prototype integral equation (8.82) yields

$$\psi(r) = \chi(r) + \lambda \sum_{k=1}^{n} f_k(r) \int dr' \, g(r') \psi(r') . \quad (8.90)$$

Multiplying by $f_k(r)$, integrating over r, and rearranging, yields the set of algebraic equations

$$c_j = b_j + \lambda \sum_{k=1}^{n} a_{jk} c_k , \qquad (8.91)$$

where

$$c_k = \int dr' g_k(r') \psi(r') , \qquad (8.92)$$

$$b_k = \int dr f_k(r) \chi(r) , \qquad (8.93)$$

$$a_{jk} = \int dr g_j(r) f_k(r) , \qquad (8.94)$$

or, if c and b denote vectors, and A denotes the matrix of constants a_{jk},

$$c = (1 - \lambda A)^{-1} b . \qquad (8.95)$$

The eigenvalues are the roots of the determinantal equation. Substituting these into $(I - \lambda A)c = 0$ yields the constants c_k which determine the solution of the original equation. This derivation may be found in *Arfken* [8.6], along with an explicit example. Even if the kernel is not exactly separable, if it is approximately so, then this procedure can yield a result which can be substituted into the original equation as a first step in an iterative solution.

Numerical Integration

Perhaps the most straightforward method of solving an integral equation is to apply a numerical integration formula such as Gaussian quadrature. An equation of the form

$$\psi(r) = \int dr' \, K(r, r') \chi(r') \qquad (8.96)$$

can be approximated as

$$\psi(r_j) = \sum_{k=1}^{n} w_k K(r_j, r'_k) \chi(r_k) , \qquad (8.97)$$

where w_k are quadrature weights, if the kernel is well behaved. However, such an approach is not without pitfalls. In light of the previous subsection, this approach is equivalent to replacing the integral equation by a set of algebraic equations. In this example we have

$$\psi_j = \sum_{k=1}^{n} M_{jk} \chi_k , \qquad (8.98)$$

so that the solution of the equation is found by inverting the matrix M. Since there is no guarantee that this matrix is not ill-conditioned, the numerical procedure may not produce meaningful results. In particular, only certain classes of integral equations and kernels will lead to stable solutions.

Having only scratched the surface regarding the very rich field of integral equations, the interested reader is encouraged to explore the references given here.

8.3 Computational Linear Algebra

Previous sections of this chapter have dealt with interpolation, differential equations, and related topics. Generally, discretization methodologies lead to classes of algebraic equations. In recent years enormous progress has been made in developing algorithms for solving linear algebraic equations, and many very good books have been written on this topic [8.30]. Furthermore, a large body of numerical software is freely available via an electronic service called *Netlib* (www.netlib.org). In addition to the widely adopted numerical linear algebra packages LAPACK, ScaLA-PACK, ARPACK, etc., there are dozens of other libraries, technical reports on various parallel computers and software, test data, facilities to automatically translate Fortran programs to C, bibliographies, names and addresses of scientists and mathematicians, and so on.

Here we discuss methods for solving systems of equations such as

$$a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n = b_1 \,,$$
$$a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n = b_2 \,,$$
$$\vdots$$
$$a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n = b_m \,. \qquad (8.99)$$

In these equations a_{ij} and b_i form the set of known quantities, and the x_i must be determined. The solution to these equations can found if they are linearly independent. Numerically, problems can arise due to truncation and roundoff errors that lead to an approximate linear dependence [8.31]. In this case the set of equations are approximately singular and special methods must be invoked. Much of the complexity of modern algorithms comes from minimizing the effects of such errors. For relatively small sets of nonsingular equations, direct methods in which the solution is obtained after a definite number of operations can work well. However, for very large systems iterative techniques are preferable [8.32].

A great many algorithms are available for solving (8.99), depending on the structure of the coefficients. For example, if the matrix of coefficients A is dense, using Gaussian elimination takes $2n^3/3$ operations; if A is also symmetric and positive definite, using the Cholesky algorithm takes a factor of two fewer operations. If A is triangular, i. e., either zero above the diagonal or zero below the diagonal, we can solve the above by simple substitution in only n^2 operations. For example, if A arises from solving certain elliptic partial differential equations, such as Poisson's equation, then $Ax = b$ can be solved using multigrid methods in only n operations.

We shall outline below how to solve (8.99) using elementary Gaussian elimination. More advanced methods, such as *conjugate gradient, generalized minimum residuals*, and the *Lanczos method* are treated elsewhere [8.33].

To solve $Ax = b$, we first use Gaussian elimination to factor the matrix A as $PA = LU$, where L is lower triangular, U is upper triangular, and P is a matrix which permutes the rows of A. Then we solve the triangular system $Ly = Pb$ and $Ux = y$. These last two operations are easily performed using standard linear algebra libraries. The factorization $PA = LU$ takes most of the time. Reordering the rows of A with P is called pivoting and is necessary for numerical stability. In the standard partial pivoting scheme, L has ones on its diagonal and other entries bounded in absolute value by one. The simplest version of Gaussian elimination involves adding multiples of one row of A to others to zero out subdiagonal entries, and overwriting A with L and U.

We first describe the decomposition of PA into a product of upper and lower triangular matrices,

$$A' = LU \,, \qquad (8.100)$$

where the matrix A' is defined by $A' = PA$. A very nice algorithm for pivoting is given in [8.3] and will not be discussed further. Writing out the indices,

$$A'_{ij} = \sum_{k=1}^{\min(i,j)} L_{ik}U_{kj} \,. \qquad (8.101)$$

We shall make the choice

$$L_{ii} = 1 \,. \qquad (8.102)$$

These equations have the remarkable property that the elements A'_{ij} of each row can be scanned in turn, writing L_{ij} and U_{ij} into the locations A'_{ij} as we go. At each position (i, j), only the current A'_{ij} and already-calculated values of $L_{i'j'}$ and $U_{i'j'}$ are required. To see how this works, consider the first few rows. If $i = 1$,

$$A'_{1j} = U_{1j} \,, \qquad (8.103)$$

defining the first row of L and U. The U_{1j} are written over the A'_{1j}, which are no longer needed. If $i = 2$,

$$A'_{21} = L_{21}U_{11} \,, \qquad\qquad j = 1$$
$$A'_{2j} = L_{21}U_{1j} + U_{2j} \,, \qquad j \geq 2 \,. \qquad (8.104)$$

The first line gives L_{21}, and the second U_{2j}, in terms of existing elements of $\boldsymbol{L}$ and $\boldsymbol{U}$. The U_{2j} and L_{21} are written over the A'_{2j}. (Remember that $L_{ii} = 1$ by definition.) If $i = 3$,

$$A'_{31} = L_{31}U_{11} , \qquad\qquad j = 1$$
$$A'_{32} = L_{31}U_{12} + L_{32}U_{22} , \qquad j = 2$$
$$A'_{3j} = L_{31}U_{1j} + L_{32}U_{2j} + U_{3j} , \quad j \geq 3 , \quad (8.105)$$

yielding in turn L_{31}, L_{32}, and U_{3j}, which are written over A'_{3j}.

The algorithm should now be clear. At the ith row

$$L_{ij} = U_{jj}^{-1}\left(A'_{ij} - \sum_{k=1}^{j-1} L_{ik}U_{kj}\right) , \qquad j \leq i-1$$
$$U_{ij} = A'_{ij} - \sum_{k=1}^{i-1} L_{ik}U_{kj} , \quad j \geq i . \qquad (8.106)$$

We observe from the first line of these equations that the algorithm may run into numerical inaccuracies if any U_{jj} becomes very small. Now $U_{11} = A'_{11}$, while in general $U_{ii} = A'_{ii} - \cdots$. Thus the absolute values of the U_{ii} are maximized if the rows are rearranged so that the absolutely largest elements of $\boldsymbol{A}'$ in each column lie on the diagonal. A little thought shows that the solutions are unchanged by permuting the rows (same equations, different order).

8.4 Monte Carlo Methods

Owing to the continuing rapid development of computational facilities and the ever-increasing desire to perform *ab initio* calcalutions, the use of Monte Carlo methods is becoming widespread as a means to evaluate previously intractable multidimensional integrals and to enable complex modeling and simulation. For example, a wide range of applications broadly classified as *Quantum Monte Carlo* have been used to compute, for example, the ground state eigenfunctions of simple molecules. Also, guided random walks have found application in the computation of Green functions, and variables chosen randomly, subject to particular constaints, have been used to mimic the electronic distribution of atoms. The latter application, used in the *classical trajectory Monte Carlo technique* described in Chapt. 58, allows the statistical quasiquantal representation of ion–atom collisions.

The *LU decomposition* can now be used to solve the system. This relies on the fact that the inversion of a triangular matrix is a simple process of back substitution. We replace ((8.99)) by two systems of equations. Written out in full, the equations for a typical column of $\boldsymbol{y}$ look like

$$L_{11}y_1 = b'_1 ,$$
$$L_{21}y_1 + L_{22}y_2 = b'_2 ,$$
$$L_{31}y_1 + L_{32}y_2 + L_{33}y_3 = b'_3 ,$$
$$\vdots , \qquad (8.107)$$

where the vector $\boldsymbol{b}'$ is $\boldsymbol{p}' = \boldsymbol{Pb}$. Thus from successive rows we obtain $y_1, y_2, y_3, \ldots$ in turn

$$U_{11}x_1 = y_1 ,$$
$$U_{12}x_1 + U_{22}x_2 = y_2 ,$$
$$U_{13}x_1 + U_{23}x_2 + U_{33}x_3 = y_3 ,$$
$$\vdots , \qquad (8.108)$$

and from successive rows of the latter we obtain $x_1, x_2, x_3, \ldots$ in turn.

Library software also exists for evaluating all the error bounds for dense and band matrices (see discussion of *Netlib* in above). Gaussian elimination with pivoting is almost always numerically stable, so the error bound one expects from solving these equations is of the order of $n\epsilon$, where ϵ is related to the condition number of the matrix $\boldsymbol{A}$. A good discussion of errors and conditioning is given in [8.3].

Here we summarize the basic tools needed in these methods, and how they may be used to produce specific distributions and make tractable the evaluation of multidimensional integrals with complicated boundaries. Detailed descriptions of these methods can be found in [8.3, 8, 34].

8.4.1 Random Numbers

An essential ingredient of any Monte Carlo procedure is the availability of a computer-generated sequence of random numbers which is not periodic and is free of other significant statistical correlations. Often such numbers are termed *pseudorandom* or *quasirandom*, in distinction to truly random physical processes. While the quality of random number generators supplied with computers has greatly improved over time, it is impor-

tant to be aware of the potential dangers which can be present. For example, many systems are supplied with a random number generator based on the *linear congruential method*. Typically a sequence of integers $n_1, n_2, n_3, \ldots$ is first produced between 0 and $N-1$ by using the recurrence relation

$$n_{i+1} = (an_i + b) \bmod N , \qquad 0 \le i < N-1$$

(8.109)

where a, b, N and the seed value n_0 are positive integers. Real numbers between 0 and (strictly) 1 are then obtained by dividing by N. The period of this sequence is at most N, and depends on the judicious choice of the constants, with N being limited by the wordsize of the computer. A user who is unsure that the character of the random numbers generated on a particular computer platform is proper can perform additional randomizing shuffles or use a portable random number generator, both procedures being described in detail by *Knuth* [8.5] and *Press* et al. [8.3], for example.

8.4.2 Distributions of Random Numbers

Most distributions of random numbers begin with sequences generated uniformly between a lower and an upper limit, and are therefore called *uniform deviates*. However, it is often useful to draw the random numbers from other distributions, such as the Gaussian, Poisson, exponential, gamma, or binomial distributions. These are particularly useful in modeling data or supplying input for an event generator or simulator. In addition, as described below, choosing the random numbers according to some weighting function can signficantly improve the efficiency of integration schemes based on Monte Carlo sampling.

Perhaps the most direct way to produce the required distribution is the *transformation method*. If we have a sequence of uniform deviates x on (0, 1) and wish to find a new sequence y which is distributed with probability given by some function $f(y)$, it can be shown that the required transformation is given by

$$y(x) = \left[\int_0^y f(y)\,dy \right]^{-1} .$$

(8.110)

Evidently, the indefinite integral must be both known and invertible, either analytically or numerically. Since this is seldom the case for distributions of interest, other less direct methods are most often applied. However, even these other methods often rely on the transformation method as one "stage" of the procedure. The transformation method may also be generalized to more than one dimension [8.3].

A more widely applicable approach is the *rejection method*, also known as *von Neumann rejection*. In this case, if one wishes to find a sequence y distributed according to $f(y)$, first choose another function $\tilde{f}(y)$, called the comparison function, which is everywhere greater than $f(y)$ on the desired interval. In addition, a way must exist to generate y according to the comparison function, such as use of the transformation method. Thus, the comparison function must be simpler or better known than the distribution to be found. One simple choice is a constant function which is larger than the maximum value of $f(y)$, but choices which are "closer" to $f(y)$ will be much more efficient.

To proceed, y is generated uniformly according to $\tilde{f}(y)$ and another deviate x is chosen uniformly on (0, 1). One then simply rejects or accepts y depending on whether x is greater than or less than the ratio $f(y)/\tilde{f}(y)$, respectively. The fraction of trial numbers accepted simply depends on the ratio of the area under the desired function to that under the comparison function. Clearly, the efficiency of this scheme depends on how few of the numbers initially generated must be rejected, and therefore on how closely the comparison function approximates the desired distribution. The Lorentzian distribution, for which the inverse definite integral is known (the tangent function), is a good comparison function for a variety of "bell-shaped" distributions such as the Gaussian (normal), Poisson, and gamma distributions.

Especially for distributions which are functions of more than one variable and possess complicated boundaries, the rejection method is impractical and the transformation method simply inapplicable. In the 1950's, a method to generate distributions for such situations was developed and applied in the study of statistical mechanics where multidimensional integrals (e.g., the partition function) must often be solved numerically, and is known as the *Metropolis algorithm*. This procedure, or its variants, has more recently been adopted to aid in the computation of eigenfunctions of complicated Hamiltonians and scattering operators. In essence, the Metropolis method generates a random walk through the space of the dependent variables, and in the limit of a large number of steps in the walk, the points visited approximate the desired distribution.

In its simplest form, the Metropolis method generates this distribution of points by stepping through this space, most frequently taking a step "downhill" but

sometimes taking a step "uphill". That is, given a set of coordinates q and a desired distribution function $f(q)$, a trial step is taken from the ith configuration q_i to the next, depending on whether the ratio $f(q_i + 1)/f(q_i)$ is greater or less than one. If the ratio is greater than one, the step is accepted, but if it is less than one, the step is accepted with a probability given by the ratio.

8.4.3 Monte Carlo Integration

The basic idea of Monte Carlo integration is that if a large number of points is generated uniformly randomly in some n-dimensional space, the number falling inside a given region is proportional to the volume, or definite integral, of the function defining that region. Though this idea is as true in one dimension as it is in n, unless there is a large number ("large" could be as little as three) of dimensions or the boundaries are quite complicated, the numerical quadrature schemes described previously are more accurate and efficient. However, since the Monte Carlo approach is based on just sampling the function at representative points rather than evaluating the function at a large number of finely spaced quadrature points, its advantage for very large problems is apparent.

For simplicity, consider the Monte Carlo method for integrating a function of only one variable; the generalization to n dimensions being straightforward. If we generate N random points uniformly on (a, b), then in the limit of large N the integral is

$$\int_a^b f(x)\,dx \approx \frac{1}{N}\langle f(x)\rangle \pm \sqrt{\frac{\langle f^2(x)\rangle - \langle f(x)\rangle^2}{N}}\,, \tag{8.111}$$

where

$$\langle f(x)\rangle \equiv \frac{1}{N}\sum_{i=1}^N f(x_i) \tag{8.112}$$

is the arithmetic mean. The probable error given is appropriately a statistical one rather than a rigorous error bound and is the one standard error limit. From this one can see that the error decreases as only $N^{1/2}$, more slowly than the rate of decrease for the quadrature schemes based on interpolation. Also, the accuracy is greater for relatively smooth functions, since the Monte Carlo generation of points is unlikely to sample narrowly peaked features of the integrand well. To estimate the integral of a multidimensional function with complicated boundaries, simply find an enclosing volume and generate points uniformly randomly within it. Keeping the enclosing volume as close as possible to the volume of interest miminizes the number of points which fall outside, and therefore increases the efficiency of the procedure.

The Monte Carlo integral is related to techniques for generating random numbers according to prescribed distributions described in Sect. 8.4.2. If we consider a normalized distribution $w(x)$, known as the *weight function*, then with the change of variables defined by

$$y(x) = \int_a^x w(x')\,dx'\,, \tag{8.113}$$

the Monte Carlo estimate of the integral becomes

$$\int_a^b f(x)\,dx \approx \frac{1}{N}\left\langle \frac{f\,[x(y)]}{w\,[x(y)]}\right\rangle\,, \tag{8.114}$$

assuming that the transformation is invertible. Choosing $w(x)$ to behave approximately as $f(x)$ allows a more efficient generation of points within the boundaries of the integrand. This occurs since the uniform distribution of points y results in values of x distributed according to w and therefore "close" to f. This procedure, generally termed the *reduction of variance* of the Monte Carlo integration, improves the efficiency of the procedure to the extent that the transformed function f/w can be made smooth, and that the sampled region is as small as possible but still contains the volume to be estimated.

9. Hydrogenic Wave Functions

This chapter summarizes the solutions of the one-electron nonrelativistic Schrödinger equation, and the one-electron relativistic Dirac equation, for the Coulomb potential. The standard notations and conventions used in the mathematics literature for special functions have been chosen in preference to the notations customarily used in the physics literature whenever there is a conflict. This has been done to facilitate the use of standard reference works such as *Abramowitz* and *Stegun* [9.1], the *Bateman* project [9.2, 3], *Gradshteyn* and *Ryzhik* [9.4], *Jahnke* and *Emde* [9.5], *Luke* [9.6, 7], *Magnus*, *Oberhettinger*, and *Soni* [9.8], *Olver* [9.9], *Szego* [9.10], and the new NIST Digital Library of Mathematical Functions project, which is preparing a hardcover update [9.11] of *Abramowitz* and *Stegun* [9.1] and an online digital library of mathematical functions [9.12]. The section on special functions contains many of the formulas which are needed to check the results quoted in the previous sections, together with a number of other useful formulas. It

includes a brief introduction to asymptotic methods.

References to the numerical evaluation of special functions are given.

9.1 Schrödinger Equation

The nonrelativistic Schrödinger equation for a hydrogenic ion of nuclear charge Z in atomic units is

$$\left(-\frac{1}{2}\nabla^2 - \frac{Z}{r}\right)\psi(r) = E\psi(r) \ . \tag{9.1}$$

9.1.1 Spherical Coordinates

The separable solutions of (9.1) in spherical coordinates are

$$\psi(r) = Y_{\ell m}(\theta, \phi) R_\ell(r) \ , \tag{9.2}$$

where $Y_{\ell m}(\theta, \phi)$ is a spherical harmonic as defined by *Edmonds* [9.13] and $R_\ell(r)$ is a solution of the radial

equation

$$\left[-\frac{1}{2}\left(\frac{\mathrm{d}^2}{\mathrm{d}r^2} + \frac{2}{r}\frac{\mathrm{d}}{\mathrm{d}r} - \frac{\ell(\ell+1)}{r^2}\right) - \frac{Z}{r}\right] R_\ell(r)$$
$$= E R_\ell(r) \ . \tag{9.3}$$

The general solution to (9.3) is

$$R_\ell(r)$$
$$= r^\ell \exp(\mathrm{i}kr)\left[A \, {}_1F_1(a;c;z) + BU(a,c,z)\right] \ , \tag{9.4}$$

where ${}_1F_1$ and U are the regular and irregular solutions of the confluent hypergeometric equation defined

in (9.130) and (9.131) below, and

$$k = \sqrt{2E} \, , \tag{9.5}$$

$$a = \ell + 1 - \mathrm{i} k^{-1} Z \, , \tag{9.6}$$

$$c = 2\ell + 2 \, , \tag{9.7}$$

$$z = -2\mathrm{i} k r \, . \tag{9.8}$$

A and B are arbitrary constants. The solution given in (9.4) has an $r^{-\ell-1}$ singularity at $r = 0$ unless $B = 0$ or a is a non-positive integer. The leading term for small r is proportional to r^ℓ when $B = 0$ and/or a is a non-positive integer. The large r behavior of the solution for (9.4) follows from (9.134), (9.135), and (9.164) below. Bound state solutions, with energy

$$E = -\frac{1}{2} Z^2 n^{-2} \tag{9.9}$$

are obtained when $a = -n + \ell + 1$ where $n > \ell$ is the principal quantum number. The properly normalized bound state solutions are

$$R_{n,\ell}(r) = \frac{2Z}{n^2} \sqrt{\frac{Z(n-\ell-1)!}{(n+\ell)!}} \left(\frac{2Zr}{n} \right)^\ell$$
$$\times \exp(-Zr/n) \, L_{n-\ell-1}^{(2\ell+1)}(2Zr/n) \, , \tag{9.10}$$

where $L_{n-\ell-1}^{(2\ell+1)}$ is the generalized Laguerre polynomial defined in (9.187). The relation in (9.188) shows that $_1F_1$ and U are linearly dependent in this case, so that (9.4) is no longer the general solution of (9.3). A linearly independent solution for this case can be obtained by replacing the $L_{n-\ell-1}^{(2\ell+1)}(2Zr/n)$ in (9.10) by the second (irregular) solution $M_{n-\ell-1}^{(2\ell+1)}(2Zr/n)$ of the Laguerre equation [see (9.194), (9.196), and (9.197)]. The first three $R_{n,\ell}$ are

$$R_{1,0}(r) = 2Z^{3/2} \exp(-Zr) \, , \tag{9.11}$$

$$R_{2,0}(r) = \left(\frac{1}{2} Z \right)^{3/2} (2 - Zr) \exp\left(-\frac{1}{2} Zr \right) , \tag{9.12}$$

$$R_{2,1}(r) = \left(\frac{1}{2} Z \right)^{3/2} \left(\frac{1}{3} \right)^{1/2} Zr \exp\left(-\frac{1}{2} Zr \right) . \tag{9.13}$$

Additional explicit expressions, together with graphs of some of them, can be found in *Pauling* and *Wilson* [9.14].

The $R_{n,\ell}$ can be expanded in powers of $1/n$ [9.15]

$$R_{n,\ell}(r) = -\left(\frac{2Z^2 (n+\ell)!}{(n-\ell-1)! n^{2\ell+4}} \right)^{1/2}$$
$$\times r^{-1/2} \sum_{k=0}^{\infty} g_k^{(\ell)} \left[(8Zr)^{1/2} \right] n^{-2k} \, , \tag{9.14}$$

where the functions $g_k^{(\ell)}(z)$ are finite linear combinations of Bessel functions:

$$g_k^{(\ell)}(z) = z^{3k} \sum_{m=0}^{k} a_{k,m}^{(\ell)} J_{2\ell+2m+k+1}(z) \, . \tag{9.15}$$

The coefficients $a_{k,m}^{(\ell)}$ in (9.15) are calculated recursively from

$$a_{k,m}^{(\ell)} = \frac{(2\ell+2m+k+1)}{32(2k+m)(2\ell+m+2k+1)}$$
$$\times \frac{1}{(2\ell+2m+k-1)}$$
$$\times \Big[(2\ell+2m+k-1) a_{k-1,m}^{(\ell)}$$
$$+ 32(k-m+1)(2\ell+m-k) a_{k,m-1}^{(\ell)} \Big] , \tag{9.16}$$

starting with the initial condition

$$a_{0,0}^{(\ell)} = 1 \, . \tag{9.17}$$

The expansion (9.14) converges uniformly in r for r in any bounded region of the complex r plane. However, it converges fast enough so that a few terms give a good description of $R_{n,\ell}$ only if r is small. The square root in (9.14) has not been expanded in inverse powers of n because it has a branch point at $1/n = 1/\ell$ which would reduce the radius of convergence of the expansion to $1/\ell$. In some cases, large n expansions of matrix elements can be obtained by inserting (9.14) for $R_{n,\ell}$ and integrating term by term; examples can be found in *Drake* and *Hill* [9.15]. An asymptotic expansion in powers of $1/n$, which is valid from r equal to an arbitrary fixed positive number through the turning point at $r = 2n^2/Z$ out to $r = \infty$, can be assembled from (9.133), (9.166)–(9.181), and (9.188) below.

The $R_{n,\ell}$ are not a complete set because the continuum has been left out. The *Sturmian* functions $\rho_{k,\ell}$, given by

$$\rho_{k,\ell}(\beta; r) = \sqrt{\frac{\beta^3 k!}{\Gamma(k+2\ell+3)}} \, (\beta r)^\ell \, \mathrm{e}^{-\beta r/2}$$
$$\times L_k^{(2\ell+2)}(\beta r) \, , \tag{9.18}$$

do form a complete orthonormal set. The positive constant β, which is independent of k and ℓ, sets the length scale for the basis set (9.18).

9.1.2 Parabolic Coordinates

The Schrödinger equation (9.1) is separable in parabolic coordinates ξ, η, ϕ, which are related to spherical coordinates r, θ, ϕ via

$$\xi = r + z = r[1 + \cos(\theta)] , \tag{9.19}$$
$$\eta = r - z = r[1 - \cos(\theta)] , \tag{9.20}$$
$$\phi = \phi . \tag{9.21}$$

This separability in a second coordinate system is related to the existence of a "hidden" $O(4)$ symmetry, which is also responsible for the degeneracy of the bound states [9.16, 17]. The solutions in parabolic coordinates are particularly convenient for derivations of the Stark effect and the Rutherford scattering cross section. The separable solutions of (9.1) in parabolic coordinates are

$$\psi(\boldsymbol{r}) = \exp(\mathrm{i}m\phi) \, N(\eta) \, \Xi(\xi) , \tag{9.22}$$

where

$$N(\eta) = \eta^{|m|/2} \exp\left(\frac{1}{2}\mathrm{i}k_1\eta\right) [A \, {}_1F_1(a_1; c; -\mathrm{i}k_1\eta)$$
$$+ BU(a_1, c, -\mathrm{i}k_1\eta)] , \tag{9.23}$$
$$\Xi(\xi) = \xi^{|m|/2} \exp\left(\frac{1}{2}\mathrm{i}k_2\xi\right) [C \, {}_1F_1(a_2; c; -\mathrm{i}k_2\xi)$$
$$+ DU(a_2, c, -\mathrm{i}k_2\xi)] , \tag{9.24}$$

with ${}_1F_1$ and U defined in (9.130), (9.131) below, and

$$k_1 = \pm k_2 = \pm\sqrt{2E} , \tag{9.25}$$
$$a_1 = \frac{1}{2}(|m| + 1) - \mathrm{i}k_1^{-1}\mu , \tag{9.26}$$
$$a_2 = \frac{1}{2}(|m| + 1) - \mathrm{i}k_2^{-1}(Z - \mu) , \tag{9.27}$$
$$c = |m| + 1 . \tag{9.28}$$

A, B, C, and D are arbitrary constants; μ is the separation constant. An important special case is the well-known *Coulomb function*

$$\psi_C(\boldsymbol{r}) = \Gamma\left(1 - \mathrm{i}k^{-1}Z\right) \exp\left(\frac{1}{2}\pi k^{-1}Z + \mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}\right)$$
$$\times {}_1F_1\left[\mathrm{i}k^{-1}Z; 1; \mathrm{i}(kr - \boldsymbol{k}\cdot\boldsymbol{r})\right] , \tag{9.29}$$

which is obtained by orienting the z-axis in the $\boldsymbol{k}$ direction and taking $m = 0$, $-k_1 = k_2 = |\boldsymbol{k}|$, $\mu = Z + \frac{1}{2}\mathrm{i}|\boldsymbol{k}|$.

ψ_C is normalized to unit incoming flux [see (9.34) below]. In applications, Z is often replaced by $-Z_1 Z_2$, so that the Coulomb potential in (9.1) becomes $+Z_1 Z_2/r$. Equation (9.232), the addition theorem for the spherical harmonics ([9.13] p. 63 Eq. 4.6.6), and the $\lambda = c = 1$ special case of (9.163) below can be used to expand ψ_C into an infinite sum of solutions of the form (9.2):

$$\psi_C(\boldsymbol{r})$$
$$= 4\pi \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} \frac{\Gamma(\ell + 1 - \mathrm{i}k^{-1}Z)}{(2\ell + 1)!}$$
$$\times (-2\mathrm{i}k)^\ell \, \mathrm{e}^{\pi k^{-1}Z/2} \, Y_{\ell m}^*(\theta_k, \phi_k) Y_{\ell m}(\theta, \phi)$$
$$\times r^\ell \mathrm{e}^{\mathrm{i}kr} \, {}_1F_1\left(\ell + 1 - \mathrm{i}k^{-1}Z; 2\ell + 2; -2\mathrm{i}kr\right) , \tag{9.30}$$

where k, θ_k, and ϕ_k are the spherical coordinates of $\boldsymbol{k}$. ψ_C can be split into an incoming plane wave and an outgoing spherical wave with the aid of (9.134) below:

$$\psi_C(\boldsymbol{r}) = \psi_{\text{in}}(\boldsymbol{r}) + \psi_{\text{out}}(\boldsymbol{r}) , \tag{9.31}$$

where

$$\psi_{\text{in}}(\boldsymbol{r}) = \exp\left(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r} - \frac{1}{2}\pi k^{-1}Z\right)$$
$$\times U\left[\mathrm{i}k^{-1}Z; 1; \mathrm{i}(kr - \boldsymbol{k}\cdot\boldsymbol{r})\right] , \tag{9.32}$$
$$\psi_{\text{out}}(\boldsymbol{r}) = -\frac{\Gamma(1 - \mathrm{i}k^{-1}Z)}{\Gamma(\mathrm{i}k^{-1}Z)} \exp\left(\mathrm{i}kr - \frac{1}{2}\pi k^{-1}Z\right)$$
$$\times U\left[1 - \mathrm{i}k^{-1}Z; 1; -\mathrm{i}(kr - \boldsymbol{k}\cdot\boldsymbol{r})\right] . \tag{9.33}$$

The functions ψ_{in} and ψ_{out} can be expanded for $kr - \boldsymbol{k}\cdot\boldsymbol{r}$ large with the aid of (9.164). The result is

$$\psi_{\text{in}}(\boldsymbol{r}) \sim \exp\left[\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r} - \mathrm{i}k^{-1}Z \ln(kr - \boldsymbol{k}\cdot\boldsymbol{r})\right]$$
$$\times \sum_{n=0}^{\infty} \frac{(-\mathrm{i})^n}{n!} \left(\frac{\Gamma(\mathrm{i}k^{-1}Z + n)}{\Gamma(\mathrm{i}k^{-1}Z)}\right)^2$$
$$\times (kr - \boldsymbol{k}\cdot\boldsymbol{r})^{-n} , \tag{9.34}$$
$$\psi_{\text{out}}(\boldsymbol{r}) \sim -\frac{\mathrm{i}\Gamma(1 - \mathrm{i}k^{-1}Z)}{\Gamma(\mathrm{i}k^{-1}Z)(kr - \boldsymbol{k}\cdot\boldsymbol{r})}$$
$$\times \exp\left[\mathrm{i}kr - \mathrm{i}k^{-1}Z \ln(kr - \boldsymbol{k}\cdot\boldsymbol{r})\right]$$
$$\times \sum_{n=0}^{\infty} \frac{\mathrm{i}^n}{n!} \left(\frac{\Gamma(1 - \mathrm{i}k^{-1}Z + n)}{\Gamma(1 - \mathrm{i}k^{-1}Z)}\right)^2$$
$$\times (kr - \boldsymbol{k}\cdot\boldsymbol{r})^{-n} . \tag{9.35}$$

Because (9.1) is an elliptic partial differential equation, its solutions must be analytic functions of the Cartesian coordinates (except at $r = 0$, where the solutions have cusps). The $n = 0$ special case of (9.138) shows that ψ_{in} and ψ_{out} are logarithmically singular at $\boldsymbol{k} \cdot \boldsymbol{r} = kr$. Thus ψ_{in} and ψ_{out} are not solutions to (9.1) at $\boldsymbol{k} \cdot \boldsymbol{r} = kr$. The logarithmic singularity cancels when ψ_{in} and ψ_{out} are added to form ψ_{C}, which *is* a solution to (9.1).

Bound state solutions, with energy

$$E = -\frac{1}{2} Z^2 (n_1 + n_2 + |m| + 1)^{-2} , \qquad (9.36)$$

are obtained when $a_1 = -n_1$ and $a_2 = -n_2$ where n_1 and n_2 are non-negative integers. The properly normalized bound state solutions, which can be put into one–one correspondence with the bound state solutions in spherical coordinates, are

$$\psi_{n_1,n_2,m}(\eta, \xi, \phi)$$

$$= \sqrt{\frac{\beta^{2|m|+4} n_1! n_2!}{2\pi Z (n_1 + |m|)! (n_2 + |m|)!}}$$

$$\times \exp\left[im\phi - \frac{1}{2}\beta(\eta + \xi) \right]$$

$$\times (\eta\xi)^{|m|/2} L_{n_1}^{(|m|)}(\beta\eta) L_{n_2}^{(|m|)}(\beta\xi) , \qquad (9.37)$$

where

$$\beta = Z(n_1 + n_2 + |m| + 1)^{-1} . \qquad (9.38)$$

9.1.3 Momentum Space

The nonrelativistic Schrödinger equation (9.1) becomes the integral equation

$$\frac{1}{2} p^2 \phi(\boldsymbol{p}) - \frac{Z}{2\pi^2} \int \frac{\phi(\boldsymbol{p}')}{(\boldsymbol{p} - \boldsymbol{p}')^2} \, \mathrm{d}^3\boldsymbol{p}' = E\phi(\boldsymbol{p}) \qquad (9.39)$$

in momentum space. Its solutions are related to the solutions in coordinate space via the Fourier transforms

$$\psi(\boldsymbol{r}) = (2\pi)^{-3/2} \int \exp(i\boldsymbol{p} \cdot \boldsymbol{r}) \phi(\boldsymbol{p}) \, \mathrm{d}^3\boldsymbol{p} , \quad (9.40)$$

$$\phi(\boldsymbol{p}) = (2\pi)^{-3/2} \int \exp(-i\boldsymbol{p} \cdot \boldsymbol{r}) \psi(\boldsymbol{r}) \, \mathrm{d}^3\boldsymbol{r} . \qquad (9.41)$$

A trick of *Fock*'s [9.16, 18] can be used to expose the "hidden" $O(4)$ symmetry of hydrogen and construct the

bound state solutions to (9.39). Let p, θ_p, ϕ_p and p', θ'_p, ϕ'_p be the spherical coordinates of $\boldsymbol{p}$ and $\boldsymbol{p}'$. Change variables from p, p' to χ, χ' via $p = \sqrt{-2E} \tan(\chi/2)$ and $p' = \sqrt{-2E} \tan(\chi'/2)$. This brings (9.39) to the form

$$2\pi^2 Z^{-1} \sqrt{-2E} \left[\sec^4(\chi/2)\phi(\boldsymbol{p}) \right]$$

$$= \int \frac{\left[\sec^4(\chi'/2)\phi(\boldsymbol{p}') \right] \sin^2(\chi') \, \mathrm{d}\chi' \sin(\theta_p) \, \mathrm{d}\theta_p \, \mathrm{d}\phi_p}{2 - 2\left[\cos(\chi)\cos(\chi') + \sin(\chi)\sin(\chi')\cos(\gamma') \right]} ,$$

$$\qquad (9.42)$$

where γ' is the angle between $\boldsymbol{p}$ and $\boldsymbol{p}'$. Equation (9.42) is solved by introducing spherical coordinates and spherical harmonics in four dimensions via a natural extension of the procedure used in three dimensions. Going to polar coordinates on x and y yields the cylindrical coordinates r_2, ϕ, z; the further step of going to polar coordinates on r_2 and z yields spherical coordinates r_3, θ, ϕ. If there is a fourth coordinate w, spherical coordinates in four dimensions are obtained via the additional step of going to polar coordinates on r_3 and w. The result is

$$x = r_4 \sin(\chi) \sin(\theta) \cos(\phi) , \qquad (9.43)$$

$$y = r_4 \sin(\chi) \sin(\theta) \sin(\phi) , \qquad (9.44)$$

$$z = r_4 \sin(\chi) \cos(\theta) , \qquad (9.45)$$

$$w = r_4 \cos(\chi) . \qquad (9.46)$$

The volume element, which is easily obtained via the same series of transformations, is

$$\mathrm{d}V = r_4^3 \, \mathrm{d}r_4 \, \mathrm{d}\Omega_4 , \qquad (9.47)$$

$$\mathrm{d}\Omega_4 = \sin^2(\chi) \, \mathrm{d}\chi \sin(\theta) \, \mathrm{d}\theta \, \mathrm{d}\phi . \qquad (9.48)$$

The four-dimensional spherical harmonics [9.2, Vol. 2, Chap. XI] are

$$Y_{n,\ell,m}(\chi, \theta, \phi) = 2^{\ell+1} \ell! \sqrt{\frac{n(n-\ell-1)!}{2\pi(n+\ell)!}} \sin^\ell(\chi)$$

$$\times C_{n-\ell-1}^{\ell+1}[\cos(\chi)] Y_{\ell m}(\theta, \phi) , \qquad (9.49)$$

where $C_{n-\ell-1}^{\ell+1}$ is a Gegenbauer polynomial and $n \geq \ell + 1$ is an integer. They have the orthonormality property

$$\int Y_{n,\ell,m}^*(\chi, \theta, \phi) Y_{n',\ell',m'}(\chi, \theta, \phi) \, \mathrm{d}\Omega_4$$

$$= \delta_{n,n'} \delta_{\ell,\ell'} \delta_{m,m'} . \qquad (9.50)$$

Equations (9.229) and (9.230) with $\lambda = 1$, equation (9.231), and the addition theorem for the three dimensional spherical harmonics $Y_{\ell m}$ can be used to show that

$$\left[1 - 2 \left[\cos(\chi)\cos(\chi') \right. \right.$$
$$\left. + \sin(\chi)\sin(\chi')\cos(\gamma') \right] t + t^2 \Big]^{-1}$$
$$= \sum_{n=1}^{\infty} \sum_{\ell=0}^{n-1} \sum_{m=-\ell}^{\ell} \frac{2\pi^2}{n} t^{n-1} Y_{n,\ell,m}(\chi, \theta, \phi)$$
$$\times Y_{n,\ell,m}^*(\chi', \theta', \phi') \tag{9.51}$$

holds for $|t| < 1$, where γ' is the angle between $\boldsymbol{p}$ and $\boldsymbol{p}'$. Multiply both sides of (9.51) by $Y_{n,\ell,m}(\chi', \theta', \phi')\, d\Omega_4'$ (where $d\Omega_4'$ is $d\Omega_4$ with χ, θ, ϕ replaced by χ', θ', ϕ') and use the orthogonality relation (9.50). The result can be rearranged to the form

$$2\pi^2 n^{-1} t^{n-1} Y_{n,\ell,m}(\chi, \theta, \phi) =$$
$$\int \frac{Y_{n,\ell,m}(\chi', \theta', \phi')\sin^2(\chi')\, d\chi' \sin(\theta)\, d\theta\, d\phi}{1 - 2\left[\cos(\chi)\cos(\chi') + \sin(\chi)\sin(\chi')\cos(\gamma')\right] t + t^2}. \tag{9.52}$$

Analytic continuation can be used to show that (9.52) is valid for all complex t despite the fact that (9.51) is restricted to $|t| < 1$. Comparing the $t = 1$ case of (9.52) with (9.42) shows that $E = -\frac{1}{2} Z^2 n^{-2}$ in agreement with (9.9), and that

$$\phi(\boldsymbol{p}) = \left\{ \begin{array}{c} \text{normalizing} \\ \text{factor} \end{array} \right\} \cos^4(\chi/2)$$
$$\times Y_{n,\ell,m}(\chi, \theta, \phi) . \tag{9.53}$$

Transforming from χ back to p brings these to the form

$$\phi(\boldsymbol{p}) = Y_{\ell m}(\theta_p, \phi_p)\, F_{n,\ell}(p) , \tag{9.54}$$

where the properly normalized radial functions are

$$F_{n,\ell}(p) = 2^{2\ell+2} n^2 \ell! \sqrt{\frac{2(n-\ell-1)!}{\pi Z^3 (n+\ell)!}} \left(\frac{np}{Z}\right)^\ell$$
$$\times \frac{Z^{2\ell+4}}{\left(n^2 p^2 + Z^2\right)^{\ell+2}}$$
$$\times C_{n-\ell-1}^{\ell+1}\left(\frac{n^2 p^2 - Z^2}{n^2 p^2 + Z^2}\right) . \tag{9.55}$$

The first three $F_{n,\ell}$ are

$$F_{1,0}(p) = 4\sqrt{\frac{2}{\pi Z^3}} \frac{Z^4}{\left(p^2 + Z^2\right)^2} , \tag{9.56}$$

$$F_{2,0}(p) = \frac{32}{\sqrt{\pi Z^3}} \frac{Z^4\left(4p^2 - Z^2\right)}{\left(4p^2 + Z^2\right)^3} , \tag{9.57}$$

$$F_{2,1}(p) = \frac{128}{\sqrt{3\pi Z^3}} \frac{Z^5 p}{\left(4p^2 + Z^2\right)^3} . \tag{9.58}$$

The $F_{n,\ell}$ satisfy the integral equation

$$\frac{1}{2} p^2 F_{n,\ell}(p)$$
$$- \frac{Z}{\pi p} \int_0^\infty Q_\ell\left(\frac{p^2 + p'^2}{2pp'}\right) F_{n,\ell}(p')\, p'\, dp'$$
$$= E F_{n,\ell}(p) , \tag{9.59}$$

which can be obtained by inserting (9.54) in (9.39). Here Q_ℓ is the Legendre function of the second kind, which is defined in (9.233) below.

9.2 Dirac Equation

The relativistic Dirac equation for a hydrogenic ion of nuclear charge Z can be reduced to dimensionless form by using the Compton wavelength $\hbar/(mc)$ for the length scale and the rest mass energy mc^2 for the energy scale. The result is

$$\left(-i\boldsymbol{\alpha} \cdot \nabla + \beta - \frac{Z\alpha}{r}\right) \psi(\boldsymbol{r}) = E\psi(\boldsymbol{r}) , \tag{9.60}$$

where $\alpha = e^2/(\hbar c)$ is the fine structure constant, and $\boldsymbol{\alpha}$, β are the usual Dirac matrices:

$$\boldsymbol{\alpha} = \begin{pmatrix} 0 & \boldsymbol{\sigma} \\ \boldsymbol{\sigma} & 0 \end{pmatrix}, \quad \beta = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}. \tag{9.61}$$

Here $\boldsymbol{\sigma}$ is a vector whose components are the two by two Pauli matrices, and I is the two by two identity matrix

given by

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix},$$

$$\sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}. \tag{9.62}$$

The solutions to (9.60) in spherical coordinates have the form

$$\psi(\mathbf{r}) = \begin{pmatrix} G(r)\,\chi_\kappa^m(\theta,\phi) \\ \\ iF(r)\,\chi_{-\kappa}^m(\theta,\phi) \end{pmatrix}, \tag{9.63}$$

where, for positive energy states, $G(r)$ is the radial part of the large component and $iF(r)$ is the radial part of the small component. For negative energy states, $G(r)$ is the radial part of the small component and $iF(r)$ is the radial part of the large component. χ is the two component spinor

$$\chi_\kappa^m = \begin{pmatrix} -\dfrac{\kappa}{|\kappa|}\left(\dfrac{\kappa + \frac{1}{2} - m}{2\kappa + 1}\right)^{1/2} Y_{|\kappa + \frac{1}{2}| - \frac{1}{2}, m - \frac{1}{2}} \\ \\ \left(\dfrac{\kappa + \frac{1}{2} + m}{2\kappa + 1}\right)^{1/2} Y_{|\kappa + \frac{1}{2}| - \frac{1}{2}, m + \frac{1}{2}} \end{pmatrix}. \tag{9.64}$$

The relativistic quantum number κ is related to the total angular momentum quantum number j by

$$\kappa = \pm\left(j + \frac{1}{2}\right). \tag{9.65}$$

Because j takes on the values $\frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \dots$, κ is restricted to the values $\pm 1, \pm 2, \pm 3, \dots$. The spinor χ_κ^m obeys the useful relations

$$\boldsymbol{\sigma}\cdot\hat{\mathbf{r}}\,\chi_\kappa^m = -\chi_{-\kappa}^m, \tag{9.66}$$

$$\boldsymbol{\sigma}\cdot\mathbf{L}\,\chi_\kappa^m = -(\kappa + 1)\,\chi_\kappa^m, \tag{9.67}$$

where $\hat{\mathbf{r}} = \mathbf{r}/r$ and $\mathbf{L} = \mathbf{r}\times\mathbf{p}$ with $\mathbf{p} = -i\nabla$. Equations (9.66), (9.67), and the identity

$$\boldsymbol{\sigma}\cdot\mathbf{p} = (\boldsymbol{\sigma}\cdot\hat{\mathbf{r}})\left(\hat{\mathbf{r}}\cdot\mathbf{p} + \frac{i\boldsymbol{\sigma}\cdot\mathbf{L}}{r}\right) \tag{9.68}$$

can be used to derive the radial equations, which are

$$\left(\frac{d}{dr} + \frac{1+\kappa}{r}\right)G(r) - \left(1 + E + \frac{Z\alpha}{r}\right)F(r) = 0, \tag{9.69}$$

$$\left(\frac{d}{dr} + \frac{1-\kappa}{r}\right)F(r) - \left(1 - E - \frac{Z\alpha}{r}\right)G(r) = 0. \tag{9.70}$$

Equations (9.158), (9.159), (9.161), and (9.162) below can be used to show that the general solution to (9.69) and (9.70) is

$$G(r) = r^\gamma \exp(-\lambda r)(1 + E)^{1/2}\{A[f_2(r) + f_1(r)]$$
$$+ B[f_4(r) + f_3(r)]\}, \tag{9.71}$$

$$F(r) = r^\gamma \exp(-\lambda r)(1 - E)^{1/2}\{A[f_2(r) - f_1(r)]$$
$$+ B[f_4(r) - f_3(r)]\}, \tag{9.72}$$

where

$$f_1(r) = \left(Z\alpha\lambda^{-1} - \kappa\right){}_1F_1(a; c; 2\lambda r), \tag{9.73}$$

$$f_2(r) = a\,{}_1F_1(a+1; c; 2\lambda r), \tag{9.74}$$

$$f_3(r) = U(a, c, 2\lambda r), \tag{9.75}$$

$$f_4(r) = \left(Z\alpha\lambda^{-1} + \kappa\right)U(a+1, c, 2\lambda r), \tag{9.76}$$

$$\lambda = (1 + E)^{1/2}(1 - E)^{1/2}, \tag{9.77}$$

$$\gamma = -1 + \left(\kappa^2 - Z^2\alpha^2\right)^{1/2}, \tag{9.78}$$

$$a = 1 + \gamma - \lambda^{-1}EZ\alpha, \tag{9.79}$$

$$c = 3 + 2\gamma. \tag{9.80}$$

A and B are arbitrary constants. Because γ is in general not an integer, the solutions have a branch point at $r = 0$, and become infinite at $r = 0$ when $\kappa = \pm 1$, which makes γ negative. The solutions for $E < -1$ and $E > +1$ are in the continuum, which implies that one of the factors $(1 + E)^{1/2}$, $(1 - E)^{1/2}$ is real with the other imaginary. Square integrable solutions, with energy

$$E_{n,\kappa} = \frac{Z}{|Z|}\left(1 + \frac{Z^2\alpha^2}{(n+1+\gamma)^2}\right)^{-1/2}, \tag{9.81}$$

are obtained when $a = -n$ where n is a non-negative integer. The properly normalized square integrable solutions are

$$G_{n,\kappa}(r) = C_{n,\kappa}(2\lambda r)^\gamma \exp(-\lambda r)\left(1 + E_{n,\kappa}\right)^{1/2}$$
$$\times \left[g_{n,\kappa}^{(2)}(r) + g_{n,\kappa}^{(1)}(r)\right], \tag{9.82}$$

$$F_{n,\kappa}(r) = C_{n,\kappa}(2\lambda r)^\gamma \exp(-\lambda r)\left(1 - E_{n,\kappa}\right)^{1/2}$$
$$\times \left[g_{n,\kappa}^{(2)}(r) - g_{n,\kappa}^{(1)}(r)\right], \tag{9.83}$$

$$g_{n,\kappa}^{(1)}(r) = \left(Z\alpha\lambda^{-1} - \kappa\right)^{1/2} L_n^{(2+2\gamma)}(2\lambda r), \tag{9.84}$$

$$g_{n,\kappa}^{(2)}(r) = -(n+2+2\gamma)\left(Z\alpha\lambda^{-1}-\kappa\right)^{-1/2}$$
$$\times L_{n-1}^{(2+2\gamma)}(2\lambda r), \tag{9.85}$$

$$C_{n,\kappa} = \sqrt{\frac{2\lambda^4 n!}{Z\alpha\Gamma(n+3+2\gamma)}}. \tag{9.86}$$

When $n = 0$, $|Z\alpha\lambda^{-1}| = |\kappa|$, and the value of κ whose sign is the same as the sign of $Z\alpha\lambda^{-1}$ is not permitted. Also, $L_{-1}^{(2+2\gamma)}(2\lambda r)$ is counted as zero, so that $g_{0,\kappa}^{(2)}(r) = 0$.

The eigenvalues and eigenfunctions for the first four states for $Z > 0$ will now be written out explicitly in terms of the variable $\rho = Z\alpha r$. For the $1S_{1/2}$ ground state, with $n = 0$, $j = \frac{1}{2}$, $\kappa = -1$, the formulae are

$$E_{0,-1} = \sqrt{1-Z^2\alpha^2}, \tag{9.87}$$

$$G_{0,-1}(r) = \sqrt{\frac{4Z^3\alpha^3(1+E_{0,-1})}{\Gamma(1+2E_{0,-1})}}(2\rho)^{E_{0,-1}-1}e^{-\rho}, \tag{9.88}$$

$$F_{0,-1}(r) = -\sqrt{\frac{4Z^3\alpha^3(1-E_{0,-1})}{\Gamma(1+2E_{0,-1})}}$$
$$\times (2\rho)^{E_{0,-1}-1}e^{-\rho}. \tag{9.89}$$

The formulae for the $2S_{1/2}$ excited state, with $n = 1$, $j = \frac{1}{2}$, $\kappa = -1$, and for the $2P_{1/2}$ excited state, with $n = 1$, $j = \frac{1}{2}$, $\kappa = 1$, can be written together. They are

$$E_{1,\kappa} = \left(\frac{1}{2}+\frac{1}{2}\sqrt{1-Z^2\alpha^2}\right)^{1/2}, \tag{9.90}$$

$$G_{1,\kappa}(r) = \sqrt{\frac{Z^3\alpha^3(2E_{1,\kappa}-\kappa)(1+E_{1,\kappa})}{2E_{1,\kappa}^2\Gamma(4E_{1,\kappa}^2+1)}}$$
$$\times \rho_1^{2E_{1,\kappa}^2-2}e^{-\rho_1/2}$$
$$\times\left[\left(2E_{1,\kappa}-\kappa-1\right)\left(2E_{1,\kappa}+\kappa\right)-\rho_1\right], \tag{9.91}$$

$$F_{1,\kappa}(r) = -\sqrt{\frac{Z^3\alpha^3(2E_{1,\kappa}-\kappa)(1-E_{1,\kappa})}{2E_{1,\kappa}^2\Gamma(4E_{1,\kappa}^2+1)}}$$
$$\times \rho_1^{2E_{1,\kappa}^2-2}e^{-\rho_1/2}$$
$$\times\left[\left(2E_{1,\kappa}-\kappa+1\right)\left(2E_{1,\kappa}+\kappa\right)-\rho_1\right], \tag{9.92}$$

where $\rho_1 = \rho/E_{1,\kappa}$. For the $2P_{3/2}$ excited state, with $n = 0$, $j = \frac{1}{2}$, $\kappa = -2$, the formulae are

$$E_{0,-2} = \sqrt{1-\frac{1}{4}Z^2\alpha^2}, \tag{9.93}$$

$$G_{0,-2}(r) = \sqrt{\frac{Z^3\alpha^3(1+E_{0,-2})}{2\Gamma(1+4E_{0,-2})}}\rho^{2E_{0,-2}-1}e^{-\rho/2}, \tag{9.94}$$

$$F_{0,-2}(r) = -\sqrt{\frac{Z^3\alpha^3(1-E_{0,-2})}{2\Gamma(1+4E_{0,-2})}}\rho^{2E_{0,-2}-1}e^{-\rho/2}. \tag{9.95}$$

9.3 The Coulomb Green's Function

The abstract Green's operator for a Hamiltonian H is the inverse $G(E) = (H-E)^{-1}$. It is used to write the solution to $(H-E)|\xi\rangle = |\eta\rangle$ in the form $|\xi\rangle = G|\eta\rangle$. It has the spectral representation

$$G(E) = \sum_j \frac{1}{E_j - E}|e_j\rangle\langle e_j|. \tag{9.96}$$

The sum over j in (9.96) runs over *all* of the spectrum of H, including the continuum. For the bound state part of the spectrum, the numbers E_j and vectors $|e_j\rangle$ are the eigenvalues and eigenvectors of H. For the continuous spectrum, $|e_j\rangle\langle e_j|$ is a projection valued measure [9.19]. The representation (9.96) shows that $G(E)$ has first order poles at the eigenvalues. The reduced Green's operator (also known as the generalized Green's operator),

which is the ordinary Green's operator with the singular terms subtracted out, remains finite when E is at an eigenvalue. It can be calulated from

$$G^{(\text{red})}(E_k) = \lim_{E\to E_k}\left\{\frac{\partial}{\partial E}\left[(E-E_k)G(E)\right]\right\}. \tag{9.97}$$

The coordinate and momentum space representatives of the abstract Green's operator are the Green's functions. The nonrelativistic Coulomb Green's function has been discussed by *Hostler* and *Schwinger* [9.20, 21]. A unified treatment of the Coulomb Green's functions for the Schrödinger and Dirac equations has been given by *Swainson* and *Drake* [9.22]. Reduced Green's functions are discussed in the third of the Swainson–Drake papers, and in the paper of *Hill* and *Huxtable* [9.23].

9.3.1 The Green's Function for the Schrödinger Equation

The Green's function $G^{(S)}$ for the Schrödinger equation (9.98) is a solution of

$$\left(-\frac{1}{2}\nabla^2 - \frac{Z}{r} - E\right) G^{(S)}\left(\mathbf{r}, \mathbf{r}'; E\right) = \delta\left(\mathbf{r} - \mathbf{r}'\right) . \tag{9.98}$$

An explicit closed form expression for $G^{(S)}$ is

$$G^{(S)}\left(\mathbf{r}, \mathbf{r}'; E\right) = \frac{\Gamma\left(1-\nu\right)}{2\pi|\mathbf{r} - \mathbf{r}'|}$$
$$\times \left[W_{\nu,\frac{1}{2}}\left(z_2\right) \frac{\partial}{\partial z_1} M_{\nu,\frac{1}{2}}\left(z_1\right) \right.$$
$$\left. - M_{\nu,\frac{1}{2}}\left(z_1\right) \frac{\partial}{\partial z_2} W_{\nu,\frac{1}{2}}\left(z_2\right) \right] , \tag{9.99}$$

where $M_{\nu,1/2}$ and $W_{\nu,1/2}$ are the Whittaker functions defined in (9.132) and (9.133) below, and

$$\nu = Z\left(-2E\right)^{-1/2} , \tag{9.100}$$

$$z_1 = \left(-2E\right)^{1/2}\left(r + r' - |\mathbf{r} - \mathbf{r}'|\right) , \tag{9.101}$$

$$z_2 = \left(-2E\right)^{1/2}\left(r + r' + |\mathbf{r} - \mathbf{r}'|\right) . \tag{9.102}$$

The branch on which $(-2E)^{1/2}$ is positive should be taken when $E < 0$. When $E > 0$, the branch which corresponds to incoming (or outgoing) waves at infinity can be selected with the aid of the asymptotic approximation

$$G^{(S)}\left(\mathbf{r}, \mathbf{r}'; E\right) \approx \frac{\Gamma\left(1-\nu\right)}{2\pi|\mathbf{r} - \mathbf{r}'|} z_2^\nu \exp\left(-\frac{1}{2}z_2\right) , \tag{9.103}$$

which holds when $z_2 \gg z_1$. This approximation is obtained by using (9.130), (9.132), (9.133), and (9.164) in (9.99). A number of useful expansions for $G^{(S)}$ can be obtained from the integral representation

$$G^{(S)}\left(\mathbf{r}, \mathbf{r}'; E\right)$$
$$= \frac{2Z}{\nu} \int_0^\infty \left[\coth\left(\frac{1}{2}\rho\right)\right]^{2\nu} \sinh\left(\rho\right)$$
$$\times I_0 \left\{\nu^{-1} Z \sinh\left(\rho\right) \left(2rr'\right)^{1/2} \left[1 + \cos\left(\Theta\right)\right]\right\}$$
$$\times \exp\left[-\nu^{-1} Z\left(r + r'\right)\cosh\left(\rho\right)\right] \mathrm{d}\rho , \tag{9.104}$$

where Θ is the angle between $\mathbf{r}$ and $\mathbf{r}'$. These expansions, and other integral representations, can be found in [9.20–

22]. The partial wave expansion of $G^{(S)}$ is

$$G^{(S)}\left(\mathbf{r}, \mathbf{r}'; E\right)$$
$$= \sum_{\ell,m} g_\ell^{(S)}\left(r, r'; \nu\right) Y_{\ell m}\left(\theta, \phi\right) Y_{\ell m}^*\left(\theta', \phi'\right) . \tag{9.105}$$

The radial Green's function $g_\ell^{(S)}$ is a solution of the radial equation

$$\left[-\frac{1}{2}\left(\frac{\mathrm{d}^2}{\mathrm{d}r^2} + \frac{2}{r}\frac{\mathrm{d}}{\mathrm{d}r} - \frac{\ell\left(\ell+1\right)}{r^2}\right) \right.$$
$$\left. - \frac{Z}{r} - E \right] g_\ell^{(S)}\left(r, r'; \nu\right) = \frac{\delta\left(r - r'\right)}{rr'} . \tag{9.106}$$

The standard method for calculating the Green's function of a second order ordinary differential equation ([9.24] pp. 354–355) yields

$$g_\ell^{(S)}\left(r, r'; \nu\right)$$
$$= \frac{(2Z)^{2\ell+2}\,\Gamma\left(\ell+1-\nu\right)}{(2\ell+1)!\nu^{2\ell+1}} \exp\left[-\nu^{-1}Z\left(r+r'\right)\right]$$
$$\times \left(rr'\right)^\ell {}_1F_1\left(\ell+1-\nu; 2\ell+2; 2\nu^{-1}Zr_<\right) [3pt]$$
$$\times U\left(\ell+1-\nu, 2\ell+2, 2\nu^{-1}Zr_>\right) , \tag{9.107}$$

where $r_<$ is the smaller of the pair r, r' and $r_>$ is the larger of the pair r, r'. Matrix elements of $g_\ell^{(S)}$ can be calculated with the aid of the formula for the double Laplace transform, which is

$$\int_0^\infty \mathrm{d}r \int_0^\infty \mathrm{d}r' \left(rr'\right)^{\ell+1} \exp\left(-\lambda r - \lambda' r'\right) g_\ell^{(S)}\left(r, r'; \nu\right)$$
$$= \frac{2\left(2\ell+1\right)!}{\ell-\nu+1}\left(\frac{\nu}{2Z}\right)^{2\ell+3}\left(\frac{4Z^2}{\left(\nu\lambda+Z\right)\left(\nu\lambda'+Z\right)}\right)^{2\ell+2}$$
$$\times {}_2F_1\left(2\ell+2, \ell-\nu+1; \ell-\nu+2; 1-\zeta\right) , \tag{9.108}$$

where

$$\zeta = \frac{2\nu Z\left(\lambda+\lambda'\right)}{\left(\nu\lambda+Z\right)\left(\nu\lambda'+Z\right)} , \tag{9.109}$$

Matrix elements with respect to Slater orbitals can be calculated from (9.108) by taking derivatives with respect to λ and/or λ' to bring down powers of r and r'. Matrix elements with respect to Laguerre polynomials can be calculated by using (9.108) to evaluate integrals

over the generating function (9.199) for the Laguerre polynomial [9.23]. Other methods of calculating matrix elements are discussed in *Swainson* and *Drake* [9.22]. The Green's function $\tilde{G}^{(S)}$ in momentum space is related to the coordinate space Green's function $G^{(S)}$ via the Fourier transforms

$$
\begin{aligned}
G^{(S)}\left(\boldsymbol{r}, \boldsymbol{r}'; E\right) = (2\pi)^{-3} \int \exp\left[\mathrm{i}\left(\boldsymbol{p}\cdot\boldsymbol{r} - \boldsymbol{p}'\cdot\boldsymbol{r}'\right)\right] \\
\times \tilde{G}^{(S)}\left(\boldsymbol{p}, \boldsymbol{p}'; E\right)\,\mathrm{d}^3\boldsymbol{p}\,\mathrm{d}^3\boldsymbol{p}',
\end{aligned}
\tag{9.110}
$$

$$
\begin{aligned}
\tilde{G}^{(S)}\left(\boldsymbol{p}, \boldsymbol{p}'; E\right) = (2\pi)^{-3} \int \exp\left[-\mathrm{i}\left(\boldsymbol{p}\cdot\boldsymbol{r} - \boldsymbol{p}'\cdot\boldsymbol{r}'\right)\right] \\
\times G^{(S)}\left(\boldsymbol{r}, \boldsymbol{r}'; E\right)\,\mathrm{d}^3\boldsymbol{r}\,\mathrm{d}^3\boldsymbol{r}'.
\end{aligned}
\tag{9.111}
$$

The Green's function $\tilde{G}^{(S)}$ is a solution of

$$
\begin{aligned}
\left(\frac{1}{2}p^2 - E\right)\tilde{G}^{(S)}\left(\boldsymbol{p}, \boldsymbol{p}'; E\right) - \frac{Z}{2\pi^2}\int \frac{1}{(\boldsymbol{p}-\boldsymbol{p}'')^2} \\
\times \tilde{G}^{(S)}\left(\boldsymbol{p}'', \boldsymbol{p}'; E\right)\,\mathrm{d}^3\boldsymbol{p}'' = \delta\left(\boldsymbol{p}-\boldsymbol{p}'\right).
\end{aligned}
\tag{9.112}
$$

An explicit closed form expression for $\tilde{G}^{(S)}$ is

$$
\begin{aligned}
&\tilde{G}^{(S)}\left(\boldsymbol{p}, \boldsymbol{p}'; E\right) \\
&= \frac{\delta\left(\boldsymbol{p}-\boldsymbol{p}'\right)}{\frac{1}{2}p^2 - E} \\
&\quad + \frac{Z}{2\pi^2 |\boldsymbol{p}-\boldsymbol{p}'|^2\left(\frac{1}{2}p^2 - E\right)\left[\frac{1}{2}(p')^2 - E\right]} \\
&\quad \times \left\{1 + \frac{\nu q}{1-\nu}\right. \\
&\quad \times \left[\left(\frac{1-q}{1+q}\right)\,{}_2F_1\left(1, 1-\nu; 2-\nu; \frac{1-q}{1+q}\right)\right. \\
&\quad \left.\left. - \left(\frac{1+q}{1-q}\right)\,{}_2F_1\left(1, 1-\nu; 2-\nu; \frac{1+q}{1-q}\right)\right]\right\},
\end{aligned}
\tag{9.113}
$$

where

$$
q = \sqrt{\frac{2E|\boldsymbol{p}-\boldsymbol{p}'|^2}{4E^2 - 4E\,\boldsymbol{p}\cdot\boldsymbol{p}' + (pp')^2}}.
\tag{9.114}
$$

9.3.2 The Green's Function for the Dirac Equation

The Green's function G_D for the Dirac equation (9.60) is a 4×4 matrix valued solution of

$$
\begin{aligned}
\left(-\mathrm{i}\alpha\cdot\nabla + \beta - \frac{Z\alpha}{r} - E\right) G_\mathrm{D}\left(\boldsymbol{r}, \boldsymbol{r}'; E\right) \\
= \delta\left(\boldsymbol{r}-\boldsymbol{r}'\right) I_4,
\end{aligned}
\tag{9.115}
$$

where I_4 is the 4×4 identity matrix. The partial wave expansion of G_D is

$$
G_\mathrm{D}\left(\boldsymbol{r}, \boldsymbol{r}'; E\right) = \sum_{\kappa, m}\begin{pmatrix} G_{11}^{\kappa,m} & -\mathrm{i}G_{12}^{\kappa,m} \\ \mathrm{i}G_{21}^{\kappa,m} & G_{22}^{\kappa,m} \end{pmatrix},
\tag{9.116}
$$

where

$$
G_{11}^{\kappa,m} = \chi_\kappa^m(\theta, \phi)\,\chi_\kappa^{m\dagger}(\theta', \phi')\,g_{11}\left(r, r'; E\right),
\tag{9.117}
$$

$$
G_{12}^{\kappa,m} = \chi_\kappa^m(\theta, \phi)\,\chi_{-\kappa}^{m\dagger}(\theta', \phi')\,g_{12}\left(r, r'; E\right),
\tag{9.118}
$$

$$
G_{21}^{\kappa,m} = \chi_{-\kappa}^m(\theta, \phi)\,\chi_\kappa^{m\dagger}(\theta', \phi')\,g_{21}\left(r, r'; E\right),
\tag{9.119}
$$

$$
G_{22}^{\kappa,m} = \chi_{-\kappa}^m(\theta, \phi)\,\chi_{-\kappa}^{m\dagger}(\theta', \phi')\,g_{22}\left(r, r'; E\right).
\tag{9.120}
$$

The identity

$$
\begin{aligned}
&\delta\left(\boldsymbol{r}-\boldsymbol{r}'\right) I_4 = \frac{\delta\left(r-r'\right)}{rr'} \\
&\times \sum_{\kappa, m}\begin{pmatrix} \chi_\kappa^m(\theta, \phi)\,\chi_\kappa^{m\dagger}(\theta', \phi') & 0 \\ 0 & \chi_{-\kappa}^m(\theta, \phi)\,\chi_{-\kappa}^{m\dagger}(\theta', \phi') \end{pmatrix}
\end{aligned}
\tag{9.121}
$$

can be used to show that the radial functions $g_{jk}\left(r, r'; E\right)$ satisfy the equation

$$
\begin{aligned}
&\begin{pmatrix} \left(1 - E - \dfrac{Z\alpha}{r}\right) & -\left(\dfrac{\mathrm{d}}{\mathrm{d}r} + \dfrac{1-\kappa}{r}\right) \\ \left(\dfrac{\mathrm{d}}{\mathrm{d}r} + \dfrac{1+\kappa}{r}\right) & -\left(1 + E + \dfrac{Z\alpha}{r}\right) \end{pmatrix} \\
&\times \begin{pmatrix} g_{11}\left(r, r'; E\right) & g_{12}\left(r, r'; E\right) \\ g_{21}\left(r, r'; E\right) & g_{22}\left(r, r'; E\right) \end{pmatrix} \\
&= \frac{\delta\left(r-r'\right)}{rr'}\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.
\end{aligned}
\tag{9.122}
$$

The solution to (9.122) is

$$
\begin{aligned}
&\begin{pmatrix} g_{11}\left(r, r'; E\right) & g_{12}\left(r, r'; E\right) \\ g_{21}\left(r, r'; E\right) & g_{22}\left(r, r'; E\right) \end{pmatrix} = \frac{(2\lambda)^{1+2\gamma}\,\Gamma(a)}{\Gamma(3+2\gamma)} \\
&\times \left[\Theta\left(r'-r\right)\begin{pmatrix} G_<(r) \\ F_<(r) \end{pmatrix}\begin{pmatrix} G_>(r') & F_>(r') \end{pmatrix}\right. \\
&\left. + \Theta\left(r-r'\right)\begin{pmatrix} G_>(r) \\ F_>(r) \end{pmatrix}\begin{pmatrix} G_<(r') & F_<(r') \end{pmatrix}\right],
\end{aligned}
\tag{9.123}
$$

where a is defined by (9.79), Θ is the Heaviside unit function, defined by

$$
\Theta(x) = \begin{cases} 1, & x > 0, \\ \frac{1}{2}, & x = 0, \\ 0, & x < 0, \end{cases} \tag{9.124}
$$

and the functions $G_<$, $F_<$, $G_>$, and $F_>$ are special cases of the homogeneous solutions (9.71 – 9.80):

$$
G_<(r) = r^\gamma \exp(-\lambda r)(1+E)^{1/2}[f_2(r) + f_1(r)], \tag{9.125}
$$

$$
F_<(r) = r^\gamma \exp(-\lambda r)(1-E)^{1/2}[f_2(r) - f_1(r)], \tag{9.126}
$$

$$
G_>(r) = r^\gamma \exp(-\lambda r)(1+E)^{1/2}[f_4(r) + f_3(r)], \tag{9.127}
$$

$$
F_>(r) = r^\gamma \exp(-\lambda r)(1-E)^{1/2}[f_4(r) - f_3(r)]. \tag{9.128}
$$

The functions $G_<(r)$ and $F_<(r)$ obey the boundary conditions at $r = 0$. The functions $G_>(r)$ and $F_>(r)$ obey the boundary conditions at $r = \infty$. Integral representations and expansions for the Dirac Green's function can be found in [9.22] and [9.25]. Matrix element evaluation is discussed in [9.22].

9.4 Special Functions

This section contains a brief list of formulae for the special functions which appear in the solutions discussed above. Derivations, and many additional formulae, can be found in the standard reference works listed in the bibliography. For numerically useful approximations and available software packages, see *Olver* et al. [9.12], and *Lozier* and *Olver* [9.26].

9.4.1 Confluent Hypergeometric Functions

The confluent hypergeometric differential equation is

$$
\left[z \frac{d^2}{dz^2} + (c - z) \frac{d}{dz} - a \right] w(z) = 0. \tag{9.129}
$$

Equation (9.129) has a regular singular point at $r = 0$ with indices 0 and $1 - c$ and an irregular singular point at ∞. The regular solution to (9.129) is the confluent hypergeometric function, denoted by $_1F_1$ in generalized hypergeometric series notation. It can be defined by the series

$$
_1F_1(a; c; z) = \frac{\Gamma(c)}{\Gamma(a)} \sum_{n=0}^{\infty} \frac{\Gamma(a+n)}{\Gamma(c+n)} \frac{z^n}{n!}. \tag{9.130}
$$

The series (9.130) for $_1F_1$ converges for all finite z if c is not a negative integer or zero. It reduces to a polynomial of degree n in z if $a = -n$ where n is a positive integer and c is not a negative integer or zero. The function $_1F_1(a; c; z)$ is denoted by the symbol $M(a, c, z)$ in *Abramowitz* and *Stegun* [9.1], in *Jahnke* and *Emde* [9.5], and in *Olver* [9.9], by $_1F_1(a; c; z)$ in both of *Luke's* books [9.6, 7] and in *Magnus* et al. [9.8], and by $\Phi(a, c; z)$ in the *Bateman* project [9.2, 3] and

Gradshteyn and *Ryzhik* [9.4]. The irregular solution to (9.129) is

$$
\begin{aligned}
U(a, c, z) = {} & \frac{\Gamma(1-c)}{\Gamma(1+a-c)} {}_1F_1(a; c; z) \\
& + \frac{\Gamma(c-1)}{\Gamma(a)} z^{1-c} \\
& \times {}_1F_1(1+a-c; 2-c; z). \tag{9.131}
\end{aligned}
$$

The function $U(a, c, z)$ is multiple-valued, with principal branch $-\pi < \arg z \leq \pi$. It is denoted by the symbol $U(a, c, z)$ in *Abramowitz* and *Stegun* [9.1], in *Magnus* et al. [9.8], and in *Olver* [9.9], by $\psi(a; c; z)$ in the first of *Luke's* books [9.6], by $U(a; c; z)$ in the second of *Luke's* books [9.7], and by $\Psi(a, c; z)$ in the *Bateman* project [9.2, 3] and *Gradshteyn* and *Ryzhik* [9.4].

The Whittaker functions $M_{\kappa,\mu}$ and $W_{\kappa,\mu}$, which are related to $_1F_1$ and U via

$$
\begin{aligned}
M_{\kappa,\mu}(z) = {} & \exp\left(-\frac{1}{2}z\right) z^{\mu + \frac{1}{2}} \\
& \times {}_1F_1\left(\mu + \frac{1}{2} - \kappa; 2\mu + 1; z\right), \tag{9.132}
\end{aligned}
$$

$$
\begin{aligned}
W_{\kappa,\mu}(z) = {} & \exp\left(-\frac{1}{2}z\right) z^{\mu + \frac{1}{2}} \\
& \times U\left(\mu + \frac{1}{2} - \kappa, 2\mu + 1, z\right), \tag{9.133}
\end{aligned}
$$

are sometimes used instead of $_1F_1$ and U. For numerical evaluation and a program, see [9.27, 28].

The regular solution can be written as a linear combination of irregular solutions via

$$
{}_1F_1(a; c; z) = \frac{\Gamma(c)}{\Gamma(c-a)} e^{i\pi\epsilon a} U(a, c, z) + \frac{\Gamma(c)}{\Gamma(a)}
$$
$$
\times e^{z+i\pi\epsilon(a-c)} U(c-a, c, -z) ,
$$

(9.134)

$$
\epsilon = \begin{cases} +1 , & \operatorname{Im} z > 0 , \\ -1 , & \operatorname{Im} z < 0 . \end{cases}
$$

(9.135)

${}_1F_1$ can also be obtained from U as the discontinuity across a branch cut:

$$
z^{c-1} \exp(-z) \, {}_1F_1(a; c; z)
$$
$$
= \frac{\Gamma(1-a)\,\Gamma(c)}{2\pi i} \Big[\big(ze^{-i\pi}\big)^{c-1} U\big(c-a, c, ze^{-i\pi}\big)
$$
$$
- \big(ze^{i\pi}\big)^{c-1} U\big(c-a, c, ze^{i\pi}\big) \Big] .
$$

(9.136)

The Wronskian of the two solutions is

$$
{}_1F_1(a; c; z) \frac{d}{dz} U(a, c, z)
$$
$$
- U(a, c, z) \frac{d}{dz} {}_1F_1(a; c; z)
$$
$$
= -\Gamma(c)\, z^{-c} \exp(z) / \Gamma(a) .
$$

(9.137)

A formula for $U(a, c, z)$ when c is the integer $n+1$ can be obtained by taking the $c \to n+1$ limit of the right-hand side of (9.131) to obtain

$$
U(a, n+1, z) = \frac{(-1)^{n+1}}{\Gamma(a-n)}
$$
$$
\times \Bigg[\frac{1}{n!} \ln(z) \, {}_1F_1(a; n+1; z)
$$
$$
+ \sum_{k=-n}^{\infty} \frac{\Gamma(a+k)\, a_k z^k}{\Gamma(a)\,(k+n)!} \Bigg] ,
$$

(9.138)

where

$$
a_k = \begin{cases} (-1)^{k+1} (-k-1)! , & -n \le k \le -1 , \\[2mm] [\Psi(k+a) - \Psi(k+1) \\ \quad - \Psi(k+n+1)] / k! , & k \ge 0 . \end{cases}
$$

(9.139)

Here Ψ is the logarithmic derivative of the gamma function:

$$
\Psi(z) = \Gamma'(z) / \Gamma(z) .
$$

(9.140)

n is a non-negative integer. When $n = 0$, the sum from $k = -n$ to -1 is omitted.

The basic integral representations for ${}_1F_1$ and U are

$$
{}_1F_1(a; c; z) = \frac{\Gamma(c)}{\Gamma(a)\,\Gamma(c-a)}
$$
$$
\times \int_0^1 e^{zt} t^{a-1} (1-t)^{c-a-1} \, dt ,
$$

(9.141)

$$
U(a, c, z) = \frac{1}{\Gamma(a)} \int_0^{\infty} e^{-zt} t^{a-1} (1+t)^{c-a-1} \, dt .
$$

(9.142)

The basic transformation formulae for ${}_1F_1$ and U are

$$
{}_1F_1(a; c; z) = e^z \, {}_1F_1(c-a; c; -z) ,
$$

(9.143)

$$
U(a, c, z) = z^{1-c} U(a-c+1, 2-c, z) .
$$

(9.144)

The recurrence relations among contiguous functions are

$$
(z+2a-c) \, {}_1F_1(a; c; z) = (a-c) \, {}_1F_1(a-1; c; z)
$$
$$
+ a \, {}_1F_1(a+1; c; z) ,
$$

(9.145)

$$
(z+a-1) \, {}_1F_1(a; c; z) = (a-c) \, {}_1F_1(a-1; c; z)
$$
$$
+ (c-1) \, {}_1F_1(a; c-1; z) ,
$$

(9.146)

$$
c \, {}_1F_1(a; c; z) = c \, {}_1F_1(a-1; c; z)
$$
$$
+ z \, {}_1F_1(a; c+1; z) ,
$$

(9.147)

$$
(a+1-c) \, {}_1F_1(a; c; z) = a \, {}_1F_1(a+1; c; z)
$$
$$
+ (1-c) \, {}_1F_1(a; c-1; z) ,
$$

(9.148)

$$
c(z+a) \, {}_1F_1(a; c; z) = a c \, {}_1F_1(a+1; c; z)
$$
$$
+ (c-a) z \, {}_1F_1(a; c+1; z) ,
$$

(9.149)

$$
c(z+c-1) \, {}_1F_1(a; c; z) = c(c-1)
$$
$$
\times {}_1F_1(a; c-1; z)
$$
$$
+ (c-a) \, {}_1F_1(a; c+1; z) ,
$$

(9.150)

$$
(z+2a-c) \, U(a; c; z) = U(a-1; c; z)
$$
$$
+ a(a-c+1) U(a+1; c; z) ,
$$

(9.151)

$$
(z+a-1) \, U(a; c; z) = U(a-1; c; z)
$$
$$
+ (c-a-1) U(a; c-1; z) ,
$$

(9.152)

$$
(c-a) \, U(a; c; z) = - U(a-1; c; z)
$$
$$
+ z U(a; c+1; z) ,
$$

(9.153)

$$(a+1-c)\,U\,(a;c;z) = a\,U\,(a+1;c;z)$$
$$+ U\,(a;c-1;z)\ , \quad (9.154)$$

$$(z+a)\,U\,(a;c;z) = a\,(a-c+1)\,U\,(a+1;c;z)$$
$$+ zU\,(a;c+1;z)\ , \quad (9.155)$$

$$(z+c-1)\,U\,(a;c;z) = (c-a-1)\,(c-1)$$
$$\times U\,(a;c-1;z) + zU\,(a;c+1;z)\ . \quad (9.156)$$

Useful differentiation formulae include

$$\frac{\mathrm{d}}{\mathrm{d}z}\,{}_1F_1\,(a;c;z) = a\,c^{-1}\,{}_1F_1\,(a+1;c+1;z)\ , \quad (9.157)$$

$$\frac{\mathrm{d}}{\mathrm{d}z}\left[z^a\,{}_1F_1\,(a;c;z)\right] = a\,z^{a-1}\,{}_1F_1\,(a+1;c;z)\ , \quad (9.158)$$

$$\frac{\mathrm{d}}{\mathrm{d}z}\left[\mathrm{e}^{-z}z^{c-a-1}\,{}_1F_1\,(a+1;c;z)\right]$$
$$= (c-a-1)\,\mathrm{e}^{-z}z^{c-a-2}\,{}_1F_1\,(a;c;z)\ , \quad (9.159)$$

$$\frac{\mathrm{d}}{\mathrm{d}z}U\,(a,c,z) = -a\,U\,(a+1,c+1,z)\ , \quad (9.160)$$

$$\frac{\mathrm{d}}{\mathrm{d}z}\left[z^a U\,(a,c,z)\right]$$
$$= a\,(a-c+1)\,z^{a-1}U\,(a+1,c,z)\ , \quad (9.161)$$

$$\frac{\mathrm{d}}{\mathrm{d}z}\left[\mathrm{e}^{-z}z^{c-a-1}U\,(a+1,c,z)\right]$$
$$= -\mathrm{e}^{-z}z^{c-a-2}U\,(a,c,z)\ . \quad (9.162)$$

An important multiplication theorem is

$${}_1F_1\,(a;c;z_1z_2)$$
$$= \sum_{k=0}^{\infty}\frac{\Gamma\,(a+k)\,\Gamma\,(\lambda+2k)}{k!\,\Gamma\,(a)\,\Gamma\,(\lambda+k)}\,(-z_1)^k$$
$$\times\,{}_2F_1\,(-k,\lambda+k;c;z_1)$$
$$\times\,{}_1F_1\,(a+k;\lambda+2k+1;z_2)\ . \quad (9.163)$$

The fundamental asymptotic expansion for large z is

$$U\,(a,c,z)$$
$$\sim z^{-a}\sum_{n=0}^{\infty}\frac{\Gamma\,(a+n)\,\Gamma\,(1+a-c+n)}{n!\,\Gamma\,(a)\,\Gamma\,(1+a-c)}\,(-z)^{-n}\ ,$$
$$-\frac{3}{2}\pi < \arg z < \frac{3}{2}\pi\ . \quad (9.164)$$

The asymptotic expansion of ${}_1F_1$ for large z is obtained by using (9.164) and

$$\exp\left[z+\mathrm{i}\pi\epsilon\,(a-c)\right]U\,(c-a,c,-z)$$
$$\sim \mathrm{e}^z z^{a-c}\sum_{n=0}^{\infty}\frac{\Gamma\,(c-a+n)\,\Gamma\,(1-a+n)}{n!\,\Gamma\,(c-a)\,\Gamma\,(1-a)}z^{-n}\ ,$$
$$-\frac{5}{2}\pi < \arg z < \frac{5}{2}\pi\ , \quad (9.165)$$

which is a consequence of (9.164), on the right-hand side of (9.134). In the asymptotic expansion (9.165), and in the asymptotic expansion for ${}_1F_1$, the change in the factor $\exp\left[\mathrm{i}\pi\epsilon\,(a-c)\right]$ as $\arg z$ passes through zero is compensated by the phase change which comes from a factor $(-z)^{a-c}$ in the asymptotic expansion of $U\,(c-a,c,-z)$. The change in the factor $\exp\,(\mathrm{i}\pi\epsilon a)$ in the first term of (9.134) as $\arg z$ passes through zero is not compensated by any other phase change. However, this discontinuity occurs in a region in which this first term is negligible compared to the second term. This is an example of the Stokes phenomenon [9.29], which occurs because the single-valued function ${}_1F_1$ is being approximated by multiple-valued functions. The large z asymptotic expansion of ${}_1F_1$ is valid for $-\frac{3}{2}\pi < \arg z < \frac{3}{2}\pi$, which is the overlap of the domain of validity of the expansions (9.164) and (9.165).

Uniform asymptotic expansions for the Whittaker functions $M_{\kappa,\mu}$ and $W_{\kappa,\mu}$ introduced in (9.132), (9.133) have been constructed via Olver's method. The following result [9.9], (p. 412, Ex. 7.3), which holds for x positive, κ large and positive, and μ unrestricted, gives the flavor of these approximations:

$$W_{\kappa,\mu}\,(4\kappa x) = \frac{2^{4/3}\pi^{1/2}\kappa^{\kappa+(1/6)}}{\phi_n\,(\kappa,\mu)\exp\,(\kappa)}\left(\frac{x\zeta}{x-1}\right)^{1/4}$$
$$\times\left\{\mathrm{Ai}\left[(4\kappa)^{2/3}\,\zeta\right]\sum_{s=0}^{n}\frac{A_s\,(\zeta)}{(4\kappa)^{2s}}\right.$$
$$+\frac{\mathrm{Ai}'\left[(4\kappa)^{2/3}\,\zeta\right]}{(4\kappa)^{2/3}}$$
$$\left.\times\sum_{s=0}^{n}\frac{B_s\,(\zeta)}{(4\kappa)^{2s}}+\epsilon_{2n+1,2}\,(4\kappa,\zeta)\right\}. \quad (9.166)$$

Here Ai is the Airy function, and $\epsilon_{2n+1,2}$ is an error term which tends to zero faster than the last term kept when

$\kappa \to \infty$ with n fixed. ζ is related to x by

$$\frac{4}{3}\zeta^{3/2} = \left(x^2 - x\right)^{1/2} - \ln\left[x^{1/2} + (x-1)^{1/2}\right],$$
$$x \geq 1 , \quad (9.167)$$

$$\frac{4}{3}(-\zeta)^{3/2} = \cos^{-1}\left(x^{1/2}\right) - \left(x - x^2\right)^{1/2} ,$$
$$0 < x \leq 1 . \quad (9.168)$$

ζ is an analytic function of x in the neighborhood of $x = 1$; conversely, x is an analytic function of ζ in the neighborhood of $\zeta = 0$. The differential form of the relations (9.167), (9.168) is

$$2\zeta^{1/2}\,d\zeta = x^{-1/2}(x-1)^{1/2}\,dx \quad x \geq 1 , \quad (9.169)$$

$$2(-\zeta)^{1/2}\,d\zeta = x^{-1/2}(1-x)^{1/2}\,dx \quad 0 < x \leq 1 . \quad (9.170)$$

A Taylor series expansion of ζ about $x = 1$ is most easily constructed by expanding the $x^{-1/2}$ in (9.169) or (9.170) about $x = 1$ and integrating term by term. The opening terms of such an expansion are

$$\zeta = 2^{-2/3}\left[(x-1) - \frac{1}{5}(x-1)^2\right.$$
$$\left. + \frac{17}{175}(x-1)^3\right] + O\left[(x-1)^4\right]. \quad (9.171)$$

The coefficient functions A_s and B_s are calculated recursively from

$$B_s(\zeta) = \frac{1}{2\zeta^{1/2}}\int_0^\zeta \left[\psi(\eta)A_s(\eta) - A_s''(\eta)\right]\frac{d\eta}{\eta^{1/2}} ,$$
$$x \geq 1 , \quad (9.172)$$

$$B_s(\zeta) = \frac{1}{2(-\zeta)^{1/2}}\int_\zeta^0 \left[\psi(\eta)A_s(\eta)\right.$$
$$\left. - A_s''(\eta)\right]\frac{d\eta}{(-\eta)^{1/2}}, \quad 0 < x \leq 1 , \quad (9.173)$$

$$A_{s+1}(\zeta) = -\frac{1}{2}B_s'(\zeta) + \frac{1}{2}\int \psi(\zeta)B_s(\zeta)\,d\zeta , \quad (9.174)$$

$$\psi(\zeta) = \frac{(4\mu^2 - 1)\zeta}{x(x-1)} + \frac{(3 - 8x)\zeta}{4x(x-1)^3} + \frac{5}{16\zeta^2} . \quad (9.175)$$

The functions $A_s(\zeta)$, $B_s(\zeta)$, and $\psi(\zeta)$, which appear to be singular at $\zeta = 0$, are actually analytic functions of ζ at $\zeta = 0$. The first few coefficient functions are:

$$A_0(\zeta) = 1 , \quad (9.176)$$

$$B_0(\zeta) = \frac{1}{4}\zeta^{-1/2}\left(\frac{x}{x-1}\right)^{3/2}\left[\left(8\mu^2 - \frac{1}{2}\right)\right.$$
$$\left. \times \left(\frac{x}{x-1}\right)^2 - \left(\frac{x}{x-1}\right) + \frac{5}{6}\right] - \frac{5}{48}\zeta^{-2} , \quad (9.177)$$

$$A_1(\zeta) = \frac{1}{4}\zeta^{-1}[B_0(\zeta) - \psi(\zeta)] + \zeta[B_0(\zeta)]^2 . \quad (9.178)$$

The function ϕ_n is calculated from

$$\phi_n(\kappa, \mu) = \sum_{s=0}^n \frac{A_s(\infty)}{(4\kappa)^{2s}} - \sum_{s=0}^{n-1}\lim_{\zeta\to\infty}\frac{\zeta^{1/2}B_s(\zeta)}{(4\kappa)^{2s+1}} . \quad (9.179)$$

The first two ϕ_n are

$$\phi_0(\kappa, \mu) = 1 , \quad (9.180)$$

$$\phi_1(\kappa, \mu) = 1 - \left(\frac{12\mu^2 - 1}{24\kappa}\right) + \left(\frac{12\mu^2 - 1}{24\kappa}\right)^2 . \quad (9.181)$$

A bound for the error term $\epsilon_{2n+1,2}$ has been given by *Olver* ([9.9] p. 410, Eq. 7.13). The extension to the complex case can be found in *Skovgarrd* [9.30]. Skovgarrd's expansions are in powers of $(4\kappa)^{-1}$ instead of $(4\kappa)^{-2}$, because the factor $1/\phi_n(\kappa, \mu)$ has been expanded out in inverse powers of 4κ in his results; as a consequence, his coefficient functions A_s and B_s differ from Olver's. The corresponding asymptotic expansions for $U\left(\mu + \frac{1}{2} - \kappa, 2\mu + 1, 4\kappa z\right)$ and for the Laguerre polynomial $L_{\kappa-\mu-1/2}^{(2\mu)}(4\kappa z)$ can be constructed with the aid of (9.133) and (9.188).

Formulae for matrix element integrals can be obtained by inserting the integral representation (9.141) and interchanging the orders of integration. An example is

$$\int_0^\infty z^\mu \,_1F_1(a_1; c_1; \lambda_1 z)\,_1F_1(a_2; c_2; \lambda_2 z)\,dz$$
$$= F_2(\mu + 1, a_1, a_2, c_1, c_2; -\lambda_1, -\lambda_2) . \quad (9.182)$$

Here F_2 is one of the hypergeometric functions of two variables introduced by Appell, which can be defined

either by the integral representation ([9.2], Vol. 1, p. 230, Eq. 2)

$$F_2(\alpha, \beta, \beta', \gamma, \gamma'; x, y)$$
$$= \frac{\Gamma(\gamma)\Gamma(\gamma')}{\Gamma(\beta)\Gamma(\beta')\Gamma(\gamma-\beta)\Gamma(\gamma'-\beta')}$$
$$\times \int_0^1 du \int_0^1 dv \, u^{\beta-1} v^{\beta'-1} (1-u)^{\gamma-\beta-1}$$
$$\times (1-v)^{\gamma'-\beta'-1} (1-ux-vy)^{-\alpha} , \qquad (9.183)$$

or by the series expansion ([9.2], Vol. 1, p. 224, Eq. 7)

$$F_2(\alpha, \beta, \beta', \gamma, \gamma'; x, y)$$
$$= \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{\Gamma(\alpha+m+n)}{m!n!\Gamma(\alpha)}$$
$$\times \frac{\Gamma(\beta+m)\,\Gamma(\beta'+n)\,\Gamma(\gamma)\,\Gamma(\gamma')}{\Gamma(\beta)\,\Gamma(\beta')\,\Gamma(\gamma+m)\,\Gamma(\gamma'+n)} x^m y^n , \qquad (9.184)$$

which converges for $|x|+|y| < 1$. Numerical evaluation of F_2 is particularly convenient in the special cases where it can be expressed in terms of ordinary hypergeometric functions $_2F_1$ ([9.2], Vol. 1, Chap. 2), which are easy to calculate, or in terms of elementary functions. The key is the formula ([9.2], Vol. 1, p. 238, Eq. 3)

$$F_2(\alpha, \beta, \beta', \alpha, \alpha; x, y)$$
$$= (1-x)^{-\beta}(1-y)^{-\beta'}$$
$$\times {}_2F_1\left(\beta, \beta'; \alpha; \frac{xy}{(1-x)(1-y)}\right) , \qquad (9.185)$$

which shows that it is necessary to get Appell functions F_2 in which the first, fourth, and fifth parameters are equal. This can be achieved by exploiting whatever freedom in the choice of a_1, a_2, c_1, and c_2 is available, and by using identities such as

$$F_2(\alpha+2, \beta, \beta', \alpha+1, \alpha+1; x, y)$$
$$= (\alpha+1)^{-1}\beta' y$$
$$\times F_2(\alpha+1, \beta, \beta'+1, \alpha+1, \alpha+1; x, y)$$
$$+ \big[F_2(\alpha+1, \beta, \beta', \alpha+1, \alpha+1; x, y)$$
$$+ 2(\alpha+1)^{-2}\beta\beta' xy$$
$$\times F_2(\alpha+2, \beta+1, \beta'+1, \alpha+2, \alpha+2; x, y) \big]$$
$$+ (\alpha+1)^{-1}\beta x$$
$$\times F_2(\alpha+1, \beta+1, \beta', \alpha+1, \alpha+1; x, y) , \qquad (9.186)$$

to obtain Appell functions F_2 for which the reduction (9.185) can be used.

9.4.2 Laguerre Polynomials

The Laguerre polynomials $L_n^{(\alpha)}$ are the polynomial solutions of the differential equation

$$\left[z\frac{d^2}{dz^2} + (\alpha+1-z)\frac{d}{dz} + n \right] L_n^{(\alpha)}(z) = 0 . \qquad (9.187)$$

They are a special case of the confluent hypergeometric function:

$$L_n^{(\alpha)}(z) = \frac{\Gamma(n+\alpha+1)}{n!\Gamma(\alpha+1)} {}_1F_1(-n; \alpha+1; z)$$
$$= \frac{(-1)^n}{n!} U(-n, \alpha+1, z) , \qquad (9.188)$$

and are given explicitly by

$$L_n^{(\alpha)}(z) = \sum_{k=0}^{n} \frac{\Gamma(\alpha+n+1)}{k!\,(n-k)!\Gamma(\alpha+k+1)} (-z)^k . \qquad (9.189)$$

The $L_n^{(\alpha)}$ are sometimes called generalized Laguerre polynomials, because $L_n^{(0)}$, which is often denoted by L_n, is the polynomial introduced by Laguerre. This Laguerre polynomial differs from the "associated Laguerre function" for which the symbol L_q^p (with p and q both integers) is often used in the physics literature. The relation between the two is

$$\left[L_q^p(z) \right]_{\text{physics}} = (-1)^{p+q} q! L_{q-p}^{(p)}(z) . \qquad (9.190)$$

The first three $L_n^{(\alpha)}$ are

$$L_0^{(\alpha)}(z) = 1 , \qquad (9.191)$$
$$L_1^{(\alpha)}(z) = \alpha+1-z , \qquad (9.192)$$
$$L_2^{(\alpha)}(z) = \frac{1}{2}(\alpha+1)(\alpha+2) - (\alpha+2)z + \frac{1}{2}z^2 . \qquad (9.193)$$

Equation (9.188) shows that the irregular solution U does not supply a linearly independent second solution. A second solution which remains linearly independent and finite when α is a positive integer is

$$M_n^{(\alpha)}(z) = -\Gamma(\alpha) \big[z^{-\alpha} {}_1F_1(-n-\alpha; 1-\alpha; z)$$
$$- \cos(\pi\alpha)\,\Gamma(1-\alpha) L_n^{(\alpha)}(z) \big] . \qquad (9.194)$$

The Wronskian of the two solutions is

$$L_n^{(\alpha)}(z) \frac{d}{dz} M_n^{(\alpha)}(z) - M_n^{(\alpha)}(z) \frac{d}{dz} L_n^{(\alpha)}(z)$$
$$= \Gamma(n+\alpha+1) z^{-\alpha-1} \exp(z)/n! . \qquad (9.195)$$

A formula for $M_n^{(\alpha)}(z)$ when α is a positive integer m can be obtained by taking the $\alpha \to m$ limit of the right-hand side of (9.194) to obtain

$$M_n^{(m)}(z) = \ln(z) L_n^{(m)}(z) + \sum_{k=-m}^{\infty} \frac{(n+m)!}{(k+m)!} b_k z^k ,$$
(9.196)

where

$$b_k = \begin{cases} -(-k-1)!/(n-k)! , & -m \le k \le -1 , \\[2mm] (-1)^k [\Psi(n+1-k) - \Psi(k+1) \\ \quad -\Psi(k+m+1)]/[k!(n-k)!] , \\ \qquad\qquad\qquad 0 \le k \le n , \\[2mm] (-1)^n (k-n-1)!/k! , & k \ge n+1 . \end{cases}$$
(9.197)

The Rodrigues formula is

$$L_n^{(\alpha)}(z) = \frac{1}{n!} z^{-\alpha} \exp(z) \frac{d^n}{dz^n} \left[z^{n+\alpha} \exp(-z) \right] .$$
(9.198)

The generating function is

$$(1-w)^{-\alpha-1} \exp\left(-\frac{wz}{1-w}\right) = \sum_{n=0}^{\infty} L_n^{(\alpha)}(z) w^n .$$
(9.199)

The Christoffel–Darboux formula is

$$\sum_{k=0}^{n} \frac{k!}{\Gamma(k+\alpha+1)} L_k^{(\alpha)}(w) L_k^{(\alpha)}(z)$$
$$= \frac{(n+1)! \left[L_n^{(\alpha)}(w) L_{n+1}^{(\alpha)}(z) - L_{n+1}^{(\alpha)}(w) L_n^{(\alpha)}(z) \right]}{\Gamma(n+\alpha+1)(w-z)} .$$
(9.200)

The orthonormality relation is

$$\int_0^{\infty} x^\alpha \exp(-x) L_n^{(\alpha)}(x) L_{n'}^{(\alpha)}(x) \, dx$$
$$= (n!)^{-1} \Gamma(n+\alpha+1) \delta_{n,n'} .$$
(9.201)

Other useful integration formulae include

$$\int_0^{\infty} x^{\alpha+1} \exp(-x) L_n^{(\alpha)}(x) L_{n'}^{(\alpha)}(x) \, dx$$
$$= \frac{\Gamma(n+\alpha+1)}{n!} \left[-n\delta_{n,n'+1} + (2n+\alpha+1) \delta_{n,n'} \right.$$
$$\left. - (n+\alpha+1) \delta_{n,n'-1} \right] ,$$
(9.202)

$$\int_0^{\infty} x^{\alpha-1} \exp(-x) L_n^{(\alpha)}(x) L_{n'}^{(\alpha)}(x) \, dx$$
$$= \frac{\Gamma(n_< +\alpha+1)}{n_<!\alpha} , \quad n_< = \min(n, n') ,$$
(9.203)

$$\int_0^{\infty} x^{\alpha-2} \exp(-x) L_n^{(\alpha)}(x) L_{n'}^{(\alpha)}(x) \, dx$$
$$= \frac{\Gamma(n_< +\alpha+1)}{n_<!\alpha(\alpha+2)} \left\{ \alpha \left[(\alpha+1)(n+n') + 4\alpha + 5 \right] \right.$$
$$\left. \times (1-n_<) + 2(n+1)(n'+1) + 2\alpha(n+n') \right\} ,$$
$$n_< = \min(n, n') .$$
(9.204)

The differentiation and recursion relations are

$$z\frac{d}{dz} L_n^{(\alpha)}(z) = n L_n^{(\alpha)}(z) - (n+\alpha) L_{n-1}^{(\alpha)}(z) ,$$
(9.205)

$$L_{n+1}^{(\alpha)}(z) = (n+1)^{-1} \left[(2n+\alpha+1-z) L_n^{(\alpha)}(z) \right.$$
$$\left. - (n+\alpha) L_{n-1}^{(\alpha)}(z) \right] .$$
(9.206)

Additional relations can be obtained as special cases of the relations listed above for the confluent hypergeometric function by using the relation (9.188).

The coefficients c_k in a Laguerre polynomial expansion such as

$$F(x) = \sum_{k=0}^{\infty} \frac{k!}{\Gamma(k+\alpha+1)} c_k$$
$$\times (\beta x)^{\alpha/2} \exp\left(-\frac{1}{2}\beta x\right) L_k^{(\alpha)}(\beta x)$$
(9.207)

are given by the integral

$$c_k = \beta \int_0^{\infty} F(x) (\beta x)^{\alpha/2} \exp\left(-\frac{1}{2}\beta x\right) L_k^{(\alpha)}(\beta x) \, dx .$$
(9.208)

The rate of convergence of the expansion (9.207) is determined by the asymptotic behavior of the integral (9.208) for large k. A convenient way of extracting this asymptotic behavior will be described with the special case

$$\alpha = 0 ,\tag{9.209}$$

$$F(x) = (x + c)^\nu \exp(-\gamma x) ,\tag{9.210}$$

as an example. Since the discussion is intended to be illustrative rather than exhaustive, only the case $\gamma < \frac{1}{2}\beta$ will be considered. The method is based on the generating function (9.199). The generating function $g(z)$ for the coefficients c_k is given in general by

$$\begin{aligned}g(z) &= \sum_{k=0}^{\infty} c_k z^n \\ &= \beta^{(2+\alpha)/2}(1-z)^{-\alpha-1} G\left[\frac{\beta(1+z)}{2(1-z)}\right],\end{aligned}\tag{9.211}$$

where G is the Laplace transform

$$G(\lambda) = \int_0^\infty x^{\alpha/2} F(x) \exp(-\lambda x) \, \mathrm{d}x .\tag{9.212}$$

The asymptotic analysis of the expansion coefficient c_k begins with the Cauchy integral for c_k, which is

$$c_k = \frac{1}{2\pi\mathrm{i}} \int_C z^{-k-1} g(z) \, \mathrm{d}z ,\tag{9.213}$$

where the contour C is a small circle which runs counterclockwise around the origin. The contour C is deformed to give integrals which can be evaluated via standard methods for the asymptotic evaluation of integrals [9.31, 32]. For the example (9.209), (9.210),

$$g(z) = \beta c^{\nu+1} (1-z)^{-1} U[1, \nu+2, t(z)] ,\tag{9.214}$$

$$t(z) = \frac{(\beta+2\gamma)c + (\beta-2\gamma)cz}{2(1-z)} .\tag{9.215}$$

This $g(z)$ has a branch point on the negative real axis at $z = -(\beta+2\gamma)/(\beta-2\gamma)$, and a combination of a branch point and an essential singularity on the positive real axis at $z = 1$. It is convenient to take the associated branch cuts to run from $-\infty$ to $-(\beta+2\gamma)/(\beta-2\gamma)$ on the negative real axis, and from $+1$ to $+\infty$ on the positive real axis. The contour C can be deformed into the sum of two contours which run clockwise around the branch cuts. Then

$$c_k = c_k^{(1)} + c_k^{(2)} ,\tag{9.216}$$

where $c_k^{(1)}$ is the contribution from a contour which runs clockwise around the branch cut from $-\infty$ to $-(\beta+2\gamma)/(\beta-2\gamma)$ on the negative real axis, and $c_k^{(2)}$ is the contribution from a contour which runs clockwise around the branch cut from $+1$ to $+\infty$ on the positive real axis. The asymptotic behavior of $c_k^{(1)}$ can be extracted in straightforward fashion via the method of *Darboux* ([9.9], pp. 309–315, 321) ([9.32], pp. 116–122). The result is

$$\begin{aligned}c_k^{(1)} &= \left(\frac{2\beta}{\beta+2\gamma}\right)\left(\frac{4\beta}{(\beta+2\gamma)(\beta-2\gamma)}\right)^\nu (-1)^k \\ &\quad \times k^\nu \left(\frac{\beta-2\gamma}{\beta+2\gamma}\right)^k \left[1 + O\left(k^{-1}\right)\right] .\end{aligned}\tag{9.217}$$

The contribution $c_k^{(2)}$ requires a somewhat different strategy. The first step writes it as an integral along the real axis from $+1$ to $+\infty$ of the jump across the branch cut. Evaluating the jump yields

$$\begin{aligned}c_k^{(2)} &= \frac{\beta}{\Gamma(-\nu)} \int_0^\infty \mathrm{d}x\, x^\nu \left[\beta + \left(\frac{1}{2}\beta - \gamma\right)x\right]^{-\nu-1} \\ &\quad \times \exp\left[-\left(\frac{1}{2}\beta - \gamma\right)c - (k+1)\ln(1+x)\right. \\ &\quad \left. - \beta c x^{-1}\right] .\end{aligned}\tag{9.218}$$

The integrand in (9.218) has a saddle point at $x \approx [\beta c/(k+1)]^{1/2}$. The asymptotics for $(k+1)c$ large can be extracted via the method of steepest descent (also known as the saddle point method) ([9.9], pp. 136–138), ([9.32], pp. 85–103), [9.31], (see Chapt. 8). However, if $k+1$ is large with $(k+1)c$ small or moderate, the steepest descent approximation breaks down because the saddle point is too close to the branch point of the integrand at $x = 0$. The breakdown can be cured by using the small x approximations $[\beta + (1/2\beta - \gamma)x]^{-\nu-1} \approx \beta^{-\nu-1}$ and $\ln(1+x) \approx x - 1/2(k+1)^{-1}\beta c$ to obtain

$$\begin{aligned}c_k^{(2)} &= \frac{2\beta}{\Gamma(-\nu)} \left(\frac{c}{(k+1)\beta}\right)^{(\nu+1)/2} \exp(\beta c) \\ &\quad \times K_{\nu+1}\left[2\sqrt{(k+1)\beta c}\right]\left[1 + O\left(k^{-1/2}\right)\right] .\end{aligned}\tag{9.219}$$

The function $K_{\nu+1}$ which appears in (9.219) is a modified Bessel function of the third kind in standard notation. The large z approximation $K_{\nu+1}(z) \approx \pi^{1/2}(2z)^{-1/2}\exp(-z)$ can be used to recover the result of a steepest descent approximation to

(9.218), which is

$$c_k^{(2)} = \frac{\pi^{1/2} \beta c^{\nu+1}}{\Gamma(-\nu)} \left[\beta c \left(k + \frac{1}{2} \right) \right]^{-(2\nu+3)/4}$$
$$\times \exp \left\{ \gamma c - 2 \left[\beta c \left(k + \frac{1}{2} \right) \right]^{1/2} \right\}$$
$$\times \left[1 + O\left(k^{-1} \right) \right] . \tag{9.220}$$

The approximation (9.219) remains valid as $c \to 0$. The approximation (9.220) does not.

The generating function method outlined above has one very nice feature: if the singularity in the complex z-plane which dominates the asymptotics is known, the analysis can be inverted to obtain a "convergence acceleration function" which builds in this singularity, and has no other singularities in the finite complex z plane. The difference between the original $F(x)$ and this convergence acceleration function will have an expansion of the form (9.207) which converges faster than the expansion of $F(x)$. Examples can be found in [9.33–36].

The contributions $c_k^{(1)}$ and $c_k^{(2)}$ exhibit two typical features. The most rapidly varying part, which is

$$[(\beta - 2\gamma) / (\beta + 2\gamma)]^k \tag{9.221}$$

for $c_k^{(1)}$, and

$$\exp \left\{ -2 \left[\beta c \left(k + \frac{1}{2} \right) \right]^{1/2} \right\} \tag{9.222}$$

for the steepest descent approximation to $c_k^{(2)}$, is determined by the location of the associated singularity. The next most important part, which is k^ν for $c_k^{(1)}$, and $(k + 1/2)^{-(2\nu+3)/4}$ for the steepest descent approximation to $c_k^{(2)}$, is determined by the nature of the singularity (i. e., by the value of ν).

9.4.3 Gegenbauer Polynomials

The Gegenbauer polynomials are a special case of the Jacobi polynomial, and of the hypergeometric function:

$$C_n^\lambda(z) = \frac{\Gamma\left(\lambda + \frac{1}{2}\right) \Gamma(2\lambda + n)}{\Gamma(2\lambda) \Gamma\left(\lambda + n + \frac{1}{2}\right)} P_n^{(\lambda - \frac{1}{2}, \lambda - \frac{1}{2})}(z)$$

$$= \frac{\Gamma(2\lambda + n)}{n! \Gamma(2\lambda)}$$
$$\times {}_2F_1\left(-n, n + 2\lambda; \lambda + \frac{1}{2}; \frac{1}{2} - \frac{1}{2}z\right) , \tag{9.223}$$

and are given explicitly by

$$C_n^\lambda(z) = \sum_{k=0}^{[n/2]} \frac{(-1)^k \Gamma(\lambda + n - k)}{k! (n - 2k)! \Gamma(\lambda)} (2z)^{n-2k} . \tag{9.224}$$

The first three C_n^λ are

$$C_0^\lambda(z) = 1 , \tag{9.225}$$
$$C_1^\lambda(z) = 2\lambda z , \tag{9.226}$$
$$C_2^\lambda(z) = 2\lambda(\lambda + 1) z^2 - \lambda . \tag{9.227}$$

Additional C_n^λ can be obtained with the aid of the recursion relation

$$C_{n+1}^\lambda(z) = (n+1)^{-1} \left[2(n+\lambda) z C_n^\lambda(z) \right.$$
$$\left. - (n + 2\lambda - 1) C_{n-1}^\lambda(z) \right] , \tag{9.228}$$

which is valid for $n \geq 1$. A generating function is

$$\left(1 - 2zt + t^2\right)^{-\lambda} = \sum_{n=0}^\infty C_n^\lambda(z) t^n . \tag{9.229}$$

An important addition theorem, which can be used to derive addition theorems for spherical harmonics in any number of dimensions, is

$$C_n^\lambda[\cos(\gamma)] = \frac{\Gamma(2\lambda - 1)}{[\Gamma(\lambda)]^2} \sum_{\ell=0}^n \frac{2^{2\ell}(2\lambda + 2\ell - 1)}{\Gamma(n + 2\lambda + \ell)}$$
$$\times \Gamma(n - \ell + 1) [\Gamma(\lambda + \ell)]^2$$
$$\times \sin^\ell(\chi) \sin^\ell(\chi')$$
$$\times C_{n-\ell}^{\lambda+\ell}[\cos(\chi)] C_{n-\ell}^{\lambda+\ell}[\cos(\chi')]$$
$$\times C_\ell^{\lambda - \frac{1}{2}}[\cos(\gamma')] , \tag{9.230}$$
$$\cos(\gamma) = \cos(\chi)\cos(\chi')$$
$$+ \sin(\chi)\sin(\chi')\cos(\gamma') . \tag{9.231}$$

9.4.4 Legendre Functions

The Legendre polynomials $P_\ell(z)$ are a special case of the Gegenbauer polynomial, and of the hypergeometric function:

$$P_\ell(z) = C_n^{1/2}(z)$$
$$= {}_2F_1\left(-n, n + 1; 1; \frac{1}{2} - \frac{1}{2}z\right) . \tag{9.232}$$

The second (irregular) solution to the Legendre equation, which appears in (9.43) above, can be defined by the integral representation

$$Q_\ell(z) = 2^{-\ell-1} \int_{-1}^{1} \left(1 - t^2\right)^\ell (z - t)^{-\ell-1} \, dt \, . \tag{9.233}$$

The first two Q_ℓ are

$$Q_0(z) = \frac{1}{2} \ln \left(\frac{z+1}{z-1}\right) , \tag{9.234}$$

$$Q_1(z) = \frac{1}{2} z \ln \left(\frac{z+1}{z-1}\right) - 1 \, , \tag{9.235}$$

Additional Q_ℓ can be obtained with the aid of the recursion relation

$$Q_{\ell+1}(z) = \left[(2\ell+1) z Q_\ell(z) - \ell Q_{\ell-1}(z)\right] / (\ell+1) \, , \tag{9.236}$$

which is valid for $\ell \geq 1$.

Atoms Part B

Part B Atoms

10. Atomic Spectroscopy

This chapter outlines the main concepts of atomic structure, with some emphasis on terminology and notation. Atomic radiation is discussed, in particular the wavelengths, intensities, and shapes of spectral lines, and a few remarks are made regarding continuous spectra. We include updated tabulations of ionization energies for the neutral atoms and transition probabilities for persistent lines of selected neutral atoms. Some sources of additional atomic spectroscopic data are mentioned.

Experimental techniques and the details of atomic theoretical methods are not covered in this chapter; these and a number of other subjects pertinent to atomic spectroscopy are treated in one or more of at least fifteen other chapters in this book.

10.1 Frequency, Wavenumber, Wavelength

The photon energy due to an electron transition between an upper atomic level k (of energy E_k) and a lower level i is

$$\Delta E = E_k - E_i = h\nu = hc\sigma = hc/\lambda_{\text{vac}} , \qquad (10.1)$$

where ν is the frequency, σ the wavenumber in vacuum, and λ_{vac} the wavelength in vacuum. The most accurate spectroscopic measurements are determinations of transition frequencies, the unit being the Hertz ($1\,\text{Hz} = 1\,\text{s}^{-1}$) or one of its multiples. A measurement of any one of the entities frequency, wavenumber, or wavelength (in vacuum) is an equally accurate determination of the others since the speed of light is exactly defined [10.1]. The most common wavelength units are the nanometer (nm), the Ångström ($1\,\text{Å} = 10^{-1}\,\text{nm}$) and the micrometer (μm). The SI wavenumber unit is the inverse meter, but in practice wavenumbers are usually expressed in inverse centimeters: $1\,\text{cm}^{-1} = 10^2\,\text{m}^{-1}$, equivalent to $2.997\,924\,58 \times 10^4\,\text{MHz}$. Energy units and conversion factors are further discussed in Chapt. 1.

10.2 Atomic States, Shells, and Configurations

A one-electron atomic *state* is defined by the quantum numbers nlm_lm_s or $nl\,jm_j$, with n and l representing the principal quantum number and the orbital angular momentum quantum number, respectively. The allowed values of n are the positive integers, and $l = 0, 1, \ldots, n-1$. The quantum number j represents the angular momentum obtained by coupling the orbital and spin angular momenta of an electron, i.e., $\boldsymbol{j} = \boldsymbol{l} + \boldsymbol{s}$, so that $j = l \pm 1/2$. The magnetic quantum numbers m_l, m_s, and m_j represent the projections of the corresponding angular momenta along a particular direction; thus, for example, $m_l = -l, -l+1 \cdots l$ and $m_s = \pm 1/2$.

The central field approximation for a many-electron atom leads to wave functions expressed in terms of products of such one-electron states [10.2,3]. Those electrons having the same principal quantum number n belong to the *shell* for that number. Electrons having both the same n value and l value belong to a *subshell*, all electrons in a particular subshell being *equivalent*. The notation for a *configuration* of N equivalent electrons is nl^N, the superscript usually being omitted for $N = 1$. A configuration of several subshells is written as $nl^N n'l'^M \cdots$. The numerical values of l are replaced by letters in writing a configuration, according to the code s, p, d for $l = 0, 1, 2$ and $f, g, h \ldots$ for $l = 3, 4, 5 \ldots$, the letter j being omitted.

The Pauli exclusion principle prohibits atomic states having two electrons with all four quantum numbers the same. Thus the maximum number of equivalent electrons is $2(2l+1)$. A subshell having this number of electrons is *full*, *complete*, or *closed*, and a subshell having a smaller number of electrons is *unfilled*, *incomplete*, or *open*. The $3p^6$ configuration thus represents a full subshell and $3s^2\,3p^6\,3d^{10}$ represents a full shell for $n = 3$.

The *parity* of a configuration is *even* or *odd* according to whether $\Sigma_i l_i$ is even or odd, the sum being taken over all electrons (in practice only those in open subshells need be considered).

10.3 Hydrogen and Hydrogen-Like Ions

The quantum numbers n, l, and j are appropriate [10.4]. A particular *level* is denoted either by nl_j or by $nl\,^2L_J$ with $L = l$ and $J = j$. The latter notation is somewhat redundant for one-electron spectra, but is useful for consistency with more complex structures. The L values are written with the same letter code used for l values, but with capital letters. The *multiplicity* of the L term is equal to $2S+1 = 2s+1 = 2$. Written as a superscript, this number expresses the *doublet* character of the structure: each term for $L \geq 1$ has two levels, with $J = L \pm 1/2$, respectively.

The Coulomb interaction between the nucleus and the single electron is dominant, so that the largest energy separations are associated with levels having different n. The hyperfine splitting of the ^{1}H 1s ground level [$1420.405\,751\,766\,7(1\,0)\,\text{MHz}$] results from the interaction of the proton and electron magnetic moments and gives rise to the famous 21 cm line. The

separations of the $2n - 1$ excited levels having the same n are largely determined by relativistic contributions, including the spin–orbit interaction, with the result that each of the $n - 1$ pairs of levels having the same j value is almost degenerate; the separation of the two levels in each pair is mainly due to relatively small Lamb shifts (see Sects. 28.2 and 27.10).

10.4 Alkalis and Alkali–Like Spectra

In the central field approximation there exists no angular-momentum coupling between a closed subshell and an electron outside the subshell, since the net spin and orbital angular momenta of the subshell are both zero. The nlj quantum numbers are, then, again appropriate for a single electron outside closed subshells. However, the electrostatic interactions of this electron with the core electrons and with the nucleus yield a strong l-dependence of the energy levels [10.5]. The differing extent of "core penetration" for ns and np electrons can in some cases, for example, give an energy difference comparable to or exceeding the difference between the np and $(n+1)p$ levels. The spin–orbit fine-structure separation between the nl $(l > 0)$ levels having $j = l - 1/2$ and $l + 1/2$, respectively, is relatively small.

10.5 Helium and Helium–Like Ions; *LS* Coupling

The energy structure of the normal $1snl$ configurations is dominated by the electron–nucleus and electron–electron Coulomb contributions [10.4]. In helium and in helium-like ions of the lighter elements, the separations of levels having the same n and having $l = $ s, p, or d are mainly determined by direct and exchange electrostatic interactions between the electrons – the spin–orbit, spin–other orbit, and other relativistic contributions are much smaller. This is the condition for *LS* coupling, in which:

(a) The orbital angular momenta of the electrons are coupled to give a total orbital angular momentum $\boldsymbol{L} = \Sigma_i \boldsymbol{l}_i$.

(b) The spins of the electrons are coupled to give a total spin $\boldsymbol{S} = \Sigma_i \boldsymbol{s}_i$.

The combination of a particular S value with a particular L value comprises a spectroscopic *term*, the notation for which is ^{2S+1}L. The quantum number $2S + 1$ is the *multiplicity* of the term. The $\boldsymbol{S}$ and $\boldsymbol{L}$ vectors are coupled to obtain the total angular momentum, $\boldsymbol{J} = \boldsymbol{S} + \boldsymbol{L}$, for a *level* of the term; the level is denoted as $^{2S+1}L_J$.

The parity is indicated by appended degree symbols on odd parity terms.

For $1snl$ configurations, $L = l$ and $S = 0$ or 1, i.e., the terms are *singlets* ($S = 0$) or *triplets* ($S = 1$). As examples of the He I structure, the ionization energy (energy required to remove one of the 1s electrons in the $1s^2$ ground configuration) is 24.5874 eV, the 1s2s ^{3}S $-^1$S separation is 0.7962 eV, the 1s2p ^{3}P° $-^1$P° separation is 0.2539 eV, and the 1s2p ^{3}P$_2^\circ$ $-^3$P$_0^\circ$ fine-structure spread is only 1.32×10^{-4} eV.

10.6 Hierarchy of Atomic Structure in *LS* Coupling

The centrality of *LS* coupling in the analysis and theoretical interpretation of atomic spectra has led to the acceptance of notations and nomenclature well adapted to discussions of particular structures and spectra [10.2]. The main elements of the nomenclature are shown in Table 10.1, most of the structural entities having already been defined in the above discussions of simple spectra. The quantum numbers in the table represent a full description for complex configurations, and the accepted names for transitions between the structural elements are also given.

As an example, the Ca I 3d4p ^{3}D$_2^\circ$ *level* belongs to the ^{3}D° *term* which, in turn, belongs to the 3d4p ^{3}(P° D° F°) triplet *triad*. The 3d4p *configuration* also has a ^{1}(P° D° F°) singlet *triad*. The 3d4s configuration has only *monads*, one ^{1}D and one ^{3}D. The 3d4s ^{3}D$_2$–3d4p ^{3}D$_3^\circ$ *line* belongs to the corresponding ^{3}D–^{3}D° triplet *multiplet*, and this multiplet belongs to the great Ca I 3d4s ^{3}D–3d4p ^{3}(P° D° F°) *supermultiplet* of three triplet multiplets discussed by *Russell* and *Saunders* in their classic paper on the alkaline-earth spectra [10.6]. The 3d4s–3d4p *transition*

Part B | 10.7

Table 10.1 Atomic structural hierarchy in LS coupling and names for the groups of all transitions between structural entities

Structural entity	Quantum numbers[a]	Group of all transitions
Configuration	$(n_i l_i)^{N_i}$	Transition array
Polyad	$(n_i l_i)^{N_i} \gamma S_1 L_1 nl$ $SL, SL' \cdots$	Supermultiplet
Term	$(n_i l_i)^{N_i} \gamma SL$	Multiplet
Level	$(n_i l_i)^{N_i} \gamma SLJ$	Line
State	$(n_i l_i)^{N_i} \gamma SLJM$	Line component

[a] The configuration may include several open subshells, as indicated by the i subscripts. The letter γ represents any additional quantum numbers, such as ancestral terms, necessary to specify a particular term

array includes both the singlet and triplet supermultiplets, as well as any (LS-forbidden) *intercombination* or *intersystem* lines arising from transitions between levels of the singlet *system* and those of the triplet *system*. The order of the two terms in the transitions as written above, with the lower-energy term on the left, is standard in atomic spectroscopy. Examples of notations for complex configurations are given in Sect. 10.8.

10.7 Allowed Terms or Levels for Equivalent Electrons

10.7.1 *LS* Coupling

The allowed LS terms of a configuration consisting of two nonequivalent groups of electrons are obtained by coupling the S and L vectors of the groups in all possible ways, and the procedure may be extended to any number of such groups. Thus the allowed terms for any configuration can be obtained from a table of the allowed terms for groups of equivalent electrons.

The configuration l^N has more than one allowed term of certain LS types if $l > 1$ and $2 < N < 4l$ (d^3–d^7, f^3–f^{11}, etc.). The recurring terms of a particular LS term type from d^N and f^N configurations are assigned sequential index numbers in the tables of *Nielson and Koster* [10.7]; the index numbers stand for additional numbers having group-theoretical significance that serve to differentiate the recurring terms, except for a few terms of f^5 and f^9, f^6 and f^8, and f^7. These remaining terms, which occur only in pairs, are further labeled A or B to indicate Racah's separation of the two terms.

The index numbers of Nielson and Koster are in practice the most frequently used labels for the recurring terms of f^N configurations. Use of their index numbers for the recurring terms of d^N configurations has perhaps the disadvantage of substituting an arbitrary number for a quantum number (the seniority) that itself distinguishes the recurring terms in all cases. The actual value of the seniority number is rarely needed, however, and a consistent notation for the d^N and f^N configurations is desirable. A table of the allowed LS terms of the l^N electrons for $l \le 3$ is given in [10.8], with all recurring terms having the index numbers of Nielson and Koster as a following on-line integer. The theoretical group labels are

also listed. Thus the d^3 ^{2}D term having seniority 3 is designated ^{2}D 2, instead of $^2_3$D, in this scheme; and the level having $J = 3/2$ is designated ^{2}D$_{3/2}$2.

10.7.2 *jj* Coupling

The allowed J values for a group of N equivalent electrons having the same j value, l_j^N, are given in Table 10.2 for $j = 1/2, 3/2, 5/2,$ and $7/2$ (sufficient

Table 10.2 Allowed J values for l_j^N equivalent electrons (jj) coupling

l_j^N	Allowed J values
$l_{1/2}$	1/2
$l_{1/2}^2$	0
$l_{3/2}$ and $l_{3/2}^3$	3/2
$l_{3/2}^2$	0, 2
$l_{3/2}^4$	0
$l_{5/2}$ and $l_{5/2}^5$	5/2
$l_{5/2}^2$ and $l_{5/2}^4$	0, 2, 4
$l_{5/2}^3$	3/2, 5/2, 9/2
$l_{5/2}^6$	0
$l_{7/2}$ and $l_{7/2}^7$	7/2
$l_{7/2}^2$ and $l_{7/2}^6$	0, 2, 4, 6
$l_{7/2}^3$ and $l_{7/2}^5$	3/2, 5/2, 7/2, 9/2, 11/2, 15/2
$l_{7/2}^4$	0, $_2$2, $_4$2, $_2$4, $_4$4, 5, 6, 8
$l_{7/2}^8$	0

for $l \leq 3$). The $l_{7/2}^4$ group has two allowed levels for each of the J values 2 and 4. The subscripts distinguishing the two levels in each case are the seniority numbers [10.9].

The allowed levels of the configuration nl^N may be obtained by dividing the electrons into sets of two groups $nl_{l+1/2}^Q\ nl_{l-1/2}^R$, $Q + R = N$. The possible sets run from $Q = N - 2l$ (or zero if $N < 2l$) up to $Q = N$ or $Q = 2l + 2$, whichever is smaller. The (degenerate) levels for a set with both Q and R nonzero have wave functions defined by the quantum numbers $(\alpha J_1, \beta J_2) J$, with J_1 and J_2 deriving from the Q and R groups, respectively. The symbols α and β represent any additional quantum numbers required to identify levels. The J values of the allowed levels for each $(\alpha J_1, \beta J_2)$ subset are obtained by combining J_1 and J_2 in the usual way.

10.8 Notations for Different Coupling Schemes

In this section we give enough examples to make clear the meaning of the different coupling-scheme notations. Not all the configurations in the examples have been identified experimentally, and some of the examples of a particular coupling scheme given for heuristic purposes may be physically inappropriate. *Cowan* [10.3] describes the physical conditions for the different coupling schemes and gives experimental examples.

10.8.1 *LS* Coupling (Russell–Saunders Coupling)

Some of the examples given below indicate notations bearing on the order of coupling of the electrons

1. $3d^7\ {}^4F_{7/2}$
2. $3d^7\ ({}^4F)4s4p({}^3P°)\ {}^6F_{9/2}°$
3. $4f^7({}^8S°)6s6p^2({}^4P)\ {}^{11}P_5°$
4. $3p^5({}^2P°)3d^2({}^1G)\ {}^2F_{7/2}°$
5. $4f^{10}({}^3K\,2)6s6p({}^1P°)\ {}^3L_6°$
6. $4f^7({}^8S°)5d\ ({}^7D°)6p\ {}^8F_{13/2}$
7. $4f^7({}^8S°)5d\ ({}^9D°)6s\ ({}^8D°)7s\ {}^9D_5°$
8. $4f^7({}^8S°)5d\ ({}^9D°)6s6p({}^3P°)\ {}^{11}F_8$
9. $4f^7({}^8S°)5d^2({}^1G)\ ({}^8G°)6p\ {}^7F_0$
10. $4f({}^2F°)\ 5d^2({}^1G)6s\ ({}^2G)\ {}^1P_1°$.

In the second example, the seven 3d electrons couple to give a ${}^4F$ term, and the 4s and 4p electrons couple to form the ${}^3P°$ term; the final ${}^6F°$ term is one of nine possible terms obtained by coupling the ${}^4F$ grandparent and ${}^3P°$ parent terms. The next three examples are similar to the second. The meaning of the index number 2 following the ${}^3K$ symbol in the fifth example is explained in Sect. 10.7.1.

The coupling in example 6 is appropriate if the interaction of the 5d and 4f electrons is sufficiently stronger than the 5d–6p interaction. The ${}^7D°$ parent term results from coupling the 5d electron to the ${}^8S°$ grandparent, and the 6p electron is then coupled to the ${}^7D°$ parent to form the final ${}^8F$ term. A space is inserted between the 5d electron and the ${}^7D°$ parent to emphasize that the latter is formed by coupling a term $({}^8S°)$ listed to the left of the space. Example 7 illustrates a similar coupling order carried to a further stage; the ${}^8D°$ parent term results from the coupling of the 6s electron to the ${}^9D°$ grandparent.

Example 8 is similar to examples 2–5, but in 8 the first of the two terms that couple to form the final ${}^{11}F$ term, i. e., the ${}^9D°$ term, is itself formed by the coupling of the 5d electron to the ${}^8S°$ core term. Example 9 shows an ${}^8G°$ parent term formed by coupling the ${}^8S°$ and ${}^1G$ grandparent terms. A space is again used to emphasize that the following $({}^8G°)$ term is formed by the coupling of terms listed before the space.

A different order of coupling is indicated in the final example, the $5d^2\ {}^1G$ term being coupled first to the external 6s electron instead of directly to the 4f core electron. The $4f({}^2F°)$ core term is isolated by a space to denote that it is coupled (to the $5d^2({}^1G)6s\ {}^2G$ term) only after the other electrons have been coupled. The notation in this particular case (with a single 4f electron) could be simplified by writing the 4f electron after the ${}^2G$ term to which it is coupled. It appears more important, however, to retain the convention of giving the core portion of the configuration first.

The notations in examples 1–5 are in the form recommended by *Russell* et al. [10.10], and used in both the Atomic Energy States [10.11] and Atomic Energy Levels [10.8, 12] compilations. The spacings used in the remaining examples allow different orders of coupling of the electrons to be indicated without the use of additional parentheses, brackets, etc.

Some authors assign a short name to each (final) term, so that the configuration can be omitted in tables of classified lines, etc. The most common scheme distinguishes the low terms of a particular SL type by the prefixes a, b, c, ..., and the high terms by z, y, x, ... [10.12].

10.8.2 jj Coupling of Equivalent Electrons

This scheme is used, for example, in relativistic calculations. The lower-case j indicates the angular momentum of one electron ($j = l \pm 1/2$) or of each electron in an l_j^N group. Various ways of indicating which of the two possible j values applies to such a group without writing the j-value subscript have been used by different authors; we give the j values explicitly in the examples below. We use the symbols J_i and j to represent total angular momenta.

1. $(6p_{1/2}^2)_0$
2. $(6p_{1/2}^2\, 6p_{3/2})_{3/2}^\circ$
3. $(6p_{1/2}^2\, 6p_{3/2}^2)_2$
4. $4d_{5/2}^3\, 4d_{3/2}^2\, (9/2,\, 2)_{11/2}$

The relatively large spin–orbit interaction of the 6p electrons produces jj-coupling structures for the $6p^2$, $6p^3$, and $6p^4$ ground configurations of neutral Pb, Bi, and Po, respectively; the notations for the ground levels of these atoms are given as the first three examples above. The configuration in the first example shows the notation for equivalent electrons having the same j value l_j^N, in this case two 6p electrons each having $j = 1/2$. A convenient notation for a particular level ($J = 0$) of such a group is also indicated. The second example extends this notation to the case of a $6p^3$ configuration divided into two groups according to the two possible j values. A similar notation is shown for the $6p^4$ level in the third example; this level might also be designated $(6p_{3/2}^{-2})_2$, the negative superscript indicating the two 6p holes. The $(J_1,\, J_2)_J$ term and level notation shown on the right in the fourth example is convenient because each of the two electron groups $4d_{5/2}^3$ and $4d_{3/2}^2$ has more than one allowed total J_i value. The assumed convention is that J_1 applies to the group on the left ($J_1 = 9/2$ for the $4d_{5/2}^3$ group) and J_2 to that on the right.

10.8.3 $J_1 j$ or $J_1 J_2$ Coupling

1. $3d^9(^2D_{5/2})4p_{3/2}\, (5/2,\, 3/2)_3^\circ$
2. $4f^{11}(^2H_{9/2}^\circ 2)6s6p(^3P_1^\circ)\, (9/2,\, 1)_{7/2}$

3. $4f^9(^6H^\circ)5d\, (^7H_8^\circ)6s6p(^3P_0^\circ)\, (8,\, 0)_8$
4. $4f^{12}(^3H_6)\, 5d(^2D)6s6p(^3P^\circ)\, (^4F_{3/2}^\circ)\, (6,\, 3/2)_{13/2}^\circ$
5. $5f^4(^5I_4)6d_{3/2}\, (4,\, 3/2)_{11/2}7s7p(^1P_1^\circ)\, (11/2,\, 1)_{9/2}^\circ$
6. $5f_{7/2}^4 5f_{5/2}^5\, (8,\, 5/2)_{21/2}^\circ\, 7p_{3/2}\, (21/2,\, 3/2)_{10}$
7. $5f_{7/2}^3 5f_{5/2}^3\, (9/2,\, 9/2)_9 7s7p(^3P_2^\circ)\, (9,\, 2)_7^\circ$

The first five examples all have core electrons in LS coupling, whereas jj coupling is indicated for the 5f core electrons in the last two examples. Since the J_1 and J_2 values in the final ($J_1,\, J_2$) term have already been given as subscripts in the configuration, the ($J_1,\, J_2$) term notations are redundant in all these examples. Unless separation of the configuration and final term designations is desired, as in some data tables, one may obtain a more concise notation by simply enclosing the entire configuration in brackets and adding the final J value as a subscript. Thus, the level in the first example can be designated as $[3d^9(^2D_{5/2})4p_{3/2}]_3^\circ$. If the configuration and coupling order are assumed to be known, still shorter designations may be used; for example, the fourth level above might then be given as $[(^3H_6)(^3P^\circ)(^4F_{3/2}^\circ)]_{13/2}$ or $(^3H_6,\, ^3P^\circ,\, ^4F_{3/2}^\circ)_{13/2}$. Similar economies of notation are of course possible, and often useful, in all coupling schemes.

10.8.4 $J_1 l$ or $J_1 L_2$ Coupling ($J_1 K$ Coupling)

1. $3p^5(^2P_{1/2}^\circ)5g\, ^2[9/2]_5^\circ$
2. $4f^2(^3H_4)5g\, ^2[3]_{5/2}$
3. $4f^{13}(^2F_{7/2}^\circ)5d^2(^1D)\, ^1[7/2]_{7/2}^\circ$
4. $4f^{13}(^2F_{5/2}^\circ)5d6s(^3D)\, ^3[9/2]_{11/2}^\circ$

The final terms in the first two examples result from coupling a parent-level $\mathbf{J}_1$ to the orbital angular momentum of a 5g electron to obtain a resultant $\mathbf{K}$, the K value being enclosed in brackets. The spin of the external electron is then coupled with the $\mathbf{K}$ angular momentum to obtain a pair of J values, $J = K \pm 1/2$ (for $K \neq 0$). The multiplicity (2) of such pair terms is usually omitted from the term symbol, but other multiplicities occur in the more general $J_1 L_2$ coupling (examples 3 and 4). The last two examples are straightforward extensions of $J_1 l$ coupling, with the $\mathbf{L}_2$ and $\mathbf{S}_2$ momenta of the "external" term (^1D and ^3D in examples 3 and 4, respectively) replacing the $\mathbf{l}$ and $\mathbf{s}$ momenta of a single external electron.

10.8.5 LS_1 Coupling (LK Coupling)

1. $3s^2 3p(^2P°)4f\ G\ ^2[7/2]_3$
2. $3d^7(^4P)4s4p(^3P°)\ D°\ ^3[5/2]°_{7/2}$

The orbital angular momentum of the core is coupled with the orbital angular momentum of the external electron(s) to give the total orbital angular momentum L. The letter symbol for the final L value is listed with the configuration because this angular momentum is then coupled with the spin of the core (S_1) to obtain the resultant K angular momentum of the final term (in brackets). The multiplicity of the $[K]$ term arises from the spin of the external electron(s).

10.8.6 Coupling Schemes and Term Symbols

The coupling schemes outlined above include those now most frequently used in calculations of atomic structure [10.3]. Any term symbol gives the values of two angular momenta that may be coupled to give the total electronic angular momentum of a level (indicated by the J value). For configurations of more than one unfilled subshell, the angular momenta involved in the final coupling derive from two groups of electrons (either group may consist of only one electron). These are often an inner group of coupled electrons and an outer group of coupled electrons, respectively. In any case the quantum numbers for the two groups can be distinguished by subscripts 1 and 2, so that quantum numbers represented by capital letters without subscripts are total quantum numbers for both groups. Thus, the quantum numbers for the two vectors that couple to give the final J are related to the term symbol as follows:

Coupling scheme	Quantum numbers for vectors that couple to give J	Term symbol
LS	$L,\ S$	^{2S+1}L
$J_1 J_2$	$J_1,\ J_2$	$(J_1,\ J_2)$
$J_1 L_2(\to K)$	$K,\ S_2$	$^{2S_2+1}[K]$
$LS_1(\to K)$	$K,\ S_2$	$^{2S_2+1}[K]$

10.9 Eigenvector Composition of Levels

The wave functions of levels are often expressed as eigenvectors that are linear combinations of basis states in one of the standard coupling schemes. Thus, the wave function $\Psi(\alpha J)$ for a level labeled αJ might be expressed in terms of LS coupling basis states $\Phi(\gamma SLJ)$:

$$\Psi(\alpha J) = \sum_{\gamma SL} c(\gamma SLJ)\ \Phi(\gamma SLJ)\,. \tag{10.2}$$

The $c(\gamma SLJ)$ are expansion coefficients, and

$$\sum_{\gamma SL} \left| c(\gamma SLJ) \right|^2 = 1\,. \tag{10.3}$$

The squared expansion coefficients for the various γSL terms in the composition of the αJ level are conveniently expressed as percentages, whose sum is 100%. Thus the percentage contributed by the pure Russell–Saunders state γSLJ is equal to $100\times |c(\gamma SLJ)|^2$. The notation for Russell–Saunders basis states has been used only for concreteness; the eigenvectors may be expressed in any coupling scheme, and the coupling schemes may be different for different configurations included in a single calculation

(with configuration interaction). "Intermediate coupling" conditions for a configuration are such that calculations in both LS and jj coupling yield some eigenvectors representing significant mixtures of basis states.

The largest percentage in the composition of a level is called the *purity* of the level in that coupling scheme. The coupling scheme (or combination of coupling schemes if more than one configuration is involved) that results in the largest average purity for all the levels in a calculation is usually best for naming the levels. With regard to any particular calculation, one does well to remember that, as with other calculated quantities, the resulting eigenvectors depend on a specific theoretical model and are subject to the inaccuracies of whatever approximations the model involves.

Theoretical calculations of experimental energy level structures have yielded many eigenvectors having significantly less than 50% purity in any coupling scheme. Since many of the corresponding levels have nevertheless been assigned names by spectroscopists, some caution is advisable in the acceptance of level designations found in the literature.

10.10 Ground Levels and Ionization Energies for the Neutral Atoms

Fortunately, the ground levels of the neutral atoms have reasonably meaningful LS-coupling names, the corresponding eigenvector percentages lying in the range from $\approx 55\%$ to 100%. These names are listed in Table 10.3, except for Pa, U, and Np; the lowest few ground-configuration levels of these atoms comprise better $5f^N(L_1 S_1 J_1)\, 6d_j 7s^2\,(J_1 j)$ terms than LS-coupling terms. As noted in Sect. 10.8.2, the jj-coupling names given there for the ground levels of Pb, Bi, and Po are more appropriate than the alternative LS-coupling designations in Table 10.3.

The ionization energies in the table are from recent compilations [10.13, 14]. The uncertainties are mainly in the range from less than one to several units in the last decimal place, but a few of the values may be in error by 20 or more units in the final place, i. e., the error could be greater than 0.2 eV. Although no more than four decimal places are given here, values for both the neutral and singly-ionized atoms are given to their full accuracies in [10.14].

Table 10.3 Ground levels and ionization energies for the neutral atoms

Z	Element	Ground configuration [a]			Ground level	Ionization energy (eV)	Z	Element	Ground configuration [a]				Ground level	Ionization energy (eV)

[a] An element symbol in brackets represents the electrons in the ground configuration of that element

10.11 Zeeman Effect

The Zeeman effect for "weak" magnetic fields (the anomalous Zeeman effect) is of special interest because of the importance of Zeeman data in the analysis and theoretical interpretation of complex spectra. In a weak field, the J value remains a good quantum number although in general a level is split into magnetic sub-levels [10.3]. The g value of such a level may be defined by the expression for the energy shift of its magnetic sublevel having magnetic quantum number M, which has one of the $2J + 1$ values, $-J, -J + 1, \ldots, J$:

$$\Delta E = gM\mu_B B . \tag{10.4}$$

The magnetic flux density is B and μ_B is the Bohr magneton ($\mu_B = e\hbar/2m_e$).

The wavenumber shift $\Delta\sigma$ corresponding to this energy shift is

$$\Delta\sigma = gM(0.466\,86B\,\text{cm}^{-1}) , \tag{10.5}$$

with B representing the numerical value of the magnetic flux density in teslas. The quantity in parentheses, the Lorentz unit, is of the order of 1 or $2\,\text{cm}^{-1}$ for typical flux densities used to obtain Zeeman-effect data with classical spectroscopic methods. Accurate data can be obtained with much smaller fields, of course, by using higher-resolution techniques such as laser spectroscopy. Most of the g values now available for atomic energy levels were derived by application of the above formula (for each of the two combining levels) to measurements of optical Zeeman patterns. A single transverse-Zeeman-effect pattern (two polarizations, resolved components, and sufficiently complete) can yield the J value and the g value for each of the two levels involved.

Neglecting a number of higher-order effects, we can evaluate the g value of a level βJ belonging to a pure LS-coupling term using the formula

$$g_{\beta SLJ} = 1 + \left\{(g_e - 1)\right. \tag{10.6}$$

$$\left.\times \frac{J(J+1) - L(L+1) + S(S+1)}{2J(J+1)}\right\} .$$

The independence of this expression from any other quantum numbers (represented by β) such as the con-

figuration, etc., is important. The expression is derived from vector coupling formulas by assuming a g value of unity for a pure orbital angular momentum and writing the g value for a pure electron spin as g_e [10.15]. A value of 2 for g_e yields the Landé formula. If the anomalous magnetic moment of the electron is taken into account, the value of g_e is 2.002 3193. "Schwinger" g values obtained with this more accurate value for g_e are given for levels of SL terms in [10.8].

The usefulness of g_{SLJ} values is enhanced by their relation to the g values in intermediate coupling. In the notation used in (10.2) for the wave function of a level βJ in intermediate coupling, the corresponding g value is given by

$$g_{\beta J} = \sum_{\gamma SL} g_{SLJ}|c(\gamma SLJ)|^2 , \tag{10.7}$$

where the summation is over the same set of quantum numbers as for the wave function. The $g_{\beta J}$ value is thus a weighted average of the Landé g_{SLJ} values, the weighting factors being just the corresponding component percentages.

Formulas for magnetic splitting factors in the $J_1 J_2$ and $J_1 L_2$ coupling schemes are given in [10.8] and [10.15]. Some higher-order effects that must be included in more accurate Zeeman-effect calculations are treated by *Bethe* and *Salpeter* [10.4] and by *Wybourne* [10.15], for example. High precision calculations for helium are given in [10.16]. See also Chapt. 13 and Chapt. 15.

10.12 Term Series, Quantum Defects, and Spectral−Line Series

The Bohr energy levels for hydrogen or for a hydrogenic (one-electron) ion are given by

$$E_n = -\frac{Z^2}{n^2} , \tag{10.8}$$

in units of the Rydberg for the appropriate nuclear mass. For a multielectron atom, the deviations of a series of (core)nl levels from hydrogenic E_n values may be due mainly to core penetration by the nl electron (low l-value series), or core polarization by the nl electron (high l-value series), or a combination of the two effects. In either case it can be shown that these deviations can be approximately represented by a constant quantum defect δ_l in the Rydberg formula,

$$E_{nl} = -\frac{Z_c^2}{(n-\delta_l)^2} = -\frac{Z_c^2}{(n^*)^2} , \tag{10.9}$$

where Z_c is the charge of the core and $n^* = n - \delta$ is the effective principal quantum number. If the core includes only closed subshells, the E_{nl} values are with respect to a value of zero for the (core)$^1S_0$ level, i.e., the $^1S_0$ level is the limit of the (core)nl series. If the quantities in (10.9) are taken as positive, they represent term values or ionization energies; the term value of the ground level of an atom or ion with respect to the ground level of the next higher ion is thus the principal ionization energy.

If the core has one or more open subshells, the series limit may be the baricenter of the entire core configuration, or any appropriate sub-structure of the core, down to and including a single level. The E_{nl} values refer to the series of corresponding (core)nl structures built on the particular limit structure. The value of the quantum defect depends to some extent on which (core)nl structures are represented by the series formula.

The quantum defect in general also has an energy dependence that must be taken into account if lower members of a series are to be accurately represented by (10.9). For an unperturbed series, this dependence can be expressed by the extended Ritz formula

$$\delta = n - n^*$$
$$= \delta_0 + \frac{a}{(n-\delta_0)^2} + \frac{b}{(n-\delta_0)^4} + \cdots , \qquad (10.10)$$

with $\delta_0, a, b \ldots$ constants for the series (δ_0 being the limit value of the quantum defect for high series members) [10.17]. The value of a is usually positive for core-penetration series and negative for core-polarization series. A discussion of the foundations of the Ritz expansion and application to high precision calculations in helium is given in [10.18].

A spectral-line series results from either emission or absorption transitions involving a common lower level and a series of successive (core)nl upper levels differing only in their n values. The principal series of Na I, $3s\,^2S_{1/2} - np\,^2P^\circ_{1/2,3/2}$ ($n \geq 3$), is an example. The regularity of successive upper term values with increasing n (10.9,10.10) is of course observed in line series; the intervals between successive lines decrease in a regular manner towards higher wavenumbers, and the series of increasing wavenumbers converges towards the term value of the lower level as a limit.

10.13 Sequences

Several types of sequences of elements and/or ionization stages are useful because of regularities in the progressive values of parameters relating to structure and other properties along the sequences. All sequence names may refer either to the atoms and/or ions of the sequence or to their spectra.

10.13.1 Isoelectronic Sequence

A neutral atom and those ions of other elements having the same number of electrons as the atom comprise an isoelectronic sequence. (Note that a negative ion having this number of electrons is a member of the sequence.) An isoelectronic sequence is named according to its neutral member; for example, the Na I isoelectronic sequence.

10.13.2 Isoionic, Isonuclear, and Homologous Sequences

An isoionic sequence comprises atoms or ions of different elements having the same charge. Such sequences have probably been most useful along the d- and f-shell rows of the periodic table. Isoionic analyses have also been carried out along p-shell rows, however, and a fine-structure regularity covering spectra of the p-shell atoms throughout the periodic table is known [10.19].

The atom and successive ions of a particular element comprise the isonuclear sequence for that element.

The elements of a particular column and subgroup in the periodic table are homologous. Thus the C, Si, Ge, Sn, and Pb atoms belong to a homologous sequence having np^2 ground configurations (Table 10.3). The singly ionized atoms of these elements comprise another example of a homologous sequence.

10.14 Spectral Wavelength Ranges, Dispersion of Air

The ranges of most interest for optical atomic spectroscopy are:

$\sim 2–20\,\mu m$	mid-infrared (ir)
700–2000 nm	near ir
400–700 nm	visible
200–400 nm	near ultraviolet (uv)
100–200 nm	vacuum uv or far uv
10–100 nm	extreme uv (euv or xuv)
< 10 nm	soft X-ray, X-ray

The above correspondence of names to ranges should not be taken as exact; the variation as to the extent of some of the named ranges found in the literature is considerable.

Wavelengths in standard air are often tabulated for the region longer than 200 nm. These wavelengths can be related to energy-level differences by conversion to the corresponding (vacuum) wavenumbers or frequencies [10.20, 21].

10.15 Wavelength (Frequency) Standards

In 2001 the Comité International des Poids et Mesures recommended values for optical frequency standards from stabilized lasers using various absorbing atoms, atomic ions, and molecules [10.22]. These frequencies range from $29\,054\,057\,446\,579$ Hz ($10.318\,436\,884\,460\,\mu$m; relative standard uncertainty 1.4×10^{-13}) for a transition in OsO_4 to $1\,267\,402\,452\,889.92$ kHz ($236.540\,853\,549\,75$ nm; relative standard uncertainty 3.6×10^{-13}) for a transition in the $^{115}In^+$ ion [10.22].

Extensive tables of wavenumbers for molecular transitions in the mid-ir range of 2.3 to $20.5\,\mu$m are included in a calibration atlas published in 1991 [10.23]. Wavenumbers of Ar I [10.24] and Ar II [10.25] emission lines having uncertainties as small as 0.0003 cm^{-1} are included in tables for these spectra covering a broad range from 222 nm to $5.865\,\mu$m. Measurements of U and Th lines (575 to 692 nm) suitable for wavenumber calibration at uncertainty levels of 0.0003 cm^{-1} or 0.0004 cm^{-1} were reported in [10.26]. Comprehensive tables of lines for U [10.27], Th [10.28], and I_2 [10.29, 30] are useful for cali-

bration at uncertainty levels of 0.002 to 0.003 cm^{-1}, the atlas of the Th spectrum extending down to 278 nm.

A 1974 compilation gives reference wavelengths for some 5400 lines of 38 elements covering the range 1.5 nm to $2.5\,\mu$m, with most uncertainties between 10^{-5} and 2×10^{-4} nm [10.31]. The wavelengths for some 1100 Fe lines selected from the Fe/Ne hollow-cathode spectrum have been recommended for reference standards over the range 183 nm to $4.2\,\mu$m, with wavenumber uncertainties 0.001 to 0.002 cm^{-1} [10.32]. Wavelengths for about 3000 vuv and uv lines (110 to 400 nm) from a Pt/Ne hollow-cathode lamp have been determined with uncertainties of 0.0002 nm or less [10.13, 33]. More recent high-accuracy measurements of ultraviolet lines of Fe I, Ge I, Kr II, and Pt I, II include some wavelengths with uncertainties smaller than 10^{-5} nm [10.34]. The wavelengths tabulated for the Kr and Pt lines in [10.34] extend from 171 to 315 nm, and the accuracies of earlier measurements of a number of spectra useful for wavelength calibration are discussed.

10.16 Spectral Lines: Selection Rules, Intensities, Transition Probabilities, f Values, and Line Strengths

The selection rules for discrete transitions are given in Table 10.4.

10.16.1 Emission Intensities (Transition Probabilities)

The total power ϵ radiated in a spectral line of frequency ν per unit source volume and per unit solid angle is

$$\epsilon_{\text{line}} = (4\pi)^{-1}\, h\nu\, A_{ki}\, N_k \, , \tag{10.11}$$

where A_{ki} is the atomic transition probability and N_k the number per unit volume (number density) of excited atoms in the upper (initial) level k. For a homogeneous light source of length l and for the optically thin case, where all radiation escapes, the total emitted line intensity (SI quantity: radiance) is

$$I_{\text{line}} = \epsilon_{\text{line}}\, l = \int_0^{+\infty} I(\lambda)\mathrm{d}\lambda$$
$$= (4\pi)^{-1}\, (hc/\lambda_0)\, A_{ki}\, N_k\, l \, , \tag{10.12}$$

where $I(\lambda)$ is the specific intensity at wavelength λ, and λ_0 the wavelength at line center.

10.16.2 Absorption f Values

In absorption, the reduced absorption

$$W(\lambda) = [I(\lambda) - I'(\lambda)]/I(\lambda) \tag{10.13}$$

is used, where $I(\lambda)$ is the incident intensity at wavelength λ, e.g., from a source providing a continuous background, and $I'(\lambda)$ the intensity after passage through the absorbing medium. The reduced line intensity from a homogeneous and optically thin absorbing medium of length l follows as

$$W_{ik} = \int_0^{+\infty} W(\lambda)\,\mathrm{d}\lambda = \frac{e^2}{4\epsilon_0\, m_e\, c^2}\, \lambda_0^2\, N_i\, f_{ik}\, l \, , \tag{10.14}$$

where f_{ik} is the atomic (absorption) oscillator strength (dimensionless).

Atomic Spectroscopy | 10.16 Spectral Lines: Selection Rules, Intensities, Transition Probabilities, *f* Values, and Line Strengths   187

Part B | 10.16

Table 10.4 Selection rules for discrete transitions

	Electric dipole (E1) ("allowed")	Magnetic dipole (M1) ("forbidden")	Electric quadrupole (E2) ("forbidden")

Rigorous rules	1. $\Delta J = 0, \pm 1$
	   (except $0 \nleftrightarrow 0$)
	2. $\Delta M = 0, \pm 1$
	   (except $0 \nleftrightarrow 0$ when $\Delta J = 0$)
	3. Parity change
		$\Delta J = 0, \pm 1$
		(except $0 \nleftrightarrow 0$)
		$\Delta M = 0, \pm 1$
		(except $0 \nleftrightarrow 0$ when $\Delta J = 0$)
		No parity change
			$\Delta J = 0, \pm 1, \pm 2$
			(except $0 \nleftrightarrow 0, 1/2 \nleftrightarrow 1/2, 0 \nleftrightarrow 1$)
			$\Delta M = 0, \pm 1, \pm 2$
			
			No parity change

With negligible configuration interaction	4. One electron jumping, with $\Delta l = \pm 1$, Δn arbitrary	No change in electron configuration; i. e., for all electrons, $\Delta l = 0, \Delta n = 0$	No change in electron configuration; *or* one electron jumping with $\Delta l = 0, \pm 2, \Delta n$ arbitrary
For *LS* coupling only	5. $\Delta S = 0$ 6. $\Delta L = 0, \pm 1$ (except $0 \nleftrightarrow 0$)	$\Delta S = 0$ $\Delta L = 0$ $\Delta J = \pm 1$	$\Delta S = 0$ $\Delta L = 0, \pm 1, \pm 2$ (except $0 \nleftrightarrow 0, 0 \nleftrightarrow 1$)

10.16.3 Line Strengths

A_{ki} and f_{ik} are the principal atomic quantities related to line intensities. In theoretical work, the *line strength S* is also widely used (see Chapt. 21):

$$S = S(i, k) = S(k, i) = |R_{ik}|^2 , \tag{10.15}$$
$$R_{ik} = \langle \psi_k | P | \psi_i \rangle , \tag{10.16}$$

where ψ_i and ψ_k are the initial- and final-state wave functions and R_{ik} is the *transition matrix element* of the appropriate multipole operator P (R_{ik} involves an integration over spatial and spin coordinates of all N electrons of the atom or ion).

10.16.4 Relationships Between *A*, *f*, and *S*

The relationships between A, f, and S for electric dipole (E1, or allowed) transitions in SI units (A in s^{-1}, λ in m, S in m^2 C^2) are

$$A_{ki} = \frac{2\pi e^2}{m_e c \epsilon_0 \lambda^2} \frac{g_i}{g_k} f_{ik} = \frac{16\pi^3}{3h \epsilon_0 \lambda^3 g_k} S . \tag{10.17}$$

Numerically, in customary units (A in s^{-1}, λ in Å, S in atomic units),

$$A_{ki} = \frac{6.6702 \times 10^{15}}{\lambda^2} \frac{g_i}{g_k} \quad f_{ik} = \frac{2.0261 \times 10^{18}}{\lambda^3 g_k} S , \tag{10.18}$$

and for S and ΔE in atomic units,

$$f_{ik} = \frac{2}{3} (\Delta E / g_i) S . \tag{10.19}$$

g_i and g_k are the statistical weights, which are obtained from the appropriate angular momentum quantum numbers. Thus for the lower (upper) level of a spectral line, $g_{i(k)} = 2J_{i(k)} + 1$ and for the lower (upper) term of a multiplet,

$$\bar{g}_{i(k)} = \sum_{J_{i(k)}} (2J_{i(k)} + 1) = (2L_{i(k)} + 1)(2S_{i(k)} + 1) . \tag{10.20}$$

The A_{ki} values for strong lines of selected elements are given in Table 10.5. For comprehensive numerical

Table 10.5 Wavelengths λ, upper energy levels E_k, statistical weights g_i and g_k of lower and upper levels, and transition probabilities A_{ki} for persistent spectral lines of neutral atoms. Many tabulated lines are resonance lines (marked "g"), where the lower energy level belongs to the ground term

^{a} A "g" following the wavelength indicates that the lower level of the transition belongs to the ground term, i.e., the line is a resonance line. Wavelengths below 2000 Å are in vacuum, and those above 2000 Å are in air

^{b} Accuracy estimates pertain to A_{ki} values: AA, uncertainty within 1%; A, within 3%; B, within 10%; C, within 25%; D, within 50%

^{c} The A_{ki}, λ, g_i, and g_k are multiplet values; see (10.20) and Sect. 10.16.5

tables of A, f, and S, including forbidden lines, see Sect. 10.21.

Experimental and theoretical methods to determine A, f, or S values as well as atomic lifetimes are discussed in Chapts. 17, 18, and 21.

Conversion relations between S and A_{ki} for the most common forbidden transitions are given in Table 10.6. Oscillator strengths f are not used for forbidden transitions, i.e., magnetic dipole (M1), electric quadrupole (E2), etc.

[Numerical example: For the $1s2p\ ^1P^\circ_1 - 1s3d\ ^1D_2$ (allowed) transition in He I at 6678.15 Å: $g_i = 3$; $g_k = 5$; $A_{ki} = 6.38 \times 10^7$ s^{-1}; $f_{ik} = 0.711$; $S = 46.9\ a_0^2\ e^2$.]

Part B | 10.16

10.16.5 Relationships Between Line and Multiplet Values

The relations between the total strength and f value of a multiplet (M) and the corresponding quantities for the lines of the multiplet (allowed transitions) are

$$S_M = \sum S_{\text{line}}, \tag{10.21}$$

$$f_M = (\bar\lambda \bar g_i)^{-1} \sum_{J_k, J_i} g_i \lambda(J_i, J_k) f(J_i, J_k). \tag{10.22}$$

$\bar\lambda$ is the weighted ("multiplet") wavelength in vacuum:

$$\bar\lambda = n\bar\lambda_{\text{air}} = hc / \overline{\Delta E}, \tag{10.23}$$

where

$$\overline{\Delta E} = \overline{E_k} - \overline{E_i}$$
$$= (\bar g_k)^{-1} \sum_{J_k} g_k E_k - (\bar g_i)^{-1} \sum_{J_i} g_i E_i \tag{10.24}$$

and n is the refractive index of standard air.

10.16.6 Relative Strengths for Lines of Multiplets in *LS* Coupling

Table 10.7 lists relative line strengths for frequently encountered symmetrical (P → P, D → D) and normal (S → P, P → D) multiplets in *LS* coupling. The strongest, or principal, lines are situated along the main diagonal of the table and are called x_1, x_2, etc. Their

strengths normally diminish along the diagonal. The satellite lines y_n and z_n are usually weaker and deviate more from the LS values than the stronger diagonal lines when departures from LS coupling are encoun-

tered. The total multiplet strengths S_M are also listed in Table 10.7. A discussion of their normalization as well as more extensive tables are given in [10.35].

10.17 Atomic Lifetimes

The radiative lifetime τ_k of an atomic level k is related to the sum of transition probabilities to all levels i lower in energy than k:

$$\tau_k = \left(\sum_i A_{ki} \right)^{-1} . \tag{10.25}$$

The *branching* fraction of a particular transition, say to state i', is defined as

$$A_{ki'} / \sum_i A_{ki} = A_{ki'} \, \tau_k . \tag{10.26}$$

If only one branch (i') exists (or if all other branches may be neglected), one obtains $A_{ki'} \, \tau_k = 1$, and

$$\tau_k = 1/A_{ki'} . \tag{10.27}$$

Precision lifetime measurement techniques are discussed in Chapts. 17 and 18.

10.18 Regularities and Scaling

10.18.1 Transitions in Hydrogenic (One–Electron) Species

The nonrelativistic *energy* of a hydrogenic transition (10.1, 10) is

$$(\Delta E)_Z = (E_k - E_i)_Z = R_Z \, hc \, Z^2 \left(1/n_i^2 - 1/n_k^2 \right) . \tag{10.28}$$

Hydrogenic Z Scaling

The spectroscopic quantities for a hydrogenic ion of nuclear charge Z are related to the equivalent quantities in hydrogen ($Z = 1$) as follows (neglecting small differences in the values of R_Z):

$$(\Delta E)_Z = Z^2 (\Delta E)_H , \tag{10.29}$$

$$(\lambda_{vac})_Z = Z^{-2} (\lambda_{vac})_H , \tag{10.30}$$

$$S_Z = Z^{-2} S_H , \tag{10.31}$$

$$f_Z = f_H , \tag{10.32}$$

$$A_Z = Z^4 A_H . \tag{10.33}$$

For large values of Z, roughly $Z > 20$, relativistic corrections become noticeable and must be taken into account.

f-value Trends

f values for high series members (large n' values) of hydrogenic ions decrease according to

$$f(n, l \to n', l \pm 1) \propto (n')^{-3} . \tag{10.34}$$

Data for some lines of the main spectral series of hydrogen are given in Table 10.8.

10.18.2 Systematic Trends and Regularities in Atoms and Ions with Two or More Electrons

Atomic quantities for a given state or transition in an *isoelectronic sequence* may be expressed as power series expansions in Z^{-1}:

$$Z^{-2} E = E_0 + E_1 Z^{-1} + E_2 Z^{-2} + \dots , \tag{10.35}$$

$$Z^2 S = S_0 + S_1 Z^{-1} + S_2 Z^{-2} + \dots , \tag{10.36}$$

$$f = f_0 + f_1 Z^{-1} + f_2 Z^{-2} + \dots , \tag{10.37}$$

where E_0, f_0, and S_0 are hydrogenic quantities. For transitions in which n does not change ($n_i = n_k$), $f_0 = 0$, since states i and k are degenerate.

For equivalent transitions of *homologous atoms*, f values vary gradually. Transitions to be compared in the case of the "alkalis" are [10.36]

$$\left(nl - n'l' \right)_{Li} \to \left[(n+1)l - (n'+1)l' \right]_{Na}$$
$$\to \left[(n+2)l - (n'+2)l' \right]_{Cu} \to \dots .$$

Complex atomic structures, as well as cases involving strong cancellation in the integrand of the transition integral, generally do not adhere to this regular behavior.

Table 10.8 Some transitions of the main spectral series of hydrogen

Transition	Customary name [a]	λ [b] (Å)	g_i [c]	g_k	A_{ki} ($10^8\,\mathrm{s}^{-1}$)	Transition	Customary name [a]	λ [b] (Å)	g_i [c]	g_k	A_{ki} ($10^8\,\mathrm{s}^{-1}$)

2–5	(H_γ)	4340.46	8	50	2.530 (−2)						

[a] L_α is often called Lyman α, H_α = Balmer α, P_α = Paschen α, etc.

[b] Wavelengths below 2000 Å are in vacuum; values above 2000 Å are in air

[c] For transitions in hydrogen, $g_{i(k)} = 2(n_{i(k)})^2$, where $n_{i(k)}$, is the principal quantum number of the lower (upper) electron shell

[d] The number in parentheses indicates the power of 10 by which the value has to be multiplied

10.19 Spectral Line Shapes, Widths, and Shifts

Observed spectral lines are always broadened, partly due to the finite resolution of the spectrometer and partly due to intrinsic physical causes. The principal physical causes of spectral line broadening are Doppler and pressure broadening. The theoretical foundations of line broadening are discussed in Chapts. 19 and 59.

10.19.1 Doppler Broadening

Doppler broadening is due to the thermal motion of the emitting atoms or ions. For a Maxwellian velocity distribution, the line shape is *Gaussian*; the full width at half maximum intensity (FWHM) is, in Å,

$$\Delta\lambda_{1/2}^{\mathrm{D}} = \left(7.16\times10^{-7}\right)\lambda\,(T/M)^{1/2} . \qquad (10.38)$$

T is the temperature of the emitters in K, and M the atomic weight in atomic mass units (amu).

10.19.2 Pressure Broadening

Pressure broadening is due to collisions of the emitters with neighboring particles (see also Chapts. 19 and 59). Shapes are often approximately Lorentzian, i. e., $I(\lambda) \propto \{1 + [(\lambda - \lambda_0)/\Delta\lambda_{1/2}]^2\}^{-1}$. In the following formulas, all FWHMs and wavelengths are expressed in Å, particle densities N in cm^{-3}, temperatures T in K, and energies E or I in cm^{-1}.

Resonance broadening (self-broadening) occurs only between identical species and is confined to lines with the upper or lower level having an electric dipole transition (resonance line) to the ground state. The FWHM may be estimated as

$$\Delta\lambda_{1/2}^{\mathrm{R}} \simeq 8.6\times10^{-30}(g_i/g_k)^{1/2}\,\lambda^2\lambda_{\mathrm{r}}\,f_{\mathrm{r}}N_i , \qquad (10.39)$$

where λ is the wavelength of the observed line; f_{r} and λ_{r} are the oscillator strength and wavelength of the resonance line; g_k and g_i are the statistical weights of its upper and lower levels. N_i is the ground state number density.

For the $1\mathrm{s}2\mathrm{p}\,^1\mathrm{P}_1^\circ - 1\mathrm{s}3\mathrm{d}\,^1\mathrm{D}_2$ transition in He I [$\lambda = 6678.15$ Å; λ_{r} ($1\mathrm{s}^2\,^1\mathrm{S}_0 - 1\mathrm{s}2\mathrm{p}\,^1\mathrm{P}_1^\circ$) = 584.334 Å; $g_i = 1$; $g_k = 3$; $f_{\mathrm{r}} = 0.2762$] at $N_i = 1\times10^{18}\,\mathrm{cm}^{-3}$: $\Delta\lambda_{1/2}^{\mathrm{R}} = 0.036$ Å.

Van der Waals broadening arises from the dipole interaction of an excited atom with the induced dipole of a ground state atom. (In the case of foreign gas broadening, both the perturber and the radiator may be in their respective ground states.) An approximate formula for the FWHM, strictly applicable to hydrogen and similar atomic structures only, is

$$\Delta\lambda_{1/2}^{\mathrm{W}} \simeq 3.0\times10^{16}\lambda^2\,C_6^{2/5}\,(T/\mu)^{3/10}N , \qquad (10.40)$$

where μ is the atom-perturber reduced mass in units of u, N the perturber density, and C_6 the inter-

action constant. C_6 may be roughly estimated as follows: $C_6 = C_k - C_i$, with $C_{i(k)} = (9.8 \times 10^{10}) \alpha_d R_{i(k)}^2$ (α_d in cm^3, R^2 in a_0^2). Mean atomic polarizability $\alpha_d \approx (6.7 \times 10^{-25}) (3I_H/4E^*)^2$ cm^3, where I_H is the ionization energy of hydrogen and E^* the energy of the first excited level of the perturber atom. $R_{i(k)}^2 \approx 2.5 [I_H/(I - E_{i(k)})]^2$, where I is the ionization energy of the radiator. Van der Waals broadened lines are red shifted by about one-third the size of the FWHM.

For the $1s2p\ ^1P_1^\circ - 1s3d\ ^1D_2$ transition in He I, and with He as perturber: $\lambda = 6678.15$ Å; $I = 198\,311$ cm^{-1}; $E^* = E_i = 171\,135$ cm^{-1}; $E_k = 186\,105$ cm^{-1}; $\mu = 2$. At $T = 15\,000$ K and $N = 1 \times 10^{18}$ cm^{-3}: $\Delta\lambda_{1/2}^W = 0.044$ Å.

Stark broadening due to charged perturbers, i.e., ions and electrons, usually dominates resonance and van der Waals broadening in discharges and plasmas. The FWHM for hydrogen lines is

$$\Delta\lambda_{1/2}^{S,H} = (2.50 \times 10^{-9})\,\alpha_{1/2}\,N_e^{2/3}\ , \tag{10.41}$$

Table 10.9 Values of Stark-broadening parameter $\alpha_{1/2}$ of the H_β line of hydrogen (4861 Å) for various temperatures and electron densities

where N_e is the electron density. The half-width parameter $\alpha_{1/2}$ for the H_β line at 4861 Å, widely used for plasma diagnostics, is tabulated in Table 10.9 for some typical temperatures and electron densities [10.35]. This reference also contains $\alpha_{1/2}$ parameters for other hydrogen lines, as well as Stark width and shift data for numerous lines of other elements, i.e., neutral atoms and singly charged ions (in the latter, Stark widths and shifts depend linearly on N_e). Other tabulations of complete hydrogen Stark profiles exist.

10.20 Spectral Continuum Radiation

10.20.1 Hydrogenic Species

Precise quantum-mechanical calculations exist only for hydrogenic species. The total power ϵ_{cont} radiated (per unit source volume and per unit solid angle, and expressed in SI units) in the wavelength interval $\Delta\lambda$ is the sum of radiation due to the recombination of a free electron with a bare ion (free–bound transitions) and bremsstrahlung (free–free transitions):

$$
\begin{aligned}
\epsilon_{cont} &= \frac{e^6}{2\pi\epsilon_0^3 (6\pi m_e)^{3/2}} N_e N_Z Z^2 \\
&\times \frac{1}{(kT)^{1/2}} \exp\left(-\frac{hc}{\lambda kT}\right) \frac{\Delta\lambda}{\lambda^2} \\
&\times \Bigg\{ \frac{2Z^2 I_H}{kT} \sum_{n \geq (Z^2 I_H \lambda/hc)^{1/2}}^{n'} \frac{\gamma_{fb}}{n^3} \exp\left(\frac{Z^2 I_H}{n^2 kT}\right) \\
&\quad + \bar\gamma_{fb}\left[\exp\left(\frac{Z^2 I_H}{(n'+1)^2 kT}\right) - 1\right] + \gamma_{ff} \Bigg\}
\end{aligned}
\tag{10.42}
$$

where N_e is the electron density, N_Z the number density of hydrogenic (bare) ions of nuclear charge Z, I_H the

ionization energy of hydrogen, n' the principal quantum number of the lowest level for which adjacent levels are so close that they approach a continuum and summation over n may be replaced by an integral. (The choice of n' is rather arbitrary; n' as low as 6 is found in the literature.) γ_{fb} and γ_{ff} are the Gaunt factors, which are generally close to unity. (For the higher free-bound continua, starting with $n'+1$, an average Gaunt factor $\bar\gamma_{fb}$ is used.) For neutral hydrogen, the recombination continuum forming H^- becomes important, too [10.37].

In the equation above, the value of the constant factor is 6.065×10^{-55} W m^4 J$^{1/2}$ sr^{-1}. [Numerical example: For atomic hydrogen ($Z = 1$), the quantity ϵ_{cont} has the value 2.9 W m^{-3} sr^{-1} under the following conditions: $\lambda = 3 \times 10^{-7}$ m; $\Delta\lambda = 1 \times 10^{-10}$ m; $N_e (= N_{Z=1}) = 1 \times 10^{21}$ m^{-3}; $T = 12\,000$ K. The lower limit of the summation index n is 2; the upper limit n' has been taken to be 10. All Gaunt factors γ_{fb}, $\bar\gamma_{fb}$, and γ_{ff} have been assumed to be unity.]

10.20.2 Many–Electron Systems

For many-electron systems, only approximate theoretical treatments exist, based on the quantum-defect

method (for results of calculations for noble gases, see, e.g., [10.38]). Experimental work is centered on the noble gases [10.39]. Modifications of the continuum by autoionization processes must also be considered.

Near the ionization limit, the f values for bound-bound transitions of a spectral series $(n' \rightarrow \infty)$ make a smooth connection to the differential oscillator strength distribution $\mathrm{d}f/\mathrm{d}\epsilon$ in the continuum [10.40].

10.21 Sources of Spectroscopic Data

Access to most of the atomic spectroscopic databases currently online is given by links at the Plasma Gate server [10.41]. Extensive data from NIST compilations of atomic wavelengths, energy levels, and transition probabilities are available from the *Atomic Spectra Database* (ASD) at the NIST site [10.13]. Section 10.15 includes additional references for wavelength tables.

11. High Precision Calculations for Helium

Exact analytic solutions to the Schrödinger equation are known only for atomic hydrogen, and other equivalent two-body systems (see Chapt. 9). However, very high precision approximations are now available for helium, which are essentially exact for all practical purposes. This chapter summarizes the computational methods and tabulates numerical results for the ground state and several singly excited states. Similar methods can be applied to other three-body problems.

Part B | 11

11.1 The Three-Body Schrödinger Equation

The Schrödinger equation for a three-body system consisting of a nucleus of charge Ze, and mass M, and two electrons of charge $-e$ and mass m_e is

$$\left[\frac{1}{2M} P_N^2 + \frac{1}{2m_e} \sum_{i=1}^{2} P_i^2 + V(\boldsymbol{R}_N, \boldsymbol{R}_i) \right] \Psi = E\Psi ,$$
(11.1)

where $\boldsymbol{P}_i = (\hbar/\mathrm{i})\nabla_i$ and

$$V(\boldsymbol{R}_N, \boldsymbol{R}_i) = -\frac{Ze^2}{|\boldsymbol{R}_N - \boldsymbol{R}_1|} - \frac{Ze^2}{|\boldsymbol{R}_N - \boldsymbol{R}_2|} + \frac{e^2}{|\boldsymbol{R}_1 - \boldsymbol{R}_2|}$$
(11.2)

depends only on the relative particle separations. Since the center of mass (c.m.) is then an ignorable coordinate, it can be eliminated by defining the relative particle coordinates

$$\boldsymbol{r}_i = \boldsymbol{R}_i - \boldsymbol{R}_N$$

to obtain

$$\left[\frac{1}{2\mu} \sum_{i=1}^{2} p_i^2 + \frac{1}{M} \boldsymbol{p}_1 \cdot \boldsymbol{p}_2 + V(\boldsymbol{r}_1, \boldsymbol{r}_2) \right] \Psi = E\Psi ,$$
(11.3)

where $\mu = m_e M/(m_e + M)$ is the electron reduced mass and the term $H_{mp} = \boldsymbol{p}_1 \cdot \boldsymbol{p}_2/M$ is called the mass polarization operator. For computational purposes, it is usual to measure distance in units of $a_\mu = (m_e/\mu)a_0$ and energies in units of $e^2/a_\mu = 2(\mu/m_e)R_\infty$ so that (11.3) assumes the dimensionless form

$$\left[-\frac{1}{2} \sum_{i=1}^{2} \nabla_{\rho_i}^2 - \frac{\mu}{M} \nabla_{\rho_1} \cdot \nabla_{\rho_2} + V(\boldsymbol{\rho}_1, \boldsymbol{\rho}_2) \right] \Psi = \varepsilon\Psi ,$$
(11.4)

where $\boldsymbol{\rho}_i = \boldsymbol{r}_i/a_\mu$, $\varepsilon = E/(e^2/a_\mu)$, and

$$V(\boldsymbol{\rho}_1, \boldsymbol{\rho}_2) = -\frac{Z}{\rho_1} - \frac{Z}{\rho_2} + \frac{1}{|\boldsymbol{\rho}_1 - \boldsymbol{\rho}_2|} .$$
(11.5)

The limit $\mu/M \to 0$ defines the infinite nuclear mass problem with eigenvalue ε_0 and eigenfunction Ψ_0. If the mass polarization term is treated as a small perturbation, then the total energy assumes the form

$$E = \left[\varepsilon_0 + \frac{\mu}{M}\varepsilon_1 + \left(\frac{\mu}{M}\right)^2 \varepsilon_2 + \cdots \right] \frac{\mu}{m_e} \frac{e^2}{a_0} ,$$
(11.6)

where $\varepsilon_1 = -\langle \Psi_0 | \nabla_{\rho_1} \cdot \nabla_{\rho_2} | \Psi_0 \rangle$ determines the first-order specific mass shift and ε_2 is the second-order coefficient. The common $(\mu/m_e)\varepsilon_0$ mass scaling of all eigenvalues determines the normal mass shift (isotope shift). Since $\mu/m = 1 - \mu/M$, the shift is $-(\mu/M)\varepsilon_0$.

11.1.1 Formal Mathematical Properties

Two–Particle Coalescences

The exact nonrelativistic wave function for any many-body system contains discontinuities or cusps in the spherically averaged radial derivative with respect to r_{ij} as $r_{ij} \to 0$, where $r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$ is any interparticle coordinate. If the masses and charges are m_i and q_i respectively, then the discontinuities are given by the Kato cusp condition [11.1]

$$\hbar^2 \left(\frac{\partial \bar{\Psi}}{\partial r_{ij}} \right)_{r_{ij}=0} = \mu_{ij} q_i q_j \Psi(r_{ij}=0) , \qquad (11.7)$$

where $\mu_{ij} = m_i m_j/(m_i + m_j)$ and $\bar{\Psi}$ denotes the wave function averaged over a sphere centered at $r_{ij} = 0$. If Ψ vanishes at $r_{ij} = 0$, then its leading dependence on r_{ij} is of the form $r_{ij}^l Y_{lm}(\mathbf{r}_{ij})$ for some integer $l > 0$ [11.2]. Equation (11.7) applies to any Coulombic system. The electron–nucleus cusp in the wave functions for hydrogen provides a simple example.

Three–Particle Coalescences

Three-particle coalescences are described by the Fock expansion [11.3–6], as recently discussed by *Myers* et al. [11.7]. For the S-states of He-like ions, the ex-pansion has the form

$$\Psi(\mathbf{r}_1, \mathbf{r}_2) = \sum_{j=0}^{\infty} \sum_{k=0}^{[j/2]} \mathcal{R}^j (\ln \mathcal{R})^k \phi_{j,k} , \qquad (11.8)$$

where [ ] denotes "greatest integer in", and $\mathcal{R} = (r_1^2 + r_2^2)^{1/2}$ is the hyperradius. The leading coefficients are

$$\phi_{0,0} = 1 ,$$

$$\phi_{1,0} = -\left(Zr_1 + Zr_2 - \frac{1}{2} r_{12} \right) \Big/ \mathcal{R} ,$$

$$\phi_{2,1} = -2Z \left(\frac{\pi - 2}{3\pi} \right) \frac{\mathbf{r}_1 \cdot \mathbf{r}_2}{\mathcal{R}^2} . \qquad (11.9)$$

The next term $\phi_{2,0}$ is known in terms of a lengthy expression [11.7–9], but higher terms have not yet been obtained in closed form. The Fock expansion has been proved convergent for all $\mathcal{R} < \frac{1}{2}$ [11.10], and extended to pointwise convergence for all $\mathcal{R}$ [11.11, 12].

Asymptotic Form

The long range behavior of many-electron wave functions has been studied from several points of view [11.13–15]. The basic result of [11.16] is that at large distances, the one-electron density behaves as

$$\rho^{1/2}(r) \approx r^{Z^*/t-1} e^{-tr} , \qquad (11.10)$$

where $t = (2I_1)^{1/2}$, I_1 is the first ionization potential (in a.u.), and $Z^* = Z - N + 1$ is the screened nuclear charge seen by the outer most electron. For hydrogenic systems with principal quantum number n, $I_1 = (Z^*)^2/2n^2$.

11.2 Computational Methods

11.2.1 Variational Methods

Most high precision calculations for the bound states of three-body systems such as helium are based on the Rayleigh–Ritz variational principle. For any normalizable trial function Ψ_{tr}, the quantity

$$E_{tr} = \frac{\langle \Psi_{tr} | H | \Psi_{tr} \rangle}{\langle \Psi_{tr} | \Psi_{tr} \rangle} \qquad (11.11)$$

satisfies the inequality $E_{tr} \geq E_1$, where E_1 is the true ground state energy. Thus E_{tr} is an upper bound to E_1. The inequality is easily proved by expanding Ψ_{tr} in the complete basis set of eigenfunctions $\Psi_1, \Psi_2, \Psi_3, \cdots$

of H with eigenvalues $E_1 < E_2 < E_3 < \cdots$, so that

$$\Psi_{tr} = \sum_{i=1}^{\infty} c_i \Psi_i , \qquad (11.12)$$

where the c_i are expansion coefficients. This can always be done in principle, even though the exact Ψ_i are not actually known. If Ψ_{tr} is normalized so that $\langle \Psi_{tr} | \Psi_{tr} \rangle = 1$, then $\sum_{i=1}^{\infty} |c_i|^2 = 1$ and

$$E_{tr} = |c_1|^2 E_1 + |c_2|^2 E_2 + |c_3|^2 E_3 + \cdots$$
$$= E_1 + |c_2|^2 (E_2 - E_1) + |c_3|^2 (E_3 - E_1) + \cdots$$
$$\geq E_1 , \qquad (11.13)$$

which proves the theorem.

The basic idea of variational calculations then is to write Ψ_{tr} in some arbitrarily chosen mathematical form with variational parameters (subject to normalizability and boundary conditions at the origin and infinity), and then adjust the parameters to obtain the minimum value of E_{tr}.

The minimization problem for the case of *linear* variational coefficients can be solved algebraically. For example, let

$$\chi_p(\alpha, \beta) = r_1^i r_2^j r_{12}^k \, e^{-\alpha r_1 - \beta r_2} \tag{11.14}$$

denote the members of a basis set, where p is an index labeling distinct triplets of nonnegative integer values for the powers $\{i, j, k\}$, and α, β are (for the moment) fixed constants determining the distance scale.

If Ψ_{tr} is expanded in the form

$$\Psi_{tr} = \sum_{p=1}^{N} c_p \chi_p(\alpha, \beta) , \tag{11.15}$$

then the solution to the system of equations $\partial E_{tr}/\partial c_p = 0$, $p = 1, \ldots, N$, is exactly equivalent to solving the N-dimensional generalized eigenvalue problem

$$\mathbf{H}c = \lambda \mathbf{O}c , \tag{11.16}$$

where c is a column vector of coefficients c_p; and $\mathbf{H}$ and $\mathbf{O}$ have matrix elements $H_{pq} = \langle \chi_p | H | \chi_q \rangle$ and $O_{pq} = \langle \chi_p | \chi_q \rangle$. There are N eigenvalues $\lambda_1, \lambda_2, \ldots \lambda_N$, of which the lowest is an upper bound to E_1.

Extension to Excited States

By the Hylleraas–Undheim–MacDonald (HUM) theorem [11.17, 18], the remaining eigenvalues $\lambda_2, \lambda_3, \ldots$ are also upper bounds to the exact energies $E_2, E_3, \ldots$, provided that the spectrum is bounded from below. The HUM theorem is a consequence of the matrix eigenvalue interleaving theorem, which states that as the dimensions of $\mathbf{H}$ and $\mathbf{O}$ are progressively increased by adding an extra row and column, the N old eigenvalues λ_p fall between the $N + 1$ new ones. Consequently, as illustrated in Fig. 11.1, all eigenvalues numbered from the bottom up must move inexorably downward as N is increased. Since the exact spectrum of bound states is obtained in the limit $N \to \infty$, no λ_p can cross the corresponding exact E_p on its way down. Thus $\lambda_p \geq E_p$ for every finite N.

11.2.2 Construction of Basis Sets

Since the Schrödinger equation (11.4) is not separable in the electron coordinates, basis sets which incorporate
Fig. 11.1 Diagram illustrating the Hylleraas–Undheim–MacDonald Theorem. The λ_p, $p = 1, \ldots, N$ are the variational eigenvalues for an N-dimensional basis set, and the E_i are the exact eigenvalues of H. The highest λ_p lie in the continuous spectrum of H

the $r_{12} = |r_1 - r_2|$ interelectron coordinate are most efficient. The necessity for r_{12} terms also follows from the Fock expansion (11.8). A basis set constructed from terms of the form (11.14) is called a Hylleraas basis set [11.19, 20]. (The basis set is often expressed in terms of the equivalent variables $s = r_1 + r_2$, $t = r_1 - r_2$, $u = r_{12}$.)

With $\chi_p(\alpha, \beta)$ defined as in (11.14), the general form for a state of total angular momentum L is

$$\Psi_{tr} = \sum_{l_1=0}^{[L/2]} \sum_p C_{p,l_1} \chi_p(\alpha, \beta) r_1^{l_1} r_2^{l_2} \mathcal{Y}_{l_1 \, L-l_1 \, L}^M(\hat{r}_1, \hat{r}_2)$$

$$\pm \text{ exchange} , \tag{11.17}$$

where

$$\mathcal{Y}_{l_1 l_2 L}^M(\hat{r}_1, \hat{r}_2) = \sum_{m_1, m_2} Y_{l_1 m_1}(\hat{r}_1) Y_{l_2 m_2}(\hat{r}_2)$$

$$\times \langle l_1 l_2 m_1 m_2 | LM \rangle \tag{11.18}$$

is the vector coupled product of angular momenta l_1, l_2 for the two electrons. The sum over p in (11.17) typically includes all terms in (11.14) with $i + j + k \leq \Omega$, where Ω is an integer determining a so-called *Pekeris shell* of terms, and the exchange term denotes the interchange of r_1 and r_2 with $(+)$ for singlet states and $(-)$ for triplet states. Convergence is studied by progressively

increasing Ω. The number of terms is

$$N = \frac{1}{6}(\Omega + 1)(\Omega + 2)(\Omega + 3) .$$

Basis sets of this type were used by many authors, culminating in the extensive high precision calculations of *Pekeris* and coworkers [11.21] for low-lying states, using as many as 1078 terms. Their accuracy is not easily surpassed because of the rapid growth of N with Ω, and because of numerical linear dependence in the basis set for large Ω. Recently, their accuracy has been surpassed by two principal methods. The first explicitly includes powers of logarithmic and half-integral terms in χ_p, as suggested by the Fock expansion [11.22–25]. This is particularly effective for S-states. The second focuses directly on the multiple distance scales required for an accurate representation of the wave function by writing the trial function in terms of the double basis set [11.26]

$$\Psi_{\mathrm{tr}} = \sum_{l_1=0}^{[L/2]} \sum_p \left[C_{p,l_1}^{(1)} \chi_p(\alpha_1, \beta_1) + C_{p,l_1}^{(2)} \chi_p(\alpha_2, \beta_2) \right]$$
$$\times r_1^{l_1} r_2^{l_2} \mathcal{Y}_{l_1 l_2 L}(\boldsymbol{r}_1, \boldsymbol{r}_2) \pm \text{exchange} , \quad (11.19)$$

where each $\chi_p(\alpha, \beta)$ is of the form (11.14), but with different values for the distance scales α_1, β_1 and α_2, β_2 in the two sets of terms. They are determined by a complete minimization of E_{tr} with respect to all four parameters, producing a natural division of the basis set into an asymptotic sector and a close-range correlation sector. The method produces a dramatic improvement in accuracy for higher-lying Rydberg states (where variational methods typically deteriorate rapidly in accuracy) and is also effective for low-lying S-states [11.27–29]. Nonrelativistic energies accurate to 1 part in 10^{16} are obtainable with modest computing resources.

Another version of the variational method is the quasi-random (or stochastic) method in which nonlinear exponential parameters for all three of r_1, r_2, and r_{12} are chosen at random from certain specified intervals [11.30, 31]. The method is remarkably accurate and efficient for low-lying states, but subject to severe roundoff error.

11.2.3 Calculation of Matrix Elements

The three-body problem has the unique advantage that the full six-dimensional volume element (in the c.m. frame) can be transformed to the product of a three-dimensional angular integral (ang) and a three-dimensional radial integral (rad) over r_1, r_2, and r_{12}. The

transformation is

$$\iint \mathrm{d}\boldsymbol{r}_1 \, \mathrm{d}\boldsymbol{r}_2 = \int_0^{2\pi} \mathrm{d}\phi \int_0^{2\pi} \mathrm{d}\varphi_1 \int_0^{\pi} \sin\theta_1 \, \mathrm{d}\theta_1$$
$$\times \int_0^{\infty} r_1 \, \mathrm{d}r_1 \int_0^{\infty} r_2 \, \mathrm{d}r_2 \int_{|r_1-r_2|}^{r_1+r_2} r_{12} \, \mathrm{d}r_{12} , \tag{11.20}$$

where θ_1, φ_1 are the polar angles of $\boldsymbol{r}_1$ and ϕ is the angle of rotation of the triangle formed by $\boldsymbol{r}_1$, $\boldsymbol{r}_2$, and $\boldsymbol{r}_{12}$ about the $\boldsymbol{r}_1$ direction. The polar angles θ_2, φ_2 are then dependent variables. The basic angular integral is

$$\langle Y_{l_1 m_1}^*(\theta_1, \varphi_1) Y_{l_2 m_2}(\theta_2, \varphi_2) \rangle_{\mathrm{ang}}$$
$$= 2\pi \delta_{l_1 l_2} \delta_{m_1 m_2} P_{l_1}(\cos\theta) , \tag{11.21}$$

where $\cos\theta \equiv \hat{\boldsymbol{r}}_1 \cdot \hat{\boldsymbol{r}}_2$ denotes the radial function

$$\cos\theta = \frac{r_1^2 + r_2^2 - r_{12}^2}{2r_1 r_2} , \tag{11.22}$$

and $P_l(\cos\theta)$ is a Legendre polynomial. The angular integral over vector-coupled spherical harmonics is [11.32]

$$\langle \mathcal{Y}_{l_1' l_2' L'}^{M'*}(\hat{\boldsymbol{r}}_1, \hat{\boldsymbol{r}}_2) \, \mathcal{Y}_{l_1 l_2 L}^{M}(\hat{\boldsymbol{r}}_1, \hat{\boldsymbol{r}}_2) \rangle_{\mathrm{ang}}$$
$$= \delta_{L,L'} \delta_{M,M'} \sum_{\Lambda} C_{\Lambda} P_{\Lambda}(\cos\theta) , \tag{11.23}$$

where

$$C_{\Lambda} = \frac{1}{2}[(2l_1+1)(2l_1'+1)(2l_2+1)(2l_2'+1)]^{1/2}$$
$$\times (-1)^{L+\Lambda}(2\Lambda+1)$$
$$\times \begin{pmatrix} l_1' & l_1 & \Lambda \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} l_2' & l_2 & \Lambda \\ 0 & 0 & 0 \end{pmatrix} \begin{Bmatrix} L & l_1 & l_2 \\ \Lambda & l_2' & l_1' \end{Bmatrix} , \tag{11.24}$$

and the sum over Λ includes all nonvanishing terms. This can be extended to general matrix elements of tensor operators by further vector coupling [11.32].

Radial Integrals

Table 11.1 lists formulas for the radial integrals arising from matrix elements of H, as well as those from the Breit interaction (see Sect. 21.1). Although they can all be written in closed form, some have been expressed as infinite series in order to achieve good numerical stability. The exceptions are formulas 5 and 10 in the Table, which became unstable as $\alpha \to \beta$. More elaborate

Table 11.1 Formulas for the radial integrals $I_0(a, b, c; \alpha, \beta) = \langle r_1^a\, r_2^b r_{12}^c\, \mathrm{e}^{-\alpha r_1 - \beta r_2}\rangle_{\mathrm{rad}}$ and $I_0^{\log}(a, b, c; \alpha, \beta) = \langle r_1^a\, r_2^b r_{12}^c$ $\ln r_{12}\, \mathrm{e}^{-\alpha r_1 - \beta r_2}\rangle_{\mathrm{rad}}$; $\psi(n) = -\gamma + \sum_{k=1}^{n-1} k^{-1}$ is the digamma function, $_2F_1(a, b; c; z)$ is the hypergeometric function, and $s = a + b + c + 5$. Except as noted, the formulas apply for $a \geq -1$, $b \geq -1$, $c \geq -1$

1. $\quad I_0(-2, -2, -1; \alpha, \beta) \quad = \dfrac{2}{\alpha} \ln\left(\dfrac{\alpha + \beta}{\beta}\right) + \dfrac{2}{\beta} \ln\left(\dfrac{\alpha + \beta}{\alpha}\right)$

2. $\quad I_0(a, b, c; \alpha, \beta) \quad = \dfrac{2}{c+2} \sum_{i=0}^{[(c+1)/2]} \binom{c+2}{2i+1} [F_{a+2i+2,\, b+c-2i+2}(\alpha, \beta) + F_{b+2i+2,\, a+c-2i+2}(\beta, \alpha)]$

$$(c \geq -1,\, s \geq 0)$$

$$\text{where } F_{p,q}(\alpha, \beta) = \begin{cases} \dfrac{q!}{(\alpha + \beta)^{p+1}\beta^{q+1}} \sum_{j=0}^{q} \dfrac{(p+j)!}{j!} \left(\dfrac{\beta}{\alpha + \beta}\right)^{j} & q \geq 0,\ p \geq 0 \\[3ex] \dfrac{p!}{\alpha^{p+q+2}} \sum_{j=p+q+1}^{\infty} \dfrac{j!}{(j-q)!} \left(\dfrac{\alpha}{\alpha + \beta}\right)^{j+1} & q < 0,\ p \geq 0 \\[3ex] 0\ ^{\mathrm{a}} & p < 0 \end{cases}$$

3. $\quad I_0(a, b, c; \alpha, \alpha) \quad = \dfrac{2^{c+3}s!}{(c+2)(2\alpha)^{s+1}} \left[\sum_{j=0}^{a+1} \binom{a+1}{j} (b+1)! \left(\dfrac{j!}{(j+b+2)!} - \dfrac{(j+c+2)!}{(j+b+c+4)!}\right) + (a \leftrightarrow b) \right]$

5. $\quad I_0(a, b, -2; \alpha, \beta) \quad = \dfrac{(a+1)!}{\alpha^{a+2}} \sum_{j=0}^{a+1} \dfrac{(b+1+j)!}{j!} \left(\dfrac{\alpha^j}{(\alpha + \beta)^{b+2+j}} - \dfrac{(-\alpha)^j}{(\beta - \alpha)^{b+2+j}}\right)$

$$\times \left[\ln\left(\dfrac{2\alpha}{\alpha + \beta}\right) - \psi(a+2-j) + \psi(1) \right] + \binom{a \leftrightarrow b}{\alpha \leftrightarrow \beta}$$

6. $\quad I_0(a, b, -2; \alpha, \alpha) \quad = \dfrac{2s!(a+1)!(b+1)!}{(2\alpha)^{s+1}} \left[\sum_{j=0}^{a+1} \dfrac{\psi(s+1-j) - \psi(a+2-j)}{j!(s-j)!} + (a \leftrightarrow b) \right]$

7. $\quad I_0(-1, -1, -3; \alpha, \beta) \quad = \dfrac{2(\beta \ln \beta - \alpha \ln \alpha)}{\alpha^2 - \beta^2} + \dfrac{2[\psi(2) - \ln \epsilon]}{\alpha + \beta}\ ^{\mathrm{b}}$

8. $\quad I_0(a, b, -3; \alpha, \beta) \quad = \left[\dfrac{(a+1)!}{\alpha^{a+1}(\alpha + \beta)^{b+2}} \sum_{j=0}^{a} \dfrac{(b+1+j)!}{j!(a+1-j)} \left(\dfrac{\alpha}{\alpha + \beta}\right)^j + \binom{a \leftrightarrow b}{\alpha \leftrightarrow \beta} \right] - \dfrac{s! \left[\ln(\alpha\beta\epsilon^2) - 2\psi(2)\right]}{(\alpha + \beta)^{s+1}}$

$$- \dfrac{(a+1)!(b+1)!}{(s+1)\alpha^{a+2}\beta^{b+1}}\, _2F_1\left(a+2, 1; s+2; \dfrac{\alpha - \beta}{\alpha}\right), \quad a \geq -1,\ b \geq -1$$

9. $\quad I_0^{\log}(-1, -1, c; \alpha, \beta) \quad = \dfrac{2(c+1)!}{\alpha^2 - \beta^2} \left(\dfrac{\ln \alpha - \psi(c+2)}{\alpha^{c+2}} - \dfrac{\ln \beta - \psi(c+2)}{\beta^{c+2}}\right)$

10. $\quad I_0^{\log}(a, b, c; \alpha, \beta) \quad = \dfrac{(a+1)!}{(c+2)\alpha^{a+c+4}} \sum_{j=0}^{a+1} \dfrac{(b+1+j)!(a+c+3-j)!}{j!(a+1-j)!} \left(\dfrac{\alpha^j}{(\alpha + \beta)^{b+2+j}} - \dfrac{(-\alpha)^j}{(\beta - \alpha)^{b+2+j}}\right)$

$$\times \left[-\psi(a+c+4-j) + \dfrac{1}{c+2} + \ln \alpha \right] + \binom{a \leftrightarrow b}{\alpha \leftrightarrow \beta}$$

11. $\quad I_0^{\log}(a, b, c; \alpha, \alpha) \quad = \dfrac{2^{c+3}s!(b+1)!}{(c+2)(2\alpha)^{s+1}} \sum_{j=0}^{a+1} \binom{a+1}{j} \left\{ \left(\dfrac{j!}{(j+b+2)!} - \dfrac{(j+c+2)!}{(j+b+c+4)!}\right) \left[\psi(s+1) - \ln \alpha - \dfrac{1}{c+2}\right] \right.$

$$\left. + \dfrac{(a+c+3-j)!}{(s+1-j)!} [\psi(s+1-j) - \psi(a+c+4-j)] \right\} + (a \leftrightarrow b)$$

$^{\mathrm{a}}$ Terms with $p < 0$ represent divergent parts which cancel from convergent differences between integrals with the same α and β

$^{\mathrm{b}}$ ϵ is the radius of an infinitesimal sphere about $r_{12} = 0$ which is omitted from the range of integration

techniques for these are discussed in [11.33]. Other cases can be derived by use of the formula

$$
\left\langle r_1^{-1} r_2^{-1} f(r_{12}) \, e^{-\alpha r_1 - \beta r_2} \right\rangle_{\text{rad}}
$$
$$
= \frac{2}{\alpha^2 - \beta^2} \int_0^\infty \left(e^{-\beta r} - e^{-\alpha r} \right) r f(r) \, \mathrm{d}r \,, \qquad (11.25)
$$

and then differentiating or integrating with respect to α or β to raise or lower the powers of r_1 and r_2.

Total Integral

The angular integral (11.23) combined with the radial integrals from Table 11.1 yields the total integral

$$
\left\langle \mathcal{Y}^{M*}_{l_1 l_2 L} \, \mathcal{Y}^{M}_{l'_1 l'_2 L} \, f(a, b, c; \alpha, \beta) \right\rangle
$$
$$
= \sum_\Lambda C_\Lambda I_\Lambda(a, b, c; \alpha, \beta) \,, \qquad (11.26)
$$

where

$$
I_\Lambda(a, b, c; \alpha, \beta) = \langle f(a, b, c; \alpha, \beta) P_\Lambda(\cos\theta) \rangle_{\text{rad}} \,,
$$
$$
f(a, b, c; \alpha, \beta) = r_1^a \, r_2^b r_{12}^c \, e^{-\alpha r_1 - \beta r_2} \,.
$$

Starting from I_0 and I_1, the general I_Λ can be efficiently calculated from the recursion relations [11.32]

$$
I_{\Lambda+1}(a, b, c; \alpha, \beta)
$$
$$
= \frac{2\Lambda+1}{c+2} I_\Lambda(a-1, b-1, c+2; \alpha, \beta)
$$
$$
+ I_{\Lambda-1}(a, b, c; \alpha, \beta), \quad c \neq -2 \qquad (11.27)
$$
$$
I_{\Lambda+1}(a, b, -2; \alpha, \beta)
$$
$$
= (2\Lambda+1) I_\Lambda^{\log}(a-1, b-1, 0; \alpha, \beta)
$$
$$
+ I_{\Lambda-1}(a, b, -2; \alpha, \beta), \quad c = -2 \qquad (11.28)
$$

where

$$
I_\Lambda^{\log}(a, b, c; \alpha, \beta)
$$
$$
= \langle f(a, b, c, \alpha, \beta) \ln r_{12} P_\Lambda(\cos\theta) \rangle_{\text{rad}} \,.
$$

The $I_\Lambda^{\log}$ integrals follow the recursion relation

$$
I_{\Lambda+1}^{\log}(a, b, c; \alpha, \beta)
$$
$$
= \frac{(2\Lambda+1)}{c+2} \left[I_\Lambda^{\log}(a-1, b-1, c+2; \alpha, \beta) \right.
$$
$$
\left. - \frac{1}{c+2} I_\Lambda(a-1, b-1, c+2; \alpha, \beta) \right]
$$
$$
+ I_{\Lambda-1}^{\log}(a, b, c; \alpha, \beta) \,. \qquad (11.29)
$$

Hamiltonian Matrix Elements

The general form of the Laplacian operator in terms of r_1, r_2, r_{12} variables is

$$
\nabla_1^2 = \frac{1}{r_1^2} \frac{\partial}{\partial r_1} \left(r_1^2 \frac{\partial}{\partial r_1} \right) + \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial}{\partial r} \right) - \frac{l_1^2}{r_1^2}
$$
$$
+ \frac{2(r_1 - r_2 \cos\theta)}{r} \frac{\partial^2}{\partial r_1 \partial r} - 2 \left(\nabla_1^Y \cdot r_2 \right) \frac{1}{r} \frac{\partial}{\partial r} \,,
$$
$$
(11.30)
$$

and similarly for ∇_2^2 with subscripts 1 and 2 interchanged. The term ∇_1^Y is understood to act only on the $\mathcal{Y}^M_{l_1 l_2 L}(\hat{r}_1, \hat{r}_2)$ part of the wave function. This term in ∇_1^2 can be easily evaluated by means of the effective operator replacement

$$
\left\langle \mathcal{Y}^{M*}_{l'_1 l'_2 L}, \nabla_1^Y \cdot r_2 \, \mathcal{Y}^M_{l_1 l_2 L} \right\rangle_{\text{ang}} \frac{1}{r_{12}} \frac{\partial g(r_{12})}{\partial r_{12}}
$$
$$
\rightarrow \frac{g(r_{12})}{2 r_1 r_2} \sum_\Lambda \tilde{C}_\Lambda P_\Lambda(\cos\theta) \qquad (11.31)
$$

for the angular part of the total integral, where

$$
\tilde{C}_\Lambda = [l'_1(l'_1+1) - l_1(l_1+1) - \Lambda(\Lambda+1)] C_\Lambda \,.
$$
$$
(11.32)
$$

The replacement (11.31) becomes an equality after radial integration with any function $g(r_{12})$ in the integrand. The matrix elements of H between arbitrary basis functions defined by

$$
\chi = r_1^a \, r_2^b r_{12}^c \, e^{-\alpha r_1 - \beta r_2} \mathcal{Y}^M_{l_1 l_2 L}(\hat{r}_1, \hat{r}_2) \,,
$$
$$
\chi' = r_1^{a'} \, r_2^{b'} r_{12}^{c'} \, e^{-\alpha' r_1 - \beta' r_2} \mathcal{Y}^M_{l'_1 l'_2 L}(\hat{r}_1, \hat{r}_2) \,,
$$

can then be written in the explicitly Hermitian form (for infinite nuclear mass)

$$
\langle \chi' | H | \chi \rangle = \frac{1}{8} \sum_\Lambda C_\Lambda \sum_{i=0}^{2} \left[A_i^{(1)} \right.
$$
$$
\times I_\Lambda(a_+ - i, b_+, c_+; \alpha_+, \beta_+)
$$
$$
+ A_i^{(2)} I_\Lambda(a_+, b_+ - i, c_+; \alpha_+, \beta_+)
$$
$$
\left. + A_i^{(3)} I_\Lambda(a_+, b_+, c_+ - i; \alpha_+, \beta_+) \right]
$$
$$
(11.33)
$$

where $a_\pm = a' \pm a$, $\alpha_\pm = \alpha' \pm \alpha$ etc., and

$$
A_0^{(1)} = -\alpha_+^2 - \alpha_-^2 + 2\alpha_- \alpha_+ (c_-/c_+) \,,
$$

$$
\begin{aligned}
A_1^{(1)} &= 2\{\alpha_+(a_+ + 2) + \alpha_- a_- \\
&\quad - [\alpha_+ a_- + \alpha_-(a_+ + 2)](c_-/c_+)\} - 8Z , \\
A_2^{(1)} &= -a_+^2 - a_-^2 - 2a_+ + 2a_-(a_+ + 1)(c_-/c_+) \\
&\quad + 2l_1(l_1 + 1)(1 - c_-/c_+) \\
&\quad + 2l_1'(l_1' + 1)(1 + c_-/c_+) , \\
A_0^{(3)} &= 0 , \qquad A_1^{(3)} = 8 , \\
A_2^{(3)} &= 2(c_+^2 - c_-^2) ,
\end{aligned}
$$

with $(c_-/c_+) = 0$ for $c_+ = 0$. The $A_i^{(2)}$ are defined similarly to $A_i^{(1)}$ with the replacements $a \to b$, $\alpha \to \beta$, $l_1 \to l_2$. The overlap integral is

$$
\langle \chi' | \chi \rangle = \sum_\Lambda C_\Lambda I_\Lambda(a_+, b_+, c_+; \alpha_+, \beta_+) . \quad (11.34)
$$

11.3 Variational Eigenvalues

High precision variational eigenvalues are available for all states of helium up to $n = 10$ and $L = 7$ [11.27–29]. The nonrelativistic values of ε_0, ε_1 and ε_2 [see (11.6)] are listed in Table 11.2 and Table 11.3. The ε_0 are the eigenvalues for infinite nuclear mass, and ε_1 and ε_2, together with (11.6) give the finite mass corrections for the isotopes ^{3}He and ^{4}He. The values of μ/M can be calculated from

$$
\frac{\mu}{M} = \left(\frac{M_A}{5.485\,799\,110\,(12) \times 10^{-4}} - N + 1 \right)^{-1}
$$
$$(11.35)$$

where M_A is the atomic mass (in amu, see [11.37] for a tabulation. For high precision work, the helium electronic binding energy of 8.48×10^{-8} amu should be added to M_A.) and N is the number of electrons. For ^{4}He, one can use directly the accurately known value of m_e/m_α to calculate $\mu/M = 1/(m_\alpha/m_e + 1)$. Values of μ/M for the first several isotopes are listed in Table 11.4, and the corresponding energy coefficients for the $1s^2\ ^1$S ground state are given in Table 11.5.

11.2.4 Other Computational Methods

Although not yet at the same level of accuracy as variational methods, certain nonvariational methods, such as finite element methods [11.34], solutions to the Faddeev equations [11.35], and the correlated-function hyperspherical-harmonic method [11.36], have their own advantages of flexibility and/or generality. A characteristic feature of these methods is that they provide direct numerical solutions to the three-body problem which in principle converge pointwise to the exact solution, rather than depending upon a globally optimized solution. Other methods particularly suited to doubly-excited states are discussed in Chapt. 25

11.3.1 Expectation Values of Operators and Sum Rules

Expectation values for various powers of the radial coordinates, together with operators appearing in the Breit interaction, are listed in Table 11.6 for the ground state of helium and He-like ions. Included are all terms required to calculate $\langle V^2 \rangle$, and the oscillator strength sum rules [11.38]

$$
S(-1) = \frac{2}{3} \langle (\boldsymbol{r}_1 + \boldsymbol{r}_2)^2 \rangle , \quad (11.36a)
$$
$$
S(0) = 2 , \quad (11.36b)
$$
$$
S(1) = -\frac{4}{3}(\varepsilon_0 - \varepsilon_1) , \quad (11.36c)
$$
$$
S(2) = \frac{2\pi Z}{3} \langle \delta(\boldsymbol{r}_1) + \delta(\boldsymbol{r}_2) \rangle , \quad (11.36d)
$$

where $S(k) = \sum_n [\varepsilon_0(n^1\text{P}) - \varepsilon_0(1^1\text{S})]^k f_{0n}$, with energies in a.u., and f_{0n} is the $1^1\text{S} - n^1\text{P}$ oscillator strength (see Sect. 11.5.1).

11.4 Total Energies

As discussed in Chapts. 21 and 27, relativistic and QED corrections must be added to the nonrelativistic eigenvalues of Sect. 11.3 before a meaningful comparison with measured transition frequencies can be made. The corrections are discussed in detail in [11.27, 28, 39].

The terms in order of decreasing size are:

1. *Relativistic corrections of $O(\alpha^2)$*

$$H_{\text{rel}} = H_{\text{NFS}} + H_{\text{FS}},$$
$$H_{\text{NFS}} = H_{\text{mass}} + H_{\text{D}} + H_{\text{ssc}} + H_{\text{oo}},$$
$$H_{\text{FS}} = H_{\text{so}} + H_{\text{soo}} + H_{\text{ss}}.$$

The various nonfine-structure (NFS) and fine-structure (FS) terms are defined in Sect. 21.1. The off-diagonal matrix elements of H_{FS} mix states of different spin and cause a break-down of LS-coupling.

2. *Anomalous magnetic moment corrections of $O(\alpha^3)$*
The general FS matrix elements between states with spins S and S' due to the anomalous magnetic moment a_e are (see Sect. 27.4)

$$\langle \gamma S | H_{\text{FS}}^{\text{anom}} | \gamma' S' \rangle = 2a_e \left\langle \gamma S \middle| H_{\text{so}} + \frac{2}{3}\delta_{S,S'} H_{\text{soo}} \right.$$
$$\left. + \left(1 + \frac{1}{2}a_e\right) H_{\text{ss}} \middle| \gamma' S' \right\rangle,$$
$$(11.37)$$

where　$a_e = (g_e - 2)/2 = \alpha/(2\pi) - 0.328\,479\alpha^2 + \cdots.$

3. *QED corrections of $O(\alpha^3)$*
The lowest order QED corrections (including NFS anomalous magnetic moment terms) can be written in the form $\Delta_{L,1} + \Delta_{L,2}$, where

$$\Delta E_{L,1} = \frac{4}{3}Z\alpha^3 \left(\ln(Z\alpha)^{-2} + \frac{19}{30} - \ln k_0\right)$$
$$\times \langle \delta(\boldsymbol{r}_1) + \delta(\boldsymbol{r}_2) \rangle \qquad (11.38)$$

$$\Delta E_{L,2} = \alpha^3 \left(\frac{89}{15} + \frac{14}{3}\ln\alpha - \frac{20}{3}\boldsymbol{s}_1 \cdot \boldsymbol{s}_2\right)$$
$$\times \langle \delta(\boldsymbol{r}_{12}) \rangle - \frac{14}{3}\alpha^3 Q, \qquad (11.39)$$

$\ln k_0$ is the two-electron Bethe logarithm defined by (27.86) and Q is the matrix element defined by (27.83). For a highly excited $1snl$ state, $\Delta E_{L,2} \to 0$, $\langle \delta(\boldsymbol{r}_1) + \delta(\boldsymbol{r}_2) \rangle \to Z^3/\pi$, $\ln k_0 \to \ln k_0(1s) = 2.984\,128\,555$, and $\Delta E_{L,1}$ reduces to the Lamb shift of the 1s core state (see Sects. 28.3.4 and 28.3.5). Thus $\Delta E_{L,1}$ represents the electron–nucleus part of the QED shift with the factor of Z^3/π replaced by the correct electron density at the nucleus. Accurate values of $\ln k_0$ for two-electron atoms and ions are tabulated in [11.40].

For the low-lying S-states and P-states of helium [11.31],

$$\ln k_0(1^1S) = 2.983\,865\,861 , \qquad (11.40a)$$

$$\ln k_0(2^1S) = 2.980\,118\,365 , \qquad (11.40b)$$

$$\ln k_0(2^3S) = 2.977\,742\,459 , \qquad (11.40c)$$

$$\ln k_0(2^1P) = 2.983\,803\,377 , \qquad (11.40d)$$

$$\ln k_0(2^3P) = 2.983\,690\,995 . \qquad (11.40e)$$

For a $1snl$ state with large l, the asymptotic expansion [11.41, 42]

$$\ln k_0(1snl) \approx \ln k_0(1s) + \frac{1}{n^3}\left(\frac{Z-1}{Z}\right)^4 \ln k_0(nl)$$
$$+ 0.316\,205(6)Z^{-6}\langle r^{-4}\rangle_{nl}$$
$$+ \Delta\beta(1snl) \qquad (11.41)$$

becomes essentially exact. Here $\ln k_0(nl)$ is the one-electron Bethe logarithm [11.43] and

$$\langle r^{-4}\rangle_{nl} = \frac{16(Z-1)^4[3n^2 - l(l+1)]}{(2l-1)2l(2l+1)(2l+2)(2l+3)} . \qquad (11.42)$$

The correction $\Delta\beta(1snl)$ for higher order terms is

$$\Delta\beta(1snl\,^1L) = 95.8(8)\langle r^{-6}\rangle - 845(19)\langle r^{-7}\rangle$$
$$+ 1406(50)\langle r^{-8}\rangle \qquad (11.43)$$

$$\Delta\beta(1snl\,^3L) = 95.1(9)\langle r^{-6}\rangle - 841(23)\langle r^{-7}\rangle$$
$$+ 1584(60)\langle r^{-8}\rangle . \qquad (11.44)$$

For example, for the $1s4f\,^1F$ state, $\beta(4\,^1F) = 2.984\,127\,1493(3)$.

For higher Z, $1/Z$ expansions of [11.40] should be used.

4. *Relativistic finite mass corrections of $O(\alpha^2\mu/M)$*
Relativistic finite mass corrections come from two sources. First, a transformation to relative coordinates as in (11.3) is applied to the pairwise Breit interactions among the three particles, generating the new terms [11.44, 45]

$$\Delta = \Delta_{oo} + \Delta_{so} + 2\frac{m_e}{M}H_{so}$$

where

$$\Delta_{oo} = \frac{-Z\alpha^2 m_e}{2M}\sum_{i,j}\frac{1}{r_i}\left[\boldsymbol{p}_j\cdot\boldsymbol{p}_i + \hat{\boldsymbol{r}}_i\cdot(\hat{\boldsymbol{r}}_i\cdot\boldsymbol{p}_j)\boldsymbol{p}_i\right] , \qquad (11.45)$$

$$\Delta_{so} = \frac{Z\alpha^2 m_e}{M}\sum_{i\neq j}\frac{1}{r_i^3}\boldsymbol{r}_i\times\boldsymbol{p}_j\cdot\boldsymbol{s}_i . \qquad (11.46)$$

Second, the mass polarization term H_{mp} in (11.3) generates second-order cross-terms between H_{mp} and H_{rel}. If the wave functions are calculated by solving (11.4) in scaled atomic units, the H_{mp} correction is then automatically included to all orders and the mass-corrected relativistic energy shift is (in units of e^2/a_0)

$$\Delta E_{rel} = \left(\frac{\mu}{m_e}\right)^3 \left\langle \left(\frac{\mu}{m_e}\right) H_{mass} + H_D + H_{ssc}\right.$$
$$+ H_{oo} + \Delta_{oo} + \left(1 + \frac{2m_e}{M}\right)H_{so}$$
$$\left. + H_{soo} + H_{ss} + \Delta_{so}\right\rangle \qquad (11.47)$$

with $\mu/m_e = 1 - \mu/M$. The difference $\Delta E_{rel} - \langle H_{rel}\rangle_\infty$ calculated for infinite nuclear mass is the relativistic finite mass correction.

5. *Higher-order corrections*
Spin-dependent terms of $O(\alpha^4)$ are known in their entirety, and have recently been calculated to high precision [11.46]. Nonrelativistic operators for the spin-independent part have recently been derived and calculated for the $1s2s\,^3S_1$ state [11.47] and $1s^2\,^1S_0$ state [11.48]. The dominant electron–nucleus part is known from the one-electron Lamb shift to be

$$\Delta E'_{L,1} = Z\alpha^3\left[\pi Z\alpha\left(\frac{427}{96} - 2\ln 2\right)\right.$$
$$\left. + 0.538\,931\frac{\alpha}{\pi}\right]$$
$$\times \langle\delta(\boldsymbol{r}_1) + \delta(\boldsymbol{r}_2)\rangle + O(\alpha^5) \qquad (11.48)$$

and the electron–electron logarithmic part is [11.49]

$$\Delta E'_{L,2} = \pi\alpha^4\ln\alpha^{-1}\langle\delta(r_{12})\rangle . \qquad (11.49)$$

As an example, $\Delta E'_{L,1}$ contributes $-50.336\,\text{MHz}$ and $-88.267\,\text{MHz}$ to the $2\,^1P$–$2\,^1S$ and $2\,^3P_J$–$2\,^3S_1$ transition frequencies respectively, while the differences between theory and experiment are $\approx 1\,\text{MHz}$ and $\approx -7\,\text{MHz}$ for the two cases (see [11.39]). Thus, two-electron corrections (for example, relativistic corrections of relative order $Z\alpha$ to $\Delta E_{L,2}$) are evidently small.

Table 11.7 lists the calculated ionization energies for all states of helium up to $n = 10$ and $L = 7$. For the D-states and beyond, the uncertainties are sufficiently small that these states can be taken as known points of reference in the interpretation of experimental transition frequencies. However,

long-range Casimir–Polder corrections [11.50–52] are not included since they still lack experimental confirmation [11.53]. The QED shifts are the largest for the S- and P-states. The contributions from $\Delta E_{L,1} + \Delta E'_{L,1}$ and $\Delta E_{L,2} + \Delta E'_{L,2}$ for these states are listed separately in Table 11.8. Applications to isotope shifts and measurements of the nuclear radius are discussed in Sects. 16.2 and 90.1

[a] Includes additional contributions of −4 MHz for the $1\,^1$S state [11.48] and 3.00(1) MHz for the $2\,^3$S state [11.47] due to electron–electron terms of $O(\alpha^4)R_\infty$

11.4.1 Quantum Defect Extrapolations

As discussed in Sect. 14.1, the ionization energies of an isolated Rydberg series of states can be expressed in the form

$$W_n = R_M(Z-1)^2/n^{*2}\,, \tag{11.50}$$

where $Z-1$ is the screened nuclear charge and n^* is the effective principal quantum number defined by an iterative solution to the equation

$$n^* = n - \delta(n^*)\,, \tag{11.51}$$

where $\delta(n^*)$ is the *quantum defect* defined by the Ritz expansion

$$\delta(n^*) = \delta_0 + \frac{\delta_2}{(n-\delta)^2} + \frac{\delta_4}{(n-\delta)^4} + \cdots \tag{11.52}$$

with constant coefficients δ_i. The absence of *odd* terms in this series is a special property of the eigenvalues of Hamiltonians of the form $H_C + V$, where H_C is a pure one-electron Coulomb Hamiltonian, and V is a local, short-range, spherically symmetric potential of arbitrary strength (see [11.54] for further discussion). For the Rydberg states of helium, odd terms must be included in the Ritz expansion (11.52) due to relativistic and mass polarization corrections, but they can be removed again by first adjusting the energies according to

$$W'_n = W_n - \Delta W_n\,, \tag{11.53}$$

where, to sufficient accuracy [11.54] [see discussion following (11.66)]

$$\Delta W_n = R_M \left\{ \frac{-3\alpha^2(Z-1)^4}{4n^4} + \left(\frac{\mu}{M}\right)^2 \frac{(Z-1)^2}{n^2} \right. $$
$$\left. \times \left[1 + \frac{5}{6}(\alpha Z)^2\right] \right\}, \tag{11.54}$$

with $Z = 2$ for helium. The quantum defect parameters listed in Table 11.9 provide accurate extrapolations to higher-lying Rydberg states, with

$$W_n = R_M/n^{*2} + \Delta W_n . \tag{11.55}$$

11.4.2 Asymptotic Expansions

The asymptotic expansion method [11.39, 55] rapidly increases in accuracy with increasing angular momentum L of the Rydberg electron, and can be used to high precision for $L \geq 7$. The method is based on a model in which:

1. the Rydberg electron, treated as a distinguishable particle, moves in the field of the core consisting of the He nucleus and a tightly bound 1s electron.
2. the core, as characterized by its various multipole moments, is perturbed by the electric field of the Rydberg electron.

A systematic perturbation expansion yields an asymptotic series of the form

$$\varepsilon_0^{nL} = -2 - \frac{(Z-1)^2}{2n^2} + a_0 \sum_{j=4}^{N} A_j \langle r^{-j} \rangle_{nL} \frac{e^2}{a_0} \, , \tag{11.56}$$

where the expectation value $\langle r^{-j} \rangle_{nL}$ is calculated with respect to the hydrogenic nL-electron wave function [11.56] and the series is truncated at the upper limit N where the series begins diverging. The leading coefficients A_j are

$$A_4 = -\frac{1}{2}\alpha_1 \, , \quad A_5 = 0 \, , \quad A_6 = -\frac{1}{2}(\alpha_2 - 6\beta_1) \, ,$$

where α_k is the 2^k-pole polarizability of the hydrogenic core and β_k is a nonadiabatic correction. The exact hydrogenic values are

$$\alpha_1 = \frac{9a_0^3}{2Z^4} \, , \quad \alpha_2 = \frac{15a_0^5}{Z^6} \, , \quad \beta_1 = \frac{43a_0^5}{8Z^6} \, .$$

All terms are known up to A_{10} (see [11.39, 55] for detailed results). The expansions for the terms ε_0, ε_1, and ε_2 in (11.6) for helium are

$$\begin{aligned}
\varepsilon_0^{nL} = & -2 - \frac{1}{2n^2} - \frac{9}{64}\langle r^{-4} \rangle \\
& + \frac{69}{512}\langle r^{-6} \rangle + \frac{3833}{15\,360}\langle r^{-7} \rangle \\
& - \left(\frac{55\,923}{65\,536} + \frac{957L(L+1)}{10\,240} \right)\langle r^{-8} \rangle \\
& - \frac{908\,185}{688\,128}\langle r^{-9} \rangle \\
& + \left(\frac{3\,824\,925}{1\,048\,576} + \frac{33\,275L(L+1)}{28\,672} \right)\langle r^{-10} \rangle \\
& + e^{(1,1)} - \frac{23}{20}e^{(1,2)} \, , \tag{11.57}
\end{aligned}$$

$$\begin{aligned}
\varepsilon_1^{nL} = & -\frac{9}{32}\langle r^{-4} \rangle + \frac{249}{256}\langle r^{-6} \rangle + \frac{319}{3840}\langle r^{-7} \rangle \\
& - \left(\frac{34\,659}{16\,384} + \frac{957L(L+1)}{5120} \right)\langle r^{-8} \rangle \\
& - \frac{14\,419}{3072}\langle r^{-9} \rangle \\
& + \left(\frac{6\,413\,781}{262\,144} + \frac{24\,155L(L+1)}{8192} \right)\langle r^{-10} \rangle \\
& + 4e^{(1,1)} - \frac{53}{5}e^{(1,2)} \, , \tag{11.58}
\end{aligned}$$

$$\begin{aligned}
\varepsilon_2^{nL} = & -\frac{1}{2n^2} - \frac{45}{64}\langle r^{-4} \rangle + \frac{165}{512}\langle r^{-6} \rangle + \frac{2555}{3072}\langle r^{-7} \rangle \\
& - \left(\frac{268\,485}{32\,768} + \frac{957L(L+1)}{2048} \right)\langle r^{-8} \rangle \\
& + \frac{598\,909}{172\,032}\langle r^{-9} \rangle \\
& + \left(\frac{3\,907\,923}{524\,288} + \frac{629\,515L(L+1)}{114\,688} \right)\langle r^{-10} \rangle \\
& + 14e^{(1,1)} - \frac{251}{10}e^{(1,2)} \, . \tag{11.59}
\end{aligned}$$

The terms $e^{(1,1)}$ and $e^{(1,2)}$ are second-order dipole–dipole and dipole–quadrupole perturbation corrections. Defining $f_p^L = (L+p)!/(L-p)!$, they are given by

$$\begin{aligned}
e^{(i,j)} = & -\frac{(2 - \delta_{j,k})2^{2i+2j+1}(2L-2i)!(2L-2j)!}{n^3(2L+2i+1)!(2L+2j+1)!} \\
& \times \left(\frac{2^{2i+2j}(2L-2i-2j)!A^{(i,j)}}{n^{2i+2j+2}(2L+2i+2j+1)!} \right. \\
& \left. + \frac{B^{(i,j)}}{n^{2i+2j+1}} \right) \tag{11.60}
\end{aligned}$$

with

$$\begin{aligned}
A^{(1,1)} = & 3n^2(3n^2 - 2f_1)(f_1 - 2)\left(45 + 623f_1^L \right. \\
& \left. + 3640f_2^L + 560f_3^L \right) \, , \\
B^{(1,1)} = & \left(9n^2 - 7f_1^L \right)\left(3n^2 - f_1^L \right) \, , \\
A^{(1,2)} = & -21n^6\left(94\,500 + 122\,850f_1^L \right. \\
& - 1\,126\,125f_2^L - 18\,931\,770f_3^L \\
& - 11\,171\,160f_4^L - 1\,029\,600f_5^L \\
& \left. - 18\,304f_6^L \right) \\
& - 15n^4\left(94\,500 - 444\,150f_1^L \right. \\
& + 7\,747\,425f_2^L + 337\,931\,880f_3^L \\
& + 375\,290\,190f_4^L + 66\,518\,760f_5^L
\end{aligned}$$

$$+ 2\,880\,416\, f_6^L + 29\,568\, f_7^L)$$
$$+ 9n^2 f_1^L \left(90\,300 - 177\,450\, f_1^L\right.$$
$$+ 1\,738\,450\, f_2^L + 133\,125\,575\, f_3^L$$
$$+ 160\,040\,870\, f_4^L + 29\,322\,216\, f_5^L$$
$$+ 1\,293\,600\, f_6^L + 13\,440\, f_7^L)$$
$$+ 2 f_1^L f_2^L f_3^L \left(45 + 252\, f_1^L - 1680\, f_2^L\right.$$
$$- 2240\, f_3^L),$$
$$B^{(1,2)} = 315 n^6 + 125 n^4 \left(3 - 5 f_1^L\right)$$
$$- 7 n^2 f_1^L \left(43 - 39 f_1^L\right) - 27 f_1^L f_2^L.$$

The accuracy of the expansion for the ε_0, ε_1, and ε_2 can be reliably estimated to be one-half of the last $\langle r^{-j} \rangle$ term included in the sum. Formulas for the $\langle r^{-j} \rangle$ are given in Table 11.10.

The asymptotic formulas for the NFS relativistic corrections are [11.39, 57]

$$\langle H_{\text{mass}} + H_D \rangle \rightarrow -\frac{\alpha^2 Z^4}{8} + h_1(nL) + \chi_1(nL)$$
$$+ \frac{(Z\alpha)^2}{2} \left(\frac{14}{3 Z^4} \langle r^{-4} \rangle \right.$$
$$\left. - \frac{5041}{240 Z^6} \langle r^{-6} \rangle \right) \qquad (11.61)$$

$$\langle H_{\text{oo}} \rangle \rightarrow \frac{\alpha^2}{Z^2} \left(\langle r^{-4} \rangle + \frac{3(Z-1)}{Z^2} \langle r^{-5} \rangle \right.$$
$$\left. - \frac{3\left(f_1^L + 8\right)}{4 Z^2} \langle r^{-6} \rangle \right), \qquad (11.62)$$

where

$$h_1(nL) = \frac{\alpha^2 (Z-1)^4}{2 n^3} \left(\frac{3}{4n} - \frac{1}{L + \frac{1}{2}}\right) \qquad (11.63)$$

is the leading one-electron Dirac energy and

$$\chi_1(nL) = \frac{\alpha^2 \alpha_1}{2} \left\{ 3 \left(\frac{Z-1}{n}\right)^2 \langle r^{-4} \rangle \right.$$
$$- (Z-1) \langle r^{-5} \rangle - \frac{4(2L-2)!}{(2L+3)!}$$
$$\times \left[4 \left(\frac{Z-1}{n}\right)^6 \left(n + \frac{9 n^2 - 5 f_1^L}{2L+1}\right) \right.$$
$$\left. + (Z-1)^2 \left(\frac{40 f_2^L + 70 f_1^L - 3}{2L+1}\right) \langle r^{-4} \rangle \right] \right\}$$
$$(11.64)$$

is the correction due to the dipole perturbation of the Rydberg electron. The relativistic recoil terms due to

Table 11.10 Formulas for the hydrogenic expectation value $\langle r^{-j} \rangle \equiv \langle nl | r^{-j} | nl \rangle$ in terms of

$$G_p^{nl} = \frac{2^p Z^p (2l - p + 2)!}{n^{p+1} (2l + p - 1)!}, \qquad f_p^l = \frac{(l + p)!}{(l - p)!}.$$

mass polarization are

$$\langle H_{\text{mass}} + H_D \rangle_{\text{RR}}$$
$$\rightarrow \frac{\mu}{M} \left[\frac{22(Z\alpha)^2(Z-1)}{9 Z^4} \langle r^{-4} \rangle + 2(Z-1) \chi_1(nL)\right]$$
$$+ \left(\frac{\mu}{M}\right)^2 \left[-\frac{5}{12} \left(\frac{\alpha Z(Z-1)}{n}\right)^2 + 4 h_1(nL)\right],$$
$$(11.65)$$

$$\langle H_{\text{oo}} \rangle_{\text{RR}} + \langle \Delta_{\text{oo}} \rangle$$
$$\rightarrow -\frac{\alpha^2 \mu}{M} \left[Z^4 + \frac{(Z-1)^4}{n^3} \left(\frac{1}{n} - \frac{3}{2L+1}\right)\right.$$
$$\left. - \frac{25[1 + 13 f(Z)]}{16 Z^2} \langle r^{-4} \rangle \right], \qquad (11.66)$$

with $f(Z) \simeq 1 + (Z - 2)/6$. The $-(5/12)[\alpha Z(Z - 1)/n]^2$ term in (11.65) is the dominant contribution in helium for $L \geq 4$. It is included in (11.54) for ΔW_n, along with the leading $1/n^2$ term from (11.59), and the $1/n^4$ term from (11.63). The complete relativistic finite

mass correction includes also the mass-scaling terms $-(\mu/M)\langle 4H_{\text{mass}} + 3H_{\text{D}} + 3H_{\text{oo}}\rangle$ obtained by expanding μ/m_{e} in (11.47). The $\langle\delta(\boldsymbol{r}_1)\rangle$ term is [11.58]

$$
\begin{aligned}
\pi\langle\delta(\boldsymbol{r}_1)\rangle &\to \frac{Z^3}{2} - \frac{31}{4Z^3}\langle r^{-4}\rangle + \frac{1447}{32Z^5}\langle r^{-7}\rangle \\
&\quad - \frac{-31(Z-1)}{2Z^3}\left(\frac{\mu}{M}\right)\langle r^{-4}\rangle + \cdots.
\end{aligned}
$$
(11.67)

$\langle\delta(\boldsymbol{r}_{12})\rangle$ vanishes exponentially as $1/n^{2L+4}$ with increasing L. The complete asymptotic expressions for the FS matrix elements are summarized by the formulas

$$
\begin{aligned}
&\langle nL\,{}^3L_J|H_{\text{FS}}|nL\,{}^3L_J\rangle \\
&\to T_{nL}(J)\{Z - 3 + 2S_L(J) + 2a_{\text{e}}[Z - 2 \\
&\quad + (2 + a_{\text{e}})S_L(J)] + (\mu/M)[2 - 4S_L()]\},
\end{aligned}
$$
(11.68)

$$
\begin{aligned}
&\langle nL\,{}^3L_J|H_{\text{FS}}|nL\,{}^1L_J\rangle \\
&\to T_{nL}(L)(Z + 1 + 2a_{\text{e}}Z - 2\mu/M)\sqrt{L(L+1)},
\end{aligned}
$$
(11.69)

where

$$
T_{nL}(J) = \begin{cases}
-\alpha^2(L+1)\langle r^{-3}\rangle/4 & J = L - 1, \\
-\alpha^2\langle r^{-3}\rangle/4 & J = L, \\
\alpha^2 L\langle r^{-3}\rangle/4 & J = L + 1,
\end{cases}
$$

$$
S_L(J) = \begin{cases}
1 & J = L, \\
\pm 1/(2J+1) & J = L \pm 1.
\end{cases}
$$

The asymptotic form for the QED term $\Delta E_{L,1}$ follows from (11.38) with the use of (11.67) for $\langle\delta(\boldsymbol{r}_1)\rangle$ and (11.41) for $\ln k_0$. The electron–electron part is

$$
\Delta E_{L,2} \to -\frac{7\alpha^3}{6\pi}\left(\langle r^{-3}\rangle + \frac{3}{Z^2}\langle r^{-5}\rangle\right).
$$
(11.70)

With the use of the formulas in this section, the variationally calculated ionization energies for the K-states ($L = 7$) in Table 11.7 can be reproduced to within ± 20 Hz. For $L > 7$, the uncertainty becomes less than 1 Hz, up to the Casimir-Polder retardation effects which have not been included.

11.5 Radiative Transitions

11.5.1 Basic Formulation

In a semiclassical picture, the interaction Hamiltonian with the radiation field is obtained by making the minimal coupling replacements

$$
\begin{aligned}
\boldsymbol{P}_{\text{N}} &\to \boldsymbol{P}_{\text{N}} - \frac{Ze}{c}\boldsymbol{A}(\boldsymbol{R}_{\text{N}}) \\
\boldsymbol{P}_i &\to \boldsymbol{P}_i + \frac{e}{c}\boldsymbol{A}_i(\boldsymbol{R}_i)
\end{aligned}
$$
(11.71)

in (11.1), where

$$
\boldsymbol{A}(\boldsymbol{R}) = c\left(\frac{2\pi\hbar}{\omega\mathcal{V}}\right)^{1/2}\hat{\boldsymbol{\epsilon}}\,\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}}
$$
(11.72)

is the time-independent part of the vector potential $\boldsymbol{A}(\boldsymbol{r}, t) = \boldsymbol{A}(\boldsymbol{r})\,\mathrm{e}^{-\mathrm{i}\omega t} + \text{c.c}$ for a photon of frequency ω, wave vector $\boldsymbol{k}$, and polarization $\hat{\boldsymbol{\epsilon}} \perp \boldsymbol{k}$ normalized to unit photon energy $\hbar\omega$ in volume $\mathcal{V}$. The linear coupling terms then yield

$$
H_{\text{int}} = -\frac{Ze}{Mc}\boldsymbol{P}_{\text{N}}\cdot\boldsymbol{A}(\boldsymbol{R}_{\text{N}}) + \frac{e}{m_{\text{e}}c}\sum_{i=1}^{2}\boldsymbol{P}_i\cdot\boldsymbol{A}(\boldsymbol{R}_i),
$$
(11.73)

and from Fermi's Golden Rule, the decay rate for spontaneous emission from state γ to γ' is

$$
w_{\gamma,\gamma'}\,\mathrm{d}\Omega = \frac{2\pi}{\hbar}|\langle\gamma|H_{\text{int}}|\gamma'\rangle|^2\rho_f,
$$
(11.74)

where $\rho_f = \mathcal{V}\omega^2\,\mathrm{d}\Omega/(2\pi c)^3\hbar$ is the number of photon states with polarization $\hat{\boldsymbol{\epsilon}}$ per unit energy and solid angle in the normalization volume $\mathcal{V}$. In the long wavelength and electric dipole approximations, the factor $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}}$ in (11.72) is replaced by unity. After integrating over angles $\mathrm{d}\Omega$ and summing over polarizations $\hat{\boldsymbol{\epsilon}}$, the decay rate reduces to

$$
w_{\gamma,\gamma'} = \frac{4}{3}\alpha\omega_{\gamma,\gamma'}|\langle\gamma|\boldsymbol{Q}_p|\gamma'\rangle|^2,
$$
(11.75)

where $\omega_{\gamma',\gamma}$ is the transition frequency and $\boldsymbol{Q}_p$ is the velocity form of the transition operator

$$
\boldsymbol{Q}_p = -\frac{Z}{Mc}\boldsymbol{P}_{\text{N}} + \frac{1}{m_{\text{e}}c}\sum_{i=1}^{N}\boldsymbol{P}_i
$$
(11.76)

for the general case of N electrons. From the commutator $[H_0, \boldsymbol{Q}_r/\hbar\omega_{\gamma,\gamma'}] = \boldsymbol{Q}_p$, where H_0 is the field-free Hamiltonian in (11.1), the equivalent length form is

$$
\boldsymbol{Q}_r = -\frac{i}{c}\omega_{\gamma,\gamma'}\left(Z\boldsymbol{R}_{\text{N}} - \sum_{i=1}^{N}\boldsymbol{R}_i\right).
$$
(11.77)

After transforming to c.m. plus relative coordinates in parallel with (11.3), the dipole transition operators become

$$Q_p = \frac{Z_p}{m_e c} \sum_{i=1}^{N} p_i , \quad Q_r = \frac{i\omega_{\gamma,\gamma'}}{c} Z_r \sum_{i=1}^{N} r_i ,$$

(11.78)

with

$$Z_p = \frac{Zm_e + M}{M} , \quad Z_r = \frac{Zm_e + M}{Nm_e + M} ,$$

and H_0 now contains the H_{mp} term. If (11.3) is solved exactly for the states $|\gamma\rangle$ and $|\gamma'\rangle$, then the identity

$$\langle\gamma|Q_p|\gamma'\rangle = \langle\gamma|Q_r|\gamma'\rangle$$

(11.79)

is satisfied to all orders in m_e/M. For a neutral atom, $N = Z$ and $Z_r = 1$. If the oscillator strength is defined by

$$f_{\gamma',\gamma} = \frac{2m_e\omega_{\gamma',\gamma}}{3\hbar} \left(\frac{Z_r}{Z_p}\right) \left|\left\langle\gamma'\left|\sum_{i=1}^{N} r_i\right|\gamma\right\rangle\right|^2$$

$$= \frac{2}{3m_e\hbar\omega_{\gamma',\gamma}} \left(\frac{Z_p}{Z_r}\right) \left|\left\langle\gamma'\left|\sum_{i=1}^{N} p_i\right|\gamma\right\rangle\right|^2$$

(11.80)

then the sum rule $\sum_{\gamma'} f_{\gamma',\gamma} = N$ remains valid, independent of m_e/M. The decay rate, summed over final states and averaged over initial states, is

$$\bar{w}_{\gamma,\gamma'} = -\frac{2\alpha\hbar\omega_{\gamma,\gamma'}^2}{m_e c^2} Z_p Z_r \bar{f}_{\gamma,\gamma'} ,$$

(11.81)

where $\bar{f}_{\gamma,\gamma'} = -(g'_\gamma/g_\gamma)\bar{f}_{\gamma',\gamma}$ is the (negative) oscillator strength for photon emission, and g'_γ, g_γ are the statistical weights of the states.

11.5.2 Oscillator Strength Table

Table 11.11 provides arrays of nonrelativistic oscillator strengths among various states of helium, including the effects of finite nuclear mass as a separate factor. In the absence of mass polarization, the correction factor would be $(1 + \mu/M)^{-1} \simeq 1 - \mu/M$. Mass polarization effects are particularly strong for P-states, and for transitions with $\Delta n = 0$.

The largest relativistic correction comes from singlet–triplet mixing between states with the same n, L, and J (e.g. $3\,^1D_2$ and $3\,^3D_2$) due to H_{FS}. The wave functions obtained by diagonalizing the 2×2 matrices

$H_0 + H_{\text{NFS}} + H_{\text{FS}}$ are then

$$\Psi(n\,^1L_L) = \Psi_0(n\,^1L_L)\cos\theta + \Psi_0(n\,^3L_L)\sin\theta$$
$$\Psi(n\,^3L_L) = -\Psi_0(n\,^1L_L)\sin\theta + \Psi_0(n\,^3L_L)\cos\theta\,.$$

Values of $\sin\theta$ are listed in Table 11.12. The corrected oscillator strengths $\tilde{f}_{\gamma,\gamma'}$ for the singlet (s) and triplet (t) components of a $\gamma \to \gamma'$ transition can then be calculated from the values in Table 11.11 according to

$$\tilde{f}^{ss}_{\gamma,\gamma'} = \omega^{ss}_{\gamma,\gamma'}\left(X^{ss}_{\gamma,\gamma'}\cos\theta_\gamma\cos\theta_{\gamma'}\right.$$
$$\left. +X^{tt}_{\gamma,\gamma'}\sin\theta_\gamma\sin\theta_{\gamma'}\right)^2,$$

$$\tilde{f}^{tt}_{\gamma,\gamma'} = \omega^{tt}_{\gamma,\gamma'}\left(X^{ss}_{\gamma,\gamma'}\sin\theta_\gamma\sin\theta_{\gamma'}\right.$$
$$\left. +X^{tt}_{\gamma,\gamma'}\cos\theta_\gamma\cos\theta_{\gamma'}\right)^2,$$

$$\tilde{f}^{st}_{\gamma,\gamma'} = \omega^{st}_{\gamma,\gamma'}\left(X^{ss}_{\gamma,\gamma'}\cos\theta_\gamma\sin\theta_{\gamma'}\right.$$
$$\left. -X^{tt}_{\gamma,\gamma'}\sin\theta_\gamma\cos\theta_{\gamma'}\right)^2,$$

$$\tilde{f}^{ts}_{\gamma,\gamma'} = \omega^{ts}_{\gamma,\gamma'}\left(X^{ss}_{\gamma,\gamma'}\sin\theta_\gamma\cos\theta_{\gamma'}\right.$$
$$\left. -X^{tt}_{\gamma,\gamma'}\cos\theta_\gamma\sin\theta_{\gamma'}\right)^2,$$

where $X^{\mathrm{ss}}_{\gamma,\gamma'} = (f^{\mathrm{ss}}_{\gamma,\gamma'}/\omega^{\mathrm{ss}}_{\gamma,\gamma'})^{1/2}$, and similarly for $X^{\mathrm{tt}}_{\gamma,\gamma'}$. From (11.80), $X_{\gamma,\gamma'}$ is proportional to the dipole *length* form of the transition operator, for which there are no spin-dependent relativistic corrections [11.59, 60]. The mixing corrections are particularly significant for D–F and F–G transitions, where intermidiate coupling prevails. The two-state approximation becomes increasingly accurate with increasing L, but for P-states, where $\sin\theta$ is small, states with $n' \neq n$ must also be included [11.61].

11.6 Future Perspectives

The variational calculations, together with quantum defect extrapolations for high n and asymptotic expansions for high L, provide essentially exact results for the entire singly-excited spectrum of helium. In this sense, helium joins hydrogen as a fundamental atomic system. The dominant uncertainties arise from two-electron QED effects beyond the current realm of standard atomic physics. Transition frequencies from the $1s2s$ $^1S_0$ state are now known to better than $\pm0.5\,\mathrm{MHz}$ (±1.8 parts in 10^9) [11.62, 63], and the fine structure intervals in the $1s2p$ ^3P state have been measured to an accuracy exceeding $1\,\mathrm{kHz}$ [11.64]. Comparisons with theory [11.65, 66] hold the promise of determining an "atomic physics" value for the fine structure constant. Transition frequencies among the $n=10$ states are known even more accurately [11.53]. Recent progress in the use of isotope the shift to deduce the size of the nucleus from the nuclear volume effect (see Sect. 90.1) has attracted a great deal of attention, especially for neutron-rich "halo" nuclei such as ^{6}He and ^{11}Li. [11.67, 68]

12. Atomic Multipoles

Often symmetries in the experiment limit the number of nonvanishing multipoles, and frequently only populations proportional to diagonal elements of the density matrix are significant. This chapter studies the physical and geometrical significance of simple multipoles and examines whether symmetries allow a complete characterization of the ensemble with state populations. More thorough treatments can be found elsewhere [12.1].

A typical atomic experiment involves the preparation of an atomic or molecular ensemble, its perturbation by a combination of collisions and external fields, and the characterization of the perturbed system through detection of emitted or scattered particles or quanta. The ensemble can be described by its density matrix, whose full specification generally requires elements between every pair of states in a complete basis set, and whose elements generally depend on spatial position, velocity, and time. The time development of such an ensemble may depend on interactions among the atoms of the ensemble with each other, with external fields, and with external perturbers. Most problems burdened by this much detail are intractable, but fortunately, significant simplifications can usually be made.

In this chapter, only ensembles of homogeneously excited, independent atoms are considered. The spatial and velocity distribution of the atoms is thus assumed to be independent of the quantum-state distribution, and the total density matrix can be factored into the product of a phase-space distribution with a state density matrix that is independent of position and velocity. The assumption is severe and prevents us from treating cases of radiation transfer (see Chapt. 19) where the degree of excitation varies as a function of position or problems of velocity-selective laser excitation. Nevertheless, many experiments in atomic physics do use ensembles that are well-described by our assumption, and even in more complex cases, our model can often serve as a starting point for analysis. Typical of the experiments for which

our approach is well suited are collisionally induced polarization relaxation experiments in a gas cell, either of an excited state or of an optically pumped ground state.

In addition, we shall for the most part focus on a few isolated manifolds, usually a ground-state manifold and one or two excited-state manifolds. Each manifold, we assume, can be described by a given eigenvalue J of the total angular momentum. The qualifier "isolated" means that coherences between manifolds oscillate rapidly in time compared to other processes and can be ignored. These assumptions permit a great simplification and frequently allow a decoupling of the equations of motion, as shown below. The density matrix within each state manifold can be described by multipole moments, which are coefficients of the expansion of the density matrix in irreducible tensor operators, as described in Chapt. 7. Each state multipole is associated with a physical electric or magnetic moment in the atom.

The amount of information which can be imparted to, or obtained from, an atomic ensemble is limited by the finite number of accessible multipole moments. The nature of that information may depend on the time evolution of the multipoles in external fields and their relaxation through collisions. The ideal experiment is a *complete* measurement that determines all the multipoles. Often *over-complete* experiments can be designed, but there is little reason for determining redundant information unless consistency checks are important.

12.1 Polarization and Multipoles

An ensemble is said to be *polarized* if there is a non-statistical distribution of atoms in magnetic sublevels. The type of polarization can be described by the *multipoles* that exist. In many experiments, symmetries in the preparation or detection of the ensemble limit the detectable polarizations to ones caused by different sublevel populations. One can then employ the relatively simple *population* (or *diagonal*) representation. The more general case is discussed in the next section.

As an introduction to the concepts, consider an atomic manifold of total angular momentum 3/2, for example an excited alkali $P_{3/2}$ state. There are four magnetic sublevels $|m\rangle$ with $m = \pm 3/2, \pm 1/2$ so that state populations are given by a four-dimensional population–density vector

$$N = \begin{pmatrix} N_{3/2} \\ N_{1/2} \\ N_{-1/2} \\ N_{-3/2} \end{pmatrix} , \tag{12.1}$$

where N_m is the density of atoms in state $|m\rangle$. If there are no external fields, the time evolution of N is given by

$$\dot{N} = \mathscr{S} - \Gamma N - \boldsymbol{\gamma} \cdot N , \tag{12.2}$$

where $\mathscr{S}$ is the source vector and gives the excitation rate to the various sublevels, Γ is the radiative decay rate, assumed the same for all levels, and $\boldsymbol{\gamma}$ is the collisional matrix, whose elements $-\gamma_{mn}$ give the collisional transition rate from n to m.

The equation of motion is most easily solved if the basis used for the state space exploits the symmetry. Define the "spherical" orthonormal basis of vectors

$$\hat{T}_0 = \frac{1}{2} \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} , \qquad \hat{T}_1 = \frac{1}{\sqrt{20}} \begin{pmatrix} 3 \\ 1 \\ -1 \\ -3 \end{pmatrix} , \tag{12.3}$$

$$\hat{T}_2 = \frac{1}{2} \begin{pmatrix} 1 \\ -1 \\ -1 \\ 1 \end{pmatrix} , \qquad \hat{T}_3 = \frac{1}{\sqrt{20}} \begin{pmatrix} 1 \\ -3 \\ 3 \\ -1 \end{pmatrix} . \tag{12.4}$$

(These relations follow from the T_{LM} with $M = 0$. See Sects. 12.2 and 12.3). The population vector N can be expanded

$$N = \sum_{L=0}^{4} n_L \hat{T}_L , \tag{12.5}$$

where the coefficients $n_L = N \cdot \hat{T}_L$ contain all the knowable information about the population distribution. The coefficient n_L is called the $2L$ multipole moment of the ensemble. In particular, $n_0 = \frac{1}{2} \sum_m N_m$ is twice the population of the entire ensemble; $n_1 = 5^{-1/2} \sum_m m N_m = 2n_0 \langle J_z \rangle / \sqrt{5}$ is the "orientation" (associated with a physical magnetic-dipole moment) of the system, $n_2 = \frac{1}{3} n_0 \langle 3J_z^2 - J^2 \rangle$ is the "alignment" (electric quadrupole moment), and $n_3 = (2n_0/\sqrt{45}) \langle J_z(5J_z + 1 - 3J^2) \rangle$ is the octupole moment of N. The source vector $\mathscr{S}$ is readily expanded in the same basis.

If the collisions are isotropic, as is usually approximately the case in gas-cell experiments, then the collision matrix $\boldsymbol{\gamma}$ is invariant under rotations and

$$\boldsymbol{\gamma} \cdot \hat{T}_L = \gamma_L \hat{T}_L . \tag{12.6}$$

The equation of motion (12.2) is separated into four uncoupled scalar equations:

$$\dot{n}_L = \mathscr{S}_L - \Gamma n_L - \gamma_L n_L . \tag{12.7}$$

If the source term $\mathscr{S}_L = \mathscr{S} \cdot \hat{T}_L$ is constant, (12.7) have the simple solutions

$$n_L(t) = n_L(\infty) \\ \qquad + [n_L(0) - n_L(\infty)] \exp[-(\Gamma + \gamma_L) t] , \tag{12.8}$$

with the steady-state value

$$n_L(\infty) = \mathscr{S}_L / (\Gamma + \gamma_L) . \tag{12.9}$$

The detection of such multipoles is discussed at the end of Sect. 12.4.

12.2 The Density Matrix in Liouville Space

If in the example of the last section the state basis is changed, say by rotating the axis of quantization, then populations are generally no longer sufficient to characterize the ensemble. In the new basis, the ensemble will have been prepared in a coherent superposition of states. An adequate description for the quantum state of an ensemble in a manifold of n quantum states requires an $n \times n$ density matrix $\boldsymbol{\rho}(t)$ as discussed in Chapt. 7.

The density matrix may be considered a vector in a space, called *Liouville space*, of n^2 dimensions. A convenient set of complex orthonormal basis vectors in this space is given by the irreducible tensor operators T_{LM}:

$$T_{LM}^* \cdot T_{L'M'} := \mathrm{Tr}\left\{ T_{LM}^\dagger T_{L'M'} \right\} = \delta_{LL'}\delta_{MM'} , \tag{12.10}$$

where the trace (Tr) expression is appropriate for the usual $n \times n$ matrix representations of the T_{LM}. Every quantum operator on the manifold can be expanded in the basis $\{T_{LM}\}$, and in particular the density matrix has an expansion

$$\boldsymbol{\rho}(t) = \sum_{LM} \rho_{LM}(t)\, T_{LM} , \tag{12.11}$$

with time-dependent coefficients

$$\begin{aligned} \rho_{LM}(t) = T_{LM}^* \cdot \boldsymbol{\rho}(t) &:= Tr\left[T_{LM}^\dagger \boldsymbol{\rho}(t) \right] \\ &= N\left\langle T_{LM}^\dagger \right\rangle \end{aligned} \tag{12.12}$$

that are identified with the multipole moments of the ensemble. Here, $\langle \cdots \rangle$ indicates the average value over the ensemble and $N = \mathrm{Tr}\{\boldsymbol{\rho}\}$ is the normalization of the density matrix $\boldsymbol{\rho}$, which is often set equal to unity but is sometimes more conveniently set equal to the total density of atoms in the manifold.

The T_{LM} are defined to transform under rotations as spherical harmonics Y_{LM} [12.2, 3]. The expansion (12.11) splits the density matrix into basis vectors T_{LM} which contain the geometric information and scalar coefficients (the multipole moments) $\rho_{LM}(t)$ which contain the physical information about state distributions.

The time dependence of $\boldsymbol{\rho}(t)$ is given by the Schrödinger equation and in the interaction picture takes the form

$$i\hbar\dot{\boldsymbol{\rho}} = [V, \boldsymbol{\rho}] , \tag{12.13}$$

where V is the interaction due to external fields (including radiation) and collisions. When V is expanded and second-order perturbation theory is applied, the time evolution (12.13) can be expressed in a form analogous to (12.2) but with an extra term [12.1]:

$$\boldsymbol{\rho} = \mathscr{S} - \boldsymbol{\Gamma} \cdot \boldsymbol{\rho} - \boldsymbol{\gamma} \cdot \boldsymbol{\rho} - i\boldsymbol{L}_0 \cdot \boldsymbol{\rho} , \tag{12.14}$$

where $\boldsymbol{L}_0$ is the *Liouville operator* arising from the interaction V_0 with slowly varying external fields. Its matrix

elements with $\boldsymbol{\rho}$ are

$$(\boldsymbol{L}_0 \cdot \boldsymbol{\rho})_{mn} = \hbar^{-1} [V_0, \boldsymbol{\rho}]_{mn} = (\omega_m - \omega_n)\, \rho_{mn} , \tag{12.15}$$

where $\omega_m - \omega_n$ are the field-induced frequency splittings between the states.

For example, in a weak magnetic field $B_0\hat{z}$ oriented along the quantization axis $\hat{z}$, $V_0 = \omega_0 J_z$ where $\omega_0 = g_J \mu_B B_0/\hbar$. Since $[J_z, T_{LM}] = M\hbar T_{LM}$ (see Chapt. 7), then assuming that the collisions are isotropic and that the radiative decay rate is the same for all states of the manifold, the expansion of $\boldsymbol{\rho}$ in T_{LM} decouples the equation of motion (12.14) into multipoles:

$$\dot{\rho}_{LM} = \mathscr{S}_{LM} - \Gamma\rho_{LM} - \gamma_L\rho_{LM} - iM\omega_0\rho_{LM} , \tag{12.16}$$

with the solution

$$\begin{aligned} \rho_{LM}(t) = \rho_{LM}(\infty) + \left[\rho_{LM}(0) - \rho_{LM}(\infty) \right] \\ \times \exp\left[-(\Gamma + \gamma_L + iM\omega_0)\, t \right] \end{aligned} \tag{12.17}$$

comprising a transient part that decays as it precesses at the angular rate ω_0 plus a steady-state part that predicts the collisionally broadened Hanle effect (see Chapt. 17):

$$\rho_{LM}(\infty) = \frac{\mathscr{S}_{LM}}{\Gamma + \gamma_L + iM\omega_0} . \tag{12.18}$$

If $M = 0$, the solutions reduce to the field-independent ones given in (12.9). On the other hand, any stray field that is not aligned with an induced multipole moment can rotate the moment and possibly cause systematic measurement errors if not taken into account. Measurements of γ_L in a gas cell at temperature T are frequently used to determine thermally averaged multipole-relaxation cross sections Q_L, defined by

$$\gamma_L = N\bar{v}Q_L , \tag{12.19}$$

where N is the density of perturbers, and the mean relative velocity is $\bar{v} = 2\pi^{-1/2}(2kT/\mu)^{1/2}$, with μ the reduced mass of the polarized-atom/perturber system. Many semiclassical and full quantum calculations of such cross sections have been made, both for atoms [12.1, 4] and for molecules [12.5].

12.3 Diagonal Representation: State Populations

An ensemble is said to be in a *coherent state* when one or more of the off-diagonal elements of the density matrix do not vanish. In a manifold of angular momentum substates of a single total angular momentum j, the ensemble has coherence if and only if it is not axially symmetric, that is, if and only if $[\boldsymbol{\rho}, J_z] \neq 0$. In an ensemble lacking coherence, or one in which any coherence that is present does not affect the observation, only the $N = 2j + 1$ diagonal elements of the $N \times N$ density matrix, those that represent state populations, need be considered. In terms of multipoles, only the N elements ρ_{L0} then play a role; the ρ_{LM} elements with $M \neq 0$ can be safely ignored. Such a *diagonal representation* is valid whenever (1) the time evolution of the system is axially symmetric and (2) either the preparation of the system or its detection is axially symmetric.

12.4 Interaction with Light

A polarized system can be prepared in a variety of ways, including beam splitting in external fields, collisional excitation (including beam-foil excitation of fast beams), or radiative excitation with directed and/or polarized light. Several options for the detection of multipoles also exist, including the measurement of the anisotropy and/or polarization of scattered particles or photons. In this section, the interaction of the atomic ensemble with dipole radiation is considered.

It is convenient to define a *detection operator* for electric dipole radiation of polarization $\hat{\boldsymbol{\epsilon}}$ by

$$\boldsymbol{D}_\lambda \left(\hat{\boldsymbol{\epsilon}} \right) = \sum_\mu \hat{\boldsymbol{\epsilon}} \cdot \boldsymbol{d} \, |\lambda\mu\rangle \, \langle\lambda\mu| \, \boldsymbol{d} \cdot \hat{\boldsymbol{\epsilon}}^* \qquad (12.20)$$

for decay to the state λ. Here, $\boldsymbol{d} = \sum_k e\boldsymbol{r}_k$ is the dipole-moment operator of the atom and μ is a magnetic sublevel of λ. The detection operator is a vector in Liouville space and can be expanded in irreducible tensor operators according to

$$\boldsymbol{D}_\lambda \left(\hat{\boldsymbol{\epsilon}} \right) = \sum_{LM} D_{\lambda LM} \left(\hat{\boldsymbol{\epsilon}} \right) \boldsymbol{T}_{LM} \,, \qquad (12.21)$$

where

$$\begin{aligned} D_{\lambda LM} \left(\hat{\boldsymbol{\epsilon}} \right) &= \boldsymbol{T}_{LM}^* \cdot \boldsymbol{D}_\lambda \left(\hat{\boldsymbol{\epsilon}} \right) \\ &= B_L \left(\lambda \right) \Phi_{LM} \left(\hat{\boldsymbol{\epsilon}} \right) \,, \end{aligned} \qquad (12.22)$$

with the dynamics contained in

$$B_L \left(\lambda \right) = (-1)^{\lambda+L+j+1} \left| d_{j\lambda} \right|^2 \begin{Bmatrix} 1 & L & 1 \\ j & \lambda & j \end{Bmatrix} \,, \qquad (12.23)$$

and the angular dependence in

$$\begin{aligned} \Phi_{LM} \left(\hat{\boldsymbol{\epsilon}} \right) &= (2L+1)^{1/2} \sum_{rs} \hat{\boldsymbol{\epsilon}} \cdot \hat{\boldsymbol{r}} \left(\hat{\boldsymbol{\epsilon}} \cdot \hat{\boldsymbol{s}} \right)^* \\ &\quad \times (-1)^{1-s} \begin{pmatrix} 1 & L & 1 \\ r & \lambda & -s \end{pmatrix} \,. \end{aligned} \qquad (12.24)$$

Here, $\hat{\boldsymbol{r}}$ and $\hat{\boldsymbol{s}}$ range over the unit spherical tensors of rank one, namely $\pm\hat{\boldsymbol{l}} = \mp \left(\hat{\boldsymbol{x}} \pm i\hat{\boldsymbol{y}} \right) / \sqrt{2}$ and $\hat{\boldsymbol{0}} = \hat{\boldsymbol{z}}$ (see also *Omont* [12.6], who gives tables of Φ_{LM}), and $d_{j\lambda}$ is a reduced matrix element of $\boldsymbol{d}$.

The intensity of radiation of polarization $\hat{\boldsymbol{\epsilon}}'$ emitted by an excited ensemble of atoms with state density matrix $\boldsymbol{\rho}$ in its radiative decay to level λ is

$$\begin{aligned} \boldsymbol{\rho}^* \cdot \boldsymbol{D}_\lambda \left(\hat{\boldsymbol{\epsilon}}' \right) &= \sum_{m,n,\mu} \langle\lambda\mu| \, \boldsymbol{d} \cdot \hat{\boldsymbol{\epsilon}}'^* \, |m\rangle \, \rho_{mn} \, \langle n| \, \boldsymbol{d} \cdot \hat{\boldsymbol{\epsilon}}' \, |\lambda\mu\rangle \\ &= \sum_{LM} \rho_{LM} D_{\lambda LM} \,, \end{aligned} \qquad (12.25)$$

and by selection of polarization or spatial distribution, individual multipole components $D_{\lambda LM}$ and hence ρ_{LM} can be determined. The source terms $\mathscr{S}_{LM}$ excited by electric-dipole radiation from an isotropic ground state are given by a linear combination of $D_{\lambda LM}$:

$$\mathscr{S}_{LM} = (2\pi)^2 \sum_{\lambda,\hat{\boldsymbol{\epsilon}}} u_{\hat{\boldsymbol{\epsilon}}} \left(\lambda \right) D_{\lambda LM} \left(\hat{\boldsymbol{\epsilon}} \right) \,, \qquad (12.26)$$

where $u_{\hat{\boldsymbol{\epsilon}}}(\lambda)$ is the energy density of exciting radiation with polarization vector $\hat{\boldsymbol{\epsilon}}$ per unit energy. From the $3-j$ symbol in (12.24), only the $L = 0, 1$, and 2 components of $\boldsymbol{\rho}$ are observable unless the splitting of the Zeeman sublevels of λ are spectroscopically resolved. Similarly, if the ground state is unpolarized and its Zeeman sublevels unresolved, then only $L = 0, 1$, and 2 components of $\boldsymbol{\rho}$ can be excited. To excite higher-order multipoles, the ground state can be polarized by optical pumping [12.7].

As an example, consider the axially symmetric system discussed in Sect. 12.1 with $j = 3/2$ in the excited state and $\lambda = 1/2$ in the ground state. Only the four

diagonal elements of $D(\hat{\boldsymbol{\epsilon}}')$,

$$
\begin{aligned}
D_m\left(\hat{\boldsymbol{\epsilon}}'\right) &= \sum_\mu \left|\langle jm\left|\hat{\boldsymbol{\epsilon}}'\cdot\boldsymbol{d}\right|\lambda\mu\rangle\right|^2 \\
&= |d_{j\lambda}|^2 \sum_{\mu r} |\hat{\boldsymbol{\epsilon}}'\cdot\hat{\boldsymbol{r}}|^2 \begin{pmatrix} \lambda & 1 & j \\ -\mu & r & m \end{pmatrix}^2,
\end{aligned}
$$

are needed for the $2j+1$ values of $m = -j, \ldots, j$, where μ ranges over the $2\lambda+1$ values from $-\lambda$ to λ and $r = \pm 1, 0$. One finds directly

$$
\begin{aligned}
\boldsymbol{D}\left(\hat{\boldsymbol{\epsilon}}'\right) = \frac{|d_{j\lambda}|^2}{12} &\left[\left|\hat{\boldsymbol{\epsilon}}'\cdot-\hat{\boldsymbol{1}}\right|^2 \begin{pmatrix} 3 \\ 1 \\ 0 \\ 0 \end{pmatrix} + \left|\hat{\boldsymbol{\epsilon}}'\cdot\hat{\boldsymbol{0}}\right|^2 \begin{pmatrix} 0 \\ 2 \\ 2 \\ 0 \end{pmatrix} \right. \\
&\left. + \left|\hat{\boldsymbol{\epsilon}}'\cdot\hat{\boldsymbol{1}}\right|^2 \begin{pmatrix} 0 \\ 0 \\ 1 \\ 3 \end{pmatrix} \right].
\end{aligned} \tag{12.27}
$$

The detected signal of polarization $\hat{\boldsymbol{\epsilon}}'$ is proportional to $\boldsymbol{N}\cdot\boldsymbol{D}(\hat{\boldsymbol{\epsilon}}')$, where $\boldsymbol{N}$ is the population–density vector (12.1). Some of the state polarization can be monitored by looking at polarized dipole radiation. If the emitted light is observed as it propagates perpendicular to the polarization vector, the intensities are given to within an overall constant of proportionality by

$$
I_{\sigma\pm} = \boldsymbol{D}\left(\pm\hat{\boldsymbol{1}}\right)\cdot\boldsymbol{N}, \quad I_\pi = \boldsymbol{D}\left(\hat{\boldsymbol{0}}\right)\cdot\boldsymbol{N}, \tag{12.28}
$$

$$
I_\sigma = \boldsymbol{D}\left(\hat{\boldsymbol{\xi}}\right)\cdot\boldsymbol{N} = \frac{1}{2}\left(I_{\sigma+}+I_{\sigma-}\right), \tag{12.29}
$$

where $\hat{\boldsymbol{\xi}}$ is any real unit vector (linear polarization vector) in the xy-plane. The intensities of polarized radiation may also be given in terms of Stokes parameters [12.8] (see also Chapt. 7). By expanding $\boldsymbol{N}$ in the spherical basis vectors $\boldsymbol{T}_L$ as in (12.5), one obtains a detected signal

$$
\boldsymbol{N}\cdot\boldsymbol{D}\left(\hat{\boldsymbol{\epsilon}}'\right) = \sum_{L=0}^{2j+1} n_L D_{\lambda L 0} \tag{12.30}
$$

$$
\begin{aligned}
= \frac{|d_{j\lambda}|^2}{12} &\left[2n_0 \right. \\
&+ \sqrt{5}\left(\left|\hat{\boldsymbol{\epsilon}}'\cdot\hat{\boldsymbol{1}}\right|^2 - \left|\hat{\boldsymbol{\epsilon}}'\cdot-\hat{\boldsymbol{1}}\right|^2\right)n_1 \\
&+ \left.\left(3\left|\hat{\boldsymbol{\epsilon}}'\cdot\hat{\boldsymbol{0}}\right|^2 - 1\right)n_2 \right].
\end{aligned} \tag{12.31}
$$

Thus there is no way to monitor the octupole polarization n_3 from the dipole radiation since $D_{\lambda LM} = 0$ for $L > 2$. To monitor the orientation n_1, the circular polarization must be measured

$$
\frac{\sqrt{5}}{3}\frac{n_1}{n_0} = \frac{I_{\sigma+}-I_{\sigma-}}{2I_\sigma+I_\pi}, \tag{12.32}
$$

since the coefficient $\boldsymbol{D}_{\lambda L 0}$ vanishes for any linear polarization. Conversely, from

$$
\frac{n_2}{2n_0} = \frac{I_\sigma - I_\pi}{2I_\sigma + I_\pi}, \tag{12.33}
$$

alignment is given by linear polarization. However, the denominator in both cases is different from that common in polarization measurements, and indeed, the ratio $(I_{\sigma+}-I_{\sigma-})/(I_{\sigma+}+I_{\sigma-})$ is *not* proportional to the orientation but contains a contribution from the alignment, and $(I_\sigma - I_\pi)/(I_\sigma + I_\pi)$ is not linear in the alignment. The expressions for other total angular momenta j are the same except for the numerical coefficients on the LHS of (12.32) and (12.33). Finally, if the desire is to measure the total excited-state population n_0 without any polarization component (which might rotate in stray external fields), one can choose linear polarization at an angle to make $D_{\lambda 20}$ disappear, namely at the "magic angle" $\theta = \arccos 3^{-1/2} = 54.74$ degrees. Of course, the same angle may be chosen to excite an unpolarized population.

12.5 Extensions

Although the discussion here has focused on cell experiments in which collisional perturbations are isotropic and state manifolds with a given total angular momentum j are well isolated, the concept of state multipoles is also useful in many applications where the collision symmetry is lower and where states with different j values interact, possibly due to the presence of fine and hyperfine structure [12.1]. Applications have been made in electron–atom collisions (Chapt. 7), atom–atom collisions [12.9], and atom–molecule collisions [12.5].

13. Atoms in Strong Fields

Interest in the effect that electric and magnetic fields have on the internal structure of atoms is as old as quantum mechanics itself. In practical terms, an atom's spectrum acts as its signature, and so it is important to understand how electric and magnetic fields alter this characteristic. In this chapter, a summary of the basic nonrelativistic and relativistic theory of electrons and atoms in external magnetic fields is given. Extensions to the case of very strong fields are then introduced for both types of fields.

13.1 Electron in a Uniform Magnetic Field

13.1.1 Nonrelativistic Theory

The nonrelativistic Hamiltonian (in Gaussian units) for an electron in an external field A is [13.1]

$$H = \frac{1}{2m}\left(p - \frac{e}{c}A\right)^2 - \mu \cdot B + eV , \qquad (13.1)$$

where A is the vector potential and V is the scalar potential. The second term in (13.1) must be included to account for the interaction of the electron magnetic moment with an external magnetic field. The potentials A and V are only defined to within a gauge transformation [13.2]:

$$A' = A + \nabla f , \quad V' = V - \frac{1}{c}\frac{\partial f}{\partial t} . \qquad (13.2)$$

We choose the gauge $\nabla \cdot A = 0$ in which the momentum operator $p = i\hbar\nabla$ and vector potential A commute. B is a constant uniform magnetic field with vector potential

$$A = \frac{1}{2}B \times r . \qquad (13.3)$$

μ is the magnetic moment of the electron:

$$\mu = \frac{1}{2}g_e\mu_B\sigma , \qquad (13.4)$$

where the σ_i are the Pauli spin matrices, $\mu_B = e\hbar/2m_e c$ is the Bohr magneton and g_e is the electron g-factor which accounts for the anomalous magnetic moment of the electron (see Sect. 27.4).

Consider now the case of a free electron in a constant uniform field in the z-direction with no scalar potential, i. e., $V = 0$ in (13.1). This case also describes an atom in the limit of strong magnetic fields such that the Coulomb interactions are negligible. In this case, which is different from (13.3), we have

$$B = B\hat{z} \text{ with } \begin{cases} A_x = -By \\ A_y = A_x = 0 \end{cases} . \qquad (13.5)$$

For this field, the operators μ_z, p_x and p_z commute with the Hamiltonian and are therefore conserved. Calling their respective eigenvalues μ_z, p_x and p_z, with $-\infty \leq p_x, p_y \leq \infty$, the eigenstates are written as

$$\psi = e^{i(p_x x + p_z z)/\hbar}\varphi(y) . \qquad (13.6)$$

Calling $y_0 = -cp_x/eB$, φ satisfies

$$-\frac{\hbar^2}{2m}\frac{d^2}{dy^2}\varphi + \frac{1}{2}m\omega_B^2(y - y_0)^2\varphi$$
$$= \left(E + \mu_z B - \frac{p_z^2}{2m}\right)\varphi , \qquad (13.7)$$

which is the Schrödinger equation for a one-dimensional harmonic oscillator with angular frequency $\omega_B = |e|B/mc$, the cyclotron frequency of the electron. The solutions to (13.7) give the eigenstates for an electron in an external homogeneous magnetic field. They are called *Landau levels* [13.1] with energies given by

$$E_n = \left(n + \frac{1}{2} + m_s\right)\hbar\omega_B + \frac{p_z^2}{2m}, \tag{13.8}$$

where $\hbar m_s = \pm\hbar/2$ is the eigenvalue of the z-component of the spin operator s, and eigenfunctions given by

$$\varphi_n(y) = \frac{1}{\sqrt{\pi^{1/2}a_B 2^n n!}}$$
$$\times \exp\left(-\frac{(y - y_0)^2}{2a_B^2}\right) H_n\left(\frac{y - y_0}{a_B}\right), \tag{13.9}$$

where $a_B = \sqrt{\hbar/m\omega_B}$ and the H_n are Hermite polynomials [13.3].

13.1.2 Relativistic Theory

The relativistic analog of (13.1) is given by the Dirac Hamiltonian

$$H_D = c\boldsymbol{\alpha}\cdot\left(\boldsymbol{p} - \frac{e}{c}\boldsymbol{A}\right) + \beta mc^2 + eV, \tag{13.10}$$

where α and β are the 4×4 matrices defined by (9.61). The eigenfunctions of the Dirac Hamiltonian (13.10) are written as four-dimensional spinors:

$$\psi_D = \begin{pmatrix} \psi^{(1)} \\ \psi^{(2)} \\ \psi^{(3)} \\ \psi^{(4)} \end{pmatrix} \equiv \begin{pmatrix} \phi_1 \\ \phi_{-1} \\ \chi_1 \\ \chi_{-1} \end{pmatrix} \equiv \begin{pmatrix} \phi \\ \chi \end{pmatrix}, \tag{13.11}$$

where ϕ and χ are two-dimensional (Pauli) spinors and ϕ_i and χ_i are functions of the coordinates of the electron.

In the case $V = 0$, the lower component χ can be eliminated in the eigenvalue equation $H_D\psi = E\psi$

to obtain a Hamiltonian equation for ϕ only, similar to (13.1) [13.4]. For a field defined by (13.5) one writes ϕ in the form (as in the nonrelativistic case)

$$\phi = e^{i(p_x x + p_z z)/\hbar} f(y). \tag{13.12}$$

Here, $f(y)$ satisfies the equation

$$-\frac{\hbar^2}{2m}\frac{d^2}{dy^2}\varphi + \frac{1}{2}m\omega_B^2(y - y_0)^2\varphi$$
$$= \left(\frac{E^2 - m^2c^4}{2mc^2} + \mu_z B - \frac{p_z^2}{2m}\right)\varphi, \tag{13.13}$$

which reduces to the nonrelativistic form (13.7) in the limit $E \to mc^2$. In (13.13), the term involving μ is not included arbitrarily as in (13.1) but is a consequence of $H_D\phi$, which predicts the value $g = 2$. The value g_e used in (13.4) includes radiative corrections to the Dirac value.

From (13.13) we obtain

$$E_n^2 = 2mc^2\left[\frac{mc^2}{2} + \left(n + \frac{1}{2} + m_s\right)\hbar\omega_B + \frac{p_z^2}{2m}\right], \tag{13.14}$$

and the eigenfunctions $\psi_{m_s}^D$ are

$$\psi_{1/2}^D = N\begin{pmatrix} \dfrac{E + mc^2}{c}\psi_n \\ 0 \\ p_z\psi_n \\ -\dfrac{i\hbar}{a_B}\sqrt{2n}\,\psi_{n-1} \end{pmatrix},$$

$$\psi_{-1/2}^D = N\begin{pmatrix} 0 \\ \dfrac{E + mc^2}{c}\psi_n \\ \dfrac{i\hbar}{a_B}\sqrt{2(n+1)}\,\psi_{n+1} \\ -p_z\psi_n \end{pmatrix}, \tag{13.15}$$

where ψ_n is defined as in (13.6) and (13.9), and N is a normalization constant.

13.2 Atoms in Uniform Magnetic Fields

13.2.1 Anomalous Zeeman Effect

Consider now the nonrelativistic Hamiltonian for a one-electron atom in the presence of an external magnetic field $\boldsymbol{B}$. The one-electron Hamiltonian can be written

as [13.5]

$$H = \frac{1}{2m}p^2 - \frac{1}{4\pi\epsilon_0}\frac{Ze^2}{r} + \xi(r)\boldsymbol{L}\cdot\boldsymbol{S}$$
$$+ \frac{\mu_B}{\hbar}(\boldsymbol{L} + g_e\boldsymbol{S})\cdot\boldsymbol{B} + \frac{e^2}{8mc^2}(\boldsymbol{B}\times\boldsymbol{r})^2, \tag{13.16}$$

where

$$\xi(r) = \frac{1}{2m^2c^2} \frac{Ze^2}{4\pi\epsilon_0} \frac{1}{r^3} . \tag{13.17}$$

The anomalous Zeeman effect corresponds to the case of *weak* magnetic fields such that the magnetic interaction is small compared with the $\boldsymbol{L} \cdot \boldsymbol{S}$ spin-orbit term. The energy shifts are obtained from a perturbation of (13.16) with $\boldsymbol{B} = 0$. The unperturbed wave functions are eigenfunctions of $\boldsymbol{L}^2$, $\boldsymbol{S}^2$, $\boldsymbol{J}^2$ and J_z, with $\boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S}$, but are not eigenfunctions of L_z or S_z. The energy levels with given values of l, s and j split in the presence of a field defined by (13.5) according to

$$\Delta E_{m_j} = g \mu_B B m_j , \tag{13.18}$$

where g is the *Landé splitting factor* given by

$$\begin{aligned} g = g_l & \frac{j(j+1) - s(s+1) + l(l+1)}{2j(j+1)} \\ & + g_e \frac{j(j+1) + s(s+1) - l(l+1)}{2j(j+1)} , \end{aligned} \tag{13.19}$$

where g_e is defined by (13.4), and $g_l = 1 - m_e/M$ to lowest order in m_e/M, where m_e is the electron mass and M is the nuclear mass. To a first approximation, it is often sufficient to take $g_e = 2$ (the Dirac value) and $g_l = 1$. In the case of a many-electron atom, j, l and s are replaced by the *total* angular momenta J, L and S. In the one-electron case (neglecting corrections to g_l or g_e) the g-value is simply

$$g \approx \frac{j + \frac{1}{2}}{l + \frac{1}{2}} , \tag{13.20}$$

which shows that the splitting of the $j = l + \frac{1}{2}$ levels is larger than that of the $j = l - \frac{1}{2}$ levels. The selection rules for the splitting of spectral lines are $\delta m_j = 0$ for components polarized parallel to the field (π components), and $\delta m_j = \pm 1$ for those perpendicular to the field (σ components).

13.2.2 Normal Zeeman Effect

For moderately strong fields up to $B \sim 10^4$ T, the quadratic $(\boldsymbol{B} \times \boldsymbol{r})^2$ term in (13.16) can be neglected. If the spin-orbit interaction term is also neglected, then the energies relative to the field-free eigenvalues E_n are given by

$$E_n(B) = E_n + \mu_B B(m_l + 2m_s) . \tag{13.21}$$

The selection rules for transitions are $\Delta m_s = 0$ and $\Delta m_l = 0, \pm 1$. The transition energy of a spectral line is split into three components, the *Lorentz triplet*

$$\Delta E_n = \Delta E_{n,0} + (\Delta m_l) \hbar \omega_L , \tag{13.22}$$

where $\Delta E_{n,0}$ is the transition energy in the absence of a field, and $\omega_L = |e|B/2m$ is the Larmor frequency. Transitions with $\Delta m_l = 0$ produce the π line at the unshifted transition energy; transitions with $\Delta m_l = \pm 1$ produce the shifted σ lines. Lorentz triplets can be observed in many-electron atoms in which the total spin is zero.

13.2.3 Paschen–Back Effect

We add now to the results of the last section the first-order perturbation caused by the spin-orbit term. The calculation can be performed in closed form for hydrogenic atoms, for which the contribution to the energy of the level n is [13.6]

$$\begin{aligned} \Delta E_n &= 0 , \quad \text{for } l = 0 \\ \Delta E_n &= \frac{\alpha^4 Z^4 \mu c^2}{2n^3} m_l m_s \\ &\quad \times \left[l \left(l + \frac{1}{2} \right) (l+1) \right] , \quad \text{for } l \neq 0 \end{aligned} \tag{13.23}$$

where μ is the reduced mass, $\mu = mM/(m+M)$. A general expression of the relativistic solution for the Paschen–Back effect can be written for the one-electron case in the Pauli approximation in which the eigenstates are given in terms of ϕ in (13.11). Call $\phi_\pm^0$ the eigenfunctions with no external field corresponding to $j = l \pm \frac{1}{2}$ with unperturbed energies $E_\pm^0$ respectively. In terms of the dimensionless variables

$$\begin{aligned} \eta &= \frac{\mu_B B}{E_+ - E_-} , \quad \epsilon = \sqrt{1 + \eta \frac{4m_j}{2l+1} + \eta^2} , \\ \gamma &= \frac{1}{\epsilon} \left(1 + \eta \frac{4m_j}{2l+1} \right) , \end{aligned} \tag{13.24}$$

the energies $E_\pm$ and wave functions $\phi_\pm$ of the states, in the presence of the field B, are

$$E_\pm = \frac{E_+^0}{2} (1 \pm \epsilon + 2m_j \eta) + \frac{E_-^0}{2} (1 \mp \epsilon - 2m_j \eta) \tag{13.25}$$

and

$$\phi_\pm = \pm \sqrt{\frac{1 \pm \gamma}{2}} \phi_+^0 + \sqrt{\frac{1 \mp \gamma}{2}} \phi_-^0 . \tag{13.26}$$

Part B | 13.2

13.3 Atoms in Very Strong Magnetic Fields

The case of *very* strong magnetic fields (i. e., $B > 10^4$ T), such as those encountered at the surface of neutron stars, is also called the *quadratic Zeeman effect*, as the last term in (13.16) is dominant. In this range, perturbation calculations fail to yield good results as the field is too large, and even at fields of the order $B \sim 10^7$ T the Landau high B approximation of (13.8) and (13.9) is not adequate.

Very accurate calculations have been performed using variational finite basis set techniques for both the relativistic Dirac and nonrelativistic Schrödinger Hamiltonians. The calculations use the following relativistic basis set [13.7] that includes nuclear size effects (R is the nuclear size) and contains both asymptotic limits, the Coulomb limit for $B = 0$ and the Landau limit for $B \to \infty$:

$$\psi_{nl}^{(k,\nu)} = \begin{cases} r^{q_k - 1 + 2n} e^{-a_{n\nu}^{(k)} r^2 - \beta \rho^2} \Omega_k & r \le R \\ b_{n\nu}^{(k)} r^{\gamma_\nu - 1 + n} e^{-\lambda r - \beta \rho^2} \Omega_k & r > R \end{cases}$$

(13.27)

with

$$\Omega_k = (\cos \theta)^{l - |m_k|} (\sin \theta)^{|m_k|} e^{im_k \phi} \omega_k , \qquad (13.28)$$

where

$$n = 0, 1, \dots, N_r, \quad k = 1, 2, 3, 4, \quad \nu = 1, 2, 3, 4 ,$$
$$q_1 = q_2 = k_0, \quad q_3 = q_4 = k_0' ,$$
$$m_k = \mu - \sigma_k/2, \quad \sigma_1 = \sigma_3 = 1, \quad \sigma_2 = \sigma_4 = -1 .$$

Here, k refers to the component $\psi^{(k)}$ in (13.11), and λ and β are variational parameters. The power of r at the origin is given by

$$k_0 = \begin{cases} |\kappa| & \text{if } \kappa < 0 \\ |\kappa| + 1 & \text{if } \kappa > 0 , \end{cases} \qquad (13.29)$$

$$k_0' = \begin{cases} |\kappa| + 1 & \text{if } \kappa < 0 \\ |\kappa| & \text{if } \kappa > 0 , \end{cases} \qquad (13.30)$$

The index ν refers to the two regular and two irregular solutions for $r > R$ that match the corresponding powers at the origin k_0 and k_0'.

$$\gamma_1 = \gamma_0, \ \gamma_2 = \gamma_0 + 1, \ \gamma_3 = -\gamma_0, \ \gamma_4 = -\gamma_0 + 1 ,$$

(13.31)

$$\gamma_0 = \sqrt{\kappa^2 - (\alpha Z)^2} , \quad \kappa = \mp \left(\nu \pm \frac{1}{2} \right) + \frac{1}{2} ,$$

(13.32)

$$\omega_1 = \begin{pmatrix} \vartheta_1 \\ 0 \end{pmatrix}, \omega_2 = \begin{pmatrix} \vartheta_{-1} \\ 0 \end{pmatrix} ,$$
$$\omega_3 = \begin{pmatrix} 0 \\ i\vartheta_{-1} \end{pmatrix}, \omega_4 = \begin{pmatrix} 0 \\ i\vartheta_{-1} \end{pmatrix} , \qquad (13.33)$$

where ϑ_k is a two-component Pauli spinor: $\sigma_z \vartheta_k = k \vartheta_i$. For even (odd) parity states, the value of l for the large components ($k = 1, 2$) is an even (odd) number greater than or equal to $|m_k|$ up to $2N_\theta$ (for even parity) or $2N_\theta + 1$ (for odd parity), while for the small components ($k = 3, 4$) it is an odd (even) number greater than or equal to $|m_k|$ up to $2N_\theta + 1$ (for even parity) or $2N_\theta$ (for odd parity), since the small component has a different nonrelativistic parity than the large component. The coefficients $a_{n\nu}^{(k)}$ and $b_{n\nu}^{(k)}$ are determined by the continuity condition of the basis functions and their first derivatives at R. For a point nucleus, the section $r \le R$ is omitted; for a nonrelativistic calculation, take $\alpha = 0$ in the basis set.

Table 13.1 presents relativistic (Dirac) energies for the ground state of one-electron atoms. Values for a point nucleus and finite nuclear size corrections are given. Table 13.2 presents the relativistic energies for $n = 2$

Table 13.1 Relativistic ground state binding energy $-E_{\text{gs}}/Z^2$ and finite nuclear size correction $\delta E_{\text{nuc}}/Z^2$ (in a.u.) of hydrogenic atoms for various magnetic fields B (in units of 2.35×10^5 T). δE_{nuc} should be added to E_{gs}

Table 13.3, which displays the relativistic corrections of the energies of the previous two tables, presents one of the most interesting relativistic results: the change in sign of the relativistic correction of the energy of the ground state at $B \sim 10^7$ T.

13.4 Atoms in Electric Fields

13.4.1 Stark Ionization

An external electric field $\boldsymbol{F}$ introduces the perturbing potential

$$V = -\boldsymbol{d} \cdot \boldsymbol{F}, \tag{13.34}$$

where

$$\boldsymbol{d} = \sum_i q_i \boldsymbol{r}_i \tag{13.35}$$

is the dipole moment of the atom, and i runs over all electrons in the atom. In the case of strong external electric fields, bound states do not exist because the atom ionizes. Consider a hydrogenic atom in a static electric field

$$\boldsymbol{F} = F\hat{\boldsymbol{z}}. \tag{13.36}$$

The total potential acting on the electron is then

$$V_{\text{tot}}(\boldsymbol{r}) = -\frac{e^2 Z}{4\pi\epsilon_0}\frac{1}{r} + eFz. \tag{13.37}$$

Consider the z-dependence of this potential. Call $\rho = \sqrt{x^2 + y^2}$ and $v(z, \rho) = V(x, y, z)$. Unlike the Coulomb case in which $v_{\text{Coul}}(\pm\infty, \rho) = 0$ resulting in an infinite

number of bound states, now $v(\pm\infty, \rho) = \pm\infty$ and v has a local maximum. On the z axis, this maximum occurs at $z_{\max} = -\sqrt{Z|e|/(4\pi\epsilon_0 F)}$ for which $v(z_{\max}, 0) = 0$. There is then a potential barrier through which the electron can tunnel, i. e., there are no bound states any longer but *resonances*. The potential barrier is shallower the stronger the field; the well can contain a smaller number of bound states and ionization occurs.

13.4.2 Linear Stark Effect

The electric field (13.36) produces a dipole potential

$$V_F = eFz = eF r\sqrt{\frac{4\pi}{3}}\, Y_{10}(\hat{\boldsymbol{r}}), \tag{13.38}$$

which does not preserve parity. A first-order perturbation calculation for the energy

$$E_n^{(1)} = \langle n|V_F|n\rangle \tag{13.39}$$

yields null results unless the unperturbed states are degenerate with states of opposite parity.

In the remainder of this chapter, atomic units will be used. Final results for energies can be multiplied by $2R_\infty hc$ to translate to SI or other units. The calculation can be carried out in detail for the case of hydrogenic

atoms [13.8]. In this case it is convenient to work in parabolic coordinates: φ denotes the usual angle in the xy-plane, and

$$\xi = r + z \,,$$
$$\eta = r - z \,. \tag{13.40}$$

The Hamiltonian for a hydrogenic atom with a field $V_F = \frac{1}{2} F (\xi - \eta)$ from (13.38) is

$$(\xi + \eta) H = \xi h_+(\xi) + \eta h_-(\eta) \,. \tag{13.41}$$

The wave function is written in the form

$$\Psi(\xi, \eta, \varphi) = \frac{1}{\sqrt{2\pi Z}} \, \psi_+(\xi) \psi_-(\eta) \mathrm{e}^{\mathrm{i} m_l \varphi} \,, \tag{13.42}$$

with the $\psi_\pm$ satisfying

$$h_\pm(x) \psi_\pm(x) = E \psi_\pm(x) \,, \tag{13.43}$$

where $x = \xi$ for ψ_+ and $x = \eta$ for ψ_-, and

$$h_\pm(x) = -\frac{2}{x} \frac{\mathrm{d}}{\mathrm{d}x} \left(x \frac{\mathrm{d}}{\mathrm{d}x} \right) - \frac{2 Z_\pm}{x} + \frac{m_l^2}{2x^2} \mp \frac{1}{2} Fx \,, \tag{13.44}$$

with

$$Z = Z_+ + Z_- \,. \tag{13.45}$$

Using the notation

$$\epsilon = \sqrt{-2E} \,,$$
$$n_\pm = Z_\pm/\epsilon - \frac{1}{2}(|m_l| + 1) \,,$$
$$n = n_+ + n_- + |m_l| + 1 \,,$$
$$n_+, N_- = 0, 1, \dots , n - |m_l| + 1 \,,$$
$$|m_l| = 0, 1, 2, \dots , n - 1 \,,$$
$$\delta n = n_+ - n_- \,, \tag{13.46}$$

where n is the principal quantum number, the unperturbed eigenfunctions are

$$\psi_\pm(x) = \frac{\epsilon \, n_\pm!^{\frac{1}{2}}}{(n_\pm + |m_l|)!^{\frac{1}{2}}} \, \mathrm{e}^{-\frac{1}{2}\epsilon x} (\epsilon x)^{\frac{1}{2}|m_l|} L_{n_\pm}^{(|m_l|)}(\epsilon x) \,, \tag{13.47}$$

where the $L_b^{(a)}$ are generalized Laguerre polynomials (Sect. 9.4.2). The zero-order eigenvalues are

$$Z_\pm^{(0)} = \left(n_\pm + \frac{m_l + 1}{2} \right) \epsilon \,. \tag{13.48}$$

The first-order perturbation yields

$$Z_\pm^{(1)} = \pm \frac{1}{4} \frac{F}{\epsilon^2} \big[6n_\pm(n_\pm + m_l + 1) + m_l(m_l + 3) + 2 \big] \,. \tag{13.49}$$

From these

$$\epsilon = \frac{Z}{n} - \frac{3}{2 \, F \left(\frac{n}{Z} \right)^2 \delta_n} \,, \tag{13.50}$$

and to first order in F,

$$E = -\frac{1}{2} \epsilon^2 \approx E^{(0)} + E^{(1)} \,,$$
$$E^{(0)} = -\frac{1}{2} \frac{Z^2}{n^2} \,,$$
$$E^{(1)} = \frac{3}{2} \frac{F}{Z} n \, \delta_n \,. \tag{13.51}$$

13.4.3 Quadratic Stark Effect

A perturbation linear in the field F yields no contribution to nondegenerate states (e.g., the ground state $n_+ = n_- = m = 0$; $n = 1$). In this case, the lowest order contribution comes from the *quadratic Stark effect*, the contribution of order F^2. The quadratic perturbation to a level $E_n^{(0)}$ caused by a general electric field $\boldsymbol{F}$ can be written in terms of the symmetric tensor α_{ij}^n as

$$E_n^{(2)} = -\frac{1}{2} \alpha_{ij}^n \, F_i \, F_j \,, \tag{13.52}$$

with

$$\alpha_{ij}^n = -2 \sum_{\substack{m \\ m \neq n}} \frac{\langle n \, |d_i| \, m \rangle \langle m \, |d_j| \, n \rangle}{E_n - E_m} \,, \tag{13.53}$$

where d_i is defined in (13.35).

For a field (13.36),

$$\Delta E_n = -\frac{1}{2} \alpha^n \, F^2 \,, \tag{13.54}$$

where

$$\alpha^n \equiv \alpha_{zz}^n = -2e^2 \sum_{\substack{m \\ m \neq n}} \frac{|\langle n \, |z| \, m \rangle|^2}{E_n - E_m} \,. \tag{13.55}$$

In terms of (13.46), a general nonrelativistic expression for the *dipole polarizability* of hydrogenic ions is [13.9]

$$\alpha^n = \frac{a_0^3 n^4}{8 Z^4} \left(17 n^2 - 3 \delta_n^2 - 9 m_l^2 + 19 \right) \,. \tag{13.56}$$

For the ground state of hydrogenic atoms,

$$\alpha^{n=1} = \frac{9 a_0^3}{2 Z^4} \,. \tag{13.57}$$

Table 13.4 lists the *relativistic* values for the ground state polarizability $\alpha_{\mathrm{rel}}^{n=1}$, obtained by calculating (13.55)

using relativistic variational basis sets [13.10]. The values are interpolated by

$$\alpha^{n=1} = \frac{a_0^3}{Z^4} \left[\frac{9}{2} - \frac{14}{3}(\alpha Z)^2 + 0.53983(\alpha Z)^4 \right] .$$

(13.58)

13.4.4 Other Stark Corrections

Third Order Corrections
For the energy correction cubic in the external field (13.36), one obtains [13.9]

$$E^{(3)} = \frac{3}{32} F^3 \left(\frac{n}{Z} \right)^7 \\ \times \delta_n \left(23n^2 - \delta_n^2 + 11m_l^2 + 39 \right) .$$

(13.59)

Relativistic Linear Stark–Shift of the Fine Structure of Hydrogen
For a Stark effect small relative to the fine structure, the degenerate levels corresponding to the same value of j split according to

$$\delta_m E_{nj} = \frac{3}{4} \sqrt{n^2 - \left(j + \frac{1}{2} \right)^2} \frac{nm}{j(j+1)} F .$$

(13.60)

Other Stark Corrections in Hydrogen
The expectation value of the delta function, is, in a.u. [13.11],

$$2\pi \langle 1s| \delta(\boldsymbol{r})| 1s \rangle = 2 - 31 F^2 .$$

(13.61)

Table 13.4 Relativistic dipole polarizabilities for the ground state of hydrogenic atoms

Z	$\alpha_{rel}^{n=1} \, Z^4 / (a_0^3)$
1	4.499 7515
5	4.493 7883
10	4.475 1644
20	4.400 8376

80	2.972 1524
90	2.587 7205
100	2.168 6483

For the Bethe logarithm β defined by

$$\beta_{1s} = \frac{\sum_n |\langle 1s |\boldsymbol{p}| n \rangle|^2 (E_n - E_{1s}) \ln |E_n - E_{1s}|}{\sum_n |\langle 1s |\boldsymbol{p}| n \rangle|^2 (E_n - E_{1s})} ,$$

(13.62)

the result is [13.12]

$$\beta_{1s} = 2.290\,981\,375\,205\,552\,301 \\ + 0.316\,205(6)\, F^2 .$$

(13.63)

These results are useful in calculating an asymptotic expansion for the two-electron Bethe logarithm [13.13].

13.5 Recent Developments

The drastic change of an atom's internal structure in the presence of external electric and magnetic fields is shown most clearly through the changes induced in its spectral features. Of these features, avoided crossings are a distinctive example. Recent work in this area by *Férez* and *Dehesa* [13.14] has suggested the use of Shannon's information entropy [13.15], defined by

$$S = -\int \rho(\boldsymbol{r}) \ln \rho(\boldsymbol{r}) \mathrm{d}\boldsymbol{r} ,$$

(13.64)

where $\rho(\boldsymbol{r}) = |\psi(\boldsymbol{r})|^2$, as an indicator or predictor of such irregular features of atomic spectra. By studying some excited states of hydrogen in parallel fields it was shown that, for the states involved, a marked confinement of the electron cloud and an information-theoretic

exchange occurs when the magnetic field strength is adjusted adiabatically through the region of an avoided crossing. The field strengths studied are characteristic of compact astronomical objects, such as white dwarfs and neutron stars.

Although the effects of strong magnetic fields on the structure and dynamics of hydrogen have been known for some time, knowledge of the helium atom in such fields has only recently become sufficient for comparison with astrophysical observations [13.16–18]. As one example of their importance, such studies have proven critical in showing the presence of helium in the atmospheres of certain magnetic white dwarfs [13.19].

In recent years, the increased sophistication and resolution of observation techniques has not only in-

creased the number of known astronomical objects, but also motivated the study of the effects of strong fields on heavier atoms [13.20].

Another interesting area of current research concerns the relationship between quantum mechanics and classically chaotic systems. For these studies, Rubidium Rydberg atoms are an ideal system since laboratory fields can easily push the atom to the strong-field limit [13.21–23].

For a very useful review of various topics up to 1998 see [13.24]; a more concise review, concerning the electronic structure of atoms, molecules, and bulk matter, including some properties of dense plasma, in strong fields, is given in [13.25].

14. Rydberg Atoms

Rydberg atoms are those in which the valence electron is in a state of high principal quantum number n. They are of historical interest since the observation of Rydberg series helped in the initial unraveling of atomic spectroscopy [14.1]. Since the 1970s, these atoms have been studied mostly for two reasons. First, Rydberg states are at the border between bound states and the continuum, and any process which can result in either excited bound states or ions and free electrons usually leads to the production of Rydberg states. Second, the exaggerated properties of Rydberg atoms allow experiments to be done which would be difficult or impossible with normal atoms.

14.1 Wave Functions and Quantum Defect Theory

Many of the properties of Rydberg atoms can be calculated accurately using quantum defect theory, which is easily understood by starting with the H atom [14.2]. We shall use atomic units, as discussed in Sect. 1.2. The Schrödinger equation for the motion of the electron in a H atom in spherical co-ordinates is

$$\left(-\frac{1}{2}\nabla^2 - \frac{1}{r}\right)\Psi(r, \theta, \phi) = E\Psi(r, \theta, \phi) , \qquad (14.1)$$

where E is the energy, r is the distance between the electron and the proton, and θ and ϕ are the polar and azimuthal angles of the electron's position. Equation (14.1) can be separated, and its solution expressed as the product

$$\Psi(r, \theta, \phi) = R(r)Y_{\ell m}(\theta, \phi) , \qquad (14.2)$$

where ℓ and m are the orbital and azimuthal-orbital angular momentum (i. e., magnetic) quantum numbers and $Y_{\ell m}(\theta, \phi)$ is a normalized spherical harmonic. $R(r)$ satisfies the radial equation

$$\frac{d^2 R(r)}{dr^2} + \frac{2}{r}\frac{dR(r)}{dr} + 2ER(r) + \frac{2R(r)}{r} = \frac{\ell(\ell+1)R}{r^2} , \qquad (14.3)$$

which has the two physically interesting solutions

$$R(r) = \frac{f(\ell, E, r)}{r} , \qquad (14.4)$$

$$R(r) = \frac{g(\ell, E, r)}{r} . \qquad (14.5)$$

The f and g functions are the regular and irregular Coulomb functions which are the solutions to a variant of (14.3). As $r \to 0$ they have the forms [14.3]

$$f(\ell, E, r) \propto r^{\ell+1} , \qquad (14.6)$$

$$g(\ell, E, r) \propto r^{-\ell} , \qquad (14.7)$$

irrespective of whether E is positive or negative. As $r \to \infty$, for $E > 0$ the f and g functions are sine and cosine waves, i. e., there is a phase shift of $\pi/2$ between them. For $E < 0$ it is useful to introduce ν, defined by $E = -1/2\nu^2$, and for $E < 0$ as $r \to \infty$

$$f = u(\ell, \nu, r)\sin \pi\nu - \nu(\ell, \nu, r)e^{i\pi\nu} , \qquad (14.8)$$

$$g = -u(\ell, \nu, r)\cos \pi\nu + v(\ell, \nu, r)e^{i\pi(\nu+1/2)} , \qquad (14.9)$$

where u and v are exponentially increasing and decreasing functions of r. As $r \to \infty$, $u \to \infty$ and $v \to 0$.

Requiring that the wave function be square integrable means that as $r \to 0$ only the f function is allowed. Equation (14.8) shows that the $r \to \infty$ boundary condition requires that $\sin \pi \nu$ be zero or ν an integer n, leading to the hydrogenic Bohr formula for the energies:

$$E = -\frac{1}{2n^2} . \tag{14.10}$$

The classical turning point of an s wave occurs at $r = 2n^2$, and the expectation values of positive powers of r reflect the location of the outer turning point, i.e.,

$$\langle r^k \rangle \approx n^{2k} . \tag{14.11}$$

The expectation values of negative powers of r are determined by the properties of the wave function at small r. The normalization constant of the radial wave function scales as $n^{-3/2}$, so that $R(r) \propto n^{-3/2} r^{\ell+1}$ for small r. Accordingly, the expectation values of negative powers of r, except r^{-1}, and any properties which depend on the small r part of the wave function, scale as n^{-3}. Using the properties of the wave function and the energies, the n-scaling of the properties of Rydberg atoms can be determined.

The primary reason for introducing the Coulomb waves instead of the more common Hermite polynominal solution for the radial function is to set the stage for single channel quantum defect theory, which enables us to calculate the wave functions and properties of one valence electron atoms such as Na. The simplest picture of an Na Rydberg atom is an electron orbiting a positively charged Na$^+$ core consisting of 10 electrons and a nucleus of charge $+11$. The ten electrons are assumed to be frozen in place with spherical symmetry about the nucleus, so their charge cloud is not polarized by the outer valence electron, although the valence electron can penetrate the ten-electron cloud. When the electron penetrates the charge cloud of the core electrons, it sees a potential well deeper than $-1/r$ due to the decreased shielding of the $+11$ nuclear charge. For Na and other alkali atoms, we assume that there is a radius r_c such that for $r < r_c$ the potential is deeper than $-1/r$, and for $r > r_c$ it is equal to $-1/r$. As a result of the deeper potential at $r < r_c$, the radial wave function is pulled into the core in Na, relative to H, as shown in Fig. 14.1. For $r \geq r_c$, the potential is a Coulomb $-1/r$ potential, and $R(r)$ is a solution of (14.3) which can be expressed
Fig. 14.1 Radial wave functions for H and Na showing that the Na wave function is pulled in toward the ionic core

as

$$R(r) = \left[f(\ell, \nu, r) \cos \tau_\ell - g(\ell, \nu, r) \sin \tau_\ell \right]/r , \tag{14.12}$$

where τ_ℓ is the radial phase shift.

Near the ionization limit, $E \sim 0$, and as a result, the kinetic energy of the Rydberg electron is greater than $1/r_c$ ($\sim 10 \, \text{eV}$) when $r < r_c$. As a result, changes in E of $0.10 \, \text{eV}$, the $n = 10$ binding energy, do not appreciably alter the phase shift τ_ℓ, and we can assume τ_ℓ to be independent of E. The ℓ dependence of τ_ℓ arises because the centrifugal $\ell(\ell+1)/r$ term in (14.3) excludes the Rydberg electron from the region of the core in states of high ℓ. Applying the $r \to \infty$ boundary condition to the wave function of (14.12) leads to the requirement that the coefficient of u vanish, i.e.,

$$\cos \tau_\ell \sin(\pi \nu) + \sin \tau_\ell \cos(\pi \nu) = 0 , \tag{14.13}$$

which implies that $\sin(\pi \nu + \tau_\ell) = 0$ or $\nu = n - \tau_\ell/\pi$. Usually τ_ℓ/π is written as δ_ℓ and termed the quantum defect, and the energies of members of the $n\ell$ series are written as

$$E = -\frac{1}{2(n - \delta_\ell)^2} = -\frac{1}{2n^{*2}} , \tag{14.14}$$

where $n^* = n - \delta_\ell$ is often termed the effective quantum number (see also Sect. 11.4.1).

Knowledge of the quantum defect δ_ℓ of a series of ℓ states determines their energies, and it is a straightforward matter to calculate the Coulomb wave function specified in (14.12) using a Numerov algorithm [14.4, 5]. This procedure gives wave functions valid for $r \geq r_c$, which can be used to calculate many of the properties of Rydberg atoms with great accuracy. The effect of core penetration on the energies is easily seen in the energy level diagram of Fig. 14.2. The Na $\ell \geq 2$ states have the same energies as hydro-

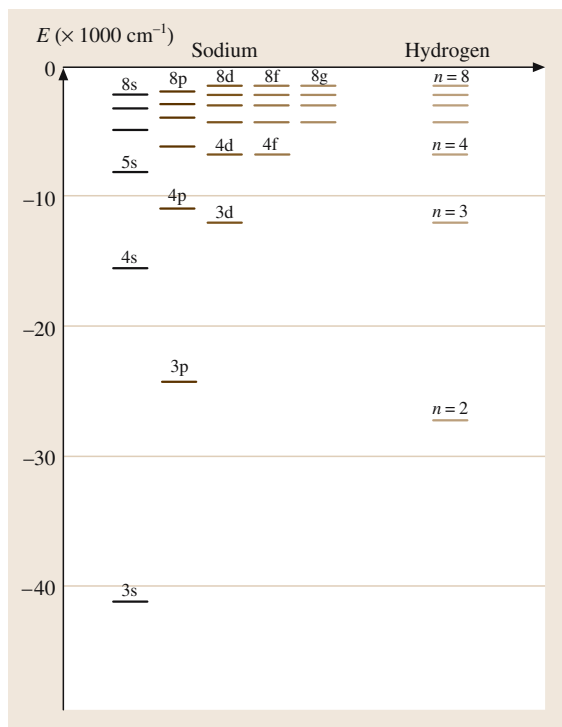
E ($\times 1000$ cm^{-1})


Fig. 14.2 Energy levels of Na and H

gen, while the s and p states, with quantum defects of 1.35 and 0.85 respectively, lie far below the hydrogenic energies.

Although it is impossible to discern in Fig. 14.2, the Na $\ell \geq 2$ states also lie below the hydrogenic energies. For these states it is not core penetration, but core polarization which is responsible for the shift to lower energy. Contrary to our earlier assumption that the outer electron does not affect the inner electrons if $r > r_c$, the outer electron polarizes the inner electron cloud even when $r > r_c$, and the energies of even the high ℓ states fall below the hydrogenic energies. The leading term in the polarization energy is due to the dipole polarizability of the core, α_d. For high ℓ states it gives a quantum defect of [14.6]

$$\delta_\ell = \frac{3\alpha_d}{4\ell^5} .\tag{14.15}$$

Quantum defects due primarily to core polarization rarely exceed 10^{-2}, while those due to core penetration are often greater than one.

14.2 Optical Excitation and Radiative Lifetimes

Optical excitation of the Rydberg states from the ground state or any other low lying state is the continuation of the photoionization cross section σ_{PI} below the ionization limit. The photoionization cross section, discussed more extensively in Chapt. 24, is approximately constant at the limit. Above and below the limit the average photoabsorption cross section is the same, as evidenced by the fact that a discontinuity is not evident in an absorption spectrum, i. e., it is not possible to see where the unresolved Rydberg states end and the continuum begins. Nonetheless, below the limit the cross section is structured by the Δn spacing of $1/n^3$ between adjacent members of the Rydberg series. In any experiment, there is a finite resolution $\Delta\omega$ with which the Rydberg states can be excited. It can arise, for example, from the Doppler width or a laser linewidth. This resolution determines the cross section σ_n for exciting the Rydberg state of principal quantum number n. Explicitly, σ_n is given by

$$\sigma_n = \frac{\sigma_{\mathrm{PI}}}{n^3 \Delta\omega} .\tag{14.16}$$

A typical value for σ_{PI} is 10^{-18} cm^2. For a resolution $\Delta\omega = 1$ cm^{-1} (6×10^{-6} a.u.) the cross section for exciting an $n = 20$ atom is 3×10^{-17} cm^2.

From the wave functions of the Rydberg states, we can also derive the n^{-3} dependence of the photoexcitation cross section. The dipole matrix element from the ground state to a Rydberg state only involves the part of the Rydberg state wave function near the core. At small r, the Rydberg wave function only depends on n through the n^{-3} normalization factor, and as a result, the squared dipole matrix element between the ground state and the Rydberg state and the cross section both have an n^{-3} dependence.

Radiative decay, which is covered in Chapt. 17, is, to some extent, the reverse of optical excitation. The general expression for the spontaneous transition rate from the $n\ell$ state to the $n'\ell'$ state is the Einstein A coefficient, given by [14.2]

$$A_{n\ell,n'\ell'} = \frac{4}{3}\mu_{n\ell,n'\ell'}^2 \omega_{n\ell,n'\ell'}^3 \frac{\alpha^3 g_>}{2g_n+1} ,\tag{14.17}$$

where $\mu_{n\ell,n'\ell'}$ and $\omega_{n\ell,n',\ell'}$ are the electric dipole matrix elements and frequencies of the $n\ell \to n'\ell'$ transitions, g_n and $g_{n'}$ are the degeneracies of the $n\ell$ and $n'\ell'$ states, and $g_>$ is the greater of g_n and $g_{n'}$. The lifetime $\tau_{n\ell}$ of the $n\ell$ state is obtained by summing the decay rates to all possible lower energy states. Explicitly,

$$\frac{1}{\tau_{n\ell}} = \sum_{n'\ell'} A_{n\ell,n'\ell'} . \tag{14.18}$$

Due to the ω^3 factor in (14.17), the highest frequency transition usually contributes most heavily to the total radiative decay rate, and the dominant decay is likely to be the lowest lying state possible. For low-ℓ Rydberg states, the lowest lying ℓ' states are bound by orders of magnitude more than the Rydberg states, and the frequency of the decay is nearly independent of n. Only the squared dipole moment depends on n, as n^{-3}, because of the normalization of the Rydberg wave function at the core. Consequently, for low-ℓ states,

$$\tau_{n\ell} \propto n^3 . \tag{14.19}$$

As a typical example, the 10f state in H has a lifetime of 1.08 μs [14.7].

The highest ℓ states, with $\ell = n-1$, have radiative lifetimes with a completely different n dependence. The only possible transitions are $n \to n-1$, with frequency $1/n^3$. In this case the dipole moments reflect the large size of both the n and $n-1$ states and have the n^2 scaling of the orbital radius. Using (14.17) for $\ell = n-1$ leads to

$$\tau_{n(n-1)} \propto n^5 . \tag{14.20}$$

Another useful lifetime, τ_n, is that corresponding to the average decay rate of all ℓ, m states of the same n. It scales as $n^{4.5}$ [14.2, 8].

Equation (14.17) describes spontaneous decay to lower lying states driven by the vacuum. At room temperature, 300 K, there are many thermal photons at the frequencies of the $n \to n \pm 1$ transitions of Rydberg states for $n \geq 10$, and these photons drive transitions to higher and lower states [14.9]. A convenient way of describing blackbody radiation is in terms of the photon occupation number $\bar{n}$, given by

$$\bar{n} = \frac{1}{e^{\omega/kT} - 1} . \tag{14.21}$$

The stimulated emission or absorption rate $K_{n\ell,n'\ell'}$ from state $n\ell$ to state $n'\ell'$ is given by

$$K_{n\ell,n'\ell'} = \frac{4}{3} \mu_{n\ell,n'\ell'} \omega_{n\ell,n'\ell'}^3 \frac{\alpha^3 \bar{n} g_>}{2g_n+1} . \tag{14.22}$$

Summing these rates over n' and ℓ' gives the total blackbody decay rate $1/\tau_n^{bb}$. Explicitly,

$$\frac{1}{\tau_{n\ell}^{bb}} = \sum_{n'\ell'} K_{n\ell,n'\ell'} . \tag{14.23}$$

The resulting lifetime $\tau_{n\ell}^T$ at any given temperature is given by

$$\frac{1}{\tau_{n\ell}^T} = 1/\tau_{n\ell} + 1/\tau_{n\ell}^{bb} . \tag{14.24}$$

For low-ℓ states with $10 < n < 20$, blackbody radiation produces a 10% decrease in the lifetimes, but for high-ℓ states of the same n, it reduces the lifetimes by a factor of ten. Since $1/\tau_{n\ell}^{bb} \propto n^{-2}$, this term must dominate normal spontaneous emission at high n.

The above discussion of spontaneous and stimulated transitions is based on the implicit assumption that the atoms are in free space. If the atoms are in a cavity, which introduces structure into the blackbody and vacuum fields, the transition rates are significantly altered [14.10]. These alterations are described in Chapt. 79. If the cavity is tuned to a resonance, it increases the transition rate by the finesse of the cavity (approximately the Q for low-order modes). On the other hand, if the cavity is tuned between resonances, the transition rate is suppressed by a similar factor.

14.3 Electric Fields

As a starting point, consider the H atom in a static electric field $\mathcal{E}$ in the z-direction, and focus on the states of principal quantum number n. The field couples ℓ and $\ell \pm 1$ states of the same m by the electric dipole matrix elements. Since the states all have a common zero field energy of $-1/2n^2$, and the off-diagonal Hamiltonian matrix elements are all proportional to $\mathcal{E}$, the eigenstates are field-independent linear combinations of the zero field ℓ states of the same m, and the energy shifts from $-1/2n^2$ are linear in $\mathcal{E}$. In this first-order approximation, the energies are given by [14.2]

$$E = -\frac{1}{2n^2} + \frac{3}{2}(n_1 - n_2)n\mathcal{E} , \tag{14.25}$$

where n_1 and n_2 are parabolic quantum numbers (see Sect. 9.1.2) which satisfy

$$n_1 + n_2 + |m| + 1 = n . \tag{14.26}$$

Consider the $m = 0$ states as an example. The $n_1 - n_2 = n - 1$ state is shifted up in energy by $\frac{3}{2}n(n-1)\mathcal{E}$ and is called the extreme blue Stark state, and the $n_2 - n_1 = n - 1$ state is shifted down in energy by $\frac{3}{2}n(n-1)\mathcal{E}$ and is called the extreme red Stark state. These two states have large permanent dipole moments, and in the red (blue) state the electron spends most of its time on the downfield (upfield) side of the proton as shown in Fig. 14.3, a plot of the potential along the z-axis. We have here ignored the electric dipole couplings to other n states, which introduce small second order Stark shifts to lower energy. As implied by (14.26), states of higher m have smaller shifts. In particular, the circular $m = \ell = n - 1$ state has no first order shift since there are no degenerate states to which it is coupled by the field.

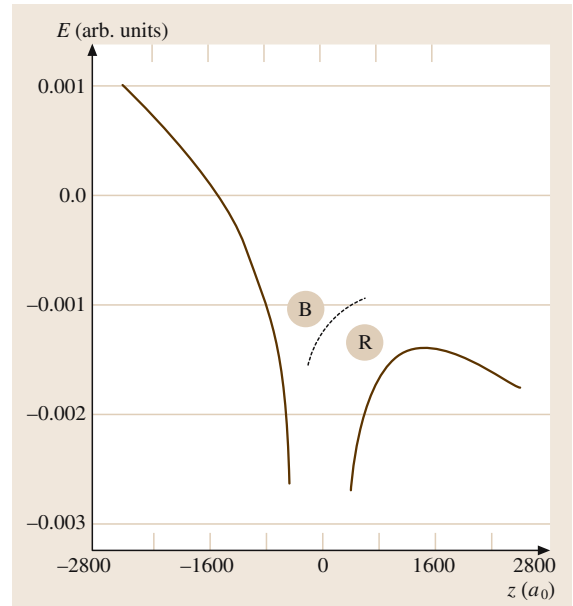
The Stark effect in other atoms is similar, but not identical to that observed in H. This point is shown by Fig. 14.4, a plot of the energies of the Na $m = 0$ levels near $n = 20$. The energy levels are similar to those of H in that most of the levels exhibit apparently linear Stark shifts from the zero field energy of the high-ℓ states. The differences, however, are twofold. First, the levels from s and p states with nonzero quantum defects join the manifold of Stark states at some nonzero field, given


Fig. 14.3 Combined Coulomb–Stark potential along the z-axis when a field of 5×10^{-7} a.u. (2700 V/cm) is applied in the z-direction (*solid*). The extreme red state (R) is near the saddlepoint, and the extreme blue (B) state is held on the upfield side of the atom by an effective potential (*dashed*) roughly analogous to a centrifugal potential
Fig. 14.4 Energies of Na $m = 0$ levels of $n \approx 20$ as a function of electric field. The *shaded region* is above the classical ionization limit

approximately by [14.4]

$$\mathcal{E} = \frac{2\delta'_\ell}{3n^5},$$ (14.27)

where δ'_ℓ is the magnitude of the difference between δ_ℓ and the nearest integer. Second, there are avoided crossings between the blue $n = 20$ and red $n = 21$ Stark states. In H these states would cross, but in Na they do not because of the finite sized Na^+ core, which also leads to the nonzero quantum defects of the ns and np states. This point, and other related points, are described in Chapt. 15.

Field ionization is both intrinsically interesting and of great practical importance for the detection of Rydberg atoms [14.11]. The simplest picture of field ionization can be understood with the help of Fig. 14.4. The potential along the z-axis of an atom in a field $\mathcal{E}$ in the z-direction is given by

$$V = -\frac{1}{r} - \mathcal{E}z.$$ (14.28)

If an atom has an energy E relative to the zero field limit, it can ionize classically if the energy E lies above the saddle point in the potential. The required field is given by

$$\mathcal{E} = \frac{E^2}{4}.$$ (14.29)

Ignoring the Stark shifts and using $E = -1/2n^2$ yields the expression

$$\mathcal{E} = \frac{1}{16n^4}.$$ (14.30)

The H atom ionizes classically as described above, or by quantum mechanical tunneling which occurs at slightly lower fields. Since the tunneling rates increase exponentially with field strength, typically an order of magnitude for a 3% change in the field, specifying the classical ionization field is a good approximation to the field which gives an ionization rate of practical interest. The red and blue states of H ionize at very different fields, as shown by Fig. 14.5, a plot of the $m = 0$ Stark states out to the fields at which the ionization rates are $10^6 \, s^{-1}$ [14.12]. First, note the crossing of the levels of different n mentioned earlier. Second, note that the red states ionize at lower fields than do the blue states, in spite of the fact that they are lower in energy. In the red states, the electron is close to the saddle point of the potential of Fig. 14.3, and it ionizes according to (14.29). If the Stark shift of the extreme red state to lower energy is taken into account, (14.30) becomes

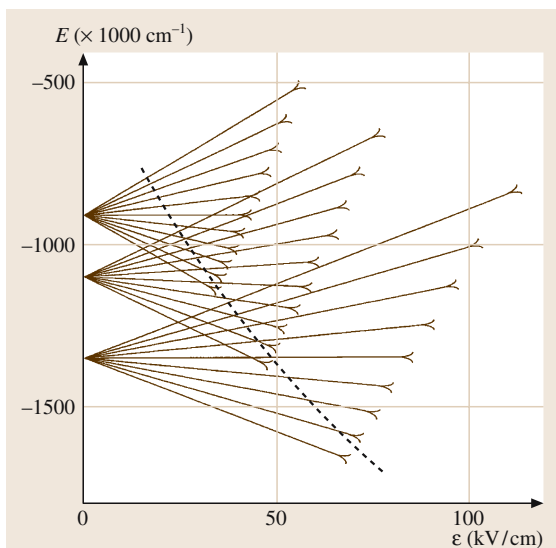
$$\mathcal{E} = \frac{1}{9n^4}.$$ (14.31)


Fig. 14.5 Energies of H $m = 0$ levels of $n = 9$, 10, and 11 as functions of electric field. The widths of the levels due to ionization broaden exponentially with fields, and the onset of the broadening indicated is at an ionization rate of $10^6 \, s^{-1}$. The *broken line* indicating the classical ionization limit, $\mathcal{E} = E^2/4$ passes near the points at which the extreme red states ionize

In the blue state the electron is held on the upfield side of the atom by an effective potential roughly analogous to a centrifugal potential, as shown by Fig. 14.3. At the same field the blue state's energy is lower relative to the saddle point of its potential, shown by the broken line of Fig. 14.3, than is the energy of the red state relative to the saddle point of its potential, given by (14.28) and shown by the solid line of Fig. 14.3. As shown by the broken line of Fig. 14.5, the classical ionization limit of (14.29) is simply a line connecting the ionization fields of the extreme red Stark states. All other states are stable above the classical ionization limit. In the Na atom, ionization of $m = 0$ states occurs in a qualitatively different fashion [14.12]. Due to the finite size of the Na^+ core, there are avoided crossings between the blue and red Stark states of different n, as is shown by Fig. 14.4. In the region above the classical ionization limit, shown by the shaded region of Fig. 14.4, the same coupling between hydrogenically stable blue states and the degenerate red continua leads to autoionization of the blue states [14.13]. As a result, all states above the classical ionization limit ionize at experimentally significant rates. In higher m states, the core coupling is smaller, and the behavior is more similar to H.

Field ionization is commonly used to detect Rydberg atoms in a state selective manner. Experiments are most often conducted at or near zero field, and afterwards the field is increased in order to ionize the atoms. Exactly how the atoms pass from the low field to the high ionizing field is quite important. The passage can be adiabatic, diabatic or anything in between. The selectivity is best if the passage is purely adiabatic or purely diabatic, for in these two cases unique paths are followed.

In zero field, optical excitation from a ground s state leads only to final np states. In the presence of an electric field, all the Stark states are optically accessible, because they all have some p character. The fact that all the Stark states are optically accessible from the ground state allows the population of arbitrary ℓ states of nonhydrogenic atoms by a technique called Stark switching [14.6, 14]. In any atom other than H, the ℓ states are nondegenerate in zero field, and each of them is adiabatically connected to one, and only one, high field Stark state, as shown by Fig. 14.4. If one of the Stark states is excited with a laser and the field reduced to zero adiabatically, the atoms are left in a single zero field ℓ state.

In zero field, the photoionization cross section is structureless. However, in an electric field, it exhibits obvious structure, sometimes termed strong field mixing resonances. Specifically, when ground state s atoms are exposed to light polarized parallel to the static field, an oscillatory structure is observed in the cross section, even above the zero field ionization limit [14.15]. The origin of the structure can be understood with the aid of a simple classical picture [14.16, 17]. The electrons ejected in the downfield direction can simply leave the atom, while the electrons ejected in the upfield direction are reflected back across the ionic core and also leave the atom in the downfield direction. The wave packets corresponding to these two classical trajectories are added, and they can interfere constructively or destructively at the ionic core depending on the phase accumulation of the reflected wave packet. Since the phase depends on the energy, there is an oscillation in the photoexcitation spectrum. This model suggests that no oscillations should be observed for light polarized perpendicular to the static field, and none are. The oscillations can also be thought of as arising from the remnants of quasistable extreme blue Stark states which have been shifted above the ionization limit, and, using this approach or a WKB approach, one can show that the spacing between the oscillations at the zero field limit is $\Delta E = \mathcal{E}^{3/4}$ [14.18, 19].

The initial photoexcitation experiments were done using narrow bandwidth lasers, so that the time dependence of the classical pictures was not explicitly observed. Using mode locked lasers it has been possible to create a variety of Rydberg wave packets [14.20, 21] and observe, in effect, the classical motion of an electron in an atom. Of particular interest, it has been possible to directly observe the time delay of the ejection of electrons subsequent to excitation in an electric field [14.22].

14.4 Magnetic Fields

To first order, the energy shift of a Rydberg atom due to a magnetic field B (the Zeeman effect) is proportional to the angular momentum of the atom. Since the states optically accessible from the ground state have low angular momenta, the energy shifts are the same as those of low-lying atomic states. In contrast, the second order diamagnetic energy shifts are proportional to the area of the Rydberg electron's orbit and scale as $B^2 n^4$ [14.23]. The diamagnetic interaction mixes the ℓ states, allowing all to be excited from the ground state, and produces large shifts to higher energies. The energy levels as a function of magnetic field are reminiscent of the Stark energy levels shown in Fig. 14.5, differing in that the energy shifts are quadratic in the magnetic field.

One of the most striking phenomena in magnetic fields is the existence of quasi-Landau resonances, spaced by $\Delta E = 3\hbar B/2$, in the photoionization cross section above the ionization limit [14.24]. The origin of this structure is similar to the origin of the strong field mixing resonances observed in electric fields. An electron ejected in the plane perpendicular to the B fields is launched into a circular orbit and returns to the ionic core. The returning wave packet can be in or out of phase with the one leaving the ionic core, and thus, can interfere constructively or destructively with it. While the electron motion in the xy-plane is bound, motion in the z-direction is unaffected by the magnetic field and is unbounded above the ionization limit, leading to resonances of substantial width. The Coulomb potential does provide some binding in the z-direction and allows the existence of quasistable three-dimensional orbits [14.25].

14.5 Microwave Fields

Strong microwave fields have been used to drive multiphoton transitions between Rydberg states and to ionize them. Here we restrict our attention to ionization. Ionization by both linearly and circularly polarized fields has been explored with both H and other atoms.

Hydrogen atoms have been studied with linearly polarized fields of frequencies up to 36 GHz [14.26]. When the microwave frequency $\omega \ll 1/n^3$, ionization of $m = 0$ states occurs at a field of $\mathcal{E} = 1/9n^4(E^2/4)$, which is the field at which the extreme red Stark state is ionized by a static field. Due to the second-order Stark effect, the blue and red shifted states are not quite mirror images of each other, and when the microwave field reverses, transitions between Stark states occur. There is a rapid mixing of the Stark states of the same n and m by a microwave field, and all of them are ionized at the same microwave field amplitude, $\mathcal{E} = 1/9n^4$. Important points are that no change in n occurs and the ionization field is the same as the static field required for ionization of the extreme red Stark state. As ω approaches $1/n^3$, the field falls below $1/9n^4$ due to Δn transitions to higher lying states, allowing ionization at lower fields. This form of ionization can be well described as the transition to the classically chaotic regime [14.27]. For $\omega > 1/n^3$ the ionization field is more or less constant, and for $\omega > 1/2n^2$ the process becomes photoionization.

The ionization of nonhydrogenic atoms by linearly polarized fields has also been investigated at frequencies of up to 30 GHz, but the result is very different from the hydrogenic result. For $\omega \ll 1/n^3$ and low m, ionization occurs at a field of $\mathcal{E} \approx 1/3n^5$ [14.28]. This is the field at which the $m = 0$ extreme blue and red Stark states of principal quantum number n and $n + 1$ have their avoided crossing. For $n = 20$ this field is $\approx 500\,\mathrm{V/cm}$, as shown by Fig. 14.4. How ionization occurs can be understood with a simple model based on a time-varying electric field. As the microwave field oscillates in time, atoms follow the Stark states of Na shown in Fig. 14.4. Even with very small field amplitudes, transitions between the Stark states of the same n are quite rapid because of the zero field avoided crossings. If the field reaches $1/3n^5$, the avoided crossing between the extreme red n and blue $n + 1$ state is reached, and an atom in the blue n Stark state can make a Landau–Zener transition to the red $n + 1$ Stark state. Since the analogous red–blue avoided crossings between higher lying states occur at lower fields, once an atom has made the $n \rightarrow n + 1$ transi-

tion it rapidly makes a succession of transitions through higher n states to a state which is itself ionized by the field.

The Landau–Zener description given above is somewhat oversimplified in that we have ignored the coherence between field cycles. When it is included, we see that the transitions between levels are resonant multiphoton transitions. While the resonant character is obscured by the presence of many overlapping resonances, the coherence substantially increases the $n \rightarrow n + 1$ transition probability even when $\mathcal{E} < 1/3n^5$. The fields required for ionization calculated using this model are lower than $1/3n^5$, in agreement with the experimental observations. Nonhydrogenic Na states of high m behave like H, because no states with significant quantum defects are included, and the $n \rightarrow n + 1$ avoided crossings are vanishingly small.

Experiments on ionization of alkali atoms by circularly polarized fields of frequency ω show that for $\omega \ll 1/n^3$, a field amplitude of $\mathcal{E} = 1/16n^4$ is required for ionization [14.29]. This field is the same as the static field required. In a frame rotating with frequency ω, the circularly polarized field is stationary and cannot induce transitions, so this result is not surprising. On the other hand, when the problem is transformed to the rotating frame, the potential of (14.28) is replaced by

$$V = -\frac{1}{r} - \mathcal{E}x - \frac{\omega^2 \rho^2}{2} , \qquad (14.32)$$

where $\rho^2 = x^2 + y^2$, and we have assumed the field to be in the x-direction in the rotating frame. This potential has a saddle point below $\mathcal{E} = 1/16n^4$ [14.30]. As n or ω is raised so that $\omega \rightarrow 1/n^3$, the experimentally observed field falls below $1/16n^4$, but not so fast as implied by (14.32). Equation (14.32) is based solely on energy considerations, and ionization at the threshold field implied by (14.32) requires that the electron escape over the saddle point in the rotating frame at nearly zero velocity. For this to happen, when ω approaches $1/n^3$, more than n units of angular momentum must be transferred to the electron, which is unlikely. Models based on a restriction of the angular momentum transferred from the field to the Rydberg electron are in better agreement with the experimental results. Small deviations of a few percent from circular polarization allow ionization at fields as low as $\mathcal{E} = 1/3n^5$. This sensitivity can be understood as follows. In the rotating frame, a field with slightly elliptical polarization appears to be

a large static field with a superimposed oscillating field at frequency 2ω. The oscillating field drives transitions to states of higher energy, allowing ionization at fields less than $\mathcal{E} = 1/16n^4$.

In the regime in which $\omega > 1/n^3$, microwave ionization of nonhydrogenic atoms is essentially the same as it is in H [14.31]. In this regime, the microwave field couples states differing in n by more than one, and the pressure or absence of quantum defects is not so important. Consequently, only for $\omega > 1/n^3$ is the microwave ionization of H and other atoms different.

14.6 Collisions

Since Rydberg atoms are large, with geometric cross sections proportional to n^4, one might expect the cross sections for collisions to be correspondingly large. In fact, such is often not the case. A useful way of understanding collisions of neutral atoms and molecules with Rydberg atoms is to imagine an atom or molecule M passing through the electron cloud of an Na Rydberg atom. There are three interactions

$$e^- - Na^+ , \quad e^- - M , \quad M - Na^+ . \tag{14.33}$$

The long range $e^- - Na^+$ interaction determines the energy levels of the Na atom. The short range of the $e^- - M$ and $M - Na^+$ interactions makes it likely that only one will be important at any given time. This approximation, termed the binary encounter approximation, is described in Chapt. 56. The $M - Na^+$ interaction can only lead to cross sections of $\approx 10 - 100\,\text{Å}^2$. On the other hand, since the electron can be anywhere in the cloud, the cross sections due to the $e^- - M$ interaction can be as large as the geometric cross section of the Rydberg atom. Accordingly, we focus on the $e^- - M$ interaction.

Consider a thermal collision between M and an Na Rydberg atom. Typically, M passes through the electron cloud slowly compared with the velocity of the Rydberg electron, and it is the $e^- - M$ scattering which determines what happens in the M–Na collision, as first pointed out by *Fermi* [14.32]. First consider the case where M is an atom. There are no energetically accessible states of atom M which can be excited by the low energy electron, so the scattering must be elastic. The electron can transfer very little kinetic energy to M, but the direction of the electron's motion can change. With this thought in mind, we can see that only the collisional mixing of nearly degenerate ℓ states of the same n has very large cross sections. The ℓ-mixing cross sections are approximately geometric at low n [14.33]. If the M atom comes anywhere into the Rydberg orbit, scattering into a different ℓ state occurs. At high n, the cross section decreases, because the probability distribution of the Rydberg electron becomes too dilute, and it becomes increasingly likely that the M atom will pass through the Rydberg electron's orbit without encountering the electron. The n at which the peak ℓ-mixing cross section occurs increases with the electron scattering length of the atom. While ℓ-mixing cross sections are large, n changing cross sections are small $(\approx 100\,\text{Å}^2)$ since they cannot occur when the Rydberg electron is anywhere close to the outer turning point of its orbit [14.34].

If M is a molecule, there are likely to be energetically accessible vibrational and rotational transitions which can provide energy to or accept energy from the Rydberg electron, and this possibility increases the likelihood of n changing collisions with Rydberg atoms [14.11]. Electronic energy from the Rydberg atom must be resonantly transferred to rotation or vibration in the molecule. In heavy or complex molecules, the presence of many rotational-vibrational states tends to obscure the resonant character of the transfer, but in several light systems the collisional resonances have been observed clearly [14.11].

Using the large Stark shifts of Rydberg atoms it is possible to tune the levels so that resonant energy transfer between two colliding atoms can occur [14.35] by the resonant dipole–dipole coupling,

$$Vd = \frac{\mu_1 \mu_2}{R^3} . \tag{14.34}$$

Here μ_1 and μ_2 are the dipole matrix elements of the upward and downward transitions in the two atoms, and R is their separation. At room temperature, this process leads to enormous cross sections, substantially in excess of the geometric cross sections. At the low temperatures $(300\,\mu\text{K})$ attainable using cold atoms, the atoms do not move, and therefore cannot collide. However, resonant dipole–dipole energy transfer is still observed due to the static dipole–dipole interactions of not two, but many atoms [14.36, 37].

Since Rydberg atoms are easily perturbed by electric fields, it is hardly a surprise that collisions of charged particles with Rydberg atoms have large cross sections. In cold Rydberg atom samples, these large cross sections can lead to the spontaneous evolution to a plasma, since the macroscopic positive charge of the cold ions can trap any liberated electrons, leading to impact ionization for a large part of the Rydberg atom sample [14.38, 39].

14.7 Autoionizing Rydberg States

The bound Rydberg atoms considered thus far are formed by adding the Rydberg electron to the ground state of the ionic core. It could equally well be added to an excited state of the core [14.40]. Figure 14.6 shows the energy levels of the ground 5s state of Sr^+ and the excited 5p state. Adding an $n\ell$ electron to the 5s state yields the bound Sr $5sn\ell$ state, and adding it to the excited 5p state gives the doubly excited $5pn\ell$ state, which is coupled by the Coulomb interaction to the degenerate $5s\epsilon\ell'$ continuum. The $5pn\ell$ state autoionizes at the rate $\Gamma_{n\ell}$ given by [14.41]

$$\Gamma_{n\ell} = 2\pi|\langle 5pn\ell|V|5s\epsilon\ell'\rangle|^2 , \tag{14.35}$$

where V denotes the Coulomb coupling between the nominally bound $5pn\ell$ state and the $5s\epsilon\ell'$ continuum. A more general description of autoionization can be found in Chapt. 25.

A simple picture, based on superelastic electron scattering from the Sr^+ 5p state, gives the scaling of the autoionization rates of (14.35) with n and ℓ. The $n\ell$ Rydberg electron is in an elliptical orbit, and each time it comes near the core it has an n-independent probability γ_ℓ of scattering superelastically from the Sr^+ 5p ion, leaving the core in the 5s state and gaining enough energy to escape from the Coulomb potential of the Sr^+ core. The autoionization rate of the $5pn\ell$ state is obtained by multiplying γ_ℓ by the orbital frequency of the $n\ell$ state, $1/n^3$ to obtain

$$\Gamma_{n\ell} = \frac{\gamma_\ell}{n^3} . \tag{14.36}$$

Equation (14.36) displays the n dependence of the autoionization rate explicitly and the ℓ dependence through γ_ℓ. As ℓ increases, the closest approach of the Rydberg electron to the Sr^+ is at a larger orbital radius, so that superelastic scattering becomes progressively less probable, and γ_ℓ decreases rapidly with increasing ℓ. The simple picture of autoionization given above implies a finite probability of autoionization each time the $n\ell$ electron passes the ionic core, so the probability of an atom's remaining in the autoionizing state should resemble stair steps [14.42], which can be directly observed using mode locked laser excitation and detection [14.43].

To a first approximation, the Sr $5pn\ell$ states can be described by the independent electron picture used above, but in states converging to higher lying states of Sr^+, the independent electron picture fails. Consider the Sr^+ $\ell \geq 4$ states of $n > 5$. They are essentially degenerate, and the field due to an outer Rydberg electron converts the zero field ℓ states to superpositions much like Stark states. The outer electron polarizes the Sr^+ core, so that the outer electron is in a potential due to a charge and a dipole, and the resulting dipole states of the outer electron display a qualitatively different excitation spectrum than do states such as the $5pn\ell$ states, which are well described by an independent particle picture [14.44]. When both electrons are excited to very high-lying states, with the outer electron in a state of relatively low ℓ, the classical orbits of the two electrons cross. Time domain measurements, made using wave packets, show that in this case autoionization is likely to occur in the first orbit of the outer electron [14.45].
Fig. 14.6 Sr^+ 5s and 5p states (—), the Rydberg states of Sr converging to these two ionic states are shown by (—), the continuum above the two ionic levels (///). The $5pn\ell$ states are coupled to the $5s\epsilon\ell'$ continua and autoionize

15. Rydberg Atoms in Strong Static Fields

Confronting classical and quantum mechanics in systems whose classical motion is chaotic is one of the fundamental problems of physics, as evidenced by the enormous outpouring of research during the last three decades [15.1, 2]. Highly excited Rydberg atoms in external fields [15.3] play a prominent role in this quest because they are the best known examples of quantum systems whose classical counterpart is chaotic. For a wide variety of field configurations and field strengths, their spectra can be measured to high precision. At the same time, since their Hamiltonians are known analytically, they are equally amenable to accurate theoretical investigations using either classical or quantum mechanics.

This chapter is restricted to a description of Rydberg atoms in strong static fields. Related

information on atoms in strong fields can be found in Chapt. 13 of this Handbook, on Rydberg atoms in Chapt. 14, and on the interaction of atoms with strong laser fields in Chapt. 74.

Different configurations of external fields have been studied: (i) an electric field, which in hydrogen leads to integrable classical dynamics [15.4, 5] (ii) a magnetic field, which produces a transition from regular to chaotic classical dynamics and which sparked the interest in Rydberg atoms as prototype examples for the study of the quantum-classical correspondence [15.6–15] and references therein (iii) parallel electric and magnetic fields [15.16, 17] (iv) crossed electric and magnetic fields which break all continuous symmetries of the unperturbed atom and thus allow one to study the transition from regularity to chaos in three coupled degrees of freedom [15.18–21] and references therein.

The hydrogen atom is the prototype example for states with a single highly excited electron under the influence of strong external fields. For an electron in the hydrogen ground state, the influence of external electric or magnetic fields becomes comparable to that of the nuclear Coulomb field when the field strengths are in the order of the atomic units of electric field strength, $F_0 = e/(4\pi\varepsilon_0 a_0^2) = 5.142\,206\,42\,(44) \times 10^{11}$ V/m, or magnetic field strength, $B_0 = \hbar/(ea_0^2) = 2.350\,517\,42\,(20) \times 10^5$ T, which is far beyond experimental reach. However, the relative importance of the external fields scales with the principal quantum number n as $n^4 F$ and $n^3 B$, so that for highly excited atoms, laboratory fields can easily be "strong". Atomic units will be used throughout this chapter.

In a non-hydrogenic atom, the influence of the inner-shell electrons can be summarized by means of a short-range effective core potential or a set of quantum defects [15.22]. For laboratory field strengths, the core is too small to be appreciably influenced by the external fields. For this reason, the field-free quantum defects can be used to model core effects even in the presence of external fields [15.23].

15.1 Scaled–Energy Spectroscopy

The Hamiltonian for a hydrogen atom in a $\hat{z}$-directed magnetic field and an electric field of arbitrary orientation is

$$H = \frac{\boldsymbol{p}^2}{2} - \frac{1}{r} + \frac{1}{2}\,BL_z + \frac{1}{8}\,B^2\rho^2 + \boldsymbol{r}\cdot\boldsymbol{F} = E\,,$$

$$(15.1)$$

where $\rho^2 = x^2 + y^2$ and L_z is the angular momentum component along the magnetic field axis. The dynamics depends on three parameters: the field strengths F and B and the energy E. We can reduce the number of independent parameters to two if we exploit a scaling property of the Hamiltonian: In terms of the scaled quantities

$$\tilde{\boldsymbol{r}} = w^{-2}\boldsymbol{r}\,, \qquad\qquad \tilde{\boldsymbol{p}} = w\boldsymbol{p}$$
$$\tilde{E} = w^2 E\,, \qquad\qquad \tilde{F} = w^4 F \qquad (15.2)$$

with the scaling parameter

$$w = B^{-1/3}\,, \qquad\qquad\qquad\qquad (15.3)$$

the scaled Hamiltonian reads

$$\tilde{H} = \frac{\tilde{\boldsymbol{p}}^2}{2} - \frac{1}{\tilde{r}} + \frac{1}{2}\,\tilde{L}_z + \frac{1}{8}\,\tilde{\rho}^2 + \tilde{\boldsymbol{r}}\cdot\tilde{\boldsymbol{F}} = \tilde{E}\,. \quad (15.4)$$

The scaled dynamics thus depends only on two parameters, the scaled energy $\tilde{E}$ and the scaled electric field strength $\tilde{F}$. Instead of the above scaling with the magnetic field strength, which is the most common one, equivalent scaling prescriptions with the electric field strength or the energy can be used [15.24].

The way of recording an atomic spectrum that is most suitable for the investigation of quantum-classical correspondence is scaled-energy spectroscopy. A scaled spectrum consists of a list of eigenvalues w_n of the scaling parameter (15.3) characterizing the quantum states for a given scaled energy $\tilde{E}$ and scaled electric field strength $\tilde{F}$. It offers the advantage that the underlying classical dynamics does not change across the spectrum, which makes the spectrum more easily accessible to a semiclassical interpretation (Sect. 15.2). For this reason, scaled-energy spectroscopy has been adopted in numerous experimental [15.4, 5, 8, 18] and theoretical investigations.

To obtain a theoretical description of a scaled spectrum, the Schrödinger equation must be rewritten in terms of the scaling parameter w. In the case of a single external field, either electric or magnetic, this procedure leads to a generalized eigenvalue equation for the scaling parameter w [15.25]. In the presence of both electric and magnetic fields, the scaled spectrum is described by a quadratic eigenvalue equation that has become tractable only recently [15.26].

In a non-hydrogenic atom, the extent of the core imposes an absolute length scale and thus breaks the scaling symmetry. However, if the extent of the Rydberg electron's orbital is large, the size of the core can be neglected and the scaling behavior is restored. This renders scaled-energy spectroscopy a useful concept also for non-hydrogenic atoms [15.4, 5, 18].

15.2 Closed–Orbit Theory

Among the most remarkable effects strong external fields produce in Rydberg atoms are the Quasi-Landau oscillations: Close to the ionization limit, the photoabsorption spectrum of Ba I in a magnetic field shows regular oscillations [15.6]. This phenomenon was given a convincing interpretation by *Starace* [15.27] and embedded by *Du* and *Delos* [15.28, 29] and *Bogomolny* [15.30] into the general framework of closed-orbit theory, which has since become the central interpretative tool for a description of Rydberg spectra in external fields [15.4, 5, 8, 18]). Recently, it has also been used for the computation of Rydberg spectra [15.31, 32].

Closed-orbit theory represents an atomic photoabsorption spectrum as a superposition of regular oscillations, each of which is related to a closed orbit

of the underlying classical dynamics, i.e., to an orbit that starts and ends at the position of the nucleus. The period of an oscillation is given by the return time of the associated closed orbit (divided by $\hbar$), the amplitude is determined on the one hand by the initial state and the polarization of the exciting photon, and on the other hand by the stability of the closed orbit. Once the initial state is specified, both can therefore be calculated within classical mechanics.

A spectrum that contains contributions from many closed orbits can look enormously complicated. Its Fourier transform, on the other hand, consists of a series of isolated peaks that can be identified with the contributions of individual closed orbits. The Fourier transform thus provides the means to identify the crucial dynam-

ics underlying a complicated spectrum. If a spectrum is recorded at constant external field strength, however, this analysis is inhibited by the fact that the oscillations are not strictly harmonic because both the return time of a closed orbit and the recurrence amplitude associated with it vary across the spectrum. This is the principal reason why scaled-energy spectroscopy (see Sect. 15.1) is customarily used. In a scaled spectrum, the period of an oscillation is given by the scaled action of the corresponding orbit and is fixed across the spectrum.

Although initially devised for atoms in magnetic fields [15.28–30], closed-orbit theory is equally applicable to atoms in electric [15.33] as well as parallel [15.34] or crossed [15.34, 35] electric and magnetic fields. In the case of non-hydrogenic atoms, the influence of the ionic core can be modelled either by means of an effective classical potential [15.35, 36] or in terms of quantum defects [15.37]. Recently, closed-orbit theory

has even been applied to the spectra of simple molecules in external fields [15.38].

Since a non-hydrogenic core is much smaller than the extent of a closed orbit (which is comparable to the size of the atomic Rydberg state), it does not appreciably modify the shape of the orbit. The peaks observed in a hydrogen spectrum are therefore also observed in the corresponding spectrum of a non-hydrogenic atom, although their strengths may be altered considerably (core shadowing) [15.37]. The principal effect of a core is to scatter the electron returning along one closed orbit into the initial direction of another, so that concatenations of hydrogenic closed orbits appear in the spectrum [15.37]. For this reason, the closed orbits of the hydrogen atom in external fields are the crucial ingredient for the interpretation of any Rydberg spectrum. They have been systematically studied for hydrogen in magnetic [15.39, 40] as well as electric [15.41] and crossed [15.42, 43] fields.

15.3 Classical and Quantum Chaos

In the absence of external electric and magnetic fields, the classical dynamics described by the atomic Hamiltonian (15.1) is integrable and completely degenerate [15.44]. When external fields are present, a transition to classical chaos can be observed whose details depend on the precise field configuration (see below). It is characterized by the break-up of invariant tori and the appearance of irregular regions in the classical phase space.

Chaos, as understood in classical mechanics, does not exist in closed quantum systems [15.45]. Nevertheless, in the dynamics of a quantum system clear indications of regularity or chaos in the underlying classical system can be found [15.2]. Most prominent among them is the statistical distribution of nearest-neighbor energy level spacings (NNS). In a classically chaotic system, energy levels show avoided crossings. Level repulsion is statistically reflected by NNS following a Wigner distribution

$$P(S) = \frac{\pi}{2} S e^{-\pi S/4} \qquad (15.5)$$

that restricts small spacings. On the other hand, integrable systems possess a complete set of quantum numbers, so that levels are allowed to cross. This gives rise to a Poissonian NNS distribution

$$P(S) = e^{-S} \qquad (15.6)$$

that favors small spacings. For mixed regular-chaotic systems, a transition from a Poisson to a Wigner NNS distribution is found [15.14].

15.3.1 Magnetic Field

An atom exposed to a magnetic field possesses rotational symmetry around the magnetic field axis, which leads in classical mechanics to the conservation of the angular-momentum component L_z along the field axis and in quantum mechanics to a good magnetic quantum number $m = L_z$. The dynamics of the rotation coordinate can thus be separated, leaving two coupled degrees of freedom.

The quantum numbers l and n that characterize the pure hydrogen states both break down in a magnetic field. However, the field affects them differently: Whereas l breaks down extensively even for small fields (l-mixing region), the breakdown of n is only achieved through considerably stronger fields or higher energies (n-mixing region). Since chaotic dynamics can only exist in at least two degrees of freedom, a single n-manifold of electronic energy levels does not have enough degrees of freedom to support chaos. Chaos can develop only when different n-manifolds mix (intermanifold chaos). The regular dynamics that prevails as long as n is approximately conserved is reflected in the existence of a second adiabatic con-

stant of motion (apart from the energy), which is given by [15.46, 47]

$$\Lambda = 4A^2 - 5A_z^2 , \tag{15.7}$$

in terms of the Runge–Lenz vector

$$A = \frac{1}{\sqrt{-2E}}\left[\frac{1}{2}(p \times L - L \times p) - \frac{r}{r}\right] , \tag{15.8}$$

and is conserved to second order in the magnetic field strength.

As the magnetic field strength increases, corresponding to an increase in the scaled energy from $-\infty$ toward zero, the classical dynamics changes from regular to almost entirely chaotic [15.13, 14]. For positive scaled energies above $\tilde{E}_c = 0.328\,782\ldots$, completely hyperbolic dynamics is reached [15.48]. In step with the onset of classical chaos, the quantum NNS distribution changes from a Poisson to a Wigner distribution [15.13, 14].

15.3.2 Parallel Electric and Magnetic Fields

In parallel fields, as in a pure magnetic field, an atom retains rotational symmetry around the field axis. It therefore shows a similar transition from regular dynamics to intermanifold chaos at scaled energies $\tilde{E} \approx 0$. At small field strengths, a second-order adiabatic invariant akin to (15.7) is given by [15.49, 50]

$$\Lambda_\beta = 4A^2 - 5(A_z - \beta)^2 + 5\beta^2 , \tag{15.9}$$

where the parameter

$$\beta = \frac{12}{5}\frac{F}{n^2 B^2} \tag{15.10}$$

measures the relative strengths of the electric and magnetic fields.

15.3.3 Crossed Electric and Magnetic Fields

In nonaligned electric and magnetic fields, the rotational symmetry of the field-free atom is broken completely, so that all three degrees of freedom are coupled. The angular momentum quantum numbers l and m break down extensively even at small field strengths; the principal quantum number n follows only gradually. Even when n is approximately conserved, however, in the crossed-fields atom two coupled degrees of freedom remain. They allow the occurrence of chaotic dynamics within a single n-manifold (intramanifold chaos) [15.51, 52].

The intramanifold dynamics can conveniently be described in terms of the vectors [15.53]

$$I_1 = \frac{1}{2}(L + A) ,$$
$$I_2 = \frac{1}{2}(L - A) , \tag{15.11}$$

that obey independent angular momentum Poisson bracket (or, in quantum mechanics, commutator) relations. For fixed n, I_1 and I_2 are restricted to the spheres

$$I_1^2 = I_2^2 = \frac{n^2}{4} . \tag{15.12}$$

They span a four-dimensional space that is a convenient representation of the intramanifold phase space.

Within a given n manifold, the position vector r can be replaced with $-\frac{3}{2}nA$ [15.54]. Using this replacement, we can rewrite the contributions to the Hamiltonian (15.1) that are linear in the field strengths as

$$H_{\text{lin}} = \omega_1 \cdot I_1 + \omega_2 \cdot I_2 \tag{15.13}$$

with the constant vectors

$$\omega_1 = \frac{1}{2}(B - 3nF) ,$$
$$\omega_2 = \frac{1}{2}(B + 3nF) . \tag{15.14}$$

The first-order Hamiltonian H_{lin} describes a precession of the vectors I_1 and I_2 around ω_1 and ω_2, respectively, and preserves the integrability of the dynamics. Intramanifold chaos arises only if the quadratic contribution to the Hamiltonian (15.1) is taken into account. It can be detected either in classical mechanics [15.51, 52] or in quantum mechanics via its imprint on the intramanifold NNS distribution [15.52].

The properties of the crossed-fields hydrogen atom above the ionization threshold provide an example of a chaotic scattering system. Classically, chaotic ionization manifests itself in a fractal dependence of the electron escape time on the initial conditions [15.55]. Experimentally, a distinction has been made between "prompt" electrons that ionize fast, and "delayed" electrons that ionize only after more than 100 ns [15.20]. The latter can be interpreted as electrons that undergo chaotic scattering and circle the nucleus many times before they escape. A detailed classical model of chaotic scattering was presented in [15.56]. In quantum mechanics, chaotic scattering can be identified through the occurrence of Ericson fluctuations in the above-threshold spectrum [15.55].

15.4 Nuclear–Mass Effects

So far, only the relative motion of the electron with respect to the ionic core has been described. This is appropriate if the nucleus can be assumed to be infinitely heavy and thus not to take part in the motion. To include the effects of a finite nuclear mass, the description must start from the coupled two-body Hamiltonian and then work toward a separation of the internal dynamics from the center-of-mass (CM) motion.

It turns out that in the presence of a magnetic field, unlike the field-free two-body problem, a complete separation of the relative and CM motions is impossible. Instead, only a pseudo-separation can be achieved, where the relative and CM motions remain coupled through a new constant of motion called the pseudomomentum K [15.57]. This coupling introduces a number of novel effects into the dynamics (see [15.58] for a detailed discussion).

The influence of the CM motion on the internal dynamics is twofold: on the one hand, the motion of the atom in the magnetic field causes an induced electric field (motional Stark effect). On the other hand, the kinetic energy of the CM motion gives rise to an additional confining potential for the internal motion that could, in principle, locate the electron at a large distance from the nucleus, and produce atomic states with a huge dipole moment.

Conversely, the motion of the CM is driven by the internal motion, most strongly so in the case of vanishing pseudomomentum. It thus reflects the transition from regular to chaotic internal dynamics: A regular internal motion leads to a regular CM motion, whereas chaotic internal dynamics, for $K = 0$, give rise to a classical diffusion of the CM.

16. Hyperfine Structure

Hyperfine structure in atomic and molecular spectra is a result of the interaction between electronic degrees of freedom and nuclear properties other than the dominant one, the nuclear Coulomb field. It includes splittings of energy levels (and thus of spectral lines) from magnetic dipole and electric quadrupole interactions (and higher multipoles, on occasion). Isotope shifts are experimentally entangled with hyperfine structure, and the so-called field effect in the isotope shift can be naturally included as part of hyperfine structure. Studies of hyperfine structure can be used to probe nuclear properties, but they are an equally important probe of the structure of atomic systems, providing especially good tests of atomic wave functions near the nucleus. There are also isotope shifts owing to the mass differences between different nuclear species, and the study of these shifts provides useful atomic information, especially about correlations between electrons.

Hyperfine effects are usually small and often, but not always, it is sufficient to consider only

diagonal matrix elements for the atomic or molecular system and for the nuclear system. In some cases, however, matrix elements off-diagonal in the atomic space, even though small, can be of importance; one possible result is to cause admixtures sufficient to make normally *forbidden* transitions possible.

In the diagonal case, one can picture each electron undergoing elastic scattering from the nucleus and returning to its initial bound state. As pointed out by *Casimir* [16.1, 2], however, the *internal conversion* of nuclear gamma-ray transitions involves the inelastic down-scattering from an excited nuclear state to a lower one as an electron goes from an initial bound state to the continuum. By further conversion of bound to continuum states, one sees the connection with electron scattering from the nucleus – elastic, inelastic, and break-up. Hyperfine structure of outer-shell electronic states is at the low momentum-transfer end of this chain of related processes.

Some of the standard textbooks which discuss hyperfine structure are [16.3–10] and a few newer texts [16.11–14]. Especially relevant are [16.15–19] and the conference proceedings [16.20–22].

The study of hyperfine structure in free atoms, ions, and molecules is part of the more extensive research area of hyperfine interactions, which includes the study of atoms and molecules in matter, both at rest, for example as part of the structure of a solid, and moving, such as ions moving through condensed or gaseous matter. This more general subject also includes the ways in which atomic electrons shield the nucleus, or anti-shield it, from external or collective fields. Thus nuclear magnetic resonance, nuclear quadrupole resonance, electron-nuclear double resonance, recoilless nuclear absorption and emission, nuclear orientation, production of polarized beams, and many other widely used techniques, are intimately connected with hyperfine effects.

Though hyperfine effects are ordinarily small in electronic systems, they can become much larger in "exotic" atoms: those with a heavier lepton or hadron as the

"light" particle. Hyperfine effects are typically related to light particle density at the nucleus, or to expectation values of r^{-3}, and thus scale as the cube of the light particle mass. The study of muonic atoms has contributed importantly to knowledge of the nuclear charge distribution [16.23–26]. There has been considerable interest in pionic atoms, where the strong interaction also contributes to hyperfine structure (e.g., [16.27, 28]), and also in kaonic, antiprotonic, and other hadronic "atoms" [16.29, 30]. See especially [16.31] for recent work on antiprotonic helium.

Some other examples of interaction between atomic and nuclear degrees of freedom are discussed in Chapt. 90.

16.1 Splittings and Intensities

16.1.1 Angular Momentum Coupling

When the nuclear system is in an isotropic environment, each nuclear state β has a definite value of nuclear angular momentum $I_\beta \hbar$, where the possible values of I_β are related to the number of nucleons (protons plus neutrons) in the same way as those for J_α are related to the number of electrons in electronic state $|\alpha\rangle$. The nuclear operators, eigenstates, and eigenvalues are related to each other in the same way as for atomic angular momentum by

$$I^2|\beta\rangle = I_\beta(I_\beta + 1)|\beta\rangle ,$$
$$I_z|\beta\rangle = M_\beta|\beta\rangle , \qquad (16.1)$$

in units with $\hbar = 1$. Shift operators move the system from one M-value to another, as for the atomic system (see Chapt. 2), and the operator I is the generator of rotations. When the combined atomic-nuclear system is considered, in an isotropic environment, it is the total angular momentum of the combined system defined by

$$F = J + I , \qquad (16.2)$$

that has definite values. The state of the combined system can be labeled by γ, so that

$$F^2|\gamma\rangle = F_\gamma(F_\gamma + 1)|\gamma\rangle ,$$
$$F_z|\gamma\rangle = M_\gamma|\gamma\rangle . \qquad (16.3)$$

The shift operators are defined as before, and it is now F that is the generator of rotations of the (combined) system, or of the coordinate frame to which the system is referred.

By the rules of combining angular momenta, the possible values of the quantum number F are separated by integer steps and run from an upper limit of $J_\alpha + I_\beta$ to a lower limit of $|J_\alpha - I_\beta|$. The number of possible eigenvalues F is the smaller of $2J_\alpha + 1$ and $2I_\beta + 1$. Experimental values of the nuclear quantum number I may be found in a number of compilations [16.32–34].

16.1.2 Energy Splittings

Electromagnetic interactions between atomic electrons and the nucleus can be expanded in a multipole series

$$H_{eN} = \sum_k T^k(N) \cdot T^k(e) ,$$
$$\equiv \sum_{k,q} (-1)^i T_q^k(N) T_{-q}^k(e) \qquad (16.4)$$

where $T^k(N)$ is an irreducible tensor operator of rank k operating in the nuclear space, and similarly $T^k(e)$ operates in the space of the electrons. Since one is taking diagonal matrix elements (in the nuclear space, at least) in states that are to a very good approximation eigenstates of the parity operator, only even electric multipoles (E0, E2, etc.) and odd magnetic multipoles (M1, M3, etc.) contribute to the series. The effects of the parity nonconserving weak interaction are considered in Chapt. 29.

The term with $k = 0$ contributes directly to the structure (and fine structure) of atomic systems, and its dominant contributions come from the external r^{-1} electrostatic field of the nucleus. The *hyperfine* Hamiltonian is defined by subtracting that term to obtain

$$H_{hfs} = \sum_i \left[T^0(N) T^0(i) - \left(-Ze^2/r_i \right) \right]$$
$$+ \sum_{k=1} T^k(N) \cdot T^k(e) , \qquad (16.5)$$

where Z is the nuclear charge number. The difference between the Ze^2/r term(s) and the full monopole term is called the *field effect* or *finite nuclear size effect* in the isotope shift, and the remaining terms contribute dipole ($k = 1$), quadrupole ($k = 2$), and higher multipoles in hyperfine structure.

Since the hyperfine Hamiltonian can be expressed as a multipole expansion, its contributions to the pattern of energy levels for the various F values in a given

J_α, I_β multiplet in first-order perturbation theory can be described relatively simply in terms of $3-j$ and $6-j$ symbols. The contribution of the term which is the scalar product of electron and nuclear operators of multipole k is

$$\Delta E_k(JIF, JIF)$$
$$= (-)^{J+I+F} \left\{ \begin{matrix} J & J & k \\ I & I & F \end{matrix} \right\}$$
$$\times \left[\begin{pmatrix} J & k & J \\ J & 0 & -J \end{pmatrix} \begin{pmatrix} I & k & I \\ I & 0 & -I \end{pmatrix} \right]^{-1} A_k , \quad (16.6)$$

where for $k \geq 1$,

$$A_k = \langle JJ | \boldsymbol{T}^k(\mathrm{e}) | JJ \rangle \cdot \langle II | \boldsymbol{T}^k(\mathrm{N}) | II \rangle . \quad (16.7)$$

The commonly used hfs coefficients A, B, etc., are related to the A_k by

$$A = A_1/IJ, \quad B = 4A_2, \quad C = A_3, \quad D = A_4 . \quad (16.8)$$

The isotope shift A_0 is the matrix element of the reduced monopole operator.

The pattern of the splitting depends on the total angular momentum F wholly through the $6-j$ symbol. Since for $k = 0$ the value of the $6-j$ symbol is independent of F, the monopole term shifts all levels of the hyperfine multiplet equally, independent of the value of F.

The F-dependence of the dipole contribution can be found from the fact that the same $6-j$ symbol would appear for any scalar product of $k = 1$ operators, for example $\boldsymbol{J} \cdot \boldsymbol{I}$. But in this product space, with J, I, and F all good quantum numbers, the diagonal matrix elements of $\boldsymbol{J} \cdot \boldsymbol{I}$ are just

$$\langle \boldsymbol{J} \cdot \boldsymbol{I} \rangle = \frac{1}{2}[F(F+1) - J(J+1) - I(I+1)] , \quad (16.9)$$

so that

$$\Delta E_1(JIF, JIF)$$
$$= \frac{1}{2} A[F(F+1) - J(J+1) - I(I+1)] , \quad (16.10)$$

where, in terms of reduced matrix elements according to the convention of *Brink* and *Satchler* ([16.35, p. 152]), (the first version given in Sect. 2.8.4)

$$A = [J(J+1)]^{-1/2} \langle J \| \boldsymbol{T}^1(\mathrm{e}) \| J \rangle [I(I+1)]^{-1/2}$$
$$\times \langle I \| \boldsymbol{T}^1(\mathrm{N}) \| I \rangle . \quad (16.11)$$

A is the magnetic dipole hyperfine structure constant for the atomic level J and nuclear state I. M1 hfs shows the same pattern of splittings as spin-orbit fine structure, described sometimes as the *Landé interval rule*.

Electric quadrupole hfs is described by the quadrupole hyperfine structure constant B. If we define the quantity $K = [F(F+1) - J(J+1) - I(I+1)]$, then

$$\Delta E_2(JIF, JIF)$$
$$= \frac{(\frac{1}{4}B)[3K(K+1)/2 - 2J(J+1)I(I+1)]}{J(2J-1)I(2I-1)} . \quad (16.12)$$

The constant B is related to the tensor operators by

$$\frac{1}{4} B = [J(2J-1)/(J+1)(2J+3)]^{-1/2}$$
$$\times \langle J \| \boldsymbol{T}^2(\mathrm{e}) \| J \rangle$$
$$\times [I(2I-1)/(I+1)(2I+3)]^{-1/2}$$
$$\times \langle I \| \boldsymbol{T}^2(\mathrm{N}) \| I \rangle , \quad (16.13)$$

For higher multipoles, see [16.36].

The multipole expansion is important because it is valid for relativistic as well as nonrelativistic situations, and for nuclear penetration effects (hyperfine anomalies discussed in Sect. 16.3.3) as well as for normal hyperfine structure. Its limitation comes from its nature as a first-order diagonal perturbation. Off-diagonal contributions, even when small, can perturb the pattern, but, more importantly, can lead to misleading values for the A_k coefficients, including the isotope shift.

16.1.3 Intensities

When hyperfine structure is observed as a splitting in an optical transition between different atomic levels, there are relations between the intensities of the components. The general rule for reduced matrix elements of a tensor operator operating in the first part of a coupled space is ([16.35, p. 152])

$$\langle JIF \| Q^\lambda(\mathrm{e}) \| J'IF' \rangle$$
$$= (-1)^{\lambda+I+F'+J}(2F'+1)^{1/2} \left\{ \begin{matrix} F & F' & \lambda \\ J' & J & I \end{matrix} \right\}$$
$$\times (2J+1)^{1/2} \langle J \| Q^\lambda(\mathrm{e}) \| J' \rangle . \quad (16.14)$$

For a dipole transition ($\lambda = 1$) connecting atomic states J and J', with fixed nuclear spin I, the line strength $S_{FF'}$ of the hyperfine component connecting F and F' is related to the line strength $S_{JJ'}$ by

$$S_{FF'} = (2F+1)(2F'+1) \left\{ \begin{matrix} F & F' & 1 \\ J' & J & I \end{matrix} \right\}^2 S_{JJ'} . \quad (16.15)$$

16.2 Isotope Shifts

Two distinct mechanisms contribute to isotope shifts in atomic energy levels and transition energies. First, there are shifts due to the different mass values of the isotopes; these *mass shifts* can again be separated into two kinds, the normal mass shift and the specific mass shift. Second, there are shifts due to different nuclear charge distributions in different isotopes. Shifts of this sort are called *field shifts*, and can be considered to be the monopole part of the hyperfine interaction.

The usual convention is to describe an isotope shift in a transition as positive when the line frequency is greater for the heavier isotope.

16.2.1 Normal Mass Shift

The *normal mass shift* occurs already for one-electron atoms, where the energy scale in the c.m. frame for the electron-nucleus system is directly proportional to the reduced mass of the system, $\mu = mM/(M+m)$, where m is the mass of the electron and M that of the nucleus. The two natural limits are those of an infinitely heavy nucleus, where $\mu = m$, and positronium, where $\mu = \frac{1}{2}m$. The normal mass shift applies to all levels of all atomic systems. The fractional shift in frequency between isotopes of mass M_H and M_L is given by

$$(\nu_H - \nu_L)/\nu_H = m(M_H - M_L)/M_H(M_L + m) , \tag{16.16}$$

or

$$(\nu_H - \nu_L)/\nu_L = m(M_H - M_L)/(M_H + m)M_L . \tag{16.17}$$

The normal mass shift between deuterium and protonic hydrogen is $(\nu_D - \nu_H)/\nu_H = 2.721 \times 10^{-4}$, amounting to $4.15\,\text{cm}^{-1}$ ($0.179\,\text{nm}$) for Balmer α. It decreases rapidly for heavy elements, with $\Delta\nu/\nu \approx (A_H - A_L)/(1823 A_H A_L)$, where the A-values are the atomic mass numbers; for the pair ^{208}Pb–^{206}Pb, $\Delta\nu/\nu$ is then 2.56×10^{-8}, corresponding to a wavelength shift of $0.000\,014\,\text{nm}$ for a line at $550\,\text{nm}$.

16.2.2 Specific Mass Shift

When the system has more than two particles the situation is more complicated; in particular, the center of mass of any particular electron and the nucleus is no longer the center of mass of the whole system. When c.m. motion is removed from the Hamiltonian, there remains a set of *mass polarization* terms

$$H_{\text{mp}} = \frac{1}{M} \sum_{j<k} \boldsymbol{p}_j \cdot \boldsymbol{p}_k , \tag{16.18}$$

where M is the nuclear mass and $\boldsymbol{p}_j$ is the momentum of the jth electron. The matrix elements of these terms can be strongly state-dependent, and the difference in their contributions for isotopes of different mass is called the *specific mass shift* (SMS). For a transition $a \to b$, the lowest-order SMS between isotopes A and A' is

$$\Delta\nu(a, b; A, A') = K^{a,b}(M_A - M_{A'})/M_A M_{A'} , \tag{16.19}$$

where

$$K^{a,b} = \langle a|\sum_{j<k}\boldsymbol{p}_j \cdot \boldsymbol{p}_k|a\rangle - \langle b|\sum_{j<k}\boldsymbol{p}_j \cdot \boldsymbol{p}_k|b\rangle . \tag{16.20}$$

It was earlier thought that the SMS, like the normal mass shift, was always very small for heavy atoms, but that has turned out not to be the case.

Since the operator $\boldsymbol{p}_1 \cdot \boldsymbol{p}_2$ resembles the product of two dipole transition operators, the matrix elements of H_{mp} vanish between simple product-type wave functions unless allowed by dipole selection rules. For example, in the $1\text{s}n\ell$ ^1L and ^3L states of helium, the only nonvanishing diagonal terms are the $\ell = 1$ exchange terms $\pm\langle 1\text{s}(1)n\text{p}(2)|\boldsymbol{p}_1 \cdot \boldsymbol{p}_2|n\text{p}(2)1\text{s}(1)\rangle$, with $(-)$ for singlet states and $(+)$ for triplet states. The resulting Hughes–Eckart level shift [16.37] is positive for singlets and negative for triplets. For other states, $\langle H_{\text{mp}}\rangle$ acquires a nonzero value due to electron correlation (configuration mixing) effects, but the resulting level shifts are correspondingly smaller. Detailed tabulations for many states of helium, including second-order corrections, are given by *Drake* and *Yan* [16.38].

For other atoms, the diagonal matrix elements of H_{mp} within a single electron configuration are weighted by the same coefficients as those that weight the Slater exchange integral G^1. Relativistic corrections have been given by *Stone* [16.39, 40]. *Bauche* and *Champeau* [16.11] provide a useful discussion of the SMS, as does *King* [16.16].

Among recent results, we mention high-precision experimental work on the difference in the splittings 2^3S_1–2^3P_J between ^{4}He and ^{3}He [16.41–43], which can be compared with theoretical results [16.43, 44], and an extensive multi-isotope study in Sm II, in which isotope-shift results are used to deduce structure information for a number of levels [16.45].

16.2.3 Field Shift

The field shift is due to different electric monopole interactions within the nucleus for different nuclei. Since the field shift is state-dependent, it contributes to the isotope shift of electronic transition frequencies. When field shifts occur between different isomeric levels of the same nuclear species, they are called *isomer shifts*.

Following *Seltzer* [16.46], (see also the summary in *Fricke* et al.[16.47]), a level shift can be written as

$$\Delta E = -e^2 \int [\rho_N(A) - \rho_N(A')]$$
$$\times \left[r_N^{-1} \int \rho_e \, d\tau_e - \int r_e^{-1} \rho_e \, d\tau_e \right] d\tau_N \,.$$
(16.21)

The electronic factor inside the second bracket can be fitted as an even power series in r_N, starting with r_N^{2j+1}. The result is that the field shift for a transition a is

$$\Delta\nu(a, AA') = F^a \lambda^{AA'} \,, \qquad (16.22)$$

with

$$\lambda^{AA'} = \delta\langle r^2 \rangle_{AA'} + (C_2/C_1)\delta\langle r^4 \rangle_{AA'}$$
$$+ (C_3/C_1)\delta\langle r^6 \rangle_{AA'} + \cdots \,, \qquad (16.23)$$

where $\delta\langle r^k \rangle_{AA'} = \langle r^k \rangle_A - \langle r^k \rangle_{A'}$. The term F^a is an electronic factor proportional to the change in electron density at the nucleus between the initial and final electronic states; in the simplest perturbation approach F^a is equal to $-(4\pi/6)Ze^2\Delta\rho_e(0)$, where $\Delta\rho_e(0)$ is the electron density at the nucleus in the lower atomic state minus that in the upper (see Sect. 90.1). The ratios C_2/C_1 etc., which weight the higher even moments, depend only on Z and not on the particular transition; values are tabulated in [16.46, 48, 49], as are F-factors for K X-ray transitions. This approach has been generalized and reformulated by *Blundell* et al. [16.49].

Measurements of isotope shifts of optical lines have long played an important role in the determination of nuclear rms radii. A more comprehensive picture of nuclear charge distributions can be found by combining optical isotope shift results with those for X-ray lines and for transitions in muonic atoms, together with results of elastic electron scattering from nuclei; a compilation of the results of such an analysis is to be found in *Fricke* et al. [16.47].

16.2.4 Separation of Mass Shift and Field Shift

From the measured isotope shift for a spectral line a between a pair of isotopes A and A', one can define a *residual isotope shift* by subtracting the normal mass shift. The residual shift is the sum of two terms, each with an electronic factor and a nuclear factor

$$\Delta\nu_{a,AA'} = K^a(M_A - M_{A'})/M_A M_{A'} + F^a \lambda^{AA'} \,.$$
(16.24)

If the field shift is assumed to be negligible, the electronic factor K^a can be extracted. Similarly, if the SMS is assumed to be negligible, from the ratios $\Delta\nu(a, A_1 A_2)/\Delta\nu(a, A_3 A_4)$, ratios of $\lambda(A_1 A_2)/\lambda(A_3 A_4)$ can be obtained, and the ratios $\Delta\nu(a, A_1 A_2)/\Delta\nu(b, A_1 A_2)$ give ratios of the electronic factors F^a/F^b.

If both contributions have to be considered, one can gain information from a *King plot* [16.16, 50] in which a *modified residual shift* $\Delta\nu'(a, AA')$ for line a is defined as

$$\Delta\nu'(a, AA') = \Delta\nu(a, AA')M_A M_{A'}/(M_A - M_{A'}) \,.$$
(16.25)

(Some authors modify the whole shift, without subtracting the normal mass shift; since the isotopic mass dependence is the same for the two mass-shift contributions, the separation proceeds as before, but with an altered definition of the constant K.) For each isotope pair AA', this defines a point in the King plot whose ordinate is, e.g., $\Delta\nu'(a, AA')$ and whose abscissa is $\Delta\nu'(b, AA')$. If the assumed additivity is valid, one finds a linear relationship between the modified shifts for line a and those for another line b according to

$$\Delta\nu'(a, AA') = (F^a/F^b)\Delta\nu'(b, AA') + K^a$$
$$- K^b(F^a/F^b) \,.$$
(16.26)

From the slope of the line one has the ratio of F-factors for the two lines, and from the intercept a relation between the K-factors. A sometimes useful variant of the King plot involves choosing a pair of isotopes, say B and B' as a reference pair [16.16, 47]. A *reduced shift* $\Delta\nu''(a, AA')$ is then defined as

$$\Delta\nu''(a, AA') = \frac{\Delta\nu(a, AA')M_A M_{A'}(M_B - M_{B'})}{(M_A - M_{A'})M_B M_{B'}} \,,$$
(16.27)

and $\Delta\nu''(a)$ is plotted vs. $\Delta\nu''(b)$.

It is not in general possible to extract F- and K-values for individual transitions from optical isotope

shifts alone, unless one has at least one calculated or otherwise reliably known value. Information about nuclear charge distributions, however, and isotopic changes in them, is available from other sources, including X-ray isotope shifts, muonic X-rays, and elastic electron scattering from nuclei. Calculated electronic factors for K X-ray transitions can be expected to be more reliable than those for optical transitions. The effects of finite nuclear size are much bigger in muonic than electronic atoms, and screening effects much smaller. Combined analyses of all four types of data lead to the best current knowledge of changes in nuclear charge parameters, and thus contribute to knowledge of the electronic factors F^a and K^a for optical transitions [16.47].

16.3 Hyperfine Structure

We discuss first *normal* hyperfine structure, in which terms coming from penetration of electrons into the nuclear charge and current distributions can be neglected; such contributions, the *anomalous* hyperfine structure, are briefly discussed in Sect. 16.3.3. See also Sect. 21.7.2.

16.3.1 Electric Multipoles

The electric quadrupole tensor operators, when penetration is neglected, are

$$\boldsymbol{T}^2(N) = \rho_{\mathrm{N}}(\boldsymbol{r}_{\mathrm{N}}) r_{\mathrm{N}}^2 \boldsymbol{C}^{(2)} , \qquad (16.28)$$

where ρ_{N} is the nuclear charge density, and

$$\boldsymbol{T}^2(\boldsymbol{e}_i) = -e r_i^{-3} \boldsymbol{C}^{(2)}(i) . \qquad (16.29)$$

The matrix element of $\boldsymbol{T}^2(\mathrm{N})$ that occurs in the expansion coefficient A_2 is just $e/2$ times the nuclear quadrupole moment Q:

$$eQ = 2\langle II | \boldsymbol{T}^2(\mathrm{N}) | II \rangle . \qquad (16.30)$$

Experimental values of Q are tabulated by *Raghavan* [16.32] and more recently discussed by *Pyykkö* [16.51]. The matrix element of $\boldsymbol{T}^2(\mathrm{e})$, summed over all electrons, also has a simple semiclassical interpretation [16.7];

$$\langle JJ | \boldsymbol{T}^2(\mathrm{e}) | JJ \rangle = (e/2) q_J$$
$$= (1/2) \langle \partial^2 V / \partial z^2 \rangle_{JJ} , \qquad (16.31)$$

where V is the electrostatic potential at the nucleus due to the electrons. The quadrupole splitting constant can thus be expressed as

$$B = 4A_2 = e^2 Q q_J = eQ \langle \partial^2 V / \partial z^2 \rangle_{JJ} . \qquad (16.32)$$

Because the matrix elements of spherical harmonics in lsj-coupled states are independent of l (aside from the parity requirement that $l + l' + k$ be even), the one-electron matrix elements of $\boldsymbol{T}^2(\mathrm{e})$ are [16.36]

$$\langle lsj \| \boldsymbol{T}^2(\mathrm{e}) \| l'sj' \rangle$$
$$= -e \langle lsj \| \boldsymbol{C}^{(2)} \| l'sj' \rangle \int r^{-3} (gg' + ff') \, \mathrm{d}r , \quad (16.33)$$

where g and f are the large and small r-multiplied Dirac radial functions, and the right-hand reduced matrix element is equal to $(-1)^{k-1} C^{jkj'}_{\frac{1}{2}0\frac{1}{2}}$ with $k = 2$ ([16.35, p. 153]).

Electric hexadecapole hyperfine structure follows similar rules [16.36]. While there is considerable indirect evidence that many nuclear states have nonzero E4 moments [16.52], their effect on hyperfine structure has been identified only occasionally [16.53, 54].

16.3.2 Magnetic Multipoles

For the magnetic multipole modes, when penetration effects are neglected, and when the the nuclear current is taken to be a sum of the orbital-current and spin-current contributions of individual nucleons, the nuclear tensor operator can be written as the sum

$$\boldsymbol{T}^k(\mathrm{N}) = (e\hbar/2m_{\mathrm{p}}c) \sum_n [k(2k-1)]^{1/2} r_n^{k-1}$$
$$\times \left[2g_{ln}(k+1)^{-1} \left(\boldsymbol{C}^{(k-1)} \boldsymbol{L}_n \right)^{(k)} \right.$$
$$\left. + g_{sn} \left(\boldsymbol{C}^{(k-1)} \boldsymbol{S}_n \right)^{(k)} \right], \qquad (16.34)$$

where $e\hbar/2m_{\mathrm{p}}c$ is the nuclear magneton, and in the extreme single-nucleon model the orbital g-factors g_{ln} are 1 for protons and 0 for neutrons, while the spin g-factors g_{sn} are 5.585 694 701(56) for protons and $-3.826\,085\,46(90)$ for neutrons. Similarly, for electron i, the atomic Mk operator can be written

$$\boldsymbol{T}^k(\boldsymbol{e}_i) = ie[(k+1)/k]^{1/2} r_i^{-k-1} \left(\boldsymbol{\alpha}_i \boldsymbol{C}_i^{(k)} \right)^{(k)} . \qquad (16.35)$$

For the magnetic dipole case, the nuclear operator of (16.29) becomes

$$T^1(\mathrm{N}) = (e\hbar/2m_\mathrm{p}c) \sum_n (g_{ln}L_n + g_{sn}S_n) . \quad (16.36)$$

The nuclear currents, however, are more complicated in the strongly interacting and relatively dense environment of real nuclear systems; renormalized g-factors can be used to take some such effects into account. For the quenching of spin matrix elements, see *Castel* and *Towner* [16.55]; for the M1 mode, the effective g-factor is typically in the neighborhood of 0.5 or 0.6 of the free-space value. It is also sometimes useful to consider effective orbital g-factors, but the effective value is smaller, with $g_\mathrm{eff}/g_\mathrm{free} = 1.05-1.1$ [16.56]. The matrix element of $T^1(\mathrm{N})$ is the nuclear magnetic dipole moment

$$\mu = \langle II | T^1(\mathrm{N}) | II \rangle . \quad (16.37)$$

Experimental values of μ are tabulated by *Raghavan* [16.32].

In the semiclassical picture where $\Delta E = -\boldsymbol{\mu} \cdot \boldsymbol{B}(0)$, the contributions to $\boldsymbol{B}(0)$ from the orbital and spin magnetism of the ith electron are

$$\boldsymbol{B}_l(0) = -2\mu_0 r_i^{-3} \boldsymbol{l}_i , \quad (16.38)$$

$$\boldsymbol{B}_s(0) = 2\mu_0 r_i^{-3}(10)^{1/2} \left[\boldsymbol{s}_i \boldsymbol{C}_i^{(2)} \right]^{(1)} , \quad (16.39)$$

while the "contact" term for s-electrons is

$$\boldsymbol{B}_\mathrm{c}(0) = -(16\pi/3)\mu_0 \rho_i(0)\boldsymbol{s} . \quad (16.40)$$

The one-electron matrix elements of $T^1(\mathrm{e})$ are [16.36]

$$\langle lsj \| T^1(\mathrm{e}) \| l'sj' \rangle = -e(\kappa + \kappa') \langle lsj \| C^{(1)} \| l'_x sj' \rangle$$
$$\times \int r^{-2} (fg' + gf') \, dr , \quad (16.41)$$

where for a given combination lsj, $\kappa = (l-j)(2j+1)$, and l_x is the opposite-parity orbital quantum number of the small Dirac component, $l_x = l+1$ for $j = l+1/2$, $l_x = l-1$ for $j = l-1/2$. Recent high precision calculations for the hyperfine structure of helium and lithium, including relativistic corrections and second-order effects, have recently been done by *Pachucki* [16.57, 58].

Magnetic octupole hyperfine structure [16.59, 60] follows similar rules [16.36, 61]. Systems studied in recent years include Eu I excited states [16.62].

16.3.3 Hyperfine Anomalies

When the electron density is nonzero inside the nucleus, the interaction with different kinds of nuclear current density is in general different; there is, for example, a sensitivity to differing radial distributions of spin and orbital currents. The result is that the ratio of A-values for two isotopes is not necessarily the same as the ratio of nuclear g-factors [16.63]. The anomaly for two nuclear species a and b is characterized by

$$^a\Delta^b = (A_a/A_b)(g_a/g_b) - 1 . \quad (16.42)$$

Δ is seldom larger than a few per cent. The theory for the M1 mode was worked out by *Bohr* and *Weisskopf* [16.64]; there are relatively recent reviews of theory and experiment [16.65, 66], and an especially clear exposition of the semiclassical limit [16.67]. Recent experimental results include transitions in isotopes of La II [16.68], and the ground state of hydrogenlike thallium [16.69]. Anomalies are expected to be considerably smaller for the electric mode.

17. Precision Oscillator Strength and Lifetime Measurements

The accuracy of oscillator strength and lifetime measurements has improved greatly in the past twenty years. Nevertheless, these high accuracies have been achieved for only a restricted number of lines belonging to a few elements and ionization stages [17.1]. Large numbers of precision measurements must still be made as improved experimental oscillator strengths are needed, both as tests of theoretical concepts, and for diagnostics and engineering applications.

A spectral line arising from a radiative transition between atomic states i and k is characterized by its wavelength λ_{ik}, its intensity and its shape. In the limit of free atoms, the intensity per atom is determined by the emission transition rate A_{ik} or absorption oscillator strength f_{ki}, and the shape by the natural width $\Gamma_i = \hbar/\tau_i$, where τ_i is the lifetime of the excited state. While classical spectroscopic methods provide precise wavelength measurements (1 part in 10^8 or better; Chapt. 10), it has only recently been possible to measure oscillator strengths and lifetimes to better than a few percent, as discussed in this chapter. Examples of applications which require an accurate knowledge of these quantities are the interpretation of astrophysical data (Chapt. 82), atmospheric physics (Chapt. 84), combustion (Chapt. 88), the modeling and diagnosis of thermonuclear plasmas (Chapt. 86), nonlinear optics (Chapt. 72), isotope separation (Chapt. 16), and the development of new types of lasers (Chapt. 71).

Precision measurements of oscillator strengths and lifetimes also provide stringent tests of atomic structure calculations. These quantities are very sensitive to the wave functions and the approximations used, particularly in cases where electron correlations (Sect. 23.2.1) and relativistic effects (Sect. 22.1) are significant. They provide experimental tests of fundamental theory; for example, of quantum electrodynamic corrections (Sect. 27.2), and of the nonconservation of parity predicted by the unified electro-weak theory (Sect. 29.1).

In applications where only modest precision is required, semi-empirical parameterizations involving quantum defects, charge screening and polarization allow a few precise measurements to be extrapolated along isoelectronic, homologous, isoionic and Rydberg sequences. Similar methods have been applied to the atomic energy levels themselves (Sect. 10.13). They allow one to produce a very large data base of moderate precision [17.2].

The spontaneous transition rate A_{ik} (Sect. 10.16.2) is the probability per unit time (s^{-1}) for an atom in any one of the g_i states of the energy level i to make a transition to any of the g_k states of the level k. The lifetime τ_i is then given by $1/\tau_i = \sum_k A_{ik}$. The branching fraction for the kth channel of the decay of level i is defined as $F_B = \tau_i A_{ik}$, and the branching ratio (Sect. 10.17) between two decay channels is $R_B = A_{ik}/A_{ij}$. Emission and absorption rate constants differ by a factor of λ_{ik}^2, and the absorption oscillator strength f_{ki} (Sect. 10.17) is defined by

$$g_k f_{ki} = C\lambda_{ik}^2 g_i A_{ik} \, , \qquad (17.1)$$

where $C = (32\pi^3 \alpha a_0^2 \text{Ry})^{-1} = 1.499\,19 \times 10^{-14}\,\text{nm}^{-2}\,\text{s}$. Because of this relationship, the words transition rate and oscillator strength will be used almost interchangeably.

17.1 Oscillator Strengths

Oscillator strengths can be determined directly through absolute emission, absorption, or dispersion measurements, or through the combined measurement of branching ratios and lifetimes. Direct measurements compare different transitions at the same time, and require sample equilibrium, a knowledge of the absolute number density, and an absolute intensity measurement. These are in contrast to time-resolved lifetime measurements, which compare relative intensities from the same transition at different times, and require no absolute measurements. However, lifetime measurements yield oscillator strengths directly only in cases where a single decay transition channel exists, such as the lowest excited level in an atom or ion. Thus, combined measurements of lifetimes and branching ratios are often used where high precision values for oscillator strengths are required. Both absorption and dispersion measurements involve the number density of the lower level of the transition, whereas emission measurements involve that of the upper level.

17.1.1 Absorption and Dispersion Measurements

Absorption measurements involve placing a sample of atoms (for example, in a gas cell, an atomic beam, an arc, a shock tube, or within the vapor column in a furnace) between a continuous light source and a spectrometer. For an isolated spectral line, the absorption cross section for a beam of photons of frequency ν passing through the sample is

$$\sigma_{ik}(\nu) = \pi\alpha(\hbar/m)g(\nu)f_{ik} , \qquad (17.2)$$

where $g(\nu)$ is the spectral distribution function per unit frequency normalized so that $\int_0^\infty g(\nu)\,\mathrm{d}\nu = 1$. If there are N atoms per unit volume, the absorption coefficient is $k_\nu = N\sigma(\nu)$. The integrated intensity lost after passing through a distance L of the sample is

$$\int_0^\infty \Delta I(\nu)\,\mathrm{d}\nu = I_0 \int_0^\infty \left(1 - \exp^{-\sigma_{ik}(\nu)NL}\right)\,\mathrm{d}\nu$$

$$\simeq I_0\pi\alpha(\hbar/m)NLf_{ik} , \qquad (17.3)$$

where the second line applies if the sample is optically thin. Otherwise, the integral can be calculated directly, if $g(\nu)$ is known, to determine f_{ik} by the curve-of-growth method.

The Furnace Method

High precision absorption measurements have been achieved by *Blackwell* and co-workers [17.3], who have used the furnace method to study the astrophysically important neutral iron spectrum. These measurements have quoted accuracies of 0.5% on a relative scale, and 2.5% on an absolute scale. This accuracy was obtained through the use of a stable and isothermal furnace, low-noise spectral intensity recording techniques, and two identical high resolution spectrometers for the simultaneous recording of pairs of absorption lines. By selecting successive line pairs of a suitable oscillator strength ratio and adjusting the temperature and vapor pressure in the furnace, a large dynamic range of oscillator strengths could be covered. Recently, corroborative studies of the uncertainties quoted in these measurements have been undertaken, including tests that are coupled to other methods that use combinations of lifetime and branching ratio measurements [17.3].

The Hook Method

The absorption measurements described above determine the oscillator strength from the line intensity. An alternative absorptive approach is the anomalous dispersion or "hook" method, which determines the oscillator strength from the index of refraction at wavelengths near the edge of an absorption line [17.1]. The advantages of this method are its large dynamic range, its insensitivity to the line shape, and the fact that it does not saturate. The absorbing gas is placed in one arm of an interferometer and a compensator is placed in the other arm. This leads to the formation of oblique interference fringes with two characteristic hooks symmetric about the center of an absorption line. The oscillator strength is determined by the wavelength separation W between the hooks. Defining $K = \lambda_{ik}N_\mathrm{f}$, where N_f is the number of fringes per unit wavelength, then

$$f_{ik} = \frac{\pi K W^2}{\lambda_{ik}^3 \alpha^2 a_0 N L} \qquad (17.4)$$

where a_0 is the Bohr radius.

Synchrotron Radiation

Storage ring synchrotron radiation facilities now provide a source of continuum radiation that can extend the wavelength range of absorption measurements. A technique [17.4] has been developed and applied that utilizes a hollow cathode discharge as an absorbing sample, synchrotron radiation as a continuum source, and a CCD

array for vacuum ultraviolet (VUV) detection. Here relative oscillator strengths were obtained using two separate detection systems. However, VUV calibration standards are presently lacking (Sect. 17.1.4), and will be required to obtain independent tests (Sect. 17.1.3) of sets of branching fractions.

17.1.2 Emission Measurements

Emission methods use, for example, a hollow cathode, wall-stabilized arc, or shock tube to excite the source. Recent developments in the methods of Fourier transform spectrometry (FTS) [17.5, 6] offer several advantages over grating spectroscopy, as discussed next.

Fourier Transform Spectrometry

As opposed to the dispersive nature of a grating spectrograph, FTS uses interference effects from a Michelson interferometer. All radiation admitted to the spectrometer is thus incident on the detectors at all times, but different wavelengths are distinguished by their spatial modulation frequencies. The interferogram from all sinusoidal signals is sampled at a prescribed interval of path length, and compared with a laser of known frequency following the same optical path. The spectrum is recovered from the interferogram by means of a fast Fourier transform (Sect. 8.1.3). Thus, for an FTS instrument, the spectral range is determined by the sampling step size, whereas the resolution depends on the maximum path difference (this is in contrast to a grating spectrometer where the sampling step determines the resolution, and the scan length determines the spectral range).

The FTS method provides a number of attractive features in precision oscillator strength measurements. The axial symmetry and the replacement of the slit by a larger aperture can provide a throughput that is two orders of magnitude greater than that of a grating instrument of the same resolution. The precision and reproducibility are determined by the laser standard and the linearity of the wavenumber scale. The resolution can be increased as necessary to resolve a specific source line. The superior resolution allows blending and self-absorption to be more readily detected. The spectral range is limited only by detectors and filters. Recently, uv FTS instruments have been constructed that operate from the visible down to 175 nm. Since all wavelengths are observed at all times, errors from drifts in source conditions during scanning are reduced.

Hollow Cathode Lamps

Hollow cathode discharge lamps are used extensively for emission branching fraction measurements [17.5]. These lamps can generate an emission spectrum of essentially any element, and the relatively low collision rates result in line profiles that are narrow and primarily Doppler broadened. The narrow line width is a major advantage when studying line-rich spectra. The low collision rates also imply that the discharges are far from local thermodynamic equilibrium (LTE). However, this does not affect the determination of branching fractions, where only the relative strengths of lines from a common upper level are measured. These measurements can then be put on an absolute basis if lifetime measurements are available for all of the upper levels.

17.1.3 Combined Absorption, Emission and Lifetime Measurements

By combining measurements obtained in emission with those obtained in absorption (or dispersion) to obtain branching ratios, and then incorporating lifetime measurements, it is possible to use a scheme that requires no knowledge of level populations [17.1]. The scheme was originally proposed by Ladenburg in 1933, and its various modern implementations are known as "leapfrogging," "linkage" and "bow ties".

The principle of "leap-frogging" or "linkage" is illustrated in Fig. 17.1a. The decay of level 1 is unbranched, so the $1 \rightarrow 2$ transition rate is assumed known (kn) from a lifetime measurement. This is used to specify the $2 \rightarrow 3$ oscillator strength using relative absorption (ab) measurements for the $2 \rightarrow 1 : 2 \rightarrow 3$ oscillator strength ratio (and appropriate factors of the wavelengths and degeneracies). In a similar manner, this is subsequently combined with relative emission (em) measurements of the $3 \rightarrow 2 : 3 \rightarrow 4$ branching ratio to determine the $3 \rightarrow 4$ transition rate.

The principle of "bow ties" is illustrated in Fig. 17.1b. The two branching ratios for $1 \rightarrow 2 : 1 \rightarrow 4$ and for $3 \rightarrow 2 : 3 \rightarrow 4$ are measured in emission (em). The two oscillator strength ratios for $2 \rightarrow 1 : 2 \rightarrow 3$ and for $4 \rightarrow 1 : 4 \rightarrow 3$ are measured in absorption (ab). After correction for wavelength and degeneracy factors between f and A values, these relationships are combined into a quantity known as the "bow tie ratio," which would be unity for ideally accurate measurements. A significant deviation from unity can be used to trace the observations that are in error. Figure 17.1b is a "simple bow tie" connecting two upper and two lower levels with four transitions. Higher order sets of measurements can
Fig. 17.1a,b Illustration of methods for the determination of ratios of oscillator strengths (ab = absorption, em = emission, kn = known)

be similarly coupled; for example, a set of transitions between three lower levels and three upper levels can be coupled by nine simple bow ties.

In cases where both lifetime and complete branching ratio measurements exist for the same upper level, then the branching ratios can be normalized to branching fractions divided by the lifetime to obtain absolute transition probabilities.

17.1.4 Branching Ratios in Highly Ionized Atoms

In highly ionized atoms, many measurements of lifetimes in the 1–5% accuracy range have been made by ANDC (Sect. 17.2.2) analysis of beam–foil measurements. However, little work exists for the precision measurement of branching ratios in highly ionized atoms, where an intensity calibration of the detection equipment is particularly difficult. In beam-foil excitation, for example, Doppler broadening and Doppler shifts, polarization due to anisotropic excitation, and the short wavelength (≤ 200 nm) nature of the radiation are not well-suited for use with standard techniques for calibrating grating spectrometer and detection systems by the use of calibrated lamps. Calibrations have been car-

ried out using synchrotron radiation, or through the use of previously known branching ratios.

One way in which lifetime measurements are used to determine branching ratios involves precision studies of the lifetimes of the individual fine structure components of a multiplet decay. If one fine structure level has a decay channel that is not available to the other levels (for example, a spin-changing transition or an autoionization mode made possible by a J-dependent intermediate coupling) then the transition rate of the extra channel can be determined by differential lifetime measurements.

The use of Si(Li) detectors in the measurement of very short wavelength radiation in highly ionized atoms also offers possibilities for branching ratio measurements. Since these devices can specify the photon energy from pulse height information without the need for a spectrometer, they can be calibrated for detection efficiency as a function of energy. This type of detection was recently used to determine the branching ratio of the magnetic dipole channel to the two-photon decay channel in the 2s $2S_{\frac{1}{2}}$ state in one-electron krypton [17.7].

Although radiometric calibration standards are available for $\lambda > 280$ nm, technical challenges exist for their extension to shorter wavelengths. The urgent need for these standards and their desired characteristics have been discussed by *Lawler* et al. [17.4], and an operational prescription for combining sources of uncertainty in their specification has been presented by *Sikström* et al. [17.8]. A semi-empirical method for obtaining line intensity standards in the VUV has also been proposed [17.9, 10] that uses intermediate coupling (IC) amplitudes deduced from measured energy level data to obtain intensity ratios. This utilizes the observation that the $n\text{s}^2 n\text{p}^2$ and $n\text{s}^2 n\text{p}(n+1)\text{s}$ configurations in the Si, Ge and Sn isoelectronic sequences exhibit negligible configuration interaction, hence the intensity ratios within their transition arrays are accurately prescribed by the IC amplitudes. For the neutral atoms the transitions occur in the visible region, and measurements confirm the validity of the empirical values. Thus, isoelectronic extensions can yield VUV standards.

17.2 Lifetimes

The total transition rate summed over all decay channels can be measured either through frequency-resolved studies of the level width, or through time-resolved studies of the level lifetime. In order to determine the natu-

ral linewidth in a field-free spectroscopic measurement, either the lifetime must be very short, or the Doppler, pressure, and instrumental broadenings must be made very small. Line widths have been determined using

Fabry–Perot spectrometry at very low temperatures and pressures, and in beam–foil studies of radiative transitions in which the lower level decays very rapidly via autoionization. The linewidth can also be determined through the use of the phase shift method. Here modulated excitation is applied to the source, thus producing similarly modulated emitted radiation, and the width can be specified from the phase shift between the two signals. Other methods involve resonance fluorescence techniques, where sub-Doppler widths are obtained because the width of the exciting radiation selects a subset of particle motions within the sample. Resonance fluorescence techniques that can be used to determine level widths include zero-field level crossing (the Hanle effect), high-field level crossing, and double optical resonance methods, but the Hanle effect is the most common.

17.2.1 The Hanle Effect

In its most commonly used form, the Hanle effect makes use of polarized resonance radiation to excite atoms in the presence of a known variable magnetic field. The magnetic substates of the sample are anisotropically excited, and the subsequent radiation possesses a preferred angular distribution. By applying the magnetic field in a direction perpendicular to the anisotropy, the angular distribution is made to precess, producing oscillations in the radiation observed at a fixed angle. At infinite precessional frequency the intensity would be proportional to the instantaneous average angular intensity, but at finite precessional frequency it depends upon the decay that has occurred during each quarter rotation. Measured as a function of magnetic field, the emitted intensity has a Lorentzian shape centered about zero field with a width that depends on the lifetime and g-factor of the level [17.2].

17.2.2 Time–Resolved Decay Measurements

The most direct method for the experimental determination of level lifetimes is through the time-resolved measurement of the free decay of the fluorescence radiation following a cutoff of the source of excitation. An important factor limiting the accuracy is the repopulation of the level of interest by cascade transitions from higher-lying levels. For this reason, decay curve measurements fall into two classes: those that involve selective excitation of the level of interest, thus eliminating cascading altogether; and those that use correlations between cascade connected decays to account for the effects of cascades.

Selective Excitation

Lifetime measurements accurate to within a few parts in 10^3 have been obtained through selective excitation produced when appropriately tuned laser light is incident on a gas cell or a thermal beam, or on a fast ion beam (Sect. 18.1). With a gas cell or thermal beam, the timing is obtained by a pulsed laser and delayed coincidence detection. With a fast ion beam, time-of-flight methods are used. In either case, after removal of the background, the decay curve of intensity vs. time is a single exponential, and the lifetime is obtained from its semilogarithmic slope. Laser-excited time-of-flight studies were first carried out by observing the optical decay of the ion in flight following excitation using a laser beam which crossed the ion beam. In these studies, the laser light was tuned to the frequency of the desired absorption transition either through the use of a tunable dye laser, or by varying the angle of intersection to exploit the Doppler effect. Recent measurements have utilized diode laser excitation in this geometry [17.11]. A number of adaptations of this technique have been developed in which the laser and ion beams are made to be collinear, and are switched into and out of resonance within a segment of the beam by use of the Doppler effect [17.12]. The collinear geometry can provide a longer excitation region and less scattering of laser light into the detector than occurs in the crossed beam geometry. In one adaptation [17.13], excitation occurs within an electrostatic velocity switch, and the time resolution is obtained by physically moving the velocity switch. In another adaptation [17.12], the ion beam is accelerated with a spatially varying voltage ramp. The resonance region is moved relative to a fixed detector by time-sweeping either the laser tuning or the ramp voltage.

While these selective excitation methods totally eliminate the effects of cascade repopulation, they are generally limited to levels in neutral and singly ionized atoms that can be accessed from the ground state by strongly absorptive E1 transitions, and the selectivity itself is a limitation. Many very precise measurements have been made by these techniques, but they have primarily involved $\Delta n = 0$ resonance transitions in neutral alkali atoms and singly ionized alkali-like ions. A summary of these measurements is given in Table 17.1, and a comparison of these values with theoretical calculations is given in [17.14].

Table 17.1 Measured np ^{2}P$_J$ lifetimes

Atom	n	J	τ (ns)
Li	2	1/2	27.20(20)[a], 27.29(4)[b]
Na	3	1/2	16.38(8)[c], 16.40(3)[b], 16.30(2)[d]

	6	3/2	6.312(16)[m]

[a][17.17]   [b][17.18]   [c][17.19]   [d][17.20]
[e][17.21]   [f][17.22]   [g][17.23]   [h][17.24]
[i][17.25]   [j][17.26]   [k][17.27]   [l][17.11]
[m][17.28]

Advances have recently been made in the measurement of transition probabilities of long-lived metastable levels. Through a laser probing technique [17.15] using an ion storage ring, an extremely long lifetime (28 s) has been measured [17.16]. The metastable level is populated in the ion source and preserved in the storage ring until it is destructively probed at variable times after excitation. The laser light is collinearly merged with the beam and tuned to a transition that promotes the population of the metastable level to a higher unstable level. The fluorescence subsequently emitted by this unstable level gives a relative measure of the population of the metastable level. Thus, by varying the delay time between the excitation and the laser probing, a decay curve of the population remaining is obtained.

Nonselective Excitation

Much more general access can be obtained by nonselective excitation methods, such as pulsed electron beam bombardment of a gas cell or gas jet, or in-flight excitation of a fast ion beam by a thin foil. Pulsed electron beam excitation can be achieved ei-

ther through use of a suppressor grid, or by repetitive high frequency deflection of the beam across a slit so as to chop the beam. Particularly in the case of weak lines, the high frequency deflection technique offers the advantages of high current and sharp cut-off times. The high currents yield high light levels, so that high resolution spectroscopic methods can be used to eliminate the effects of line blending. Pulsed electron excitation methods are well suited to measurements in neutral and near neutral ions (although for very long lifetimes in ionized species, the decay curves can be distorted if particles escape from the viewing volume through the Coulomb explosion effect [17.29]). However, for highly ionized atoms, the only generally applicable method is thin foil excitation of a fast ion beam. Nonselective excitation techniques can also be applied to measurements such as the phase shift method [17.30] and the Hanle effect [17.31], in which case cascade repopulation also can become a serious problem. However, most of the attempts to eliminate or account for cascade effects have occurred in decay curve studies.

In beam–foil studies, the excitation is created in the dense solid environment of the foil, after which the ions emerge into a field free, collision free, high vacuum region downstream from the foil. A time-resolved decay curve is obtained by translating the foil upstream or downstream relative to the detection apparatus. The beam is a very tenuous plasma, which has both advantages and disadvantages. The low density avoids the effects of collisional de-excitation and radiation trapping, but also produces relatively low light levels. This requires fast optical systems with a corresponding reduction in wavelength dispersion, and care must be taken to avoid blending of these Doppler broadened lines. Methods have been developed by which grating monochromators can be refocussed to a moving light source, thus utilizing the angular dependence of the Doppler effect to narrow and enhance the lines.

In these nonselective excitation methods, the decay curve involves a sum of many exponentials, one corresponding to the primary level, and one to each level that cascades (either directly or indirectly) into it. Decay exponentials do not comprise an orthogonal set of functions, and the representation of an infinite sum by a finite sum through curve fitting methods (Sect. 8.1.2) can lead to large errors. Fortunately, alternative methods to exponential curve fitting exist, which permit the accurate extraction of lifetimes to be made from correlated sets of nonselectively populated decay curves.

ANDC Method

Precision lifetime values have been extracted from cascade-affected decay curves by a technique known as the arbitrarily normalized decay curve (ANDC) method (Sect. 18.1.1, [17.32]), which exploits dynamical correlations among the cascade-related decay curves. These correlations arise from the rate equation that connects the population of a given level to those of the levels that cascade directly into it. The instantaneous population of each level n is, to within constant factors ξ_n involving the transition probabilities and detection efficiencies, proportional to the intensity of radiation $I_n(t)$ emitted in any convenient decay branch. In terms of these intensities, the population equation for the level n can be written in terms of its direct cascades from levels i as

$$\frac{\mathrm{d}I_n}{\mathrm{d}t}(t_\mathrm{p}) = \sum_i \xi_i I_i(t_\mathrm{p}) - I_n(t_\mathrm{p})/\tau_n \,. \qquad (17.5)$$

Thus, if all decay curves are measured at the same discrete intervals of time t_p, the population equation provides a separate independent linear relationship among these measured decay curves for each value of t_p, with common constant coefficients given by the lifetime τ_n and the normalization parameters ξ_i. Although the sum over cascades is formally unbounded, the dominant effects of cascading from highly excited states are often accounted for by indirect cascading through the lower states, in which case the sum can be truncated after only a few terms. ANDC analysis consists of using this equation to relate the measured $I_k(t_\mathrm{p})$ (using numerical differentiation or integration) to determine τ_k and the ξ_i through a linear regression. If all significant direct cascades have been included, the goodness-of-fit will be uniform for all time subregions, indicating reliability. If important cascades have been omitted or blends are present, the fit will vary over time subregions, indicating a failure of the analysis. Very rugged algorithms have been developed [17.33] that permit accurate lifetimes to be extracted even in cases where statistical fluctuations are substantial, and studies of the propagation and correlation of errors have been made. Clearly the ANDC method is most easily applied to systems for which repopulation effects are dominated by a small number of cascade channels. Further applications are discussed in Sect. 18.1.1.

17.2.3 Other Methods

Coincidence measurements provide another method for elimination of cascade effects. While the low count rates and correspondingly high accidental rates make the application of these methods difficult for optical spectra, the use of Si(Li) detectors for the very short wavelength emission in very highly ionized systems offers new possibilities [17.34] for these measurements.

Another method of accounting for cascading involves the combined use of a laser and beam–foil excitation [17.35, 36]. The beam–foil excitation provides a source of ions in excited states, and a chopped laser is used to stimulate transitions between two excited states. By subtracting the decay curves obtained with laser on and with laser off, the cascade-free, laser-produced portion of the decay curve is obtained.

17.2.4 Multiplexed Detection

Recently, the detection efficiency and reliability of beam–foil measurements have been improved through the use of position sensitive detectors (PSD), which permits measurement of decay curves as a function both of wavelength and of time since excitation. The PSD is mounted at the exit focus of the analyzing monochromator, where it records all lines within a given wavelength interval simultaneously, including reference lines with the same Doppler shifts. Decay curves can be constructed by integrating over a line profile, and that profile can be examined for exponential content to eliminate blending. The time dependent backgrounds underlying the decay curves are directly available from the neighboring channels.

The use of multiplexed detection greatly enhances the data collection efficiency, and causes many possible systematic errors to cancel in differential measurements. Effects such as fluctuations in the beam current, degradation of the foil, divergence of the beam, etc., affect all decay curves in the same way.

The most accurate measurement [17.37] made by beam–foil excitation ($\pm 0.26\%$) used a type of multiplexed detection in which two spectrometers simultaneously viewed the decays of the $^1P_1$ and $^3P_1$ levels of the 1s3p configuration in neutral helium. The $^1P_1$ emission exhibited the desired multi-exponential decay curve (with only weak cascading), whereas the $^3P_1$ emission exhibited a zero field quantum beat pattern superimposed on its decay because of the anisotropic excitation of that level. The quantum beats provided an in-beam time base calibration which permitted this high precision.

18. Spectroscopy of Ions Using Fast Beams and Ion Traps

A knowledge of the spectra of ionized atoms is of importance in many fields. A wide variety of light sources are available for the study of such spectra. In recent years, techniques coming under the broad headings of fast beams and ion traps have been used extensively for such studies. This chapter will consider the advantages each technique has for particular applications.

18.1 Spectroscopy Using Fast Ion Beams

A beam of ionized atoms has several advantages as a spectroscopic source. Unlike arcs, sparks, and high temperature plasmas, the ions can be studied in an environment that is free of electric and magnetic fields and relatively free of interparticle collisions [18.1]. Standard accelerator techniques can be used to produce a well-collimated, mass-analyzed beam of ions having a low velocity spread. In principle, virtually any charge state of any element, isotopically pure if required, can be obtained. Finally, the well-defined velocity of the ions permits the study of processes evolving in time in terms of their spatial evolution along the beam. This is particularly important in the case of lifetime measurements.

18.1.1 Beam–Foil Spectroscopy

A beam of ions passing through a thin (50–200 nm) foil emerges in a range of ionization states, with the mean charge state increasing with the incident energy [18.2]. Thin foils made from a light element, usually carbon, are used to minimize particle scattering and energy straggling. Thus, a F^+ beam of 0.5 MeV that enters a carbon foil emerges with a mean charge of about $+2e$, while a Xe ion beam at 180 MeV emerges with a mean charge of about $+29e$. The outer electrons are distributed over many different states, most of which then decay to lower states by photon emission as the ions move away from the foil. The beam-foil interaction is a highly nonselective excitation process, which is an advantage for spectroscopic studies but causes a problem for lifetime

measurements. (Methods for tackling this problem are discussed in Sect. 17.2.2.) A major disadvantage of the beam-foil light source is its low intensity; consequently, scanning spectrometers have usually been equipped with photon-counting detectors. In recent years, however, position sensitive detectors have become available, which permit the simultaneous recording of information over a wide spectral range, resulting in a greatly improved detection efficiency (Sect. 44.4).

The intrinsic properties of the beam-foil interaction are important in understanding its usefulness for spectroscopic studies. The electrons of the moving ion are shielded from the travelling ion core as the ion passes through the foil and are then recaptured into a statistical distribution of outer states. The probability that more than one electron in a given ion will be captured in an excited state is high relative to other light sources, and hence the technique has been used extensively to study doubly- and multiply-excited states [18.3] (Sect. 64.1). The interaction also favours the production of high-L Rydberg states [18.4] (Chapt. 14). At low incident ion energies, electron capture can give a downstream beam containing neutral and even negative ions. The first observation of photon emission between bound states in a negative ion was achieved using beam-foil excitation [18.5]. A more recent example of multiple excitation in a negative ion is the identification in lithium-like He^- of the $2p^3\ ^4S^o$ state in which all three electrons are excited [18.6,7]. The observation of the same triply excited level in neutral Li has resulted in one of the most pre-

cise (40 ppm) wavelength measurements in beam-foil spectroscopy [18.8]. The time-resolution inherent in the beam-foil source can also be used to aid in the identification of transitions from long-lived states, such as intercombination transitions [18.9] (Sect. 10.16). Here the beam foil spectrum is first recorded close to the foil and then far downstream (a few mm to a few cm); "far" in this context means that the short-lived states have had time to decay. The intercombination (or other long-lived) transitions are then easily identified by their relatively strong intensity in the (overall much weaker) downstream spectrum. This has been a decisive step in identifying laboratory lines with lines in the solar corona [18.10, 11]. A recent example of beam-foil spectroscopic analysis is given in [18.12].

One problem with using fast ions as a light source for precision wavelength measurements is the inevitable Doppler broadening of the spectral lines. However, this can be removed by appropriately refocusing the spectrometer [18.13, 14]. Furthermore, since the Doppler width varies with the wavelength, and the line width of a given grating spectrometer used on a fast ion beam usually is dominated by spectrometer geometry, not by diffraction, Doppler broadening often becomes less important in measurements at shorter wavelengths, as in the UV or EUV. This is the primary range of emission from the more highly-ionized atoms, and that is where beam-foil spectroscopy really comes into its own. For example, the leading terms omitted in calculations of the wavelength of the $1s2s\,^3S - 1s2p\,^3P^o$ transition in He-like ions [18.15] scale as Z^4, with the result that measurements made with higher-Z ions need not have as high a precision for a meaningful test of the calculation as would be required for a low-Z ion. The beam-foil measurement for the leading ($J = 1$ to $J = 2$) component in Ni^{26+} [18.16] has an uncertainty of 0.02%, which is about equal to that in the calculation. The two values agree well within this limit. (Naturally, measurements made using the beam-laser techniques discussed in Sect. 18.1.3 yield results with a much higher precision, but such measurements are restricted to low-Z ions because of the excitation energy steps and transition wavelengths involved; the theoretical uncertainties in this case are also much smaller.)

Turning now to beam-foil lifetime measurements, here the intensity of a given transition is studied as a function of the time that has elapsed since excitation, usually by stepping the foil upstream. Because of the nonselective nature of the excitation, the possibility exists that the state being studied is itself being repopulated by higher-lying states, resulting in a de-

cay curve that consists of the sum of exponential terms, one term corresponding to the primary level being studied and the other terms to higher-lying levels involved in repopulating that level. The analysis of such decay curves can be problematic. Several computer routines have been developed to tackle this problem, such as DISCRETE [18.17] and HOMER [18.18]. One useful trick here is to record the decay curve for each of the major transitions repopulating a given primary level and then include the lifetimes obtained for those transitions as fixed parameters in fitting the decay curves for that primary level. A more rigorous method to include the decay data from the repopulating transitions in the analysis of the primary lifetime is the ANDC technique described in detail in Sect. 17.2.2. An additional problem may arise in the measurement of very short lifetimes, which tend to be associated with short-wavelength transitions for which no lenses are available to focus the beam at the spectrometer entrance slit. The observation region is then defined by the spectrometer aperture and extends for a finite length along the beam that can be comparable to, or even greater than, the decay length for that transition. Here it is necessary to fit the decay curve including the vignetted region around the foil [18.19, 20]. Lifetimes in the picosecond regime have been successfully measured in this way.

18.1.2 Beam–Gas Spectroscopy

While the use of a gas target in place of a foil has the obvious advantage that it cannot break, the loss of a tightly-localized excitation region means that the fine time-resolution of the beam-foil light source is largely lost. The beam-gas source, however, has two main advantages. First, the passage of a beam of fast, highly-stripped ions through a neutral gas results in the production of recoil ions (Sect. 65.2) that are moving very slowly relative to the beam ions, thus reducing the Doppler broadening problem mentioned earlier. Secondly, it is possible to study details of the interaction between the gas and beam ions, such as charge-exchange reactions, as they occur, rather than merely observing their consequences. Such experiments have experienced a resurgence with the advent of the ECR ion source [18.21, 22]. A recent example of such work is given in [18.23].

When a fast beam of highly-charged ions passes through a neutral gas, it leaves a trail of ionized gas atoms in its wake. These ions recoil from the interaction region with relatively low velocities ($v/c = 10^{-4} - 10^{-5}$).

Furthermore, the recoil velocities tend to be restricted to a narrow range of angles approximately perpendicular to the beam direction. Hence, observation of the radiation emitted by the recoil ions transverse to their motion, i.e., along a direction parallel to the beam, gives a very low Doppler width, $\Delta\lambda_D/\lambda$ being typically 10^{-6}, the limit imposed by the thermal motion of the target gas atoms. Recoil ion spectroscopy is therefore a useful procedure for precision wavelength measurements for highly-stripped ions, such as He-like Ar^{16+} recoil ions produced by a beam of $2\,GeV$ U^{70+} ions [18.24]. The energies and charge states of the recoil ions may be determined using standard time-of-flight techniques [18.25], and detecting the recoil ions in coincidence with their progenitor ions yields information on the dependence of the recoil energy on the details of the ionizing collision [18.26]. In later developments, the differentially pumped gas target has first been replaced by a supersonic jet target which reduces the thermal motion of the target particles, and then by a cold atom sample in an atom trap; replacing optical detection by position-sensitive fast-timing detectors for all collision products, the technique of COLTRIMS (cold target recoil ion momentum spectroscopy) can now be employed to study the momentum distribution of the collision partners (developed largely by the groups of H. Schmidt-Böcking (Frankfurt) and C. L. Cocke (Manhattan, Kansas)).

Measurements made on the projectile ions themselves also yield useful information about electron-capture processes. The strength of such a process is described in terms of its cross section (Sect. 63.1.2). Recent work has shifted from measurements of the total cross section for electron capture to more detailed studies of the individual capture channels [18.27]. Such studies provide much more stringent tests of theoretical models of ion–atom charge transfer processes. They often involve such techniques as spectroscopy of the optical radiation or of the Auger electrons (Sect. 25.1.1) emitted by the ions after electron exchange. This topic is covered in Chaps. 51, 64, and 65. A further example is the study by *Prior* et al. [18.28] of the angular distribution of Auger electrons emitted by doubly-excited states formed in hydrogen-like projectile ions with an energy of 40 keV, following double-electron capture from target helium atoms. They found that significant alignment of the magnetic substates of the projectile ions can result from electron capture. Such anisotropies in the Auger electron emission demonstrate the danger of using single-angle measurements to determine cross sections.

18.1.3 Beam–Laser Spectroscopy

As for the beam-foil source, excitation of a beam of fast ions by a transverse tuneable laser produces the localized excitation required for high temporal resolution. Now, however, the excitation is highly selective, permitting the population of just a single level. The laser-induced-fluorescence (LIF) signal as a function of the distance along the beam from the excitation region is therefore described by a single exponential decay, for which an exact analysis with rigorous error bounds is possible. The restriction to levels that can be accessed by electric dipole (E1) transitions from the ground and metastable levels may be overcome by combining laser excitation with a nonselective mode of excitation, as in beam-gas-laser [18.29, 30] or beam-foil-laser [18.31] measurements. A discussion of precision lifetime measurements using laser excitation of a fast beam is given in Sect. 17.2.2. Here the discussion will be limited to precision optical spectroscopy. Examples of precision beam-laser wavelength measurements may be found in [18.32, 33]. A further example is the measurement of the spin-forbidden $1s2s\ ^1S_0 - 1s2p\ ^3P_1$ interval in N^{5+} [18.34], where the experimental value, $986.321\,(7)\,cm^{-1}$ is in agreement with the calculated value, $986.58\,(30)\,cm^{-1}$ [18.34]. An example of a similar measurement in a molecular ion is given in [18.35], while a recent study of the hyperfine structure in a rare-earth ion is given in [18.36].

A major aim in beam-laser spectroscopy is to minimize the width of the LIF signal. The instrumental linewidth of the laser itself can be reduced to below 1 kHz, so that the width of the LIF signal is usually dominated by the velocity spread of the ions and by the divergences of the ion and laser beams. The effects of beam divergence can be minimized by using a collinear geometry, in which the ion and laser beams are parallel. If the angle between the ion and laser beams is θ, the Doppler-shifted laser frequency, as measured in the ion's rest frame, is $f_L(1 - \beta\cos\theta)$, where f_L is the laser frequency and $\beta = v/c$ and is much less than unity. Hence the range in frequency resulting from a beam divergence $\Delta\theta$ is given by $f_L\beta\sin\theta\,\Delta\theta$, which tends to zero as θ tends to zero. One disadvantage of the collinear geometry is that, if the laser is brought into resonance with an atomic transition by adjusting the ion velocity and/or the laser frequency, the LIF signal is produced over the entire overlap region between the ion and laser beams. The resonance can be restricted to a desired region by setting the ion velocity to be slightly off resonance. The velocity can

then be adjusted locally for resonance with the laser by passing the ion beam through a Faraday cage electrode to which an adjustable voltage is applied [18.37, 38]. The width of the resonance signal here is usually dominated by the spread in the ion velocity, $c\,\Delta\beta$, usually arising in the ion source being used. The width resulting from a given $\Delta\beta$ can therefore be reduced by using a higher ion energy. This is known as kinematic compression. In terms of the ion energy E, the range in the ion energy ΔE and the ion mass M, the Doppler width of the LIF signal is given by $f_L \Delta E/(2Mc^2E)^{1/2}$, and thus decreases as E is increased.

A more significant improvement in frequency resolution is made possible by including rf resonance in a laser double-resonance experiment. Here the ions are brought into resonance with an off resonance laser using two separate Faraday cage electrodes. The first resonance depletes the population in the ion state from which excitation occurs, thus weakening the second resonance signal. An rf field is then applied to the ions between the two electrodes. Tuning the frequency of this field over the region that corresponds to fine- or hyperfine-structure intervals in the ion can then repopulate the state from which laser excitation occurs, thus re-establishing the second laser LIF resonance signal. The width of the resonance signal is now determined by the *transit-time broadening* that results from the finite time spent by the ions in the rf field. For example, in the experi-

ments by *Sen* et al. [18.38] with a beam of ^{131}Eu$^+$ ions at 1.35 keV, the width of the laser-rf double-resonance signal was 59 kHz, compared with a width of 45 MHz obtained using a single LIF resonance.

18.1.4 Other Techniques of Ion–Beam Spectroscopy

Ion beams find uses in many other applications, three of the main areas involving storage rings (discussed in Sect. 18.2.2), merged beams, and studies of the ion-surface interaction at grazing incidence. Merged beam experiments usually study recombination processes involving electrons and atomic or molecular ions (Sect. 54.1 regarding recombination processes). The advantage of using merged beams is that the time development of the processes may be studied spatially, while maintaining a low relative velocity between the ions and the electrons. This permits measurements at the low energies of importance in studies of Rydberg state formation and in some astrophysical applications. A very different type of experiment studies the ion-surface interaction using a well-collimated ion beam at grazing incidence on a clean, flat surface. Such experiments have revealed very large atomic orientations [18.39]. This orientation can be passed on to the nuclei of the atoms via the hyperfine interaction, thus providing a source of oriented nuclei.

18.2 Spectroscopy Using Ion Traps

A basic purpose of ion traps is to confine ions to the field of view of detectors for time intervals that are longer than the radiative lifetimes of long-lived atomic levels of possible interest. At thermal energies, the ion velocities are large enough to leave a typical detection zone within microseconds. Electrostatic (Kingdon), magnetic (Penning), and radiofrequency (Paul) traps have served for this task for decades (Chapt. 75), with recent additions to the armory by electrostatic mirrors of various shapes [18.40, 41]. Two trap varieties of particular interest for spectroscopy, the electron beam ion trap and the heavy-ion storage ring, will be treated in Sects. 18.2.1 and 18.2.2, respectively.

Collisions with the neutral atoms and molecules of the residual gas cause charge exchange, and thus loss of the ion species. Therefore, an ultrahigh vacuum is of primary importance. Over the last three decades the figure of merit has moved from pressures of about 10^{-8} mbar to about 10^{-11} mbar. Further improvements can be ex-

pected from working with traps at liquid helium temperature; in fact, even ion traps as large as an ion storage ring at Aarhus (Sect. 18.2.1) have been cooled considerably to vary both the vacuum and the amount of blackbody radiation experienced by ions in weakly bound states.

The energy steps in multiply charged ions are regularly larger than what is available from lasers, at least for excitation from the ground state. Hence, single-ion trapping and laser spectroscopic investigation are rarely an option for these ions; many ions are needed to provide a sufficiently strong emission signal. The production of quantities of multiply charged ions used to be achieved by electron bombardment of a dilute gas inside the trap volume, or by ablation from a surface. Evidently, this is detrimental to any subsequent measurements, since the residual gas is still present. Precision work like mass spectrometry that exploits the ion cyclotron motion of stored ions, or detailed studies of the radiative processes (including the effects of the interrogating laser field)

in ions nowadays employ a sequence of ion traps. In a first trap, the ions of interest are produced and possibly cooled by laser light or other mechanisms, and then, by applying electric fields, the ions of interest are moved to a second trap that works under better vacuum conditions or that can be more finely tuned. In the same sense, a heavy-ion storage ring is being fed by an isotopically pure, charge-state selected ion beam. Any loss of ions, measured by whatever means, is thus proportional to the loss of the ion species of interest.

18.2.1 Electron Beam Ion Traps

Electron beam ion traps (EBIT) make use of the attractive potential of a high-density electron beam, as well as of the space charge compensation that is provided by the electron beam to any ion cloud already trapped. Most electron beam ion traps generate the high-current density electron beam by feeding the beam from an electron gun into a magnetic field that then compresses and guides the beam. In most cases, superconducting magnets with fields of 3 to 8 T are being used, and current densities of the order of 10^4 A/cm^2 are reached. This high current density corresponds to an electron density of the order of 10^{11} /cm^3. This low-density environment, roughly comparable to tokamak discharges, is one of the factors that renders the electron beam ion trap a very interesting device for laboratory astrophysics. The magnetic field helps to confine any ion cloud that is produced from the residual gas (or gas bled in) or from injected low charge ions. However, the ions could move away along the field lines, if they were not stopped by potential barriers provided by electrically charged drift tubes. Obviously, the basic design is the same as that of a Penning trap, with the permanent electron beam added. In fact, EBIT with the electron beam on has been said to operate in electronic trapping mode [18.42]; while the same device with the electron beam off ("magnetic trapping mode") still works as a Penning trap. This option of producing an ion cloud with intense electron bombardment and then studying the ions without the electron beam present is the basis for a variety of experiments on charge exchange (CX) reactions and long-lived excited levels [18.43] (see below).

The first working electron beam ion trap, EBIT-I, has been set up at Livermore [18.44, 45]. The successful operation instigated an upgrade to SuperEBIT, the first such machine that was able to completely ionize all naturally occurring elements [18.46]. Based mostly on the Livermore design, some 8 to 10 EBITs are now either running or under construction around the world. The EBIT operating principles have, for example, been described by *Currell* [18.47].

Ionization of ions trapped in the combination of electrical fields proceeds as long as the electron beam energy is high enough to overcome the ionization potential. Thus, the highest charge state can be pre-selected by the appropriate choice of the electron beam energy. The technical effort required to reach, for example, bare uranium in SuperEBIT is much smaller than in an ion accelerator. In both cases the ionization is achieved by frequent energetic collisions of ions with electrons. In SuperEBIT, the ions are (practically) stationary, and the design energy of SuperEBIT, 250 keV, is enough to remove even the last electron of uranium. At a heavy-ion accelerator, the electrons are stationary (in a foil target), and the ions are fast. Consequently an ion energy per nucleon that is higher by the proton/electron mass ratio is required – some 500 MeV/amu. Such energetic ion beams are only available in a few large accelerator laboratories, whereas an electron beam ion trap with its auxiliary equipment fits into an office-sized laboratory space. Of course, there are experiments that need specific properties of either fast ion beams or stationary ions, so both types of devices have their specific merit.

The ions in an EBIT are not only stationary in the sense that they are localized in a cloud, and moving either way along the magnetic field with the same probability, but their energy (temperature) can also be controlled by the height of the potential barriers. The voltages on the confining drift tubes are usually chosen to be few hundred volts. This makes for barrier potentials $+qeU$ (charge state q, elementary charge e, voltage U) that are higher for highly charged ions than for low-charge state ions. This not only benefits the confinement of highly charged ions directly; light ions (residual gas or purposely bled in gases) may become fully ionized by the collisions with the electron beam and by charge exchange, but they still have a larger chance to evaporate from the trap and thus they cool the remaining ion cloud. Under typical conditions, the ion cloud may have a temperature of a few keV. This can be lowered by introducing a cooling gas and by lowering the potential barriers. With Cs^{45+} in the trap, this has been demonstrated by reducing the (thermal) Doppler spread of X-ray emission lines until it was smaller than the natural line width of the emitter, thus yielding a measurement of femtosecond level lifetimes from highly resolved X-ray spectra [18.48].

The other good level lifetime range of an EBIT reaches from a few microseconds (limited by practical switching issues) to many milliseconds. Under direct optical (X-ray, EUV, visible) observation of a spectral feature, the electron beam is used to produce an ion cloud with ions of a desired charge state. When the electron beam is stopped, all direct excitation and prompt emission ceases. Any later photon signal relates to delayed emission from long-lived levels, or from excitation by charge transfer collisions (highly charged ions capturing electrons from the residual gas atoms). CX is an important loss mechanism, and the CX signal also serves as a monitor of the number of ions remaining in the trap. Owing to the excellent vacuum in cryogenic EBITs, trapping times of many seconds, if not minutes have been observed [18.43]. The ion loss rate is the major correction to the apparent decay time of the delayed photon signal. For atomic level lifetimes of a few milliseconds and less, this correction is small (a few percent or less). EBIT lifetime measurements that take this correction into account yield results that agree with those from heavy-ion storage rings [18.49] and that are, at uncertainties of 0.5% and less, remark-

ably consistent with theory in a case for which the theory can do very well (see Fig. 18.1). This observation can be turned around and interpreted as a demonstration of the reliability of the experimental techniques that then can be applied to more complex cases in which theory evidently has problems (for examples, see [18.50, 51]).

An EBIT is an excellent light source for precision spectroscopy of highly charged ions because it not only gives access to all charge states of all elements, but it does so at low particle densities. Of particular interest to precision spectroscopy have been the ions with a single valence electron (Li, Na, Cu isoelectronic sequences) that are rather amenable to calculation. Such spectra of ions up to $Z = 60$ or 70 have been measured at low-density plasmas like the tokamak, and they have been found to agree well with theory. Higher charge states were then reached in laser-produced plasmas (Sect. 44.1.2), but the wavelength results seemed to deviate from the theoretical trend that had supported the tokamak results. There also were (very few) high-nuclear charge Z data from fast ion beams. Electron beam ion trap data have now confirmed that the trend of the tokamak data was correct and that theory [including second-order quantum electrodynamics (QED) contributions] provides a good description of the $n = 3$ (Na sequence) [18.52] and $n = 4$ levels (Cu sequence) [18.53] up to $Z = 92$, within the 40 ppm error margin of the EBIT results for the heaviest Cu-like ions. The agreement with theory for the Zn-like ions of the same elements is much poorer. As the QED contributions are rather similar, this is a problem of theory with the computational treatment of two (and more) valence electrons in the same shell.

The atomic systems purportedly under best theoretical control are H-like ions, with only one electron in total. In high-Z H-like ions, the lines of highest interest are in the hard X-ray range ($n = 1-2$), or are severely lifetime-broadened (2s–2p) and in the EUV. One line is in the visible (for a number of ions), where it is accessible to high-resolution spectroscopy, and not even notably broadened, because its upper level has a millisecond-range lifetime: the M1 transition between the hyperfine levels of the ground state. For two isotopes (of Bi and Pb), this transition has been induced by laser radiation in a heavy-ion storage ring ([18.54], see below), and for 5 isotopes (of Re, Ho, and Tl) emission spectroscopy at the SuperEBIT electron beam ion trap [18.55] was successful. Using the ion cloud (with its cross section largely determined by the electron beam diameter of about

Fig. 18.1 The lifetime of the 1s2s ^{3}S$_1$ level in the He isoelectronic sequence varies by 15 orders of magnitude from He (about 6000 s) to Xe^{52+} (a few picoseconds). The figure shows the deviation of selected experimental results from calculations, and indicates the dominant experimental techniques for the various lifetime ranges. The consistency of experimental results from a heavy-ion storage ring (TSR Heidelberg) and an electron beam ion trap (Livermore EBIT-II) with theory in the low-Z range is impressive. (After [18.50]).

70 μm) as a light source without a further entrance slit, a high-efficiency transmission grating spectrometer, and a position-sensitive detector, lines from two Tl isotopes were recorded simultaneously [18.55]. The differential effects of the two nuclei yielded additional information on the charge distribution in the nucleus, on top of the magnetic moment distribution that makes up the dominant effect. These results are required for a better interpretation of parity nonconservation (PNC; Chapt. 29) measurements of neutral Tl atoms, in which the nuclear magnetic moments so far have been treated only as a point dipole. Corresponding measurements are also being done on Li-like ions, and again the most precise data so far (on Bi) have been obtained at SuperEBIT.

One of the pertinent problems in astrophysics is the cataloguing of spectral lines in all spectral ranges, both for identifying spectral features and thus learning about the composition of a light source, and for modeling of the light source in order to understand its "operating conditions". Even data bases that claim "practical completeness", however, are found to be grossly incomplete in the EUV and soft-X-ray ranges that have been opened to high-resolution observations by the grating spectrometers on board the *Chandra* and *XMM-Newton* spacecrafts. Here observations at electron beam ion traps fill in much of the needed data, at comparable quality. Moreover, an EBIT as a kind of analog computer does more than provide correct line positions: the spectra show line ratios from a light source with known electron energy (and the option of known temperature by simulating a Maxwellian energy distribution [18.56]) and particle density. This serves both as a check on collisional-radiative models and as an immediate data resource for astrophysics.

Most X-ray data from EBITs have been collected using solid state detectors [Si(Li), Ge] that offer high detection efficiency (large solid angle) and signal timing on the microsecond scale, but feature poor spectral resolution. High-resolution instruments like crystal spectrometers are necessary to analyze spectra in any detail; equipped with position-sensitive detectors, such instruments do much better than scanning spectrometers in terms of data collection rate and calibration. However, they suffer from the low diffraction efficiency of the crystals. Recently a new device, the microcalorimeter, has started to show its interesting properties. In these devices, small absorbers at mK-temperatures show a measurable temperature increase when absorbing an X-ray photon, and the signal is proportional to the deposited photon energy [18.57]. The

linewidth of the best devices is below 10 eV (not as good as a crystal spectrometer, but much better than a traditional solid state diode), the sensor pixels can be grouped in arrays to make for a larger area and for cross references among pixels (which helps with calibration and with the rejection of cosmic ray events), and the signal processing is fast enough to permit time resolution on the millisecond range. A spaceflight engineering spare has been used at the Livermore EBITs to study, for example, soft-X-rays of light elements as seen from CX near comets [18.58], or measure the (10 ms) time constant of the M3 decay in a Ni-like ion (Xe^{26+}) [18.59].

Last, but not least, the well defined and adjustable electron beam energy permits detailed studies of the interaction of fast electrons with highly charged ions. This includes, for example, the spectroscopy of dielectronic recombination (DR) resonances, or the exploration of radiative recombination (RR) (Chapt. 55). These processes can be investigated up to the highest ion charges, where relativistic and QED contributions (like the Generalized Breit interaction) matter.

18.2.2 Heavy–Ion Storage Rings

With foil-excited ion beams and long level-lifetimes, decay curves spread out along the beam, and the signal from a given width of the field of view may drop to the detector background level. The decay lengths of microsecond lifetime levels are on the order of 10 m, and those of millisecond levels are tens of kilometers. In such cases it is advantageous to curve the beam line around on itself, forming a storage ring, in which the ions pass in front of the detector over and over again. Heavy-ion storage rings need excellent vacuum conditions (10^{-11} mbar and better) to reach storage times of seconds, minutes, or hours, depending on the electronic structure of the stored ions and on the ion beam energy. The dominant loss processes are electron capture and loss, small angle scattering, and large angle (inelastic) scattering as with any fast ion beams [18.60], but these are aggravated here by the much longer path lengths.

Storage rings (for example, TSR Heidelberg, ASTRID Aarhus, CRYRING Stockholm, ESR Darmstadt), with magnetic dipoles and quadrupoles for beam transport and focusing, sort the stored particles by their momentum. The typical ion beam energies range from a few dozen keV total to hundreds of MeV per nucleon (ESR). Electrostatic storage rings (ELISA Aarhus and more under construction) have only electrical fields and

select by particle energy, usually below about 100 keV (for a review, see [18.61]). They are more suitable for low-charge heavy ions and ion molecules, including biomolecules, than the magnetic rings that can handle very fast particles. Magnetic storage rings usually have electron cooler sections in which a "cool" electron beam (with a low longitudinal velocity spread from kinematic compression) of almost the same velocity as the circulating ion beam is merged with the latter for a path of a few meters (and is then deflected out again). By scattering among electrons and ions, the momentum spread of the electrons (small) and ions (larger) equilibrates, leaving the ion beam with a narrower momentum distribution and thus cooled. Cooling, which typically takes a few seconds, improves the storage behaviour of the ion beam and the energy resolution of, for example, dielectronic recombination (DR) studies (Chapt. 55). For these, the same electron cooler is now tuned to provide electrons at a well defined but different velocity. Thus the electron cooler can serve as an electron target, without the complications of a foil target in beam-foil spectroscopy. The difference velocity can be chosen from a wide range, including zero. Extremely low energy collisions are being investigated for the study of DR and for the recombination of molecular radicals. When a beam of molecular ions is injected, storage is long enough to let some of the internal degrees of freedom relax, and then a beam of molecular ions can be extracted that are closer to their ground state.

A cooled ion beam, with its narrow velocity distribution, is also of interest for laser-ion interaction studies, offering higher resolution and better signal. Laser-assisted electron capture in the electron cooler, as well as laser spectroscopy on high-lying levels populated by DR, are possible. One of the problems with precision wavelength measurements involving fast ions is, as always the accurate determination of the velocity, as a step towards determining Doppler corrections. At TSR Heidelberg, a beam of Li$^+$ ions was subjected to a laser beam from ahead, tuned to one of the 2s–2p transitions. A second laser beam from behind probed the position of the Lamb dip in the velocity distribution and thus assured that it would meet the same velocity group of the multi-MeV stored ions. Accurate off-line calibrations of the laser frequencies then permitted a test of the Doppler formula to a relative precision of 2.2×10^{-7} [18.62].

The Doppler shift determination in any observation of fast ions requires accurate angle measurements. These are nontrivial, because the detection efficiency of any finite size spectrometer or extended detector may be non-uniform as a function of position or angle. One technique calls for segmented ("granular") X-ray detectors, the strips of which are calibrated individually [18.63]. Relativity changes the emission pattern seen in the laboratory rest frame to one that favours forward emission. This is beneficial for zero-degree spectroscopy, that is, an observation along the ion beam path. At ESR Darmstadt, bare ions captured an electron in the electron cooler section, and the resulting X-rays were detected from straight ahead (behind the next dipole magnet that deflected the ion beam). This geometry maximizes the Doppler shift, but minimizes the uncertainty relating to geometry. Also, after electron capture, the ion in the bending magnet section follows a trajectory that differs from that of the unperturbed ions. The ion can be detected and, in coincidence with the X-ray detector, make for a very clean and charge-specific spectrum. Similar coincidence measurements make it possible to use a low-pressure gas jet target in a high-energy ion storage ring, evaluating only coincidences of X-ray photons and charge-changing events [18.63]. Fast ions (energetic enough to achieve the desired charge state) can also be decelerated in a storage ring, which helps to do systematic checks of the Doppler effect and to work at lower Doppler shift [18.63].

As mentioned in Sect. 18.2.1, laser-resonance techniques have been used to find the ground state hyperfine transition in two H-like heavy isotopes. In one of them, the lifetime was also measured, by recording the fluorescence decay from the ion beam after switching off the laser [18.54]. For lower charge states, one can exploit the excitation that ions carry into the ring from their production in the ion source, or from stripping processes in the injector accelerator [18.64]. Lifetimes from half a millisecond to several seconds have been measured this way by passive observation [18.50], with an accuracy of better than 0.2% in favourable cases. Other techniques use excitation by DR in the ring [18.65], or laser probing of the remaining metastable level population so that fluorescence is emitted near a photomultiplier detector [18.66]. With a stored beam of negative ions, even blackbody radiation may be sufficient to photodetach the weakly bound last electron; the ensuing neutral atom is not deflected at the next bending section and leaves the ring to be detected. All in all, lifetime measurements at storage rings reach from 10 µs to about 1 min.

19. Line Shapes and Radiation Transfer

The shapes of collisionally broadened atomic lines is a topic almost as old as Fraunhofer's discovery of the existence of discrete lines. *Lorentz* provided the first quantitative theory in 1906 [19.1], and *Weisskopf* advanced this to the *impact theory* by 1933 [19.2]. *Holtsmark* [19.3], *Kuhn* [19.4] and *Margenau* [19.5] meanwhile developed the *quasistatic* or *statistical* theory which describes the line wing, and *Jablonski* put this on a quantum mechanical footing in the context of free–free molecular radiation [19.6, 7]. By the 1940s, satellite bands in the line wings, and a variety of high and low pressure line shapes and broadening rates had been measured. Initial confusion regarding the validity of the contrasting *impact* versus *static* approaches was largely resolved by unified treatments of the Fourier integral theory [19.8–13]. *Baranger* then provided a quantum basis for the impact theory, including level degeneracies [19.14]. Descriptions can be found in a variety of reviews and references therein, including [19.2, 5, 15–20]. The broadening of molecular lines involves the additional complication of rotationally nonadiabatic collisions; this was initially addressed by *Anderson* [19.12, 13] and later with great thoroughness by *van Kranendonk* [19.21]. This chapter and most of the above theories are concerned with

neutral atomic gases, which is sometimes called *pressure broadening*. In plasmas, electron, ion, and neutral collisions all contribute to the line shapes and strengths; thus the emitted lines provide a powerful diagnostic of plasma conditions. Neither molecular nor plasma broadening will be covered here; the latter is reviewed in [19.17–20, 22], and in Chapts. 59 and 48.

Part B | 19

19.1 Collisional Line Shapes

The neutral-gas theories described above generally used phenomenological or long range forms of the atomic and molecular interactions, and most measurements were not sufficiently detailed to test the validity of these parameterizations or the theoretical approximations. A great deal of the work since mid century has been directed towards obtaining more realistic and accurate descriptions of these interactions and of the full line shapes. In addition, many new types of observations have stimulated variations on the basic theories and descriptions. This includes topics such as collision-induced forbidden transitions, satellite shapes, spectral and polarization redistribution, orientation and align-

ment effects, Doppler-free spectroscopy and very low temperature collisions. Most of these topics are beyond the scope of this brief and basic description of neutral collisional line shapes.

19.1.1 Voigt Line Shape

An atomic (or molecular or ionic) line has an intrinsic Lorentzian shape that reflects the Fourier transform of the exponentially decaying spontaneous emission. For a spontaneous decay rate Γ, the fullwidth at half maximum (FWHM) is $\Delta\omega = \Gamma$. Due to the Maxwellian distribution of atomic velocities v in a thermal va-

por, and the Doppler shift $\Delta\omega_D = v/\lambda$, the resonance frequencies of atoms in the laboratory frame have a Gaussian distribution. The Doppler width of this distribution is approximately $\omega_0 u/c$, where ω_0 is the resonant frequency and u is the mean thermal velocity. The full line shape is thus a convolution of the natural Lorentzian with the thermal Gaussian; a Voigt profile. In the presence of collisions, the line from each atom broadens, shifts and becomes asymmetric, and this is normally convoluted with the Gaussian velocity distribution to obtain the complete line shape. Collisions may also cause weak or dipole-forbidden transitions to become stronger as well as broader.

19.1.2 Interaction Potentials

Theories of collisional line shapes consider an ensemble average of collisional interactions. For atomic gases, the description of each individual collision or interaction generally starts with a molecular model for a pair of interacting atoms, since the Born–Oppenheimer approximation is appropriate for thermal atomic collisions (electron velocities $\gg$ nuclear velocities) [19.23]. The radiative transition then occurs between adiabatic

Fig. 19.1 Diagrammatic representation of a free–free molecular radiative transition and the classical Franck–Condon principle. Adiabatic potentials (V_u and V_g), the difference potential equal to the classical transition frequency (*dashed*), nuclear kinetic energies and wave functions $\Phi_u(R)$ and $\Phi_g(R)$ are indicated. The position R_C is the classical radiation position for the initial (E_u) and final (E_g) energies shown

electronic molecular states that separate to the atomic states of the transition under consideration. The notation $V_u(R)$ denotes the electronic energy of the upper state, and $V_g(R)$ the lower state, where R is the internuclear separation, and the total atomic energies are E_1 and E_0 with $E_1 - E_0 = h\omega_0$ (Fig. 19.1). The next simplification is to assume that the atom-pair statistically branch into adiabatic motion along each of the molecular states associated with the initial atomic state, and radiation to each of the final states is summed independently, assuming they are also completely adiabatic. This ignores an inevitable nonadiabatic coupling between the states as their energy separation decreases to zero at large R, but as discussed below this has been shown to have a very minor effect on line broadening. The single-collision problem then reduces to calculating the spectrum of a molecular transition between each upper and lower pair of adiabatic states, for each initial state of internuclear motion and all possible final motions, and summing these weighted by the rate of initial collisional motions. However, such calculations are only necessary to elucidate particular quantum features, because the *classical oscillator approximation*, *impact approximation, quasistatic approximation*, and *classical Franck–Condon principle* provide major conceptual and calculational simplifications. These are presented in the context of free–free transitions in the following sections.

19.1.3 Classical Oscillator Approximation

Consider a free–free molecular radiative transition of energy $\hbar\omega = E_u - E_g$ between upper (u) and lower (g) states of total energy E_u and E_g, as shown in Fig. 19.1. Each elastic scattering state is the product of an electronic adiabatic state $\phi(r, R)$ and a nuclear motion state $\Phi(R)$ of the molecule. The electronic states u and g have effective potentials

$$V_q^e = V_q + l(l+1)/R^2 , \qquad (19.1)$$

where $q = $ u or g. Examples of such $V(R)$ and $\Phi(R)$ for the case of $l = 0$ are shown in Fig. 19.1. The electric dipole radiation operator that couples these states is normally a weak perturbation that does not alter these potentials or wave functions. For definiteness assume the atom is initially in the upper state, and that an atom pair approach with kinetic energy $\mathcal{T}_i$ and separate with $\mathcal{T}_f$, as indicated. The intensity I, or transition probability, is proportional to the squared matrix element of the dipole operator $er = e\Sigma_i r_i$ between initial and final

states:

$$I \propto \left| \int d^3 R \int d^3 \boldsymbol{r}\, \Phi_u(R)^* \phi_u(\boldsymbol{r}, R)^* e\boldsymbol{r} \phi_g(\boldsymbol{r}, R) \Phi_g(R) \right|^2$$

$$= \mu^2 \left| \int d^3 R\, \Phi_u(R)^* \Phi_g(R) \right|^2 , \qquad (19.2)$$

where the last factor is the Franck–Condon factor, μ is the dipole moment, here assumed to be the atomic value independent of R, and $d^3 R = 4\pi R^2\, dR$ for diatomics. The $\Phi(R)$ can be represented, in the WKB approximation, as

$$R\Phi_q = k_q^{-1/2} \exp\left[-i \int\limits_0^\infty dR\, k_q(R) \right], \qquad (19.3)$$

where

$$k_q = \left\{ 2M\left[E_q - V_q^e(R)\right] \right\}^{1/2} / \hbar \qquad (19.4)$$

and M is the reduced mass of the atom pair ($\hbar^2 k^2 / 2M$ is the kinetic energy in Fig. 19.1).

The integrand in the second line of (19.2) then contains $\exp[i \int d^3 R (k_u - k_g)]$. If one multiplies $k_u - k_g$ by $(k_u + k_g)/(k_u + k_g)$, the exponent becomes

$$\frac{2M(\omega - \omega_c)}{\hbar(k_u + k_g)} ,$$

and if one further defines a variable $t(R)$ by $dt = dR/v(R)$ with $v(R) = \hbar(k_u + k_g)/2M$, the exponent becomes $i \int \omega_c(t')\, dt' - i\omega t$, where

$$\omega_c(R) = [V_u(R) - V_g(R)]/\hbar \qquad (19.5)$$

and $R(t)$ is the classical trajectory in the average potential. Thus, the Franck–Condon factor reduces to the squared Fourier transform of $\exp[i \int^t \omega_c(t')\, dt']$, where $\hbar\omega_c(R) = V_u(R) - V_g(R)$ (Fig. 19.1). This is the *classical oscillator approximation* (COA), in which the atoms are considered to be a classical oscillator at $\omega_c(R)$ during the collisional interaction, and $R(t)$ is the classical orbit.

The $\sqrt{k}$ in the denominator of the WKB wave function leads to $1/v(R)$ in the nuclear density at R, again corresponding to classical motion. This COA is used as the starting point in many line shape calculations. It is apparent that the COA breaks down when the initial- and final-state orbits are significantly different, or when the Born–Oppenheimer or WKB approximation is not valid. However, the COA is normally a very good approximation for thermal atomic vapors when $h(\omega - \omega_0) \ll k_B T$,

since most orbits are then straight lines within the R region that yields the observed radiation.

One further conceptual and mathematical simplification is to subtract ω_0 from $\omega_c(t')$ and from ω by defining $\Delta\omega_c = \omega_c - \omega_0$ and $\Delta\omega = \omega - \omega_0$. The Franck–Condon factor in (19.2) then becomes

$$I(\omega) = \left(\frac{4\mu^2 \omega^4}{3c^3} \right)$$

$$\times \left| \int dt \exp\left[i \int\limits^t \Delta\omega_c(t')\, dt' - i\Delta\omega t \right] \right|^2_{\mathrm{av}} , \qquad (19.6)$$

where the prefactors that yield the correct intensity are explained in [19.12, 13] (Sect. 10.6). The average is, in general, over a sequence of collisions leading to an integral over collision velocity and impact parameter, weighted by the rate of occurrence.

In the next section, the character of the broadened line core is obtained by the traditional method of evaluating (19.6) using the impact approximation.

19.1.4 Impact Approximation

Atomic collisions in thermal vapors typically occur in a time interval $\tau_c < 1$ ps, whereas the time between significant collisions is much longer at vapor pressures below a few atmospheres. Thus, one can consider the atom as radiating its unperturbed frequency ω_0 most of the time, but occasionally suffering a rapid, strong perturbation. If the duration of a collision is τ_c, then $\phi(t) = \int^t \Delta\omega_c(t')\, dt'$ in the exponent of (19.6) undergoes a net phase shift $\Delta\theta$ in a time τ_c, and is constant between collisions. If $\Delta\omega \ll 1/\tau_c$, then one can approximate this phase shift as instantaneous; this is the essential assumption of the *impact approximation*. When the factor $\exp[i\Delta\theta(b, v)]$, which then occurs in (19.6) is averaged over collision rates with velocity v and impact parameter b this leads to $(\gamma_c - i\delta)t$ in place of $\phi(t)$, where γ_c and δ are given by [19.15]

$$\gamma_c = \int\limits_0^\infty n(v) v\, dv \int\limits_0^\infty 2\pi b [1 - \cos \Delta\theta(b, v)]\, db ,$$

$$\delta = \int\limits_0^\infty n(v) v\, dv \int\limits_0^\infty 2\pi b \sin \Delta\theta(b, v)\, db .$$

Including the spontaneous emission dipole decay rate $\exp(-\Gamma t/2)$, the Fourier integral produces the normal-

ized Lorentzian line shape

$$I(\omega) = \frac{(\Gamma/2 + \gamma_c)}{\pi\left[(\Gamma/2 + \gamma_c)^2 + (\Delta\omega - \delta)^2\right]} . \qquad (19.7)$$

The full line shape is then a Voigt profile with a Lorentzian-component half width $\Gamma + 2\gamma_c$ and a shift of δ from ω_0. The shift can be understood as the perturbed oscillator frequency advancing relative to ω_0 by the average value of $\sin\Delta\theta$, or alternately as indicating the direction of the frequency shift of $V_u - V_g$. The Lorentz approximation corresponds to taking $1 - \cos\Delta\theta = 1$ or 0, with the former representing a collision. This gives $\gamma = 1/\Delta t_c$, where Δt_c is the average time between strong collisions.

The b for which $\Delta\theta(b, \langle v \rangle) = 1$ is called the Weisskopf radius (R_W). The collisional line width $2\gamma_c$ can be thought of as a collisional rate $n\langle v \rangle Q$, where $Q = \pi R_W^2$. The importance of R_W is that γ_c and δ result primarily from atomic interactions in the region $R \approx R_W$. Since the size of an electronic wave function increases with increasing excitation energy, $|\Delta V(R)| = |V(R) - V(\infty)|$ is normally larger for the upper state of a transition. (High Rydberg states can be an exception.) Since $\Delta\theta = 1$ for $b = R_W$ and $\Delta\theta \approx (\Delta V/\hbar)\tau_c$, then $\Delta V(R_W) \approx \hbar/\tau_c$. For a typical $\tau_c = 1$ ps this implies $\Delta V(R_W)/hc \approx 5\,\text{cm}^{-1}$, which is a relatively weak, long range interaction. Thus, reasonable approximations to the necessary $V(R)$ can often be obtained from atomic perturbation theory. Simple expressions for γ_c and δ are obtained for $V_i - V_f = A/R^n$ with $n > 2$ [19.24]. The case of $n = 3$ corresponds to the resonant interaction between identical atoms, while $n = 6$ corresponds to the van der Waals interaction, which holds at long range for foreign gas interactions. This result for one pair of adiabatic states must be averaged over all of the pairs that separate to each atomic state.

Higher order approximations obtain an asymmetric line, rather than a pure Lorentzian, due to the asymmetry of $\Delta V(R)$ [19.24]. In the line core this asymmetry appears as a multiplicative correction $1 + \Delta\omega/D$, where $|D| \approx 1/\tau_c$ [19.25], and with increasing detuning it increases until at $|\Delta\omega| > 1/\tau_c$ the static wing approaches the quasistatic limit described in Sect. 19.1.7. If $\Delta V(R)$ changes monotonically with decreasing R, only one side of the line has a static contribution and the other, antistatic side falls off exponentially at $|\Delta\omega| > \tau_c$ [19.11]. However, this situation is seldom observed, as more than one difference potential generally contributes and there is usually a static contribution on both sides of the line. Another factor that produces a small divergence from the Voigt profile is the velocity dependence of the

shift and width. When combined with the higher velocities of atoms emitting or absorbing in the Doppler wing, this produces an asymmetry in the Doppler wings [19.26, 27].

19.1.5 Examples: Line Core

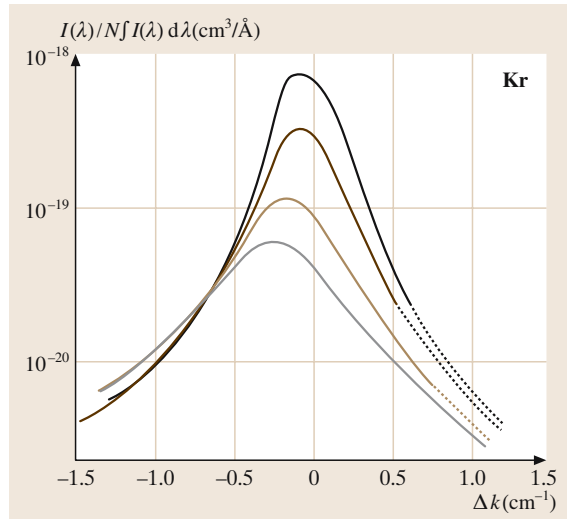
It is possible to deconvolve a Voigt line shape to separate the Doppler and Lorentzian components, and thereby deduce broadenings of considerably less than the Doppler width ([19.28] and references therein). However, the broadening is most easily observed at perturber densities where the collisional broadening exceeds the Doppler broadening. Such a pressure-dependent line shape is shown in Fig. 19.2, for a range of perturber density n_P such that the broadening exceeds the Doppler width and hyperfine structure, yet the line core is described by the impact theory [19.29]. In Fig. 19.2 the normalized line intensity has been divided by n_P; as the line wings are proportional to n_P they are constant in such a plot, while the line center broadens and shifts with increasing n_P. For this case of fairly heavy atoms, $(2\pi c\tau_c)^{-1} = \Delta k_c$ corresponds to $\approx 0.5\,\text{cm}^{-1}$, and the line becomes asymmetric and non-Lorentzian beyond $\approx 1\,\text{cm}^{-1}$ (Fig. 19.3a); the red wing intensity falls more slowly and the blue wing more rapidly than $(\Delta\omega)^{-2}$. This behavior is typical for most heavy perturbers, and is


Fig. 19.2 Normalized line shape of the Rb $5P_{3/2} - 5S_{1/2}$ transition broadened by Kr, for Kr densities of 4.5, 9, 18, and $27 \times 10^{18}\,\text{cm}^{-3}$ (*top* to *bottom*). Hyperfine structure and instrumental resolution cause $\approx 0.3\,\text{cm}^{-1}$ of the broadening shown
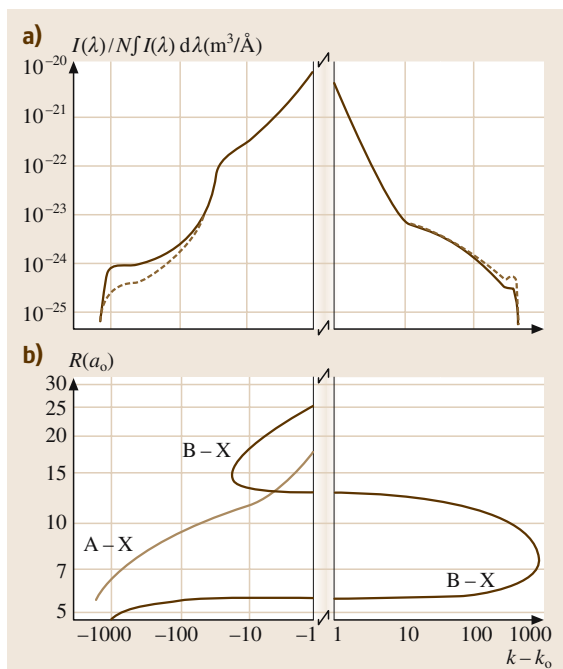

Fig. 19.3a,b Normalized intensity in the wings of the Rb $5P_{3/2} - 5S_{1/2}$ transition broadened by Kr, in frequency units of $k = 1/\lambda$. The measured spectrum in **(a)** is from [19.29–31]. The *solid line* is at 310 K and the *dashed line* at 540 K. The difference potentials corresponding to the A, B and X states of Rb − Kr, taken from [19.32], are shown in **(b)**

attributed to a long range attractive V_u which dominates $V_u - V_g$.

For the lowest n_P shown in Fig. 19.2, a convolution with the Doppler, hyperfine and instrumental broadenings showed that the line is essentially a symmetric Lorentzian for $|\Delta k| < \Delta k_c$ [19.29]. However, at the highest density, the half-height point is beginning to fall outside of Δk_c; the impact approximation is marginally valid for describing the half width of the line at this density. Most early experiments were done at more than 10 times this density [19.15]; most of the line-core was at $|\Delta k| > \Delta k_c$ and describable by the static theory (Sect. 19.1.7) rather than the impact approximation. The impact approximation was also not valid under these conditions because collisions overlap in time. These very broad lines are well represented by the multiple-perturber, static theories that assume scalarly additive perturber interactions [19.5, 8]. This transition between an impact and quasistatic line core, and to multiple perturber interactions, occurs at lower pressures

for transitions to higher states, as the interactions have a longer range. In addition, nearby intensity peaks or satellites often occur, and strongly affect the line as pressure increases. An example calculation, based on an interpretation of measured spectra [19.16], is shown in Fig. 19.4. This shows how a line with a satellite feature progressively broadens and finally blends with the satellite as n_P increases.

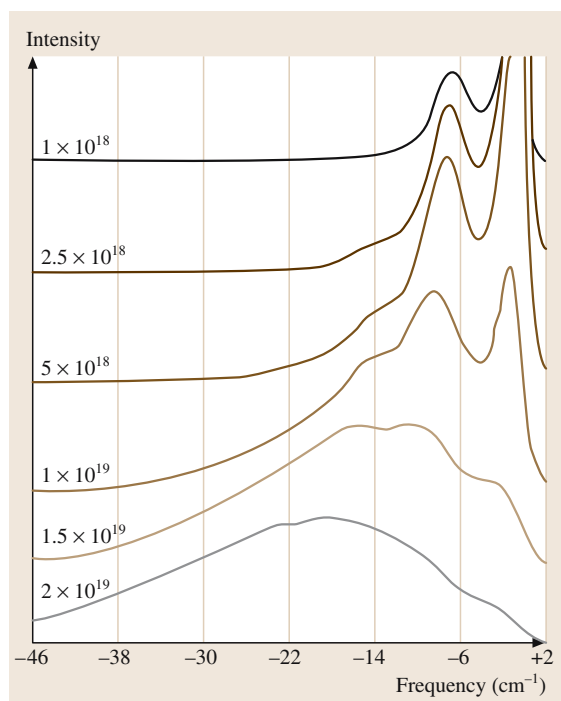
With the advent of saturated-absorption (Doppler free) spectroscopy, collisional line broadening can be measured at much lower densities, where $2\gamma_c \ll \Delta\omega_D$. In principle, this can allow measurement of line broadenings and shifts, although with a complication that affects the line shape; the same collisions that produce optical phase shifts also change the atomic velocity. These velocity changes have a minor effect outside the Doppler envelope where high pressure measurements are normally made, but they are quite important in saturated absorption line shapes. This affects primarily the low intensity wings of the line, so it does not prevent measuring the broadening and shift of the nearly Lorentzian core.


Fig. 19.4 Calculated line shapes of the $Cs(9P_{1/2} - 6S_{1/2})$ line broadened by Xe at the densities indicated (from [19.16]). The assumed interaction is based on measured line shapes, but data corresponding to the calculated conditions are not available

Part B | 19.1

Details can be found in [19.33] and references therein. Two-photon absorption yields Doppler free lines that are not affected by velocity changing collisions. This provides the most exacting test of line shapes. These narrow lines are precisely Lorentzian, with a broadening that reflects the upper state interaction since this is usually much stronger than that of the ground state. The technique has been used to measure the broadening of two photon transitions to many excited states [19.34,35].

19.1.6 Δ and γ_c Characteristics

Since 1970, neutral broadening has generally been measured in the $|\Delta\omega| < 1/\tau_c$ region where the impact approximation and (19.7) is valid. Measurements through 1982 are tabulated in [19.16], and through 1992 in [19.36]. More recent measurements are tabulated in the NIST Reference Data bibliography, which is accessible (free) at the web site http://physics.nist.gov/PhysRefData. These involve primarily metal vapor resonance lines broadened by noble gases. For collisions with the heavier (more polarizable) gases, the sizes of these measured broadening rate coefficients generally fall within a factor of 10 range, and approximately fit the prediction of (19.7) with $\Delta V_u(R) - \Delta V_g(R) = C_6 R^{-6}$ [19.37] and C_6 given by a simple effective quantum number formula. This occurs because the potentials are fairly close to van der Waals for $R \geq R_W$ and the broadening is insensitive to details of the potentials at $R < R_W$ since $\cos\Delta\theta$ in (19.7) averages to ≈ 0 for the closer (strong) collisions. It also occurs because the full quantum solution for broadening by a van der Waals interaction, with Zeeman degeneracies, yields nearly the same result as the above single-level theory with an average C_6 [19.38].

For the heavy, more polarizable perturbers, the excited state interactions are attractive and red shifts occur, but the measured shifts have a very poor correlation with the van der Waals prediction. As b decreases and $\Delta\theta(b, v)$ increases, $\sin\Delta\theta$ oscillates and major cancellations occur in the average of $\sin\Delta\theta$ in (19.7). The shift is therefore only a fraction of the broadening and is very sensitive to the interaction throughout the region $R \approx R_W$. This often differs considerably from the van der Waals form, at the typical $\approx 5\,\text{cm}^{-1}$ interaction energy at R_W. The shape of the red wing just beyond $\Delta\omega_c$ also frequently fails to fit that expected for a van der Waals interaction [19.29]. Thus, the often good agreement of γ_c with van der Waals numbers is not a reliable indicator of the actual $V(R)$ in the relevant R region, even for heavy noble gas perturbers.

For He and sometimes Ne perturbers, a repulsive interaction due to charge overlap normally dominates at $R \approx R_W$, causing a blue shift as well as a larger broadening than the van der Waals prediction.

19.1.7 Quasistatic Approximation

The impact approximation is valid for $|\Delta\omega| \ll 1/\tau_c$, where the $1/\tau_c$ is typically $1-10\,\text{cm}^{-1}$. For larger $|\Delta\omega|$ the line shape becomes asymmetric, with higher intensity on the wing corresponding to the long-range $V_u(R) - V_g(R)$. At large detunings where $\Delta\omega \gg 1/\tau_c$ a major simplification occurs. The COA describes the interacting atom pair as an oscillator of frequency $\omega_c(R) = [V_u(R) - V_g(R)]/\hbar$ when at separation R. Since R is time dependent during the classical orbit, ω_c is as well and the Fourier spectrum is broadened relative to the simple distribution of $\omega_c(t)$ that occurs during the orbit. But if the motion is sufficiently slow, the intensity at ω reduces to the probability of finding the atom pair at the appropriate $R(\omega = \omega_c)$. The spectrum then reduces, at low pressure, to the probability distribution of pair separations R, subject to (19.5) between R and ω. This is the binary quasistatic, static, or statistical spectrum, which accurately describes most line wings for $|\Delta\omega| > 1/\tau_c$. When the pressure is large enough to yield a significant probability of one perturber at $R \leq R_c$, multiple-perturber interactions must also be considered as in [19.5].

This intuitive deduction of the statistical spectrum from the COA [19.4] can also be obtained more formally from (19.6) by expanding the exponent about the time during a collision when $\omega_c(t) = \omega$. Alternatively, it follows directly from (19.2) using WKB wave functions to evaluate free–free molecular Franck–Condon factors [19.6, 7]. This result is identical to the classical Franck–Condon principle (CFCP), originally established in the context of bound–bound molecular radiation.

The CFCP yields important insights for all molecular radiation. Again consider (19.2) with the substitution of the WKB wave functions ϕ_q, given below it. Examples of ϕ_u and ϕ_g are given in Fig. 19.1. For large detunings $\omega - \omega_0$, as shown in Fig. 19.1, the integrand on the right side oscillates rapidly everywhere except at the stationary phase point R_c, where $k_u = k_g$. As a consequence, the dominant contribution to the integral occurs at R_c and one can consider the transition to be localized at R_c. Since $k_u(R_c) = k_g(R_c)$, $\mathcal{T}_u(R_c) = \mathcal{T}_g(R_c) = \mathcal{T}_c$ also holds, and as can be seen in Fig. 19.1 it then follows that $\hbar\omega = V_u(R_c) - V_g(R_c)$. Thus, radiation at

frequency ω "occurs" when the atoms are near R_c, where the electronic state energies differ by $\hbar\omega$. Note that this holds for all initial kinetic energies and angular momenta, as long as the conditions for validity of the Born–Oppenheimer and WKB approximations hold for the initial and final nuclear motions. This is the CFCP, which is equivalent to the classical-oscillator model for radiation at large detunings from the atomic transition.

Another insight evident from Fig. 19.1 is that the photon energy associated with the frequency difference $\omega - \omega_c$ is supplied by nuclear kinetic energy $\hbar(\omega - \omega_0) = \mathcal{T}_i - \mathcal{T}_f$. This transformation of nuclear into electronic energy takes place as the nuclei move from large R to R_c on one $V(R)$ and back to large R on the other.

If an absorbing or emitting atom interacts as $V_i(R)$ with a density n_P of perturbers in a vapor of temperature T, the probability of a perturber at separation $R \to R + dR$ is $n_P 4\pi R^2 \exp[-V_i(R)/k_B T]\,dR$ if the interatomic motion is in equilibrium. Inverting (19.5) for $R(\omega)$ yields $dR = d\omega/(d\omega/dR)$, and this pair of relations yields the (single perturber) quasistatic (QS) spectrum

$$I(\omega) = Nn_P\Gamma 4\pi R(\omega)^2$$
$$\times \exp[-V_i(\omega)/k_B T]/[d\omega(R)/dR]\,, \quad (19.8)$$

where N is the radiator density and $I(\omega)$ the radiation per unit volume and frequency interval.

Figure 19.3a gives an example of far wing emission line shapes versus photon energy in units of cm^{-1}, for the Kr broadened Rb D2 line for which $\Delta k_c \approx 0.7\,cm^{-1}$. These data are normalized by dividing by perturber density, so they are independent of perturber density for the density region of the experiment. The excited state produces two $V_u(R)$, called the A and B states, while the ground state produces one $V_g(R)$, called the X state. Each of these potentials has a single minimum at long range and is strongly repulsive at close range, but the well depths and positions are very different [19.32]. This causes the complex forms of $V_u(R) - V_g(R)$ that are shown in Fig. 19.3b. There I have plotted $\ln(R)$ vertically and $\ln(\Delta V(R)/hc)$ horizontally, where ΔV refers to $V_A - V_X$ and $V_B - V_X$. The right side of (19.8) can also be written as the exponential and constant factors times $dR^3(\omega)/d\omega$. Since $\ln[R^3(\omega)] \propto \ln[R(\omega)]$, the static spectrum at $\Delta k = \Delta\omega/2\pi c$ is proportional to the slopes of the curves in Fig. 19.3b, divided by $|\Delta k|$ due to the $\ln(\Delta k)$ horizontal axis. One can see qualitatively that the overall spectrum follows such a relation to the lines in Fig. 19.3b; in fact in most spectral regions this relation is quantitatively accurate.

The temperature dependence in Fig. 19.3a corresponds to the exponential factors in (19.8) [19.30]. At large R, both $\Delta V(R)$ are attractive, and this causes a large intensity on the negative Δk (red) wing. However, once $|\Delta k|$ exceeds $\approx 20\,cm^{-1}$, where $V_B - V_X$ reverses direction, the red wing intensity drops rapidly. This extremum in $\Delta V(R)$ causes a satellite at $\approx -20\,cm^{-1}$, although it is spread out by the finite collision speed and does not cause a distinct peak in the spectrum. Satellite features are discussed in more detail in the next paragraph. The antistatic blue wing drops rapidly for several decades, then suddenly flattens beyond $\approx 10\,cm^{-1}$ due to the positive portion of $V_B - V_X$ at small R. The remaining blue wing is the B–X band, and has a satellite at $\approx 350\,cm^{-1}$ as $V_B - V_X$ passes through another extremum. The theory predicts this at $800\,cm^{-1}$, but clearly represents all the basic aspects correctly. This satellite is also spread out by finite collision speed, but a definite intensity peak remains. The red wing beyond $\approx 50\,cm^{-1}$ is the A–X band. The feature near $-1000\,cm^{-1}$ is due to the exponential factor in (19.8), not an extremum in $\Delta V(R)$; the feature essentially disappears if the normalized intensity is extrapolated to infinite temperature.

19.1.8 Satellites

In regions of the wing where the intensity falls slowly with increasing frequency, motional broadening of the static spectrum is not noticeable and the static spectrum is a good approximation. However, if $\Delta V(R)$, or equivalently $\omega_c(R)$, has an extremum at some R_S, the denominator of (19.8) is zero at $\omega(R_S) = \omega_S$. This produces a local maximum, or satellite, in the far wing intensity, as seen in Fig. 19.3a at $350\,cm^{-1}$. If one expands $\omega(R)$ in a Taylor series about $R = R_S$ this produces in (19.8) a square root divergence of finite area, with no intensity beyond ω_S. The area under this feature is meaningful, but not its shape; the quasistatic assumption is clearly not valid for such sharp features. The more accurate satellite shape is obtained by returning to (19.2) and expanding $V_u(R)$, $V_g(R)$ and the WKB wave functions about R_S, or using (19.6) with $\omega_c(t)$ expanded about $t(R_S)$. *Sando* and *Wormhoudt* used the former method to obtain a universal satellite shape [19.39]. *Szudy* and *Baylis* improved the expansion to yield a smooth transition to the quasistatic spectrum at smaller detunings [19.37]. This result is nearly the same as Sando et al. in the spectral region of the satellite, but it more accurately connects to the adjacent static line wing. Intensity undulations between the satellite and the line occur in this calculation; these arise from alter-

nating constructive and destructive interference between two contributions to the same frequency from $R > R_S$ and $R < R_S$. This can not be seen in the low resolution of Fig. 19.3a, but such undulations are seen near the $350\,\text{cm}^{-1}$ satellite [19.31]. At antistatic detunings beyond ω_S, which are not quasistatically allowed, the calculated intensities decay exponentially. This is also observed experimentally [19.31] and is the same behavior predicted for the antistatic wing of a line [19.11].

At higher perturber densities and closer to the line core, corresponding to larger R interactions, the multiple perturber probability distribution must be included. If the interactions are additive, this leads to a secondary satellite at twice the detuning of the low pressure satellite, as seen in Fig. 19.4.

The wings of a collisionally broadened atomic line are molecular radiation. In the context of molecular bound state spectroscopy, a satellite is a "head of band heads," corresponding to a frequency region where bound–bound band heads congregate. This occurs, of course, at the classical satellite frequency and when $V_u(R) - V_g(R)$ has an extremum [19.40].

An extremum in $\Delta V(R)$ is the most common cause of satellites, but similar looking features can occur for other reasons. Forbidden bands often appear in the wings of forbidden atomic transitions, due to an increase in the transition dipole moment $\mu(R)$ resulting from the collisional interaction. These are described, in the QS approximation, by (19.8) with Γ replaced by $\Gamma(R)$. If $\Gamma(R)$ increases rapidly with decreasing R, the intensity increases as ω moves into the far wing until the dR^3 and exponential factors cause a net decrease at small R. This leads to forbidden bands far from the atomic frequency, such as those in [19.41]. In some cases, a collision-induced feature also appears at the frequency of the forbidden transition. The shapes of such features, which also include radiative collisions, in which both atoms change state, are calculated and reviewed in [19.42].

A variety of related line shape phenomena has been investigated, including the relation between absorbed and emitted wavelengths (spectral redistribution), the dependence of fluorescence polarization on absorbed wavelength (polarization redistribution), and high power effects. Some references regarding these phenomena are [19.43–47].

19.1.9 Bound States and Other Quantum Effects

The validity of the QS spectrum requires the validity of the WKB approximation in the initial and final state,

but it is not restricted to free–free molecular transitions. In fact, the equilibrium probability distribution in (19.8) must include bound states in an attractive $V_i(R)$. The QS spectrum describes the *average* behavior of bound–free and bound–bound molecular bands, as well as the free–free radiation implied by the above method of derivation. The quantum character is expressed in the discrete bound–bound lines that make up this average, and in *Condon oscillations*, where the intensity oscillates about the average $I_{QS}(\omega)$. The latter occur as oscillations in Franck–Condon factors in the bound–bound case, and as smooth oscillations in bound–free spectra and low resolution bound–bound spectra. An additional quantum feature occurs in regions of the spectrum dominated by classical turning points, usually at the far edge of a line wing where the intensity is dropping rapidly. There, quantum tunneling past the edge of the classically allowed region spreads the spectrum. Yet another is the energy $h\omega_0/2$ of the ground vibrational state, which effectively adds to $k_B T$ in (19.8) for attractive V_i. All of these quantum features become more pronounced as the reduced mass decreases; examples and details can be found in [19.40, 48–50].

19.1.10 Einstein *A* and *B* Coefficients

The relationship between absorption coefficient $B_{12}(\omega)$, stimulated emission coefficient $B_{21}(\omega)$ and spontaneous emission coefficient $A_{21}(\omega)$ are given by the Einstein relations; $A_{21}/B_{21} = 8\pi h\lambda^{-3}$ and $B_{21}/B_{12} = g_1/g_2$. These relations are most familiar for atomic lines, but if they are referred to the density of absorbers $dN_g/d\omega$ and emitters $dN_u/d\omega$ that emit or absorb at ω, then they also apply to the wings of lines, i. e.,

$$k(\omega) = B_{12}(\omega) \left(\frac{2\pi h}{\lambda} \right) \left(\frac{g_u}{g_g} \right) \frac{dN_g}{d\omega}$$
$$= \frac{1}{4}\lambda^2 A_{21}(\omega) \left(\frac{g_u}{g_g} \right) \frac{dN_g}{d\omega} \,, \tag{19.9}$$

$$g(\omega) = \frac{1}{4}\lambda^2 A_{21}(\omega) \frac{dN_u}{d\omega} \,, \tag{19.10}$$

$$I(\omega) = \hbar\omega A_{21}(\omega) \frac{dN_u}{d\omega} \,. \tag{19.11}$$

Here $k(\omega)$ is the absorption coefficient due to lower state atoms, $g(\omega)$ is the stimulated emission coefficient and $I(\omega)$ the spontaneous emission due to excited state population, and g_u and g_g are the statistical weights of the atomic states. For absorbing atoms of density N_g and perturber density n_P, the QS approximation with

equilibrated internuclear motion sets

$$\frac{\mathrm{d}N_{\mathrm{g}}}{\mathrm{d}\omega} = N_{\mathrm{g}} n_{\mathrm{P}} 4\pi R^2 \frac{\mathrm{d}R}{\mathrm{d}\omega} \exp\left(-\frac{V_{\mathrm{g}}}{k_{\mathrm{B}}T}\right) , \qquad (19.12)$$

and equivalently for a radiating atom density N_{u} with perturber interaction V_{u}. Normally most of the radiation, and $\mathrm{d}N_{\mathrm{g}}/\mathrm{d}\omega$, is concentrated at the atomic line, so integrating over $\mathrm{d}\omega$ near the line leads to the relations

$$\int_0^\infty k(\omega)\,\mathrm{d}\omega = \frac{1}{2}\lambda^2 A_{21} N_{\mathrm{g}} \left(\frac{g_{\mathrm{u}}}{g_{\mathrm{g}}}\right) , \qquad (19.13)$$

$$\int_0^\infty I(\omega)\,\mathrm{d}\omega = A_{21} N_{\mathrm{u}} \left(\frac{h\omega}{2\pi}\right) , \text{ etc.} \qquad (19.14)$$

Note that

$$\frac{g(\omega)/N_{\mathrm{u}}}{k(\omega)/N_{\mathrm{g}}} \propto \exp\left(-\frac{\hbar\omega}{k_{\mathrm{B}}T}\right) ; \qquad (19.15)$$

if $N_{\mathrm{u}}/N_{\mathrm{g}}$ is also in equilibrium at T, this yields the correct equilibrium relation between $k(\omega)$, $g(\omega)$, $I(\omega)$, and a black body spectrum. While these relations are much more general than the QS theory, the latter provides a helpful conceptual basis. The above expressions in terms of spontaneous emission thus cover all cases.

19.2 Radiation Trapping

Atoms and ions efficiently absorb their own resonance radiation, and their emission can be reabsorbed before escaping a vapor. Molecules are less efficient absorbers, since each electronic transition branches into multiple-line bands, but interesting effects result if such reabsorption occurs. This emission and reabsorption process is fundamental to the formation of stellar lines, where it is called *radiation transfer*, and to confined vapors and plasmas where it is also called *radiation diffusion* or *trapping*. Fraunhofer's observation of dark lines in the stellar spectrum result from this radiation transfer process. Highly sophisticated treatments of line formation in inhomogeneous and nonequilibrium plasmas containing many species [19.19, 20] also apply to laboratory plasmas, but the simplifications inherent in a one- or two-element, confined plasma with cylindrical or planar symmetry leads to easier treatments. This sections discusses only a uniform density and temperature, confined atomic vapor.

The flourescent lamp in which 254 nm mercury radiation diffuses to the walls and excites a phosphor, provides a prime example of radiation trapping. Its improvement motivated the seminal *Biberman* [19.51, 52] and *Holstein* [19.53, 54] theories, continuing through modern theory and experiment that is particularly relevant to electrodeless and compact lamps. Dense clouds of cold, trapped atoms are also influenced by radiation trapping. Reference [19.55] provides and excellent overview of this topic, which we will not discuss here. The effect of radiation trapping on the *polarization* of flourescent radiation played a major role in developing a correct understanding of the coherent response of atoms to radiation. This is reviewed in [19.44], and will not be covered here. *Molisch* and *Oehry* [19.56] have provided a detailed discussion of research on radiation transport up to 1998.

19.2.1 Holstein–Biberman Theory

An atom in a dense vapor may be excited by externally applied radiation plus the fluorescence from other excited atoms within the vapor, and it will decay by spontaneous emission (neglecting stimulated emission). This is expressed by the Holstein–Biberman equation

$$\mathrm{d}n(\mathbf{r},t)/\mathrm{d}t = S(\mathbf{r},t) + \gamma \int_{\mathrm{vol}} K(\mathbf{r}-\mathbf{r}')n(\mathbf{r}',t)\,\mathrm{d}^3\mathbf{r}'$$
$$- \gamma n(\mathbf{r},t) , \qquad (19.16)$$

where $n(\mathbf{r},t)$ is the excited state density at position $\mathbf{r}$, $S(\mathbf{r},t)$ is the excitation rate due to externally applied radiation, γ is the spontaneous emission rate, the kernel $K(\mathbf{r}-\mathbf{r}')$ is the probability of a reabsorption at $\mathbf{r}$ due to fluorescence by an atom at $\mathbf{r}'$, and the integral is over the vapor filled volume [19.51–54]. Since $K(\mathbf{r},\mathbf{r}')$ is assumed the same for all excited atoms, this contains an implicit assumption that all atoms emit the same fully redistributed spectrum. The solution of this linear integral equation, subject to boundary values at the vapor boundary, can be expressed as a sum over an orthogonal set of solutions $n(\mathbf{r},t)_i = n(\mathbf{r})_i \exp(-g_i\gamma t)$ of the homogeneous equation

$$n(\mathbf{r},t) = \sum_{i=1}^{\infty} a(t)_i n(\mathbf{r})_i , \qquad (19.17)$$

where, if $S(\mathbf{r}, t) = S(\mathbf{r}) f(t)$, then $a(t)_i = \bar{a}_i \int_{-\infty}^{t} f(t')$ $\times \exp[-g_i \gamma(t - t')] dt'$ and $\bar{a}_i = \int S(\mathbf{r}) n(\mathbf{r})_i d^3\mathbf{r}$. Here $n(\mathbf{r}, t)_i$ is the ith normal mode and $g_i \gamma$ is the decay rate of this mode, as it would decay without change in its shape $n(\mathbf{r})_i$ from a pulse of excitation.

Two shapes of vapor regions have been studied in detail: an infinitely long cylinder of radius R and the region between two infinite parallel plates with separation L. The first three symmetric modes of the latter slab geometry are shown with unit height in Fig. 19.5. A spatial integration over the normalized $i = 1$ or fundamental mode yields 1 and all others integrate to zero, so $a(t)_1$ equals the total excited state population. g_1 is the escape probability; i. e., the probability of photon escape averaged over the fundamental mode distribution of emitters $n(\mathbf{r})_1$. Since $n(\mathbf{r}, t)$ must be everywhere positive, the negative contributions of the higher order modes only reduce the density in some regions. The g_i can vary from 0 to 1 and increase with increasing i, so that higher order modes die out faster after pulsed excitation. The ratios of decay rates is $g_i : g_3 : g_5 = 1 : 3.7 : 6.4$ for the symmetric slab modes shown in Fig. 19.5. For steady state excitation, (19.17) yields $a(t)_i = \bar{a}_i / g_i \gamma$, so the lower order modes are more heavily weighted because they decay more slowly. The fundamental mode decay rate $g_1 \gamma$ is of primary interest in most situations, and we will now discuss its properties.

The kernel $K(x)$ is the probability of fluorescence transport over a distance x followed by reabsorption, averaged over the emitted frequency distribution. It is conceptually useful to express it in terms of the spectrally averaged transmission $T(x)$

$$K(x) = \frac{1}{4\pi x^2} \frac{dT(x)}{dx}, \qquad (19.18)$$

$$T(x) = \int_0^\infty \mathcal{L}(\omega) \exp[-k(\omega)x] d\omega,$$

where $\mathcal{L}(\omega)$ is the emission line shape normalized to unit area, and $x = |\mathbf{r} - \mathbf{r}'|$. If one assumes that the fluorescence frequency of an atom does not depend on the frequency it absorbed (i. e., complete spectral redistribution), this leads to $k(\omega) = \kappa \mathcal{L}(\omega)$, where $\kappa = (\lambda^2/8\pi)$ $(g_u/g_g) n \Gamma$ and g_u and g_g are statistical weights. This simplification applies under most conditions and will be used here; its range of validity and more accurate treatments are discussed below.

The transmission factor $\mathcal{L}(\omega)$ and the integrand of (19.18) are shown in Fig. 19.6, for a Gaussian line shape and several values of $k_0 x$, where k_0 is the line center absorption coefficient. At small $k_0 x$, the transmitted spectrum is similar to $\mathcal{L}(\omega)$; for these conditions $T(x) \simeq \exp(-k_{av}x)$, where $k_{av} \simeq 0.7k_0$ is the average attenuation. For $k_0 x > 5$, the transmission is small except at the edges of the line. The transmitted radiation is then predominantly in the ω region near ω_1, defined by $k_0 x \mathcal{L}(\omega_1) = 1$. Since the integrand is sharply peaked near ω_1, this leads to simple analytic forms for $T(x)$. In

Fig. 19.5 The first three symmetric eigenfunctions ($j = 0.2, 4$) of radiation trapping between slab windows, for a Doppler line profile, from [19.57–59]. The windows are at ± 1
Fig. 19.6 Gaussian emission spectrum $\mathcal{L}(\omega)$ (*short-dash line*), transmissions $T(\omega)$ (*long-dash lines*), and transmitted intensities (*solid lines*) for $k_0 x = 2$, 10, and 50

the large $k_0 x$ limit, $T(x) \simeq [k_0 x(\pi \ln k_0 x)^{1/2}]^{-1}$ in the Gaussian case, and $T(x) \simeq (\pi k_0 x)^{-1/2}$ for a Lorentzian line shape. These asymptotic forms of $T(x)$ are compared with the exact $T(x)$ in Fig. 19.7; $T(x)$ follows the asymptotic formulas for $k_0 x > 5$ and 10, respectively. $T(x)$ for several Voigt line shapes is also shown in Fig. 19.7; these follow the Gaussian $T(x)$ at smaller $k_0 x$, then rise above as ω_1 moves into the Lorentzian wing.

For radiative escape from a cell, transmission over distances near the cell dimension (R or L) is most important, since transport over this distance often escapes the vapor and transport over much smaller distances does not have much effect. The escape probability g_1, averaged over the fundamental mode distribution, is close to $T(R)$ or $T(L/2)$, while the higher order modes are related to the same asymptotic forms of $T(x)$ at smaller distances. Thus, in the large $k_0 L$ slab case,

$$
g_i = \begin{cases} \dfrac{G_i}{k_0 L(\frac{1}{2}\ln k_0 L)^{1/2}} & \text{Gaussian line} \quad (19.19\text{a}) \\[3mm] \dfrac{G_1'}{(k_0 L)^{1/2}} & \text{Lorentzian line,} \, (19.19\text{b}) \end{cases}
$$

with $G_1 = 1.03$ and $G_1' \simeq 0.65$. For an infinite cylinder, the same equations hold with $L/2 \rightarrow R$ and slightly larger G_i values. Exact G_i and G_1' values can be found in [19.57–59].

19.2.2 Additional Factors

As noted above, the line shape of a two-level atom in a thermal vapor is a Voigt shape; a convolution of a Lorentzian of width $\Gamma + 2\gamma_c$ with a Gaussian of width $\Delta\omega_D$. In most cases, $\Delta\omega_D \gg \Gamma$, so in the absence of a buffer gas the line shape is nearly Gaussian at low density (n). As a result, ω_1 is in the Gaussian region of the line at low density and g_1 behaves similarly to the Gaussian transmission in Fig. 19.7 with x replaced by the confinement dimension. k_0 is proportional to n, so from (19.19a) g_1 is approximately inversely proportional to n for $k_0 L > 5$. As n increases, ω_1 moves further into the wing of the line, and when ω_1 reaches the Lorentzian tail of the Voigt line profile a transition to (19.19b) occurs, where k_0 corresponds to a purely Lorentzian line. (That the core of the line does not have a Lorentzian shape does not matter, since the fraction of emission well into the Lorentzian wing is nearly the same as that of a pure Lorentzian line.)

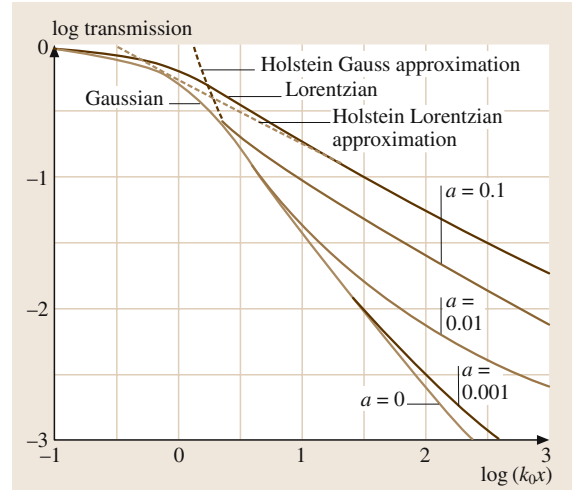
In the absence of a collision, a two level atom reradiates in its rest frame the same frequency it absorbed.


Fig. 19.7 Transmission $T(x)$ versus distance in units of $k_0 x$, for Voigt line shapes with the a parameters indicated, where $a = (\ln 2)^{1/2}\Delta\omega_{\text{Lor}}/\Delta\omega_{\text{Gauss}}$. The Gaussian limit corresponds to $a = 0$ and the Lorentzian limit to $a = 1$. The Holstein, large $k_0 x$, approximations are also indicated

Thermal motion redistributes this coherent scattering frequency within the Doppler envelope when the emission and absorption are in different directions, but it does not transfer it into the natural Lorentzian wing outside the Doppler envelope. This leads to the property that an atomic vapor will scatter frequencies in the natural wing, but will not emit in this wing unless it absorbed there or is excited by or during a collision. With line broadening collisions, a fraction $\Gamma/(\Gamma + 2\gamma_c)$ of optical attenuation is coherently scattered and a fraction $2\gamma_c/(\Gamma + 2\gamma_c)$ is redistributed into "incoherent" emission with a Lorentzian spectrum of width $\Gamma + 2\gamma_c$ centered at $\omega_0 + \delta$ in the reference frame of the moving atom. This redistributed emission can escape in the Lorentzian wing of the Voigt line. In this radiation transport problem, the consequence is that (19.19b) with $k_0 = n(\lambda^2/2\pi)(\Gamma/\gamma_c)(g_u/g_g)$, corresponding to a Lorentzian with $\Gamma_{\text{Total}} = 2\gamma_c$ not $\Gamma + 2\gamma_c$, provides the best approximation to g_1 in the density region where ω_1 is in the Lorentzian wing of the line. Since $k_0 \propto n/\gamma_c$ and in the absence of a buffer gas $\gamma_c = k_c n$, where k_c is the rate coefficient for self broadening collisions, g_1 becomes independent of n. In fact, $k_c \propto \Gamma$ as well, so g_1 is also independent of Γ. For the case of a $J = 0$ ground state and a $J = 1$ excited state, $g_1 = 0.21(\lambda/L)^{1/2}$; the broadening coefficient for other cases can be found in [19.60]. If the

broadening is due to a buffer gas, $\gamma_c = k_c n_B$ in (19.19b) yields

$$g_1 \propto \left(\frac{n_B}{n}\right)^{1/2} ; \qquad (19.20)$$

this has been studied in [19.64].

Post et al. have numerically evaluated g_1 for all values of $k_0 L$ for slab and cylinder geometries, by integrating the radiative escape probability $g(z)$ over the fundamental mode distribution $N(z)$, where z is the position between the windows [19.65]. To obtain $g(z)$ they integrate over the angular distribution of the emission, using $T(x)$ from the exact line shape. Thus all features of the calculation correspond to the Holstein–Biberman theory for an isolated line without approximation. As will now be discussed real atomic vapors are generally not that simple.

Many atomic "lines" have multiple components due to hyperfine structure and isotope shifts; some components are isolated while others are separated by less than a Doppler line width and overlap. The absorption line shape then becomes a weighted sum over components, each with an equivalent Voigt shape. In a high density vapor or a plasma, collisions will usually distribute the excited state population between the isotopes and hyperfine states in proportion to their isotopic fraction and statistical weight. The emission line shape $\mathcal{L}(\omega)$ is then a similarly weighted distribution over components. Since radiation only escapes in the wings of a line component at high $k_0 L$, overlapping components act almost as a single component. If the line has M isolated components, the right-hand side of (19.19a) and (19.19b) become sums over the fraction f_j of the intensity in the j component times the escape probability for that component. The latter is obtained, for large $k_0 L$, by replacing k_0 with $k_0 f_j$ in (19.19a) and (19.19b). The net result, after summing over components, is an increase in g_i by a factor of $\approx M$ in the Gaussian case and $\approx M^{1/2}$ in the Lorentzian. This approximation was obtained by Holstein in the context of the Hg 254 nm radiation under conditions appropriate to the fluorescent lamp [19.66]. Walsh made a more detailed study of these overlapping components [19.67], and the dependence of g_1 on the ratio of line separation to Doppler width is also given in [19.63].

19.2.3 Measurements

The overall behavior of g_1 versus n is shown in Fig. 19.8 for the Na($3P_{3/2}$) or D2 resonance line in pure Na vapor [19.62, 63]. In this type of experiment the fundamental mode decay rate is established by a combination of optimally exciting that spatial mode and of waiting until the fluorescence decay is exponential in time after termination of the excitation. A transition to approximately $1/n$ behavior, corresponding to (19.19a), is seen to occur at $k_0 L/2 \approx 5$. At $k_0 L/2 \approx 100$ the transition to n^0 behavior, corresponding to a self-broadened Lorentzian line in (19.19b), can be seen. The behavior at $k_0 L < 5$ fits the Milne diffusion theory [19.68] as well as the Post et al. theory shown as a solid line; this is also similar to $T(L/2)$, as seen in Fig. 19.7. For $5 < k_0 L/2 < 100$, the behavior is similar to (19.19a) (dashed line), but the Post et al. theory (solid line) is $\approx 20\%$ higher due to the inclusion of the Na hyperfine structure (hfs splitting $\simeq$ Doppler width). For $k_0 L/2 > 1000$, the Post theory converges to the Holstein–Lorentzian-line result with $\Gamma_{Total} = 2\gamma_c$.

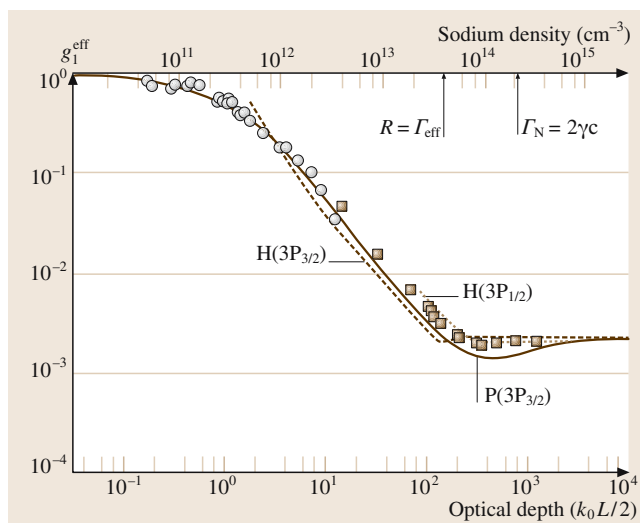
The experiment is complicated in the $50 < k_0 L/2 < 500$ region by fine structure mixing [19.62]. The $3P_{3/2}$ state was excited, but at high densities, collisions populate the $3P_{1/2}$ state, which has a smaller g_1 than the $3P_{3/2}$ state (Fig. 19.8). At low densities, $g_1^{eff} = g_1(3P_{3/2})$, and at high densities these states are statistically populated


Fig. 19.8 Radiative escape probability g_1 for Na vapor excited to the $3P_{3/2}$ state, for a slab geometry. The Holstein approximation for the $3P_{3/2} - 3S_{1/2}$ (D2) line and the $3P_{1/2} - 3S_{1/2}$ (D1) line are indicated as *dashed lines*. The Post-type calculation of [19.61] for the D2 line is indicated as a *solid line*. *Solid squares* are data from [19.62], and *open circles* are data from [19.63]. The effective escape probability corresponds to the D2 line rate at low densities but a combination of D1 and D2 at high densities

and $g_1^{\text{eff}} = \frac{1}{3}g_1(3P_{1/2}) + \frac{2}{3}g_1(3P_{3/2})$. The transition density where the fine structure mixing rate R equals Γ_{eff} is indicated in Fig. 19.8. The theory is also complicated in this intermediate $k_0 L$ region by the necessity of including incomplete frequency redistribution [19.65]; this leads to the dip in g_1 near $k_0 L \approx 500$. While the overall behavior of the data in Fig. 19.8 is consistent with the Post et al. theory, there is $\approx 30\%$ systematic discrepancy at $k_0 L/2 = 10-100$ and the dip near 500 is not seen. Part of this difference probably results from the experimental geometry, which was between a slab and a cylinder of radius $R = L/2$; g_1 for the cylinder is 17% larger than the slab value used in Fig. 19.8.

The fundamental mode decay rate has also been measured for the Hg 254 nm [19.69] and 185 nm [19.65] lines, for the Ne resonance line [19.70] and for the Ar resonance line [19.71]. The Hg measurements are complicated by multiple isotopes and hyperfine structure, producing a mixture of partially overlapping and isolated lines combined with density-dependent uncertainties in excited state populations of the various isotopes. Serious efforts to model and measure these effects have been made [19.65, 67, 69, 72]. The Ne and Ar measurements have similar complications, as will now be discussed.

In essence, g_1 behaves like the Gaussian $T(x = L/2)$ in Fig. 19.7 until n is large enough for ω_1 to approach the collision induced Lorentzian wing of the Voigt line. g_1 then decreases more slowly since the line wing does not fall off as rapidly as a Gaussian. With continued increase in n, ω_1 moves further into the Lorentzian wing, a broader spectral region escapes and g_1 reaches a minimum. Finally, when the entire escaping spectral region is Lorentzian, g_1 reaches the constant value described above. Independent and detailed treatments of this density region, including incomplete frequency redistribution, predict a dip in g_1 as seen in Fig. 19.8 [19.65, 71, 73, 74]. However, this has not been clearly confirmed experimentally. In Fig. 19.8 this dip occurs where fine structure mixing also occurs, and in addition the data are higher than the calculations throughout this n region. *Post* et al. [19.65] did observe such a dip for the Hg (149 nm) resonance line, but the data do not fit the calculation at other densities; hyperfine and isotopic structure within the line cause major complications. This long-standing issue has finally been clarified by *Menningen* and *Lawler* [19.75], who measured the decay of the Hg (185 nm) resonance line following laser excitation. They observed a clear dip in g_1 due to incomplete redistribution. They also carried out sophisticated Monte Carlo simulations, obtaining

g_1 values that compared favorably with the measurements. By extending the simulations over a large range of a parameter space, they constructed an analytic formula for g_1 of a single-component line in cylindrical geometry [19.76]. This formula includes effects of incomplete frequency redistribution and varying ratios of Doppler broadening, radiative broadening and collisional broadening, so that it can be applied to any resonance line. *Payne* et al. [19.71] did not observe the predicted dip for the Ar resonance line; again a minor isotope with an isolated line occurs and could be very important at these high optical depths. *Phelps* [19.70] reported such a dip for the Ne 74.3 nm resonance line, but with rather large uncertainties due to the necessity of correcting for other collisional effects. Again there are isotopes with isolated lines that may have effected the data. Thus, experiments have verified the essential aspects of the above theories, but quantitative agreement in all aspects has not yet been achieved.

The fact that the escaping radiation is concentrated in the wings of the line, near the unity optical depth point ω_1, is reflected in the emitted spectrum. Calculated examples are shown in [19.74]; the Gaussian case looks somewhat like the transmitted spectra in Fig. 19.6 for $x \approx L/4$. These spectra, and all results described so far, are calculated assuming no motion of the atoms. This is appropriate in the central region of the vapor, because the distance moved in an excited state lifetime ($L_v = v/\Gamma$) is much smaller than L. In fact, resonant collisions between excited and ground state atoms further limits the distance an excited atom moves in one direction before transfer of excitation. However, near the window or wall of the container, atomic motion will cause wall collisions of excited atoms and loss of radiation. This loss will be primarily within the Doppler core of the line, since these frequencies can only escape if emitted near the vapor edge. This loss depends on the excited state density in the neighborhood of the wall, and can be significant if $L_v > 1/k_0$. The excited atom density near the wall must be self consistent with the radiation transport and wall quenching. This situation has been modeled and studied experimentally ([19.77] and references therein).

Additional aspects of radiation trapping, such as higher-order spatial modes and non-uniform absorber distributions, can be significant in lighting plasmas (and trapped atom clouds). Propagator function techniques have been developed for modeling radiation transport when the excitation has unusual temporal or spatial character [19.78, 79]. Non-uniform absorber spatial distributions can be particularly important at high power densities, and have been considered in [19.80].

20. Thomas–Fermi and Other Density-Functional Theories

The key idea in Thomas–Fermi theory and its generalizations is the replacement of complicated terms in the kinetic energy and electron–electron repulsion energy contributions to the total energy by relatively simple functionals of the electron density ρ. This chapter first describes Thomas–Fermi theory, and then its various generalizations which attempt to correct, with varying success, some of its deficiencies. It concludes with an overview of the Hohenberg-Kohn and Kohn-Sham density functional theories.

In the early years of quantum physics, *Thomas* [20.1] and *Fermi* [20.2–5] independently invented a simplified theory, subsequently known as *Thomas–Fermi theory*, to describe nonrelativistically an atom or atomic ion with a large nuclear charge Z and a large number of electrons N. Many qualitative features of this model can be studied analytically, and the precise solution can be found by solving numerically a nonlinear ordinary differential equation. *Lenz* [20.6] demonstrated that this equation for the electrostatic potential could be derived from a variational expression for the energy as a functional of the electron density. Refinements to Thomas–Fermi theory include a term in the energy functional to account for electron exchange effects introduced by *Dirac* [20.7], and nonlocal gradient corrections to the kinetic energy introduced by *von Weizsäcker* [20.8].

Although the Hartree–Fock method or other more elaborate techniques for calculating electronic structure now provide much more accurate results (Chaps. 21, 22, and 23), Thomas–Fermi theory provides quick estimates and global insight into the total energy and other properties of a heavy atom or ion. A rigorous analysis of Thomas–Fermi theory by *Lieb* and *Simon* [20.9, 10] showed that it is asymptotically exact in that it yields the correct leading asymptotic behavior, for both the total nonrelativistic energy and the electronic density, in the limit as both Z and N tend to infinity, with the ratio Z/N fixed. (In a real atom, of course, relativistic and other effects become increasingly important as Z increases.) However, Thomas–Fermi theory has the property that molecules do not bind, as first noted by *Sheldon* [20.11] and proved by *Teller* [20.12]. That the interatomic potential energy curve for a homonuclear diatomic molecule is purely repulsive was demonstrated by *Balàzs* [20.13]. This 'no binding' property of clusters of atoms was used by *Lieb* and *Thirring* [20.14] to prove the *stability of matter*, in the sense that as the number of particles increases, the total nonrelativistic energy decreases only linearly rather than as a higher power of the number of particles, as it would if electrons were bosons rather than fermions. Lieb went on to explore the mathematical structure of the modifications of the Thomas–Fermi model when gradient terms (von Weizsäcker) and/or exchange (Dirac) terms are included [20.15, 16]. A review article by *Spruch* [20.17] explicates the linkage between long-developed physi-

cal intuition and the mathematically rigorous results obtained in the 1970's and 1980's. The older literature was reviewed by *Gombás* [20.18, 19] and by *March* [20.20].

An outgrowth of Thomas–Fermi theory is the general density functional theory initiated by *Hohenberg* and *Kohn* [20.21] and by *Kohn* and *Sham* [20.22], as discussed in Sect. 20.3 of this chapter.

20.1 Thomas–Fermi Theory

20.1.1 Thomas–Fermi Theory

In a D-dimensional Euclidean space, the expectation value of the electronic kinetic energy operator in a quantum state ψ can be approximated by

$$\frac{\hbar^2}{m_\mathrm{e}} 2\pi^2 \frac{D}{D+2} \left(\frac{D}{2\Omega_D}\right)^{2/D} \int \rho^{(D+2)/D}(\boldsymbol{r})\, \mathrm{d}^D r \,, \tag{20.1}$$

where

$$\Omega_D = D\pi^{D/2}/\Gamma\,(1+D/2) \tag{20.2}$$

is the surface area of a unit hypersphere in D dimensions [20.17, p. 176]. These expressions can easily be derived by considering the energy levels of a system of a large number of noninteracting fermions confined to a D-dimensional box. Specialization to the physically interesting case of $D = 3$ yields the well-known expression

$$\frac{\hbar^2}{m_\mathrm{e}} 2\pi^2 \frac{3}{5} \left(\frac{3}{2\Omega_3}\right)^{2/3} \int \rho^{5/3}(\boldsymbol{r})\, \mathrm{d}\boldsymbol{r} \,, \tag{20.3}$$

where

$$\Omega_3 = 3\pi^{3/2}/\Gamma\,(1+3/2) = 4\pi \,. \tag{20.4}$$

The electron–nucleus attraction energy in a three-dimensional space is given exactly by

$$\int \rho(\boldsymbol{r})V(\boldsymbol{r})\, \mathrm{d}\boldsymbol{r} \,, \tag{20.5}$$

where $V(\boldsymbol{r})$ is the Coulomb potential due to a single nucleus ($V(\boldsymbol{r}) = -Z/r$) or to several nuclei [$V(\boldsymbol{r}) = -\sum_i Z_i/|\boldsymbol{r} - \boldsymbol{R}_i|$]. The electron–electron Coulomb repulsion energy in a three-dimensional space is approximated by

$$\frac{1}{2} \int \frac{\rho(\boldsymbol{r})\rho(\boldsymbol{r}')}{|\boldsymbol{r} - \boldsymbol{r}'|}\, \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{r}' \,, \tag{20.6}$$

which tends to overestimate the actual repulsion energy because it includes the self-energy of the densities of individual electrons. This is, however, a higher-order effect for a system with a large number of electrons concentrated in a small region of space. As was suggested by *Fermi* and *Amaldi* [20.23], this overestimation can be approximately corrected for an atom with N electrons by multiplying this term by the ratio of the number of ordered pairs of different electrons to the total number of ordered pairs

$$\frac{N(N-1)}{N^2} = 1 - \frac{1}{N} \,. \tag{20.7}$$

This is approximately correct for an atom, with many electrons concentrated close together, but it would still be an overestimate for a diffuse system, such as one composed of N electrons and N protons separated by large distances of $O(R)$, for which the ground-state electron–electron repulsion term should be proportional to $\frac{1}{2}N(N-1)/R$ rather than to N times a constant of $O(1)$. For this reason the Fermi–Amaldi correction, which complicates the mathematical analysis without eliminating the unphysical overestimation of the electron–electron repulsion term, is not usually included. It is evident that the treatment of both the electronic kinetic energy term and the electron–electron repulsion energy term depends on the assumption that the number N of electrons (actually, the number of electrons *per atom*) is large. Hence the Thomas–Fermi model is sometimes called the *statistical model* of an atom.

The three contributions to the total energy are now added together and one seeks to minimize their sum, the Lenz functional [20.6]

$$\begin{aligned}
E[\rho] = {} & \frac{\hbar^2}{m_\mathrm{e}} 2\pi^2 \frac{3}{5} \left(\frac{3}{2\Omega_3}\right)^{2/3} \int \rho^{5/3}(\boldsymbol{r})\, \mathrm{d}\boldsymbol{r} \\
& + \int \rho(\boldsymbol{r})V(\boldsymbol{r})\, \mathrm{d}\boldsymbol{r} + \frac{1}{2} \int \frac{\rho(\boldsymbol{r})\rho(\boldsymbol{r}')}{|\boldsymbol{r} - \boldsymbol{r}'|}\, \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{r}' \,,
\end{aligned} \tag{20.8}$$

over all admissible densities ρ. The mathematical question now arises: what is an admissible density? The answer was provided by *Lieb* and *Simon* [20.9, 10]: a density for which both

$$\int \rho(\boldsymbol{r})\, \mathrm{d}\boldsymbol{r} \,, \tag{20.9}$$

the total number of electrons, and

$$\int \rho^{5/3}(\mathbf{r})\, \mathrm{d}\mathbf{r} \, , \tag{20.10}$$

which is proportional to the estimate of their kinetic energy, are finite, automatically yields finite values of the other terms in the expression for the energy. As Lieb and Simon proved, the minimization of this functional over all such densities yields a well-determined result.

Carrying out the variation of $E[\rho]$ with respect to ρ yields the Euler–Lagrange equation

$$0 = \frac{\hbar^2}{m_e} 2\pi^2 \left(\frac{3}{2\Omega_3}\right)^{2/3} \rho^{2/3}(\mathbf{r})$$
$$+ V(\mathbf{r}) + \int \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}\, \mathrm{d}\mathbf{r}' \, . \tag{20.11}$$

The sum of the last two terms is of course the negative of the total electrostatic potential $\phi(\mathbf{r})$, so one sees that in Thomas–Fermi theory the density is proportional to the 3/2-power of the potential. To simplify subsequent manipulations, let

$$\frac{\hbar^2}{m_e} 2\pi^2 \left(\frac{3}{2\Omega_3}\right)^{2/3} = \frac{\hbar^2}{2m_e} (3\pi^2)^{2/3} = \gamma_p \, , \tag{20.12}$$

so that

$$\gamma_p \rho^{2/3}(\mathbf{r}) = \phi(\mathbf{r}) \, . \tag{20.13}$$

By Poisson's theorem,

$$-\nabla^2 \phi = 4\pi \left[\sum_i Z_i \delta^{(3)}(\mathbf{r} - \mathbf{R}_i) - \rho(\mathbf{r}) \right] , \tag{20.14}$$

and from (20.13) one has $\rho = \gamma_p^{-3/2} \phi^{3/2}$, so from the integral equation for the electronic density ρ one obtains the differential equation

$$-\nabla^2 \phi = 4\pi \left[\sum_i Z_i \delta^{(3)}(\mathbf{r} - \mathbf{R}_i) - \gamma_p^{-3/2} \phi^{3/2} \right] \tag{20.15}$$

for the potential ϕ. In the case of a single nucleus, the usual separation of variables in spherical polar coordinates yields for ϕ the ordinary differential equation

$$\frac{1}{r} \frac{\mathrm{d}^2}{\mathrm{d}r^2}(r\phi) = 4\pi \gamma_p^{-3/2} \phi^{3/2} \, , \tag{20.16}$$

whose similarity to Emden's equation, which Eddington had used to study the internal constitution of stars, was

recognized by *Milne* [20.24]. The numerical solution of this equation with the appropriate boundary conditions at $r = 0$ and $r = \infty$ was extensively discussed by *Baker* [20.25], and accurate solutions tabulated by *Tal* and *Levy* [20.26]. The numerical solution determines that the total energy of a neutral atom is

$$E = -3.678\,745\,21\ldots\, \gamma_p^{-1} Z^{7/3}$$
$$= -1.537\,490\,24\ldots\, Z^{7/3}\, \mathrm{Ry} \, . \tag{20.17}$$

Another possibility is to do the constrained minimization over all densities which obey

$$\int \rho(\mathbf{r})\, \mathrm{d}\mathbf{r} = \lambda \, , \tag{20.18}$$

where λ is the number of electrons, which for purposes of mathematical analysis is allowed to be nonintegral. One then introduces a Lagrange multiplier $-\mu$, the *chemical potential*, to correspond with this constraint, and thereby obtains the Euler–Lagrange equation

$$0 = \frac{\hbar^2}{m_e} 2\pi^2 \left(\frac{3}{2\Omega_3}\right)^{2/3} \rho^{2/3}(\mathbf{r})$$
$$+ V(\mathbf{r}) + \int \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}\, \mathrm{d}\mathbf{r}' + \mu \, , \tag{20.19}$$

which holds wherever ρ is positive. As was shown by *Lieb* and *Simon* [20.9, 10], this procedure too is well-defined. The analogue of (20.13), the relationship between the density and the electrostatic potential for the neutral atom, is now

$$\gamma_p \rho^{2/3}(\mathbf{r}) = [\phi(\mathbf{r}) - \mu]_+ \, , \tag{20.20}$$

where $[f]_+ = \max(f, 0)$. The corresponding differential equation for the potential ϕ is

$$-\nabla^2 \phi = 4\pi \left[\sum_i Z_i \delta^{(3)}(\mathbf{r} - \mathbf{R}_i) \right.$$
$$\left. - \gamma_p^{-3/2} [\phi(\mathbf{r}) - \mu]_+^{3/2} \right] . \tag{20.21}$$

Lieb and Simon rigorously proved a large number of results concerning the solution of the Thomas–Fermi model. When $V(\mathbf{r})$ is a sum of Coulomb potentials arising from a set of nuclei of positive charges Z_i, with $\sum_i Z_i = Z$, then the energy $E(\lambda)$ is a continuous, monotonically decreasing function of λ for $0 \le \lambda \le Z$, and its derivative $\mathrm{d}E/\mathrm{d}\lambda$ is the chemical potential $-\mu(\lambda)$, which vanishes at $\lambda = Z$. For λ in this range, there is a unique minimizing density ρ, whereas for $\lambda > Z$ there

is no unique minimizing ρ, since one can place arbitrarily large clumps of charge with arbitrarily low energy arbitrarily far away from the nuclei. In the atomic case, with a single nucleus, $\rho(r)$ is a spherically symmetric monotonically decreasing function of r.

Moreover, for an atom or atomic ion, the Thomas–Fermi density obeys the *virial theorem*

$$2\langle \mathcal{T} \rangle = -\langle V \rangle = -2E \,, \tag{20.22}$$

and for a neutral atom the electronic kinetic energy, electron–nucleus attraction energy, and electron–electron repulsion energy terms in the expression for the total energy satisfy the ratios $3 : -7 : 1$.

It is straightforward to examine the behavior of the Thomas–Fermi density ρ in the limit as either $r \to 0$ or $r \to \infty$. For large r, the electron density vanishes identically outside a sphere of finite radius for a positive ion. For a neutral atom, the ordinary differential equation (20.16) for the potential ϕ can be analyzed to show that

$$\phi(r) \simeq \gamma_p \,(3\gamma_p/\pi)^2 \, r^{-4} \,, \tag{20.23}$$

from which it follows that

$$\rho(r) \simeq (3\gamma_p/\pi)^3 \, r^{-6} \,, \tag{20.24}$$

independent of Z. This implies that as $Z \to \infty$, a neutral atom described by the Thomas–Fermi model has a finite size defined in terms of a radius within which all but a fixed amount of electronic probability density is located. For example, if one defines the size of an atom as that value of r_a for which

$$\int\limits_{|\boldsymbol{r}| \geq r_a} \rho(\boldsymbol{r}) \, \mathrm{d}\boldsymbol{r} = \frac{1}{2} \,, \tag{20.25}$$

one finds that in the large-Z limit

$$r_a = \left(\frac{8\pi}{3}\right)^{1/3} \frac{3\gamma_p}{\pi} \,. \tag{20.26}$$

In atomic units, $\gamma_p = \frac{1}{2}(3\pi^2)^{2/3}$, and

$$r_a = (9\pi)^{2/3} \, a_0 \simeq 9.3 \, a_0 \,, \tag{20.27}$$

which is about what one would expect for a 'real' nonrelativistic atom with a large nuclear charge Z. On the other hand, the characteristic distance scale in Thomas–Fermi theory, defined as the 'average' value of r, or in terms of a radius within which a fixed *fraction* of electronic probability density is located, is proportional to $Z^{-1/3}$, which shrinks to 0 as $Z \to \infty$. The resolution of this paradox is that outside the typical 'core' scale of

distance set by $Z^{-1/3}$, within which most of the electron density is located, there resides in the 'mantle' region a fraction of electrons proportional to $Z^{2/3}/Z = Z^{-1/3}$, and almost all of these are concentrated within a sphere of radius of about 10 a_0.

Moving deeper into the core and approaching the nucleus, the $-Z/r$ singularity in the electron–nucleus Coulomb potential dominates the smeared-out electron–electron potential, so one readily finds that

$$\rho(r) \simeq \left(\frac{Z}{\gamma_p \, r}\right)^{3/2} \,. \tag{20.28}$$

This singularity is integrable but unphysical, since it arises from the approximation of the local kinetic energy by $\rho^{5/3}$, which breaks down where ρ is rapidly varying on a length scale proportional to $1/Z$. In a 'real' nonrelativistic heavy atom governed by the Schrödinger equation, the actual electron density at the nucleus is finite, being proportional to Z^3. This unphysical singularity in the electron density in Thomas–Fermi theory can be eliminated by adding a gradient correction to the Thomas–Fermi kinetic energy term.

20.1.2 Thomas–Fermi–von Weizsäcker Theory

The semiclassical approximation (20.3) for the quantum kinetic energy in terms of a power of the density is capable of improvement, particularly in regions of space where the density is rapidly varying. The incorporation of such corrections leads to a gradient expansion for the kinetic energy [20.27]. The leading correction is of the form

$$\frac{\hbar^2}{2m} \int \left| \left(\nabla \rho^{1/2}\right)(\boldsymbol{r}) \right|^2 \, \mathrm{d}\boldsymbol{r} \,. \tag{20.29}$$

Addition of such a term to the Thomas–Fermi expression for the kinetic energy yields a theory which avoids many of the unphysical features of ordinary Thomas–Fermi theory at very short and moderately large distances. The more important points, as rigorously proved in Lieb's review article [20.15, 16], are as follows. The leading features of the energy are unchanged; for large Z the energy $E(Z)$ of a neutral atom or atomic ion is still proportional to $Z^{7/3}$, but now there enter higher-order corrections arising from the gradient terms of order $Z^{7/3} Z^{-1/3} = Z^2$ and higher powers of $Z^{-1/3}$. The maximum number of electrons which can be bound by an atom of nuclear charge Z is no longer exactly Z, but a slightly larger number; thus Thomas–Fermi–von Weizsäcker theory allows for the formation of negatively charged atomic ions. It was further proven by

Benguria and *Lieb* [20.28] that in the Thomas–Fermi–von Weizsäcker model a neutral atom can bind at most one extra electron, and that a neutral molecule can bind at most as many extra electrons as it has nuclei.

The effect on the electronic density ρ is more profound. While the general shape and properties of ρ in the 'core' and 'mantle' regions is unchanged, the fact that $\nabla \rho^{1/2}$ need not, and in general does not, vanish when ρ vanishes on some surface implies that for a positive ion ρ no longer vanishes outside of a sphere, as it does in the case of Thomas–Fermi theory, but instead extends over all space. For positive ions, neutral atoms, and negative ions alike, 'differential inequality' techniques [20.29] can be used to show that $\rho(r)$ decays exponentially for large r, with the constant in the exponential proportional to $\mu^{1/2}(\lambda)$. For small r, the gradient terms dominate the energy expression, so one finds that the electronic density no longer diverges as $r \to 0$, but instead tends to a finite limit, with a first derivative which obeys a relation analogous to the Kato cusp condition [20.30] (see Sect. 11.1.1).

The study of molecules within the Thomas–Fermi–von Weizsäcker model involves several subtleties and pitfalls, which can lead to physical absurdities. Since two neutral atoms with different nuclear charges will in general have different chemical potentials, a pair of such atoms placed a long distance apart will *spontaneously ionize*, with a small amount of electric charge being transferred from one to the other until the chemical potentials of the positively charged ion and the negatively charged ion become equal. The result is a long-range Coulomb attraction between them [20.31]. This phenomenon does *not* occur in the real world, since the amount of electric charge which can be transferred is quantized in units of $-e$, and it is empirically true that the smallest atomic ionization potential exceeds the largest atomic electron affinity. For two neutral atoms with the same nuclear charges, the situation is more subtle. Nonetheless, a careful analysis shows that in this case too, though no spontaneous ionization occurs, there is a long-range attractive interaction between them arising from the overlap of the exponentially small tails of the electron clouds. Since electron correlation is not included in this model, it could not be expected to describe attractive van der Waals forces.

In summary, the Thomas–Fermi–von Weizsäcker model yields a more realistic picture of a single atom than does the Thomas–Fermi model. However, it does not provide a useful picture for understanding the interaction between atoms at large distances. These kinds of unphysical features provide a glimpse into the compli-

cated nature of the universal density functional, which must include terms which rigorously suppress an unphysical feature like spontaneous ionization of a distant pair of heteronuclear atoms [20.32, 33]. It is evident from the mathematical properties of Thomas–Fermi–von Weizsäcker theory and related models that a density functional which 'fixes up' the Thomas–Fermi expression simply by adding a few gradient terms and/or simple exchange terms and the like must still differ in important ways from the universal density functional, particularly for properties of extended systems.

20.1.3 Thomas–Fermi–Dirac Theory

The effect of the exchange of electrons can be approximated, following *Dirac* [20.7], by including in the Thomas–Fermi energy functional an expression of the form

$$-\frac{1}{4\pi^3} \left(3\pi^2\right)^{4/3} \int \rho^{4/3}(\boldsymbol{r}) \, \mathrm{d}\boldsymbol{r} \; . \tag{20.30}$$

Minimization of the resulting Thomas–Fermi–Dirac energy functional over all admissible densities ρ whose integral is λ yields a well-defined $E(\lambda)$, which has the correct behavior for $\lambda \leq Z$, and it has been shown that for an atom the exchange correction to the energy is of order $Z^{5/3}$. However, this model exhibits unphysical behavior for $\lambda > Z$, because one can obtain a completely artificial lowering of the energy by placing many small clumps of electrons a large distance from the nucleus, for which the negative $\int \rho^{4/3} \, \mathrm{d}\boldsymbol{r}$ term dominates the energy expression [20.15, 16]. At the conclusion of his original article, Dirac clearly stated that the correction he had derived, although giving a better approximation in the interior of an atom, gives "a meaningless result for the outside of the atom" [20.7]. It is therefore clear that any physically reasonable theory must somehow profoundly modify this correction in the region where the electronic density is very small.

20.1.4 Thomas–Fermi–von Weizsäcker–Dirac Theory

One can also include the Dirac exchange correction in the Thomas–Fermi–von Weizsäcker energy functional. In this case, however, the mathematical foundations of the theory are still incomplete ([20.15, 16, pp. 638−9]). Nonetheless, it is clear that this theory too suffers from the unphysical lowering of the energy by small clumps of electrons at large distances from the nucleus.

In summary, one can say that the inclusion of Dirac's exchange correction in its most straightforward form

leads to an improvement of energies for positive ions or neutral atoms, but to unphysical behavior for systems where the charge of the electrons exceeds the nuclear charge, in line with Dirac's own observations on the limitations of his correction [20.7]. We see here again a manifestation of how complicated must be the behavior of the true universal density functional.

20.1.5 Thomas–Fermi Theory with Different Spin Densities

As was remarked by *Lieb* and *Simon* [20.10], it is possible to consider a variant of Thomas–Fermi theory with a pair of spin densities ρ_α and ρ_β for the spin-up and spin-down electrons, with the two adding together to produce the total electronic density ρ. This theory has been rigorously formulated and analyzed by *Goldstein*

and *Rieder* [20.34]. Because the problem is nonlinear, the mathematical complications are substantial, and the theory is not a trivial extension of ordinary Thomas–Fermi theory. *Goldstein* and *Rieder* first considered the case where the total number of electrons of each type of spin is specified in advance [20.35]. There is no mathematical obstacle to constructing such a spin-polarized Thomas–Fermi theory, but it does not yield the kind of spontaneous spin-polarization that one observes in the ground states of many real quantum mechanical atoms and molecules, which is not surprising in view of the fact that such spin-polarization in accord with Hund's first rule arises from exchange and correlation effects not included in this simple functional. However, in the case where the electronic spins (but *not* their currents) are coupled to an external magnetic field, the ground state is naturally spin-polarized [20.34].

20.2 Nonrelativistic Energies of Heavy Atoms

Thomas–Fermi theory suggests that (20.17) provides the leading term in a power series expansion for the nonrelativistic energy of a neutral atom of the form

$$E(Z) = -\left(c_7 Z^{7/3} + c_6 Z^{6/3} + c_5 Z^{5/3} + \cdots\right)$$

(20.31)

with $c_7 = 1.537\,490\,24\ldots$ Ry, $c_6 = -1$ Ry, and $c_5 \simeq 0.5398$ Ry. The c_6 term was first calculated by *Scott* [20.36] from the observation that it arises from the energy of the innermost electrons for which the electron–electron interaction can be neglected. The difference between the exact and Thomas–Fermi energies for this case of noninteracting electrons yields the correct c_6 [20.17, 37]. A mathematically nonrigorous but physically insightful justification of the Scott correction was provided in 1980 by *Schwinger* [20.38]. This result has now been rigorously proved, with upper and lower bounds coinciding [20.39–43].

The c_5 term is much more subtle, since it arises from a combination of effects from the exchange interaction and from the bulk motion of electrons in the Thomas–Fermi potential. A general analytic procedure devised by *Schwinger* [20.44] yields the above value, in good agreement with a much earlier estimate by *March* and *Plaskett* [20.45].

A numerical check of these results, based on a fit to Hartree–Fock calculations for Z up to 290 with correlation corrections, yielded the values [20.46]

$c_5 = 0.55 \pm 0.02$ Ry and $c_4 \simeq 0$. It seems likely that, because of shell structure, the terms c_4 and beyond have an oscillatory dependence on Z [20.47]. The oscillatory structure and other refinements of Thomas–Fermi theory are considered in a series of papers by *Englert* and *Schwinger* [20.48–50].

Iantchenko, *Lieb*, and *Siedentop* [20.51] have proven Lieb's 'strong Scott conjecture' that for small r, the rescaled density for the exact quantum system converges to the sum of the densities of the bound noninteracting hydrogenic orbitals; the properties of this function were explored by *Heilman* and *Lieb* [20.52]. *Fefferman* and *Seco* [20.53] have rigorously proved the correctness of Schwinger's procedure for calculating not just the $O(Z^{6/3})$ Scott correction but also the $O(Z^{5/3})$ exchange term. Their full proof includes a demonstration that the Hartree–Fock energy agrees with the exact quantum energy through $O(Z^{5/3})$, with an error of smaller order [20.54]. Numerous auxiliary theorems and lemmas are published in [20.55–58]. Progress toward obtaining higher-order oscillatory terms is described in [20.59–63]. The analytical evaluation of accurate approximations to the energy of a heavy atom, or at least of the contributions to that energy of all but the few outermost electronic orbitals, would be of particularly great value if it led to the construction of more accurate and better justified pseudopotentials [20.64–67] for describing the valence orbitals.

20.3 General Density Functional Theory

The literature on general density functional theory and its applications is enormous, so any bibliography must be selective. The reader interested in learning more could begin by consulting a number of review articles [20.68–73], collections of articles [20.74–76], and conference proceedings [20.77–87], and the recent textbooks by *Parr* and *Yang* [20.88] and by *Dreizler* and *Gross* [20.89].

20.3.1 The Hohenberg–Kohn Theorem for the One-Electron Density

In 1964 *Hohenberg* and *Kohn* [20.21] argued that there exists a universal density functional $F[\rho]$, independent of the external potential $V(\boldsymbol{r})$, such that minimization of the sum

$$F[\rho] + \int \rho(\boldsymbol{r}) V(\boldsymbol{r}) \, \mathrm{d}\boldsymbol{r} \,, \qquad (20.32)$$

subject to the constraint

$$\int \rho(\boldsymbol{r}) \, \mathrm{d}\boldsymbol{r} = N \text{ (a positive integer)} \,, \qquad (20.33)$$

yields the ground state energy of a quantum-mechanical N-electron system moving in this external potential. However, Hohenberg and Kohn's 'theorem' is like a mathematical 'existence theorem'; no procedure exists to calculate explicitly this unknown universal functional, which surely is extremely complicated if it can be written down at all in closed form. (E. Bright Wilson, however, defined it, implicitly and whimsically, as follows: "Take the ground-state density and integrate it to find the total number of electrons. Find the cusps in the density to locate all nuclei, and then use the cusp condition – that the radial derivative of the density at the cusp is minus twice the nuclear charge density at each cusp – to determine the charges on each nucleus. Finally solve Schrödinger's equation for the ground-state density or any other property that is desired" (paraphrased by B. I. Dunlap, in [20.83, p. 3], from J. W. D. Connolly).)

Moreover, Hohenberg and Kohn glossed over two problems: it is not clear a priori that every well-behaved ρ is derivable from a well-behaved properly antisymmetric many-electron wave function (the so-called *n*-representability problem, since *n* was used by Hohenberg and Kohn to represent the density of electrons), and it is also not clear a priori that every well-behaved density ρ can be derived from a quantum-mechanical many-electron wave function ψ which is the properly antisymmetric ground-state wave function for a system of electrons moving in some external potential $V(\boldsymbol{r})$ (the so-called *v*-representability problem, since Hohenberg and Kohn used *v* in place of V).

The *n*-representability problem was solved by *Gilbert* [20.90] and by *Harriman* [20.91], who gave a prescription for starting from an arbitrary well-behaved ρ and from it constructing a many-electron wave function ψ which generated that ρ [20.33, 92]. The *v*-representability problem is much more formidable, as demonstrated by the discovery that there are well-behaved densities ρ which are *not* the ground-state densities for any fermionic system in an external potential V [20.92, 93]. Following Percus' definition of a universal kinetic energy functional for independent fermion systems [20.94], *Levy* [20.95] proposed to circumvent this *v*-representability problem by modifying the definition of $F[\rho]$ so that instead of being defined in terms of densities which might not be *v*-representable, it is defined as

$$F[\rho] = \min \left[\psi, (T + V) \psi \right] \,, \qquad (20.34)$$

with the minimum being taken over all properly antisymmetric normalized ψ's which yield that ρ.

A great deal of effort has been devoted to trying to find approximate representations of the universal functional $F[\rho]$. One route is mathematical, and features a careful exploration of the abstract properties which $F[\rho]$ must have. Another route is numerical, and can be characterized as involving the guessing of some *ansatz* with a general resemblance to Thomas–Fermi–von Weizsäcker–Dirac theory, with some flexible parameters which are determined by least-squares fitting of the energies resulting from insertion of Hartree–Fock densities into the trial functional to theoretical Hartree–Fock energies, or the like. If, however, the basic *ansatz* exhibits unphysical features in the case of negatively charged ions or heteronuclear molecules, it is not likely that the optimization of parameters in that *ansatz* will get one closer to the true universal density functional. In the opinion of this writer, significant progress in density functional theory based solely upon the one-electron density is likely to require a major revolution in our mathematical understanding of this field, with a useful procedure made explicit for constructing progressively better approximations to the universal density functional, which, like π or other transcendental numbers, probably will never be written down exactly in closed form. Moreover, the numerical solution of the highly nonlinear Euler–Lagrange

equations for a very complicated density functional is likely to require large amounts of computer time, as well as problems with landing in local minima of the energy.

20.3.2 The Kohn–Sham Method for Including Exchange and Correlation Corrections

Density functional theory posed solely in terms of the one-electron density and based upon the Hohenberg–Kohn variational principle provides no general procedure for accurately calculating relatively small energy differences such as excitation energies, ionization potentials, electron affinities, or the binding energies of molecules. There is, however, a powerful method inspired by the Hohenberg–Kohn variational principle, which has been used with great success in the calculation of such quantities. This is the Kohn–Sham variational method [20.22].

The key idea in the Kohn–Sham variational method is to replace the nonlocal exchange term in the Hartree–Fock equations with an exchange-correlation potential, which at least in principle can be used to determine energies exactly. The oldest, simplest, and most common *ansatz* used for the exchange-correlation potential involves the local density approximation (LDA), in which one assumes that the exchange-correlation potential for the actual system under study has the same functional form as does the exchange-correlation potential for a uniform interacting gas of electrons. If the density is not too small or not too rapidly varying, the exchange part of this potential can be approximated by $\rho^{1/3}$, which appears in Dirac's first-order approximation for exchange energies, with a systematic procedure for deriving higher-order corrections in a gradient expansion. The correlation part of this potential is accurately known from *Ceperley* and *Alder*'s quantum Monte Carlo calculation of the properties of the uniform electron gas [20.96]. One therefore retains the important features of the quantum theory based on wave functions, with a determinantal approximation to ψ, while approximately including exchange and correlation effects through a simply computable effective potential. Higher corrections, which are important for quantitative accuracy, can be incorporated by taking account of the variation of ρ by means of a gradient expansion [20.27] involving $\nabla\rho$ and higher derivatives [20.89, Chapt. 7], thus yielding a generalized gradient approximation (GGA) for the exchange-correlation potential.

The Kohn–Sham procedure has become the backbone for the vast majority of accurate calculations of the electronic structure of solids [20.72, 86]. In the 1990's, motivated by *Becke*'s work on constructing simple gradient-corrected exchange potentials [20.97–103], and incorporating the Lee, Yang, and Parr (LYP) expression for the correlation potential [20.104] derived from *Colle* and *Salvetti*'s correlation-energy formula [20.105–107], the Kohn–Sham method is finding increasing application in efficiently estimating relatively small energy differences of relevance to chemistry [20.108–110] (However, Becke's gradient-corrected exchange potential does *not* have the correct $1/r$ behavior at large r, as was observed by several authors [20.111–113]). For definitive results, however, one must still resort to an ab initio theory which at least in principle converges toward the correct result.

The generation of improved generalized gradient approximations has recently become a growth industry, with increasingly many proposals of increasingly greater complexity [20.97, 104, 113–125]. Inevitably, some expressions work better for some properties than for others. It is found that usually most of the errors in the long-range tails of the exchange and correlation potentials tend to cancel each other, thus leading to better overall energies than one could reasonably expect [20.126]. Under these circumstances, it is important to have benchmarks for testing the accuracy of the various approximations. Such comparisons have been carried out for two important sets of two-electron systems [20.127–129]:

1. a pair of electrons moving in harmonic potential wells and coupled by the Coulomb repulsion, which yields an exactly solvable system;
2. helium-like ions of variable nuclear charge Z, for which extremely accurate energies and wave functions are available which take account of the behavior of the exact but unknown wave function in the vicinity of all two-particle coalescences and the three-particle coalescence.

The results indicate that the approximate exchange-correlation potentials differ quite considerably from the true exchange-correlation potentials, thus indicating the need for further analytical work in understanding how to design accurate exchange-correlation potentials, and for devising tests of exchange-correlation potentials for larger atoms and for molecules.

Another important way of testing the validity of various approximate exchange and correlation potentials is checking whether they obey inequalities

imposed by such general properties as scaling and the Hellmann–Feynman theorem. Such general tests have been devised by *Levy* and his co-workers [20.130–139], who have found that many of the commonly used approximate potentials violate general inequalities which must be obeyed by the exact potential. These abstract results are helpful in designing potentials which should be better approximations to the true potential.

20.3.3 Density Functional Theory for Excited States

The Hohenberg–Kohn theorem and the Kohn–Sham method were originally formulated in terms of the ground electronic state. These techniques can be extended to calculate the ground state of a given symmetry [20.140], but that leaves unresolved the issue of using density functional theory to calculate the energies of excited states for a given symmetry. Using the Rayleigh–Ritz principle for ensembles, general abstract procedures for generalizing density functional theory to excited state calculations have been formulated by *Theophilou* [20.141] and by several other workers [20.142–151]. Unfortunately, the errors typically seem to be much larger than for ground-state density functional theory.

20.3.4 Relativistic and Quantum Field Theoretic Density Functional Theory

At a formal level, one can discuss the development of density functional theory for a relativistic system of electrons. For an overview of this challenging subject, see the discussions by *Dreizler* and *Gross* [20.89, Chapt. 8] and by *Dreizler* [20.152]. Much of the formalism carries over, but no good way has yet been found of incorporating vacuum polarization corrections.

20.4 Recent Developments

During the last eight years there has continued to be exponentially growing interest in applications of density functional theory of the Kohn-Sham variety to atoms and molecules, especially those of chemical relevance which are too large for accurate ab initio electronic structure calculations. The awarding of the 1998 Nobel Prize in Chemistry to Walter Kohn and John A. Pople recognised their individual contributions to this increasingly important field. Their Nobel lectures were published the following year in the *Reviews of Modern Physics* [20.153, 154].

Since a comprehensive summary of the wide-ranging developments in density functional theory during the past decade is not feasible within the limited space available for this supplementary section, I will briefly cite some of the most extensive surveys of various aspects of this field that have appeared since 1995.

Many aspects of density functional theory were reviewed in four consecutive volumes of *Topics in Current Chemistry* published in 1996 [20.155], and in 1999 an entire volume of *Advances in Quantum Chemistry* was devoted to density functional theory [20.156]. This has also been the subject of several conference proceedings [20.157–159] and introductory textbooks [20.160, 161]. Developments in time-dependent density functional theory for chemical systems have been surveyed in two very recent review articles [20.162, 163].

Although the locality of DFT was proved for a large class of functionals [20.164–166], this issue has come under recent dispute. The question that has been raised is whether there exists an exact Thomas-Fermi model for non-interacting electrons. If such an exact model does not exist, as it is a direct consequence of the Hohenberg-Kohn theorem, then DFT would be incomplete.

Nesbet [20.167–171] has argued that such a theory would be inconsistent with the Pauli exclusion principle for atoms of more than two electrons (or for a two electron atom where both electrons are in the same spin state). The contention is that if only the total electron density were normalized (which corresponds to only one Lagrange multiplier), as in the TF model, then no shell structure can exist; hence such a system would violate the exclusion principle.

A counter-example has recently been constructed by *Lindgren* and *Salomonson* [20.172] showing that shell structure can indeed be generated through a single Lagrange multiplier. In addition, they have verified numerically that a local Kohn-Sham potential can reproduce to high accuracy the many-body electron density and the 2s eigenvalue for the 1s2s ^{3}S state of neutral helium.

21. Atomic Structure: Multiconfiguration Hartree–Fock Theories

This chapter outlines variational methods for the determination of wave functions either in nonrelativistic LS or relativistic LSJ theory. The emphasis is on Hartree–Fock and multiconfiguration Hartree–Fock theory though configuration interaction methods are also mentioned. Some results from the application of these methods to a number of atomic properties are presented.

Part B | 21

21.1 Hamiltonians: Schrödinger and Breit–Pauli

The state of a many-electron system is described by a wave function Ψ that is the solution of a partial differential equation (called the wave equation),

$$(H - E)\Psi = 0 \,, \tag{21.1}$$

where H is the Hamiltonian operator for the system and E the total energy. The operator H depends on the system (atomic, molecular, solid-state, etc.) as well as the underlying quantum mechanical formalism (nonrelativistic, Breit–Pauli, Dirac–Coulomb, or Dirac–Breit, etc.). In atomic systems, the Hamiltonian of the nonrelativistic Schrödinger equation is (in atomic units)

$$H_{\mathrm{nr}} = -\frac{1}{2} \sum_{i=1}^{N} \left(\nabla_i^2 + \frac{2Z}{r_i} \right) + \sum_{i<j} \frac{1}{r_{ij}} \,. \tag{21.2}$$

Here Z is the nuclear charge of the atom with N electrons, r_i is the distance of electron i from the nucleus,

and r_{ij} is the distance between electron i and electron j. This equation was derived under the assumption of a point-nucleus of infinite mass. The term $2Z/r$ represents the nuclear attraction and $1/r_{ij}$ the inter-electron repulsion. The operator H_{nr} has both a discrete and continuous spectrum: for the former, $\Psi(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N)$ has a probability interpretation and consequently must be square integrable. In the Breit–Pauli approximation, the Hamiltonian is extended to include relativistic corrections up to relative order $(\alpha Z)^2$. It is convenient to write the Breit–Pauli Hamiltonian as the sum [21.1]

$$H_{\mathrm{BP}} = H_{\mathrm{nr}} + H_{\mathrm{rel}} \,, \tag{21.3}$$

where H_{rel} represents the relativistic contributions. The latter may again be subdivided into nonfine-structure (NFS) and fine structure (FS) contributions:

$$H_{\mathrm{rel}} = H_{\mathrm{NFS}} + H_{\mathrm{FS}} \,. \tag{21.4}$$

The NFS contributions

$$H_{\text{NFS}} = H_{\text{mass}} + H_{\text{D}} + H_{\text{ssc}} + H_{\text{oo}} \tag{21.5}$$

shift nonrelativistic energy levels without splitting the levels. The mass-velocity term

$$H_{\text{mass}} = -\frac{\alpha^2}{8} \sum_i \nabla_i^4 \tag{21.6}$$

corrects for the variation of mass with velocity; the one- and two-body Darwin terms

$$H_{\text{D}} = -\frac{\alpha^2 Z}{8} \sum_i \nabla_i^2 r_i^{-1} + \frac{\alpha^2}{4} \sum_{i<j} \nabla_i^2 r_{ij}^{-1} \tag{21.7}$$

are the corrections of the one-electron Dirac equation due to the retardation of the electromagnetic field produced by an electron; the spin–spin contact term

$$H_{\text{ssc}} = -\frac{8\pi\alpha^2}{3} \sum_{i<j} (s_i \cdot s_j) \delta(r_{ij}) \tag{21.8}$$

accounts for the interaction of the spin magnetic moments of two electrons occupying the same space; the orbit–orbit interaction

$$H_{\text{oo}} = -\frac{\alpha^2}{2} \sum_{i<j} \left(\frac{p_i \cdot p_j}{r_{ij}} + \frac{r_{ij}(r_{ij} \cdot p_i) \cdot p_j}{r_{ij}^3} \right) \tag{21.9}$$

accounts for the interaction of two orbital moments.

The FS contributions

$$H_{\text{FS}} = H_{\text{so}} + H_{\text{soo}} + H_{\text{ss}} , \tag{21.10}$$

split the nonrelativistic energy levels into a series of closely-spaced fine structure levels. The nuclear spin–orbit interaction

$$H_{\text{so}} = \frac{\alpha^2 Z}{2} \sum_i \frac{1}{r_i^3} (l_i \cdot s_i) , \tag{21.11}$$

represents the interaction of the spin and angular magnetic moments of an electron in the field of the nucleus. The spin–other-orbit term

$$H_{\text{soo}} = -\frac{\alpha^2}{2} \sum_{i\neq j} \left(\frac{r_{ij}}{r_{ij}^3} \times p_i \right) \cdot (s_i + 2s_j) , \tag{21.12}$$

and the spin–spin term

$$H_{\text{ss}} = \alpha^2 \sum_{i<j} \frac{1}{r_{ij}^3} \left[s_i \cdot s_j - \frac{3}{r_{ij}^2} (s_i \cdot r_{ij})(s_j \cdot r_{ij}) \right] , \tag{21.13}$$

arise from spin-dependent interactions with the other electrons in the system.

21.2 Wave Functions: LS and LSJ Coupling

In the configuration interaction model, the approximate wave function Ψ for a many-electron system is expanded in terms of configuration state functions (CSF).

The assignment of nl quantum numbers to electrons specifies a configuration, often written as $(n_1 l_1)^{q_1} (n_2 l_2)^{q_2} \cdots (n_m l_m)^{q_m}$, where q_i is the occupation of subshell $(n_i l_i)$. Associated with each subshell are one-electron spin-orbitals

$$\phi(r, \theta, \varphi, \sigma) = (1/r) P_{nl}(r) Y_{lm_l}(\theta, \varphi) \chi_{m_s}(\sigma) ,$$

where $P_{nl}(r)$ is the radial function, $Y_{lm_l}(\theta, \varphi)$ a spherical harmonic, and $\chi_{m_s}(\sigma)$ a spinor. Each CSF is a linear combination of products of one-electron spin-orbitals, one for each electron in the system, such that the sum is an eigenfunction of the total angular momenta operators L^2, L_z and the total spin operators S^2, S_z. It can be considered to be a product of radial factors, one for each electron, an angular and a spin factor obtained by vector coupling methods. It also is required to be antisymmetric with respect to the interchange of any pair of electron co-ordinates. Often, the specification of the configuration and the final LS quantum numbers is sufficient to define the configuration state, but this is not always the case. Additional information about the order of coupling or the seniority of a subshell of equivalent electrons may be needed. Let γ specify the configuration information and any additional information about coupling to uniquely specify the configuration state function denoted by $\Phi(\gamma LS)$.

The wave function for a many-electron system is usually labeled in the same manner as a CSF and generally designates the largest component. Thus, in the LS approximation,

$$\Psi(\gamma LS) = \sum_{\alpha=1}^{M} c_\alpha \Phi(\gamma_\alpha LS) .$$

However, cases are known where the configuration states are so highly mixed that no dominant component can be found. Then the assignment is made using other criteria. Clearly no two states should have the same label.

In the LSJ scheme, the angular and spin momenta are coupled to form an eigenstate of the total momenta J^2, J_z. The label often still includes an LS designation, as in $2p^2 {}^3P_2$, but only the subscript J is a good quantum number. Thus,

$$\Psi(\gamma LSJ) = \sum_{\alpha=1}^{M} c_\alpha \Phi(\gamma_\alpha L_\alpha S_\alpha J) . \qquad (21.14)$$

21.3 Variational Principle

Variational theory shows the equivalence between solutions of the wave equation, $(H - E)\psi = 0$, and stationary solutions of a functional. For bound states where approximate solutions Ψ are restricted to a square integrable subspace, say $\tilde{\mathcal{H}}$, the best solutions are those for which the energy functional

$$\mathcal{E}(\Psi) = \langle \Psi | H | \Psi \rangle / \langle \Psi | \Psi \rangle \qquad (21.15)$$

is stationary. The condition $\delta\mathcal{E}(\Psi) = 0$ leads to

$$\langle \delta\Psi | H - E | \Psi \rangle = 0, \ \ \forall \, \delta\Psi \in \tilde{\mathcal{H}}, \ \ E = \mathcal{E}(\Psi) . \qquad (21.16)$$

Several results readily follow. The eigenvalues of H are bounded from below. Let $E_0 \le E_1 \le \cdots$. Then

$$E_0 \le \mathcal{E}(\Psi), \ \ \forall \, \Psi \in \tilde{\mathcal{H}} . \qquad (21.17)$$

Consequently, for any approximate wave function, the computed energy is an upper bound to the exact lowest eigenvalue. By the Hylleraas–Undheim–MacDonald theorem (see Sect. 11.3.1) the computed excited states are also upper bounds to the exact eigenvalues, provided that the correct number of states lies below.

21.4 Hartree–Fock Theory

In the Hartree–Fock (HF) approximation, the approximate wave function consists of only one configuration state function. The radial function of each spin–orbital is assumed to depend only on the nl quantum numbers. These are determined using the variational principle and the nonrelativistic Schrödinger Hamiltonian.

The energy functional can be written as an energy expression for the matrix element $\langle \Phi(\gamma LS) | H | \Phi(\gamma LS) \rangle$. Racah algebra may be used to evaluate the spin–angular contributions, resulting in two types of radial integrals:

One–Body
Let $\mathcal{L}$ be the differential operator

$$\mathcal{L} = \frac{d^2}{dr^2} + \frac{2Z}{r} - \frac{\ell(\ell+1)}{r^2} . \qquad (21.18)$$

Then,

$$I(nl, n'l') = -\frac{1}{2} \int_0^\infty P(nl; r) \\ \times \mathcal{L} P(n'l'; r) \, dr . \qquad (21.19)$$

Two–Body
The other integrals arise from the multipole expansion of the two-electron part

$$\frac{1}{r_{12}} = \sum_k \frac{r_<^k}{r_>^{k+1}} P^k(\cos\theta) , \qquad (21.20)$$

where θ is the angle between the vectors $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$, and $r_<, r_>$ are the lesser and greater of r_1, r_2, respectively. In general, let a, b, c, d be four nl quantum numbers, two from the left (bra) and two from the right (ket) CSF. Then

$$R^k(ab, cd) = \int_0^\infty \int_0^\infty P(a; r_1) P(b; r_2) \\ \times \frac{r_<^k}{r_>^{k+1}} P(c; r_1) P(d; r_2) \, dr_1 \, dr_2 ,$$

$$(21.21)$$

which is called a Slater integral. It has the symmetries

$$R^k(ad, cb) \equiv R^k(cb, ad) \equiv R^k(cd, ab) \\ \equiv R^k(ab, cd) .$$

In the Hartree–Fock approximation, the Slater integrals that occur depend on only two sets of quantum numbers. These special cases are denoted separately as

$$F^k(a, b) \equiv R^k(ab, ab) \text{ and}$$
$$G^k(a, b) \equiv R^k(ab, ba) . \quad (21.22)$$

The former is the direct interaction between a pair of orbitals whereas the latter arises from the exchange operator.

The energy expression may be written as

$$\mathcal{E}(\gamma LS) = \sum_i^m q_i \left[I(n_i l_i, n_i l_i) \right.$$

$$+ \frac{q_i - 1}{2} \sum_{k=0}^{2l_i} f_k(i, i) F^k(n_i l_i, n_i l_i) \right]$$

$$+ \sum_{j<i} q_i q_j \left[\sum_{k=0}^{2\min(l_i, l_j)} f_k(i, i) F^k(n_i l_i, n_j l_j) \right.$$

$$\left. + \sum_{k=|l_i-l_j|}^{l_i+l_j} g_k(i, j) G^k(n_i l_i, n_j l_j) \right] .$$

$$(21.23)$$

In general, the coefficients $f_k(i, j)$ and $g_k(i, j)$ depend not only on the configuration, but also on the coupling. An extremely useful concept, introduced by Slater, is the "average energy of a configuration", $\mathcal{E}(\text{av})$. This is a weighted average of all possible LS terms, where the weighting factor is $(2L+1)(2S+1)$. In this case the coefficients have simple formulas that depend on the configuration:

$$f_k(i, i) = 1, k = 0 ,$$

$$= - \left(\frac{2l_i + 1}{4l_i + 1} \right) \begin{pmatrix} l_i & k & l_i \\ 0 & 0 & 0 \end{pmatrix}^2 , k > 0$$

$$f_k(i, j) = 1, i \neq j \text{ and } k = 0 ,$$
$$= 0, i \neq j \text{ and } k > 0 ,$$

$$g_k(i, j) = - \left(\frac{2l_i + 1}{4l_i + 1} \right) \begin{pmatrix} l_i & k & l_j \\ 0 & 0 & 0 \end{pmatrix}^2 . \quad (21.24)$$

Let $\Im(P_a)$ be an integral that depends on P_a. Then $\delta\Im$ is defined as the first-order term of $\Im(P_a + \delta P_a) - \Im(P_a)$. To derive the first-order variation of the F^k and G^k integrals (and R^k in general) it is convenient to re-place the variables (r_1, r_2) by (r, s) and introduce the function

$$Y^k(ab; r) = r \int_0^\infty \frac{r_<^k}{r_>^{k+1}} P(a; s) P(b; s) \, \mathrm{d}s$$

$$= \int_0^r \left(\frac{s}{r} \right)^k P(a; s) P(b; s) \, \mathrm{d}s$$

$$+ \int_r^\infty \left(\frac{r}{s} \right)^{k+1} P(a; s) P(b; s) \, \mathrm{d}s \quad (21.25)$$

so that

$$F^k(a, b) = \int_0^\infty P^2(a; r) \left(\frac{1}{r} \right) Y^k(bb; r) \, \mathrm{d}r \quad (21.26)$$

and

$$G^k(a, b) = \int_0^\infty P(a; r) P(b; r) \left(\frac{1}{r} \right) Y^k(ab; r) \, \mathrm{d}r .$$

$$(21.27)$$

Then the variations are

$$\delta I(a, b) = -\frac{1}{2} (1 + \delta_{a,b}) \int_0^\infty \delta P(b; r) \mathcal{L} P(b; r) \, \mathrm{d}r ,$$

$$\delta F^k(a, b) = 2(1 + \delta_{a,b}) \int_0^\infty \delta P(a; r) P(a; r)$$

$$\times \left(\frac{1}{r} \right) Y^k(bb; r) \, \mathrm{d}r ,$$

$$\delta G^k(a, b) = 2 \int_0^\infty \delta P(a; r) P(b; r) \left(\frac{1}{r} \right) Y^k(ab; r) \, \mathrm{d}r .$$

$$(21.28)$$

The part of the expression that depends on $P(n_i l_i; r)$, for example, is the negative of the removal energy of the entire $(n_i l_i)^{q_i}$ subshell, say $-\bar{\mathcal{E}}[(n_i l_i)^{q_i}]$. The stationary condition for a Hartree–Fock solution applies to this expression, but since the variations must be constrained in order to satisfy orthonormality assumptions, Lagrange multipliers λ_{ij} need to be introduced. The stationary condition applies to the functional

$$\mathcal{F}[P(n_i l_i)] = -\bar{\mathcal{E}}[(n_i l_i)^{q_i}]$$

$$+ \sum_j \delta_{l_i, l_j} \lambda_{ij} \langle P(n_i l_i) | P(n_j l_j) \rangle .$$

$$(21.29)$$

Applying the variational conditions to each of the integrals, and dividing by $-q_i$, we get the equation

$$\left(\frac{d^2}{dr^2} + \frac{2}{r}[Z - Y(n_i l_i; r)] - \frac{l(l+1)}{r^2} - \varepsilon_{ii} \right)$$
$$\times P(n_i l_i; r)$$
$$= \frac{2}{r} X(n_i l_i; r) + \sum_{j \neq i} \delta_{l_i, l_j} \varepsilon_{ij} P(n_j l_j; r) , \qquad (21.30)$$

where

$$Y(n_i l_i; r) = (q_i - 1) \sum_k f_k(i, i) Y^k(n_i l_i n_i l_i; r)$$
$$+ \sum_{j \neq i} q_j Y^k(n_j l_j n_j l_j; r) ,$$
$$X(n_i l_i; r) = \sum_{j \neq i} q_j \sum_k g_k(i, j) Y^k(n_i l_i n_j l_j; r)$$
$$\times P(n_j l_j; r) . \qquad (21.31)$$

21.4.1 Diagonal Energy Parameters and Koopmans' Theorem

The diagonal (ε_{ii}) and off-diagonal (ε_{ij}) energy parameters are related to the Lagrange multipliers by $\varepsilon_{ii} = 2\lambda_{ii}/q_i$ and $\varepsilon_{ij} = \lambda_{ij}/q_i$. In fact,

$$\varepsilon_{ii} = \frac{2}{q_i} \bar{E}[(n_i l_i)^{q_i}]$$
$$- (q_i - 1) \sum_k f_k(i, i) F^k(n_i l_i, n_i l_i) \qquad (21.32)$$

where $\bar{E}[(n_i l_i)^{q_i}]$ is the Hartree–Fock value of the removal energy functional $\bar{\mathcal{E}}[(n_i l_i)^{q_i}]$. In the special case where $q_i = 1$, ε_{ii} is twice the removal energy, or ionization energy. This is often referred to as Koopmans' Theorem; but, as discussed in Sect. 21.4.3, if a rotation of the radial basis leaves the wave function unchanged while transforming the matrix of energy parameters (ε_{ij}), the removal energies are extreme values obtained by setting the off-diagonal energy parameters to zero. For multiply occupied shells, $\varepsilon_{ii}/2$ can be interpreted as an average removal energy, with a correction arising from the self-interaction.

21.4.2 The Fixed-Core Hartree–Fock Approximation

The above derivation has assumed that the solution is stationary with respect to *all* allowed variations. In practice, it may be convenient to assume that certain radial functions are "fixed" or "frozen". In other words, these radial functions are assumed to be given. Such approximations are often made for core orbitals and so, this is called a fixed-core HF approximation.

21.4.3 Brillouin's Theorem

The Hartree–Fock approximation has some special properties not possessed by other single configuration approximations. One such property is referred to as satisfying Brillouin's theorem, though, in complex systems with multiple open shells of the same symmetry, Brillouin's theorem is not always obeyed.

Let $\Phi^{HF}(\gamma LS)$ be a Hartree–Fock configuration state, where γ denotes the configuration and coupling scheme. With $\Phi^{HF}(\gamma LS)$ are associated the m Hartree–Fock radial functions $P^{HF}(n_1 l_1; r)$, $P^{HF}(n_2 l_2; r)$, $\ldots$, $P^{HF}(n_m l_m; r)$. These radial functions define the occupied orbitals. To this set may be added virtual orbitals that maintain the necessary orthonormality conditions. Let one of the radial functions (nl) be replaced by another $(n'l)$, either occupied or virtual, without any change in the coupling of the spin–angular factor. Let the resulting function be denoted by $F(nl \rightarrow n'l)$.

The perturbation of the Hartree–Fock radial function, $P(nl; r) \rightarrow P^{HF}(nl; r) + \epsilon P(n'l; r)$ induces a perturbation $\Phi^{HF}(\gamma LS) \rightarrow \Phi^{HF}(\gamma LS) + \epsilon F(nl \rightarrow n'l)$. But the Hartree–Fock energy is stationary with respect to such variations and so,

$$\langle \Phi^{HF}(\gamma LS) \mid H \mid F(nl \rightarrow n'l) \rangle = 0 . \qquad (21.33)$$

If the function $F(nl \rightarrow n'l)$ is a CSF for a configuration γ^*, or proportional to one, then Brillouin's theorem is said to hold between the two configuration states. When $n'l$ is a virtual orbital, it may happen that $F(nl \rightarrow n'l)$ is a linear combination of CSFs, as in the $2p \rightarrow 3p$ replacement from $2p^3\,{}^2P$, yielding a linear combination of $\{2p^2(^1S)3p,\ 2p^2(^3P)3p,\ 2p(^1D)3p\}$, the linear combination being determined by coefficients of fractional parentage. Thus, Brillouin's theorem will not hold for any of the three individual configuration states in the above equation, only for the linear combination.

When perturbations are constrained by orthogonality conditions between occupied orbitals, the perturbation is of the form of a rotation, where both are perturbed simultaneously,

$$P(nl; r) \rightarrow P(nl; r) + \epsilon P(n'l; r) ,$$
$$P(n'l; r) \rightarrow P(n'l; r) - \epsilon P(nl; r) . \qquad (21.34)$$

Then the perturbation has the form $F(nl \rightarrow n'l, n'l \rightarrow -nl)$. For $1s^2 2s\,{}^2S$, the simultaneous perturbations,

$F(1s \rightarrow 2s, 2s \rightarrow -1s)$, lead to a linear combination of $\{1s2s^2 {}^2S, 1s^3 {}^2S\}$. The CSF for the $1s^3 {}^2S$ is identically zero by antisymmetry, and so Brillouin's theorem holds for the lithium-like ground state. In the $1s2s {}^3S$ state, neither the $1s \rightarrow 2s$ nor the $2s \rightarrow 1s$ substitutions are allowed; in fact, it can be shown that for these states, Brillouin's theorem holds for all mono-excited configurations. The same is not true for $1s2s {}^1S$ where the simultaneous perturbations lead to the condition

$$\left\langle \Phi^{HF}(1s2s {}^1S) | H | \left[\Phi\left(1s^2\right) - \Phi\left(2s^2\right) \right] \right\rangle = 0 . \tag{21.35}$$

Thus, Brillouin's theorem is not obeyed for either the $\Phi\left(1s^2\right)$ or $\Phi\left(2s^2\right)$ CSF in an HF calculation for 1s2s.

The importance of Brillouin's theorem lies in the fact that certain interactions have already been included to first order. This has the consequence that certain classes of diagrams can be omitted in many-body perturbation theory [21.2].

21.4.4 Properties of Hartree–Fock Functions

Term Dependence

The radial distribution for a given nl orbital may depend significantly on the LS term. A well known example is the $1s^2 2s2p$ configuration in Be which may couple to form either a ${}^3P$ or ${}^1P$ term. The energy expression differs only in the exchange interaction, $\pm(1/3)G^1(2s, 2p)$, where the $+$ refers to ${}^1P$ and the $-$ to ${}^3P$. Clearly, the energies of these two terms differ. What is not quite as obvious is the extent to which the $P(2p)$ radial functions differ for the two states. The most affected orbital is the one that is least tightly bound, which in this case is the 2p orbital. Figure 21.1 shows the two radial functions. The ${}^1P$ orbital is far more diffuse (not as localized) as the one for ${}^3P$. Such a change in an orbital is called LS term dependence.

Orbital Collapse

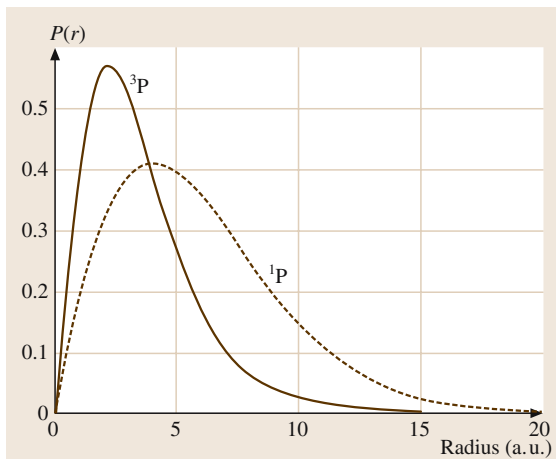
Another phenomenon, called *orbital collapse*, occurs when an orbital rapidly contracts as a function of the energy. This could be an LS dependent effect, but it can also occur along an isoelectronic sequence. This effect is most noticeable in the high-l orbitals. In hydrogen, the mean radius of an orbital is $\langle r \rangle = (1/2)[3n^2 - l(l+1)] a_0$. Thus, the higher-$l$ orbitals are more contracted; but in neutral systems, the high-l orbitals have a higher energy and are more diffuse. This is due, in part, to the $l(l+1)/r^2$ angular momentum barrier that appears in the definition of the $\mathcal{L}$ operator.


Fig. 21.1 A comparison of the 2p Hartree–Fock radial functions for the $1s2p {}^{1,3}P$ states of Be

In the Hartree model, it is possible for $V(r) + l(l+1)/r^2$ to have two wells: an inner well and an outer shallow well. As the lowest eigenfunction changes rapidly from the outer well to the inner well, as Z changes, orbital collapse is said to occur.

Quantum Defects and Rydberg Series

Spectra of atoms often exhibit phenomena associated with a Rydberg series of states where one of the electrons is in an nl orbital, with n assuming a sequence of values. An example is the $1s^2 2snd {}^3D$ series in Be, $n = 3, 4, 5, \ldots$. For such a series, an useful concept is that of a quantum defect parameter δ. In hydrogen, the ionization energy (I_P) in atomic units is $1/(2n^2)$. In complex neutral systems, the effective charge would be the same at large r. As n increases, the mean radius becomes larger and the probability of the electron being in the hydrogen-like potential increases. Thus, one could define an effective quantum number, $n^* = n - \delta$, such that

$$I_P(nl) = (1/2)/(n - \delta)^2 . \tag{21.36}$$

Table 21.1 The effective quantum number and quantum defect parameters of the 2snd Rydberg series in Be

| n | ${}^3D$ | | ${}^1D$ | |
	n^*	$\delta(nl)$	n^*	$\delta(nl)$
3	2.968	0.032	3.014	−0.014
4	3.960	0.040	4.012	−0.012
5	4.957	0.043	5.013	−0.013
6	5.955	0.045	6.013	−0.013

For ionized systems, the equation must be modified to $I_P(nl) = (1/2)[(Z - N + 1)/(n - \delta)]^2$.

Often, this parameter is defined with respect to observed data, but it can also be used to evaluate Hartree–Fock energies, where $I_P = \varepsilon_{nl,nl}/2$, so that $\varepsilon_{nl,nl} = [(Z - N + 1)/(n - \delta)]^2$. Table 21.1 shows the effective quantum number and quantum defect for the Hartree–Fock $2snd$ ^{3}D and ^{1}D orbitals in Be as a function of n. For the triplet part the quantum defect is positive whereas for the singlet it is negative. This is the effect of exchange. Note that as n increases the quantum defect becomes constant. This observation is often the basis for determining ionization potentials from observed data.

21.5 Multiconfiguration Hartree–Fock Theory

The Hartree–Fock method predicts many atomic properties remarkably well; but when analyzed carefully, systematic discrepancies can be observed. Consider the ionization potentials tabulated in Table 21.2 compared with the observed values. In these calculations, the energy of the ion was computed using the same radial functions as for the atom. Thus, no "relaxation" effects were included.

The observed data include other effects as well, such as relativistic effects, finite mass and volume of the nucleus, but these are small for light atoms. For these systems, the largest source of discrepancy arises from the fact that the Hartree–Fock solution is an independent particle approximation to the exact solution of Schrödinger's equation. Neglected entirely is the notion of "correlation in the motion of the electrons"; each electron is assumed to move independently in a field determined by the other electrons. For this reason, the error in the energy was defined by Löwdin [21.3], to be the correlation energy, that is,

$$E^{\text{corr}} = E^{\text{exact}} - E^{\text{HF}} . \tag{21.37}$$

In this definition, E^{exact} is not the observed energy – it is the exact solution of Schrödinger's equation which itself is based on a number of assumptions.

21.5.1 Z-Dependent Theory

An indication of the important correlation corrections can be obtained from a perturbation theory study of the exact wave function. In the following section, we follow closely the approach taken by *Layzer* et al. [21.4] in the study of the Z-dependent structure of the total energy.

Let us introduce a new scaled length, $\rho = Zr$. Then the Hamiltonian becomes

$$H = Z^2 (H_0 + Z^{-1} V) , \tag{21.38}$$

where

$$H_0 = -\frac{1}{2} \sum_i \left(\nabla_i^2 + \frac{2}{\rho} \right) , \tag{21.39}$$

$$V = \sum_{i > j} \frac{1}{\rho_{ij}} , \tag{21.40}$$

and Schrödinger's equation becomes

$$\left(H_0 + Z^{-1} V \right) \psi = \left(Z^{-2} E \right) \psi . \tag{21.41}$$

With $Z^{-1} V$ regarded as a perturbation, the expansions of ψ and E in the powers of Z^{-1} are

$$\psi = \psi_0 + Z^{-1} \psi_1 + Z^{-2} \psi_2 + \cdots , \tag{21.42}$$

in the ρ unit of length, and

$$E = Z^2 \left(E_0 + Z^{-1} E_1 + Z^{-2} E_2 + Z^{-3} E_3 + \cdots \right) . \tag{21.43}$$

The zero-order equation is

$$H_0 \psi_0 = E_0 \psi_0 . \tag{21.44}$$

The solutions of this equation are products of hydrogenic orbitals.

Table 21.2 Observed and Hartree–Fock ionization potentials for the ground states of neutral atoms, in eV. (See also Table 10.3.)

Atom	Obs.	HF	Diff.
Li	5.39	5.34	0.05
Be	9.32	8.42	0.90
B	8.30	8.43	−0.13
C	11.26	11.79	−0.53
N	14.53	15.44	−0.91
O	13.62	14.45	−0.85
F	17.42	18.62	−1.20
Ne	21.56	23.14	−1.58

Part B | 21.5

Let $|(nl)vLS\rangle$ be a configuration state function constructed by vector coupling methods from products of hydrogenic orbitals. Here (nl) represents a set of N quantum numbers $(n_1l_1, n_2l_2, \ldots, n_Nl_N)$ and v any additional quantum numbers such as the coupling scheme or seniority needed to distinguish the different configuration states. Then,

$$H_0|(nl)vLS\rangle = E_0|(nl)vLS\rangle , \tag{21.45}$$

$$E_0 = -\frac{1}{2}\sum_i \frac{1}{n_i^2} . \tag{21.46}$$

Since E_0 is independent of the l_i, different configurations may have the same E_0; that is, E_0 is degenerate. According to first-order perturbation theory for degenerate states, ψ_0 then is a linear combination of the degenerate configuration state functions $|(nl')v'LS\rangle$ with the same set of principal quantum numbers n_i and parity π. The coefficients are components of an eigenvector of the interaction matrix $\langle (nl')v'LS|V|(nl)vLS\rangle$, and E_1 is the corresponding eigenvalue. This is the set of configurations referred to as the *complex* by *Layzer* [21.5] and denoted by the quantum numbers $(n)\pi LS$.

The zero-order wave function ψ_0 describes the many-electron system in a general way. It can be shown that the square of the expansion coefficients of ψ_0 over the degenerate set of configuration states can be interpreted as a probability that the many-electron system is in that configuration state, that ψ_1 is then a weighted linear combination of first-order corrections to each such configuration state. Let us now assume the nondegenerate case where $\psi_0 = \Phi(\gamma LS)$. The configurations interacting with γLS are of two types: those that differ by a single electron (single substitution S) and those that differ by two electrons (double substitution D). The former can be further subdivided into three categories: (i) Those that differ from γLS by one principal quantum number but retain the same spin–angular coupling. These configuration states are part of *radial correlation*. (ii) Those that differ by one principal quantum number but differ in their coupling. If the only change is the coupling of the spins, the configuration states are part of *spin-polarization*. (iii) Those that differ in the angular momentum of one electron and are accompanied by a change in angular coupling of the configuration state and possibly also the spin coupling. The latter represent *orbital-polarization*.

The sums over intermediate states involve infinite sums. In practice, the set of orbitals is finite. In the nondegenerate case, these orbitals can be divided into occupied orbitals and unoccupied, or virtual, orbitals

depending on whether or not they occur in the *reference configuration* that defines γLS. Single and double (SD) replacements of occupied orbitals by other occupied or virtual orbitals generate the set of configurations that interact with ψ_0. Consider the $1s^22s$ ground state of Li and the {1s, 2s, 3s, 4s, 2p, 3p, 4p, 3d, 4d, 4f} set of orbitals. The 1s and 2s orbitals are occupied and all the other orbitals are virtual orbitals, vl. The set of replacements can then be classified as follows:

Replacement	Configuration	Type of correlation
$1s \rightarrow 2s$	$1s2s^2$	Radial and spin-polarization
$2s \rightarrow vs$	$1s^2vs$	Radial
$1s \rightarrow vs$	$1svs(^1S)2s$	Radial
	$1svs(^3S)2s$	Spin-polarization
$1s2s \rightarrow vlv'l$	$1svlv'l$	Core-polarization
$1s^2 \rightarrow vlv'l$	$2svlv'l$	Core

The above discussion has considered only the Z-dependence of the wave function, but the notion can readily be extended to other properties. For example, in transition studies, the dipole transition matrix element decreases as $1/Z$, whereas the transition energy increases linearly with Z for $\Delta n = 0$ transitions, and quadratically as Z^2 otherwise. A first-order theory for oscillator strengths (FOTOS) [21.6] is based on similar concepts.

21.5.2 The MCHF Approximation

In the multiconfiguration Hartree–Fock (MCHF) method, the wave function is approximated by a linear combination of orthogonal configuration states so that

$$\Psi(\gamma LS) = \sum_i^m c_i \Phi(\gamma_i LS) , \tag{21.47}$$

where

$$\sum_i^m c_i^2 = 1 .$$

Then the energy expression becomes

$$\mathcal{E}[\Psi(\gamma LS)] = \sum_i^m \sum_j^m c_i c_j H_{ij} \tag{21.48}$$

where

$$H_{ij} = \langle \Phi(\gamma_i LS)|H|\Phi(\gamma_j LS)\rangle . \tag{21.49}$$

Because $H_{ij} = H_{ji}$, the sum over i, j may be limited to the diagonals and the lower part of the matrix $\boldsymbol{H} = (H_{ij})$,

called the *interaction* matrix. Let $c = (c_i)$ be a column vector of the expansion coefficients, also called *mixing coefficients*. Then the energy of the system is

$$E = c^T H c . \tag{21.50}$$

Let P be the column vector of radial functions, $(P_a, P_b, \ldots)^T$. Since the interaction matrix elements depend on the radial functions, it is clear that the energy functional depends on both P and c.

In deriving the MCHF equations, the energy needs to be expressed in terms of the radial functions and c. From the theory of angular momenta, it follows that

$$H_{ij} = \sum_{ab} q_{ab}^{ij} I(a,b) + \sum_{abcd;k} v_{abcd;k}^{ij} R^k(ab, cd) , \tag{21.51}$$

where the sum over *ab* or *abcd* covers the occupied orbitals of configuration states *i* and *j*.

Substituting into the energy expression (21.48), and interchanging the order of summation, we get

$$\mathcal{E}(\Psi) = \sum_{ab} q_{ab} I(a,b) + \sum_{abcd;k} v_{abcd;k} R^k(ab, cd) , \tag{21.52}$$

where

$$q_{ab} = \sum_i \sum_j c_i c_j q_{ab}^{ij} \quad \text{and}$$

$$v_{abcd;k} = \sum_i \sum_j c_i c_j v_{abcd;k}^{ij} .$$

In this form, the energy is expressed as a list of integrals and their contribution to the energy – a form suitable for the derivation of the MCHF radial equations.

As in the derivation of the Hartree–Fock equations, the stationary principle must be applied to a functional that includes Lagrange multipliers for all the constraints. Thus,

$$\mathcal{F}(P, c) = \mathcal{E}(\Psi) + \sum_{a<b} \delta_{\ell_a, \ell_b} \lambda_{ab} \langle a|b \rangle - E \sum_i c_i^2 . \tag{21.53}$$

In deriving the stationary conditions with respect to variations in c_i, the most convenient form for $\mathcal{E}(\Psi)$ is (21.48), which leads to the secular equation

$$Hc = Ec . \tag{21.54}$$

Thus, the Lagrange multiplier E is the total energy of the system.

The requirement of a stationary condition with respect to variations in the radial functions leads to a system of equations with exactly the same form as the Hartree–Fock equations except: (i) the occupation numbers q_{aa} are not integers but rather *expected* occupation numbers, and (ii) the function $X(r)$ arises not only from the exchange of electrons within a configuration state, but also from interactions between configuration states.

A solution of the MCHF problem requires the simultaneous solution of the secular equation and the variational radial equations. When the latter are assumed to be given, then only the secular problem needs to be solved and the problem is called a *configuration interaction* (CI) problem. If any radial function is optimized, the calculation is called a *multi-configuration Hartree–Fock* (MCHF) calculation. The iterative procedure for its solution is the MCHF-SCF method, details of which can be found in [21.7].

21.5.3 Systematic Methods

For MCHF calculations with only a few configuration states, the latter must be carefully chosen. According to first-order perturbation theory, the expansion coefficient is $c_i = \langle \Phi_i | H | \Phi_0 \rangle / (E_0 - E_i)$. Clearly, configurations near in energy to the state under investigation are candidates for a strong interaction, but it is also important to remember the numerator in this expression. Generally, the latter is large if the electrons in the two configurations occupy the same region of space. Thus in the ground state of beryllium, the strongest mixing is with $2p^2 \, {}^1S$, even though the energy of the latter is far removed from the energy of $2s^2 \, {}^1S$. In highly ionized systems, the complex identifies the configurations that might interact strongly, but for neutral systems, there are many exceptions, particularly in atoms such as the transition metals where the 4s and 4p subshells may be filled before the 3d subshell.

For large scale computation, it is desirable to define the configuration states systematically in terms of an active set (AS) of orbitals. Several notations are commonly used for this set. A very simple designation is "the $n = 4$ active set" in that all orbitals up to and including those with principal quantum number $n = 4$ are included. Another notation common in quantum chemistry is one where the number of orbitals of each symmetry is specified, as in 4s3p2d1f.

Closely associated with this set is the set of configuration states that can be generated. The latter is referred to as the complete active space (CAS). Often the CAS is defined relative to a set of closed shells (or subshells) common to all configurations. For example, the com-

plex for the $3s^2 3p^2\,^3P$ ground state of Si, is a neon-like core, $1s^2 2s^2 2p^6$, coupled to the $\{N = 4, \pi = \text{even}, ^3P\}$ CAS of the active set $\{3s, 3p, 3d\}$. If the AS is extended to $\{3s, 3p, 3d, 4s, 4p, 4d, 4f\}$, then all single, double, triple, quadruple (SDTQ) replacements from the outer four electrons are generated. Of course, the number of CSF increase rapidly, both with the size of the active set and with the number of electrons N defining the CAS. For this reason, other models may be used, such as multi-reference singles and doubles (MR–SD) modeled on the results of Z-dependent perturbation theory. These multi-reference functions may be extended to include all important contributors to a wave function. Calculations in which correlation is restricted to a few outer electrons is called *valence correlation*.

A consequence of a CAS expansion is that the MCHF problem is over determined: a rotation of radial functions of the same symmetry merely transforms the CSFs and the expansion coefficients. The wave function and energy do not change. When similar situations occur in Hartree–Fock theory, Koopmans' theorem requires that the lagrange multiplier associated with the rotation be set to zero. In MCHF calculations, the degree of freedom is usually used to eliminate a CSF or, more precisely, to determine that solution for which a specific CSF has a zero expansion coefficient. A generalized Brillouin's Theorem (GBT) then holds. In the case of the helium ground state (or any ns^2 pair function), applying GBT leads to the *natural orbital expansion* of the form $\{1s^2, 2s^2, 3s^2, \ldots, 2p^2, 3p^2, \ldots, 3d^2, \ldots\}$ in which all CSF differ by two electrons. For other symmetries, such as $1s2p\,^3P$, a *reduced form* [21.8] can also be defined in which all CSF differ by two electrons, but now involves different sets of orthonormal radial functions for the different partial waves as in $\{1s2p_1, 2s3p_1, 3s4p_1, \ldots, 2p_23d_1, 3p_24d_1, \ldots\}$.

Such expansions yield the fastest rate of convergence, but are difficult to apply in complex systems. For a history of Brillouin's theorem and its use in solving multi-configuration self-consistent field problems see [21.9].

21.5.4 Excited States

For ground states or atomic states lowest in their symmetry, the variational procedure is a minimization procedure, and consequently any approximate energy is an upper bound. For all others the energies are stationary. Such calculations may be difficult. One of the most difficult has been the HF calculation for $1s2s\,^1S$ and, once obtained is disappointing since the energy is too low. Excited state calculations become minimization problems through the use of the Hylleraas–Undheim–MacDonald theorem (Sect. 11.3.1). Consider a CAS calculation over the active set $\{1s, 2s\}$ for which the CSFs are $\{1s^2, 1s2s, 2s^2\}$. In determining orbitals, we have a degree of freedom so one CSF may be removed. Selecting $2s^2$ has the consequence that the eigenvalue for the $1s2s$ state to be determined is now the second eigenvalue, and hence an upper bound to the exact.

21.5.5 Autoionizing States

The MCHF variational method may be applied to core excited states imbedded in the continuum, provided that certain CSFs with filled shells are omitted. An example is $1s2s2p^2\,^2P$ of Lithium. An MCHF calculation omitting $1s^2np$ configuration states represents the localized charge distribution of a state in the continuum. However, the resulting energy is not guaranteed to be an upper bound to the exact energy.

The saddle-point variational method, as described in Chapt. 25 is a minimax method for such states.

21.6 Configuration Interaction Methods

Configuration interaction (CI) methods differ from variational methods like MCHF in that the radial functions are assumed to be fixed, and hence known in advance. There are several situations where these methods can be used effectively:

MCHF with Breit–Pauli
Since the Breit–Pauli operators are valid only as first order perturbations, variational calculations for the Breit–Pauli Hamiltonian are not justified. Instead, MCHF calculations are performed to provide a basis for

LSJ wave functions of (21.14). The expansion coefficients are obtained as a CI calculation. Usually such expansions are a concatenation of the expansions of all the LS terms of a configuration and possibly some close lying configurations. Most Breit–Pauli codes require a single orthonormal basis. In order to have an orbital basis that simultaneously describes the correlation of all these LS terms from a systematic procedure, the MCHF derivation described earlier has been extended to derive systems of coupled equations for linear combinations of energy functionals, one for each LS term and

eigenstate. With this extension, it has been possible to perform "spectrum" calculations in which all LSJ levels up to a certain point in the spectrum are included. This requires a balanced correlation approach so that the energy differences with respect to the ground state is in good agreement with the observed excitation energy. Once wave functions have been obtained for each level, transition probabilities can be computed. With all E1 transitions between these levels and some E2/M1 transitions, the lifetimes of levels can be obtained [21.10].

Full–Core Methods

The full-core plus correlation method (FCPC) [21.16] is a configuration interaction method. It is mostly used for an atomic system in which a well defined "core" is present. For example, in a system such as the three-electron $1s^2nl$ or the four-electron $1s^2nln'l'$, the system has a $1s1s$ core. In this case, the wave function for an N-electron system is written as

$$
\begin{aligned}
\Psi(1, 2, 3, \dots, N) = {} & \\
& \mathcal{A}\phi_{1s1s}(1, 2) \sum_i C_i \Phi_i(3, 4, \dots, N) \\
& + \mathcal{A} \sum_j D_j \psi_j(1, 2, 3, \dots, N) ,
\end{aligned}
$$

where $\phi_{1s1s}(1, 2)$, the wave function of the core, is used as a single term, and $\mathcal{A}$ denotes antisymmetrization. The relaxation of the core and other correlation effects are accounted for by the last term in this equation. The correlation effect of the $1s1s$ core is, in general, very strong and it is difficult to fully account for this effect in a conventional N-electron wave function. If inaccurate results are obtained from such a wave function, it may be difficult to distinguish between errors coming from the core part or from the other parts. In the FCPC, the correlation effect in $\phi_{1s1s}(1, 2)$ can be precalculated to a desired accuracy such that ψ_j no longer contains the contribution from the unperturbed core. In physical processes such as ionization, optical transitions and others, the $1s1s$ core wave function in the final state does not change much from that of the initial state. Using the same $\phi_{1s1s}(1, 2)$ for the core may minimize possible errors due to the inaccuracy of the core wave function. The application of this method is not limited to systems with $1s1s$ cores. For example, for the lithium-like $1s2snp$ $^4P^o$, for $n \geq 4$, the $1s2s$ ^3S can also be considered as an appropriate "core".

From a computational view point, the FCPC wave function has the advantage that it reduces the matrix size of the secular equation substantially. This drastically

Table 21.3 Comparison of theoretical and experimental energies for Be $1s^2 2s^2$ ^1S in hartrees. All theoretical values include some form of extrapolation

Ref.	Method	$-E_{\text{NR}}$	$-E_{\text{rel}}$

[21.15]	Experiment		14.669 6759

reduces the memory and CPU time needed on a computer. This method has been quite successful in getting accurate results for four-electron systems as shown in Table 21.3. See [21.13] for more details.

Slater Type Orbitals

The essential characteristic of a radial function can be well represented by the expansion

$$
P_{nl}(r) = \sum_j c_{jnl}\phi_{jnl}(r) ,
$$

where

$$
\phi_{jnl}(r) = \left(\frac{(2\zeta_{jnl})^{2I_{jnl}+1}}{(2I_{jnl})} \right)^{1/2} r^{I_{jnl}} \exp(-\zeta_{jnl}r)
$$

is a *Slater type orbital* (STO). Optimized sets of parameters have been tabulated for many Hartree–Fock wave functions and these may be used to represent the core [21.17]. Others may be added and selected orbitals *exponent optimized* (only the exponent is varied) so as to augment the basis. This method has been used effectively by A. Hibbert as implemented in the *Configuration Interaction Version 3* program [21.18].

Spline Basis

The analytic basis methods described in the previous section have some similarities with MCHF in that linear combinations of STOs first represent orbitals which then define the CSFs. These bases result in extensive cancellation as shown by *Hansen* et al. [21.19]. An expansion in B-spline basis functions, $B_{i,k}(r)$, which are a basis for a piecewise polynomial subspace (see Chapt. 8), provide a more flexible basis with very little cancellation in this representation.

By solving a radial equation with a well chosen potential using the spline Galerkin method that leads to a matrix eigenvalue problem, a complete set of orbitals for a piecewise polynomial space can be obtained. The resulting orthogonal orbital basis may then be used in

CI calculations. Such methods have been reviewed by *Hansen* et al. [21.19]. Methods that deal directly with the primitive B-spline basis have been applied to the study of Rydberg series [21.20], though orthogonality to target orbitals was still required. More recently, by using non-orthogonal theory, an Rmatrix-CI method has been developed that leads to a generalized eigenvalue prob-

lem. As in the close-coupling approximation, the wave function is expressed in terms of one or more "targets," each coupled to a Rydberg orbital, and an arbitrary number of pseudo-states. Each Rydberg orbital is expressed as a linear combination of B-splines but there is no requirement of orthogonality of the Rydberg orbital to the orbitals defining the target function [21.21]

21.7 Atomic Properties

The discussion so far has concentrated entirely on determining accurate wave functions based on expressions for the energy. Energy levels are a by-product of such calculations, but once a wave function is known a number of atomic properties can be evaluated.

21.7.1 Isotope Effects

The isotope shift observed in atomic transitions can be separated into a mass shift and a field shift. The mass shift is due to differences in the nuclear mass of the isotopes, and is the dominant effect for light atoms. The volume shift arises from the finite volume of the nuclear charge distribution, and is important for heavy atoms. From a physical point of view the field shift is the more interesting, since it yields information about differences in the nuclear charge distribution between the isotopes.

The isotope shift in a transition is given as the difference between the shift for the upper and lower level. The individual shifts are often large, but cancel, and therefore it is necessary to calculate them very accurately in order to get a reliable value for the difference. The energy shifts are evaluated in first-order perturbation theory with wave functions obtained from the zero-order Schrödinger Hamiltonian, H_0.

Mass Shift
Up to this point, the nuclear mass has been taken to be infinite. If instead it has a finite value M, an N-electron atom turns into an $(N+1)$-particle dynamical system. A transformation to center of mass $\boldsymbol{R}$ plus relative coordinates $\boldsymbol{r}_i' = \boldsymbol{r}_i - \boldsymbol{r}_{\text{nuc}}$ yields the transformed Hamiltonian [21.22]

$$H = \frac{P^2}{2M_{\text{tot}}} + \sum_{i=1}^{N} \frac{p_i'^2}{2\mu} + \sum_{i<j}^{N} \frac{\boldsymbol{p}_i' \cdot \boldsymbol{p}_j'}{M} + V(\boldsymbol{r}_i'),$$

(21.55)

where $M_{\text{tot}} = M + Nm$ is the total mass and $\mu = Mm/(M+m)$ is the reduced mass. The first term is

the kinetic energy of the center of mass, which can be neglected if $\boldsymbol{R}$ is an ignorable coordinate. For the remaining terms, introduce the scaled distances $\boldsymbol{\rho}_i = \boldsymbol{r}_i'/a_\mu$, where $a_\mu = (m/\mu)a_0$ is the scaled Bohr radius. If the potential is entirely Coulombic, then H assumes the form

$$H = -\frac{1}{2} \sum_{i=1}^{N} \nabla_{\rho_i}^2 - \frac{\mu}{M} \sum_{i<j}^{N} \nabla_{\rho_i} \cdot \nabla_{\rho_j} + V(\rho_i)$$

(21.56)

in units of e^2/a_μ. This can be written in the form $H = H_0 + H_{\text{MP}}$, where H_0 includes the first and last terms of (21.56), and

$$H_{\text{MP}} = -\frac{\mu}{M} \sum_{i<j}^{N} \nabla_{\rho_i} \cdot \nabla_{\rho_j} \quad (e^2/a_\mu)$$

(21.57)

is the additional *mass polarization* term.

Equation (21.56) gives rise to two kinds of mass shifts. First, since H is identical to the infinite mass Hamiltonian, all its eigenvalues E_0 are multiplied by $a_0/a_\mu = \mu/m$, resulting in the *normal mass shift* (nms)

$$\Delta E_{\text{nms}} = -(\mu/M)E_0 .$$

(21.58)

Second, if H_{MP} is treated as a first order perturbation, then the resulting *specific mass shift* (sms) is

$$\Delta E_{\text{sms}} = \langle \Psi_0 \mid H_{\text{MP}} \mid \Psi_0 \rangle \quad (e^2/a_\mu)$$

(21.59)

where Ψ_0 is an eigenvector of H_0. The specific mass shift parameter S is defined by

$$S = \left\langle \Psi_0 \mid -\sum_{i<j}^{N} \nabla_{\rho_i} \cdot \nabla_{\rho_j} \mid \Psi_0 \right\rangle .$$

(21.60)

Field Shift
The field shift of an atomic energy level is due to the extended nuclear charge distribution. The field inside the nucleus deviates from the Coulomb field of a point

charge, and this is reflected in the calculated levels. For light atoms, the resulting energy correction to the level E_0 is expressed in terms of the nonrelativistic electron probability at the origin, $|\Psi(0)|^2$:

$$E_{\text{fs}} = \frac{2\pi}{3} Z \langle r_N^2 \rangle |\Psi(0)|^2 , \tag{21.61}$$

where $\langle r_N^2 \rangle$ is the mean square radius of the nucleus. For heavier atoms ($Z > 10$) it becomes necessary to include a relativistic correction factor. Numerical values of this correction factor can be found in [21.23].

Table 21.4 shows the convergence of an MCHF calculation for the specific mass shift parameter and the electron density at the nucleus of the ground state of Boron II as the active set increases. The calculated $^{11}\text{B} - {}^{10}\text{B}$ isotope shift is $13.3\,\text{mÅ}$ with an estimated uncertainty of 1%. The size of the isotope shift is similar to the limit of resolution of the Goddard High Resolution Spectrograph aboard the Hubble Space Telescope [21.24].

21.7.2 Hyperfine Effects

The magnetic hyperfine structure (hfs) is due to an interaction between the magnetic field generated by the electrons and the nuclear magnetic dipole moment. The interaction couples the nuclear and electronic angular momenta to a total momentum $\boldsymbol{F} = \boldsymbol{I} + \boldsymbol{J}$, and the interaction energy can be written as the expectation value of a scalar product between an electronic and a nuclear tensor operator [21.25] (see Chapt. 16)

$$W_{M1}(J) = \langle \gamma_I \gamma_J IJFM_F \mid \boldsymbol{T}^{(1)} \\ \cdot \boldsymbol{M}^{(1)} \mid \gamma_I \gamma_J IJFM_F \rangle . \tag{21.62}$$

The nuclear operator $\boldsymbol{M}^{(1)}$ is related to the scalar magnetic dipole moment, μ_I, according to

$$\langle \gamma_I II \mid M_0^{(1)} \mid \gamma_I II \rangle = \mu_I . \tag{21.63}$$

Table 21.4 Specific mass shift parameter and electron density at the nucleus as a function of the active set

Active set	S (a.u.)	$|\psi(0)|^2$
HF	0.000 00	72.629
2s 1p	−0.020 17	72.452
3s 2p 1d	0.625 18	72.490
4s 3p 2d 1f	0.624 81	72.497
5s 4p 3d 2f 1g	0.601 69	72.501
6s 5p 4d 3f 2g 1h	0.598 03	72.503
7s 6p 5d 4f 3g 2h 1i	0.597 09	72.504

The magnetic dipole moments are known quantities, obtained with high accuracy from experiments. For a recent tabulation see [21.26].

The electronic operator is

$$\boldsymbol{T}^{(1)} = \frac{\alpha^2}{2} \sum_{i=1}^{N} \Bigg\{ 2\boldsymbol{l}^{(1)}(i) r_i^{-3} \\ - g_s \sqrt{10} \big[\boldsymbol{C}^{(2)}(i) \times \boldsymbol{s}^{(1)}(i) \big]^{(1)} r_i^{-3} \\ + g_s \frac{8}{3} \pi \delta(\boldsymbol{r}_i) \boldsymbol{s}^{(1)}(i) \Bigg\} , \tag{21.64}$$

where $g_s = 2.002\,3193$ is the electron spin g-factor, $\delta(\boldsymbol{r})$ the three-dimensional delta function and $C_q^{(k)} = \sqrt{4\pi/(2k+1)} Y_{kq}$, with Y_{kq} being a normalized spherical harmonic. The first term of the electronic operator represents the magnetic field generated by the orbiting electric charges and is called the orbital term. The second term represents the field generated by the orbiting magnetic dipole moments, which are coupled to the spin of the electrons. This is the spin-dipole term. The last term represents the contact interaction between the nuclear magnetic dipole moment and the electron magnetic moment. It is called the Fermi contact term and contributes only for s-electrons.

By recoupling I and J, the interaction energy can be rewritten as

$$W_{M1}(J) = (-1)^{I+J-F} W(IJIJ; F1) \\ \times \langle \gamma_J J \| \boldsymbol{T}^{(1)} \| \gamma_J J \rangle \langle \gamma_I I \| \boldsymbol{M}^{(1)} \| \gamma_I I \rangle , \tag{21.65}$$

where $W(IJIJ; F1)$ is a W coefficient of Racah. When the magnetic dipole interaction constant

$$A_J = \frac{\mu_I}{I} \frac{1}{[J(J+1)(2J+1)]^{\frac{1}{2}}} \langle \gamma_J J \| \boldsymbol{T}^{(1)} \| \gamma_J J \rangle \tag{21.66}$$

is introduced, the energy is given by

$$W_{M1}(J) = \frac{1}{2} A_J C , \tag{21.67}$$

where $C = F(F+1) - J(J+1) - I(I+1)$. In theoretical studies, the A-factor is often given as a linear combination of the hyperfine parameters

$$a_l = \langle \gamma L S M_L M_S \mid \sum_i l_0^{(1)}(i) r_i^{-3} \mid \gamma L S M_L M_S \rangle , \tag{21.68}$$

$$a_d = \langle \gamma L S M_L M_S |$$
$$\sum_i 2 C_0^{(2)}(i) s_0^{(1)}(i) r_i^{-3} | \gamma L S M_L M_S \rangle , \quad (21.69)$$

$$a_c = \langle \gamma L S M_L M_S |$$
$$\sum_i 2 s_0^{(1)}(i) r_i^{-2} \delta(r_i) | \gamma L S M_L M_S \rangle , \quad (21.70)$$

where $M_L = L$ and $M_S = S$. These parameters correspond to the orbital, spin-dipole and Fermi contact term of the electronic operator.

The electric hyperfine structure is due to the interaction between the electric field gradient produced by the electrons and the nonspherical charge distribution of the nucleus. The interaction energy is

$$W_{E2}(J) = \langle \gamma_I \gamma_J I J F M_F | \boldsymbol{T}^{(2)}$$
$$\cdot \boldsymbol{M}^{(2)} | \gamma_I \gamma_J I J F M_F \rangle , \quad (21.71)$$

where the nuclear operator $\boldsymbol{M}^{(2)}$ is related to the scalar electric quadrupole moment, Q, according to

$$\langle \gamma_I I I | M_0^{(2)} | \gamma_I I I \rangle = \frac{Q}{2} . \quad (21.72)$$

The electronic operator is

$$\boldsymbol{T}^{(2)} = - \sum_{i=1}^N \boldsymbol{C}^{(2)}(i) r_i^{-3} , \quad (21.73)$$

and represents the electric field gradient. By introducing the electric quadrupole interaction constant B,

$$B_J = 2Q \left(\frac{J(2J-1)}{(J+1)(2J+1)(2J+3)} \right)^{\frac{1}{2}}$$
$$\times \langle \gamma_J J \| \boldsymbol{T}^{(2)} \| \gamma_J J \rangle , \quad (21.74)$$

the interaction energy can be written as

$$W_{E2}(J) = B_J \frac{\frac{3}{4} C(C+1) - I(I+1) J(J+1)}{2I(2I-1)J(2J-1)} . \quad (21.75)$$

In many cases the electric hyperfine interaction is weaker than the magnetic and manifests itself as a small deviation from the Landé interval rule for the magnetic hfs. If the electronic part of the interaction can be calculated accurately, a value of the electric quadrupole moment Q, which is a difficult quantity to measure with direct nuclear techniques, can be deduced from the measured B-factor. A recent tabulation of nuclear quadrupole moments is given in [21.27].

Table 21.5 shows the convergence of an MCHF active space calculation for two different isotopes for the $1s^2 2s 2p\,^1P$ state of B II [21.24]. Some oscillations are

Table 21.5 MCHF Hyperfine constants (in MHz) for the $1s^2 2s 2p\,^1P$ state of B II

observed since each new "layer" of orbitals may localize in different regions of space.

21.7.3 Metastable States and Lifetimes

States above an ionization threshold may decay via a radiationless transition to a continuum. When the interaction with the continuum is spin-forbidden the state is metastable. The $nsnp^2\,^4P$ of negative ions, for example, decay through Breit–Pauli interactions with $nsnp^2$ doublets. The latter, in turn interact with continuum states, thus opening a decay channel. Such metastable states may be treated as bound states.

The foundation for the theory of autoionization was laid down by Fano [21.28], where he developed a configuration interaction (CI) theory for autoionization. Let $\Psi_b(N; \gamma L S)$ be a normalized, multiconfiguration component of a discrete perturbor for an N-electron system, in which all orbitals are bound orbitals, decaying exponentially for large r. Let Ψ_k be an asymptotically normalized continuum component of the wave function, also for an N-electron system, at energy E, of the form,

$$\Psi_k(N; E \gamma' L S) = | \Psi_b(N-1; \beta \tilde{L} \tilde{S}) \cdot \phi(kl) L S \rangle , \quad (21.76)$$

where $\Psi_b(N-1; \beta \tilde{L} \tilde{S})$ is a bound MCHF wave function for the $(N-1)$-electron target system. Then, in the LS-coupling scheme, the width of the autoionizing state is given by the "Golden Rule"

$$\Gamma = 2\pi V_{E_0}^2 , \quad (21.77)$$

where

$$V_{E_0} = \langle \Psi_b(N; \gamma L S) | H - E_0 | \Psi_k(N; E_0 \gamma' L S) \rangle . \quad (21.78)$$

A similar formula can be derived for the LSJ-scheme and the Breit–Pauli Hamiltonian. In the above equation,

$E_0 = \langle \Psi_b(N; \gamma LS)|H|\Psi_b(N; \gamma LS)\rangle$. The energy of the core, or target, is $E_{target} = \langle \Psi_b(N-1; \beta\tilde{L}\tilde{S})|H|\Psi_b(N-1; \beta\tilde{L}\tilde{S})\rangle$, where H in the latter equation is the Hamiltonian for an $(N-1)$-electron system.

The wave function for the continuum component is assumed to have only one unknown, namely $\phi(kl) = P_{kl}(r)|ls\rangle$, the one-particle continuum function, where $|ls\rangle$ is the known spin–angular part. The radial equation for $P_{kl}(r)$ has exactly the same form as (21.26), except that $\varepsilon_{nl,nl} = -k^2$, where $E_0 = E_{target} + k^2/2$. The radial function can be obtained iteratively using an SCF procedure from outward integration.

One of the more accurate calculations of a lifetime is that for He$^-$ $1s2s2p$ $^4P_{5/2}$ by *Miecznik* et al. [21.29]. In this case, a lifetime of $(345\pm10)\,\mu s$ was found and compared with a recent experimental value of $(350\pm15)\,\mu s$ [21.30]. In this LSJ state, the ^4P interacts with the $1s^2kf\,^2F$. It was found that correlation in the target of the continuum orbital modified the lifetime. In calculations like these, it is always a question whether orthogonality conditions should be applied [as in projection operator formalism (see Chapt. 25)]. Some theorems relating to this question have been published by *Brage* et al. [21.31].

The position and widths of autoionizing resonances can also be determined from the study of photoionization or photodetachment using a spline Galerkin method together with inverse iteration. No boundary condition need be applied nor is there an inner and outer region. Resonance properties are obtained from a fitting of the cross-section [21.32]. Non-orthogonal, spline-based R-matrix methods with an inner and outer region have also been developed where there is no need of the "Buttle correction" and, at the same time, the non-orthogonality eliminates the need of certain pseudo-states [21.33]. For an extensive review of the application of splines in atomic and molecular physics, see [21.34].

21.7.4 Transition Probabilities

The most fundamental quantity for the probability of a transition from an initial state i to a final state f is the reduced matrix element related to the line strength by

$$S^{1/2} = \langle \Psi_i||O||\Psi_f\rangle, \qquad (21.79)$$

where O is the transition operator. In the case of the electric dipole transition, there are two frequently used forms: the length form $O = \sum_j \boldsymbol{r}_j$, and the velocity form, $O = \sum_j \nabla_j/E_{if}$, where $E_{if} = E_f - E_i$. For exact *non-relativistic* wave functions, the two forms are equivalent, but for approximate wave functions, the ma-

trix elements in general differ. Thus, the computation of the line strength and the oscillator strength, or f-value, where

$$f = (2/3)E_{if}S/[(2S_i+1)(2L_i+1)],$$

forms a critical test of the wave function in nonrelativistic theory and also the model describing a many-electron system. The same operators are often also used in Breit–Pauli calculations. In this case, the velocity form of the operator has neglected some terms of order $(\alpha Z)^2$ and the length value is preferred.

Some well-known discrepancies between theory and experiment existed for more than a decade for the resonance transitions of Li and Na. For the nonrelativistic 2s–2p transition in Li, a full-core CI [21.35] calculation produced f-values of $(0.747\,04, 0.747\,04, 0.753\,78)$ for the length-, velocity-, and acceleration form, respectively. When relativistic corrections were included, the value changed to $0.747\,15$, in agreement with a number of theories, tabulated to only four decimal places. A fast beam-laser experiment by *Gaupp* et al. [21.36], yielded a value of 0.7416 ± 0.0012 but this value was revised in 1996 by a beam-gas-laser experiment in perfect agreement with theory [21.37]. In the case of the resonance transition in Na, when theory included correlation in the core as well as core-polarization and some relativistic effects, results were in agreement with an almost simultaneous cascade of new experimental values [21.38].

For MCHF calculations of transition data, an important consideration is that the matrix element is between two different states. For independently optimized wave functions, the orbitals of the initial and final states are not orthonormal, as assumed when Racah algebra techniques are used to evaluate the transition matrix element. Through the use of biorthogonal transformations, the orbitals and the coefficients of expansion of the wave functions of the initial and final state can be transformed efficiently so that standard Racah algebra techniques may be applied [21.39]. Table 21.6 shows the convergence of an MCHF calculation for the ground state of Boron from independently optimized wave functions.

21.7.5 Electron Affinities

By definition, the electron affinity is $A_e = E(A^-) - E(A)$. Thus it is the energy difference between Hamiltonians differing by one electron. Correlation plays a very important role in the binding of the extra electron in the negative ion. It has been known for a long time that the alkali metals have a positive electron affinity, but

only recently has it been found, theoretically [21.40] and experimentally [21.41], that some of the alkaline earths may also be able to bind an extra electron. The d-electrons need to play a strong role, so Be and Mg, do not have a positive A_e, but according to the most recent experimental measurement, the electron affinity for Ca is 18 meV [21.42]. A calculation based on the spline methods and using a model potential with adjustable parameters to describe the core, obtained a value of 17.7 meV [21.43] in close agreement with experiment.

Atomic systems such as Ca are often thought of as two-electron systems and indeed, for qualitative descriptions, many observations can be explained. A number of physical effects need to be considered when predicting such electron affinities:

(i) Valence correlation is crucial for obtaining binding.

(ii) Intershell correlation between the valence electrons and the core (core polarization) is also important. The first electron may polarize the core considerably, but this is reduced by the second electron since the two avoid each other dynamically and prefer to be on opposite sides of the core.

(iii) Core rearrangement, which occurs because of the presence of one or more outer electrons, and is particularly large if any of these penetrate the core. In the case of Ca^+, the fixed-core Hartree–Fock energy of 3d ^{2}D state is 300 meV higher if computed in the fixed potential the Ca^{+2} ion compared with a fully variational calculation!

(iv) Intracore exclusion effects due to the presence of an

^{a} [21.44]

extra valence electron which reduces the correlation of the core.

(v) Relativistic shift effects, which are present in observed levels and are particularly important for s-electrons.

Model potential methods attempt to capture all but valence correlation in a potential so that calculations for Calcium, for example, can proceed as though for a two-electron system. A review of various theoretical approaches, many of which include different effects, may be found in [21.45].

For small systems such as Li, the electron affinity has been computed [21.46] to experimental accuracy [21.47] of (0.6176 ± 0.0002) eV. In neutral oxygen, it has been found that there is an isotope effect on the electron affinity [21.48].

21.8 Summary

More comprehensive treatments of atomic structure may be found [21.49, 50]. An atomic structure package is available for many of the calculations described here [21.51]. A review of the application of systematic procedures to the prediction of atomic properties has been published [21.52, 53].

22. Relativistic Atomic Structure

Relativistic quantum mechanics is required for the description of atoms and molecules whenever their orbital electrons probe regions of space with high potential energy near the atomic nuclei. Primary effects of a relativistic description include changes to spatial and momentum distributions; spin–orbit interactions; quantum electrodynamic corrections such as the Lamb shift; and vacuum polarization. Secondary effects in many–electron systems arise from shielding of the outer electrons by the distributions of electrons in penetrating orbitals; they change orbital binding energies and dimensions and so modify the order in which atomic shells are filled in the lower rows of the Periodic Table.

Relativistic atomic and molecular structure theory can be regarded as a simplification of the fundamental description provided by quantum electrodynamics (QED). This treats the atom or molecule as an assembly of electrons and atomic nuclei interacting primarily by exchanging photons. This model is far too difficult and general for most purposes, and simplifications are required. The most important of these is the representation of the nuclei as classical charge distributions, or even as point particles. Since the motion of the nuclei is usually slow relative to the electrons, it is often adequate to treat the nuclear motion nonrelativistically, or even to start from nuclei in fixed positions, correcting subsequently for nuclear motion.

The emphasis in this chapter is on relativistic methods for the calculation of atomic structure for general many–electron atoms based on an effective Hamiltonian derived from QED in the manner sketched in Sect. 22.2 below. An understanding of the Dirac equation, its solutions and their numerical approximation, is essential material for studying many–electron systems, just as the corresponding properties of the Schrödinger equation underpin Chapt. 21. We shall use atomic units throughout. Where it aids interpretation we shall, however, insert factors of c, m_e and $\hbar$. In these units, the velocity of

light, c, has the numerical value $\alpha^{-1} = 137.035\,999\,11(46)$, where α is the fine structure constant.

Part B | 22

22.1 Mathematical Preliminaries

22.1.1 Relativistic Notation: Minkowski Space–Time

An *event* in Minkowski space-time is defined by a 4-vector $x = \{x^\mu\}$ ($\mu = 0, 1, 2, 3$) where $x^0 = ct$ is the time coordinate and x^1, x^2, x^3 are Cartesian coordinates in 3-space. The bilinear form (The Einstein suffix convention, in which repeated pairs of Greek subscripts are assumed to be summed over all values 0, 1, 2, 3, will be used where necessary in this chapter.)

$$(x, y) = x^\mu g_{\mu\nu} y^\nu , \tag{22.1}$$

in which

$$g = (g_{\mu\nu}) = (g^{\mu\nu}) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} \tag{22.2}$$

are called *metric coefficients*, defines the metric of Minkowski space.

22.1.2 Lorentz Transformations

Lorentz transformations are defined as linear mappings Λ such that

$$(\Lambda x, \Lambda y) = (x, y) \tag{22.3}$$

so that

$$g_{\mu\nu} = \Lambda^\rho{}_\mu \, g_{\rho\sigma} \, \Lambda^\sigma{}_\nu . \tag{22.4}$$

This furnishes 10 equations connecting the 16 components of Λ; at most 6 components can be regarded as independent parameters. The (infinite) set of Λ matrices forms a regular matrix group (with respect to matrix multiplication) called the Lorentz group, $\mathcal{L}$, designated O(3,1) [22.1, 2].

22.1.3 Classification of Lorentz Transformations

Rotations

Lorentz transformations with matrices of the form

$$\Lambda = \begin{pmatrix} 1 & \mathbf{0}^\top \\ \mathbf{0} & \boldsymbol{R} \end{pmatrix} , \tag{22.5}$$

where $\boldsymbol{R} \in$ SO(3) is an orthogonal 3×3 matrix with determinant $+1$, and $\mathbf{0}$ is a null three dimensional column vector, correspond to three-dimensional space rotations. They form a group isomorphic to SO(3).

Boosts

Lorentz transformations with matrices of the form

$$\Lambda = \begin{pmatrix} \gamma(v) & \gamma(v)\boldsymbol{v}^\top \\ \gamma(v)\boldsymbol{v} & \boldsymbol{I}_3 + (\gamma(v) - 1)\boldsymbol{n}\boldsymbol{n}^\top \end{pmatrix} , \tag{22.6}$$

with $\boldsymbol{v} = v\boldsymbol{n}$ a three dimensional column vector, $|\boldsymbol{n}| = 1$, $v = |\boldsymbol{v}|$ and $\gamma(v) = (1 - v^2/c^2)^{-1/2}$, are called *boosts*. The matrix Λ describes an 'active' transformation from an inertial frame in which a free classical particle is at rest to another inertial frame in which its velocity is $\boldsymbol{v}$.

Boosts form a submanifold of $\mathcal{L}$ though they do not in general form a subgroup. However, the set of boosts in a fixed direction $\boldsymbol{n}$ form a one-parameter subgroup.

Discrete Transformations

The matrices

$$P = \begin{pmatrix} 1 & \mathbf{0}^\top \\ \mathbf{0} & -\boldsymbol{I}_3 \end{pmatrix}, \ T = \begin{pmatrix} -1 & \mathbf{0}^\top \\ \mathbf{0} & \boldsymbol{I}_3 \end{pmatrix} \text{ with } PT = -\boldsymbol{I}_4 \tag{22.7}$$

are called discrete Lorentz transformations and form a subgroup of the Lorentz group along with the iden-

tity I_4. The matrix P performs *space* or *parity inversion*; the matrix T performs *time reversal*.

Infinitesimal Lorentz Transformations

The proper Lorentz transformations close to the identity are of particular importance: they have the form

$$\Lambda^\mu_\nu = \delta^\mu_\nu + \epsilon \omega^\mu_\nu + \cdots ,$$
$$(\Lambda^{-1})^\mu_\nu = \delta^\mu_\nu - \epsilon \omega^\mu_\nu + \cdots , \tag{22.8}$$

where

$$\omega_{\mu\nu} = -\omega_{\nu\mu}$$

and ϵ is infinitesimal. The *infinitesimal generators*, components $\omega_{\mu\nu}$, can be treated as quantum mechanical observables: see Sect. 22.2.1.

The Lorentz Group

The Lorentz group $\mathcal{L}$ is a Lie group with a six-dimensional group manifold which has four connected components, namely

$$\mathcal{L}^\uparrow_+ \equiv \left\{ \Lambda \in \mathcal{L} \,|\, \Lambda^0{}_0 \geq 1, \det\Lambda = +1 \right\} , \tag{22.9}$$

$$\mathcal{L}^\uparrow_- \equiv \left\{ \Lambda \in \mathcal{L} \,|\, \Lambda^0{}_0 \geq 1, \det\Lambda = -1 \right\} = P\mathcal{L}^\uparrow_+ , \tag{22.10}$$

$$\mathcal{L}^\downarrow_+ \equiv \left\{ \Lambda \in \mathcal{L} \,|\, \Lambda^0{}_0 \leq 1, \det\Lambda = -1 \right\} = T\mathcal{L}^\uparrow_+ , \tag{22.11}$$

$$\mathcal{L}^\downarrow_+ \equiv \left\{ \Lambda \in \mathcal{L} \,|\, \Lambda^0{}_0 \leq 1, \det\Lambda = +1 \right\} = PT\mathcal{L}^\uparrow_+ . \tag{22.12}$$

The connected component $\mathcal{L}^\uparrow_+$ containing the identity is a Lie subgroup of $\mathcal{L}$ called the *proper Lorentz group*. All its group elements can be obtained from boosts and rotations. It is not simply connected because the subgroup of rotations is not simply connected. The group is also noncompact as the subset of boosts is homeomorphic to $\mathcal{R}^3$.

These topological properties of $\mathcal{L}^\uparrow_+$ are essential for understanding the properties of relativistic wave equations. In particular the multiple connectedness forces the introduction of spinor representations, and to the appearance of half-integer angular momenta or spin.

22.1.4 Contravariant and Covariant Vectors

Contravariant 4-vectors (such as events x) transform according to the rule

$$a^\mu \mapsto a^{\mu\prime} = \Lambda^\mu{}_\nu a^\nu . \tag{22.13}$$

Covariant 4-vectors can be formed by writing

$$a_\mu = g_{\mu\nu} a^\nu , \tag{22.14}$$

so that

$$a^\mu a_\mu = a^\mu g_{\mu\nu} a^\nu = (a, a) \tag{22.15}$$

is invariant with respect to Lorentz transformations. Similarly, we can construct a contravariant 4-vector from a covariant one by writing

$$a^\mu = g^{\mu\nu} a_\nu . \tag{22.16}$$

The transformation law for covariant vectors is therefore

$$a_\mu \mapsto a'_\mu = [\Lambda^{-1}]^\nu{}_\mu a_\nu . \tag{22.17}$$

The most important example of a covariant vector is the 4-momentum operator

$$p_\mu = \mathrm{i}\frac{\partial}{\partial x^\nu} \quad \mu = 0, 1, 2, 3 . \tag{22.18}$$

From this we derive the *contravariant* 4-momentum operator with components p^μ by writing

$$p^\mu = g^{\mu\nu} p_\nu$$
$$= \left(\mathrm{i}\frac{\partial}{\partial x^0}, -\mathrm{i}\frac{\partial}{\partial x^1}, -\mathrm{i}\frac{\partial}{\partial x^2}, -\mathrm{i}\frac{\partial}{\partial x^3} \right) , \tag{22.19}$$

in agreement with nonrelativistic expressions.

22.1.5 Poincaré Transformations

More generally, a Poincaré transformation is obtained by combining Lorentz transformations and space-time translations:

$$\Pi(x) = \Lambda x + a . \tag{22.20}$$

The set of all Poincaré transformations, $\Pi = (a, \Lambda)$, with the composition law

$$(a_1, \Lambda_1)(a_2, \Lambda_2) = (a_1 + \Lambda_1 a_2, \Lambda_1 \Lambda_2) , \tag{22.21}$$

also forms a group, $\mathcal{P}$.

Properties of the Lorentz and Poincaré groups will be introduced as needed. For a concise account of their properties see [22.3]. For more detail on relativistic quantum mechanics in general see textbooks such as [22.3, 4].

22.2 Dirac's Equation

We present Dirac's equation for an electron in a classical electromagnetic field defined by the 4-potential $A_\mu(x)$:

Covariant Form

$$\left\{ \gamma^\mu \left[p_\mu - eA_\mu(x) \right] - m_e c \right\} \psi(x) = 0 . \qquad (22.22)$$

where

$\gamma^\mu (\mu = 0, 1, 2, 3)$, are 4×4 matrices.

$\psi(x)$ is a 4-component spinor wave function.

Here, and elsewhere in this chapter, identity matrices are omitted when it is safe to do so.

Dirac Gamma Matrices

- Anticommutation relations:

$$\gamma^\mu \gamma^\nu + \gamma^\nu \gamma^\mu = 2g^{\mu\nu} .$$

- Standard representation:

$$\gamma^0 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

$$\gamma^i = \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix} \quad i = 1, 2, 3 ,$$

where $\sigma_i (i = 1, 2, 3)$ are Pauli matrices [22.1–4].

Noncovariant Form

In the majority of atomic structure calculations, a frame of reference is chosen in which the nuclear center is taken to be fixed at the origin. In this case it is convenient to write Dirac's equation in noncovariant form. Then functions of

$$x = (x^0, \boldsymbol{x}) ,$$

where $x^0 = ct$, can be regarded as functions of the time t and the position 3-vector $\boldsymbol{x}$, so that (22.22) is replaced by

$$i \frac{\partial}{\partial t} \psi(\boldsymbol{x}, t) = \hat{\boldsymbol{h}}_D \psi(\boldsymbol{x}, t) \qquad (22.23)$$

where the scalar and 3-vector potentials are defined by

$$\phi(\boldsymbol{x}, t) = cA^0(x) ,$$
$$A(\boldsymbol{x}, t) = \left[A^1(x), A^2(x), A^3(x) \right] , \qquad (22.24)$$

and

$$\hat{\boldsymbol{h}}_D = \left\{ c\boldsymbol{\alpha} \cdot \left[\boldsymbol{p} - eA(\boldsymbol{x}, t) \right] + e\phi(\boldsymbol{x}, t) + \beta m_e c^2 \right\} \qquad (22.25)$$

defines the Dirac Hamiltonian. The matrices $\boldsymbol{\alpha}$, with Cartesian components $(\alpha^1, \alpha^2, \alpha^3)$, and β, have the standard representation

$$\beta = \gamma^0 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \qquad (22.26)$$

$$\alpha^i = \gamma^0 \gamma^i = \begin{pmatrix} 0 & \sigma^i \\ \sigma^i & 0 \end{pmatrix} \quad i = 1, 2, 3 . \qquad (22.27)$$

22.2.1 Characterization of Dirac States

The solutions of Dirac's equation span representations of the Lorentz and Poincaré groups, whose infinitesimal generators can be identified with physical observables. The Lorentz group algebra has 10 independent self-adjoint infinitesimal generators: these can be taken to be the components p^μ of the four-momentum (which generate displacements in each of the four coordinate directions); the three generators, J_i, of rotations about each coordinate axis in space; and the pseudovector w_μ. The irreducible representations can be characterized by invariants

$$(p, p) = m_e^2 c^2 , \qquad (22.28)$$

$$(w, w) = -m_e^2 c^2 s^2 = -\frac{3}{4} m_e^2 c^2 , \qquad (22.29)$$

where p is the momentum four-vector and s is a 3-vector defined in terms of Pauli matrices by

$$s_i = \frac{1}{2} \sigma_i , \quad i = 1, 2, 3 .$$

which can be interpreted as the electronic angular momentum (intrinsic spin) in its rest frame. For more detail see [22.3] and the original papers [22.5, 6].

22.2.2 The Charge–Current 4-Vector

Dirac's equation (22.22) is covariant with respect to Lorentz (22.3) and Poincaré (22.20) transformations, provided that there exists a nonsingular 4×4 matrix $S(\Lambda)$

with the property

$$\psi'(x) = S(\Lambda)\psi\left[\Lambda^{-1}(x-a)\right] . \qquad (22.30)$$

The matrices $S(\Lambda)$ are characterized by the equation

$$S^{-1}(\Lambda)\gamma^\lambda S(\Lambda) = \Lambda^\lambda{}_\mu \gamma^\mu . \qquad (22.31)$$

The most important observable expression required in this chapter is the *charge–current four-vector*

$$j^\mu = ec\overline{\psi}(x)\gamma^\mu\psi(x) , \qquad (22.32)$$

where the Dirac adjoint is defined by

$$\overline{\psi}(x) = \psi^\dagger(x)\gamma^0 , \qquad (22.33)$$

and the dagger denotes spinor conjugation and transposition. Since

$$\begin{aligned}
\overline{\psi}'(x) &= \overline{\psi}\left[\Lambda^{-1}(x-a)\right]\gamma^0 S(\Lambda)^\dagger \gamma^0 \\
&= \overline{\psi}\left[\Lambda^{-1}(x-a)\right]S^{-1}(\Lambda) ,
\end{aligned}$$

$j^\mu(x)$ transforms as a 4-vector

$$j^{\mu'}(x) = \Lambda^\mu{}_\nu j^\nu(x)$$

by virtue of (22.31). The component $j^0(x)$ can be interpreted as a multiple of the *charge density* $\rho(x)$,

$$j^0(x) = ec\rho(x) = ec\overline{\psi}(x)\gamma^0\psi(x) = ec\psi^\dagger(x)\psi(x) \qquad (22.34)$$

and the space-like components as the *current density*

$$j^i(x) = ec\overline{\psi}(x)\gamma^i\psi(x) = ec\psi^\dagger(x)\alpha^i\psi(x) . \quad (22.35)$$

The charge–current density satisfies a continuity equation, which in noncovariant form reads

$$\frac{\partial\rho(x)}{\partial t} + \sum_{i=1}^{3}\frac{\partial j^i(x)}{\partial x^i} = 0 ,$$

or, in covariant notation,

$$\partial_\mu j^\mu = 0 . \qquad (22.36)$$

This is readily proved by using the Dirac equation (22.22) and its Dirac adjoint. Equation (22.36) is clearly invariant under Poincaré transformations, and this yields the important property that *electric charge* is conserved in Dirac theory.

22.3 QED: Relativistic Atomic and Molecular Structure

22.3.1 The QED Equations of Motion

The conventional starting point [22.7–10] for deriving equations of motion in quantum electrodynamics (QED) is a Lagrangian density of the form

$$\mathcal{L}(x) = \mathcal{L}_{\text{em}}(x) + \mathcal{L}_{\text{e}}(x) + \mathcal{L}_{\text{int}}(x) . \qquad (22.37)$$

The first term is the Lagrangian density for the free electromagnetic field, $F^{\mu\nu}(x)$,

$$\mathcal{L}_{\text{em}}(x) = -\frac{1}{4}F^{\mu\nu}F_{\mu\nu} , \qquad (22.38)$$

the second term is the Lagrangian density for the electron–positron field in the presence of the external potential $A_{\text{ext}}^\mu(x)$,

$$\mathcal{L}_{\text{e}}(x) = \bar{\psi}(x)\left\{\gamma_\mu\left[p^\mu - eA_{\text{ext}}^\mu(x)\right] - m_{\text{e}}c\right\}\psi(x) . \qquad (22.39)$$

We assume that the electromagnetic fields are expressible in terms of the four-potentials by

$$F^{\mu\nu} = \partial^\mu A_{\text{tot}}^\nu - \partial^\nu A_{\text{tot}}^\mu ,$$

where

$$A_{\text{tot}}^\mu(x) = A_{\text{ext}}^\mu(x) + A^\mu(x)$$

is the sum of a four-potential $A_{\text{ext}}^\mu(x)$ describing the fields generated by classical external charge–current distributions, and a quantized field $A^\mu(x)$ which through

$$\mathcal{L}_{\text{int}}(x) = -j_\mu(x)A^\mu(x) , \qquad (22.40)$$

accounts for the interaction between the uncoupled electrons and the radiation field. The field equations deduced from (22.37) are

$$\begin{aligned}
\left\{\gamma_\mu\left[p^\mu - A_{\text{ext}}^\mu(x)\right] - m_{\text{e}}c\right\}\psi(x) &= \gamma_\mu(x)\psi(x)A^\mu(x) \\
\partial_\mu F^{\mu\nu}(x) &= j^\nu(x) , \qquad (22.41)
\end{aligned}$$

and clearly exhibit the coupling between the fields.

Quantum electrodynamics requires the solution of the system (22.41) when $A^\mu(x)$, $\psi(x)$ and its adjoint $\bar{\psi}(x)$ are quantized fields. This formulation is purely formal: it ignores all questions of zero-point energies, normal ordering of operators, choice of gauge associated with the quantized photon field, or the need to include (infinite) counterterms to render the theory finite.

22.3.2 The Quantized Electron–Positron Field

Furry's bound interaction picture of QED [22.7, 11] exploits the fact that a one-electron model is often a good

starting point for a more accurate calculation of atomic or molecular properties. The electrons are described by a field operator

$$\psi(x) = \sum_{E_m > E_F} a_m \psi_m(x) + \sum_{E_n < E_F} b_n^\dagger \psi_n(x) ,$$

(22.42)

where $E_F \geq -mc^2$ is a "Fermi level" separating the states describing electrons (bound and continuum) from the positron states (lower continuum) in the chosen time-independent model potential $V(\boldsymbol{r})$. Equation (22.42) is written as if the spectrum were entirely discrete, as in finite matrix models; more generally, this must be replaced by integrals over the continuum states together with a sum over the bound states. We assume that the amplitudes $\psi_m(x)$ are orthonormalized (which can be achieved, for example, by enclosing the system in a finite box). The operators a_m and $a_m^\dagger$ respectively annihilate and create electrons, and b_n and $b_n^\dagger$ perform the same role for vacancies in the "negative energy" states, which we interpret as antiparticles (positrons). These operators satisfy the *anticommutation* rules (see Sect. 6.1.1)

$$\left[a_m, a_{m'}^\dagger\right] = \delta_{m,m'} ,$$
$$\left[b_n, b_{n'}^\dagger\right] = \delta_{n,n'} ,$$

(22.43)

where $[a, b] = ab + ba$. All other anticommutators vanish. The operator representing the number of electrons in state m is then

$$N_m = a_m^\dagger a_m ,$$

(22.44)

having the eigenvalues 0 or 1; the states of a system of noninteracting electrons and positrons can therefore be labeled by listing the occupation numbers, 0 or 1 of the one-electron states participating.

We define the *vacuum state* as the (reference) state $|0\rangle$ in which $N_m = N_n = 0$ for all m, n, so that

$$a_m|0\rangle = b_n|0\rangle = 0 .$$

(22.45)

The operator representing the total number of particles is given by

$$N = \int \psi^\dagger(x)\psi(x)\, dx = \sum_{E_m > E_F} N_m + \sum_{E_n < E_F} (1 - N_n) .$$

This is not quite satisfactory: $N = \sum_{E_n < E_F} 1$ is infinite for the vacuum state, as are the total charge and energy of the vacuum.

These infinite "zero-point" values can be eliminated by introducing *normal ordered operators*. A product of

annihilation and creation operators is in normal order if it is rearranged so that all annihilation operators are to the right of all creation operators. Such a product has a null value in the vacuum state. In performing the rearrangement, each anticommutator is treated as if it were zero. We denote normal ordering by placing the operators between colons. Thus $: a_m^\dagger a_m : = a_m^\dagger a_m$ whilst $: b_n b_n^\dagger : = -b_n^\dagger b_n$. This means that if we *redefine* N by

$$N = \int : \psi^\dagger(x)\psi(x) : dx = \sum_{E_m > E_F} N_m - \sum_{E_n < E_F} N_n ,$$

(22.46)

then $\langle 0|N|0\rangle = 0$. The same trick eliminates the infinity from the total energy of the vacuum;

$$H_0 = \int : \psi^\dagger(x)\hat{\boldsymbol{h}}_D \psi(x) : dx$$
$$= \sum_{E_m > E_F} N_m E_m - \sum_{E_n < E_F} N_n E_n ,$$

(22.47)

so that $\langle 0|H_0|0\rangle = 0$.

The current density operator is given by the commutator of two field variables

$$j^\mu(x) = -\frac{1}{2} ec \left[\bar{\psi}(x)\gamma^\mu, \psi(x) \right] ,$$

(22.48)

where the Dirac adjoint, $\bar{\psi}(x)$ is defined by (22.33). The definition (22.48) differs from (22.32) by expressing the total current as the difference between the electron (negatively charged) and positron (positively charged) currents. We can write

$$j^\mu(x) =: j^\mu(x) : + ec \, \text{Tr} \left[\gamma^\mu S_F(x, x) \right] ,$$

(22.49)

where $S_F(x, y)$ is the Feynman causal propagator, defined below. Since $\langle 0| : j^\mu(x) : |0\rangle = 0$, the last term in (22.49) is the *vacuum polarization current* due to the asymmetry between positive and negative energy states induced by the external field. From this, the net charge of the system is

$$Q = \frac{1}{c} \int j^0(x)\, d^3x$$

(22.50)

$$= -e \left(\sum_{E_m > E_F} N_m - \sum_{E_n < E_F} N_n \right) + Q_{\text{vac}} .$$

Q_{vac} is the total charge of the vacuum, which vanishes for free electrons, but is finite in the presence of an external field (the phenomenon of *vacuum polarization*). Note that whilst Q is conserved for all processes, the total number of particles need not be; it is always possible to

add virtual states incorporating electron–positron pairs without changing Q.

22.3.3 Quantized Electromagnetic Field

The four-potential of the quantized electromagnetic field can be expressed in terms of a spectral expansion over the field modes in, for example, plane waves

$$
A_\mu(x) = \int \frac{\mathrm{d}^3 k}{2(2\pi)^3 k_0} \sum_{\lambda=0}^{3} \Big[q^{(\lambda)}(k)\epsilon_\mu^{(\lambda)}(k)\,\mathrm{e}^{-\mathrm{i}k\cdot x}
$$
$$
+ q^{(\lambda)\dagger}(k)\epsilon_\mu^{(\lambda)*}(k)\,\mathrm{e}^{\mathrm{i}k\cdot x} \Big] . \tag{22.51}
$$

The vectors $\epsilon_\mu^{(\lambda)}(k)$ describe the polarization modes; there are four linearly independent vectors, which may be assumed real, for each k on the positive light cone. Two of these ($\lambda = 1, 2$) can be chosen perpendicular to the photon momentum $\boldsymbol{k}$ (*transverse polarization*); one component ($\lambda = 3$) along $\boldsymbol{k}$ (*longitudinal polarization*); and the final component ($\lambda = 0$) is time-like (*scalar polarization*). The operators $q^{(\lambda)}(k)$ and $q^{(\lambda)\dagger}(k)$ describe respectively photon absorption and emission. They satisfy commutation relations

$$
\left[q^{(\lambda)}(k), q^{(\lambda')\dagger}(k') \right] = \delta_{\lambda,\lambda'}\delta_{k,k'}, \ \lambda, \lambda' = 1, 2, 3
$$
$$
\left[q^{(0)}(k), q^{(0)\dagger}(k') \right] = -\delta_{k,k'} ; \tag{22.52}
$$

all other commutators vanish. The photon vacuum state, $|0\rangle_\gamma$, is such that

$$
q^{(\lambda)}(k)|0\rangle_\gamma = 0 . \tag{22.53}
$$

Further details may be found in the texts [22.7–10].

22.3.4 QED Perturbation Theory

The textbook perturbation theory of QED, see for example [22.7, 8, 10, 12] and other works, has been adapted for applications to relativistic atomic and molecular structure and is also the source of methods of nonrelativistic many-body perturbation theory (MBPT). We offer a brief sketch emphasizing details not found in the standard texts.

The Perturbation Expansion
The Lagrangian approach leads to an interaction Hamiltonian

$$
H_\mathrm{I} = - \int j^\mu(x) A_\mu(x) \, \mathrm{d}\boldsymbol{x} . \tag{22.54}
$$

In the interaction representation, this gives an equation of motion

$$
\mathrm{i}\hbar\partial_t|\Phi(t)\rangle = H_\mathrm{I}(t)|\Phi(t)\rangle , \tag{22.55}
$$

where $|\Phi(t)\rangle$ is the QED state vector, and

$$
H_\mathrm{I}(t) = \exp(\mathrm{i}H_0 t/\hbar)\, H_\mathrm{I} \exp(-\mathrm{i}H_0 t/\hbar) ,
$$

where $H_0 = H_\mathrm{em} + H_\mathrm{e}$ is the Hamiltonian for the uncoupled photon and electron–positron fields. If $S(t, t')$ is the *time development* operator such that

$$
|\Phi(t)\rangle = S(t, t')|\Phi(t')\rangle ,
$$

then

$$
\mathrm{i}\hbar\partial_t S(t, t') = H_\mathrm{I}(t) S(t, t') .
$$

The equivalent integral equation, incorporating the initial condition $S(t, t) = 1$,

$$
S(t, t_0) = 1 - \frac{\mathrm{i}}{\hbar} \int_{t_0}^{t} H_\mathrm{I}(t_1) S(t_1, t_0)\, \mathrm{d}_1 t , \tag{22.56}
$$

can be solved iteratively, giving

$$
S(t, t_0) = 1 + \sum_{n=1}^{\infty} S^{(n)}(t, t_0) , \tag{22.57}
$$

where

$$
S^{(n)}(t, t_0) = (-\mathrm{i}/\hbar)^n \int_{t_0}^{t} \mathrm{d}t_1 \int_{t_0}^{t_1} \mathrm{d}t_2 \cdots \int_{t_0}^{t_{n-1}} \mathrm{d}t_n
$$
$$
\times H_\mathrm{I}(t_1) H_\mathrm{I}(t_2) \cdots H_\mathrm{I}(t_n) .
$$

This can be put into a more symmetric form by using *time-ordered* operators. Define the T-product of two operators by

$$
T\left[A(t_1) B(t_2) \right] = \begin{cases} A(t_1) B(t_2) , & t_1 > t_2 \\ \pm B(t_2) A(t_1) , & t_2 > t_1 \end{cases} \tag{22.58}
$$

where the *positive* sign refers to the product of photon operators and the *negative* sign to electrons. Then

$$
S^{(n)}(t, t_0) = \frac{(-\mathrm{i}/\hbar)^n}{n!} \int_{t_0}^{t} \mathrm{d}t_1 \int_{t_0}^{t} \mathrm{d}t_2 \cdots \int_{t_0}^{t} \mathrm{d}t_n
$$
$$
\times T\left[H_\mathrm{I}(t_1) H_\mathrm{I}(t_2) \cdots H_\mathrm{I}(t_n) \right] . \tag{22.59}
$$

The operator $S(t, t')$ relates the state vector at time t to the state vector at some earlier time $t' < t$. Its ma-

trix elements therefore give the transition amplitudes for different processes, for example the emission or absorption of radiation by a system, or the outcome of scattering of a projectile from a target. The techniques for extracting cross-sections and other observable quantities from the *S*-operator are described at length in the texts [22.7, 8, 10, 12].

Although the use of normal ordering means that the charge and mass of the reference state, the vacuum, is zero, it fails to remove other infinities due to the occurrence of divergent integrals. The method of extracting finite quantities from this theory involves *renormalization* of the charge and mass of the electron. We shall refer especially to [22.10, Chapt. 8] for a detailed discussion. The most difficult technical problems are posed by *mass renormalization*. Formally, we modify the interaction Hamiltonian to read

$$j^{\mu}(x)A_{\mu}(x) - \delta M(x) \, ,$$

where $\delta M(x)$ is the *mass renormalization operator*

$$\delta M(x) = \frac{1}{2}\delta m\big[\bar{\psi}(x), \psi(x)\big]$$

where δm is infinite.

A further problem is that electrons in a many-electron atom or molecule move in a potential which is quite unlike that of the bare nucleus. It is therefore useful to introduce a local *mean field* potential, say $U(x)$, representing some sort of average interaction with the rest of the electron charge distribution, so that the zero-order orbitals satisfy

$$\Big[c\boldsymbol{\alpha}\cdot\boldsymbol{p} + \beta c^2 + V_{\text{nuc}}(\boldsymbol{x}) + U(\boldsymbol{x}) - E_m\Big]\psi_m(\boldsymbol{x}) = 0 \, . \tag{22.60}$$

With this starting point, the interaction Hamiltonian becomes

$$H_{\text{I}}(x) = H_{\text{I}}^{(1)}(x) + H_{\text{I}}^{(2)}(x) \, , \tag{22.61}$$

where

$$H_{\text{I}}^{(1)}(x) = -U(x), \ \ H_{\text{I}}^{(2)}(x) = j^{\mu}(x)A_{\mu}(x) - \delta M(x) \, ,$$

and the electron current is defined in terms of the mean field orbitals of (22.60). The expression $H_{\text{I}}^{(2)}(x)$ is sometimes referred to as a *fluctuation potential*. The term $j^{\mu}(x)A_{\mu}(x)$ is proportional to the electron charge, e, which serves as an ordering parameter for perturbation expansions.

Effective Interactions

Although the S-matrix formalism provides in principle a complete computational scheme for many-electron systems, it is generally too cumbersome for practical use, and approximations are necessary. Usually, this is a matter of selecting a subset of dominant contributions to the perturbation series depending on the application. We are faced with the evaluation of *T*-products of the form

$$T\left[\phi(t_1)\phi(t_2)\cdots\phi(t_n)\right]$$

which is done using Wick's Theorem [22.10, p. 25].

In the simplest case,

$$T\left[\phi(t_1)\phi(t_2)\right] = \ : \phi(t_1)\phi(t_2) : \\ + \langle 0\,|\,T\left[\phi(t_1)\phi(t_2)\right]|\,0\rangle \, . \tag{22.62}$$

The vacuum expectation value is called a *contraction*. More generally, we have

$$T\left[\phi(t_1)\phi(t_2)\cdots\phi(t_n)\right] \\ = \ : \phi(t_1)\phi(t_2)\cdots\phi(t_n) : \\ + \Big\{\langle 0|T[\phi(t_1)\phi(t_2)]|0\rangle : \phi(t_3)\cdots\phi(t_n) : \\ + \text{permutations}\Big\} \\ + \Big\{\langle 0|T[\phi(t_1)\phi(t_2)]|0\rangle\langle 0|T[\phi(t_3)\phi(t_4)]|0\rangle \\ \times : \phi(t_5)\cdots\phi(t_n) : + \text{permutations}\Big\}\cdots .$$

This result has the effect that a *T*-product with an odd number of factors vanishes. A rigorous statement can be found in all standard texts; each term in the expansion gives rise to a Feynman diagram which can be interpreted as the amplitude of a physical process. As an example, consider the simple but important case

$$S^{(2)} = \frac{(\text{i}e)^2}{2!}T\left[j^{\mu}(x)A_{\mu}(x).j^{\nu}(y)A_{\nu}(y)\right] . \tag{22.63}$$

One of the terms (there are others) found by using Wick's Theorem is

$$j^{\mu}(x)j^{\nu}(y)\langle 0|T\left[A_{\mu}(x)A_{\nu}(y)\right]|0\rangle \, .$$

We see that this involves the contraction of two photon amplitudes

$$-\frac{1}{2}D_{F\mu\nu}(x-y) = \langle 0\,|\,T\left[A_{\mu}(x)A_{\nu}(y)\right]|\,0\rangle \, ,$$

which plays the role of a *propagator* (22.69): it relates the photon amplitudes at two space-time points x, y.

With the introduction of a spectral expansion for the electron current (22.48), the contribution to the energy of the system becomes

$$\frac{1}{2} \sum_{pqrs} : a_p^\dagger a_q^\dagger a_s a_r : \langle pq|V|rs \rangle , \tag{22.64}$$

which can be interpreted, in the familiar language of ordinary quantum mechanics, as the energy of two electrons due to the electron–electron interaction V which is directly related to the photon propagator.

22.3.5 Propagators

Propagators relate field variables at different space-time points. Here we briefly define those most often needed in atomic and molecular physics.

Electrons
Define Feynman's causal propagator for the electron–positron field by the contraction

$$S_F(x_2, x_1) = \langle 0|T[\psi(x_2)\bar\psi(x_1)]|0 \rangle . \tag{22.65}$$

This has a spectral decomposition of the form

$$S_F(x_2, x_1) = \begin{cases} \sum_{E_m > E_F} \psi_m(x_2)\bar\psi_m(x_1) & t_1 > t_2 , \\ -\sum_{E_n < E_F} \psi_n(x_2)\bar\psi_n(x_1) & t_1 < t_2 , \end{cases} \tag{22.66}$$

which ensures that positive energy solutions are propagated forwards in time, and negative energy solutions backwards in time in accordance with the antiparticle interpretation of the negative energy states. By noting that the stationary state solutions $\psi_m(x)$ have time dependence $\exp(-iE_m t)$, we can write (22.66) in the form

$$S_F(x_2, x_1) = \frac{1}{2\pi i} \int_{-\infty}^{\infty} \sum_n \frac{\psi_n(x_2)\bar\psi_n(x_1)}{E_n - z(1 + i\delta)} e^{-iz(t_2 - t_1)} \, dz$$
$$= \frac{1}{2\pi i} \int_{-\infty}^{\infty} G(x_2, x_1, z)\gamma^0 e^{-iz(t_2 - t_1)} \, dz , \tag{22.67}$$

where δ is a small positive number, the sum over n includes *the whole spectrum*, and where the Green's function $G(x_2, x_1, z)$, in the specific case in which the

potential of the external field $a^\mu(x)$ has only a scalar time-independent part, $V_{nuc}(x)$, satisfies

$$\left[c\boldsymbol{\alpha} \cdot \boldsymbol{p} + \beta c^2 + (V_{nuc}\boldsymbol{x}) - z\right] G(\boldsymbol{x}, \boldsymbol{y}, z)$$
$$= \delta^{(3)}(\boldsymbol{x}_2 - \boldsymbol{x}_1) . \tag{22.68}$$

$G(\boldsymbol{x}_2, \boldsymbol{x}_1, z)$ is a meromorphic function of the complex variable z with branch points at $z = \pm c^2$, and cuts along the real axis (c^2, ∞) and $(-\infty, -c^2)$. The poles lie on the segment $(-c^2, c^2)$ at the bound eigenvalues of the Dirac Hamiltonian for this potential.

Photons
The photon propagator $D_{F\mu\nu}(x_2 - x_1)$ is constructed in a similar manner:

$$-\frac{1}{2} D_{F\mu\nu}(x_2 - x_1) = \langle 0 | T[A_\mu(x_2)A_\nu(x_1)] | 0 \rangle , \tag{22.69}$$

where μ_0 is the permeability of the vacuum. This has the integral representation

$$D_{F\mu\nu}(x_2 - x_1) = g_{\mu\nu} D_F(x_2 - x_1)$$
$$= -g_{\mu\nu} \frac{i}{(2\pi)^4} \int d^4q \, D(q^2) , \tag{22.70}$$

where

$$D(q^2) = \frac{1}{q^2 + i\delta} ,$$

and δ is a small positive number. This is not unique, as the four-potentials depend on the choice of gauge; for details see [22.8, Sect. 77]. The various forms for the electron–electron interaction given below express such gauge choices.

22.3.6 Effective Interaction of Electrons

The expression (22.63) can be viewed in several ways: it is the interaction of the current density $j^\mu(x)$ at the space-time point x with the four-potential due to the current $j^\mu(y)$; the interaction of the current density $j^\mu(y)$ with the four-potential due to the current $j^\mu(x)$; or, as is commonly assumed in nonrelativistic atomic theory, the effective interaction between two charge density distributions, as represented by (22.64). In terms of the corresponding Feynman diagram, it can be thought of as the energy due to the exchange of a virtual photon.

The form of V depends on the choice of gauge potential, as follows.

Feynman Gauge

$$\langle pq|V|rs \rangle$$
$$= \int \int \psi_p^\dagger(\boldsymbol{x}) \psi_r(\boldsymbol{x}) v_{sq}^F(\boldsymbol{x}, \boldsymbol{y}) \psi_q^\dagger(\boldsymbol{y}) \psi_s(\boldsymbol{y}) \, \mathrm{d}^3 x \, \mathrm{d}^3 y$$
$$(22.71)$$

where

$$v_{sq}^F(\boldsymbol{x}, \boldsymbol{y}) = \frac{\mathrm{e}^{\mathrm{i}\omega_{sq}R}}{R} (1 - \boldsymbol{\alpha}_x \cdot \boldsymbol{\alpha}_y) , \qquad (22.72)$$

with

$$\boldsymbol{R} = \boldsymbol{x} - \boldsymbol{y}, \quad R = |\boldsymbol{R}|, \quad \omega_{sq} = \frac{E_s - E_q}{c} .$$

This interaction gives both a real and an imaginary contribution to the energy; only the former is usually taken into account in structure calculations. Since the orbital indices are dummy variables, it is usual to symmetrize the interaction kernel by writing

$$\bar{v}^F(\boldsymbol{x}, \boldsymbol{y}) = \frac{1}{2} \left[v_{sq}^F(\boldsymbol{x}, \boldsymbol{y}) + v_{rp}^F(\boldsymbol{x}, \boldsymbol{y}) \right] ,$$

which places the orbitals on an equal footing.

Coulomb Gauge

Here the Feynman propagator is replaced by that for the Coulomb gauge, giving

$$v_{sq}^T(\boldsymbol{x}, \boldsymbol{y}) = \frac{\mathrm{e}^{\mathrm{i}\omega_{sq}R}}{R} - \left[\boldsymbol{\alpha}_x \cdot \boldsymbol{\alpha}_y \frac{\mathrm{e}^{\mathrm{i}\omega_{sq}R}}{R} \right.$$
$$\left. + (\boldsymbol{\alpha}_x \cdot \nabla)(\boldsymbol{\alpha}_y \cdot \nabla) \frac{\mathrm{e}^{\mathrm{i}\omega_{rp}R} - 1}{\omega_{rp}^2 R} \right] \quad (22.73)$$

in which the operator ∇ involves differentiation with respect to $\boldsymbol{R}$.

Symmetrization is also used with this interaction.

Breit Operator

The *low frequency limit*, $\omega_{rp} \to 0$, $\omega_{sq} \to 0$, is known as the Breit interaction:

$$\lim_{\omega_{rp}, \omega_{sq} \to 0} v_{sq}^T(\boldsymbol{x}, \boldsymbol{y}) = \frac{1}{R} + v^B(\boldsymbol{R}) , \qquad (22.74)$$

where

$$v^B(\boldsymbol{R}) = -\frac{1}{2R} \left(\boldsymbol{\alpha}_x \cdot \boldsymbol{\alpha}_y + \frac{\boldsymbol{\alpha}_x \cdot \boldsymbol{R} \, \boldsymbol{\alpha}_y \cdot \boldsymbol{R}}{R^2} \right) .$$

Gaunt Operator

This is a further approximation in which $v^B(\boldsymbol{R})$ is replaced by

$$v^G(\boldsymbol{R}) = -\frac{\boldsymbol{\alpha}_x \cdot \boldsymbol{\alpha}_y}{R} , \qquad (22.75)$$

the residual part of the Breit interaction being neglected.

Comments

The choice of gauge should not influence the predictions of QED for atomic and molecular structure when the perturbation series is summed to convergence, so that it should not matter if the unapproximated effective operators are taken in Feynman or Coulomb gauge. However, this need not be true at each order of perturbation. It has been shown that the results are equivalent, order by order, if the orbitals have been defined in a *local* potential, but not otherwise. There have also been suggestions that the Feynman operator introduces spurious terms in lower orders of perturbation that are canceled in higher orders [22.13]. For this reason, most structure calculations have used Coulomb gauge.

It is often argued, following *Bethe* and *Salpeter* [22.14, Sect. 38], that the Breit interaction should only be used in first order perturbation theory. The reason is the approximation $\omega \to 0$; however, this approximation is quite adequate for many applications in which the dominant interactions involve only small energy differences.

22.4 Many–Body Theory For Atoms

The relativistic theory of atomic structure can be viewed as a simplification of the QED approach using an effective Hamiltonian operator in which the Dirac electrons interact through the effective electron–electron interaction of Sect. 22.3.6. This approach retains the dominant terms from the perturbation solution; those that are omitted are small and can, with sufficient trouble, be taken into account perturbatively [22.10, 15]. In particular, radiative correction terms requiring renormalization are explicitly omitted, and their effects incorporated at a later stage. Once a model has been chosen, the techniques and methods used for practical calculations acquire a close resemblance to those of the nonrelativistic theory described, for example in Chapt. 21.

22.4.1 Effective Hamiltonians

The models which are closest to QED are those in which the full electron–electron interaction is included, usually in Coulomb gauge. We define a Fock space Hamiltonian

$$H_{DCB} = H_0 + H_1 + H_2 \qquad (22.76)$$

where, as in (22.47),

$$H_0 = \sum_{E_m > E_F} N_m E_m - \sum_{E_n < E_F} N_n E_n , \qquad (22.77)$$

in which the states are those determined with respect to a mean-field central potential $U(\boldsymbol{x})$ as in (22.60)

$$\left[c\boldsymbol{\alpha} \cdot \boldsymbol{p} + \beta c^2 + V_{nuc}(\boldsymbol{x}) + U(\boldsymbol{x}) - E_m\right]\psi_m(\boldsymbol{x}) = 0 ,$$

and

$$H_1 = -\sum_{pq} : a_p^\dagger a_q : \langle p|U(\boldsymbol{x})|q\rangle$$

$$H_2 = \frac{1}{2}\sum_{pqrs} : a_p^\dagger a_q^\dagger a_r a_s : \langle pq|V|sr\rangle .$$

Here the sums run only over states p with $E_p > E_F$; this means that states with $E_p < E_F$ are treated as inert.

The models are named according to the choice of V from Sect. 22.5.3.

Dirac–Coulomb–Breit Models
These incorporate the *full* Coulomb gauge operator (22.73) or the less accurate Breit operator (22.74). The fully retarded operator is usually taken in the symmetrized form. The Gaunt operator (22.75) is sometimes considered as an approximation to the Breit operator.

Dirac–Coulomb Models
The electron–electron interaction is simply taken to be the static $1/R$ potential. Note that although the equations are relativistic, the choices of electron–nucleus interaction all implicitly restrict these models to a frame in which the nuclei are fixed in space. The full electron–electron interaction is gauge invariant; however, it is common to start from the Dirac–Coulomb operator, in which case the gauge invariance is lost. Since radiative transition rates are sensitive to loss of gauge invariance [22.16] the choice of potential in (22.76) can make a big difference. Such choices may also affect the rate of convergence in correlation calculations in which the relativistic parts of the electron–electron interaction are treated as a second, independent, perturbation.

22.4.2 Nonrelativistic Limit: Breit–Pauli Hamiltonian

The nonrelativistic limit of the Dirac–Coulomb–Breit Hamiltonian is described in Chapt. 21. The derivation is given in many texts, for example [22.8, 10, 14], and in principle involves the following steps:

1. Express the relativistic 4-spinor in terms of nonrelativistic Pauli 2-spinors of the form (see Sect. 21.2)

$$\phi_{nlm_l,m_s}(\boldsymbol{x}) = \text{const.} \frac{P_{nl}(r)}{r} Y_{lm_l}(\theta, \phi) \chi_{m_s}(\sigma) ,$$

where χ_{m_s} is a 2-component eigenvector of the spin operator $\boldsymbol{s}$ to lowest order in $1/c$.
2. Extract effective operators to order $1/c^2$.

Thus the Breit–Pauli Hamiltonian is written as the sum of terms of Sect. 21.2 which can be correlated with specific parts of the parent relativistic operator:

1. One-body terms originate from the Dirac Hamiltonian: they are H_{mass} (21.5), the one-body part of H_{Darwin} (21.7) and the spin–orbit couplings H_{so} (21.11) and H_{soo} (21.12). The forms given in these equations assume that the electron interacts with a point-charge nucleus and only require the Coulomb part of the electron–electron interaction.
2. Two-body terms, including the two-body parts of H_{Darwin} (21.7), the spin–spin contact term H_{ssc} (21.8), the orbit–orbit term H_{oo} (21.9) and the spin–spin term H_{ss} (21.13) originate from the Breit interaction.

22.4.3 Perturbation Theory: Nondegenerate Case

We give a brief resumé of the Rayleigh–Schrödinger perturbation theory following *Lindgren* [22.17]. The material presented here supplements the general discussion of perturbation theory in Chapt. 5. First consider the simplest case with a nondegenerate reference state Φ belonging to the Hilbert space $\mathcal{H}$ satisfying

$$H_0|\Phi\rangle = E_0|\Phi\rangle , \qquad (22.78)$$

which is a first approximation to the solution of the full problem

$$H|\Psi\rangle = E|\Psi\rangle, \quad H = H_0 + V . \qquad (22.79)$$

Next, introduce a projection operator P such that

$$P = |\Phi\rangle\langle\Phi|, \quad P|\Phi\rangle = |\Phi\rangle ,$$

and its complement $Q = 1 - P$, projecting onto the complementary subspace $\mathcal{H} \setminus \{\Phi\}$. With the *intermediate normalization*

$$\langle \Phi | \Psi \rangle = \langle \Phi | \Phi \rangle = 1 \ ,$$

it follows that

$$P | \Psi \rangle = | \Phi \rangle \langle \Phi | \Psi \rangle = | \Phi \rangle \ ,$$

so that the perturbed wave function can be decomposed into two parts:

$$| \Psi \rangle = (P + Q) | \Psi \rangle = | \Phi \rangle + Q | \Psi \rangle \ .$$

Thus, with intermediate normalization,

$$E = \langle \Phi | H | \Psi \rangle = E_0 + \langle \Phi | V | \Psi \rangle \ .$$

We now use this decomposition to write (22.79) in the form

$$(E_0 - H_0) | \Psi \rangle = (V - \Delta E) | \Psi \rangle \ , \tag{22.80}$$

where $\Delta E = \langle \Phi | V | \Psi \rangle$. Thus

$$(E_0 - H_0) Q | \Psi \rangle = Q(V - \Delta E) | \Psi \rangle \ . \tag{22.81}$$

Introduce the *resolvent operator*

$$R = \frac{Q}{E_0 - H_0} \ , \tag{22.82}$$

which is well-defined except on $\{\Phi\}$. Then the perturbation contribution to the wave function is

$$Q | \Psi \rangle = R(V - \Delta E) | \Psi \rangle = R(V | \Psi \rangle - | \Psi \rangle \langle \Phi | V | \Psi \rangle) \ .$$

The *Rayleigh–Schrödinger* perturbation expansion can now be written

$$| \Psi \rangle = | \Phi \rangle + | \Psi^{(1)} \rangle + | \Psi^{(2)} \rangle + \cdots$$
$$E = E_0 + E^{(1)} + E^{(2)} + \cdots$$

The contributions are ordered by the number of occurrences of V, the leading terms being

$$| \Psi^{(1)} \rangle = R V | \Phi \rangle \ ,$$
$$| \Psi^{(2)} \rangle = \left(R V R V - R^2 V P V \right) | \Phi \rangle \ ,$$

and so on. The corresponding contribution to the energy can then be found from

$$E^{(n)} = \langle \Phi | V | \Psi^{(n-1)} \rangle \ .$$

22.4.4 Perturbation Theory: Open–Shell Case

Consider now the case in which there are several unperturbed states, $| \Phi^{(a)} \rangle$, $a = 1, 2, \ldots, d$, having the same energy E_0, which span a d-dimensional linear subspace (the *model space*) $\mathcal{M} \subset \mathcal{H}$, so that

$$H_0 | \Phi^{(a)} \rangle = E_0 | \Phi^{(a)} \rangle, \quad a = 1, 2, \ldots, d \ .$$

Let P be the projector onto $\mathcal{M}$, and Q onto the orthogonal subspace $\mathcal{M}^\perp$.

The perturbed states $| \Psi^{(a)} \rangle$, $a = 1, 2, \ldots, d$ are related to the unperturbed states by the *wave operator* Ω,

$$| \Psi^{(a)} \rangle = \Omega | \Phi^{(a)} \rangle, \quad a = 1, 2, \ldots, d \ .$$

The *effective Hamiltonian*, H_{eff}, is defined so that

$$H_{\text{eff}} | \Phi^{(a)} \rangle = E^{(a)} | \Phi^{(a)} \rangle \ ,$$

and thus

$$\Omega H_{\text{eff}} | \Phi^{(a)} \rangle = E^{(a)} | \Psi^{(a)} \rangle = H \Omega | \Phi^{(a)} \rangle \ .$$

Thus on the domain $\mathcal{M}$ we can write an operator equation

$$\Omega H_{\text{eff}} P = H \Omega P \ , \tag{22.83}$$

known as the Bloch equation. We now partition H_{eff} so that

$$H_{\text{eff}} P = (H_0 + V_{\text{eff}}) P \ ,$$

enabling a reformulation of (22.83) as the commutator equation

$$[\Omega, H_0] P = (V \Omega - \Omega V_{\text{eff}}) P \ . \tag{22.84}$$

With the intermediate normalization convention of Sect. 22.4.3, this becomes

$$| \Psi^{(a)} \rangle = P | \Phi^{(a)} \rangle$$

so that $P \Omega P = P$ and

$$H_{\text{eff}} P = P H \Omega P \ , \quad V_{\text{eff}} P = P V \Omega P \ .$$

Then (22.84) can be put in the final form

$$[\Omega, H_0] P = (V \Omega - \Omega P V \Omega) P \ . \tag{22.85}$$

The general Rayleigh–Schrödinger perturbation expansion can now be generated by expanding the wave operator order by order

$$\Omega = 1 + \Omega^{(1)} + \Omega^{(2)} + \cdots \ ,$$

and inserting into (22.85), resulting in a hierarchy of equations

$$\left[\Omega^{(1)}, H_0\right]P = (V - PV)P = QVP \ ,$$
$$\left[\Omega^{(2)}, H_0\right]P = \left(QV\Omega^{(1)} - \Omega^{(1)}PV\right)P \ ,$$

and so on, with $H_{\text{eff}}^{(n)} = PV\Omega^{(n-1)}$.

22.4.5 Perturbation Theory: Algorithms

The techniques of QED perturbation theory of Sect. 22.3.4 can be utilized to give computable expressions for perturbation calculations order by order. They exploit the second quantized representation of operators of Sect. 22.4.1 along with the use of diagrams to express the contributions to the wave operator and the energy as sums over virtual states. The use of Wick's theorem to reduce products of normally-ordered operators, and the *linked-diagram* or *linked-cluster* theorem are explained in *Lindgren*'s article [22.17] and Chapt. 5. Further references and discussion of features which can exploit vector-processing and parallel-processing computer architectures may be found in [22.18].

The theory can also be recast so as to sum certain classes of terms to completion. This depends on the possibility of expressing the wave operator as a normally ordered exponential operator

$$\Omega = \{\exp S\} = 1 + \{S\} + \frac{1}{2!}\{S^2\} + \cdots \ ,$$

where the normally ordered operator S is known as the *cluster* operator. Expanding S order by order leads to the *coupled cluster expansion* (see also Chapts. 5 and 27).

22.5 Spherical Symmetry

A popular starting point for most calculations in atomic and molecular structure is the independent particle central field approximation. This assumes that the electrons move independently in a potential field of the form

$$A_0(x) = \frac{1}{c}\phi(r) \ , \quad r = |\boldsymbol{x}| \ ;$$
$$A_i(x) = 0 \ , \quad i = 1, 2, 3 \ . \tag{22.86}$$

Clearly $\phi(r)$ is left unchanged by any rotation about the origin, $r = 0$, but transforms as the component $A_0(x)$ of a 4-vector under other types of Lorentz and Poincaré transformation such as boosts or translations. However, solutions in central potentials of this form have a simple form which is convenient for further calculation.

With this restriction on the 4-potential, Dirac's Hamiltonian becomes

$$\hat{\boldsymbol{h}}_{\text{D}} = \left\{c\boldsymbol{\alpha} \cdot \boldsymbol{p} + e\phi(r) + \beta m_{\text{e}}c^2\right\} \ . \tag{22.87}$$

Consider stationary solutions with energy E satisfying

$$\hat{\boldsymbol{h}}_{\text{D}}\psi_E(x) = E\psi_E(x) \ .$$

Since $\hat{\boldsymbol{h}}_{\text{D}}$ is invariant with respect to rotation about $r = 0$, it commutes with the generators J_1, J_2, J_3 mentioned in Sect. 22.1.1, corresponding to components of the total angular momentum $\boldsymbol{j}$ of the electron, usually decomposed into an orbital part $\boldsymbol{l}$ and a spin part $\boldsymbol{s}$,

$$\boldsymbol{j} = \boldsymbol{l} + \boldsymbol{s} \tag{22.88}$$

where

$$l_j = \mathrm{i}\epsilon_{jkl}x_k\partial_l \ , \quad j = 1, 2, 3$$
$$s_j = \frac{1}{2}\epsilon_{jkl}\sigma_{kl} \ , \quad j = 1, 2, 3 \ .$$

22.5.1 Eigenstates of Angular Momentum

We can construct simultaneous eigenstates of the operators $\boldsymbol{j}^2$ and j_3 by using the product representation $\mathcal{D}^{(l)} \times \mathcal{D}^{(1/2)}$ of the rotation group SO(3), which is reducible to the Clebsch–Gordan sum of two irreps

$$\mathcal{D}^{(l+1/2)} \oplus \mathcal{D}^{(l-1/2)} \ . \tag{22.89}$$

We construct a basis for each irrep from products of basis vectors for $\mathcal{D}^{(1/2)}$ and $\mathcal{D}^{(l)}$ respectively. $\mathcal{D}^{(1/2)}$ is a 2-dimensional representation spanned by the simultaneous eigenstates ϕ_σ of $\boldsymbol{s}^2$ and s_3

$$\boldsymbol{s}^2\,\phi_\sigma = \frac{3}{4}\phi_\sigma, \quad s_3\,\phi_\sigma = \sigma\phi_\sigma, \quad \sigma = \pm\frac{1}{2} \ ,$$

for which we can use 2-rowed vectors

$$\phi_{1/2} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad \phi_{-1/2} = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \ .$$

The representation $\mathcal{D}^{(l)}$ is $(2l+1)$-dimensional; its basis vectors can be taken to be the spherical harmonics

$$\left\{Y_l^m(\theta, \varphi) \,|\, m = -l, -l+1, \ldots, l\right\},$$

so that

$$l^2 Y_l^m(\theta, \varphi) = l(l+1)\hbar^2 Y_l^m(\theta, \varphi) ,$$
$$l_3 Y_l^m(\theta, \varphi) = m\hbar Y_l^m(\theta, \varphi) .$$

We shall assume that spherical harmonics satisfy the standard relations

$$l_\pm Y_l^m(\theta, \varphi) = [l(l+1) - m(m \pm 1)]^{1/2} \hbar Y_l^{m\pm 1}(\theta, \varphi) ,$$

where $l_\pm = l_1 \pm l_2$, so that

$$Y_l^m(\theta, \varphi) = \left(\frac{2l+1}{4\pi}\right)^{1/2} C_l^m(\theta, \varphi) ,$$

$$C_l^m(\theta, \varphi) = (-1)^m \left(\frac{(l-m)!}{(l+m)!}\right)^{1/2} P_l^m(\theta) e^{im\varphi} ,$$

$$\text{if } m \geq 0 ,$$

$$C_l^{-m}(\theta, \varphi) = (-1)^m C_l^m(\theta, \varphi)^* . \qquad (22.90)$$

Basis functions for the representations $\mathcal{D}^j$ with $j = l \pm \frac{1}{2}$ have the form (The order of coupling is significant, and great confusion results from a mixing of conventions. Here we couple in the order l, s, j. The same spin-angle functions are obtained if we use the order s, l, j but there is a phase difference $(-1)^{l-j+1/2} = (-1)^{(1-a)/2}$. You have been warned!)

$$\chi_{j,m,a}(\theta, \varphi)$$
$$= \sum_\sigma \left\langle l, m-\sigma, \frac{1}{2}, \sigma \,\middle|\, l, \frac{1}{2}, j, m \right\rangle Y_l^{m-\sigma}(\theta, \varphi)\phi_\sigma$$
$$(22.91)$$

where $\langle l, m-\sigma, \frac{1}{2}, \sigma \,|\, l, \frac{1}{2}, j, m \rangle$ is a Clebsch–Gordan coefficient with

$$l = j - \frac{1}{2}a, \quad a = \pm 1,$$
$$m = -j, -j+1, \ldots, j-1, j .$$

Inserting explicit expressions for the Clebsch–Gordan coefficients gives

$$\chi_{j,m,-1}(\theta, \varphi) = \begin{pmatrix} -\left(\frac{j+1-m}{2j+2}\right)^{1/2} Y_{j+1/2}^{m-1/2}(\theta, \varphi) \\ \left(\frac{j+1+m}{2j+2}\right)^{1/2} Y_{j+1/2}^{m+1/2}(\theta, \varphi) \end{pmatrix} ,$$

$$\chi_{j,m,1}(\theta, \varphi) = \begin{pmatrix} \left(\frac{j+m}{2j}\right)^{1/2} Y_{j-1/2}^{m-1/2}(\theta, \varphi) \\ \left(\frac{j-m}{2j}\right)^{1/2} Y_{j-1/2}^{m+1/2}(\theta, \varphi) \end{pmatrix} .$$
$$(22.92)$$

The vectors (22.92) satisfy

$$j^2 \chi_{j,m,a} = j(j+1)\chi_{j,m,a}, \quad s^2 \chi_{j,m,a} = \frac{3}{4}\chi_{j,m,a} ,$$
$$l^2 \chi_{j,m,a} = l(l+1)\chi_{j,m,a}, \quad l = j - \frac{1}{2}a, \quad a = \pm 1 .$$
$$(22.93)$$

The parity of the angular part is given by $(-1)^l$, with the two possibilities distinguished by means of the operator

$$K' = -(j^2 - l^2 - s^2 + 1) = -(2s \cdot l + 1) \qquad (22.94)$$

so that

$$K'\chi_{j,m,a} = k'\chi_{j,m,a}, \quad k' = -\left(j + \frac{1}{2}\right)a, \quad a = \pm 1 .$$

The basis vectors are orthonormal on the unit sphere with respect to the inner product

$$(\chi_{j',m',a'} \mid \chi_{jma})$$
$$= \int \int \chi_{j',m',a'}^\dagger(\theta, \varphi)\chi_{j,m,a}(\theta, \varphi) \sin\theta \, d\theta \, d\varphi$$
$$= \delta_{j',j}\delta_{m',m}\delta_{a',a} . \qquad (22.95)$$

22.5.2 Eigenstates of Dirac Hamiltonian in Spherical Coordinates

Eigenstates of Dirac's Hamiltonian (22.87) in spherical coordinates with a spherically symmetric potential $V(r) = e\phi(r)$,

$$\hat{h}_D \psi_E(r) = E\psi_E(r) , \qquad (22.96)$$

are also simultaneous eigenstates of j^2, of j_3 and of the operator

$$K = \begin{pmatrix} K' & 0 \\ 0 & -K' \end{pmatrix} , \qquad (22.97)$$

where K' is defined in (22.94) above. Denote the corresponding eigenvalues by j, m and κ, where

$$\kappa = \pm\left(j + \frac{1}{2}\right) . \qquad (22.98)$$

Then the simultaneous eigenstates take the form

$$\psi_{E\kappa m}(r) = \frac{1}{r}\begin{pmatrix} P_{E\kappa}(r)\chi_{\kappa,m}(\theta, \varphi) \\ iQ_{E\kappa}(r)\chi_{-\kappa,m}(\theta, \varphi) \end{pmatrix} , \qquad (22.99)$$

where $\kappa = -(j+1/2)a$ is the eigenvalue of K', and the notation $\chi_{\kappa,m}$ replaces the notation $\chi_{j,m,a}$ used previously in (22.91). The factor i in the lower component

ensures that, at least for bound states, the radial amplitudes $P_{E\kappa}(r)$, $Q_{E\kappa}(r)$ can be chosen to be real. This decomposition into radial and angular factors exploits the identity

$$\boldsymbol{\sigma}\cdot\boldsymbol{p}\left[\frac{F(r)}{r}\chi_{\kappa,m}(\theta,\varphi)\right]$$
$$= i\hbar\frac{1}{r}\left(\frac{\mathrm{d}F}{\mathrm{d}r}+\frac{\kappa F}{r}\right)\chi_{-\kappa,m}(\theta,\varphi) \qquad (22.100)$$

and gives a reduced eigenvalue equation

$$\begin{pmatrix} mc^2 - E + V & -c\left(\frac{\mathrm{d}}{\mathrm{d}r}-\frac{\kappa}{r}\right) \\ c\left(\frac{\mathrm{d}}{\mathrm{d}r}+\frac{\kappa}{r}\right) & -mc^2 - E + V \end{pmatrix} \begin{pmatrix} P_{E\kappa}(r) \\ Q_{E\kappa}(r) \end{pmatrix} = 0 .$$
$$(22.101)$$

Angular Density Distributions

It is a remarkable fact that the angular density distribution

$$A_{\kappa,m}(\theta,\varphi) = \chi_{\kappa,m}(\theta,\varphi)^{\dagger}\chi_{\kappa,m}(\theta,\varphi), \qquad (22.102)$$

where $m = -j, -j+1, \ldots, j-1, j$, is *independent of the sign of* κ; the equivalence of

$$A_{j+1/2,m}(\theta,\varphi) = \frac{1}{4\pi}\frac{(j-m)!}{(j+m)!}$$
$$\times\left[(j-m+1)^2\left|P_{j+1/2}^{m-1/2}(\mu)\right|^2+\left|P_{j+1/2}^{m+1/2}(\mu)\right|^2\right],$$

and

$$A_{-(j+1/2),m}(\theta,\varphi) = \frac{1}{4\pi}\frac{(j-m)!}{(j+m)!}$$
$$\times\left[(j+m)^2\left|P_{j-1/2}^{m-1/2}(\mu)\right|^2+\left|P_{j-1/2}^{m+1/2}(\mu)\right|^2\right],$$

where $\mu = \cos\theta$, was demonstrated by *Hartree* [22.19].

Angular densities for the lowest $|\kappa|$ values are given in Table 22.1. The corresponding nonrelativistic angular densities

$$A_{l,m}(\theta,\varphi)_{nr} = \left|Y_l^m(\theta,\varphi)\right|^2$$
$$= \frac{2l+1}{4\pi}\frac{(l-m)!}{(l+m)!}\left|P_l^{|m|}(\mu)\right|^2 ;$$

are listed in Table 22.2.

Radial Density Distributions

The probability density distribution $\rho_{E\kappa m}(\boldsymbol{r})$ associated with the stationary state (22.99) is given by

$$\rho_{E,\kappa,m}(\boldsymbol{r}) = \frac{1}{r^2}\left[|P_{E,\kappa}(r)|^2 A_{\kappa,m}(\theta,\varphi)\right.$$
$$\left. + |Q_{E,\kappa}(r)|^2 A_{-\kappa,m}(\theta,\varphi)\right]. \qquad (22.103)$$

Table 22.1 Relativistic angular density functions

$|\kappa|$	$|m|$	$4\pi A_{|\kappa|,m}(\theta,\varphi)$
1	$\frac{1}{2}$	1
2	$\frac{3}{2}$	$\frac{3}{2}\sin^2\theta$
	$\frac{1}{2}$	$\frac{1}{2}(1+3\cos^2\theta)$
3	$\frac{5}{2}$	$\frac{15}{8}\sin^4\theta$
	$\frac{3}{2}$	$\frac{3}{8}\sin^2\theta(1+15\cos^2\theta)$
	$\frac{1}{2}$	$\frac{3}{4}(3\cos^2\theta-1)^2+3\sin^2\theta\cos^2\theta$

Table 22.2 Nonrelativistic angular density functions

l	$|m|$	$4\pi A_{l,m}(\theta,\varphi)_{nr}$
0	0	1
1	1	$\frac{3}{2}\sin^2\theta$
	0	$3\cos^2\theta$
2	2	$\frac{15}{8}\sin^4\theta$
	1	$\frac{15}{2}\sin^2\theta\cos^2\theta$
	0	$\frac{5}{4}(3\cos^2\theta-1)^2$

Since $A_{\kappa,m}$ does not depend on the sign of κ, the angular part can be factored so that

$$\rho_{E,\kappa,m}(\boldsymbol{r}) = \frac{D_{E,\kappa}(r)}{r^2}A_{|\kappa|,m}(\theta,\varphi),$$

where

$$D_{E,\kappa}(r) = \left[|P_{E,\kappa}(r)|^2+|Q_{E,\kappa}(r)|^2\right] \qquad (22.104)$$

defines the *radial density* distribution.

Subshells in j–j Coupling

The notion of a *subshell* depends on the observation that the set $\{\psi_{E,\kappa,m}, m = -j, \ldots, j\}$ have a common radial density distribution. The simplest atomic model is one in which the electrons move independently in a mean field central potential. Since

$$\sum_{m=-j}^{j}\rho_{E,\kappa,m}(\boldsymbol{r}) = \frac{2j+1}{4\pi}\frac{D_{E,\kappa}(r)}{r^2}, \qquad (22.105)$$

a state of $2j+1$ independent electrons, with one in each member of the set $\{\psi_{E,\kappa,m}, m = -j, \ldots, j\}$, has a spherically symmetric probability density. If E belongs to the point spectrum of the Hamiltonian, then (22.105) gives a distribution localized in r, and we refer to the states $\{E, \kappa, m\}$, $m = -j, \ldots, j$ as belonging to the subshell $\{E, \kappa\}$.

The notations in use for Dirac central field states are set out in Table 22.3. Here l is associated with the orbital angular quantum number of the upper pair of

Table 22.3 Spectroscopic labels and angular quantum numbers

Label:	s	$\overline{p}$	p	$\overline{d}$	d	$\overline{f}$	f
$\kappa = -(j+\frac{1}{2})a$	-1	$+1$	-2	$+2$	-3	$+3$	-4
$j = l + \frac{1}{2}a$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{3}{2}$	$\frac{3}{2}$	$\frac{5}{2}$	$\frac{5}{2}$	$\frac{7}{2}$
a	1	-1	1	-1	1	-1	1
$l = j - \frac{1}{2}a$	0	1	1	2	2	3	3
$\overline{l} = j + \frac{1}{2}a$	1	0	2	1	3	2	4

components and $\overline{l}$ with the lower pair. Note the useful equivalence

$$\kappa(\kappa+1) = l(l+1) .$$

Defining $\overline{\kappa} := -\kappa$ we have also $\overline{\kappa}(\overline{\kappa}+1) = \overline{l}(\overline{l}+1)$.

22.5.3 Radial Amplitudes

Textbooks on quantum electrodynamics usually contain extensive discussions of the formalism associated with the Dirac equation but rarely go beyond the treatment of the hydrogen atom Chapt. 10. *Greiner*'s textbook [22.4] is an honorable exception, with many worked examples. A more exhaustive list of problems in which exact solutions are known is contained in [22.20]; it is particularly rich in detail about equations of motion and Green's functions in external electromagnetic fields of various configurations; coherent states of relativistic particles; charged particles in quantized plane wave fields. It also incorporates discussion of extensions of the Dirac equations due to Pauli which include explicit interaction terms arising from anomalous magnetic or electric moments.

Atoms and molecules with more than one electron are not soluble analytically so that numerical models are needed to make predictions. The solutions are sensitive to boundary conditions on which we focus in this section. For large r, solutions of (22.101) can be found proportional to $\exp(\pm\lambda r)$, where

$$\lambda = +\sqrt{c^2 - E^2/c^2} . \tag{22.106}$$

Thus λ is *real* when $-c^2 \le E \le c^2$, and *pure imaginary* otherwise.

Singular Point at $r = 0$
Singularities of the nuclear potential near $r = 0$ have a major influence on the nature of solutions of the Dirac equation. Suppose that the potential has the form

$$V(r) = -\frac{Z(r)}{r} , \tag{22.107}$$

so that $Z(r)$ is the effective charge seen by an electron at radius r from the nuclear center. The dependence of $Z(r)$ on r may reflect the finite size of the nuclear charge distribution, so far treated as a point, or the screening due to the environment. Assume that $Z(r)$ can be expanded in a power series of the form

$$Z(r) = Z_0 + Z_1 r + Z_2 r^2 + \cdots \tag{22.108}$$

in a neighborhood of $r = 0$. This property characterizes a number of well-used models

1. *Point nucleus*: $Z_0 \ne 0$; $Z_n = 0$, $n > 0$.
2. *Uniform nuclear charge distribution*:

$$V(r) = \begin{cases} -\dfrac{3Z}{2a}\left(1 - \dfrac{r^2}{3a^2}\right), & 0 \le r \le a , \\ -\dfrac{Z}{r} , & r > a . \end{cases} \tag{22.109}$$

This gives the expansion $Z_0 = -3Z/2a$, $Z_1 = 0$, $Z_2 = +Z/2a^3$, $Z_n = 0$ for $n > 2$ when $r \le a$.
3. *Fermi distribution*: The nuclear charge density has the form

$$\rho_{\text{nuc}}(r) = \frac{\rho_0}{1 + \exp[(r-a)/d]} ,$$

where ρ_0 is chosen so that the total charge on the nucleus is Z.

Other nuclear models, reflecting the density distributions deduced from nuclear scattering experiments, can be found in the literature.

Series Solutions Near $r = 0$
Any solution for the radial amplitudes of Dirac's equation in a central potential

$$u(r) = \begin{pmatrix} P(r) \\ Q(r) \end{pmatrix} , \tag{22.110}$$

with radial density

$$D(r) = P^2(r) + Q^2(r) ,$$

can be expanded in a power series near the singular point at $r = 0$ in the form

$$u(r) = r^\gamma \left(u_0 + u_1 r + u_2 r^2 + \cdots\right) , \tag{22.111}$$

where

$$u_k = \begin{pmatrix} p_k \\ q_k \end{pmatrix} , \quad k = 1, 2, \ldots$$

and γ, p_k, q_k are constants which depend on the nuclear potential model.

Point Nuclear Models

For a Coulomb singularity, $Z_0 \neq 0$, the leading coefficients satisfy

$$-Z_0 p_0 + c(\kappa - \gamma)q_0 = 0,$$
$$c(\kappa + \gamma)p_0 - Z_0 q_0 = 0, \tag{22.112}$$

so that

$$\gamma = \pm\sqrt{\kappa^2 - \frac{Z_0^2}{c^2}},$$
$$\frac{q_0}{p_0} = \frac{Z_0}{c(\kappa - \gamma)} = \frac{c(\kappa + \gamma)}{Z_0}. \tag{22.113}$$

Finite Nuclear Models

Finite nuclear models, for which $Z_0 = 0$, have no singularity in the potential at $r = 0$. The indicial equation (22.113) reduces to $\gamma = \pm|\kappa|$, so that for $\kappa < 0$,

$$P(r) = p_0 r^{l+1} + O(r^{l+3}), \tag{22.114}$$
$$Q(r) = q_1 r^{l+2} + O(r^{l+4}), \tag{22.115}$$

with

$$q_1/p_0 = (E - mc^2 + Z_1)/[c(2l+3)],$$
$$q_0 = p_1 = 0,$$

and for $\kappa \geq 1$,

$$P(r) = p_1 r^{l+1} + O(r^{l+3}), \tag{22.116}$$
$$Q(r) = q_0 r^l + O(r^{l+2}), \tag{22.117}$$

with

$$p_1/q_0 = -(E - mc^2 + Z_1)/[c(2l+1)],$$
$$p_0 = q_1 = 0.$$

In both cases the solutions consist of either purely *even* powers or purely *odd* powers of r, contrasting strongly with the point nucleus case, where both even and odd powers are present in the series expansion.

The Nonrelativistic Limit

For a solution linked to a nonrelativistic state with orbital angular momentum l, one expects the nonrelativistic limit

$$P(r) = O(r^{l+1}), \quad c \to \infty.$$

The limiting behavior reveals some significant features.

Finite nuclear models.
The behavior is entirely regular:

$$P(r) = O(r^{l+1}), \quad Q(r) = O(c^{-1}) \to 0.$$

Point nuclear models.
Since

$$\gamma = |\kappa| - \frac{Z^2}{2c^2|\kappa|} + \cdots,$$

(22.113) shows that the leading coefficient p_0 *vanishes* in the limit so that,

$$P(r) \approx p_1 r^{l+1}\left[1 + O(r^2)\right], \quad \text{when } \kappa \geq 1, \ l = \kappa. \tag{22.118}$$

All higher powers of *odd* relative order vanish in the limit for both components. The behavior in the case $\kappa < 0$ is entirely regular.

22.5.4 Square Integrable Solutions

Square integrable solutions require $\int D_{E,\kappa}(r)\,dr$ to be finite; since the solutions are smooth, except possibly near the singular endpoints $r \to 0$ and $r \to \infty$, we focus on the behavior at the endpoints:

r → ∞

For *real* values of λ the condition

$$\int_R^\infty D_{E,\kappa}(r)\,dr < \infty, \quad 0 < R < \infty,$$

requires that $P_{E\kappa}(r)$, $Q_{E\kappa}(r)$ are proportional to $\exp(-\lambda r)$ with $\lambda > 0$.

This means that bound states can only exist when E lies in the interval $-c^2 \leq E \leq c^2$. Outside this interval solutions are necessarily of scattering type and so

$$\int_R^\infty D_{E,\kappa}(r)\,dr$$

diverges when $|E| > c^2$.

r → 0

This limit requires

$$\int_0^{R'} D_{E,\kappa}(r)\,dr < \infty, \quad R' > 0.$$

Since $D_{E,\kappa}(r) \sim r^{\pm 2\gamma}$ as $r \to 0$, this condition holds when $\pm\gamma > -\frac{1}{2}$. Only the solution with $\gamma > 0$ satisfies the condition when $|\gamma| > \frac{1}{2}$, or $Z < \alpha^{-1}\sqrt{\kappa^2 - 1/4}$, and the solution with $\gamma < 0$ must be disregarded. This corresponds to the *limit point case* of a second-order differential operator [22.21]. In the special case $|\kappa| = 1$ or $j = \frac{1}{2}$ this limits Z to be smaller than $c\sqrt{3}/2 \approx 118.6$. For $Z > c\sqrt{3}/2$, both solutions are square integrable near the origin (the *limit circle case*) and the differential operator is no longer essentially self-adjoint.

The Coulomb potential must have a finite expectation for any physically acceptable solution, so that we also require

$$\int_0^{R'} D_{E,\kappa}(r) \frac{dr}{r} < \infty, \quad R' > 0.$$

This is always satisfied by the solution with $\gamma > 0$ for all $|Z| < \alpha^{-1}|\kappa|$, but not by the solution with $\gamma < 0$. Imposing this condition restores essential self-adjointness (on a restricted domain) for $118 < Z \leq 137$.

22.5.5 Hydrogenic Solutions

The wave functions for hydrogenic solutions of Dirac's equation are presented in Sect. 22.8.2. Here we note some properties of hydrogenic solutions that reveal dynamical effects of relativity in the absence of screening by orbital electrons. In this case $Z_0 = Z$, $Z_n = 0$, $n > 0$. When $-c^2 < E < c^2$ we have bound states. The parameter λ, (22.106), can conveniently be written

$$\lambda = Z/N, \tag{22.119}$$

so that rearranging (22.106) gives

$$E = +c^2\sqrt{1 - \frac{Z^2}{N^2 c^2}}, \tag{22.120}$$

essentially equivalent to Sommerfeld's fine structure formula. In the formal nonrelativistic limit, $c \to \infty$, we have

$$E = c^2 - \frac{Z^2}{2N^2} + O(1/c^2)$$

so that N is closely related to the principal quantum number, n, appearing in the Rydberg formula. As in Sect. 22.8.2, we write $\rho = 2\lambda r$.

Define the *inner quantum number*

$$n_r = -a = -\gamma + \frac{NE}{c^2}, \qquad n_r = 0, 1, 2, \dots .$$

Substitute for E from (22.120) to get

$$\begin{aligned} N &= \left[(n_r + \gamma)^2 + \alpha^2 Z^2\right]^{1/2} \\ &= \left[n^2 - 2n_r(|\kappa| - \gamma)\right]^{1/2}, \end{aligned} \tag{22.121}$$

where $n = n_r + |\kappa|$ is the *principal quantum number*, the exact equivalent of the principal quantum number of the nonrelativistic state to which the Dirac solution reduces in the limit $c \to \infty$. With this notation, the radial amplitudes for bound hydrogenic states are

$$\begin{aligned} P_{E\kappa}(r) &= \mathcal{N}_{E\kappa}(c + E/c)^{1/2}\rho^\gamma e^{-\rho/2}\big[-n_r M(-n_r + 1, \\ &\quad 2\gamma + 1; \rho) + (N - \kappa)M(-n_r, 2\gamma + 1; \rho)\big], \end{aligned} \tag{22.122}$$

$$\begin{aligned} Q_{E\kappa}(r) &= \mathcal{N}_{E\kappa}(c - E/c)^{1/2}\rho^\gamma e^{-\rho/2}\big[-n_r M(-n_r + 1, \\ &\quad 2\gamma + 1; \rho) - (N - \kappa)M(-n_r, 2\gamma + 1; \rho)\big], \end{aligned} \tag{22.123}$$

where

$$\mathcal{N}_{E\kappa} = \left(\frac{\alpha Z}{2N^2(N - \kappa)} \cdot \frac{\Gamma(2\gamma + n_r + 1)}{n_r! \left[\Gamma(2\gamma + 1)\right]^2}\right)^{1/2}$$

is the normalization constant. For definitions of the confluent hypergeometric functions $M(a, b; c; z)$ see [22.22, Sect. 13.1].

Table 22.4 lists expectation values of simple powers of the radial variable $\rho = 2Zr/N$ from [22.23]

Table 22.4 Radial moments $\langle \rho^s \rangle$

s	Nonrelativistic	Relativistic[a]
2	$2n^2[5n^2 + 1 - 3l(l+1)]$	$2\left[N^2(5N^2 - 2\kappa^2)R^2(N) + N^2(1-\gamma^2) - 3\kappa N^2 R(N)\right]$
1	$3n^2 - l(l+1)$	$-\kappa + (3N^2 - \kappa^2)R(N)$
0	1	1
-1	$\dfrac{1}{2n^2}$	$\dfrac{n\gamma + (|\kappa| - \gamma)|\kappa|}{2\gamma N^3}$
-2	$\dfrac{1}{2n^3(2l+1)}$	$\dfrac{\kappa^2 R(N)}{2\gamma^2 N^3(2\gamma - \mathrm{sgn}\kappa)}$
-3	$\dfrac{1}{4n^3 l(l+1)(2l+1)}$	$\dfrac{N^2 + 2\gamma^2\kappa^2 - 3N^2\kappa R(N)}{4N^5\gamma(\gamma^2 - 1)(4\gamma^2 - 1)}$

[a] $R(N) = \sqrt{1 - Z^2/N^2 c^2}$

and [22.24]. Simple algebra, using the inequalities $\gamma < |\kappa|$ and $N < n$, yields the inequality

$$\langle \rho^s \rangle_{n\kappa} < \langle \rho^s \rangle_{nl}, \quad s > 0 \, ;$$

the inequality is reversed for $s < 0$. In the same way, it is easy to deduce that relativistic hydrogenic eigenvalues lie below the nonrelativistic eigenvalues

$$\epsilon_{n\kappa} < \epsilon_{nl} \, .$$

Thus, in the absence of screening, Dirac orbitals both *contract* and are *stabilized* with respect to their nonrelativistic counterparts. The relativistic and nonrelativistic expectation values approach each other as the *relativistic coupling constant, $Z/c = \alpha Z \to 0$*. This formal *nonrelativistic limit* is approached as $\alpha \to 0$ or $c \to \infty$, in which the speed of light is regarded as infinite.

22.5.6 The Free Electron Problem in Spherical Coordinates

The radial equation (22.101) for the free electron ($V(r) = 0$) gives a pair of first order ordinary differential equations

$$(mc^2 - E) P_{E\kappa}(r) = c \left(\frac{\mathrm{d}}{\mathrm{d}r} - \frac{\kappa}{r} \right) Q_{E\kappa}(r) \, ,$$

$$c \left(\frac{\mathrm{d}}{\mathrm{d}r} + \frac{\kappa}{r} \right) P_{E\kappa}(r) = (mc^2 + E) Q_{E\kappa}(r) \, , \quad (22.124)$$

from which we deduce that

$$\frac{\mathrm{d}^2 P_{E\kappa}(r)}{\mathrm{d}r^2} + \left(p^2 - \frac{\kappa(\kappa+1)}{r^2} \right) P_{E\kappa}(r) = 0 \, ,$$

$$\frac{\mathrm{d}^2 Q_{E\kappa}(r)}{\mathrm{d}r^2} + \left(p^2 - \frac{\bar{\kappa}(\bar{\kappa}+1)}{r^2} \right) Q_{E\kappa}(r) = 0 \, ,$$

$$(22.125)$$

where $p^2 = m^2 c^2 - E^2/c^2 = \boldsymbol{p} . \boldsymbol{p}$ and the angular quantum numbers κ and $\bar{\kappa}$ are associated respectively with the upper and lower components. These are defining equations of Riccati–Bessel functions [22.22, Sect. 10.1.1] of orders l and $\bar{l}$ respectively, where

$$\kappa(\kappa+1) = l(l+1), \quad \bar{\kappa}(\bar{\kappa}+1) = \bar{l}(\bar{l}+1) \, .$$

Thus the solutions of (22.125) are functions of the variable $x = pr$ of the form

$$P_{E\kappa}(r) = A x f_l(x), \quad Q_{E\kappa}(r) = B x f_{\bar{l}}(x) \, ,$$

where the ratio of A and B is determined by (22.124) and where $f_l(x)$ is a spherical Bessel function of the

first, second or third kind [22.22, Sect. 10.1.1]. Thus

$$P_{E\kappa}(r) = \mathcal{N} \left(\frac{E + mc^2}{\pi E} \right)^{1/2} x f_l(x) \, ,$$

$$Q_{E\kappa}(r) = \mathcal{N} \mathrm{sgn}(\kappa) \left(\frac{E - mc^2}{\pi E} \right)^{1/2} x f_{\bar{l}}(x) \, .$$

$$(22.126)$$

Equations (22.124) require that Riccati–Bessel solutions of the same type be chosen for both components. The possibilities are:

Standing Waves

The two solutions of the same type are $f_l(x) = j_l(x)$, $f_l(x) = y_l(x)$. The $j_l(x)$ are bounded everywhere, including the singular points $x = 0$, $x \to \infty$ and have zeros of order l at $x = 0$. The $y_l(x)$ are bounded at infinity but have poles of order $l+1$ at $x = 0$.

Progressive Waves

The spherical Hankel functions (functions of the third kind) are linear combinations

$$h_l^{(1)}(x) = j_l(x) + \mathrm{i} y_l(x), \quad h_l^{(2)}(x) = j_l(x) - \mathrm{i} y_l(x) \, .$$

Recalling that p is *real* if and only if $|E| > mc^2$, we see that $h_l^{(1)}(x)$, $h_l^{(2)}(x)$ are bounded as $x \to \infty$ and have poles of order $l+1$ at $x = 0$. Notice that when $|E| < mc^2$, which does not occur for a free particle, p becomes pure imaginary and no solution exists which is finite at both singular points.

The normalization constant $\mathcal{N}$ can be determined by using the well-known result

$$\int_0^\infty j_l(pr) j_l(p'r) r^2 \, \mathrm{d}r = \frac{\pi}{2p^2} \delta(p - p') \, .$$

The choice $\mathcal{N} = 1$ ensures that

$$\int_0^\infty \left[P_{E\kappa}^\dagger(r) P_{E'\kappa}(r) + Q_{E\kappa}^\dagger(r) Q_{E'\kappa}(r) \right] \mathrm{d}r = \delta(p - p') \, .$$

Noting that

$$\delta(E - E') = \left| \frac{\mathrm{d}p}{\mathrm{d}E} \right| \delta(p - p') \, ,$$

and $\mathrm{d}p/\mathrm{d}E = c^2 p/E$ gives

$$\int_0^\infty \left[P_{E\kappa}^\dagger(r) P_{E'\kappa}(r) + Q_{E\kappa}^\dagger(r) Q_{E'\kappa}(r) \right] \mathrm{d}r = \delta(E - E') \, .$$

when $\mathcal{N} = (|E|/c^2 p)^{1/2}$.

22.6 Numerical Approximation of Central Field Dirac Equations

The main drive for understanding methods of numerical approximation of solutions of Dirac's equation comes from their application to many-electron systems. Approximate wave functions for atomic or molecular states are usually constructed from products of one-electron orbitals, and their determination exploits knowledge gained from the treatment of one-electron problems. Whilst the numerical methods described here are strictly one-electron in character, extension to many-electron problems is relatively straightforward.

22.6.1 Finite Differences

The numerical approximation of eigensolutions of the first order system of differential equations (22.101)

$$
E \begin{pmatrix} P_{E\kappa}(r) \\ Q_{E\kappa}(r) \end{pmatrix}
$$
$$
= \begin{pmatrix} mc^2 + V(r) - c\left(\frac{\mathrm{d}}{\mathrm{d}r} - \frac{\kappa}{r}\right) \\ c\left(\frac{\mathrm{d}}{\mathrm{d}r} + \frac{\kappa}{r}\right) - mc^2 + V(r) \end{pmatrix} \begin{pmatrix} P_{E\kappa}(r) \\ Q_{E\kappa}(r) \end{pmatrix}
$$

(22.127)

can be achieved by more or less standard finite difference methods given in texts such as [22.25]. For states in either continuum, $E > mc^2$ or $E < -mc^2$, the calculation is completely specified as an *initial value problem* for a prescribed value of E starting from power series solutions in the neighborhood of $r = 0$. Solutions of this sort exist for all values of (complex) E except at the bound eigensolutions in the gap $-mc^2 < E < mc^2$. For bound states, the calculation becomes that of a *two-point boundary value problem* in which the eigenvalue E has to be determined iteratively along with the numerical solution. We concentrate on the latter, which is more involved.

It is convenient to write

$$
\epsilon_{n\kappa} = E_{n\kappa} - mc^2 , \tag{22.128}
$$

so that ϵ approaches the nonrelativistic eigenvalue in the limit $c \to \infty$. For the one-electron problem, (22.101) can be written in the general form

$$
J \frac{\mathrm{d}u}{\mathrm{d}s} + \frac{1}{c}\frac{\mathrm{d}r}{\mathrm{d}s}\left[r\epsilon + W(s)\right]u(s) = \chi(s)\frac{\mathrm{d}r}{\mathrm{d}s} , \tag{22.129}
$$

where $u(s)$ and $\chi(s)$ are two-component vectors, such that

$$
u(s) = \begin{pmatrix} P(s) \\ Q(s) \end{pmatrix} , \quad J = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} ,
$$

$$
W(s) = \begin{pmatrix} -rV(r) & -c\kappa \\ -c\kappa & 2rc^2 - rV(r) \end{pmatrix} ,
$$

and $r(s)$ is a smooth differentiable function of a new independent variable s. This facilitates the use of a uniform grid for s mapping onto a suitable nonuniform grid for r. Common choices are

$$
r_n = r_0\,\mathrm{e}^{s_n} , \quad s_n = nh , \quad n = 0, 1, 2, \ldots, N ,
$$

for suitable values of the parameters r_0 and h, and

$$
A\,r_n + \log\left(1 + \frac{r_n}{r_0}\right) = s_n , \quad n = 0, 1, 2, \ldots, N ,
$$

where A is a constant, chosen so that the spacing in r_n increases exponentially for small values of n and approaches a constant for large values of n. The exponentially increasing spacing is appropriate for tightly bound solutions, but a nearly linear spacing is advisable to ensure numerical stability in the tails of extended and continuum solutions.

The most convenient numerical algorithm involves *double shooting* from $s_0 = 0$ and $s_N = Nh$ towards an intermediate *join* point $s = Jh$, adjusting ϵ until the trial solutions have the right number of nodes and have left- and right-limits at $s = Jh$ which agree to a pre-set tolerance (commonly about 1 part in 10^8).

The *deferred correction* method [22.26, 27] allows the precision of the numerical approximation to be improved as the iteration converges. Consider the simplest implicit linear difference scheme for the first order system

$$
\frac{\mathrm{d}y}{\mathrm{d}s} = F[y(s), s] ,
$$

based on the trapezoidal rule of quadrature, is

$$
z_{j+1} - z_j = \frac{1}{2}h(F_{j+1} + F_j) , \tag{22.130}
$$

which has a local truncation error $O(h^2)$. The precision can be improved, at the expense of increasing the computational cost per iterative cycle, by adding higher order difference terms to the right-hand side in (22.130). Use of the trial solution from the previous cycle leaves the stability properties of (22.130) are unaltered, but the converged solution has much higher accuracy.

To apply this to the Dirac system, write $f(s) = \mathrm{d}r/\mathrm{d}s$ and

$$
A_j^{\pm} = J \pm \frac{h}{2c}f(s_j)W(s_j) .
$$

Also consider a slightly generalized problem in which $V(r)$ is replaced by a discretized potential $U_j^{(\nu)}$ that may change from one iteration to the next as in a self-consistent field calculation. The first iteration is

$$A_{j+1}^{+(0)} U_{j+1}^{(1)} - A_j^{-(0)} U_j^{(1)}$$
$$+ \epsilon^{(0)} \frac{h}{2c} \left[r_{j+1} f(s_{j+1}) U_{j+1}^{(1)} + r_j f(s_j) U_j^{(1)} \right]$$
$$= \frac{1}{2} h \left[f(s_{j+1}) \chi(s_{j+1})^{(0)} + f(s_j) \chi(s_j)^{(0)} \right], \tag{22.131}$$

where superscript 0 refers to initial estimates and superscript 1 to the result of the first iteration. On the $(\nu + 1)$-th iteration, we solve

$$A_{j+1}^{+(\nu)} U_{j+1}^{(\nu+1)} - A_j^{-(\nu)} U_j^{(\nu+1)}$$
$$+ \epsilon^{(\nu)} \frac{h}{2c} \left[r_{j+1} f(s_{j+1}) U_{j+1}^{(\nu+1)} + r_j f(s_j) U_j^{(\nu+1)} \right]$$
$$= \frac{1}{2} h \left[f(s_{j+1}) \chi(s_{j+1})^{(\nu)} + f(s_j) \chi(s_j)^{(\nu)} \right]$$
$$+ \frac{1}{12} \delta^3 U_{j+1/2}^{(\nu)} + \cdots, \tag{22.132}$$

where $\delta^3 U_{j+1/2}^{(\nu)}$ is the central-difference correction of order 3 [22.22, Sect. 25.1.2]. Higher order difference corrections (at least to order 5) are included in modern codes to improve the accuracy and numerical stability of weakly bound solutions. This deferred correction algorithm can be shown to converge asymptotically to the required solution of the differential system with a local truncation error of order $O(h^{2p+2})$ when difference corrections of order $2p + 1$ are employed [22.28].

22.6.2 Expansion Methods

Methods of solving the Dirac equation which represent the one-electron wave function as a linear combination of sets of square integrable functions (basis sets) have become popular in the last 10 years. Simple and rigorous criteria for choosing effective basis sets for this purpose are now available, and classes of functions that satisfy these criteria are known. Consequently, cheap and accurate calculations of the electronic structure of atoms and molecules are now a practical possibility.

Finite difference algorithms generate eigensolutions one at a time. Basis set methods replace the differential operator $\hat{h}_D$ of (22.87) with a finite symmetric (in some cases complex Hermitian) matrix of dimension $2N$. The spectrum of this operator, which is of course a pure point spectrum, consists of three pieces: N eigensolutions with $E < -mc^2$ ($\epsilon < -2mc^2$) representing the

eigenstates of the lower continuum; $N_b < N$ eigensolutions in the gap $-mc^2 < E < mc^2$ ($-2mc^2 < \epsilon < 0$) corresponding to bound states; and $N - N_b$ eigensolutions with $E > mc^2$ ($\epsilon > 0$) representing the eigenstates of the upper continuum. For properly chosen basis sets, the approximation properties of bound state eigensolutions are similar to those of the equivalent nonrelativistic eigensolutions. Solutions at continuum energies have the correct behavior near $r = 0$, but their amplitudes decrease exponentially like bound state solutions at large values of r. The criteria on which this description rests are as follows:

A. The eigenstates of $\hat{h}_D$ are 4-component central field spinors whose components are coupled. The basis functions should therefore also consist of 4-component spinors of the form

$$\Phi_{\kappa m}(\mathbf{r}) = \frac{1}{r} \left[\begin{array}{c} f_\kappa^L(r) \chi_{\kappa,m}(\theta, \varphi) \\ i f_\kappa^S(r) \chi_{-\kappa,m}(\theta, \varphi) \end{array} \right]. \tag{22.133}$$

B. The spinor basis functions should, as far as practicable, satisfy the boundary conditions near $r = 0$ of Sect. 22.5.3. They should also be square integrable at infinity.

C. Acceptable spinor basis functions should satisfy the relation

$$i\hbar \frac{f_\kappa^S(r)}{r} \chi_{-\kappa,m}(\theta, \varphi) \to \boldsymbol{\sigma} \cdot \boldsymbol{p} \frac{f_\kappa^L(r)}{r} \chi_{\kappa,m}(\theta, \varphi) \tag{22.134}$$

in the *nonrelativistic limit*, $c \to \infty$.

D. Acceptable spinor basis functions must have *finite expectation values* of component operators of $\hat{h}_D$, namely $\boldsymbol{\alpha} \cdot \boldsymbol{p}$, β and $V(r)$.

Finite Basis Set Formalism

Assume that each solution of the target problem is approximated as a linear combination

$$\psi_{\kappa m}(\mathbf{r}) = \frac{1}{r} \left(\begin{array}{c} \sum_j c_{\kappa j}^L f_{\kappa j}^L(r) \chi_{\kappa,m}(\theta, \varphi) \\ i \sum_j c_{\kappa j}^S f_{\kappa j}^S(r) \chi_{-\kappa,m}(\theta, \varphi) \end{array} \right), \tag{22.135}$$

where $c_{\kappa j}^L, c_{\kappa j}^S$ $j = 1 \cdots N$, are arbitrary constants, so that each j-term on the right-hand side has the form (22.133). This enables us to construct a *Rayleigh quotient*

$$W[\psi] = \frac{\langle \psi | \hat{h}_D | \psi \rangle}{\langle \psi | \psi \rangle}, \tag{22.136}$$

where both $\langle\psi|\hat{\pmb{h}}_{\mathrm{D}}|\psi\rangle$ and $\langle\psi|\psi\rangle$ are quadratic expressions in the expansion coefficients c_j^L, c_j^S. By requiring that $W[\psi]$ shall be stationary with respect to arbitrary variations in the expansion coefficients, we arrive at the matrix eigenvalue equation

$$f_\kappa \begin{pmatrix} c_\kappa^L \\ c_\kappa^S \end{pmatrix} = \epsilon \begin{pmatrix} S_\kappa^{LL} & 0 \\ 0 & S_\kappa^{SS} \end{pmatrix} \begin{pmatrix} c_\kappa^L \\ c_\kappa^S \end{pmatrix} , \qquad (22.137)$$

where the matrix Hamiltonian is denoted by

$$f_\kappa = \begin{pmatrix} V_\kappa^{LL} & c\Pi_\kappa^{LS} \\ c\Pi_\kappa^{SL} & V_\kappa^{SS} - 2mc^2 S_\kappa^{SS} \end{pmatrix} ,$$

c_κ^L, c_κ^S are N-vectors, and V_κ^{LL}, V_κ^{SS}, S_κ^{LL}, S_κ^{SS}, Π_κ^{LS} and Π_κ^{SL} are all $N \times N$ matrices. Using superscripts T to denote either of the letters L, S, the elements of the matrices are defined by

$$S_{\kappa ij}^{TT} = \int_0^\infty f_{i\kappa}^{T*}(r) f_{j\kappa}^T(r)\, dr , \qquad (22.138)$$

$$V_{\kappa ij}^{TT} = \int_0^\infty f_{i\kappa}^{T*}(r) V(r) f_{j\kappa}^T(r)\, dr , \qquad (22.139)$$

and

$$\Pi_{\kappa ij}^{LS} = \int_0^\infty f_{i\kappa}^{L*}(r) \left(-\frac{d}{dr} + \frac{\kappa}{r} \right) f_{j\kappa}^S(r)\, dr ,$$
$$\qquad (22.140)$$

$$\Pi_{\kappa ij}^{SL} = \int_0^\infty f_{i\kappa}^{S*}(r) \left(\frac{d}{dr} + \frac{\kappa}{r} \right) f_{j\kappa}^L(r)\, dr . \qquad (22.141)$$

If $f_{i\kappa}^L(r)$ and $f_{i\kappa}^S(r)$ vanish at both $r = 0$ and $r \to \infty$, then a simple integration by parts shows that Π_κ^{LS} and Π_κ^{SL} are Hermitian conjugate matrices.

Physically Acceptable Basis Sets

The four criteria described above are exploited in the following way:

A. The structure of (22.133) ensures (i) that the upper and lower components have properly matched angular behavior. It also emphasizes that the radial parts are part of a spinor structure which should be kept intact when making approximations.

B. The nuclear singularity drives the dynamics of the electronic motion. It is therefore important that

approximate trial solutions should have the correct analytic character as defined in Sects. 22.5.3 and 22.5.4. An expansion of $f_{i\kappa}^L(r)$ and $f_{i\kappa}^S(r)$ at $r = 0$ must reproduce this analytic behavior *exactly* if the approximation is to be physically reliable. The boundary conditions are part of the definition of a quantum mechanical operator; changing them gives a different operator with a different eigenvalue spectrum, so that trial functions which do not satisfy the boundary conditions of the physical problem cannot reproduce the physical solution. The behavior as $r \to \infty$ is less crucial. Provided a bound wavefunction is well approximated over the region containing most of the electron density, the results are insensitive to many choices.

C. The correct reduction of the Dirac equation to Schrödinger's equation in the nonrelativistic limit (for example see [22.4, p. 97]) depends upon the operator identity

$$p^2 = (\sigma \cdot p)(\sigma \cdot p) .$$

In the basis set formalism, the matrix equivalent of this equation is

$$T_{lij} = \frac{1}{2} \sum_{k=1}^N \Pi_{\kappa ik}^{LS} \Pi_{\kappa kj}^{SL} , \qquad (22.142)$$

where

$$T_{lij} = \int_0^\infty f_{i\kappa}^{L*}(r) \frac{1}{2} \left(-\frac{d^2}{dr^2} + \frac{l(l+1)}{r^2} \right) f_{j\kappa}^L(r)\, dr$$

is the ij-element of the nonrelativistic radial kinetic energy matrix. *This is not true in general unless criterion C holds* [22.29, 30]. The criterion can only be satisfied by matched pairs of functions $f_{i\kappa}^L(r)$, $f_{i\kappa}^S(r)$, ruling out all choices of basis set in which large and small components are not matched in pairs. Another way of viewing this result is to observe that for a general basis set, the sum over intermediate states in (22.142) is necessarily incomplete. The Hermitian conjugacy property, $\Pi_{\kappa ij}^{LS} = \Pi_{\kappa ji}^{SL}$ ensures that the omitted terms give real and non-negative contributions. Thus all other choices of basis set cause (22.142) to *underestimate* the nonrelativistic kinetic energy [22.29] and to give spuriously large relativistic energy corrections.

We emphasize that (22.134) need only be true in the limit $c \to \infty$; however, basis sets used for finite values of c should be smooth functions of c^{-1} as $c \to \infty$

so that the equality

$$\mathrm{i}\hbar\,\frac{f_\kappa^S(r)}{r}\,\chi_{-\kappa,m}(\theta,\varphi) = \boldsymbol{\sigma}\cdot\boldsymbol{p}\,\frac{f_\kappa^L(r)}{r}\,\chi_{\kappa,m}(\theta,\varphi) \tag{22.143}$$

holds *in the limit*.

D. This ensures that the basis functions are in the domain of the Dirac operator; the meaning of this statement can be made precise in a functional analytic discussion such as in [22.3]. Some implications for the finite basis set approach are given in the author's paper [22.15, pp. 235–253], which discusses the convergence of expectation values of operators for approximate Dirac wavefunctions obtained by this method. Here the main importance is that a (possibly singular) multiplicative operator $V(r)$ (say, $-Z/r$) has $N\times N$ matrices $\boldsymbol{V}_\kappa^{\mathrm{LL}}$, $\boldsymbol{V}_\kappa^{\mathrm{SS}}$ with *finite* elements. This must be true both for exact solutions and for approximations if the wave functions are to represent physical states. In particular, both matrices must have a *lowest eigenvalue* $V_{\min}^{(N)}$ say. Consider now the quantity $(\psi|\hat{\boldsymbol{h}}_{\mathrm{D}}(\lambda)|\psi)$, where

$$\hat{\boldsymbol{h}}_{\mathrm{D}}(\lambda) = \left(c\boldsymbol{\alpha}\cdot\boldsymbol{p} + \beta m_{\mathrm{e}}c^2\right) + \lambda V(r)\,.$$

With $\lambda = 0$ we have a free Dirac particle with a two-branched continuous spectrum $E > mc^2$ and $E < -mc^2$. A negative definite $V(r)$ has always $(\psi|V(r)|\psi) > V_{\min}$; clearly,

$$V_{\min}^{(N)} \ge V_{\min} > -2mc^2\,, \tag{22.144}$$

for all values of N. So if we increase λ from 0 to 1, the eigenvalues of trial solutions corresponding to eigenvalues in the upper continuum at $\lambda = 0$ will be smoothly decreasing functions of λ bounded below by $V_{\min}$ for all values of N. It follows that *the upper set of eigenvalues has a fixed lower bound* in the gap $\left(-mc^2, mc^2\right)$ for each finite matrix approximation. If the basis set satisfies suitable completeness criteria in an appropriate Hilbert space as $N\to\infty$ (see [22.15, pp. 235–253], [22.31] for more details) we see that, if (22.144) holds for all values of N, the infinite sequence $\{E_{N+i}^{(N)},\ N = N_0, N_0+1, \dots\}$ of eigenvalues approximating the ith bound state has a finite lower bound, and therefore, by the completeness of the real numbers, it must have a limit point E_i in the bound state gap $\left(-mc^2, mc^2\right)$. Thus Rayleigh–Ritz approximations for Dirac's Hamiltonian converge in the same fashion as the corresponding nonrelativistic Rayleigh–Ritz approximations [22.30, 31].

22.6.3 Catalogue of Basis Sets for Atomic Calculations

A. L-Spinors:

L-spinors [22.31] are related to Dirac hydrogenic functions in much the same way as Sturmian functions [22.32, 33] are related to Schrödinger hydrogenic functions (Sect. 22.3). They are solutions of the differential equation system

$$\begin{pmatrix} \dfrac{1}{2} - \dfrac{\alpha_{n_r\kappa} Z\mu^2}{cx} & -\dfrac{\mathrm{d}}{\mathrm{d}x} + \dfrac{\kappa}{x} \\[2mm] \dfrac{\mathrm{d}}{\mathrm{d}x} + \dfrac{\kappa}{x} & -\dfrac{1}{2} - \dfrac{Z}{\alpha_{n_r\kappa}\mu^2 cx} \end{pmatrix} \begin{pmatrix} \dfrac{f_{n_r\kappa}^L(x)}{\mu} \\[2mm] \mu f_{n_r\kappa}^S(x) \end{pmatrix} = 0\,, \tag{22.145}$$

where $x = 2\lambda r$ is a scaled radial coordinate, with fixed λ which can be related to an energy parameter $E_0^R = c^2\sqrt{1 - \lambda^2/c^2}$, and μ^2, a root of the equation $\mu^4 - 2c\mu^2/\lambda + 1 = 0$, is given by

$$\mu^2 = \frac{c}{\lambda}\left(1 + E_0^R/c^2\right)\,. \tag{22.146}$$

This choice ensures that $f_{n_r\kappa}^L(x)$ tends smoothly to the corresponding Coulomb Sturmian in the nonrelativistic limit $c\to\infty$ [22.31]. L^2 boundary conditions are satisfied if $\alpha_{n_r\kappa} = N_{n_r\kappa}\lambda/Z$; when $\alpha_{n_r\kappa} = 1$, then $f_{n_r\kappa}^L(x)$, $f_{n_r\kappa}^S(x)$ respectively coincide with the Dirac–Coulomb eigenfunctions $P_{n\kappa}(r)$ and $Q_{n\kappa}(r)$ having principal quantum number $n = n_r + |\kappa|$. The explicit form for L-spinors, in terms of Laguerre polynomials (see Sect. 9.3.2), $L_{n_r}^{(2\gamma)}(x)$, is

$$f_{\kappa,n_r}^{(L)}(x) = \mathcal{N}_{n_r,\kappa}\, x^\gamma \mathrm{e}^{-x/2}\Bigg[-(1-\delta_{n_r,0}) L_{n_r-1}^{(2\gamma)}(x)$$
$$+ \frac{(N_{n_r,\kappa}-\kappa)}{(n_r+2\gamma)} L_{n_r}^{(2\gamma)}(x)\Bigg]\,, \tag{22.147}$$

$$f_{\kappa,n_r}^{(S)}(x) = \mathcal{N}_{n_r,\kappa}\, x^\gamma \mathrm{e}^{-x/2}\Bigg[-(1-\delta_{n_r,0}) L_{n_r-1}^{(2\gamma)}(x)$$
$$- \frac{(N_{n_r,\kappa}-\kappa)}{(n_r+2\gamma)} L_{n_r}^{(2\gamma)}(x)\Bigg]\,, \tag{22.148}$$

where

$$\mathcal{N}_{n_r\kappa} = \left(\frac{n_r!\,(2\gamma+n_r)}{2N_{n_r\kappa}(N_{n_r\kappa}-\kappa)\,\Gamma(2\gamma+n_r)}\right)^{1/2} \tag{22.149}$$

is chosen so that the diagonal elements g_{n_r,n_r}^κ of the Gram (or overlap) matrix are unity for both large and

small components. Both Gram matrices are tri-diagonal with non-zero off-diagonal elements

$$
\begin{aligned}
g_{n_r,(n_r+1)}^{(\kappa)} &= g_{(n_r+1),n_r}^{(\kappa)} \\
&= \frac{\eta^T}{2} \left(\frac{(n_r+1)(2\gamma+n_r+1)(N_{n_r\kappa}-\kappa)}{N_{n_r\kappa} N_{(n_r+1),\kappa}(N_{(n_r+1),\kappa}-\kappa)} \right)^{1/2},
\end{aligned}
$$

(22.150)

where $T = L, S$, $\eta^L = -1$ and $\eta^S = +1$. This convention facilitates the construction of the blocks of the matrix Hamiltonian (22.137), which are banded when the operators are the powers r^n, $n > -1$. The properties of Laguerre polynomials ensure that the matrix of the Coulomb potential is diagonal. For a full discussion of L-spinors, their orthogonality and completeness properties, and applications to hydrogenic atoms see [22.31].

L-spinors are most useful for hydrogenic problems, either for isolated atoms or for atoms in strong electromagnetic fields (see Chapt. 13). The equivalent nonrelativistic Coulomb Sturmians have for a long time been used to study the Zeeman effect on high Rydberg levels, especially in the region where chaotic behavior is expected [22.34] (see Chapt. 15).

B. S-Spinors:

S-spinors have the functional form of *the most nearly nodeless* L-spinors characterized by the minimal value of n_r, and can be viewed as the relativistic analogues of Slater functions (STOs). When κ is negative, take $n_r = 0$, so that

$$
\begin{aligned}
f_{\kappa,0}^{(L)}(x) &= -f_{\kappa,0}^{(S)}(x) \\
&= \mathcal{N}_{\kappa,0}\, x^\gamma \exp(-x/2) \frac{N_{0,\kappa}-\kappa}{2\gamma} L_0^{(2\gamma)}(x) .
\end{aligned}
$$

When κ is positive, we must take $n_r = 1$, and then

$$
\begin{aligned}
f_{\kappa,1}^{(L)}(x) &= \mathcal{N}_{1,\kappa}\, x^\gamma e^{-x/2} \\
&\quad \times \left[-L_0^{(2\gamma)}(x) + \frac{N_{1,\kappa}-\kappa}{1+2\gamma} L_1^{(2\gamma)}(x) \right], \\
f_{\kappa,1}^{(S)}(x) &= \mathcal{N}_{1,\kappa}\, x^\gamma e^{-x/2} \\
&\quad \times \left[-L_0^{(2\gamma)}(x) - \frac{N_{1,\kappa}-\kappa}{1+2\gamma} L_1^{(2\gamma)}(x) \right].
\end{aligned}
$$

These can be simplified by inserting the explicit expressions $L_0^{(2\gamma)}(x) = 1$, $L_1^{(2\gamma)}(x) = 2\gamma + 1 - x$. We define a *set of* S-*spinors* with exponents $\{\lambda_m, m = 1, 2, \ldots, N\}$ by rewriting the above in the form

$$
f_m^{(T)}(r) = A^T g_m(\gamma, r) + B^T g_m(\gamma+1, r) ,
$$

(22.151)

where $T = L, S$, $g_m(\theta, r) = r^\theta e^{-\lambda_m r}$,

$$
\begin{aligned}
A^L &= A^S = 1, \ B^L = B^S = 0 \quad \text{for } \kappa < 0 , \\
A^L &= \frac{(\kappa+1-N_{1,\kappa})(2\gamma+1)}{2(N_{1,\kappa}-\kappa)} \\
A^S &= \frac{(\kappa-1-N_{1,\kappa})(2\gamma+1)}{2(N_{1,\kappa}-\kappa)} \Bigg\} \quad \text{for } \kappa > 0 , \\
B^L &= B^S = 1
\end{aligned}
$$

(22.152)

and

$$
\gamma = \sqrt{\kappa^2 - Z^2/c^2}, \quad N_{1,\kappa} = \sqrt{\kappa^2 + 2\gamma + 1} .
$$

The choice of the set of positive real exponents $\{\lambda_m, m = 1, 2, \ldots, N\}$, must be such as to assure Rayleigh–Ritz convergence [22.15, pp. 235–253)] and to maximize the rate at which it is attained. In particular, if *one* particular exponent is chosen to have the value $\lambda_m = Z/N_{n_r,\kappa}$, then the corresponding S-spinor is a true hydrogenic solution. In this case the trial solution is exact. Clearly, S-spinors inherit desirable properties of L-spinors and, in particular, satisfy criteria A–D.

All elements of the matrix Hamiltonian of the Dirac hydrogenic problem can be expressed in terms of Euler's integral for the gamma function [22.22, Sect. 6.1.1]:

$$
\Gamma(z) = k^z \int_0^\infty t^{z-1} e^{-kt}\, \mathrm{d}t , \quad (\mathcal{R}z > 0 , \ \mathcal{R}k > 0)
$$

and are therefore readily written down and evaluated. The effectiveness of this method depends upon the choice of exponent set: see D below. We refer to calculations using this scheme for many-electron systems in Sect. 22.7.

C. G-Spinors:

The G-spinors are the relativistic analogues of nonrelativistic spherical Gaussians (SGTO), popular in quantum chemistry for studying the electronic structure of atoms and molecules. They satisfy the relativistic boundary conditions for a *finite size* nuclear charge density distribution at $r = 0$, and are therefore the most convenient for relativistic molecular electronic structure calculations. They are defined so that (22.143) holds for finite c as well as in the nonrelativistic limit, which is equivalent to

$$
f_m^{(S)}(r) = \text{const.} \left(\frac{\mathrm{d}}{\mathrm{d}r} + \frac{\kappa}{r} \right) f_m^{(L)}(r) .
$$

(22.153)

Thus, if

$$f_m^{(L)}(r) = \mathcal{N}_{l,m}^{(L)}\, r^{l+1} \mathrm{e}^{-\lambda_m r^2}\, , \qquad (22.154)$$

$$f_m^{(S)}(r) = \mathcal{N}_{l,m}^{(S)} \left[(\kappa+l+1)r^l - 2\lambda_m r^{l+2} \right] \mathrm{e}^{-\lambda_m r^2}\, . \qquad (22.155)$$

Note that the leading term in (22.155) vanishes when $\kappa < 0$, so that the radial amplitude $r^{-1} f_m^{(S)}(r)$ is never singular, even in the s-state case when $\kappa = -1$, $l = 0$.

D. Exponent Sets for S- and G-Spinors:

Quantum chemists are familiar with the use of nonrelativistic STO and GTO basis sets, and there are extensive collections of optimized exponents which permit economical calculations for atomic and molecular calculations [22.35–37]. These sets are a good starting point for relativistic calculations also. By and large, the compilations ignore mathematical completeness, which although desirable is unattainable in practice. However, basis sets can almost always be constructed to give adequate numerical precision for most purposes.

An effective alternative to optimization, especially for atoms, is to use geometrical sequences $\{\lambda_m\}$ of the form

$$\lambda_m = \alpha_N \beta_N^{m-1}, \qquad m = 1, 2, \dots, N\, , \qquad (22.156)$$

which depend upon just two parameters α_N, β_N. A convenient way to do this is to find a pair α_{N_0}, β_{N_0} for small N_0, say $N_0 = 9$, in a cheap and simple nonrelativistic calculation and then to increase N systematically using relations such as

$$\frac{\alpha_N}{\alpha_{N_0}} = \left(\frac{\beta_N - 1}{\beta_{N_0} - 1} \right)^a, \quad \text{or} \quad \frac{\ln \beta_N}{\ln \beta_{N_0}} = \left(\frac{N_0}{N} \right)^b\, ,$$

where a, b are positive constants. Experience shows that no linear dependence problems (caused by ill-conditioning of the S^T matrices) are encountered when $\beta_N > 1.2$ for S-spinors, with N up to about 30, or $\beta_N > 1.5$ for G-spinors with N up to about 50.

E. Other Types of Analytic Basis Sets; Variational Collapse:

The earliest work with atoms [22.38, 39] used STO functions of the form $\{r^\gamma \exp(-\lambda_m r), \ m = 1, \dots N\}$ for both large and small components, whilst *Kagawa* [22.40, 41] used integer powers instead of the noninteger γ. *Drake* and *Goldman* [22.42] used functions of the form

$\{r^{\gamma+i} \exp(-\lambda r), i = 0, \dots N - 1\}$. For hydrogenic problems, these worked well for negative κ states, but gave a single spurious eigenvalue for positive κ, which could be simply deleted from the basis set. Various test calculations are included in the review article [22.43, Sect. IV]. Other attempts to use GTOs in the early 1980's led to problems interpreted as a failure of the Rayleigh–Ritz method because of the presence of "negative energy states" with a spectrum unbounded below: so-called "variational collapse". It is clear that all these approaches fail to observe three, and sometimes all, of the four criteria for acceptable basis sets. They are incapable of satisfying the physical boundary conditions, and it is therefore hardly surprising that they give unphysical spectra.

Several procedures have been advocated to overcome the problem, of which the two most popular are "kinetic balance" and projection operators. Kinetic balance, suggested by *Lee* and *McLean* [22.44], advocates augmenting a GTO basis, common to both large and small components, with additional functions to "balance the set kinetically". This appears to "fix up" the problem for the upper spectrum, but introduces spurious states, mainly in the lower part of the spectrum, as well as increasing the size of the small component basis set. There is no rigorous nonrelativistic limit, and no mathematical proof of convergence such as that guaranteed by criteria A–D. A model with spurious negative energy states cannot furnish a consistent physical interpretation of negative energy solutions as positron states, expected of a proper relativistic theory.

If "variational collapse" is attributed to the absence of a lower bound to the Dirac spectrum as a whole, the idea of introducing a projection operator to eliminate collapse seems attractive. This is easy to do for free electrons, where the operators

$$\Lambda^\pm = \frac{\hat{h}_{\mathrm{D}} \pm E}{2|E|}\, ,$$

select positive/negative energy solutions. Unfortunately, this cannot be done in the presence of a potential except by an approximation which complicates calculations and reduces the efficiency of algorithms. The "negative energy sea" also depends upon the choice of potential; perturbing the potential (as long as it does not change the domain of the Hamiltonian) induces a unitary transformation taking one set of eigenstates into another which inevitably mixes the old positive and negative energy states. For example a relativistic calculation on a hydrogenic atom in which the nuclear

charge is perturbed gives incorrect answers if the negative energy contribution to the perturbation series is omitted [22.45].

In any event, the finite matrix eigensolutions include both positive energy and negative energy states. It is therefore a simple matter to exclude the negative energy states if their contribution is expected to be negligible; this is the *no virtual-pair approximation*. The negative energy solutions are inert spectators for most atomic processes, just as are those positive energy solutions which lie deep in the atomic core. It is easy to go beyond the no virtual-pair approximation if the physical problem demands it.

Finite Element Methods:

Johnson et al. [22.46, 47], following earlier work on relativistic ion–ion collisions by *Bottcher* and *Strayer* [22.48], popularized the use of a basis of B-splines in relativistic atomic calculations. See Sect. 8.1.1. The method has mainly been of use in relativistic many-body calculations on the spectra of heavy ions. See Sect. 21.6 for spline-Galerkin representations in nonrelativistic atomic structure, such as [22.49]. *Parpia* and *Fischer* explored the spline-Galerkin approach for the Dirac equation [22.50], but this method has not been extended so far to relativistic many-electron atoms.

22.7 Many–Body Calculations

22.7.1 Atomic States

The construction of atomic many-electron wavefunctions from products of central field Dirac orbitals is employed to simplify the algorithms for calculating electronic structures and properties. This can be either in the context of expansions in Slater determinants of the traditional type, or by use of Racah algebra. A complete description of the methods of the latter sort used in popular computer codes is found in [22.27, Sect. 2].

22.7.2 Slater Determinants

An antisymmetric state of N independent electrons in configuration space can be constructed in the form

$$\{\alpha_1, \alpha_2, \dots, \alpha_N\} \tag{22.157}$$
$$= \langle \boldsymbol{x}_1, \boldsymbol{x}_2, \dots, \boldsymbol{x}_n | a_{\alpha_1}^\dagger a_{\alpha_2}^\dagger \cdots a_{\alpha_N}^\dagger |0\rangle$$
$$= \frac{1}{N!} \begin{vmatrix} \psi_{\alpha_1}(\boldsymbol{x}_1) & \psi_{\alpha_2}(\boldsymbol{x}_1) & \cdots & \psi_{\alpha_N}(\boldsymbol{x}_1) \\ \psi_{\alpha_1}(\boldsymbol{x}_2) & \psi_{\alpha_2}(\boldsymbol{x}_2) & \cdots & \psi_{\alpha_N}(\boldsymbol{x}_2) \\ \cdots & \cdots & \cdots & \cdots \\ \psi_{\alpha_1}(\boldsymbol{x}_N) & \psi_{\alpha_2}(\boldsymbol{x}_N) & \cdots & \psi_{\alpha_N}(\boldsymbol{x}_N) \end{vmatrix}$$

This *Slater determinant* is an antisymmetric eigenfunction of H_0 corresponding to the energy $\sum E_{\alpha_n}$ and of the angular momentum projection $J_3 = \sum j_{3,\alpha_n}$ corresponding to the eigenvalue $M_3 = \sum m_{3,\alpha_n}$. Defining the parity of a Dirac electron orbital as that of its upper component, $(-1)^{l_{\alpha_n}}$, we see that this has parity $\Pi(-1)^{l_{\alpha_n}}$.

22.7.3 Configurational States

Configurational state functions (CSF) having specified total angular momentum J and parity Π can be constructed by vector addition of the individual angular momenta: $\boldsymbol{J} = \sum \boldsymbol{j}_{\alpha_n}$. We write such states as

$$\phi(\gamma J M) = \sum_{\{m_{\alpha_n}\}} \langle \gamma J M | m_{\alpha_1}, m_{\alpha_2} \dots, m_{\alpha_N} \rangle \times \{\alpha_1, \alpha_2, \dots, \alpha_N\} , \tag{22.158}$$

where $\langle \gamma J M | m_{\alpha_1}, m_{\alpha_2} \dots, m_{\alpha_N} \rangle$ is a generalized Clebsch–Gordon coefficient, and γ defines the angular momentum coupling scheme.

A list of orbital quantum numbers, $\{\alpha_1, \alpha_2, \dots, \alpha_N\}$ defines an electron *configuration*. If the configuration belongs to a single subshell, then the states share a common set of labels $\{n, \kappa\}$ where n is the principal quantum number. In $j - j$ coupling, the α-subshell states of N_α equivalent electrons can therefore be identified (we can suppress the projection M_α and the parity Π_α) by the labeling α^{N_α}, γ_α, J_α, where γ_α distinguishes degenerate states of the same J_α. For $j - j$ coupling, such labels are needed only for $j \geq \frac{5}{2}$; the *seniority scheme*, [22.27, Sects. 2.3, 2.4)], provides a complete classification for $j < \frac{9}{2}$. A list of states of configurations j^N, classified in terms of the *seniority number* v and of *total angular momentum* J, appears in Table 22.5.

22.7.4 CSF Expansion

Atomic state functions (ASF) are linear superpositions of CSF's, of the form

$$\Psi(\gamma \Pi J) = \sum_{\alpha=1}^{N} c_\alpha \phi(\gamma_\alpha J) , \tag{22.159}$$

where c_α are a set of (normally) real coefficients. These coefficients are usually chosen so that $\Psi(\gamma \Pi J)$ is an

Table 22.5 j^N configurational states in the seniority scheme. The multiplicity of each unresolved degenerate state is indicated by a superscript

j	N	v	J

eigenstate of the many-electron Hamiltonian matrix in a finite subspace of CSF's.

22.7.5 Matrix Element Construction

A full presentation of the reduction of matrix elements between CSF's to computable form is beyond the scope of this chapter. There are two approaches: one is based on expanding all CSF's and ASF's in Slater determinants, whilst the other exploits the properties of central field orbital spinors. The principles underlying the first are straightforward and may be found in atomic physics texts and review articles such as [22.26, 27].

The use of second quantization and diagrammatic methods of the quantum theory of angular momentum provides a powerful means of reducing matrix elements between atomic CSF's to a linear combination of radial integrals in a systematic way. The method, which is fully explained in [22.27], leads to a complete classification of matrix element expressions for all the one- and two-electron operators treated in this chapter. A full implementation within the $j - j$ coupling seniority scheme is available in various versions of the GRASP code [22.51–53].

22.7.6 Dirac–Hartree–Fock and Other Theories

The notation above echoes that of the nonrelativistic theory of Chapt. 21, and it is possible to proceed along similar lines.

Dirac–Hartree–Fock Theory

Dirac–Hartree–Fock theory works exactly as described in Sect. 21.4; relativistic counterparts of Koopmans' theorem, fixed-core approximations, Brillouin's theorem are easy to obtain. The properties of Dirac–Hartree–Fock functions closely resemble those of Hartree–Fock functions, though allowance must be made for the fact that, for example, np orbitals $\left(\text{with } \kappa = -2, \; j = \frac{3}{2}\right)$ and $n\bar{p}$ orbitals $\left(\text{with } \kappa = +1, \; j = \frac{1}{2}\right)$ have different spatial distributions as a consequence of the dynamical and indirect effects of relativity. For further insight see [22.23, 26].

Most such calculations are currently made with updated versions of the codes of *Desclaux* [22.54] or *Grant* [22.51–53] which rely on finite difference methods resting on the techniques of Sect. 22.6.1. Further details may be found in the code descriptions.

Finite Matrix Methods for Atoms and Molecules

In view of the rapid pace of development of finite matrix methods, especially for the treatment of relativistic molecular electronic structure in the Born–Oppenheimer (fixed nucleus) approximation, it seems appropriate to give a brief outline of the extension of the one-electron equations of Sect. 22.4.2 to the many-electron case.

The method of approximation generalizes the one-body approximation scheme of Sect. 22.6.2 to the many-body problem based on the effective Hamiltonian of

Sect. 22.4.1. This leads to an energy functional of the form

$$E = E_0 + E_1 \tag{22.160}$$

where E_0 is the expected value of H_0 (22.76) and E_1 the expected value of H_1 for the finite basis many-body trial function. This leads to matrix Dirac–Fock equations of the form

$$FX = ESX . \tag{22.161}$$

In general, the Fock matrix F is a sum of several matrices

$$F = f + g + b , \tag{22.162}$$

where, for each symmetry κ and nuclear center, A, of the molecule, f can be partitioned into blocks

$$f_{A\kappa} = \begin{pmatrix} V_{A\kappa}^{LL} & c\Pi_{A\kappa}^{LS} \\ c\Pi_{A\kappa}^{SL} & V_{A\kappa}^{SS} - 2mc^2 S_{A\kappa}^{SS} \end{pmatrix} . \tag{22.163}$$

The matrix

$$g = \begin{pmatrix} J^{LL} - K^{LL} & -K^{LS} \\ -K^{SL} & J^{SS} - K^{SS} \end{pmatrix} \tag{22.164}$$

is the matrix of the Coulomb repulsion part of the electron–electron interaction and

$$b = \begin{pmatrix} B^{LL} & B^{LS} \\ B^{SL} & B^{SS} \end{pmatrix} . \tag{22.165}$$

is the matrix of the Breit interaction.

In the atomic (one nuclear center) case, following [22.55], these matrices can also be blocked by symmetry κ. Using superscripts T to label the L or S components, and the notation $\bar{T}$ to denote the complementary label: $\bar{T} = S$ when $T = L$ or $\bar{T} = L$ when $T = S$, then the direct Coulomb part J_κ^{TT} has matrix elements

$$J_{\kappa pq}^{TT} = \sum_{\kappa' rs} (2j'+1) \left(D_{\kappa' rs}^{TT} J_{\kappa pq,\kappa' rs}^{0,TTTT} + D_{\kappa' rs}^{\bar{T}\bar{T}} J_{\kappa pq,\kappa' rs}^{0,TT\bar{T}\bar{T}} \right) , \tag{22.166}$$

whilst the exchange part $K_\kappa^{TT'}$ has the form

$$K_{\kappa pq}^{TT'} = \sum_{\kappa' rs} \sum_\nu (2j'+1) b_\nu(jj') D_{\kappa' rs}^{TT'} K_{\kappa pq,\kappa' rs}^{\nu,TT'TT'} , \tag{22.167}$$

where TT' denotes any combination of component labels. Here $D_\kappa^{TT'}$ is a density matrix with elements

$$D_{\kappa pq}^{TT'} = c_{\kappa p}^{T*} c_{\kappa q}^{T'} , \tag{22.168}$$

where $c_{\kappa p}^T$ are the expansion coefficients. The Breit interaction matrices have the similar form

$$B_{\kappa pq}^{TT} = \sum_{\kappa' rs} \sum_\nu (2j'+1) e_\nu(jj') D_{\kappa' rs}^{\bar{T}\bar{T}} K_{\kappa pq,\kappa' rs}^{\nu,TT\bar{T}\bar{T}} , \tag{22.169}$$

and

$$B_{\kappa pq}^{T\bar{T}} = \sum_{\kappa' rs} \sum_\nu (2j'+1) D_{\kappa' rs}^{\bar{T}T}$$
$$\times \left[d_\nu(\kappa\kappa') K_{\kappa pq,\kappa' rs}^{\nu,T\bar{T}\bar{T}T} + g_\nu(\kappa\kappa') M_{\kappa pq,\kappa' rs}^{\nu,T\bar{T}\bar{T}T} \right] . \tag{22.170}$$

The matrix elements are constructed from standard radial integrals

$$J_{\kappa pq,\kappa' rs}^{\nu,TTT'T'} = \int_0^\infty \int_0^\infty f_{\kappa p}^T(r_1) f_{\kappa q}^T(r_1) U_\nu(r_1, r_2)$$
$$\times f_{\kappa' r}^{T'}(r_2) f_{\kappa' s}^{T'}(r_2) \, dr_2 \, dr_1 \tag{22.171}$$

where

$$U_\nu(r_1, r_2) = \begin{cases} r_1^\nu / r_2^{\nu+1} & \text{for } r_1 < r_2 , \\ r_2^\nu / r_1^{\nu+1} & \text{for } r_1 > r_2 . \end{cases}$$

Similarly

$$K_{\kappa pq,\kappa' rs}^{\nu,TT'TT'} = J_{\kappa p,\kappa' r,\kappa q,\kappa' s}^{\nu,TTT'T'} \tag{22.172}$$

and

$$M_{\kappa pq,\kappa' rs}^{\nu,T\bar{T}\bar{T}T} = \int_0^\infty \int_{r_1}^\infty f_{\kappa p}^T(r_1) f_{\kappa' r}^{\bar{T}}(r_1) U_\nu(r_1, r_2)$$
$$\times f_{\kappa q}^{\bar{T}}(r_2) f_{\kappa' s}^T(r_2) \, dr_2 \, dr_1 . \tag{22.173}$$

Further details about the coefficients $b_\nu(jj')$, $e_\nu(jj')$, $d_\nu(\kappa\kappa')$ and $g_\nu(\kappa\kappa')$ may be found in [22.55].

This formalism has been implemented for closed shell atoms with both S-spinors and G-spinors [22.55]. Computational aspects of calculating the radial integrals using S-spinors are discussed in [22.56, 57], and can be adapted with relatively small modifications to G-spinor basis sets. As yet, there have been relatively few applications by comparison with codes based on finite difference methods, but the potential can be gauged from papers such as [22.55, 58–61], which deal with Dirac–Fock and Dirac–Fock–Breit calculations, many-body perturbation theory and coupled-cluster schemes.

G-spinor basis sets provide the most promising technique for application to the electronic struc-

ture of molecules; computer codes are under active development.

Electron Correlation in Atomic Calculations

Here we use the term *correlation* to denote methods which go beyond the single determinant approximation of Dirac–Hartree–Fock theory. These include *configuration interaction* schemes, in which each ASF is represented as a linear combination of CSF's built from previously determined orbital spinors and *multiconfiguration Dirac–Fock* calculations in which the orbitals are optimized simultaneously. Calculations representative of state of the art techniques will be found in [22.62, 63].

Many-body perturbation theory calculations and coupled-cluster calculations are not well suited to calculations with finite difference codes, because of the expense of calculating more than a limited orbital basis and all the matrix elements required. Calculations based on finite matrix methods enable this sort of calculation to be done more economically. Some justification for the use of finite matrix methods in relativistic many-body theory is given in [22.15, pp. 235–253].

The relativistic version of quantum defect theory [22.64, 65] also gives insight into the competing roles of relativistic dynamics and screening in atoms. Compared with nonrelativistic quantum defect theory, it has been under-used.

22.7.7 Radiative Corrections

The term "radiative corrections" is usually interpreted to mean QED contributions to energies, expectation values or rates of atomic or molecular processes that arise from interaction between the electron–positron and photon fields, apart from those directly attributable to the nonrelativistic Coulomb interaction. This includes the relativistic and retardation effects embodied in the effective interaction between electrons as well as contributions from processes that are not so included. We consider two such processes, the electron self-energy and the vacuum polarization, which involve interactions of the same formal order as those giving rise to the covariant electron–electron interaction discussed above, but which are formally infinite. These are the lowest order processes requiring renormalization. See [22.7, 8, 10, 15] for more details.

Electron Self–Energy

For a one-electron system, the renormalized expression for the self-energy of an electron in the state *a*

in Feynman gauge is

$$
\begin{aligned}
\Delta E_a = \lim_{\Lambda \to \infty} \mathcal{R} \Bigg[&-\mathrm{i}\alpha\pi . mc^2 \int \bar{\psi}_a(x_2) \gamma^\mu S_{\mathrm{F}}(x_2, x_1) \\
&\times \gamma^\nu \psi_a(x_1) g_{\mu\nu} D_{\mathrm{F}}^\Lambda(x_2 - x_1) \, \mathrm{d}^3 x_2 \, \mathrm{d}^3 x_1 \\
&\times \mathrm{d}(t_2 - t_1) - \delta m(\Lambda) \langle \psi_a | \beta | \psi_a \rangle \Bigg],
\end{aligned}
$$

(22.174)

where

$$
\delta m(\Lambda) = \frac{\alpha}{\pi} mc^2 \left[\frac{3}{4} \ln(\Lambda^2) + \frac{3}{8} \right] .
$$

This represents the contribution from virtual processes involving the exchange of a single photon. The photon propagator has been modified to give the photon and effective mass Λ, so that the denominator of $D(q^2)$ (22.69) becomes $q^2 - \Lambda^2 + \mathrm{i}\delta$. The two parts of this formula diverge as $\Lambda \to \infty$, though the limit of their difference is finite. This makes calculation difficult and expensive. There are several approaches:

1. For atomic number $Z \lesssim 20$, an expansion in powers of the electron–nucleus coupling parameter $\alpha Z = Z/c$ is satisfactory.
2. At larger atomic numbers an expansion in αZ evidently fails to converge, and nonperturbative methods must be sought. This too is computationally difficult and expensive. The results for hydrogenic ions have been tabulated [22.66] for atomic numbers in the range $1 \leq Z \leq 100$. (See [22.10, Chapt. 2] for an up-to-date summary biased towards applications to the spectroscopy of highly-ionized atoms.)
3. Processes involving more than one virtual photon are hard to calculate, and have mostly been ignored. See [22.10] for references.

Vacuum Polarization

The contribution of vacuum polarization is next in order of importance in the list of radiative corrections in atoms. As shown by (22.49), the nuclear potential generates a current in the vacuum that is responsible for a short-range screening of the nuclear charge. This can be represented as a local perturbing potential which is easy to take into account [22.67–69].

22.7.8 Radiative Processes

The operator $j^\mu(x) A_\mu(x)$ which occurs in the interaction Hamiltonian (22.61) describes processes in

which the number of photons present can increase or decrease by one. The Fock space operator may be written

$$H_{\text{int}} = \sum_{a,b} \sum_{\rho} \left[a_a^\dagger a_b q_\rho^\dagger M_{ab}^{(\rho)\dagger}(t) + a_a^\dagger a_b q_\rho M_{ab}^{(\rho)}(t) \right] ,$$

(22.175)

where the first set of terms in the sum represents emission of a photon in the mode labeled ρ and the second to absorption of a photon by the same initial state. The operators a_a and $a_a^\dagger$ are anticommuting annihilation and creation operators of electrons, whilst q_ρ and $q_\rho^\dagger$ are *commuting* annihilation and creation operators of photons. If ω denotes photon frequency, then

$$M_{ab}^{(\rho)\dagger}(t) = M_{ab}^{(\rho)} e^{i(E_a - E_b + \omega)t} ,$$

$$M_{ab}^{(\rho)}(t) = M_{ab}^{(\rho)} e^{i(E_a - E_b - \omega)t} ,$$

where

$$M_{ab}^{(\rho)} = \left(\frac{\omega}{\pi c} \right)^{1/2} \int \psi_a^\dagger(\boldsymbol{x}) \left[\boldsymbol{\Phi}^{(\rho)}(\boldsymbol{x}) + c\boldsymbol{\alpha} \cdot \boldsymbol{A}^{(\rho)}(\boldsymbol{x}) \right]$$
$$\times \psi_b(\boldsymbol{x}) \, \mathrm{d}^3 x$$

is the transition amplitude. For a discussion of this expression including the effect of gauge transformations on the computed amplitudes, the elimination of angular coordinates for atomic central field orbitals and connection with the nonrelativistic limit, see [22.10, 16, 27].

22.8 Recent Developments

22.8.1 Technical Advances

Relativistic atomic structure continues to develop to meet modern demands for high quality calculations on many-electron atoms. The computing power now available makes it possible to carry out multi-configurational Dirac–Hartree–Fock (MCDHF) or configuration interaction (CI) calculations on a scale unimaginable when this chapter was first drafted. Some of the software currently available is surveyed below.

On the theoretical side, there have been new technical applications of tensor operator theory. Whilst the approach initiated by *Fano* [22.27, 70] continues to be the basis on which many relativistic and nonrelativistic calculations are based, recent work aims to simplify the calculation, not only by exploiting second quantization techniques and the coupling of tensor operators, but by better utilization of quasispin methods [22.71–74]. A new *jj*-coupling package along these lines [22.75] has been constructed for evaluation of fractional parentage coefficients, reduced fractional parentage coefficients (in which the dependence on particle number is extracted as a quasispin $3j$-symbol), matrix elements of unit tensors T^k and double tensor operators $W^{k_q k_j}$, from which to construct many-particle matrix elements of physical operators. *Fritzsche* et al. [22.76–80] have recently published utilities which exploit the capabilities of the Maple computer algebra system to evaluate Racah algebra expressions.

22.8.2 Software for Relativistic Atomic Structure and Properties

Many software packages for relativistic atomic physics calculations can now be downloaded from the internet. The earliest codes, which generate many-electron wavefunctions and bound energy levels, taking account of the full relativistic electron–electron interaction and QED corrections, of *Desclaux* [22.54] and *Grant* et al. [22.51], though now much modified, are still in use, as is the code of *Chernysheva* and *Yakhontov* [22.81]. These codes can use various (MC)DHF and CI procedures, albeit with not more than a few hundred CSF. A more recent version of Grant et al.'s code appeared in 1989 [22.52] and GRASP92 embodied major changes to the user interface and to file-handling to permit calculations with very large CSF sets [22.53]. Most earlier calculations were of the AL or EAL type, in which a large number of states are treated together using a common orbital set. These are cheap and work well for highly ionized, few-electron systems but the results only have modest accuracy. More accurate treatment of electron correlation requires MCDHF calculations on single levels (OL calculations) or small groups of fine structure levels (EOL calculations). The CSF sets are chosen through some active space (AS) procedure as in nonrelativistic MCHF [22.82]; complete active spaces (CAS) are often too large for practical use, so that the AS must be restricted in some way, for example by using only SD (single and double) replacements from the reference CSF set. With such large CSF basis sets it is not

practical or desirable to diagonalize the complete Hamiltonian matrix, and *Davidson*'s version [22.83, 84] of the Lanczos algorithm, as implemented by *Stathopoulos* and *Fischer* [22.85], is used in GRASP92 to construct the small number of eigenvalues and eigenvectors of physical importance.

This approach generally gives highly accurate wavefunctions and energy levels for a small number of atomic states. Each state is determined in a separate SCF calculation, and therefore has *its own set of orbitals*. The GRASP software for calculating radiative transition probabilities was based on the assumption that initial and final states of a transition are described by *the same orbital set*. Most if this machinery can still be used by way of a procedure to express sets of non-orthogonal orbitals as a biorthonormal system [22.86]. An adaptation for GRASP92 was used, for example, to calculate radiative transition probabilities for lines of the C III spectrum [22.87] and the oscillator strengths of the $n\,\mathrm{d}\,^2\mathrm{D}_{3/2} - (n+1)\mathrm{p}\,^2\mathrm{P}^0_{1/2,3/2}$ lines in Lu ($n = 5$) and Lw ($n = 6$) which are very sensitive to correlation effects [22.88]. These two calculations involved CSF sets of order 300,000. Desclaux's code, which uses an expansion of the many-electron wavefunction in determinantal wavefunctions rather than the Fano approach using *jj*-coupled CSFs, has similarly been modernized [22.89]; its capabilities are rather similar to those of GRASP. There is no published description.

GRASP92 has been enhanced recently with new utilities to calculate hyperfine interactions [22.90–92] and isotope shifts [22.93]. *Fritzsche* et al. have developed a new suite of programs, RATIP (an acronym for Relativistic Atomic Transition and Ionization Properties), which uses MCDHF wavefunctions from GRASP92 to study a range of atomic properties [22.94, 95]. Like Desclaux's package, this expresses *jj*-coupled symmetry functions in terms of Slater determinants [22.96] and also provides the relevant utilities for coefficients of fractional parentage and the calculation of angular coefficients. The package supports CI calculations of ASF and energy levels taking account of the Breit interaction and QED estimates. A new utility [22.97] permits calculation of relaxed orbital radiative transition probabilities and lifetimes within the RATIP framework. The code generates continuum orbitals, which enable calculation of Auger energies, relative intensities and angular distributions, and should also enable calculation of photoionization cross-sections and angular distributions. The papers cited contain information on how to obtain the programs, many of which are also obtainable from the Computer Physics Communications International Program Library [22.98].

23. Many-Body Theory of Atomic Structure and Processes

All atoms except hydrogen are many-body systems, in which the interelectron interaction plays an important or even decisive role. The aim of this chapter is to describe a consistent method for calculating the structure of atoms and the characteristics of different atomic processes, by applying perturbation theory to take into account the interelectron interaction. This method involves drawing a characteristic diagram based on the structure or process. This is then used to create an analytical expression to the lowest order in the interelectron interaction. Higher-order corrections are subsequently generated.

This technique was invented about half a century ago in quantum electrodynamics by *Feynman* [23.1], then modified and adjusted for multiparticle systems by a number of authors. Its application to atomic structure and atomic processes required further modifications, which were initiated at the end of the fifties (see, e.g., [23.2]) and later. The corresponding technique was successfully applied to the calculation of a wide variety of characteristics and processes in many papers and several review articles [23.3, 4]. The increasing amount of experimental data available has led to improved accuracy for this technique, so that it can be applied to current problems considering not only atoms and ions, both positive and negative [23.5–8], but also molecules [23.9], clusters [23.10] and fullerenes.

The elements of the diagrammatic technique, which form a convenient and simple "language", are given together with the rules for creating "sentences" using basic "words". A kind of "dictionary" helps to translate diagrammatic "sentences" into analytical expressions suitable for calculations.

An essential part of the program is to learn how the simplest approximation can be improved, and what are the mechanisms and processes connected with, and responsible for, higher-order corrections.

When the diagrammatic technique of many-body theory is used, it is unnecessary to be restricted to a finite number of lowest-order terms in the interelectron interaction. On the contrary, some infinite sequences may be taken into account. The sum of all many-body diagrams is completely equivalent to the many-particle Schrödinger equation. Therefore, taking all of them into account is just as complicated as solving the corresponding equation. Compared with other approaches, the diagrammatic technique can easily uncover hidden approximations and transparently demonstrate possible sources of corrections.

23.1 Diagrammatic Technique

23.1.1 Basic Elements

Each physical atomic process (or a process with participation of a molecule, cluster or fullerenes) involves an electronic interaction with a projectile or external field, in general time-dependent, or a mutual interelectronic interaction. By convention, the ground state of the atom (if it is not degenerate) is regarded as the vacuum state. Then the simplest process in this target is excitation of an electron to an unoccupied level, leaving behind a vacancy. The basic elements of a diagram are

(23.1)
where (a) with an arrow directed to the right represents an electron excited to a vacant level; (b) with an arrow directed to the left represents a vacancy; (c) with a cross represents the static Coulomb interaction; (d) represents the interelectron Coulomb interaction; (e) represents interaction with a time-dependent external field, usually electromagnetic; and (f) represents the very act of interaction.

The elements (23.1a–f) in combination can describe the following real or virtual basic processes

(23.2)
which represent (a) photon absorption by the vacuum with electron–vacancy pair creation; (b) electron excitation; and (c) vacancy excitation. Diagrams (23.2) depict processes as developing in time, shown increasing from left to right. A vacancy can be thought of as an antiparticle to the electron, moving backward in time. The time-reverse of processes (23.2) represent processes of photon emission due to annihilation of an electron–vacancy pair, vacancy transition, and electron inelastic scattering, respectively.

A static [for example, Coulomb (23.1c)] field can virtually create an electron–vacancy pair, or affect the moving electron or vacancy, as shown in the following

diagrams:

(23.3)
Just as for (23.2), diagrams (23.3) have their time-reversed counterparts.

Inclusion of interelectron interaction leads to a number of processes of which some examples are

(23.4)
Here, (23.4a) describes creation of two electron–vacancy pairs, (23.4b) represents the simplest picture of electron inelastic scattering, (23.4c) depicts vacancy decay with electron–vacancy pair creation, (23.4d) stands for electron–electron scattering, (23.4e) represents a process which can be called electron–vacancy annihilation and creation, while (23.4f) shows electron–vacancy scattering.

23.1.2 Construction Principles for Diagrams

The foundations of diagrammatic techniques are discussed in a number of books such as [23.11]. This chapter presents recipes for the construction and evaluation of diagrams corresponding to various atomic processes [23.12].

The basic procedure is to connect the initial and final states of the atom, drawn at the left and right sides of the diagram, using any of the elements in (23.1). In doing so, the following rules apply:

1. At each dot (23.1f), only three lines can meet: wavy (or dashed) and electron–vacancy.
2. A vacancy cannot be transformed into an electron or vice versa.

3. Electrons and vacancies can be created only pairwise from the vacuum.
4. Only linked diagrams are allowed; i. e. only those having no parts entirely disconnected from one another.

The simplest or initial approximation to a process is represented by a diagram which includes the lowest possible number of elements (23.1–23.4). Higher-order corrections can be derived by including additional elements of interaction with the static field of the nucleus (23.1c) and between electrons and/or vacancies (23.1d).

As an illustration of the method, consider the following three processes:

1. one-electron photoionization – the initial state is a photon while the simplest final state is an electron–vacancy pair. They can be combined together giving the basic diagram (23.2a).
2. elastic electron scattering – the initial and final states are single electrons. To describe the simplest scattering process, the interaction with the Coulomb field must be taken into account, leading to (23.3b). To account for interelectron interaction, the simplest element
$$(23.5)$$

must be introduced. It is a modification of (23.4b) accounting for the interaction of an incoming electron with all target electrons individually, not altering their states. This is emphasized by the loop in which the same vacancy leaving the lower dot reenters it. Indistinguishability of all electrons as fermions is taken into account by permutation of the electron (vacancy) line ends, as illustrated in the following diagrams:

$$(23.6)$$

Diagram (23.6a) is obtained from (23.5) by permutation of the electron lines on one side of the interelectron interaction. Diagram (23.6b) is equivalent to (23.6a), but is simpler to draw.

3. inelastic electron scattering – the initial state is a single electron. For the final state we choose one with two electrons and therefore a single vacancy. The simplest diagram in this case is given by (23.4b).

To illustrate the description of the ground state characteristics, consider the contributions to the ground state energy of an atom. If this state is not degenerate, its potential energy is given by vacuum diagrams which have no free lines in the initial or final states. The simplest vacuum diagrams are
$$(23.7)$$

Higher-order corrections to all these diagrams can be obtained by adding elements such as a static external field (23.3) or interelectron interaction (23.4) without changing the initial and final states of the processes. The lowest-order processes are represented by (23.2a), (23.5), (23.6), (23.4b), and (23.7). There are many corrections even in the next order of interaction, either with an external field or with electrons or vacancies. To illustrate, only one correction to each process will be presented:

1. Simple photoionization (23.2a) may be combined with (23.4e) to obtain
$$(23.8)$$

This describes the effect of the creation of another electron–vacancy pair, after annihilation of the first one formed by absorption of the initial photon.
2. Simple elastic electron scattering (23.5) can be combined with an extra interaction term (23.4f) between the incoming electron and the vacancy of the loop (23.5), to obtain
$$(23.9)$$

3. Simple inelastic electron scattering (23.4b) can also be combined with (23.4f), accounting for the interaction of an electron and vacancy created in the lowest-order process, to obtain
(23.10)

4. The ground state energy term (23.7b) can be combined with (23.7b) and the element (23.3c) of the interaction between the vacancy in the (23.7b) loops and the static field to obtain
(23.11)

Higher-order corrections can be constructed step by step by introducing further elements of interaction. In some cases, classes of diagrams may be taken into account up to infinite order by solving closed systems of integral or differential equations.

23.1.3 Correspondence Rules

These rules describe how to obtain an analytical expression corresponding to a given diagram. One starts by choosing a zero-order approximation which can be that of independent electrons moving in the Coulomb field of an atomic nucleus. Atoms with completely occupied shells, or subshells having a non-degenerate ground state, can be chosen as the vacuum. Electron (vacancy) states are characterized in this case by the quantum numbers n, ℓ, m_ℓ, and $\sigma = \pm 1/2$.

The first correspondence rule is to substitute a matrix element for each interaction:

Diagram (23.2) $\rightarrow \langle p|W|q \rangle$,
Diagram (23.3) $\rightarrow \langle p|U|q \rangle$,
Diagram (23.4) $\rightarrow \langle pt|V|qs \rangle$,   (23.12)

where W is the interaction potential of an electron with the external time-dependent field, U is the interaction potential of an electron (vacancy) with an external static field, for example that of the nucleus, and V is the Coulomb interelectron interaction. Each of the letters p, q, t, s represents a full set of n, ℓ, m_ℓ, σ quantum numbers. Vacancy states are below (and include) the highest occupied energy level, called the Fermi level, so that $p \leq F$. Electron states are above the Fermi level so that $q > F$. Thus diagram (23.2a) is represented by $\langle p|W|q \rangle$ with $p \leq F$ and $q > F$.

Apart from initial and final states, each diagram can have sections, i.e., intervals between successive interactions. For instance (23.9) and (23.10) each have one section. Each section is represented by an inverse energy denominator $\varepsilon_\mathrm{d}^{-1}$. It includes the sum over all vacancy energies $\sum_{\mathrm{vac}} \varepsilon_i$ minus the sum of the electron energies $\sum_{\mathrm{el}} \varepsilon_n$ to which the entrance energy E of the diagram (e.g. $\hbar\omega$ for a time-dependent field) must be added:

$$\varepsilon_\mathrm{d}^{-1} = \left(\sum_{\mathrm{vac}} \varepsilon_i - \sum_{\mathrm{el}} \varepsilon_n + E \right)^{-1}.$$ (23.13)

The second correspondence rule is to identify sections and write down their energy denominators. After attributing to each electron (vacancy) line a letter, denoting its state, the analytical expression for a diagram is given by

Analytical Expression
= (the product of all interaction matrix elements)
$\times$ (all energy denominators)$^{-1}$
$\times (-1)^L$ summed over all intermediate
electron and vacancy states,   (23.14)

where L is equal to the sum of the total number of vacancy lines and closed vacancy or electron–vacancy loops.

Although electrons are fermions, the summation in (23.14) has no additional restrictions caused by the Pauli principle. It runs over all electron ($> F$) and vacancy ($\leq F$) states, including those where two or more electrons (or vacancies) are in the same state. The correspondence rules (23.12), (23.13), and (23.14) can be illustrated by giving as examples the analytical expressions of two diagrams (23.8) and (23.9).

Attributing letters denoting electron and vacancy states, diagram (23.8) becomes
(23.15)

According to (23.12–23.14), the analytical formula

$$A_{if}(\omega) = \sum_{r>F, t\le F} \frac{\langle t|W|r\rangle\langle ri|V|tf\rangle}{\varepsilon_t - \varepsilon_r + \omega}(-1)^{2+1}$$

(23.16)

is obtained. The symbol $\sum$ includes summation over discrete levels and integration. In (23.16), the intermediate state is $r > F$, $t \le F$ and the diagram has two vacancies (t and i) and one loop rt. Integration must be performed over those states r which belong to the continuum.

Assigning letters denoting states, (23.9) appears as

(23.17)

where $p, q, p', r > F$, while $t \le F$. According to (23.14),

$$\Delta E = \sum_{r,q>F; t\le F} \frac{\langle pt|V|qr\rangle\langle qr|V|p't\rangle}{\varepsilon_t - \varepsilon_q - \varepsilon_r + \varepsilon_p}(-1)^{1+1},$$

(23.18)

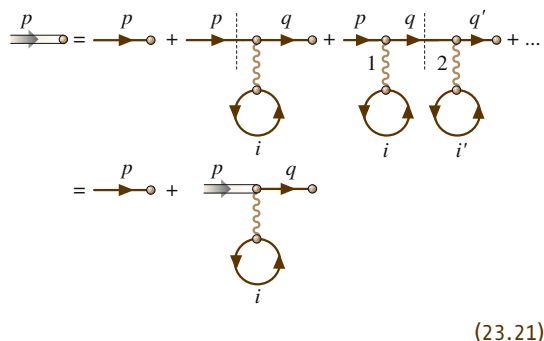
where the intermediate states are $q, r > F$ and $t \le F$. It has one vacancy and one electron–vacancy loop rt.

An intermediate state in a diagram can be real or virtual. It is real if the energy conservation law can be fulfilled, i. e. if for some values of the section energy the following relation holds:

$$E = \sum_{el}\varepsilon_n - \sum_{vac}\varepsilon_i .$$

(23.19)

If (23.19) can be fulfilled, a prescription for avoiding the singularity in (23.13) is to substitute the expression $\varepsilon_d^{-1}Q$, where

$$Q = \lim_{\eta\to 0}\left(E - \sum_{el}\varepsilon_n + \sum_{vac}\varepsilon_i + i\eta\right)^{-1}$$
$$= P\left(E - \sum_{el}\varepsilon_n + \sum_{vac}\varepsilon_i\right)^{-1}$$
$$- i\pi\delta\left(E - \sum_{el}\varepsilon_n + \sum_{vac}\varepsilon_i\right),$$


(23.20)

for ε_d^{-1}. Here P denotes that the principal value is to be taken on integration over intermediate state energies. The result of (23.20) can thus be complex.

An intermediate state is virtual if the energy conservation law (23.19) is violated for all values of the section energy. In general, the bigger the virtuality, i. e. the difference $E - \sum_{el}\varepsilon_n + \sum_{vac}\varepsilon_i$, the smaller the contribution to the amplitude of the process.

23.1.4 Higher–Order Corrections and Summation of Sequences

An important feature of the diagrammatic technique is the convenience in constructing higher-order corrections and in the summation of infinite sequences of diagrams. According to (23.13), each new interaction line leads to an additional interaction matrix element, extra energy denominator and summation over new intermediate states.

An important example of infinite summation is that of determining the one-electron states. The interaction with the nucleus (23.3b) and with atomic electrons (23.5) and (23.6) is not small and must be taken into account non-perturbative; i. e., these elements must be iterated infinitely. To simplify the drawing, only the element (23.5) is repeated, leading to the diagrammatic equation:

(23.21)

Indeed, everything in the infinite sum which is in front of the dashed line repeats the infinite sum itself, thus leading to a closed equation of the form

$$\langle\tilde{p}| = \langle p| + \sum_{q>F}\langle\tilde{p}i|V|qi\rangle\frac{1}{-\varepsilon_q + \varepsilon_p}\langle q| .$$

(23.22)

The two interactions leading to (23.21) can be permuted, so that the interaction 1 can be after 2. This leads to

extension of the sum to include states with $q \leq F$. As a result, the summation in (23.22) must be performed over all states q.

Interaction with the nucleus and the other electrons affects also the occupied (or vacancy) states i in (23.21) and therefore the latter must be modified by inserting the elements (23.3b), (23.5), and (23.6) into them. Here again, the vacancy line in (23.5) and (23.6) must be modified by including the corrections (23.3b), (23.5), (23.6) and so on. Finally, the diagrammatic equation

$$(23.23)$$

is obtained. The doubled line for i emphasizes that the vacancy wave function is determined by an equation similar to (23.21). The corresponding analytical equation looks like (23.22), but includes also the Coulomb interaction with the nucleus and the exchange interaction with other atomic electrons. The summation over q in this equation is extended over all q, not only $q > F$. Multiplying the corresponding equation by $(\hat{H}_0 - \varepsilon_p)$ from the right (atomic units are used in this chapter: $e = m_e = \hbar = 1$), where $\hat{H}_0 = -\nabla^2/2$, and using the completeness of the functions $\sum_q |q\rangle\langle q| = \delta(\boldsymbol{r} - \boldsymbol{r}')$, results in the equation

$$\left[-\frac{\nabla^2}{2} - \frac{Z}{r} + \sum_{i \leq F} \int \frac{\mathrm{d}\boldsymbol{r}'}{|\boldsymbol{r}' - \boldsymbol{r}|} |\phi_i(\boldsymbol{r}')|^2 - \varepsilon_p \right] \phi_p(\boldsymbol{r})$$
$$= \sum_{i \leq F} \int \frac{\mathrm{d}\boldsymbol{r}'}{|\boldsymbol{r}' - \boldsymbol{r}|} \phi_i^*(\boldsymbol{r}') \phi_p(\boldsymbol{r}') \phi_i(\boldsymbol{r}) \quad (23.24)$$

for the electron wave function $\phi_p(\boldsymbol{r})$. Here $\phi_i(\boldsymbol{r})$ are wave functions determined by equations similar to (23.24). These are the Hartree–Fock (HF) equations.

HF includes a part for interelectron interaction matrix elements, namely that given by (23.5) and (23.6). The rest is called the residual interaction, and its inclusion leads beyond the HF frame, accounting for correlations.

When a perturbative approach is used, it is essential to define the zero-order approximation. In this chapter, and very often in the literature, the Hartree–Fock approximation is used in this role. To simplify the drawing of diagrams, from now on single (rather than double) lines will represent electrons (vacancies), whose wave functions are determined in the HF approximation by (23.24). Obviously, in this case elements (23.3a), (23.5) and (23.6) should not be added to any other diagrams.

The procedure used in deriving (23.21) and (23.23) is in fact more general. Let us separate all diagrams describing elastic scattering which do not include a single one-electron or one-vacancy state as intermediate. Depicting their total contribution by a square, the precise one-particle state is determined by an infinite sequence of iterative diagrams which can be summed, similarly to (23.21), by

$$(23.25)$$

Here the single line stands for an HF state. Using the correspondence rule (23.14), an analytical equation similar to the Schrödinger equation can be derived with the operator $\hat{\boldsymbol{\Sigma}}$ playing the role of an external potential. The essential difference is, however, that this "potential" depends in principle upon the energy and state of the particle. The same kind of iterative procedure leading to (23.21) or (23.23) will be used several times in this chapter.

Other zero-order approximations can be chosen. But then diagrams with corrections of the type (23.3a) must be included, with the external static field potential equal to the difference between the HF and the chosen one.

To calculate the numerical value of a given diagram or a sequence of diagrams one needs to know, according to the description given above, the matrix elements of external fields and interelectron interactions obtained with the help of one-electron HF wave functions. The required calculational procedures are described in [23.13].

23.2 Calculation of Atomic Properties

23.2.1 Electron Correlations in Ground State Properties

A major advantage of the diagrammatic technique in many-body theory is that it is usually unnecessary to know the total wave function of the atom. On the contrary, only actively participating electrons or vacancies appear in a diagram. The HF zero-order approximation for one-electron and one-vacancy wave functions is used in what follows. All atomic characteristics and cross sections for atomic processes calculated with HF form the one-electron approximation. Everything beyond the HF frame, i. e., caused by residual interaction, are called correlation corrections or correlations. They can be calculated using the many-body perturbation theory (MBPT) [23.3], random phase approximation (RPA) [23.14] and random phase approximation with exchange (RPAE) or its generalized version GRPAE [23.12, 13].

The simplest diagrammatic expression for the correlation energy is given by the two diagrams

$$\text{(23.26)}$$

The analytical expression $\Delta E_{\text{corr}}^{(2)}$ for (23.26a) is

$$\Delta E_{\text{corr}}^{(2)} = \sum_{k,n>F;i,j\leq F} \frac{\langle ij|V|kn\rangle \langle kn|V|ij\rangle}{\varepsilon_i + \varepsilon_j - \varepsilon_k - \varepsilon_n} . \quad \text{(23.27)}$$

The analytical expression for (23.26b) differs from (23.27) by the sign and an exchange matrix element $\langle kn|V|ji\rangle$ instead of a direct $\langle kn|V|ij\rangle$ one. The contribution (23.26) overestimates the correlation energy by $\approx 10\%$.

Diagrams (23.26) can also be used to describe the interaction potential of two atoms, designated A and B. Let the ki states belong to A and nj to B. At large distances R between the atoms, the contribution of (23.26b) is exponentially small. Because the vacancies i and j are located inside atoms A and B respectively, the interelectron potential $V = |\mathbf{r}_A - \mathbf{r}_B + \mathbf{R}|^{-1}$ at large distances $R \gg R_{A,B}$, ($R_{A,B}$ are atomic radii), can be expanded as a series in powers of R^{-1}. The first term giving a non-vanishing contribution to (23.27) is $V \simeq R^{-3}[(\mathbf{r}_A \cdot \mathbf{r}_B) - 3(\mathbf{r}_A \cdot \mathbf{n})(\mathbf{r}_B \cdot \mathbf{n})]$, $\mathbf{n}$ being the unit

vector in the direction of $\mathbf{R}$. Substituted into (23.26), this potential leads to the expression

$$U(R) = -\frac{C_6}{R^6} \quad \text{(23.28)}$$

for the interatomic potential [23.15], where

$$C_6 \approx \sum_{k,n>F;i,j\leq F} \frac{|\langle i|\mathbf{r}|k\rangle|^2 |\langle j|\mathbf{r}|n\rangle|^2}{(\varepsilon_i + \varepsilon_j - \varepsilon_k - \varepsilon_n)} . \quad \text{(23.29)}$$

Calculations [23.16] show that the inclusion of higher-order corrections is important for obtaining accurate values for ΔE_{corr} and C_6. However, to improve accuracy by taking into account the corrections to diagrams (23.26) requires considerable effort. Indeed, there are several types of corrections to (23.26) such as (i) screening of the Coulomb interelectron interaction by the electron–vacancy excitations; (ii) interaction between vacancies ij; (iii) interaction between electrons and vacancies $ki(nj)$ $(kj(ni))$; and (iv) interaction between electrons kn. Corrections to the HF field itself which acts upon electrons k, n and vacancies i, j are discussed in Sect. 23.2.3.

Screening of the Coulomb interelectron interaction is very important, and in many cases must be taken into account non-perturbative. The simplest way to do this is to use RPA, which defines the effective interelectron interaction $\tilde{\Gamma}$ as a solution of an integral equation, shown diagrammatically by

$$\text{(23.30)}$$

If V in (23.27) is replaced by $\tilde{\Gamma}$, an expression for ΔE_{corr} in RPA can be derived.

Exchange is very important in atoms and molecules, so diagram (23.30) can be modified to include this effect, thus leading to the effective interaction Γ in RPAE [23.12, 13, 16]:

$$\text{(23.31)}$$

Replacing V in (23.27) by Γ gives a rather accurate expression for ΔE_{corr} in RPAE. Taking into account

screening also affects the long-range interatomic interaction considerably by altering the constant C_6 in (23.28).

The ground state energy of an atom or molecule is modified by an external field. For a not too intense electromagnetic field, the simplest correction to the ground state energy is given by the diagrams

$$(23.32)$$

Considering a dipole external field, its interaction with the atomic electrons is given by $W = \sum_{i \leq F} \boldsymbol{E} \cdot \boldsymbol{r_i}$, $\boldsymbol{E}$ being the strength of the field. The ground state energy shift is given by $\Delta E = -\alpha(\omega)E^2/2$, where $\alpha(\omega)$ is the dynamical dipole polarizability and ω is the frequency of the field. According to (23.32), $\alpha(\omega)$ is determined by

$$\alpha(\omega) = \sum_{k > F; i \leq F} \frac{2|\langle i|z|k\rangle|^2(\varepsilon_k - \varepsilon_i)}{(\varepsilon_k - \varepsilon_i)^2 - \omega^2}, \qquad (23.33)$$

where z is a component of the vector $\boldsymbol{r}$.

RPAE corrections to $\alpha(\omega)$ are discussed in Sect. 23.2.5 in connection with the photoionization process.

Non-dipole polarizabilities of other multipolarities can be obtained in the lowest order of interelectron interaction using (23.32) with a properly chosen interaction operator between the electromagnetic field and an electron, instead of $W = \sum_{i \leq F} \boldsymbol{E} \cdot \boldsymbol{r_i}$.

23.2.2 Characteristics of One–Particle States

A single vacancy or electron can propagate from one instant of interaction to another, as described to zero order by elements (23.1b) [or (23.1a)] with dots (23.1f) at the ends. This line represents an HF one-particle state with a given angular momentum, spin, and total momentum. Accounting for virtual or real atomic excitations leads, for a vacancy, to a diagram similar to (23.25) but with oppositely directed arrows. Because the interaction with these excitations is usually much smaller than the energy distance between shells, in the sum over q only the term $q = i$, i being the considered vacancy state, need be taken into account. Interaction with the vacuum leaves the angular momentum, spin, and total momentum unaltered. It can however change the energy, and lead to a finite lifetime for a vacancy state.

Analytically, the vacancy propagation in the HF approximation is described by the one-particle HF Green's function G^{HF}:

$$G_i^{HF}(E) = 1/(\varepsilon_i - E). \qquad (23.34)$$

Solving (23.25) for a vacancy i with only Σ_{ii} terms included gives

$$G_i(E) = 1/[\varepsilon_i + \Sigma_{ii}(E) - E]. \qquad (23.35)$$

The pole in $G(E)$ which determines the vacancy energy is shifted from $E = \varepsilon_i$ to $E_i = \varepsilon_i + \Sigma_{ii}(E_i)$. The quantity $\Sigma_{ii}(E)$ is called the self-energy, and is in general a complex function of energy, its imaginary part determining the lifetime of the vacancy i. Near E_i, (23.35) can be written in the form

$$G_i(E) \approx F_i/[\varepsilon_i + \Sigma_{ii}(E_i) - E] = F_i/(E_i - E), \qquad (23.36)$$

where

$$F_i = \left(1 - \frac{\partial \Sigma_{ii}(E)}{\partial E}\bigg|_{E=E_i}\right)^{-1} \qquad (23.37)$$

is called the *spectroscopic factor*. It characterizes the probability for more complicated configurations to be admixed into a single vacancy state i [23.12].

An important problem is to calculate the self-energy part $\Sigma(E)$. The first nonzero contributions are

$$(23.38)$$

Specific calculations [23.16] demonstrate that if the intermediate electron states n [in (23.38a)] and kn [in (23.38b)] are found in the field of vacancies jj' and $ii'j$, the diagrams (23.38) are able to reproduce the values of the correlation energy shift with about 5% accuracy. For outer subshell vacancies, the contributions (23.38a) and (23.38b) are almost equally important, to a large extent cancelling each other. For example, (23.38a) shifts the outer 3p vacancy in Ar to lower binding energies by 0.1 Ry, while the contribution of (23.38b) is −0.074 Ry. The total value 0.026 Ry is small and close to the experimental one, which is 0.01 Ry. For inner vacancies, (23.38a) is dominant because the intermediate states in (23.38b) have large virtualities and are therefore small. The main contribution to the sum over j' comes from the term $j' = i' = i$, which gives for the energy

shift of level i

$$\Delta\varepsilon_i = \Sigma_{ii}^{(2)}(\varepsilon_i) = \sum_{n>F;\, j\leq F} \frac{|\langle n|r^{-1}|j\rangle|^2}{\varepsilon_n - \varepsilon_j}\,. \qquad (23.39)$$

The value (23.39) is positive. Most important higher-order corrections will be included if V in (23.38a) is replaced by Γ from (23.31).

The physical meaning of diagram (23.38a) is transparent: it accounts for configuration mixing of one vacancy i and "two vacancies jj' – one electron n" states in the lowest order in the interelectron interaction. Diagram (23.38b) is not as transparent, and for $i = i'$ its intermediate state appears to violate the Pauli principle. However, as noted in connection with (23.14), the Pauli principle should not be considered as a restriction in constructing intermediate states.

Diagram (23.38a) and its exchange can have an imaginary part, which gives the probability of Auger decay $\gamma_i^{(A)}$, calculated to the lowest order in the interelectron interaction. For (23.38a) one has

$$\gamma_i^{(A)} = \mathrm{Im}\,[\Sigma_{ii}(E_i)]$$
$$= 2\pi \sum_{j,j'\leq F;\, n>F} |\langle in|V|jj'\rangle|^2 \delta(\varepsilon_j + \varepsilon_{j'} - \varepsilon_n - \varepsilon_i)\,.$$
$$(23.40)$$

The width $\gamma_i^{(A)}$ is usually much smaller than $\mathrm{Re}[\Sigma_{ii}(E_i)]$, but there are several exceptional cases with abnormally large Auger widths, among which the most impressive is the 4p-vacancy in Xe with its $\gamma_{4p} \approx 10\,\mathrm{eV}$.

Higher-order corrections include those which are taken into account when V in (23.40) is replaced by Γ from (23.31). The others include jj' vacancy–vacancy interaction, the interaction between vacancies jj' and the electron n and so on. As noted above, all of these can be obtained step by step by inserting the elements (23.4) into (23.38). To select the most important corrections, a physical idea and/or experience are necessary. For instance, if the energy transferred in the decay process $\Delta\varepsilon = \varepsilon_{j'} - \varepsilon_j$ is close to some threshold energies of atomic intermediate or outer shells, corrections which include virtual excitation of this shell must be taken into account.

The contribution to the spectroscopic factor from (23.38a) is given according to (23.37) by

$$F_i^{(2)} \equiv \left(1 + \sum_{j,j'\leq F;\, n>F} \frac{|\langle in|V|j'j\rangle|^2}{(\varepsilon_j + \varepsilon_{j'} - \varepsilon_n - \varepsilon_i)^2}\right)^{-1}\,.$$
$$(23.41)$$

Generally, for any Fermi particle, $F_i \leq 1$ [23.17] because there cannot be more than one particle in a given state. Note that the integrand in (23.41) is the lowest-order admixture of the $jj'n$ state to a pure one-vacancy state i. A small F value means strong mixing. For atoms, F_i is usually close to 1, but there are exceptions where F is small. For example, F_{5s} in Xe is about 0.33 [23.12].

The operator $\Sigma_{ij(n)}(\varepsilon)$ has non-diagonal matrix elements, which leads to admixture of other one-vacancy j or one-electron n states to the vacancy i. A measure of this admixture is given by the ratio $\Sigma_{ij(n)}(\varepsilon_i)/(\varepsilon_{j(n)} - \varepsilon_i)$.

In higher orders, decay processes more complex than those described by the imaginary part of (23.38a) become possible. For example, this could be a two-electron Auger decay in which the transition energy is distributed between two outgoing electrons. An example of the lowest-order diagram for this process is

$$(23.42)$$
This is one of those diagrams which describe the mixing of a pure one-vacancy state with a quite complex configuration $jj_1 j_2 \varepsilon_1 \varepsilon_2$.

23.2.3 Electron Scattering

Propagation of an electron in a discrete level or in a scattering state can be described in the same way as for a vacancy. The electron wave function is determined by (23.25). Using the correspondence rule (23.14), (23.25) can be expressed analytically in the form

$$\left[-\frac{\nabla^2}{2} - \frac{Z}{r} + \sum_{i\leq F}\int \frac{\mathrm{d}\boldsymbol{r}'}{|\boldsymbol{r}'-\boldsymbol{r}|}\,|\phi_i(\boldsymbol{r}')|^2 - \varepsilon \right]\psi_\varepsilon(\boldsymbol{r})$$
$$= \sum_{i\leq F}\int \frac{\mathrm{d}\boldsymbol{r}'}{|\boldsymbol{r}'-\boldsymbol{r}|}\phi_i^*(\boldsymbol{r}')\psi_\varepsilon(\boldsymbol{r}')\phi_i(\boldsymbol{r})$$
$$+ \int \hat{\Sigma}(\boldsymbol{r},\boldsymbol{r}',\varepsilon)\psi_\varepsilon(\boldsymbol{r}')\mathrm{d}\boldsymbol{r}'\,.$$
$$(23.43)$$

The terms with the Coulomb interelectron interaction $|\boldsymbol{r}'-\boldsymbol{r}|^{-1}$ determine the Hartree–Fock self-consistent potential. The last term in (23.43) represents the nonlocal energy dependent polarization interaction of the continuous spectrum electron with the target atom. Although

(23.43) resembles the ordinary Schrödinger equation, because of the energy dependence of the self-energy part $\hat{\Sigma}(\boldsymbol{r}, \boldsymbol{r}', \varepsilon)$, it is not the same. Consequently, the wave function $\psi_\varepsilon(\boldsymbol{r})$, often called a Dyson orbital, must be normalized according to the condition

$$(\psi_{\varepsilon'} | \psi_\varepsilon) = F_\varepsilon \delta(\varepsilon' - \varepsilon) , \tag{23.44}$$

where

$$F_\varepsilon = \left[1 - \left(\varepsilon \left| \frac{\partial \hat{\Sigma}(\boldsymbol{r}, \boldsymbol{r}', E)}{\partial E} \right| \varepsilon \right) \Big|_{E=\varepsilon} \right]^{-1} . \tag{23.45}$$

This is different from that for ordinary wave functions by the factor $F_\varepsilon < 1$. In F_ε, the matrix element of the operator $\partial \hat{\Sigma}(\boldsymbol{r}, \boldsymbol{r}', E)/\partial E$ is calculated between states $\psi_\varepsilon(\boldsymbol{r})$. It is seen that F_ε is the same spectroscopic factor as determined by (23.37), but for a continuous spectrum or an excited electron state.

The object described by the wave function $\psi_\varepsilon(\boldsymbol{r})$ differs from an individual electron because it can be unstable, and its state is mixed with those of more complicated configurations, such as "two electrons" $k'k'' -$ one vacancy j''. This object is called a *quasi-electron*.

Equation (23.43) also determines the energies of electrons in discrete levels which are shifted from their HF values. Contrary to the case of deep vacancies, it is impossible to predict the sign of the energy shift without detailed calculations.

For incoming electron energies ε higher than the target ionization threshold, the operator $\hat{\Sigma}(\boldsymbol{r}, \boldsymbol{r}', \varepsilon)$ acquires an imaginary part, thus becoming an optical potential for the projectile. The additional elastic scattering phase shifts from their HF values can be expressed via matrix elements of $\hat{\Sigma}(r, r', \varepsilon)$ between the wave functions $\phi_\varepsilon^*(r)$ and $\psi_\varepsilon(r)$; but to find numbers for these phase shifts, the self-energy part or polarization interaction $\hat{\Sigma}(\boldsymbol{r}, \boldsymbol{r}', \varepsilon)$ must be calculated. It appears that the second-order projectile–target interactions

$$\tag{23.46}$$

provide a reasonably good approximation [23.10, 12].

The expression for $\hat{\Sigma}(\boldsymbol{r}, \boldsymbol{r}', \varepsilon)$ simplifies at distances far from the target. Only (23.46a) contributes in this region, while other terms are exponentially small. Expanding the Coulomb interelectron interactions in (23.46a) in powers of $r_{1'}/r_1 \ll 1$, $r_{2'}/r_2 \ll 1$

gives

$$\Sigma(\boldsymbol{r}, \boldsymbol{r}', \varepsilon) = -\delta(\boldsymbol{r} - \boldsymbol{r}') \frac{\alpha^{\mathrm{HF}}(0)}{2r^4} , \quad r, r' \to \infty \tag{23.47}$$

where $\alpha^{\mathrm{HF}}(0)$ is the static ($\omega = 0$) dipole polarizability determined by (23.33).

Accounting for each additional interaction between the projectile and target increases the power of r in the denominator of (23.47). Most important is the interaction between target electrons. By including this, the asymptotic expression (23.47) is also modified, where instead of $\alpha^{\mathrm{HF}}(0)$, the RPAE polarizability $\alpha^{\mathrm{RPAE}}(0)$ appears. If the target–projectile interelectron interaction is taken into account to second order as in (23.46) while all the rest is included exactly, the expression for $\hat{\Sigma}(\boldsymbol{r}, \boldsymbol{r}', \varepsilon)$ for $r, r' \to \infty$ is still given by (23.46), but with the exact static polarizability.

Many experimental results for low energy electron scattering by noble gases, alkalis, and alkaline earths agree well with calculations of elastic scattering phase shifts obtained by solving equation (23.42) in which $\hat{\Sigma}(\boldsymbol{r}, \boldsymbol{r}', \varepsilon)$ is given by (23.46) with RPAE corrections taken into account. Total cross sections are reproduced with an accuracy as high as several percent, including the Ramsauer minimum region. This is illustrated in Fig. 23.1 for the $e^- +$ Xe case [23.18]. This approximation is also reasonably good in describing the angular distributions. As the projectile energy ε increases, the contribution of (23.46) decreases rapidly.

The approach presented here applies to other incoming particles, such as for instance positrons e^+.
Fig. 23.1 Electron–Xe atom elastic scattering cross section [23.12]. *Solid line*: including polarization interaction; *dashed line*: HF; *dash-dotted line*: experiment

The exchange between e^+ and target electrons must be omitted by discarding (23.6) and all but (23.46a) terms in the polarization interaction $\hat{\Sigma}(\boldsymbol{r}, \boldsymbol{r}', \varepsilon)$. The incoming positron in its intermediate state k' [see (23.46a)] interacts strongly with the virtually excited electron k'', forming a positronium-like object. Corresponding diagrams are obtained by inserting elements (23.4d) for the e^+–e^- interaction into (23.46a). Summation of the infinite sequence of such diagrams corresponds to substituting the product $\phi_{k'}(\boldsymbol{r_1})\phi_{k''}(\boldsymbol{r_2})$ in the intermediate state of (23.46a) by the exact e^+e^- wave function in the field of a target with a vacancy j. Such a program is very complicated, and a simplification has proved to be satisfactory. Only the positronium (Ps) binding is taken into account by subtracting its binding energy in the denominator of (23.13). This is equivalent to adding the Ps ionization potential I_{Ps} to ε in (23.46) [23.19]. It enhances the polarization interaction and leads to an interesting qualitative feature: the possibility of alteration of the sign of the interaction (23.46). Indeed, instead of $\alpha(0)$, the corresponding expression for e^+-atom collision includes $\alpha(I_{Ps})$. For alkalis, the binding energy is less than I_{Ps}, and for the energy region $\hbar\omega > I_{Ps}$ the polarizability (23.33) is negative, while $\alpha(0) > 0$. This leads to a repulsive polarization interaction, rather than the usual attractive one. This difference affects the cross section qualitatively [23.20].

Another, more complicated, approximation substitutes $\phi_{k'}(\boldsymbol{r}_1)\phi_{k''}(\boldsymbol{r}_2)$ by the product of the precise Ps wave function $\psi_{Ps}(|\boldsymbol{r}_1 - \boldsymbol{r}_2|)$ and the wave function of the free motion of the Ps center of gravity [23.21]

According to the diagrams (23.23), (23.43) describes the target with an additional electron. If the target is a neutral atom, solution of (23.43) with discrete energy values describes negative ion states; both ground and excited.

Again, as in Sect. 23.2.2, diagrams (23.46) with RPAE corrections form a reasonably good starting point for calculating the negative ion binding energies, even in cases when this binding is comparatively small, as in alkaline earth negative ions [23.22]. The inclusion of only the outer shell polarizability (j is a vacancy in the outer shell) leads to overbinding of the additional electron forming the negative ion. Only the inclusion of screening due to inner shell excitations yields good agreement with experiment. For instance, recent measurements of Ca^- affinity [23.23] give about 20 meV, while the calculations without inner shell excitations give about 50 meV [23.22]. Their inclusion must considerably reduce the theoretical value.

23.2.4 Two–Electron and Two–Vacancy States

One can construct a diagrammatic equation for the wave function of a two-electron or a two-vacancy state by separating all diagrams describing two-electron (two-vacancy) scattering which do not include these states as intermediate, and denoting their total contribution by a circle. Then the exact two-electron (vacancy) state is determined by the infinite sequence of diagrams

$$(23.48)$$

The analytic equation for two electrons in an atom interacting with each other can be written in the form

$$\left(\hat{H}_1^{HF} + \hat{\Sigma}_1 + \hat{H}_2^{HF} + \hat{\Sigma}_2 + \hat{Q}\hat{\Pi}_{12} - \varepsilon \right)$$
$$\times \psi_{12}(\boldsymbol{r_1} \cdot \boldsymbol{r_2}) = 0 . \qquad (23.49)$$

Here $\hat{H}_{1(2)}^{HF}$ is the HF part of the one-particle Hamiltonian in (23.24), $\hat{\Pi}_{12}$ is the effective interelectron interaction and $\hat{Q}$ is the projection operator

$$\hat{Q} = 1 - n_1 - n_2 , \qquad (23.50)$$

with $n_{1(2)}$ being the Fermi step function, $n_{1(2)} = 1$ for $1(2) \le F$ and $n_{1(2)} = 0$ for $1(2) > F$. The function $n_{1(2)}$ thus eliminates contributions of vacant states. The operator $\hat{Q}$ takes into account the fact that propagation of two electrons (or, more precisely, quasi-electrons due to the presence of $\hat{\Sigma}$) takes place in a system of other particles which occupy all levels up to the Fermi level. The presence of $\hat{Q}$ makes (23.49) essentially different from a simple two-electron Schrödinger equation: $\hat{Q}$ requires that after each act of interaction described by $\hat{\Pi}_{12}$, both participants either remain electrons or become vacancies.

Diagrams (23.48) describe the states of two electrons outside the closed shell core, or electron scattering by an atom with one electron outside the closed shells. In general, $\hat{\Pi}_{12}$ is nonlocal, dependent upon ε, and can

have an imaginary part. The lowest-order approximation to $\hat{\Pi}_{12}$ is $V = |\boldsymbol{r}_1 - \boldsymbol{r}_2|^{-1}$. Equation (23.49) must be solved in order to obtain, for example, the excitation spectrum of two electrons in atoms with two electrons outside closed subshells, such as Ca. Instead of V, the interaction Γ from (23.31) can be used, which would account for screening due to virtual excitation of inner shell electrons. For low level two-electron excitations, the energy dependence of $\hat{\Pi}_{12}$ can be neglected.

The same type of equation can be obtained for two-vacancy states, describing their energies, decay widths, and structure due to configuration mixing with more complex states. For inner and intermediate shell vacancies, however, the corresponding corrections can be taken into account perturbatively, and the screening by outer shells is not essential. The admixture of outer shell excitation with inner vacancies is important, leading to satellites of the main spectral lines.

The interaction between vacancies leads to correlation two-vacancy decay processes in which the energy is carried away by a single electron or photon. Some diagrams exemplifying these processes in the lowest possible order of interaction are

(23.51)

Even in this order, there are several diagrams giving together the amplitude of the correlation Auger (23.51a) and radiative (23.51b) decay. For inner shells, a specific feature of such processes is that the released energy is about twice that for a single vacancy decay. Of course, in these cases the decay probability is relatively small. It is not, however, necessarily much smaller than that of individual vacancies if the energies of the intermediate and initial states are close to each other.

The presence of residual two-body forces leads to effective multiparticle interactions. The simplest diagram presenting a three-electron interaction is given by

(23.52)

The role of multi-particle interactions in atomic structure is far from being clear. Diagrams similar to (23.52) are important if it is of interest to calculate the energy levels of atoms with three or more electrons (or vacancies) outside of closed shells. This is a very complicated calculation because even two electrons in the Coulomb field of the nucleus is a difficult three-body problem.

23.2.5 Electron–Vacancy States

The one-electron–one-vacancy state is the simplest excitation of a closed shell system under the action of an external time-dependent field, represented by (23.2a). Beginning with electrons and vacancies described in the HF approximation, the result of residual interactions leads to excitations of more complex states, including those with two or more electron–vacancy pairs. The interaction can also lead to a single electron–vacancy pair. Let us concentrate on the latter case and separate all diagrams describing electron–vacancy interaction which do not include these states as intermediate, and denote them by a circle. Then the exact electron–vacancy state is determined by the infinite sequence of diagrams

(23.53)

Contrary to the electron–electron case in Sect. 23.2.4, the analytical expression corresponding to (23.53) cannot be represented as a Schrödinger-type equation. Indeed, being symmetric under time reversal, (23.53) leads to an equation depending, unlike (23.49), upon the second power of the electron–vacancy energy ω. Note that R in (23.53) and $\hat{\Pi}$ in (23.46) are different.

It is necessary to solve (23.53) when calculating the photoabsorption amplitude, which can then be represented as

(23.54)

The amplitude for elastic photon scattering is also expressed via the exact electron–vacancy state, determined

by (23.53) to be

$$\text{(23.55)}$$

The other case where it is necessary to solve (23.53) is the scattering of electrons, both elastic and inelastic, by atoms with a vacancy in their outer shell, such as the halogens.

The simplest approximation to R is given by the Coulomb interaction to lowest order (23.4e) and (23.4f). With such R, the sequence of diagrams (23.53) is the same as (23.31) and thus forms the RPAE, which is often used to describe photoionization and other atomic processes. Both terms (23.4e) and (23.4f) contribute to the electron–vacancy in (23.53) only if the external field is spin independent, such as an ordinary photon. For a magnetic interaction, which is proportional to spin, the term (23.4e) does not contribute.

23.2.6 Photoionization in RPAE and Beyond

In RPAE, the photoionization amplitude $\langle k|D(\omega)|i\rangle$ is determined by solving an integral equation obtained from (23.53) and (23.54) using the correspondence rule (23.14) [23.12]:

$$
\begin{aligned}
&\langle k|D(\omega)|i\rangle \\
&= \langle k|d|i\rangle \\
&+ \sum_{k'>F;\,i'\le F} \left(\frac{\langle k'|D(\omega)|i'\rangle\langle ki'|V|ik'-k'i\rangle}{\omega - \varepsilon_{k'} + \varepsilon_{i'} + i\eta} \right. \\
&\left. - \frac{\langle i'|D(\omega)|k'\rangle\langle kk'|V|ii'-i'i\rangle}{\omega - \varepsilon_{k'} - \varepsilon_{i'} - i\eta} \right),
\end{aligned}
\tag{23.56}
$$

where d is the dipole operator describing the photon–electron interaction and $V = |\boldsymbol{r}_1 - \boldsymbol{r}_2|^{-1}$. To obtain the RPAE photoionization cross section, the usual expression (24.19) must be multiplied by the square modulus of the ratio $\langle k|D(\omega)|i\rangle/\langle k|d|i\rangle$, with $\omega = \varepsilon_k + I_i$. The RPAE corrections described by the term in square brackets in (23.56) are very large for outer and intermediate electron shells. Through the sum over i', if only terms with the same energies $\varepsilon_{i'} = \varepsilon_i$ are included, (23.56) accounts for intra-shell correlations. By adding terms with $\varepsilon_{i'} \neq \varepsilon_i$, the effect of inter-shell correlations is taken into account.

For atoms, (23.56) has to be solved numerically, but can be presented in a symbolical operator form

that creates the possibility of qualitative analyzes of its solutions:

$$D(\omega) = d + D(\omega)\chi(\omega)U, \tag{23.57}$$

where U is a combination of the direct V_{d} and exchange V_{e} Coulomb interelectron potentials, $U = V_{\mathrm{d}} - V_{\mathrm{e}}$, $\chi(\omega) = \chi_1(\omega) + \chi_2(\omega)$, $\chi_1(\omega) = 1/(\omega - \omega' + i\eta)$ and $\chi_2(\omega) = 1/(\omega + \omega')$, with ω' being the excitation energy of the virtual electron–vacancy state. Using Γ from (23.31), one can present $D(\omega)$ as

$$D(\omega) = d + d\chi(\omega)\Gamma(\omega). \tag{23.58}$$

Equation (23.57) allows a rather simple, also symbolic, solution

$$D(\omega) = d/[1 - \chi(\omega)U]. \tag{23.59}$$

If the denominator in (23.59) has a solution Ω determined by the equation

$$1 - \chi(\Omega)U = 0, \tag{23.60}$$

at $\Omega > I$, where I is the atomic ionization potential, then the cross section has a powerful maximum called a giant resonance with energy Ω.

A giant resonance is of a collective nature, in the sense that it appears to be due to coherent virtual excitation of all electrons of at least one considered multi-electron subshell.

These intra-shell correlations are most important for multielectron shells with large photoionization cross sections. Their inclusion leads to a quantitative description of the above mentioned giant resonances – huge maxima in the photoionization cross sections. An example is the $4\mathrm{d}^{10}$ photoionization cross section of Xe shown in Fig. 23.2 [23.12], where satisfactory agreement with experiment is demonstrated.

It appears that all RPAE intra-shell time-forward diagrams, such as that on the first line in (23.53), and the first term in brackets in (23.56) with $\varepsilon_{i'} = \varepsilon_i$, may be taken into account by the matrix element $\langle \tilde{k}|d|i\rangle$. This is the one-electron approximation, but with the function $\tilde{\phi}_k(\boldsymbol{r})$ calculated in the term-dependent HF approximation [23.12]. Term-dependency means that only the total angular momentum and spin and their projections for the electron–vacancy pair are conserved, being equal to that of the incoming photon. The individual values for the electron and vacancy angular momentum and spin are not considered to be good quantum numbers. Thus the term-dependent HF includes a large fraction of RPAE correlations.
Fig. 23.2 Photoabsorption in the vicinity of the $4d^{10}$ subshell threshold in Xe [23.7]. *Solid line*: RPAE; *dashed line*: experiment

RPAE permitted to the prediction of interference resonances. To describe them, let us consider a situation in which the direct HF amplitude d_s is small, while there are other electrons with large photoionization amplitude D_b, $D_b(\omega) \gg d_s$. Then, from (23.57) one has

$$D_s(\omega) \approx d_s + D_b(\omega)\chi(\omega)$$
$$U_{bs} \approx D_b(\omega)\chi(\omega)U_{bs} \gg d_s \qquad (23.61)$$

if the inter-transition interaction U_{bs} is not too small. The enhancement of the photoionization amplitude described by (23.61) manifests itself as a resonance in the partial cross section of s electrons photoionization. Very often the term $D_b(\omega)\chi(\omega)U_{bs}$ and d_s are of opposite sign, so that the total amplitude acquires two minima, along with an extra maximum, thus forming a rather complicated structure in the partial cross section that was named *interference* or *correlation* resonance.

Usually, these resonances are manifestations of inter-shell correlations. These are taken into account if the sum over i' in (23.56) includes terms with $\varepsilon_{i'} \neq \varepsilon_i$. An example is the $5s^2$ subshell in Xe, which is strongly affected by the outer $5p^6$ and inner $4d^{10}$ neighboring electrons. Due to this interaction, the $5s^2$ cross section is completely altered, as illustrated in Fig. 23.3 [23.12]. The RPAE results predict a qualitative feature of the experimental data, namely the formation of a maximum and two minima in the cross section. The second minimum is not seen in Fig. 23.3, since it lies at considerably higher ω.

RPAE is able to describe a number of other effects, such as *giant autoionizational* resonance (decay

of a powerful discrete excitation into a continuum, with which the excitation interacts strongly), *continuous spectrum autoionization* (modification of a broad continuous spectrum excitation due to its strong interaction with a narrow continuum that happens in negative ions [23.22]) and *quadrupole giant resonances* [23.24].

Above we concentrated on dipole Giant resonances. Quadrupole amplitudes in RPAE are determined by an equation similar to (23.57):

$$Q(\omega) = q + Q(\omega)\chi(\omega)U, \qquad (23.62)$$

where q is the quadrupole amplitude in HF approximation.

Giant quadrupole resonance was found in excitations of $4d^6$ electrons in Xe [23.25]. Its direct observation in photoabsorption is almost impossible, since the corresponding cross section is very small due to the inclusion of the extra factor $\alpha^2 = 1/c^2 \approx 10^{-4}$ as compared to the dipole cross section. However, the quadrupole amplitude leads to noticeable corrections to the angular distributions of photoelectrons where their relative contribution is considerably bigger.

Note that the amplitude of electron elastic scattering on an atom with a vacancy is expressed in RPAE via Γ given by (23.31) [23.26].

For the inner or deep intermediate shells, RPAE proves to be insufficient. First, screening of the Coulomb interaction between the outgoing or virtually excited electron and the vacancy [see (23.4f)] must be taken into account. This can be done by replacing V by Γ
Fig. 23.3 Photoionization of $5s^2$ electrons in Xe [23.7]. *Solid line*: RPAE with effects of $5p^6$ and $4d^{10}$ included; *dashed line*: $5s^2$ electrons only; *dash-dotted line*: with effect of $5p^6$ electrons; *dash-double-dotted line*: with effect of $4d^{10}$ electrons; *dotted line*: experiment

from (23.31). The ionization potential (or the energy of the vacancy i) must also be corrected, which requires inclusion of at least the contribution from the first term of (23.38). It has been demonstrated [23.27] that the screening of the electron–vacancy interaction can be taken into account by calculating the wave function of the virtually excited or outgoing electron in the self-consistent HF field of an ion instead of that of a neutral atom. A method which uses only these one-particle wave functions in (23.54) (23.56) is called the generalized RPAE or GRPAE. The use of this approximation considerably improves the agreement with experiment near the intermediate shell thresholds, decreasing there the cross section value and shifting its maximum to higher energies. GRPAE permitted to disclose *intra-doublet resonances* that results from interaction of electrons belonging to two components of the spin-orbit doublet, e.g., $3d_{3/2}$ and $3d_{5/2}$ in Xe, Cs and Ba atoms [23.24, 28].

RPAE and GRPAE corrections affect not only the cross sections but also characteristics of the photoelectron angular distribution, i.e., dipole and non-dipole angular anisotropy parameters [23.12, 16, 24]. As an example, Fig. 23.4a presents the partial cross sections [23.28] while Fig. 23.4b depicts the dipole anisotropy parameter β [23.24] for $3d_{5/2}$ and $3d_{3/2}$ electrons in Cs. The effect of intra-doublet resonance – an additional maximum in the $3d_{5/2}$ cross section under the action of $3d_{3/2}$ electrons – is clearly seen.

Figure 23.5 depicts the non-dipole angular anisotropy parameter γ_{5s} for 5s electrons in Xe [23.29]. The parameter γ_{ns} (in Fig. 23.5, $n = 5$) is given by the simple formula [23.16]

$$\gamma_{ns}(\omega) = 6[|Q_{ns}(\omega)|/|D_{ns}(\omega)|]\cos(\Delta_q - \Delta_d) ,$$
(23.63)

where $Q_{ns}(D_{ns})$ are the RPAE (GRPAE) quadrupole (dipole) photoionization amplitudes and $\Delta_q(\Delta_d)$ are their phases. Thus, $\gamma_{ns}(\omega)$ is sensitive to the presence of interference, dipole, and quadrupole resonances. The latter is presented by a small but noticeable maximum on the high energy slope of the huge maximum, caused by the presence of the giant dipole resonance. The variation of γ_{5s} near the 5s threshold is determined by the resonant behavior of $\cos(\Delta_q - \Delta_d)$, called *phase resonance* [23.24].

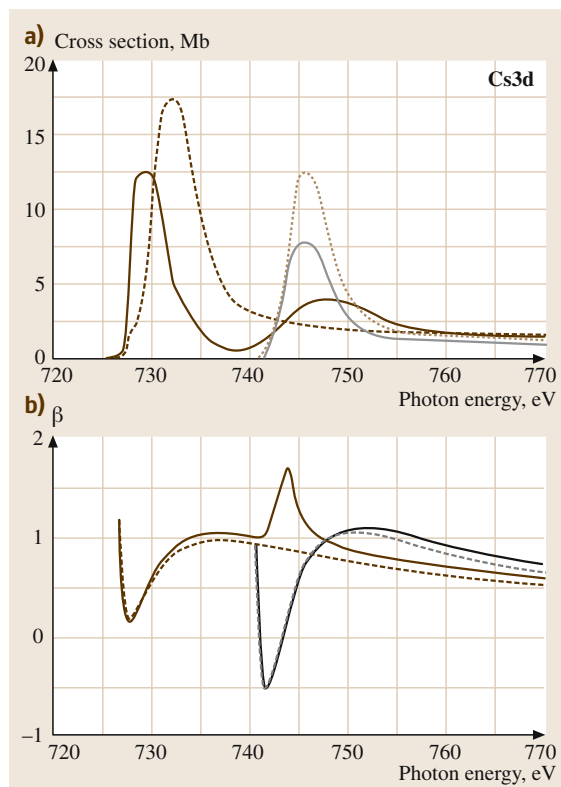
Close to inner shell thresholds, the Auger decay of a deep vacancy must be taken into account. Due to decay, the photoelectron instantly finds itself in the field of at least two vacancies instead of one, leading


Fig. 23.4a,b Intra-doublet resonance in $3d^{10}$ Cs. (**a**) Partial photoionization cross sections $\sigma_{5/2}$ and $\sigma_{3/2}$ [23.28], (**b**) Dipole angular anisotropy parameters $\beta_{5/2}$ and $\beta_{3/2}$. *Solid line*: data for 5/2 with account of 3/2; *Dash-dotted line*: data for 5/2 without account of 3/2; *Dotted line*: data for 3/2 with account of 5/2; *Dashed line*: data for 3/2 without account of 5/2

to considerable growth of the threshold cross section. Diagrammatically, the effect of decay may be described by

(23.64)

Here, the double line emphasizes that starting from the instant of decay, the photoelectron moves in the field $j_1 j_2$ of double instead of a single i vacancy. For inner vacancies, this is a strong effect which can lead even to recapture of the photoelectron into some of the discrete levels in the field of the double vacancy $j_1 j_2$.

Part B | 23.2
Fig. 23.5 Nondipole anisotropy parameter $\gamma_{5s}(\omega)$ of $5s^2$ electrons in Xe [23.29]

So-called Post-collision interactions in photoionization can be taken into account by this diagram when the Auger electron is much faster than the photoelectron [23.30]. If their speed is of the same order, their mutual Coulomb repulsion must be accounted for, leading to additional alteration of energy and angular redistributions.

A photoelectron can excite or knock out another atomic electron. To lowest order in the residual interelectron interaction, this process can be represented by
$$(23.65)$$

While the formation of an initial electron–vacancy ki_1 pair requires RPAE or GRPAE for its description, the second step of (23.65) can be reasonably well reproduced by the lowest-order term in V. It appears that process (23.65) has a high probability for not too fast photoelectrons, changing considerably the cross section [23.31] for ionization by creating a vacancy i_1.

A comparatively simple diagram

$$(23.66)$$

describes the photoionization process in which a more complicated state is created in the ion than a single vacancy, e.g. a state with two vacancies and one electron. Here the doubled arrow indicates that the electron is in a discrete level n.

Diagrams (23.64–23.66) present some corrections which mix electron–vacancy and two-electron–two-vacancy configurations. Each additional interaction line increases the number of possible physical processes considerably. With growth of the number of particles actively participating in a process, the calculational difficulties increase enormously. However, this is not a shortcoming of the diagrammatic approach, but a specific feature of more and more complex physical processes.

23.2.7 Photon Emission and Bremsstrahlung

The amplitude of photon emission in lowest order is given by the time-reverse of (23.2c):

$$(23.67)$$

This diagram represents ordinary Bremsstrahlung; i.e. a process of projectile deceleration in the field of the target. If the target has internal structure as atoms do, it can be really or virtually excited during the collision process. The simplest excitation means creation of an

electron–vacancy pair. The annihilation of this pair results via the time-reverse of (23.2a) in photon emission. The process thus looks like
(23.68)

To obtain the total Bremsstrahlung amplitude, the terms (23.67) and (23.68) must be summed. The polarization radiation (PR) created by the mechanism (23.68) has a number of features which are different from the ordinary Bremsstrahlung (OB) represented by (23.67). The intensity is proportional to $1/M_p^2$ for OB, where M_p is the projectile mass, and the spectrum, at least for high ε_k, is proportional to $1/\omega$. On the other hand, the PR intensity is almost completely independent of M_p and its frequency dependence is quite complex, being determined by the target polarizability $\alpha(\omega)$ [23.32]. PR is most important for frequencies ω of the order of and higher than the target's ionization potential. At sufficiently large distances and for neutral targets, PR starts to predominate over OB. Close to discrete excitations of the k' electron, the contribution (23.68) becomes resonantly enhanced.

Higher-order corrections are important in the PR amplitude. First, the Coulomb interaction V in (23.68) must be replaced by Γ from (23.31).

The analytical expression for the total Bremsstrahlung amplitude, including RPAE corrections to (23.68), is given by the expression

$$\langle k|A(\omega)|k'\rangle = \langle k|d|k'\rangle + \sum_{k''>F;\, i\leq F} \langle ki|V|k'k''\rangle$$

$$\times \lim_{\eta\to +0} \frac{2(\varepsilon_{k''}-\varepsilon_i)}{\omega^2-(\varepsilon_{k''}-\varepsilon_i)^2+i\omega\eta}\langle i|D(\omega)|k''\rangle\,.$$

(23.69)

To derive the Bremsstrahlung spectrum, the usual general expression must be multiplied by the square modulus of the ratio $\langle k|A(\omega)|k'\rangle/\langle k|d|k'\rangle$. If the incoming electron is slow, corrections (23.46) also become important. The intermediate state in (23.68) includes two electrons k' and k, and a vacancy i. The extent of interaction between them could be considerable.

An important feature of PR is that it is nonzero even if the projectile is neutral, but is able to polarize the target. For example, it leads to emission of continuous spectrum radiation in atom–atom collisions, whose intensity for frequencies of the order of the ionization potentials is close to that in electron–atom collisions.

The second and higher orders in the residual interaction involve processes more complicated than (23.68), for instance those which include simultaneous photon emission and target excitation (ionization) [23.33].

23.3 Concluding Remarks

It is most convenient to apply diagrammatic techniques to closed shell atoms whose ground state is non-degenerate. Degeneracy means that some of the energy denominators (23.13) become zero with nonzero statistical weight. All such contributions must be summed to eliminate this degeneracy. This leads to strong mixing of some states. For example, the energy required for electron–vacancy transitions jn [see (23.38)] within an open shell is zero, thus leading to strong mixing of i and ijn states. If a pair with zero excitation energy has nonzero angular momentum, taking into account the mixing within such a pair destroys angular momentum as a characteristic of a one-vacancy state. This makes all calculations much more complicated, reflecting a specific feature of the degenerate physical system.

In using the diagrams and formulas presented above, it is essential that the interelectron and electron–nucleus interactions be purely potential. Inclusion of

retardation and spin-dependence in the interparticle interaction makes the calculations much more complicated. These parts of the interaction appear as relativistic corrections. They are comparatively small in all but the heaviest atoms, and can be taken into account perturbatively. Beyond lowest order, these additional interactions are strongly altered when virtual excitations of electron–vacancy pairs and the Coulomb interaction between them is taken into account. An example is given by the sequence of diagrams

(23.70)
where the heavy dashed line stands for the spin-dependent interelectron interaction. Note that here there are no electron–vacancy loops as in (23.28) because the Coulomb interaction is unable to affect the electron spin and thus to transfer spin excitations.

The same kind of diagram describes the one-particle field acting upon an electron or vacancy due to the presence of spin-orbit interaction or weak interaction between electrons and the nucleus. For instance, the effective weak potential includes contributions from the

sequence

$$\tag{23.71}$$

This is another example demonstrating how flexible and convenient the many-body approach is for considering different processes and interactions.

24. Photoionization of Atoms

This chapter outlines the theory of atomic photoionization, and the dynamics of the photon−atom collision process. Those kinds of electron correlation that are most important in photoionization are emphasized, although many qualitative features can be understood within a central field model. The particle−hole type of electron correlations are discussed, as they are by far the most important for describing the single photoionization of atoms near ionization thresholds. Detailed reviews of atomic photoionization are presented in [24.1] and [24.2]. Current activities and interests are well-described in two recent books [24.3, 4]. Other related topics covered in this volume are experimental studies of photon interactions at both low and high energies in Chapts. 61 and 62, photodetachment in Chapt. 60, theoretical descriptions of electron correlations in Chapt. 23, autoionization in Chapt. 25, and multiphoton processes in Chapt. 74.

24.1 General Considerations

24.1.1 The Interaction Hamiltonian

Consider an N-electron atom with nuclear charge Z. In the nonrelativistic approximation, it is described by the Hamiltonian

$$H = \sum_{i=1}^{N} \left(\frac{p_i^2}{2m} - \frac{Ze^2}{r_i} \right) + \sum_{i>j=1}^{N} \frac{e^2}{|\mathbf{r}_i - \mathbf{r}_j|} \ . \qquad (24.1)$$

The one-electron terms in brackets describe the kinetic and potential energy of each electron in the Coulomb field of the nucleus; the second set of terms describe the repulsive electrostatic potential energy between electron pairs. The interaction of this atom with external electromagnetic radiation is described by the additional terms obtained upon replacing $\mathbf{p}_i$ by $\mathbf{p}_i + (|e|/c)\mathbf{A}(\mathbf{r}_i, t)$,

where $\mathbf{A}(\mathbf{r}_i, t)$ is the vector potential for the radiation. The interaction Hamiltonian is thus

$$H_{\text{int}} = \sum_{i=1}^{N} \left\{ \frac{+|e|}{2mc} [\mathbf{p}_i \cdot \mathbf{A}(\mathbf{r}_i, t) + \mathbf{A}(\mathbf{r}_i, t) \cdot \mathbf{p}_i] \right.$$
$$\left. + \frac{e^2}{2mc^2} |\mathbf{A}(\mathbf{r}_i, t)|^2 \right\} \ . \qquad (24.2)$$

Under the most common circumstance of single-photon ionization of an outer-subshell electron, the interaction Hamiltonian in (24.2) may be simplified considerably. First, the third term in (24.2) may be dropped, as it introduces two-photon processes (since it is of second order in $\mathbf{A}$). In any case, it is small compared with single photon processes since it is of second order in the coupling constant $|e|/c$. Second, we choose the Coulomb gauge

for A, which fixes the divergence of A as $\nabla \cdot A = 0$. A thus describes a transverse radiation field. Furthermore p and A now commute and hence the first and second terms in (24.2) may be combined. Third, we introduce the following form for A:

$$A(r_i, t) = \left(\frac{2\pi c^2 \hbar}{\omega V} \right)^{\frac{1}{2}} \hat{\boldsymbol{\epsilon}} e^{i(k \cdot r_i - \omega t)} . \tag{24.3}$$

This classical expression for A may be shown [24.5] to give photoabsorption transition rates that are in agreement with those obtained using the quantum theory of radiation. Here k and ω are the wave vector and angular frequency of the incident radiation, $\hat{\boldsymbol{\epsilon}}$ is its polarization unit vector, and V is the spatial volume. Fourth, the *electric dipole* (E1) approximation, in which $\exp[i(k \cdot r_i)]$ is replaced by unity, is usually appropriate. The radii r_i of the atomic electrons are usually of order 1 Å. Thus for $\lambda \gg 100$ Å, $|k \cdot r_i| \ll 1$. Now $\lambda \gg 100$ Å corresponds to photon energies $\hbar\omega \ll 124$ eV. For outer atomic subshells, most of the photoabsorption occurs for much smaller photon energies, thus validating the use of the E1 approximation. (This approximation cannot be used uncritically, however. For example, photoionization of excited atoms (which have large radii), photoionization of inner subshells (which requires the use of short wavelength radiation), and calculation of differential cross sections or other measurable quantities that are sensitive to the overlap of electric dipole and higher multipole amplitudes all require that the validity of the electric dipole approximation be checked.) Use of all of the above conventions and approximations allows the reduction of H_{int} in (24.2) to the simplified form

$$H_{\text{int}} = \frac{+|e|}{mc} \left(\frac{2\pi c^2 \hbar}{\omega V} \right)^{\frac{1}{2}} \sum_{i=1}^{N} \hat{\boldsymbol{\epsilon}} \cdot p_i \exp(-i\omega t) . \tag{24.4}$$

H_{int} thus has the form of a harmonically time-dependent perturbation. According to time-dependent perturbation theory, the photoionization cross section is proportional to the absolute square of the matrix element of (24.4) between the initial and final electronic states described by the atomic Hamiltonian in (24.1). Atomic units, in which $|e| = m = \hbar = 1$, are used in what follows.

24.1.2 Alternative Forms for the Transition Matrix Element

The matrix element of (24.4) is proportional to the matrix element of the momentum operator $\sum_i p_i$. Alternative expressions for this matrix element may be obtained from the following operator equations involving commutators of the exact atomic Hamiltonian in (24.1):

$$\sum_{i=1}^{N} p_i = -i \left[\sum_{i=1}^{N} r_i, H \right], \tag{24.5}$$

$$\left[\sum_{i=1}^{N} p_i, H \right] = -i \sum_{i=1}^{N} \frac{Z r_i}{r_i^3} . \tag{24.6}$$

Matrix elements of (24.5) and (24.6) between eigenstates $\langle \psi_0 |$ and $| \psi_f \rangle$ of H having energies E_0 and E_f respectively give

$$\langle \psi_0 | \sum_{i=1}^{N} p_i | \psi_f \rangle = -i\omega \langle \psi_0 | \sum_{i=1}^{N} r_i | \psi_f \rangle , \tag{24.7}$$

$$\langle \psi_0 | \sum_{i=1}^{N} p_i | \psi_f \rangle = \frac{-i}{\omega} \langle \psi_0 | \sum_{i=1}^{N} \frac{Z r_i}{r_i^3} | \psi_f \rangle , \tag{24.8}$$

where $\omega = E_f - E_0$. Matrix elements of $\sum_{i=1}^{N} p_i$, $\sum_{i=1}^{N} r_i$, and $\sum_{i=1}^{N} Z r_i / r_i^3$ are known as the "velocity," "length," and "acceleration" forms of the E1 matrix element.

Equality of the matrix elements in (24.7) and (24.8) does not hold when approximate eigenstates of H are used [24.6]. In such a case, qualitative considerations may help to determine which form is most reliable. For example, the length form tends to emphasize the large r part of the approximate wave functions, the acceleration form tends to emphasize the small r part of the wave functions, and the velocity form tends to emphasize intermediate values of r.

If instead of employing approximate eigenstates of the exact H, one employs exact eigenstates of an approximate N-electron Hamiltonian, then inequality of the matrix elements in (24.7) and (24.8) is a measure of the nonlocality of the potential in the approximate Hamiltonian [24.7, 8]. The exchange part of the Hartree–Fock potential is an example of such a nonlocal potential. Nonlocal potentials are also implicitly introduced in configuration interaction calculations employing a finite number of configurations [24.7, 8]. One may eliminate the ambiguity of which form of the E1 transition operator to use by requiring that the Schrödinger equation be gauge invariant. Only the length form is consistent with such gauge invariance [24.7, 8].

However, equality of the alternative forms of the transition operator does not necessarily imply high accuracy. For example, they are exactly equal when one

uses an approximate local potential to describe the N-electron atom, as in a central potential model, even though the accuracy is often poor. The length and velocity forms are also exactly equal in the random phase approximation [24.9], which does generally give accurate cross sections for single photoionization of closed shell atoms. No general prescription exists, however, for ensuring that the length and velocity matrix elements are equal at each level of approximation to the N-electron Hamiltonian.

24.1.3 Selection Rules for Electric Dipole Transitions

If one ignores relativistic interactions, then a general atomic photoionization process may be described in LS-coupling as follows:

$$\mathcal{A}(L, S, M_L, M_S, \pi_\mathcal{A}) + \gamma(\pi_\gamma, \ell_\gamma, m_\gamma)$$
$$\longrightarrow \mathcal{A}^+(\bar{L}\bar{S}\pi_{\mathcal{A}^+})\varepsilon\ell(L', S', M_{L'}, M_{S'}) . \qquad (24.9)$$

Here the atom $\mathcal{A}$ is ionized by the photon γ to produce a photoelectron with kinetic energy ε and orbital angular momentum ℓ. The photoelectron is coupled to the ion $\mathcal{A}^+$ with total orbital and spin angular momenta L' and S'. In the electric dipole approximation, the photon may be regarded as having odd parity, i. e., $\pi_\gamma = -1$, and unit angular momentum, i. e., $\ell_\gamma = 1$. This is obvious from (24.7) and (24.8), where the E1 operator is seen to be a vector operator. The component m_γ of the photon in the E1 approximation is ± 1 for right or left circularly polarized light and 0 for linearly polarized light. (The z axis is taken as $\hat{\boldsymbol{k}}$ in the case of circularly polarized light and as $\hat{\boldsymbol{\epsilon}}$ in the case of linearly polarized light, where $\boldsymbol{k}$ and $\hat{\boldsymbol{\epsilon}}$ are defined in (24.3).) Angular momentum and parity selection rules for the E1 transition in (24.9) imply the following relations between the initial and final state quantum numbers:

$$L' = L \oplus 1 = \bar{L} \oplus \ell , \qquad (24.10)$$
$$M_{L'} = M_L + m_\gamma = M_{\bar{L}} + m_\ell , \qquad (24.11)$$
$$S' = S = \bar{S} \oplus \frac{1}{2} , \qquad (24.12)$$
$$M_{S'} = M_S = M_{\bar{S}} + m_s , \qquad (24.13)$$
$$\pi_\mathcal{A}\pi_{\mathcal{A}^+} = (-1)^{\ell+1} . \qquad (24.14)$$

Equation (24.14) follows from the parity $(-1)^\ell$ of the photoelectron. The direct sum symbol $\oplus$ denotes the vector addition of $\boldsymbol{A}$ and $\boldsymbol{B}$ i.e, $\boldsymbol{A} \oplus \boldsymbol{B} = A + B, A + B - 1, \ldots, |A - B|$.

In (24.9), the quantum numbers $\alpha \equiv \bar{L}, \bar{S}, \pi_{\mathcal{A}^+}, \ell, L', S', M_{L'}, M_{S'}$ (plus any other quantum numbers

needed to specify uniquely the state of the ion $\mathcal{A}^+$) define a final state *channel*. All final states that differ only in the photoelectron energy ε belong to the same channel. The quantum numbers $L', S', M_{L'}, M_{S'}$, and $\pi_{\text{tot}} = (-1)^\ell \pi_{\mathcal{A}^+}$ are the only good quantum numbers for the final states. Thus the Hamiltonian (24.1) mixes final state channels having the same angular momentum and parity quantum numbers but differing quantum numbers for the ion and the photoelectron; i. e., differing $\bar{L}, \bar{S}, \pi_{\mathcal{A}^+}$, and ℓ but the same $L', S', M_{L'}, M_{S'}$ and $(-1)^\ell \pi_{\mathcal{A}^+}$.

24.1.4 Boundary Conditions on the Final State Wave Function

Photoionization calculations obtain final state wave functions satisfying the asymptotic boundary condition that the photoelectron is ionized in channel α. This boundary condition is expressed as

$$\psi_{\alpha E}^-(\boldsymbol{r}_1\boldsymbol{s}_1, \ldots, \boldsymbol{r}_N\boldsymbol{s}_N)$$
$$\underset{r_N \to \infty}{\longrightarrow} \theta_\alpha(\boldsymbol{r}_1\boldsymbol{s}_1, \ldots, \hat{\boldsymbol{r}}_N\boldsymbol{s}_N) \frac{1}{\mathrm{i}(2\pi k_\alpha)^{\frac{1}{2}}} \frac{1}{r_N} \mathrm{e}^{\mathrm{i}\Delta_\alpha}$$
$$- \sum_{\alpha'} \theta_{\alpha'}(\boldsymbol{r}_1\boldsymbol{s}_1, \ldots, \hat{\boldsymbol{r}}_N\boldsymbol{s}_N) \frac{1}{\mathrm{i}(2\pi k_{\alpha'})^{\frac{1}{2}}} \frac{1}{r_N} \mathrm{e}^{-\mathrm{i}\Delta_{\alpha'}} S_{\alpha'\alpha}^\dagger ,$$
$$\qquad (24.15)$$

where the phase appropriate for a Coulomb field is

$$\Delta_\alpha \equiv k_\alpha r_N - \frac{1}{2}\pi\ell_\alpha + \frac{1}{k_\alpha} \log 2k_\alpha r_N + \sigma_{\ell_\alpha} . \quad (24.16)$$

The minus superscript on the wave function in (24.15) indicates an "incoming wave" normalization: i. e., asymptotically $\psi_{\alpha E}^-$ has outgoing spherical Coulomb waves only in channel α, while there are incoming spherical Coulomb waves in all channels. $S_{\alpha'\alpha}^\dagger$ is the Hermitian conjugate of the S-matrix of scattering theory, θ_α indicates the coupled wave function of the ion and the angular and spin parts of the photoelectron wave function, k_α is the photoelectron momentum in channel α and ℓ_α is its orbital angular momentum, and σ_{ℓ_α} in (24.16) is the Coulomb phase shift.

While one calculates channel functions $\psi_{\alpha E}^-$, experimentally one measures photoelectrons which asymptotically have well-defined linear momenta $\boldsymbol{k}_\alpha$ and well-defined spin states $m_{\frac{1}{2}}$, and ions in well-defined states $\bar{\alpha} \equiv \bar{L}\bar{S}M_{\bar{L}}M_{\bar{S}}$. The wave function appropriate for this experimental situation is related to the channel functions by uncoupling the ionic and electronic orbital and

spin angular momenta and projecting the photoelectron angular momentum states ℓ_α, m_α onto the direction $\hat{k}_\alpha$ by means of the spherical harmonic $Y_{\ell_\alpha m_\alpha}^\star(k_\alpha)$. This relation is [24.1]:

$$
\begin{aligned}
&\psi_{\bar{\alpha}k_\alpha}^-(r_1 s_1, \ldots, r_N s_N) \\
&= \sum_{\ell_\alpha m_\alpha} \frac{i^{\ell_\alpha} \exp(-i\sigma_{\ell_\alpha})}{k_\alpha^{\frac{1}{2}}} Y_{\ell_\alpha m_\alpha}^\star(\hat{k}_\alpha) \\
&\quad \times \sum_{LM_L SM_S} \langle \bar{L}M_{\bar{L}}\ell_\alpha m_\alpha | LM_L \rangle \\
&\quad \times \langle \bar{S}M_{\bar{S}}\tfrac{1}{2}m_{\frac{1}{2}} | SM_S \rangle \psi_{\alpha E}^-(r_1 s_1, \ldots, r_N s_N) , \quad (24.17)
\end{aligned}
$$

where the coefficients in brackets are Clebsch–Gordon coefficients. This wave function is normalized to a delta function in momentum space, i. e.,

$$
\int \left(\psi_{\bar{\alpha}k_\alpha}^-\right)^\dagger \psi_{\bar{\alpha}' k_{\alpha'}}^- \, d^3 r = \delta_{\bar{\alpha}\bar{\alpha}'}\delta(k_\alpha - k_{\alpha'}) . \quad (24.18)
$$

The factors $i^{\ell_\alpha} \exp(-i\sigma_{\ell_\alpha})k_\alpha^{-\frac{1}{2}}$ ensure that for large r_N (24.17) represents a Coulomb wave (with momentum k_α) times the ionic wave function for the state $\bar{\alpha}$ plus a sum of terms representing incoming spherical waves. Thus only the ionic term $\bar{\alpha}$ has an outgoing wave. One uses the wave function in (24.17) to calculate the angular distribution of photoelectrons.

24.1.5 Photoionization Cross Sections

If one writes H_{int} in (24.4) as $H_{\text{int}}(t) = H_{\text{int}}(0)\,e^{-i\omega t}$, then from first order time-dependent perturbation theory, the transition rate for transition from an initial state with energy E_0 and wave function ψ_0 to a final state with total energy E_f and wave function $\psi_{\bar{\alpha}k_\alpha}^-$ is

$$
\begin{aligned}
dW_{k_\alpha} =\ &2\pi |\langle \psi_0 | H_{\text{int}}(0) | \psi_{\bar{\alpha}k_\alpha}^- \rangle|^2 \\
&\times \delta(E_f - E_0 - \omega)k_\alpha^2 \, dk_\alpha \, d\Omega(\hat{k}_\alpha) . \quad (24.19)
\end{aligned}
$$

The delta function expresses energy conservation and the last factors on the right are the phase space factors for the photoelectron. Dividing the transition rate by the incident photon current density c/V, integrating over dk_α,

and inserting $H_{\text{int}}(0)$, the differential photoionization cross section is

$$
\frac{d\sigma_{\bar{\alpha}}}{d\Omega} = \frac{4\pi^2}{c}\frac{k_\alpha}{\omega} \left| \hat{\boldsymbol{\epsilon}} \cdot \langle \psi_0 | \sum_{i=1}^N \boldsymbol{p}_i | \psi_{\bar{\alpha}k_\alpha}^- \rangle \right|^2 . \quad (24.20)
$$

Implicit in (24.19) and (24.20) is an average over initial magnetic quantum numbers $M_{L_0} M_{S_0}$ and a sum over final magnetic quantum numbers $M_{\bar{L}} M_{\bar{S}} m_{\frac{1}{2}}$. The length form of (24.20) is obtained by replacing each $\boldsymbol{p}_i$ by $\omega\boldsymbol{r}_i$ (24.7).

Substitution of the final state wave function (24.17) in (24.20) permits one to carry out the numerous summations over magnetic quantum numbers and obtain the form

$$
\frac{d\sigma_{\bar{\alpha}}}{d\Omega} = \frac{\sigma_{\bar{\alpha}}}{4\pi}[1 + \beta P_2(\cos\theta)] \quad (24.21)
$$

for the differential cross section [24.10]. Here $\sigma_{\bar{\alpha}}$ is the partial cross section for leaving the ion in the state $\bar{\alpha}$, β is the asymmetry parameter [24.11], $P_2(\cos\theta) = \frac{3}{2}\cos^2\theta - \frac{1}{2}$, and θ indicates the direction of the outgoing photoelectron with respect to the polarization vector $\hat{\boldsymbol{\epsilon}}$ of the incident light. The form of (24.21) follows in the electric dipole approximation from general symmetry principles, provided that the target atom is unpolarized [24.12]. The partial cross section is given in terms of reduced E1 matrix elements involving the channel functions in (24.15) by

$$
\sigma_{\bar{\alpha}} = \frac{4\pi^2}{3c}\omega[L]^{-1}\sum_{\ell_\alpha L'}\left| \langle \psi_0 \| \sum_{i=1}^N r_i^{[1]} \| \psi_{\alpha E}^- \rangle \right|^2 . \quad (24.22)
$$

The β parameter has a much more complicated expression involving interference between different reduced dipole amplitudes [24.1]. Thus measurement of β provides information on the relative phases of the alternative final state channel wave functions, whereas the partial cross-section in (24.22) does not. From the requirement that the differential cross section in (24.21) be positive, one sees that $-1 \le \beta \le +2$.

24.2 An Independent Electron Model

The many-body wave functions ψ_0 and $\psi_{\alpha E}^-$ are usually expressed in terms of a basis of independent electron wave functions. Key qualitative features of photoionization cross sections can often be interpreted in terms

of the overlaps of initial and final state one electron radial wave functions [24.1, 13]. The simplest independent electron representation of the atom, the central potential model, proves useful for this purpose.

24.2.1 Central Potential Model

In the central potential (CP) model the exact H in (24.1) is approximated by a sum of single-particle terms describing the independent motion of each electron in a central potential $V(r)$:

$$H_{CP} = \sum_{i=1}^{N} \left[\frac{p_i^2}{2m} + V(r_i) \right] . \tag{24.23}$$

The potential $V(r)$ must describe the nuclear attraction and the electron–electron repulsion as well as possible and must satisfy the boundary conditions

$$V(r) \xrightarrow[r \to 0]{} -Z/r \quad \text{and} \quad V(r) \xrightarrow[r \to \infty]{} -1/r \tag{24.24}$$

in the case of a neutral atom. H_{CP} is separable in spherical coordinates and its eigenstates can be written as Slater determinants of one-electron orbitals of the form $r^{-1} P_{n\ell} Y_{\ell m}(\Omega)$ for bound orbitals and of the form $r^{-1} P_{\varepsilon\ell}(r) Y_{\ell m}(\Omega)$ for continuum orbitals. The one-electron radial wave functions satisfy

$$\frac{\mathrm{d}^2 P_{\varepsilon\ell}(r)}{\mathrm{d}r^2} + 2 \left[\varepsilon - V(r) - \frac{\ell(\ell+1)}{2r^2} \right] P_{\varepsilon\ell}(r) = 0 , \tag{24.25}$$

subject to the boundary condition $P_{\varepsilon\ell}(0) = 0$, and similarly for the discrete orbitals $P_{n\ell}(r)$. *Hermann* and *Skillman* [24.14] have tabulated a widely used central potential for each element in the periodic table as well as radial wave functions for each occupied orbital in the ground state of each element.

24.2.2 High Energy Behavior

The hydrogen atom cross section, which is nonzero at threshold and decreases monotonically with increasing photon energy, serves as a model for inner-shell photoionization cross sections in the X-ray photon energy range. A sharp onset at threshold followed by a monotonic decrease above threshold is precisely the behavior seen in X-ray photoabsorption measurements. A simple hydrogenic approximation at high energies may be justified theoretically as follows: (1) Since a free electron cannot absorb a photon (because of kinematical considerations), at high photon energies one expects the more strongly bound inner electrons to be preferentially ionized as compared with the outer electrons. (2) Since the $P_{n\ell}(r)$ for an inner electron is concentrated in a very small range of r, one expects the integrand of the radial dipole matrix element to be negligible except for those

values of r where $P_{n\ell}(r)$ is greatest. (3) Thus it is only necessary to approximate the atomic potential locally, e.g., by means of a screened Coulomb potential

$$V_{n\ell}(r) = - \left(\frac{Z - s_{n\ell}}{r} \right) + V_{n\ell}{}^{\mathrm{o}} \tag{24.26}$$

appropriate for the $n\ell$ orbital. Here $s_{n\ell}$ is the "inner-screening" parameter, which accounts for the screening of the nuclear charge by the other atomic electrons, and $V_{n\ell}^{\mathrm{o}}$ is the "outer-screening" parameter, which accounts for the lowering of the $n\ell$ electrons' binding energy due to repulsion between the outer electrons and the photoelectron as the latter leaves the atom. The potential in (24.26) predicts hydrogen-like photoionization cross sections for inner-shell electrons with onsets determined by the outer-screening parameters $V_{n\ell}^{\mathrm{o}}$.

Use of more accurate atomic central potentials in place of the screened hydrogenic potential in (24.26) generally enables one to obtain photoionization cross sections below the keV photon energy region to within 10% of the experimental results [24.15]. For $\ell > 0$ subshells and photon energies in the keV region and above, the independent particle model becomes increasingly inadequate owing to coupling with nearby ns-subshells, which generally have larger partial cross sections at high photon energies [24.16]. For high, but still nonrelativistic photon energies, i. e., $\omega \ll mc^2$, the energy dependence of the cross section for the $n\ell$ subshell within the independent particle model is [24.17]

$$\sigma_{n\ell} \sim \omega^{-\ell - \frac{7}{2}} . \tag{24.27}$$

However, when interchannel interactions are taken into account, the asymptotic energy dependence for subshells having $\ell > 0$ becomes independent of ℓ [24.18]:

$$\sigma_{n\ell} \sim \omega^{-\frac{9}{2}} (\ell > 0) . \tag{24.28}$$

This result stems from coupling of the $\ell > 0$ photoionization channels with nearby s-subshell channels.

24.2.3 Near Threshold Behavior

For photons in the vuv energy region, i. e., near the outer-subshell ionization thresholds, the photoionization cross sections for subshells with $\ell \geq 1$ frequently have distinctly nonhydrogenic behavior. The cross section, instead of decreasing monotonically as for hydrogen, rises above threshold to a maximum (the so called *delayed maximum* above threshold). Then it decreases to a minimum (the *Cooper minimum* [24.19, 20]) and rises to

a second maximum. Finally the cross section decreases monotonically at high energies in accordance with hydrogenic behavior. Such nonhydrogenic behavior may be interpreted as due either to an effective potential barrier or to a zero in the radial dipole matrix element. We examine each of these effects in turn.

The *delayed maximum* above outer subshell ionization thresholds of heavy atoms (i. e., $Z \gtrsim 18$) is due to an effective potential barrier seen by $\ell = 2$ and $\ell = 3$ photoelectrons in the region of the outer edge of the atom (24.25). This effective potential lowers the probability of photoelectron escape until the photoelectrons have enough excess energy to surmount the barrier. Such behavior is nonhydrogenic. Furthermore, in cases where an inner subshell with $\ell = 2$ or 3 is being filled as Z increases (as in the transition metals, the lanthanides and the actinides) there is a double well potential. This double well has profound effects on the 3p-subshell spectra of the transition metals, the 4d-subshell spectra of the lanthanides, and the 5d-subshell spectra of the actinides, as well as on atoms with Z just below those of these series of elements [24.1, 21, 22].

Cross section minima arise due to a change in sign of the radial dipole transition matrix element in a particular channel [24.23, 24]. Rules for predicting their occurrence were developed by *Cooper* [24.19, 20]. Studies of their occurrence in photoionization from excited states [24.25], in high Z atoms [24.26], and in relativistic approximation [24.27] have been carried out. Only recently has a proof been given [24.28] that such minima do not occur in atomic hydrogen spectra. For other elements, there are further rules on when and how many minima may occur [24.29–31].

Often within such minima, one can observe effects of weak interactions that are otherwise obscured. Relativistic and weak correlation effects on the asymmetry parameter β for s-subshells is a notable example [24.32]. *Wang* et al. [24.33] have also emphasized that near such minima in the E1 amplitudes, one cannot ignore the effects of quadrupole and higher corrections to the differential cross section. Central potential model calculations [24.33] show that quadrupole corrections can be as large as 10% of the E1 cross section at such cross section minima, even for low photon energies.

24.3 Particle–Hole Interaction Effects

The experimental photoionization cross sections for the outer subshells of the noble gases (The noble gases have played a prominent role in the development of the theory of photoionization for two reasons. These were among the first elements studied by experimentalists with synchrotron radiation beginning in the 1960's. Also, their closed-shell, spherically symmetric ground states simplified the theoretical analysis of their cross sections.) near the ionization thresholds can be understood in terms of interactions between the photoelectron, the residual ion, and the photon field which are called, in many-body theory language, "particle–hole" interactions (see Chapt. 47). These may be described as interactions in which two electrons either excite or de-excite each other out of or into their initial subshell locations in the unexcited atom. To analyze the effects of these interactions on the cross section, it is convenient to classify them into three categories: intrachannel, virtual double excitation, and interchannel. These alternative kinds of particle–hole interactions are illustrated in Fig. 24.1 using both many-body perturbation theory (MBPT) diagrams and more "physical" scattering pictures. We discuss each of these types of interaction in turn.

24.3.1 Intrachannel Interactions

The MBPT diagram for this interaction is shown on the left in Fig. 24.1a; on the right a slightly more pictorial description of this interaction is shown. The wiggly line indicates a photon, which is absorbed by the atom in such a way that an electron is excited out of the $n\ell$ subshell. During the escape of this excited electron, it collides or interacts with another electron from the same subshell in such a way that the second electron absorbs all the energy imparted to the atom by the photon; the first electron is de-excited back to its original location in the $n\ell$ subshell. For closed-shell atoms, the photoionization process leads to a $^1P_1$ final state in which the intrachannel interaction is strongly repulsive. This interaction tends to broaden cross section maxima and push them to higher photon energies as compared with the results of central potential model calculations.

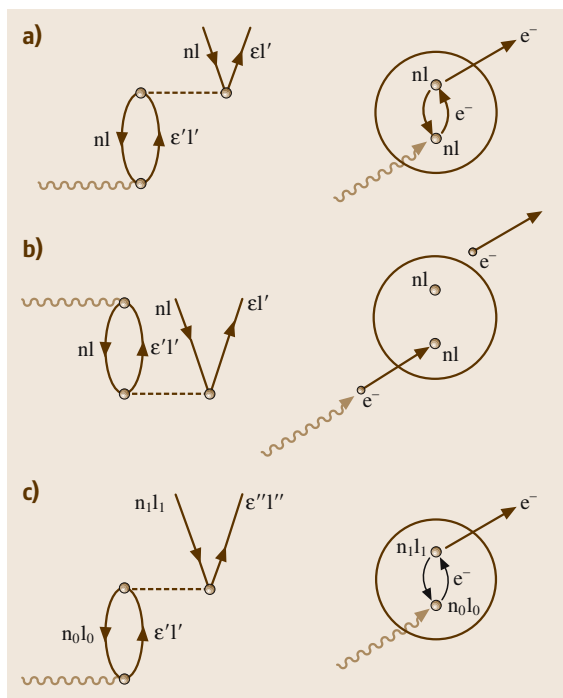
Intrachannel interaction effects are taken into account automatically when the correct Hartree-Fock (HF) basis set is employed in which the photoelectron sees a net Coulomb field due to the residual ion and is coupled to the ion to form the appropriate total orbital L and


Fig. 24.1a–c MBPT diagrams (*left*) and scattering pictures (*right*) for three kinds of particle–hole interaction: **(a)** intrachannel scattering following photoabsorption; **(b)** photoabsorption by a virtual doubly-excited state; **(c)** interchannel scattering following photoabsorption

spin S angular momenta. Any other basis set requires explicit treatment of intrachannel interactions.

24.3.2 Virtual Double Excitations

The MBPT diagram for this type of interaction is shown on the left in Fig. 24.1b. Topologically, this diagram is the same as that on the left in Fig. 24.1a. In fact, the radial parts of the two matrix elements are identical; only the angular factors differ. A more pictorial description of this interaction is shown on the right of Fig. 24.1b. The ground state of the atom before photoabsorption is shown to have two electrons virtually excited out of the $n\ell$ subshell. In absorbing the photon, one of these electrons is de-excited to its original location in the $n\ell$ subshell, while the other electron in ionized. These virtual double excitations imply a more diffuse atom than in central-potential or HF models, with the effect that the overly repulsive intrachannel interactions are weakened, leading to cross sections for noble gas atoms

that are in very good agreement with experiment with the exception that resonance features are not predicted.

24.3.3 Interchannel Interactions

The interchannel interaction shown in Fig. 24.1c is important, particularly for s subshells. This interaction has the same form as the intrachannel interaction shown in Fig. 24.1a, except now when an electron is photoexcited out of the $n_0\ell_0$ subshell, it collides or interacts with an electron in a different subshell – the $n_1\ell_1$ subshell. This interaction causes the second electron to be ionized, and the first electron to fall back into its original location in the $n_0\ell_0$ subshell.

Interchannel interaction effects are usually very conspicuous features of photoionization cross sections. When the interacting channels have partial photoionization cross sections which differ greatly in magnitude, one finds that the calculated cross section for the weaker channel is completely dominated by its interaction with the stronger channel. At the same time, it is often a safe approximation to ignore the effect of weak channels on stronger channels. In addition, when the interacting channels have differing binding energies, their interchannel interactions lead to resonance structure in the channel with lower binding energy (arising from its coupling to the Rydberg series in the channel with higher binding energy).

At high photon energies, s-subshell partial cross sections dominate over $\ell > 0$ subshell partial cross sections [(24.27), (24.28)]. Hence interchannel interactions of $\ell > 0$ subshells with nearby s-subshells change independent particle model predictions significantly. In particular, as noted in Sect. 24.3.2, such interactions can drastically change the magnitudes of the $\ell > 0$ partial cross sections [24.16] as well as their asymptotic energy behavior [24.18].

24.3.4 Photoionization of Ar

An example of both the qualitative features exhibited by photoionization cross sections in the vuv energy region and of the ability of theory to calculate photoionization cross reactions is provided by photoionization of the $n = 3$ subshell of argon, i. e.,

$$\begin{aligned} \text{Ar}3\text{s}^2 3\text{p}^6 + \gamma &\rightarrow \text{Ar}^+ 3\text{s}^2 3\text{p}^5 + \text{e}^- \\ &\rightarrow \text{Ar}^+ 3\text{s}3\text{p}^6 + \text{e}^- \, . \end{aligned} \tag{24.29}$$
Figure 24.2 shows the MBPT calculation of *Kelly* and *Simons* [24.34], which includes both intrachannel

and interchannel interactions as well as the effect of virtual double excitations. The cross section is in excellent agreement with experiment [24.35, 36], even to the extent of describing the resonance behavior due to discrete members of the $3s \rightarrow \varepsilon p$ channel.

Figure 24.2 illustrates most of the features of photoionization cross sections described so far. First, the cross section rises to a delayed maximum just above the threshold because of the potential barrier seen by photoelectrons from the 3p subshell having $\ell = 2$. For photon energies in the range of 45–50 eV, the calculated cross section goes through a minimum because of a change in sign of the $3p \rightarrow \varepsilon d$ radial dipole amplitude. The HFL and HFV calculations include the strongly repulsive intrachannel interactions in the ^{1}P final-state channels and calculate the transition amplitude using the length (L) and velocity (V) form respectively for the electric dipole transition operator (24.7). With respect to the results of central potential model calculations, the HFL and HFV results have lower and broader maxima at higher energies. They also disagree with each other by a factor of two! Inclusion of virtual double excitations results in length and velocity results that agree to within 10% with each other and with experiment, except that the resonance structures are not reproduced. Finally, taking into account the interchannel interactions, one obtains the length and velocity form results shown in Fig. 24.2 by dash-dot and dashed curves re-
Fig. 24.2 Photoionization cross section for the 3p and 3s subshells of Ar. HFL and HFV indicate the length and velocity results obtained using HF orbitals calculated in a ^{1}P$_1$ potential. *Dot-dash* and *dashed lines* represent the length and velocity results of the MBPT calculation of *Kelly* and *Simons* [24.34]. Only the four lowest $3s \rightarrow n$p resonances are shown; the series converges to the 3s threshold at 29.24 eV. Experimental results are those of *Samson* [24.35] above 37 eV and of *Madden* et al. [24.36] below 37 eV (After [24.34])

spectively. Agreement with experiment is excellent and the observed resonances are well-reproduced.

24.4 Theoretical Methods for Photoionization

24.4.1 Calculational Methods

Most of the ab initio methods for the calculation of photoionization cross sections (e.g., the MBPT method [24.37], the close-coupling (CC) method [24.38], the R-matrix method [24.39, 40], the random phase approximation (RPA) method [24.9], the relativistic RPA method [24.41], the transition matrix method [24.42, 43], the multiconfiguration Hartree-Fock (MCHF) method [24.44–46], etc.) have successfully calculated outer p-subshell photoionization cross sections of the noble gases by treating in their alternative ways the key interactions described above, i. e., the particle–hole interactions. In general, these methods all treat both intrachannel and interchannel interactions to infinite order and differ only in their treatment of ground state correlations. (The exception is MBPT, which often treats interchannel interactions between weak and strong

channels only to first or second order.) These methods therefore stand in contrast to central potential model calculations, which do not treat any of the particle–hole interactions, and single-channel term-dependent HF calculations, which treat only the intrachannel interactions. The key point is that selection of the interactions that are included in a particular calculation is more important than the method by which such interactions are handled.

Treatment of photoionization of atoms other than the noble gases presents additional challenges for theory. For example, elements such as the alkaline earths, which have s^2 outer subshells, require careful treatment of electron pair excitations in both initial and final states. Open shell atoms have many more ionization thresholds than do the noble gases. Treatment of the resultant rich resonance structures typically relies heavily on quantum defect theory [24.46] (see Chapt. 32). All the methods

listed above can be used to treat elements other than the noble gases, but a method which has come to prominence because of the excellent results it obtains for both alkaline earth and open-shell atoms is the eigenchannel R-matrix method [24.47].

24.4.2 Other Interaction Effects

A number of interactions, not of the particle–hole type, lead to conspicuous effects in localized energy regions. When treating photoionization in such energy regions, one must be careful to choose a theoretical method which is appropriate. Among the interactions which may be important are the following:

Relativistic and Spin–Dependent Interactions

The fact that $j = \ell - \frac{1}{2}$ electrons are contracted more than $j = \ell + \frac{1}{2}$ electrons at small distances has an enormous effect on the location of cross section minima in heavy elements [24.15, 48]. It may explain the large observed differences in the profiles of a resonance decaying to final states that differ only in their fine structure quantum numbers [24.49].

Inner–Shell Vacancy Rearrangement

Inner-shell vacancies often result in significant production of satellite structures in photoelectron spectra. Calculations for inner subshell partial photoionization cross sections are often substantially larger than results of photoelectron measurements [24.50–52]. This differ-

ence is attributed to such satellite production, which is often not treated in theoretical calculations.

Polarization and Relaxation Effects

Negative ion photodetachment cross sections often exhibit strong effects of core polarization near threshold. These effects can be treated semi-empirically, resulting in excellent agreement between theory and experiment [24.53]. Even for inner shell photoionization cross sections of heavy elements, ab initio theories do not reproduce measurements near threshold without the inclusion of polarization and relaxation effects [24.54, 55].

An Example

The calculation of the energy dependence of the asymmetry parameter β for the 5s subshell of xenon requires the theoretical treatment of all of the above effects. In the absence of relativistic interactions, β for Xe 5s would have the energy-independent value of two. Deviations of β from two are therefore an indication of the presence of these relativistic interactions. The greatest deviation of β from two occurs in the localized energy region where the partial photoionization cross section for the 5s subshell has a minimum. In this region, however, relativistic calculations show larger deviations from two than are observed experimentally. Inner shell rearrangement and relaxation effects play an important role [24.56, 57] and must be included to achieve good agreement with experiment.

24.5 Recent Developments

One of the most intensively studied areas in atomic photoionization in recent years has been the double photoionization of the helium atom. Extensive sets of experimental measurements for the two electron angular distributions (i. e., the triply differential cross sections) have provided stringent tests for various theoretical models and their treatments of electron correlations. A number of excellent reviews of this field have been published recently [24.58–60].

Another intensively studied area has been the analysis and measurement of non-dipole effects in photoionization, which were first observed in the X-ray region [24.61] but have been found to be significant even in the vuv photon energy region [24.62, 63]. In general, these effects stem from interference between electric quadrupole and the (usual) electric dipole transition amplitudes in differential cross sections (for a recent review,

see [24.64]). Besides asymmetries in the photoelectron angular distributions, non-dipole effects lead also to new features for spin-resolved measurements [24.65, 66], and for the case of polarized atoms [24.67]. Recently, non-dipole effects have been predicted to be significant also in double photoionization of helium at relatively low photon energies [24.68].

Finally, both experimental and theoretical studies of ionic species have flourished over the past decade. In particular, photodetachment of negative ions near excited atomic thresholds provides an opportunity to study correlated, three-body Coulomb states unencumbered by Rydberg series. Only with the advent of powerful computer workstations have theorists been able to carry out numerical calculations for such high, doubly excited states with spectroscopic accuracy. Following experiments for photodetachment of H$^-$ with excita-

tions of atomic levels in H($n > 2$), theorists developed propensity rules for identifying and characterizing the dominant photodetachment channels [24.69–71]. More recently, experimental and theoretical interest shifted to the negative alkali ions (e.g., Li$^-$ and Na$^-$), which for low photon energies have outer electron detachment spectra grossly resembling that of H$^-$. However, the negative alkali spectra contain clear signatures of propensity-rule-forbidden states that become increasingly prominent as the atomic number increases (owing to the nonhydrogenic inner electron cores). A brief review of low energy negative alkali photodetachment is given in [24.72]. Among the more general features brought to light by these studies is the mirroring of resonance profiles in alternative partial cross sections, which appears to be a very general phenomenon common to photodetachment and photoionization processes involving highly excited residual atoms or ions [24.73].

Recently, high energy (K-shell) photodetachment of the negative ions Li$^-$ and He$^-$ (resulting in two elec-

tron ionization) has been studied both experimentally and theoretically [24.74, 75]. These studies represent the first results for inner shell photodetachment. There is general agreement between theory and experiment well above the K edge, but the theoretical cross sections at the K edge are significantly higher than the experimental measurements. The latter discrepancy is now understood as arising from recapture of the low-energy detached electron following Auger decay of the inner-shell vacancy, which when taken into account theoretically has been shown to provide results that agree with experiment [24.76, 77]. Also, the first experimental data together with theoretical analyses were recently presented for photoionization of ground and metastable positive ions (O$^+$ and Sc^{++}) [24.78, 79]. With the advent of data for photoionization of positive ions it now becomes possible (using the principle of detailed balance) to make connections to data for electron–ion photo-recombination cross sections [24.79].

24.6 Future Directions

The construction of high brightness synchrotron light sources and the increasing use of lasers are providing the means to study atomic photoionization processes at an unparalleled level of detail. The synchrotrons generally produce photons in the soft X-ray and X-ray regions. Thus, inner shell vacancy production and decay, satellite production, and multiple ionization phenomena are all being increasingly studied. Laser sources are allowing production of atoms in tailored initial states. Studies of ions, both negativeand positive, in

well-specified states are also increasingly being carried out. Thus, photoionization of excited atoms and ions and, in particular, complete measurements of particular photoionization processes, are now possible. Recent collections of short review papers provide references to these topics [24.3, 4]. In addition, two recent reviews of experimental results for noble gas atom photoionization [24.80] and for metal atom photoionization [24.81] also provide valuable information on the current state of the correspondingtheoretical results.

25. Autoionization

The phenomenon of autoionization, or more particularly the autoionization state itself, is treated for the most part in this chapter as a bound state. The process is rigorously a part of the scattering continuum (Chapt. 47), but, due mostly to the work of *Feshbach* [25.1], a rigorous formulation can be established whereby the main element of the theory can be made into a bound state problem with the scattering elements built around it. The major constituent of both these features is accomplished with projection operators. A brief description of the above elements of the theory, centered around projection operators, is the aim of this chapter [25.2], although some additional methods are discussed in Sect. 25.5. Rydberg units are used unless otherwise noted.

25.1 Introduction

25.1.1 Auger Effect

Autoionization falls within the general class of phenomena known as the Auger effect. In the Auger effect an atomic system "seemingly" (Sect. 25.1.3) spontaneously decays into a partition of its constituent parts.

25.1.2 Autoionization, Autodetachment, and Radiative Decay

If the initial, composite system is neutral, or positively charged, and its constituent decay particles are an electron and the residual ion, then the process is called *autoionization*. If the original system is a negative ion, so that the residual heavy particle system is neutral, then the process is technically called *autodetachment*; for the most part, the physics and the mathematical treatment are the same.

It is also possible, before electron emission takes place, that the system will alternatively decay radiatively to an autoionization state of lower energy, or a true bound state of the composite system. The latter process is called *radiative stabilization* (which is a basic part of dielectronic recombination (Chapt. 55)).

25.1.3 Formation, Scattering, and Resonances

Autoionizing states are formed by scattering processes and photoabsorption. These are the inverses of the autoionization and photon emission processes by which they can decay. In the scattering process, formation of the autoionization state corresponds to a resonance

in the scattering cross section (Chapt. 47). Autoionization is the process which corresponds to the decay of the resonance. The decay of the resonance (autoionization) is then seen to be the last half of the resonant scattering process. Strictly speaking therefore, the resonant or autoionization state, although it may be long-lived, is not completely stationary, and that is the reason that the word "seemingly" was used to describe the Auger process. The compound system can also be formed by absorption of photons impinging on a bound state (usually the ground state) of the compound system, in which case the autionization state shows up as a "line" in the absorption spectrum.

25.2 The Projection Operator Formalism

In the energy domain where the Schrödinger equation (SE)

$$H\Psi = E\Psi \tag{25.1}$$

describes scattering, the wave function does not vanish at infinity, i. e.,

$$\lim_{r_i \to \infty} \Psi \neq 0 , \tag{25.2}$$

where r_i is the radial coordinate of ith electron.

The basic idea of the projection operator formalism [25.1] is to define projection operators P and Q which separate Ψ into scattering-like ($P\Psi$) and quadratically integrable ($Q\Psi$) parts:

$$\Psi = P\Psi + Q\Psi . \tag{25.3}$$

Implicit in (25.3) are

completeness: $P + Q = 1$,

idempotency: $P^2 = P$, $Q^2 = Q$,

orthogonality: $PQ = 0$, $\tag{25.4}$

and the asymptotic properties

$$\lim_{r_i \to \infty} \begin{cases} P\Psi = \lim_{r_i \to \infty} \Psi \\ Q\Psi = 0 \end{cases} . \tag{25.5}$$

25.2.1 The Optical Potential

Straightforward manipulation of (25.1) and (25.3) leads to an important relation between $Q\Psi$ and $P\Psi$:

$$Q\Psi = (E - QHQ)^{-1} QHP\Psi . \tag{25.6}$$

From (25.6) a basic equation for $P\Psi$ (which, by virtue of (25.5), contains all the scattering information) emerges:

$$(PHP + V_{op} - E)P\Psi = 0 . \tag{25.7}$$

The most significant part of (25.7) is the optical potential V_{op} given by

$$V_{op} = PHQ(E - QHQ)^{-1}QHP . \tag{25.8}$$

V_{op} is a nonlocal potential; the most incisive way to give it meaning is to the define the QHQ problem.

25.2.2 Expansion of V_{op}: The QHQ Problem

The following eigenvalue problem constitutes the heart of the projection operator formalism:

$$QHQ\Phi_n = \mathcal{E}_n \Phi_n . \tag{25.9}$$

For calculational purposes, it is best to recast (25.9) in the variational form

$$\delta \left(\frac{\langle \Phi QHQ\Phi \rangle}{\langle \Phi Q\Phi \rangle} \right) = 0 . \tag{25.10}$$

This equation may yield a discrete plus a continuous spectrum in an energy domain where the SE has only a continuous spectrum. Moreover, if the Q operator is appropriately chosen, then the discrete eigenvalues $\mathcal{E}_n$ are close to the desired class of many-body resonances, called variously Feshbach resonances, core-excited [25.3], or doubly-excited states. In terms of these solutions, V_{op} has the expansion

$$V_{op} = \sum \int PHQ|\Phi_n\rangle(E - \mathcal{E}_n)^{-1}\langle\Phi_n|QHP . \tag{25.11}$$

25.3 Forms of *P* and *Q*

25.3.1 The Feshbach Form

Projection operators are not unique. *Feshbach* [25.1] has sketched a derivation of a "robust" projection operator for the general N-electron target system. Robust means that $Q\Phi$ is devoid of open channels. The complete expression for P, including inelastic channels has been derived in [25.5]

$$P = \sum_{i=1}^{N+1} \left[\boldsymbol{\psi}\big(r^{(i)}\big)\big\rangle \cdot \big\langle \boldsymbol{\psi}\big(r^{(i)}\big) \right. \\ \left. + {\sum_{\lambda_\alpha}}' \frac{\boldsymbol{v}_\alpha(r_i) \cdot \boldsymbol{\psi}\big(r^{(i)}\big)\big\rangle\big\langle \boldsymbol{v}_\alpha(r_i) \cdot \boldsymbol{\psi}\big(r^{(i)}\big)}{\lambda_\alpha - 1} \right],$$

(25.12)

where the prime on the second summation means that terms with $\lambda_\alpha = 1$ are to be omitted, r_i denotes the radial coordinate of electron i, and $r^{(i)}$ stands for the angular and spin coordinates of electron i plus all coordinates of the remaining N electrons. Thus $r^{(i)}$ indicates the totality of all coordinates of the $(N+1)$ electrons *except* the radial coordinate of the ith electron r_i. $\boldsymbol{\psi}(r^{(i)})$ is the vector channel wave function in which the angular momentum and spin of the electron i are coupled to the target in state ν ($\nu = 0, \dots, \nu_{\max}$). A component of a vector labels the inelastic channel, and dot products represent sums over channels. The Q operator is then made explicit by completeness: $Q = 1 - P$, (25.4).

The α-indexed quantities in (25.12) arise from exchange; they are the eigensolutions of the integral eigenvalue problem

$$\boldsymbol{v}_\alpha(r_i) = \lambda_\alpha \langle \mathbf{K}(r_i|r_j) \cdot \boldsymbol{v}_\alpha(r_j)\rangle_{r_j} .$$

(25.13)

Here, $\mathbf{K}(r_i|r_j)$ is a matrix with components

$$K_{\mu\nu}(r_i|r_j) \propto N\big\langle \psi_\mu\big(r^{(i)}\big)\psi_\nu\big(r^{(j)}\big)\big\rangle_{r^{(ij)}} ,$$

(25.14)

and $r^{(ij)}$ indicates that all variables, except r_i and r_j are integrated over. In the inelastic regime, therefore, the $[\boldsymbol{v}_\alpha, \lambda_\alpha]$ are not associated with specific channels, but rather with the totality of open channels. This means that every component of $\boldsymbol{v}_\alpha$ is associated with all inelastic channels [25.5]. The $\boldsymbol{v}_\alpha$ are orthogonal, and can be normalized so that $\langle \boldsymbol{v}_\alpha \cdot \boldsymbol{v}_\beta \rangle = \delta_{\alpha\beta}$. The λ_α obey several sum rules [25.4], of which the most useful is

$$\sum_{\alpha=1}^{n_\lambda} (\lambda_\alpha)^{-1} = \sum_{\nu=0}^{\nu_{\max}} \langle K_{\nu\nu}(r|r)\rangle_r ,$$

(25.15)

where n_λ is the number of eigenvalues of (25.13). The v_α can be accurately calculated by use of a variational principle [25.4]. A test of (25.15) for the lowest He$^-$ (^{2}S) resonance, using Hylleraas functions to construct Q in the evaluation of QHQ, is shown in Table 25.1 [25.4], and results for the resonance position are compared in Table 25.2.

Table 25.1 Test of sum rule (25.15) for the lowest He$^-$ (1s2s^2 ^{2}S) autodetachment state [25.4]. Projection operators are based on a 4 term Hylleraas ϕ_0 and the variational form of v_α given below. Values of other constants are given in [25.4]

$$\phi_0 \propto (1 + C_1 r_1 + C_2 r_2 + C_{12} r_{12}) \exp(-\gamma_1 r_1 - \gamma_2 r_2) \\ + (r_1 \leftrightarrow r_2) ,$$
$$v_\alpha \propto \big(c_{11}^{(\alpha)} + c_{12}^{(\alpha)} r\big) \exp(-\gamma_1 r) \\ + \big(c_{21}^{(\alpha)} + c_{22}^{(\alpha)} r\big) \exp(-\gamma_2 r) ,$$

and the variational eigenvalues are [25.4]

$$\lambda_1 = 1.009\,453 \qquad \lambda_2 = 232.8540$$
$$\lambda_3 = 80\,101.08 \qquad \lambda_4 = 4\,817\,341$$

Summation	Value (Ry^{-1})
$\displaystyle\sum_{\alpha=1}^{4}(\lambda_\alpha)^{-1}$	0.994 9425
$\langle K(r|r)\rangle_r$	0.994 9514

Table 25.2 Comparison of methods for calculating the energy of the lowest He$^-$ (1s2s^2 ^{2}S) autodetachment state. The QHQ results are denoted $(\hat{\mathcal{E}} - E_0)_{\text{Quasi}}$ for the quasi-projection method and $(\mathcal{E} - E_0)_{\text{Complete}}$ for the complete projection method [25.4]. The entries labeled "Other results" give the full resonant energy. Units are eV

25.3.2 Reduction for the $N = 1$ Target

Explicit rigorous P and Q operators of the above type are only possible for $N = 1$ (i.e. hydrogenic) targets. In that case, spin can be easily eliminated by using spatially symmetric or antisymmetric wave functions. In the elastic region, P and Q reduce to [25.11, 12]

$$P = P_1 + P_2 - P_1 P_2 ; \quad Q = 1 - P_1 - P_2 + P_1 P_2 . \tag{25.16}$$

Here the $P_i = \phi(r_i)\rangle\langle\phi(r_i)$ are purely spatial projectors. Forms for the inelastic continuum are easily generalized [25.13].

There have been many calculations of QHQ for two-electron systems ($N = 1$), starting with fundamental work of *O'Malley* and *Geltman* [25.13]. A small sample is given in Table 25.3. They are given for their historical importance, demonstrating for the first time the convergence of eigenvalues to well defined values in the continuum. All eigenvalues (below the $n = 2$ threshold, in this case) correspond to resonances.

Table 25.3 Energies $\mathcal{E}_s$ of the He(2s2p^{1}P^0) autoionization states below He$^+$ ($n = 2$) threshold from the variational calculations of *O'Malley* and *Geltman* [25.13]. Units are Ry. N is the number of terms in the trial function

N	$s = 1$	$s = 2$	$s = 3$
9	-1.37708	-1.17892	-1.09716
15	-1.38044	-1.18312	-1.10432
20	-1.38216	-1.18348	-1.10828
25	-1.38316	-1.19000	-1.11188

25.3.3 Alternative Projection and Projection–Like Operators

Two alternative methods based on the idea of projection are available: quasi-projectors and hole projection operators.

Quasi-projectors [25.14] relax the condition of idempotency, but still maintain a discrete spectrum, which is in a one-to-one correspondence with resonances, with a predeterminable number of exceptions [25.2].

Hole projection operators have proven to be a more practical and effective approach [25.15]. The method uses one-particle (say, hydrogenic) orbitals, $\phi_n(q; \boldsymbol{r})$, to build holes via projectors, $[1 - \sum_n \phi_n\rangle\langle\phi_n]$, operating on the $(N + 1)$-particle wave function. The Rayleigh–Ritz functional is minimized with respect to the parameters in Φ, but it is maximized with respect to q, the nonlinear parameter in all the ϕ_n. In a model case, this *minimax* procedure has been shown [25.15] to optimize the eigenvalues to describe resonance energies; many calculations since then [25.16] have verified the minimax criteria in many-electron systems. More recently, the technique has been combined with complex rotation, so as to enable calculation of other resonant quantities [25.17]. Remarkably accurate results have been obtained.

Finally, hole projectors are ideally suited for inner-shell vacancy states of many-electron systems if high accuracy is required [25.2]. Effectively, this amounts to a reliable method for optimizing parameters of a hole orbital to be used in an Auger transition integral for filling such a vacancy, although that method has apparently never been used (Chapt. 62).

25.4 Width, Shift, and Shape Parameter

25.4.1 Width and Shift

Here one requires $P\Psi$ as well as $Q\Psi$. The former is obtained from a "nonresonant continuum," defined as the scattering solution of

$$\left[PHP + V_s^{(\mathrm{nr})} - E\right]P\Psi_s^{(\mathrm{nr})} = 0 , \tag{25.17}$$

where the nonresonant potential,

$$V_s^{(\mathrm{nr})} = V_{\mathrm{op}} - PHQ\Phi_s\rangle(E - \mathcal{E}_s)^{-1}\langle\Phi_s QHP , \tag{25.18}$$

excludes the resonant state s from the optical potential. In terms of $P\Psi_s^{(\mathrm{nr})}$, whose phase shift, η_0, is smooth in the vicinity of $E \approx \mathcal{E}_s$, a solution of the complete problem, (25.7), can be constructed [25.13] with a phase shift $\eta_0 + \eta_r$, where the additional phase shift

$$\eta_r = \arctan\left(\frac{\Gamma/2}{(\mathcal{E}_s + \Delta_s) - E}\right) \tag{25.19}$$

exhibits typical resonant behavior ($0 < \eta_r < \pi$). From (25.19) it is clear that the "true" position of the resonance is

$$E_s(E) = \mathcal{E}_s + \Delta_s(E) . \tag{25.20}$$

The width Γ_s and shift Δ_s are given by [25.13]:

$$\Gamma_s(E) = 2k|\langle\Psi_s^{(\mathrm{nr})}(E) PHQ \Phi_s\rangle|^2 , \tag{25.21}$$

$$\Delta_s(E) = \langle\Phi_s QHP G_P(E) PHQ\Phi_s\rangle , \tag{25.22}$$

where k is the scattering momentum (i. e. $k^2 = E - E_0$), and G_P is the Green's function associated with (25.17); G_P can be simplified from the form given in [25.13] [(2.28) of first article of [25.2]].

Equation (25.20) is an implicit equation for the energy at which the resonance occurs. It can be solved graphically [25.18], and that energy defines the Feshbach resonant energy E_F, which differs (very slightly) from the Breit–Wigner energy (Sect. 25.4.3 and Fig. 25.1).

25.4.2 Shape Parameter

The shape of an isolated radiative transition between an autoionization state and some other state can be described by Γ, E, and an additional parameter q_s, often called the shape parameter [25.19]. The ratio of transition probabality (in, say, absorption from an initial state labeled $i\rangle$) through the resonant state to its nonresonant value, parametrized in its Fano form [25.19] on the left-hand side of (25.23), can be equated to its meaning in Feshbach terms on the right-hand side of (25.23):

$$\frac{(e_s + q_s)^2}{1 + e_s^2} = \frac{|\langle P\Psi + Q\Psi|T|i\rangle|^2}{|\langle P\Psi_s^{(nr)} + Q\Psi_s^{(nr)}|T|i\rangle|^2} , \qquad (25.23)$$

where e_s is the scaled energy

$$e_s = (E - E_s)/(\Gamma_s/2) \qquad (25.24)$$

and T is a radiative transition operator (25.25).

To analyze (25.23) in the Feshbach formalism, the key point [25.13] is to recognize that the bras on the right-hand side must include P as well as Q parts of the respective wave functions, as is indicated in (25.23). That is because the T operator is a perturbation and not part of the dynamical problem. With T in length form

$$T \propto \sum_{j=1}^{N+1} z_j , \qquad (25.25)$$

the rhs of (25.23) can be calculated by noting that $P\Psi_s$ and $P\Psi_s^{(nr)}$ can be, in principle, determined from (25.7) and (25.17). $Q\Psi_s$ is then derived from $P\Psi_s$ using (25.6). But $Q\Psi_s^{(nr)}$ excludes the sth term from the right-hand side of (25.6):

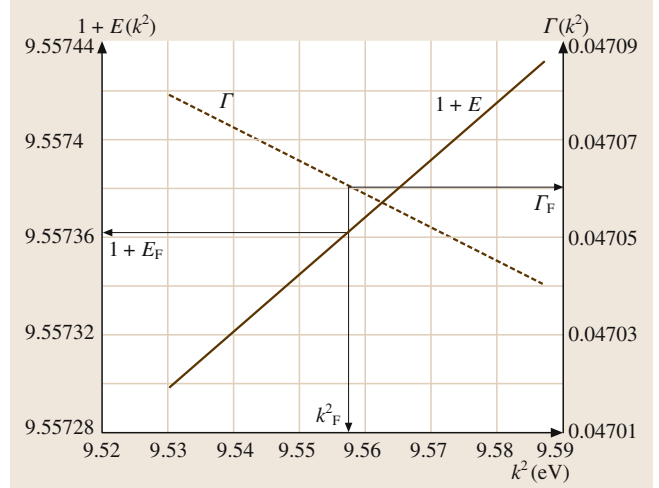
$$Q\Psi_s^{(nr)} = \sum_{n \neq s} \frac{\Phi_n\rangle\langle\Phi_n QHP\Psi^{(nr)}\rangle}{E - \mathcal{E}_n} . \qquad (25.26)$$


Fig. 25.1 Precision calculation of $H^-(^1S)$ resonance. *Solid curve*: $E + 1$ vs. k^2, where $E = \mathcal{E} + \Delta$, (25.20). k_F^2 is that value of k^2 at which $E + 1 = k^2$. *Dashed curve* is Γ vs. k^2 from (25.21), and $\Gamma_F = \Gamma(k_F^2)$. *Curves* are from calculations of [25.18]; results are $E_F = 9.557\,35$ eV and $\Gamma_F = 0.047\,0605$ eV. Applying corrections, (25.31) gives finally $E_{BW} = E_F + O(10^{-6})$, $\Gamma_{BW} = 0.047\,17$ eV

With use of these relations in the rhs of (25.23) an explicit formula for q_s was derived in [25.2]; it is given by

$$q_s = \frac{\langle\Phi_s\tilde{Q}|T|i\rangle}{k\langle i|T|\Psi_s^{(nr)}\rangle\langle\Psi_s^{(nr)}|PHQ\Phi_s\rangle} , \qquad (25.27)$$

where

$$\tilde{Q} = Q + QHPG_s + \sum_{n \neq s} \frac{QHPG_sHQ|\Phi_n\rangle\langle\Phi_n}{E - \mathcal{E}_n} . \qquad (25.28)$$

The Green's function G_s in (25.28) is the one associated with (25.17). It can be expanded in terms of the eigensolutions of (25.17), but its spectrum may have a discrete as well as continuous part, in which case,

$$G_s = \sum_\nu{}' \frac{P\Psi_\nu^{(nr)}\rangle\langle P\Psi_\nu^{(nr)}}{E_s - E_\nu}$$
$$+ \frac{\wp}{\pi} \int \frac{P\Psi_s^{(nr)}(E')\rangle\langle P\Psi_s^{(nr)}(E')\sqrt{E'}\,dE'}{E_s - E'} . \qquad (25.29)$$

The sum over ν refers to the discrete part of the spectrum of (25.17) (if there is one), and $\wp$ denotes a principal value integral over the continuum solutions. The latter are always assumed to be normalized as

Table 25.4 Comparison of high precision calculations with experiment for the resonance parameters of the He(^{1}P^0) resonances below the $n = 2$ threshold. For photoabsorption, the appropriate Rydberg constant is $R_M = R_\infty/(1 + m/M)$ [25.20]. The value used here is $R_M = 13.603\,833$ eV, and $E_0 = -79.0151$ eV [25.6]

plane waves (not energy normalized) throughout this chapter.

Equation (25.27) is a nontrivial example of what can be done with the projection operator technique. Not only does it allow very accurate calculations ([25.17, 20] and footnote e of Table 25.4), but it provides a theoretical incisiveness which far exceeds all previous resonance formalisms.

A formula for the resonant scattering cross section can be derived which is of the same form as the left-hand side of (25.23); however, in that case, the parameter corresponding to q_s is related to the nonresonant phase shift [25.25], and has no quantitative relationship to the above shape parameter (q_s).

25.4.3 Relation to Breit–Wigner Parameters

Inferring resonance parameters from experimental data is generally done by fitting to resonance formulae in which the resonance parameters are assumed to be energy independent. A phase shift for example would be inferred by assuming

$$\eta(E) = \delta_0(E) + \arctan\left(\frac{\Gamma_{\mathrm{BW}}/2}{E_{\mathrm{BW}} - E}\right) . \tag{25.30}$$

The relation between the above Breit–Wigner parameters and those of the Feshbach theory has been derived in lowest order by *Drachman* [25.26]:

$$E_{\mathrm{BW}} = E_{\mathrm{F}} - (1/4)\Gamma_{\mathrm{F}}(\mathrm{d}\Gamma_{\mathrm{F}}/\mathrm{d}E)_{E=E_{\mathrm{F}}} ,$$
$$\Gamma_{\mathrm{BW}} = \Gamma_{\mathrm{F}}(1 + \mathrm{d}\Delta_{\mathrm{F}}/\mathrm{d}E)_{E=E_{\mathrm{F}}} ,$$
$$\delta_0(E) = \eta_0(E) - (1/2)\,\mathrm{d}\Gamma_{\mathrm{F}}/\mathrm{d}E . \tag{25.31}$$

In only one precision calculation (for the lowest ^{1}S resonance in electron–hydrogen scattering) have these differences, thus far, been evaluated [25.18]. A précis is given in Fig. 25.1.

25.5 Other Calculational Methods

We now briefly review two calculational methods used for basic applications in autoionization of few body systems: (a) complex rotation and (b) a pseudopotential method.

25.5.1 Complex Rotation Method

Complex rotation, which is based on a theorem of *Balslev* and *Combes* [25.27], has been extensively applied

with great accuracy. Two additional basic systems to be mentioned here are H^- and Ps^- (Ps = positronium). In complex rotation the particle distances are multiplied by a common phase factor

$$r_i \rightarrow r_i \, e^{i\theta} \, . \tag{25.32}$$

Under this replacement the Hamiltonian undergoes the transformation

$$H \rightarrow T \, e^{-2i\theta} + V \, e^{-i\theta} \tag{25.33}$$

(only Coulomb interactions are assumed). A real variational wave function Φ is used (for the applications here, they are of Hylleraas form, multiplied by rotational harmonics of symmetric Euler angles of the desired angular momentum, parity, and spin [25.31]). The functional

$$[E] = \frac{\langle \Phi | H | \Phi \rangle}{\langle \Phi | \Phi \rangle} = \frac{\langle \Phi | T | \Phi \rangle \, e^{-2i\theta} + \langle \Phi | V | \Phi \rangle \, e^{-i\theta}}{\langle \Phi | \Phi \rangle} \tag{25.34}$$

is then evaluated. Minimization of (25.34) with respect to the linear parameters, for a given value of θ, is carried out in the usual way, but by virtue of the complex dependence on rotation angle the matrix elements H_{ij} in the matrix eigenvalue equation

$$\det |H_{ij}(\theta) - E\Delta_{ij}| = 0 \tag{25.35}$$

are complex. Thus the solution of (25.35) gives rise to complex eigenvalues $E_\lambda = E_\lambda(\theta)$. For a given λ, the optimum θ is the one for which $E_\lambda(\theta)$ is effectively stationary as a function of θ [25.29]. Note that no projection operators are used: the real part of E_λ corresponds to the Breit–Wigner (i. e., experimental) position of the resonance, and $Im(E_\lambda) = \Gamma_{BW}/2$, where Γ_{BW} corresponds to the Breit–Wigner width of the resonance. These parameters thus include the full Feshbach values plus corrections (25.31).

Using Hylleraas wave functions with up to 1230 terms in the complex rotation method, resonance parameters have been obtained for resonance states of H^- below the $n = 2$ and 3 thresholds of H which compare very well with those obtained using the projection-operator, R-matrix and close-coupling methods. Results for the $^1D^e$ states of H^- are given in the Table 25.5. Similar calculations for Ps^- have been carried out [25.32]. The complex rotation method has been applied to the autoionization states of many different systems including muonic systems [25.33], as well as to study the combined effect of electric field and spin-orbit interaction on resonance parameters [25.34].

25.5.2 Pseudopotential Method

The second method that is included in this section is done so for the reason that it represents a rather different idea for the calculation of autoionization rather than being a more elaborate application of methodologies that are already known, with results too numerous to be referenced here. The method, described as a pseudopotential approach, was introduced by *Martin* et al. [25.35]. An effective Hamiltonian H_{eff} is defined as

$$H_{eff} = H + MP \, , \tag{25.36}$$

where M is a scalar parameter (i. e., a number), which will be taken to be very large, multiplying the P operator, (25.16). [Applications have thus far been restricted to one-electron targets and resonances below $n = 3$ excited state.] In practice, one minimizes the expectation value of H_{eff}, i. e.,

$$\delta \left(\frac{\langle \Psi_v | H_{eff} | \Psi_v \rangle}{\langle \Psi_v \Psi_v \rangle} \right) = 0 \, , \tag{25.37}$$

using an arbitrary, quadratically integrable, variational function Ψ_v.

In order to understand the nature of the spectrum that arises from this variation, we imagine Ψ_v divided into its P and Q space components:

$$\Psi_v = Q\Psi_v + P\Psi_v = \Psi_v^Q + \Psi_v^P \, . \tag{25.38}$$

Table 25.5 Comparison of resonance parameters (in eV) obtained from different methods for calculating $^1D^e$ states in H^-

Threshold n	Complex-cordinate rotation [25.29]		R-matrix [25.28]		Feshbach projection [25.20] (25.31)	
	E	Γ	E	Γ	E_F	Γ_F
2	10.124 36	0.008 62	10.1252	0.008 81	10.1244	0.010
3	11.811 02	0.045 12	11.810 97[a]	0.044 49[a]		

[a] Close coupling (18-state), [25.30]

The expectation value $\langle \Psi_v | H_{\text{eff}} | \Psi_v \rangle$ is written in matrix form as

$$\langle \Psi_v | H_{\text{eff}} | \Psi_v \rangle$$
$$= \left\langle \left(\Psi_v^Q \ \Psi_v^P \right) \begin{pmatrix} H_{QQ} & H_{QP} \\ H_{PQ} & H_{PP} + M \end{pmatrix} \begin{pmatrix} \Psi_v^Q \\ \Psi_v^P \end{pmatrix} \right\rangle .$$
$$(25.39)$$

The eigenvalue problem resulting from (25.37) reduces to finding the eigenvalues of the determinant

$$\det \begin{pmatrix} \langle H_{QQ} \rangle - \lambda & \langle H_{QP} \rangle \\ \langle H_{PQ} \rangle & \langle H_{PP} \rangle + M - \lambda \end{pmatrix} = 0 . \quad (25.40)$$

Note that only the bottom right component contains the term M. As a result, in the limit of large M, the eigenvalues, which can readily be solved for from (25.39), are

$$\lim_{M \to \text{large}} \lambda = \begin{cases} M + \langle H_{PP} \rangle \\ \langle H_{QQ} \rangle \end{cases} . \quad (25.41)$$

The lower eigenvalue is the desired Feshbach resonant energy $\mathcal{E}_F = \langle H_{QQ} \rangle$. The width is calculated from [with our normalization, (25.21)]

$$\Gamma = 2k | \langle \Psi_\lambda | H_{\text{eff}} | \chi_E \rangle |^2 \quad (25.42)$$

where χ_E is the solution of the exchange approximation

$$(H_{PP} - E) \chi_E = 0 \quad (25.43)$$

It is emphasized that this method only calculates the Feshbach energy; thus the shifts are not included. On the other hand the method uses no projection operators in calculating the matrix elements of H, and only the matrix elements of P by itself occur. This is much easier than a standard QHQ calculation (Sect. 25.2.2).

In practice, the matrix in (25.39) will expand to an $N \times N$ matrix, where N is the number of linear parameters in Ψ_v, and (if one uses a Hylleraas form of Ψ_v, for example) the matrix in (25.39) will not overtly divide itself into the simple form of this heuristic exposition pictured in (25.39) or (25.40). Nevertheless, the conclusion holds; in detail, the eigenvalue spectrum will span a range of values with those below the threshold, appropriate to the P operator being used, corresponding to real resonances, and the largest eigenvalue will approach the value of M used in the specific calculation.

A sample of results for the He(^{1}P) resonances below the $n = 2$ threshold of He$^+$ taken from [25.35], with some comparisons, is given in Table 25.6. Note that the value of $\mathcal{E}_F$ of the second resonance in the *Martin* et al. [25.35] calculation is lower than the rigorous QHQ calculation [25.20]. It is believed that this may be due to the residual M dependence of H_{eff}.

25.6 Related Topics

This chapter is necessarily of limited scope. Within the projection operator formalism, overlapping resonance theory [25.37] is discussed in Sect. 47.1.3. Recent calculations [25.38] have shown that such effects, when present, can induce significant alteration of isolated resonance results. Other prominent items not included are stabilization methods [25.39] and hyperspherical coordinate methods [25.40, 41]. The latter methods have the appealing property of presenting energies as a function of the hyperradius, $R = \left(\sum_i r_i^2 \right)^{1/2}$, which

look like potential energy curves of diatomic molecules as a function of the intermolecular separation, which is also usually denoted by R. The molecular structure analogy has also been used to uncover additional (approximate) symmetries with corresponding quantum labels [25.40, 41]. They thus have a global character not present in the foregoing methods. On a purely quantitative level, however, they are not generally as accurate as methods based on the projection operator or complex rotation formalism.

There are many other areas in which autoionization can play an important role, such as satellite line formation [25.42], inner-shell ionization [25.43], to mention only a few (Chapt. 62 and [25.44]). In addition, significant application of the phenomena associated with autoionization to diagnostics of astrophysical [25.45] and fusion [25.46] plasmas, for example, shows that autoionization has considerable applied utility.

26. Green's Functions of Field Theory

The discussion in this chapter is restricted to Green's function techniques as applied to problems in atomic physics, specifically to the calculation of higher order (correlation, Breit, as well as radiative) corrections to energy levels, and also of transition amplitudes for radiative transitions of atoms which are gauge invariant (GI) at every level of approximation.

Green's function techniques were first applied to many-electron atoms in 1971 as specific instances of the use of field theory techniques in many-particle problems [26.1, 2]. They initially provided alternative derivations of known approximations such as the Hartree–Fock (HF) approximation

and random phase approximation (RPA). The starting point for the derivations was a nonrelativistic (NR) field-theoretical effective Hamiltonian for the system, which involved the nucleus–electron potential and only Coulomb interactions between electrons.

It subsequently became apparent that it was possible to formulate the problem more generally, with the full quantum electrodynamic (QED) Hamiltonian as a starting point [26.3, 4]. Thus, the theory contains both relativity, and virtual and real transverse photons, as well as the Coulomb interaction between the electrons. The relativistic (R) approximate equations, such as the Dirac–Fock (DF) and relativistic random phase approximation (RRPA) are the natural outcomes of the formalism, and the NR results can be viewed as approximations to these R cases. Moreover, the Green's function approach (GFA) now provides a means of carrying out programs involving systematic approximations of successively higher and higher accuracy. The GFA provides a framework which allows one to make corrections to results obtained in the DF approximation or in the coupled cluster approximation (CCA) and many-body perturbation theory (MBPT), including magnetic (Breit type) interactions [26.5, 6]. It ensures that there is neither double counting nor omission of contributions. For radiative transitions, the formalism allows for a systematic treatment of such effects which is gauge independent that at any given level of approximation [26.7–10]. (It should be noted that there is a subtle difference between gauge invariance and gauge independence. The first refers to the transition amplitude and the second to quantities which are directly observable experimentally.) Finally, the GFA is numerically implementable.

Renormalization can be carried out for radiative corrections, resulting in finite and calculable expressions [26.11–13]. The integro-differential equations (i. e., the Dyson equations) needed to calculate energies or transition amplitudes in nontrivial approximations are also soluble [26.8, 9, 14].

In quantum field theory, Green's functions are defined in terms of vacuum expectation values of products of field operators. While this restriction can be relaxed, expectation values must still be taken for a nondegenerate state. As a practical matter, this requirement ultimately restricts one to consider atoms with electron numbers associated only with closed shells or subshells, and those with closed shells or subshells plus or minus one or two electrons. The corresponding Green's functions considered here are the two- and four-point functions for energy levels, and the three- and five-point functions for transition amplitudes (leading to oscillator strengths). The restriction in electron numbers is clearly not a severe one. It allows one to cover many atomic species.

Starting from relativistic QED, the electron field operator $\psi(\boldsymbol{r}, t)$ written in the Heisenberg picture, satisfies equal-time anticommutation relations

$$\left[\psi(\boldsymbol{r}, t), \psi(\boldsymbol{r}', t)\right] = \left[\psi^{\dagger}(\boldsymbol{r}, t), \psi^{\dagger}(\boldsymbol{r}', t)\right] = 0 \,, \quad (26.1)$$

$$\left[\psi(\boldsymbol{r}, t), \psi^{\dagger}(\boldsymbol{r}', t)\right] = \delta^3(\boldsymbol{r} - \boldsymbol{r}') \,. \quad (26.2)$$

(Spinor labels are suppressed.)

The time-translation operator, acting on any Heisenberg operator $\mathcal{O}(\boldsymbol{r}, t) = \{\psi(\boldsymbol{r}, t), \psi^\dagger(\boldsymbol{r}, t), j_\mu(\boldsymbol{r}, t), \ldots\}$, is

$$\mathcal{O}(\boldsymbol{r}, t) = \mathrm{e}^{\mathrm{i}\mathcal{H}t}\mathcal{O}(\boldsymbol{r}, 0)\,\mathrm{e}^{-\mathrm{i}\mathcal{H}t}\,, \qquad (26.3)$$

where $\mathcal{H}$ is the full QED Hamiltonian.

Notations and Definitions

For brevity, plainface numbers are used to denote both a coordinate and time, while boldface numbers denote a coordinate vector alone. For example,

$$\begin{aligned}
1 &\equiv (\boldsymbol{1}, t_1) \equiv (\boldsymbol{r}_1, t_1)\,, \\
\mathrm{d}^3\boldsymbol{1} &\equiv \mathrm{d}^3\boldsymbol{r}_1\,, \\
\mathrm{d}^4 1 &\equiv \mathrm{d}^3\boldsymbol{r}_1\,\mathrm{d}t_1\,.
\end{aligned} \qquad (26.4)$$

For radiative transitions, $\mathcal{M}_{fi}^{N'}(k_0)$ denotes the transition amplitude for the emission of a single photon of energy k_0 for an N'-electron atom from an initial energy $E_i^{N'}$ to a final energy $E_f^{N'}$, where

$$\mathcal{M}_{fi}^{N'}(k_0) \equiv (2\pi)^4\delta\big(E_f^{N'} - E_i^{N'} - k_0\big)M_{fi}^{N'}(k_0)\,. \qquad (26.5)$$

The notation on the right-hand side of (26.5) is somewhat redundant, since k_0 is taken to be $k_0 = E_f^{N'} - E_i^{N'}$.

The current density operators at $t = 0$ are given respectively by

$$\begin{aligned}
&j_\mu(\boldsymbol{r}, 0) \\
&= \begin{cases}
\dfrac{1}{2}\displaystyle\int \mathrm{d}^3\boldsymbol{1}\,\mathrm{d}^3\boldsymbol{2}\left[\psi^\dagger(\boldsymbol{1}, 0), u_\mu^{\mathrm{R}}(\boldsymbol{12}; \boldsymbol{r})\psi(\boldsymbol{2}, 0)\right], \\
\qquad\qquad\qquad\qquad\qquad \text{for R} \\[1em]
\displaystyle\int \mathrm{d}^3\boldsymbol{1}\,\mathrm{d}^3\boldsymbol{2}\,\psi^\dagger(\boldsymbol{1}, 0)u_\mu^{\mathrm{NR}}(\boldsymbol{12}; \boldsymbol{r})\psi(\boldsymbol{2}, 0)\,, \\
\qquad\qquad\qquad\qquad\qquad \text{for NR}
\end{cases}
\end{aligned} \qquad (26.6)$$

with

$$\begin{aligned}
&u_\mu(\boldsymbol{12}; \boldsymbol{r}) \\
&= \begin{cases}
e\alpha_\mu\delta^3(\boldsymbol{1}-\boldsymbol{r})\delta^3(\boldsymbol{2}-\boldsymbol{r})\,, \qquad\qquad\quad \text{for R} \\[1em]
e\left[1, \left(\dfrac{1}{2\mathrm{i}m}\right)(\nabla_2 - \nabla_1)\delta^3(\boldsymbol{1}-\boldsymbol{r})\delta^3(\boldsymbol{2}-\boldsymbol{r})\right], \\
\qquad\qquad\qquad\qquad\qquad\quad \text{for NR}\,,
\end{cases}
\end{aligned} \qquad (26.7)$$

where $\alpha_\mu = (\boldsymbol{\alpha}, 1)$, and the components of $\boldsymbol{\alpha}$ are the usual Dirac matrices.

The corresponding charge operators are defined as

$$\mathcal{Q} = \begin{cases}
\dfrac{1}{2}e\displaystyle\int \mathrm{d}^3\boldsymbol{1}\left[\psi^\dagger(\boldsymbol{1}, 0), \psi(\boldsymbol{1}, 0)\right]\,, & \text{for R} \\[1em]
e\displaystyle\int \mathrm{d}^3\boldsymbol{1}\,\psi^\dagger(\boldsymbol{1}, 0)\psi(\boldsymbol{1}, 0)\,, & \text{for NR}\,.
\end{cases} \qquad (26.8)$$

The transition amplitude for a photon of polarization four-vector $\epsilon^\mu(k)$, momentum $\boldsymbol{k}$, energy $k_0(k_0 = |\boldsymbol{k}|)$, and photon attachment point $\boldsymbol{r}$ is

$$M_{fi}^{N'}(k_0) = \int \mathrm{d}^3\boldsymbol{r}\,\frac{\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}}{\sqrt{2k_0}}M_{fi}^{N'}(\boldsymbol{r}; k_0)\,. \qquad (26.9)$$

In terms of the current density operator, $M_{fi}^{N'}(\boldsymbol{r}; k_0)$ can be written as

$$\begin{aligned}
M_{fi}^{N'}(\boldsymbol{r}; k_0) &= \left\langle {}^{N'}_f \left| \epsilon^\mu(k)j_\mu(\boldsymbol{r}, 0) \right| {}^{N'}_i \right\rangle \\
&\equiv \left\langle {}^{N'}_f \left| j^k(\boldsymbol{r}, 0) \right| {}^{N'}_i \right\rangle\,,
\end{aligned} \qquad (26.10)$$

where $\left| {}^{N'}_n \right\rangle$ is a state of leptonic charge number N', with N' corresponding to an atom of N' electrons, with total energy $E_n^{N'}$. The term *lepton charge* is used to refer to the charge of electrons and positrons.

In the dipole approximation, $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} \approx 1$, $\epsilon^\mu j_\mu$ contains the quantity

$$\epsilon^\mu(k)u_\mu(\boldsymbol{12}; \boldsymbol{r}) \equiv \lambda_k(\boldsymbol{r})\delta(\boldsymbol{1}-\boldsymbol{r})\delta(\boldsymbol{2}-\boldsymbol{r})\,, \qquad (26.11)$$

where, in the radiation gauge,

$$\lambda_k(\boldsymbol{r}) = \begin{cases}
e\boldsymbol{\epsilon}(k)\cdot\boldsymbol{\alpha}\,, & \text{velocity form} \\
\mathrm{i}ek_0\boldsymbol{\epsilon}(k)\cdot\boldsymbol{r}\,, & \text{length form}\,.
\end{cases} \qquad (26.12)$$

26.1 The Two-Point Green's Function

The two-point Green's function, or one-body propagator [26.3, 4], for a system of lepton charge Ne is defined as the expectation value of a time-ordered product

$$G^N(1, 1') \equiv -\mathrm{i}\left\langle {}^N_0 \left| T\left[\psi(1)\psi^\dagger(1')\right] \right| {}^N_0 \right\rangle\,, \qquad (26.13)$$

where $\left| {}^N_0 \right\rangle$ is the ground state of leptonic charge number N, with N corresponding to an atom with electron number N in a filled shell or subshell ($N = 2, 4, 8, \ldots$).

The relative time $(t_1 - t_1')$ Fourier transform of (26.13) yields the spectral representation of

$G^N(\mathbf{1}, \mathbf{1}')$:

$$G_\omega^N = \sum_j \!\!\!\!\!\!\int \frac{|u^j\rangle\langle u^j|}{\omega - \varepsilon^j + \mathrm{i}\eta} + \sum_\zeta \!\!\!\!\!\!\int \frac{|v^\zeta\rangle\langle v^\zeta|}{\omega - \varepsilon^\zeta + \mathrm{i}\eta} \ , \quad \eta = 0^+ \ ,$$

(26.14)

where

$$G_\omega^N(\mathbf{1}, \mathbf{1}') \equiv \langle\mathbf{1}|G_\omega^N|\mathbf{1}'\rangle, \ u^j(\mathbf{r}) \equiv \langle\mathbf{r}\,|u^j\rangle, \ \text{etc.},$$

(26.15)

and where the symbol $\sum\!\!\!\!\!\!\int$ denotes a summation over discrete and integration over continuous states. The two terms in (26.14) are obtained by counting each time-ordering separately in (26.13), introducing a complete set of intermediate states and using the time translation operator (26.3). The functions $u^j(\mathbf{r})$ and $v^\zeta(\mathbf{r})$ are defined by

$$u^j(\mathbf{r}) \equiv \left\langle {N \atop 0} \left| \psi(\mathbf{r}, 0) \right| {N+1 \atop j} \right\rangle,$$

$$\left\langle {N \atop 0} \left| \psi(\mathbf{r}, t) \right| {N+1 \atop j} \right\rangle = \mathrm{e}^{\mathrm{i}(E_0^N - E_j^{N+1})t} u^j(\mathbf{r}) \ ,$$

(26.16)

and

$$v^\zeta(\mathbf{r}) \equiv \left\langle {N-1 \atop \zeta} \left| \psi(\mathbf{r}, 0) \right| {N \atop 0} \right\rangle,$$

$$\left\langle {N-1 \atop \zeta} \left| \psi(\mathbf{r}, t) \right| {N \atop 0} \right\rangle = \mathrm{e}^{\mathrm{i}(E_\zeta^{N-1} - E_0^N)t} v^\zeta(\mathbf{r}) \ .$$

(26.17)

Here, $\left| {N \atop 0} \right\rangle$ is the ground state of an atom of lepton charge number N (corresponding to a nondegenerate state – a closed shell or subshell) of energy E_0^N, $\left| {N+1 \atop j} \right\rangle$ an atomic state of total energy E_j^{N+1} and leptonic charge number $N+1$, and $\left| {N-1 \atop \zeta} \right\rangle$ is the state of energy E_ζ^{N-1} and leptonic charge number $N-1$. These several states satisfy the eigenvalue equations

$$\mathcal{H} \left| {N \atop 0} \right\rangle = E_0^N \left| {N \atop 0} \right\rangle,$$

$$\mathcal{H} \left| {N+1 \atop j} \right\rangle = E_j^{N+1} \left| {N+1 \atop j} \right\rangle,$$

$$\mathcal{H} \left| {N-1 \atop \zeta} \right\rangle = E_\zeta^{N-1} \left| {N-1 \atop \zeta} \right\rangle.$$

(26.18)

The energy parameters ε^j and ε^ζ are defined by

$$\varepsilon^j \equiv E_j^{N+1} - E_0^N \ ,$$

(26.19)

$$\varepsilon^\zeta \equiv E_0^N - E_\zeta^{N-1} \ .$$

(26.20)

Equations (26.19) and (26.20) are generalizations of Koopmans's theorem [26.15] (see Sect. 21.4.1). In the DF approximation, the state $\left| {N+1 \atop j} \right\rangle$ can be thought of as N effective particles (electrons) making up the core,

plus one valence electron, with energy label j. The atom can also be an isoelectronic ion with nuclear charge number Z. In this (DF) approximation, the state $\left| {N-1 \atop \zeta} \right\rangle$ is one of two possible types. It can have N independent electrons making up the core, with one of the core electrons missing, or equivalently the N electron core with one electron–hole, with energy label ζ. There is a finite number N of such hole states, which shall be labeled a. There are no other states in the NR (HF) case. In the R (DF) case, the second group of states $\left| {N-1 \atop \zeta} \right\rangle$ can also describe an atom with a core of N electrons, plus one positron. Its continuum energy label, will be taken as $\zeta = \bar{\ell}$. This energy will appear with a negative sign in (26.14).

The second step in leading to an explicit $G^N(1, 1')$ is the generation of a Dyson equation which it satisfies. In both the DF and HF approximations, the Dyson equation can be obtained through a successive series of steps [26.11]. Working in the Coulomb gauge (see Sect. 27.2), begin with the Coulomb interaction between electrons and neglect the exchange of transverse virtual photons. The Dyson equation for the resulting two-point function is then expanded as a power series in the electron–electron (ee) interaction

$$V_{ee} \equiv V = \frac{\alpha}{|\mathbf{x} - \mathbf{y}|} \ ,$$

(26.21)

resulting in an infinite set of Feynman diagrams ($\alpha = e^2/4\pi$ in rationalized mks units). As a next approximation, consider only diagrams involving single Coulomb exchanges and their iterates ("ladders"). That is, set aside for later consideration nonladder Feynman diagrams of two or more Coulomb photons and their iterates (e.g., two crossed Coulomb photon lines). A summation of the infinite set of these remaining terms generates an equation for a propagator labeled $G_{\omega,\mathrm{Coul}}^N$, which contains Coulomb radiative corrections in its kernel. Finally, modify the kernel by isolating these radiative corrections (self energy and vacuum polarization) by constructing a spectral representation of $G_\omega^{\text{"0"}}$ which mimics that for the usual QED propagator, which is a vacuum (rather than an N-lepton ground state) expectation value. This requires shifting the poles corresponding to core energies of the atom from the upper to the lower complex ω plane. The shifting of poles is accomplished by means of the equation

$$\frac{1}{x - \mathrm{i}\eta} - \frac{1}{x + \mathrm{i}\eta} = 2\pi\mathrm{i}\delta(x) \ ,$$

(26.22)

which, when used to shift the poles of core electrons in the ω plane, gives

$$G^N_{\omega,\text{Coul}} = 2\pi i \sum_{a=1}^{N} |v^a\rangle\langle v^a| \, \delta(\omega - \varepsilon^a) + G^{"0"}_{\omega} \; . \tag{26.23}$$

It is the first term on the right-hand side of this equation which occurs in the kernel of (26.24) below and generates the DF approximation.

Some of the terms set aside in the course of this sequence of approximations are reconsidered in Sect. 26.4 to obtain more accurate energy results. What remains at the end of this sequence is an approximation to G^N_ω of (26.14), designated as $G^N_{\omega,\text{DF}}$, and which satisfies the self-consistent Dyson equation

$$G^N_{\omega,\text{DF}} = g_\omega + g_\omega \Sigma^N_{\text{DF}} G^N_{\omega,\text{DF}} \; , \tag{26.24}$$

where $\sum^N_{\text{DF}}$ is the kernel defined in (26.27). For the R (DF) case,

$$g^{-1}_\omega = \omega - h^{\text{R}}(\boldsymbol{r}), \; h^{\text{R}}(\boldsymbol{r}) = \boldsymbol{\alpha} \cdot \boldsymbol{p} + m\beta - Z\alpha/r \; , \tag{26.25}$$

and the corresponding h^{NR}, used in the HF case, is

$$h^{\text{NR}}(\boldsymbol{r}) = \frac{\boldsymbol{p}^2}{2m} - \frac{Z\alpha}{r} \; . \tag{26.26}$$

The function g_ω in (26.25) is the R or NR Coulomb Green's function. It is the solution of the corresponding inhomogeneous c-number Schrödinger or Dirac equation. It is a single-particle equation which has had a long history of specific treatments (see Chapt. 9 and [26.16–19]). It is the semiclassical limit of the two-point propagator we consider here when only the c-number nuclear Coulomb potential is kept and all other (q-number) interactions are turned off.

In the DF and HF approximations in (26.14), we replace ε^j by $e_j > 0$, $|u^j\rangle$ by $|j\rangle$ (the valence energies and states of an atom with $N+1$ electrons and a frozen relaxed core of N electrons), ε^ζ by $e_a > 0$, $|u^\zeta\rangle$ by $|a\rangle$, for the N discrete electron core states, and ε^ζ by $e_{\bar{\ell}} < 0$, $|u^\zeta\rangle$ by $|\bar{\ell}\rangle$, for the continuum of negative energy states (which do not appear in the HF approximation). The kernel Σ^N_{DF} contains *only* core states $|a\rangle$, in *both* the DF and HF approximations, and is given by the sum over states

$$\left\langle m \left| \Sigma^N_{\text{DF}} \right| n \right\rangle = \alpha \sum_{a=1}^{N} \int \mathrm{d}^3 x \, \mathrm{d}^3 y \frac{1}{|\boldsymbol{x} - \boldsymbol{y}|} \langle m|\boldsymbol{x}\rangle \langle a|\boldsymbol{y}\rangle$$
$$\times (\langle \boldsymbol{x}|n\rangle \langle \boldsymbol{y}|a\rangle - \langle \boldsymbol{x}|a\rangle \langle \boldsymbol{y}|n\rangle)$$
$$\equiv \sum_{a=1}^{N} \left[\left({}^m_a \, |V|\, {}^n_a \right) - \left({}^m_a \, |V|\, {}^a_n \right) \right]$$
$$\equiv \sum_{a=1}^{N} \left[{}^m_a \, |V|\, {}^n_a \right] \tag{26.27}$$

for arbitrary states m and n. The first term in brackets is the Hartree term and the second is the electron exchange term in the DF (HF) approximation. The DF (HF) equation is the homogeneous equation corresponding to the inhomogeneous (26.24). Thus,

$$\left(e_n - h - \Sigma^N_{\text{DF}}\right)|n\rangle = 0, \qquad \langle n|n'\rangle = \delta_{nn'} \; . \tag{26.28}$$

The states $|n\rangle$ (valence, core, and negative energy states) are orthonormal and complete. In the coordinate basis, (26.28) takes the more familiar form

$$[e_n - h(\boldsymbol{x})] \langle \boldsymbol{x}|n\rangle - \left\langle \boldsymbol{x} \left| \Sigma^N_{\text{DF}} \right| n \right\rangle = 0 \; , \tag{26.29}$$

where

$$\left\langle \boldsymbol{x} \left| \Sigma^N_{\text{DF}} \right| n \right\rangle = \sum_m \sum_{a=1}^{N} \langle \boldsymbol{x}|m\rangle \left[{}^m_a \, |V|\, {}^n_a \right]$$
$$\equiv \sum_{a=1}^{N} \left[{}^x_a \, |V|\, {}^n_a \right]$$
$$\equiv \int V_{\text{DF}}(\boldsymbol{x}, \boldsymbol{y}) \, \mathrm{d}^3 y \, \langle \boldsymbol{y}|n\rangle \; . \tag{26.30}$$

One can also generate equations corresponding to higher approximations than DF using the same approach. For example, one can obtain a Brueckner equation [26.20],

$$\left[e_n - h - \Sigma^N_{\text{DF}} - \Sigma^N_{\text{B}}(e_n) \right] |n\rangle = 0 \; , \tag{26.31}$$

and the states now satisfy the orthonormality condition

$$\lim_{\omega \to e_n} \int \mathrm{d}^3 x \, \mathrm{d}^3 y \, \langle n|\boldsymbol{x}\rangle \langle \boldsymbol{y}|n'\rangle$$
$$\times \left(\frac{\{(\omega - e_n)\delta^3(\boldsymbol{x} - \boldsymbol{y}) - \langle \boldsymbol{x} | \{ \Sigma^N_{\text{B}}(\omega) - \Sigma^N_{\text{B}}(e_n) \} | \boldsymbol{y}\rangle\}}{\omega - e_n} \right)$$
$$= \delta_{nn'} \; , \tag{26.32}$$

where the energy-dependent kernel $\Sigma_{\text{B}}(e_n)$ arises from irreducible Feynman diagrams involving two Coulomb photons. The kernel is given by

$$\left\langle m \left| \Sigma^N_{\text{B}}(e_n) \right| n \right\rangle$$
$$= \sum_{a,i,j} \frac{1/2}{e_n + e_a - e_i - e_j} \left[{}^m_a \, \left| V \right| \, {}^i_j \right] \left[{}^i_j \, \left| V \right| \, {}^n_a \right]$$

$$+ \sum_{a,b,i} \frac{1/2}{e_n + e_i - e_a - e_b} \left[\begin{smallmatrix} m \\ i \end{smallmatrix} \Big| V \Big| \begin{smallmatrix} a \\ b \end{smallmatrix} \right] \left[\begin{smallmatrix} a \\ b \end{smallmatrix} \Big| V \Big| \begin{smallmatrix} n \\ i \end{smallmatrix} \right] .$$

(26.33)

$\sum$ involves summations over core states (a, b), and summation and integration over valence states (i, j). In perturbation theory, the lowest order contribution of $\Sigma_B(e_n)$ is an ee correlation term.

26.2 The Four–Point Green's Function

The four-point Green's function [26.4, 8, 11], or two-body propagator, is defined as

$$G^N(12, 1'2')$$
$$\equiv -\left\langle \begin{smallmatrix} N \\ 0 \end{smallmatrix} \Big| T \left[\psi(1)\psi^\dagger(1')\psi(2)\psi^\dagger(2') \right] \Big| \begin{smallmatrix} N \\ 0 \end{smallmatrix} \right\rangle . \quad (26.34)$$

In order to avoid unnecessary complication, only simple ladders of $V_{ee} \equiv V$ are considered. There are 4! possible time orderings. Of these, there are four groups of four with $t_1, t_{1'} > t_2, t_{2'}$, $t_1, t_{1'} < t_2, t_{2'}$, $t_1, t_2 > t_{1'}, t_{2'}$, and $t_1, t_2 < t_{1'}, t_{2'}$, corresponding to the particle–hole (PH/HP) and the two-particle/two-hole (2P/2H) cases for the first eight and last eight time orderings, respectively. For each of these cases, introduce a total time and relative time variable defined by

$$T = \frac{1}{2}(t_1 + t_{1'}), T' = \frac{1}{2}(t_2 + t_{2'}) ,$$
$$t = t_1 - t_{1'}, t' = t_2 - t_{2'} , \quad (26.35)$$

for the first eight cases (PH/HP) and

$$T = \frac{1}{2}(t_1 + t_2), T' = \frac{1}{2}(t_{1'} + t_{2'}) ,$$
$$t = t_1 - t_2, t' = t_{1'} - t_{2'} , \quad (26.36)$$

for the last eight cases (2P/2H). For a particular set of eight time orderings, a time translation with respect to the relevant c.m. time t or t', followed by a separate Fourier transformation for each case with respect to $T - T'$ (with integration variable $d\Omega$), yields contributions with poles in the separately defined Ω-planes at

$$\omega_{(i\alpha)} = E^N_{(i\alpha)} - E^N_0, \text{ for PH} \quad (26.37a)$$
$$-\omega_{(i\alpha)} = E^N_0 - E^N_{(i\alpha)}, \text{ for HP} \quad (26.37b)$$

$$\omega_{(ij)} = E^{N+2}_{(ij)} - E^N_0, \text{ for 2P} \quad (26.38a)$$
$$\omega_{(ab)} = E^N_0 - E^{N-2}_{(ab)}, \text{ for 2H} . \quad (26.38b)$$

Equations (26.37a,b) parallel (26.19) and (26.20) as generalizations of Koopmans' theorem. The spectral

representation is of a form similar to (26.14), with wave functions corresponding to (26.16) and (26.17) given by

$$\chi_{(ia)}(11') \equiv \left\langle \mathbf{1} \left| \chi_{(ia)}(t) \right| \mathbf{1}' \right\rangle e^{-i\omega_{(ia)}T}$$
$$= \left\langle \begin{smallmatrix} N \\ 0 \end{smallmatrix} \Big| T \left[\psi(1)\psi^\dagger(1') \right] \Big| \begin{smallmatrix} N \\ (ia) \end{smallmatrix} \right\rangle \quad (26.39)$$

for the PH/HP case and

$$\varphi_{(ij)}(12) \equiv \langle \mathbf{12} | \varphi_{(ij)}(t) \rangle e^{-i\omega_{(ij)}T}$$
$$= \left\langle \begin{smallmatrix} N \\ 0 \end{smallmatrix} \Big| T \left[\psi(1)\psi(2) \right] \Big| \begin{smallmatrix} N+2 \\ (ij) \end{smallmatrix} \right\rangle , \quad (26.40)$$

$$\gamma_{(ab)}(1'2') \equiv \langle \mathbf{1}'\mathbf{2}' | \gamma_{(ab)}(t') \rangle e^{-i\omega_{(ab)}T'}$$
$$= \left\langle \begin{smallmatrix} N-2 \\ (ab) \end{smallmatrix} \Big| T \left[\psi(1')\psi(2') \right] \Big| \begin{smallmatrix} N \\ 0 \end{smallmatrix} \right\rangle , \quad (26.41)$$

for the 2P and 2H cases, respectively. The antisymmetry under exchange follows from the definitions (26.40) and (26.41):

$$\zeta_{(\tau)}(12) = -\zeta_{(\tau)}(21) , \quad \zeta_{(\tau)} = \varphi_{(ij)}, \gamma_{(ab)} , \quad (26.42)$$

where it is understood that the suppressed spinor indices are interchanged as well as the coordinate and time variables.

The three amplitudes defined above satisfy Bethe–Salpeter (BS) equations. The PH/HP case is the analog of the positronium atom and the 2P case is analogous to He. For the case of Coulomb ladder exchanges, to which we have restricted ourselves, these BS equations can be reduced to simpler ones, with the relative time set equal to zero (the Salpeter equation [26.21]). The corresponding BS wave functions in the DF (HF) basis (rather than the coordinate basis), are for PH/HP,

$$\left\langle m \left| \bar\chi_{(ia)} \right| n \right\rangle \equiv \int d^3\mathbf{1} \, d^3\mathbf{1}' \langle m | \mathbf{1} \rangle \langle \mathbf{1} | \chi_{(ia)}(0) | \mathbf{1}' \rangle \langle \mathbf{1}' | n \rangle ,$$

(26.43)

with $m = k$ and $n = c$, or $m = c$ and $n = k$, and for 2P/2H,

$$\left\langle mn \left| \bar\xi_{(\tau)} \right\rangle \equiv \int d^3\mathbf{1} \, d^3\mathbf{2} \langle m | \mathbf{1} \rangle \langle n | \mathbf{2} \rangle \left\langle \mathbf{12} \left| \zeta_{(\tau)}(0) \right\rangle ,$$

(26.44)

where $\zeta_{(\tau)} = \varphi_{(ij)}, \gamma_{(ab)}$. The states $|i\rangle, |j\rangle, |a\rangle, |b\rangle, |m\rangle,$ and $|n\rangle$ label one-particle DF (HF) eigenkets and

e_i, e_j, e_a, e_b, e_m, and e_n, the corresponding eigenvalues.

In the PH/HP case, the BS equation is

$$- (\omega_{(ia)} - e_k + e_c) \langle i \,|\, \bar\chi_{(ia)} \,|\, a \rangle$$

$$= \sum_{b}\!\!\!\!\!\!\int \left\{ \left[{}^{k}_{b} \,\middle|\, V \,\middle|\, {}^{j}_{c} \right] \langle j \,|\, \bar\chi_{(ia)} \,|\, b \rangle \right.$$

$$\left. + \left[{}^{k}_{j} \,\middle|\, V \,\middle|\, {}^{b}_{c} \right] \langle b \,|\, \bar\chi_{(ia)} \,|\, j \rangle \right\} , \qquad (26.45)$$

$$(\omega_{(ia)} - e_c + e_k) \langle a \,|\, \bar\chi_{(ia)} \,|\, i \rangle$$

$$= \sum_{j,b}\!\!\!\!\!\!\int \left\{ \left[{}^{c}_{b} \,\middle|\, V \,\middle|\, {}^{j}_{k} \right] \langle j \,|\, \bar\chi_{(ia)} \,|\, b \rangle \right.$$

$$\left. + \left[{}^{c}_{j} \,\middle|\, V \,\middle|\, {}^{b}_{k} \right] \langle b \,|\, \bar\chi_{(ia)} \,|\, j \rangle \right\} .$$

In the 2P/2H case, the coupled pairs of BS equations are

$$- (\omega_{(\tau)} - e_c - e_d) \langle cd | \bar\xi_{(\tau)} \rangle$$

$$= \sum_{m>n}\!\!\!\!\!\!\int \left[{}^{c}_{d} \,\middle|\, V \,\middle|\, {}^{m}_{n} \right] \langle mn \,|\, \bar\xi_{(\tau)} \rangle , \qquad (26.46)$$

$$(\omega_{(\tau)} - e_k - e_\ell) \langle k\ell | \bar\xi_{(\tau)} \rangle$$

$$= \sum_{m>n}\!\!\!\!\!\!\int \left[{}^{k}_{\ell} \,\middle|\, V \,\middle|\, {}^{m}_{n} \right] \langle mn \,|\, \bar\xi_{(\tau)} \rangle ,$$

with m and n in these equations labeling either both core, or both valence states.

26.3 Radiative Transitions

For the majority of applications, one begins with the function $\Gamma^N(12; 3)$, the reducible three-point vertex:

$$\Gamma^N(12; 3) = - \left\langle {}^{N}_{0} \,\middle|\, T\left[\psi(1) j^k(3) \psi^\dagger(2) \right] \middle|\, {}^{N}_{0} \right\rangle . \qquad (26.51)$$

The usual strategy is followed. The spectral representation serves to identify the functions of ultimate interest. (Energies are not relevant in this case.) One then generates Dyson equations in the chosen approximation by summing an infinite series of perturbation terms.

There are 3! time orderings in (26.51). As with the four-point function, not all of them are subsequently useful. The two useful cases are $t_1 > t_3 > t_2$, and $t_2 > t_3 > t_1$. To obtain a spectral representation for these two cases, one first carries out a time translation of t_3, using the operator $\exp(i\mathcal{H}t_3)$ of (26.3), so that $t_1 \to \tau_1 = t_1 - t_3$, $t_2 \to \tau_2 = t_2 - t_3$. One then

The wave functions also satisfy the additional conditions:

$$\langle c \,|\, \bar\chi_{(ia)} \,|\, d \rangle = \langle k \,|\, \bar\chi_{(ia)} \,|\, \ell \rangle = 0 ,$$
$$\text{PH/HP (no 2P/2H terms)} \qquad (26.47)$$

$$\langle ck \,|\, \bar\varphi_{(ij)} \rangle = \langle ck \,|\, \bar\gamma_{(ab)} \rangle = 0 ,$$
$$\text{2P/2H (no PH/HP terms)} \qquad (26.48)$$

The single indices a, b, c, d refer to core and i, j, k, ℓ to valence DF (HF) states. The BS wave functions satisfy the orthonormality conditions

$$\sum_{k,c} \left(\langle k \,|\, \bar\chi_{(ia)} \,|\, c \rangle \langle c \,|\, \bar\chi_{(ia)'} \,|\, k \rangle \right.$$
$$\left. + \langle c \,|\, \bar\chi_{(ia)} \,|\, k \rangle \langle k \,|\, \bar\chi_{(ia)'} \,|\, c \rangle \right) = \delta_{(ia)(ia)'} , \qquad (26.49)$$

for the PH/HP case, and

$$\pm \left(\sum_{c>d} \langle \bar\xi_{(\tau)} \,|\, cd \rangle \langle cd \,|\, \bar\xi_{(\tau')} \rangle \right.$$

$$\left. - \sum_{k>\ell} \langle \bar\xi_{(\tau)} \,|\, k\ell \rangle \langle k\ell \,|\, \bar\xi_{(\tau')} \rangle \right) = \delta_{(\tau)(\tau')} , \qquad (26.50)$$

where $+(-)$ corresponds to the 2H(2P) case and $(\tau) = (ab)$ or (ij).

The PH/HP case in the GFA, involving Coulomb ladders for the ee interaction, is just the R and NR RPA [26.2]. The labels c, d should also refer to antiparticles, but the contributions of the integrals from these terms to (26.45) and (26.46) are negligible.

introduces complete sets of intermediate states. The functions defined in connection with the two-point function in (26.16) and (26.17) will now appear, as well as the radiative transition amplitude, defined in (26.10). If one next carries out a separate time translation of τ_1 and τ_2 and Fourier-transforms the resulting expressions, one obtains (with **3** replaced by $\boldsymbol{r}$)

$$\Gamma^N(\boldsymbol{r}; \omega_1 \omega_2)$$

$$= \sum_{j\ell}\!\!\!\!\!\!\int \frac{|u^j\rangle M^{N+1}_{j\ell}(\boldsymbol{r}) \langle u^\ell|}{(\omega_1 - \varepsilon_j + i\eta)(\omega_2 - \varepsilon_\ell + i\eta)}$$

$$+ \sum_{\zeta\chi}\!\!\!\!\!\!\int \frac{|v^\zeta\rangle M^{N-1}_{\zeta\chi}(\boldsymbol{r}) \langle v^\chi|}{(\omega_1 - \varepsilon_\zeta - i\eta)(\omega_2 - \varepsilon_\chi - i\eta)} + \cdots .$$

$$(26.52)$$

We next define the three-point irreducible electron vertex Λ^N from the reducible vertex Γ^N (the electron "legs" in Γ^N are missing in Λ^N) as

$$\left\langle \mathbf{1} \left| \Gamma^N(\mathbf{r}; \omega_1\omega_2) \right| \mathbf{2} \right\rangle$$
$$\equiv \int \int d^3\mathbf{1}' \, d^3\mathbf{2}' \left\langle \mathbf{1} \left| G_{\omega_1}^N \right| \mathbf{1}' \right\rangle \left\langle \mathbf{1}' \left| \Lambda^N(\mathbf{r}; \omega_1\omega_2) \right| \mathbf{2}' \right\rangle$$
$$\times \left\langle \mathbf{2}' \left| G_{\omega_2}^N \right| \mathbf{2} \right\rangle , \tag{26.53}$$

and pick out the residues of the ω_1 and ω_2 poles at specific energies ε_m and ε_n. [$\Lambda^N(\mathbf{r}; \omega_1\omega_2)$ has no such poles.] With the equivalent of the DF(HF) approximation to the Dyson equations (26.57) below, the corresponding kets form an orthonormal set, and scalar products are calculated with respect to $\langle m|$ and $|n\rangle$. The second term on the right-hand side of (26.52) refers to hole states and is of less interest than the first term describing 1P–1P transitions. From the first term, the transition matrix element in terms of Λ^N is

$$M_{fi}^{N+1}(\mathbf{r}; k_0) = \left\langle f \left| \Lambda^N(\mathbf{r}; e_f e_i) \right| i \right\rangle . \tag{26.54}$$

Generation of a Dyson Equation

The approximation of only Coulomb "ladder" ee interactions in the two-point Green's function produces an infinite set of Feynman diagrams to which one end of a single transverse photon line is attached in all possible ways. A resummation of these diagrams generates the $G_{\omega,\mathrm{Coul}}^N$ functions, which are approximated by the DF (HF) propagators written in their spectral form. The scalar products leading to (26.54) can then be taken.

A further simplification results because of the Coulomb ladder approximation, which is the same as in the four-point Green's function case: the relative time can be set equal to zero, which corresponds to integrating over the relative frequency, $\omega = \omega_1 - \omega_2$. With the total frequency defined as $\Omega = \frac{1}{2}(\omega_1 + \omega_2)$, and the definitions

$$\bar{\Lambda}^N(\mathbf{r}, \Omega) = \frac{1}{2\pi} \int d\omega \, \Lambda^N\left(\mathbf{r}; \omega + \frac{1}{2}\Omega, \omega - \frac{1}{2}\Omega\right),$$
$$\left\langle m \left| \bar{\Lambda}^N(\Omega) \right| n \right\rangle$$
$$= \int d^3\mathbf{r} \, \frac{e^{i\mathbf{k}\cdot\mathbf{r}}}{\sqrt{2k_0}} \left\langle m \left| \bar{\Lambda}^N(\mathbf{r}, \Omega) \right| n \right\rangle ,$$
$$\Omega_{mn} = e_n - e_m = k_0 , \tag{26.55}$$

with a relation similar to (26.55) for the quantity $\lambda_k(r)$ defined in (26.11), i. e.,

$$\left\langle m \left| \lambda(k_0) \right| n \right\rangle = \int d^3\mathbf{r} \, \frac{e^{i\mathbf{k}\cdot\mathbf{r}}}{\sqrt{2k_0}} \langle m|\lambda_k(r)|n\rangle , \tag{26.56}$$

the matrix elements in the DF (HF) basis are [26.14, 20]

$$\left\langle m \left| \bar{\Lambda}^N(k_0) \right| n \right\rangle$$
$$= \langle m|\lambda(k_0)|n\rangle$$
$$+ \sum_{aj} \left\{ \frac{1}{e_a - e_j + k_0} \left[{}^m_j \left| V \right| {}^n_a \right] \left\langle a \left| \bar{\Lambda}^N(k_0) \right| j \right\rangle \right.$$
$$+ \left. \frac{1}{e_a - e_j - k_0} \left[{}^m_a \left| V \right| {}^n_j \right] \left\langle j \left| \bar{\Lambda}^N(k_0) \right| a \right\rangle \right\} . \tag{26.57}$$

As discussed in Sect. 26.1, the label a should include not just hole states but also negative energy states, which have been neglected in (26.57). Note also that only PH or HP matrix elements appear on the right-hand side of (26.57). Therefore, a closed set of inhomogeneous linear algebraic equations for $\langle b|\bar{\Lambda}^N(k_0)|\ell\rangle$ and $\langle \ell|\bar{\Lambda}^N(k_0)|b\rangle$ results from setting $m = b, n = \ell$ or $m = \ell$, $n = b$, respectively, in (26.57). These equations can be solved numerically, and the resulting $\left\langle a \left| \bar{\Lambda}^N(k_0) \right| j \right\rangle$ and $\left\langle j \left| \bar{\Lambda}^N(k_0) \right| a \right\rangle$ substituted in (26.57) to obtain the final result

$$M_{fi}^{N+1}(k_0) \equiv \left\langle f \left| \bar{\Lambda}^N(k_0) \right| i \right\rangle . \tag{26.58}$$

An integro-differential equation form, which provides the option of choosing alternative numerical techniques [26.14], is obtained from (26.57), after some rearrangement and passage to a coordinate basis. Defining $m_{fi}(k_0)$ from $\lambda(k_0)$ in analogy with the definition of $M_{fi}^{N+1}(k_0)$ from $\bar{\Lambda}^N(k_0)$ in (26.58), one has

$$M_{fi}^{N+1}(k_0) = m_{fi}(k_0) + \sum_a (\langle a|\lambda(k_0)|A^-\rangle$$
$$+ \langle A^+|\lambda(k_0)|a\rangle) , \tag{26.59}$$

where

$$[h(\mathbf{r}) \mp k_0 - e_a] \left\langle \mathbf{r} \left| A^\pm \right\rangle + \sum_a \left[{}^{\mathbf{r}}_a \left| V \right| {}^{A_\pm}_a \right] \right.$$
$$= - \sum_j \langle \mathbf{r}|j\rangle\langle j| \left[v_\pm + \mathcal{V}_\pm \right] |a\rangle , \tag{26.60}$$

$$\langle j|v_+|a\rangle = \left[{}^j_i \left| V \right| {}^a_f \right], \quad \langle j|v_-|a\rangle = \left[{}^j_f \left| V \right| {}^a_i \right], \tag{26.61}$$

$$\langle j|\mathcal{V}_\pm|a\rangle = \sum_b \left\{ \left[{}^j_b \left| V \right| {}^a_{B_\pm} \right] + \left[{}^j_{B_\mp} \left| V \right| {}^a_b \right] \right\} . \tag{26.62}$$

The three-point Green's function, as can be seen from this summary, describes transition amplitudes

for radiative transitions between two valence states of atoms with closed shells (subshells) plus one electron (the 1P case). In the Coulomb ladder approximation, closely related to the DF equation, the photon vertex $\langle\mathbf{1}\,|\,\Lambda^N(\mathbf{r};\omega_1\omega_2)\,|\,\mathbf{2}\rangle$ of (26.53), is nonlocal in space, rather than the local vertex $\langle\mathbf{1}\,|\lambda_k(\mathbf{r})|\,\mathbf{2}\rangle$ of (26.11) [as follows from the factor of $\delta^3(\mathbf{1}-\mathbf{r})\delta^3(\mathbf{2}-\mathbf{r})$]. The presence of these additional nonlocal contributions to $M_{fi}^{N+1}(k_0)$ is made apparent in (26.59). The $m_{fi}(k_0)$ term is the contribution of the local vertex. Of course, if one knew the *exact* $N+1$ electron wave functions and energies, only the local vertex would enter and a GI result would be obtained. However, the length and velocity versions of (26.12) are equal and GI even in the approximation just discussed [26.3, 7]. Gauge invariance is an *essential* constraint on radiative transition amplitudes. It has been proven for general gauges not only in the present approximation, but also in the ones discussed below [26.8, 10], all of them arising in the GFA. Since the effective potential in the DF (or HF) approximation is nonlocal, the effective current must also be nonlocal in order to maintain the GI.

The somewhat more complicated Dyson equation satisfied by the nonlocal vertex corresponding to the Brueckner approximation has also been generated [26.22], and put in a numerically implementable form.

An alternative approximation [26.3, 7] for transition matrix elements, proposed earlier [26.2] than the one just discussed, is based on the RPA [our PH/HP case, with wave function $\bar{\chi}_{(fa)}$ the solution of (26.45)]. Reference to (26.6), (26.7), (26.10) and (26.11) gives immediately

$$M_{fa}^N(\mathbf{r};\omega_{(fa)}) = -\lambda_k(\mathbf{r})\,\langle\mathbf{r}\,|\,\bar{\chi}_{(fa)}\,|\,\mathbf{r}\rangle \,, \qquad (26.63)$$

where $k_0 = k = \omega_{(fa)}$ and N corresponds to atoms with a closed shell or subshell of electrons.

Aside from being a different approximation to transition amplitudes than (26.54), (26.63) covers a different set of cases than does (26.54), since the corresponding

initial states i in (26.54) are restricted to core states a in (26.63). Thus, for example, the case $N=2$ in (26.54) can describe transitions between any two valence states of Li. The corresponding case for (26.63) is $N=4$, but only transitions to a higher level, originating in the 1s or 2s level of Li, can be described by the formalism.

Finally, we shall discuss radiative transitions [26.8] for 2P atoms (closed shell/subshell plus two valence electrons). The general case involves a five-point nonlocal vertex. However, in the ladder approximation, this reduces to transition matrix elements which contain combinations of DF, 2P BS wave functions, and three-point functions. The final expressions are

$$M_{fi}^{N+2}(\mathbf{r};k_0)$$
$$= \left\langle\bar{\zeta}_{(fp)}\left|\left(\frac{\bar{\Lambda}^N(\mathbf{r},k_0)}{k_0-\Delta H}V - V\frac{\bar{\Lambda}^N(\mathbf{r},k_0)}{k_0-\Delta H}\right)\right|\bar{\zeta}_{(iq)}\right\rangle.$$
$$(26.64)$$

The expressions appearing in this equation are, in more detail, in the DF basis:

$$\left\langle\begin{matrix}m\\n\end{matrix}\,\left|\,\frac{\bar{\Lambda}^N(\mathbf{r},k_0)}{k_0-\Delta H}\,\right|\,\begin{matrix}q\\s\end{matrix}\right\rangle \equiv \frac{\left\langle m\,\left|\,\bar{\Lambda}^N(\mathbf{r},k_0)\,\right|\,q\right\rangle\delta_{ns}}{k_0+e_q-e_m}\,,$$
$$(26.65)$$

where m, n, q, s label DF states (P or H), $\left|\begin{matrix}q\\s\end{matrix}\right\rangle \equiv |qs\rangle \equiv |q\rangle|s\rangle$; (26.65) serves to define ΔH, as a difference of two DF Hamiltonians, the argument $\mathbf{r}$ of $\bar{\Lambda}$ refers to the electron which emits the photon, and

$$\left\langle\begin{matrix}m\\n\end{matrix}\,\left|\,V\,\right|\,\bar{\zeta}_{(\tau)}\right\rangle = \sum_{cd}^{f}\left\langle\begin{matrix}m\\n\end{matrix}\,\left|\,V\,\right|\begin{matrix}c\\d\end{matrix}\right\rangle\left\langle cd\,\left|\,\bar{\zeta}_{(\tau)}\right.\right\rangle$$
$$+ \sum_{k\ell}^{f}\left\langle\begin{matrix}m\\n\end{matrix}\,\left|\,V\,\right|\begin{matrix}k\\\ell\end{matrix}\right\rangle\left\langle k\ell\,\left|\,\bar{\zeta}_{(\tau)}\right.\right\rangle.\qquad(26.66)$$

In (26.66) we used the fact that, in the DF basis, $|\bar{\zeta}_{(\tau)}\rangle$ only has 2P or 2H components (26.46, 26.48).

26.4 Radiative Corrections

This section summarizes radiative corrections for 1P/1H atoms, starting from the two-point Green's function. The Dyson equations are generated and solved perturbatively for the energy to order $\alpha^5 m$ (α^3 a.u.). The perturbation theory starts from the DF solution as the zero-order one.

As done for the three-point function in Sect. 26.3, the Dyson equation for radiative corrections involving

a single transverse photon is generated by expanding the two-point propagator to all orders in the Coulomb ladder approximation, inserting a transverse virtual photon in all possible ways, and then resumming. The resulting integral equation [26.23] is quite complicated, containing even the three-point vertex in its inhomogeneous term, as well as a mass counter term to eliminate divergences.

It is sufficient for the present purposes to expand these vertices through first order matrix elements of $V_{ee} \equiv V$, but to exclude matrix elements of type $\begin{bmatrix} m \\ a \end{bmatrix} |V| \begin{bmatrix} n \\ a \end{bmatrix}$ (where a is the label for core states), since these are already included in the DF approximation [see (26.27)].

Other radiative corrections are also generated, which include Coulomb photons. Two of these corrections, involving only such photons, have already been referred to in the text between (26.21) and (26.23). Finally, to order $\alpha^5 m$, corrections involving two transverse photons must be included.

Systematic application of the pole-shifting process in (26.23) to the one- and two-transverse-photon and the Coulomb-photon expressions yields two types of terms: first, photon exchange (of one transverse photon or of two-photons of either kind, Coulomb or transverse) between core and valence states; and second, self-energy and vacuum polarization contributions. Among the photon exchange terms, one can identify those contributions included in other approaches (at least for a few special cases, such as those arising from a single transverse photon interaction, and from two Coulomb interactions and Coulomb–Breit interactions with positive energy intermediate electron states). These are electron correlation terms which are included as part of a MBPT calculation [26.5], or one which involves consideration of an infinite subset of MBPT terms [26.6]. They need not be re-evaluated. The terms not covered by calculations of the type in [26.5, 6], which are of $O(m\alpha^5 c^2)$, involve retardation in Coulomb-transverse photon exchange, negative energy intermediate electron states for two Coulomb and Coulomb-transverse photon exchanges, two transverse photon exchange, self-energy and vacuum polarization terms, as well as anomalous magnetic moment corrections.

After lengthy calculation, one obtains final results in finite analytic form, which are numerically implementable. The results given below are obtained after further approximations. First, the remnants of the original integral equation are solved iteratively. Second, the self-energy terms are calculated in a joint expansion [26.24–26] in α and αZ, and are thus only valid for low Z in isoelectronic sequences. Finally, there are characteristic logarithmic terms generated by low virtual photon momenta in the self-energy contributions. A standard approach is to scale these with a factor of $(\alpha Z)^2$ to obtain Bethe log (BL) terms as constants independent of α, together with constant log (CL) terms of the form $\ln(\alpha Z)^2$. The BL terms are independent of Z for hydrogenic ions, and remain nearly so for other atoms. BL and CL terms are associated with both nuclear and ee Coulomb potentials. The ee CL terms arising from core and valence self-energy terms are canceled exactly by those coming from Coulomb and transverse photon exchange. Thus, the numerous and rather complicated corresponding ee BL terms, which also are *individually* small compared to their associated CL terms, should additionally almost cancel, and are therefore neglected.

One finally obtains (with all state labels denoting principal and orbital quantum numbers as well as spin indices: $n \equiv (n, \ell; m_s)$)

$$\Delta E(n, \ell) = Z |\langle \mathbf{0}|n\rangle|^2 F(n, \ell) , \qquad (26.67)$$

in a.u., where $\langle \mathbf{0}|n\rangle \equiv \langle \mathbf{0}|n, 0\rangle$ is the s-state HF wave function at the origin of coordinates, and serves to define an effective (shielded) nuclear charge $Z_{n,\text{eff}}$:

$$\langle \mathbf{r}|n, \ell\rangle \equiv \Psi_{n,\ell}(\mathbf{r}), \ |\langle \mathbf{0}|n\rangle|^2 \equiv \frac{1}{\pi n^3} (Z_{n,\text{eff}} \alpha)^3 . \qquad (26.68)$$

(Just as in hydrogen, for which the final expressions for the radiative corrections require NR and not R wave functions and energies, so in this case we use HF (NR) and not DF (R) quantities.) $F(n, \ell)$ consists of a valence or hole contribution $F_{v,h}$, a core term $F_{\text{core}}(n, \ell)$, and one due to photon exchange between electrons $F_{ee}(n, \ell)$:

$$F(n, \ell) = F_{v,h}(n, \ell) + F_{\text{core}}(n, \ell) + F_{ee}(n, \ell) , \qquad (26.69)$$

$$F_{v,h}(n, \ell) = \frac{4}{3} \left[N(Z)\delta_{\ell 0} + L(n\ell) + U_{v,h}^{so}(n\ell) \right] , \qquad (26.70)$$

$$F_{\text{core}}(n, \ell) = \frac{4}{3Z} \Big[N(Z)\rho(n\ell) + L_{\text{core}}(n\ell) + U(n\ell) + U_{\text{core}}^{so}(n\ell) \Big] , \qquad (26.71)$$

$$F_{ee}(n, \ell) = \frac{4}{3Z} \left[E(Z)K^C(n\ell) + K^L(n\ell) \right] , \qquad (26.72)$$

with $U_{v,h}^{so}(n\ell)$ and $U_{\text{core}}^{so}(n\ell)$ being the spin-orbit terms,

$$N(Z) = \ln \frac{1}{(Z\alpha)^2} + \frac{19}{30} + Z\alpha C_5 , \qquad (26.73)$$

$$C_5 = 3\pi \left(1 + \frac{11}{128} - \frac{1}{2}\ln 2 \right) , \qquad (26.74)$$

$$E(Z) = -\frac{7}{2}\ln \frac{1}{Z\alpha} + \frac{59}{20} - \frac{9}{8}\pi , \qquad (26.75)$$

$$L(n\ell) = \frac{i/4\pi}{|\langle \mathbf{0}|n\rangle|^2} \left\langle n, \ell \left| \left[\mathbf{p} \cdot \mathcal{L}_B(n\ell) \frac{\mathbf{r}}{r^3} \right. \right. \right. \\ \left. \left. \left. - \frac{\mathbf{r}}{r^3} \mathcal{L}_B(n\ell) \cdot \mathbf{p} \right] \right| n, \ell \right\rangle , \qquad (26.76)$$

$$\mathcal{L}_B(n\ell) \equiv \ln \frac{Z^2}{2|e_n - H|} , \qquad (26.77)$$

H the HF Hamiltonian, $e_n \equiv e(n\ell)$ the HF energy,

$$U_{v,h}^{so}(n\ell) = \frac{3/16\pi}{|\langle 0|n\rangle|^2} \left\langle n \left| \frac{1}{r^3} \right| n \right\rangle C_\ell , \qquad (26.78)$$

where

$$C_\ell = \begin{cases} \ell & j = \ell + \frac{1}{2} \\ -(\ell+1) & j = \ell - \frac{1}{2} \end{cases} , \qquad (26.79)$$

$$\rho(n\ell) = \frac{i/4\pi}{|\langle 0|n\rangle|^2} \sum_a \sum_{jk} \oint \left\{ \frac{(e_k - e_j)(e_a - 2e_k + e_j)}{e_a - e_j} \left[{}^n_a | V |^n_j \right] \langle j|r|k\rangle \cdot \langle k|p|a\rangle + \text{c.c.} \right\} , \qquad (26.80)$$

$$L_{\text{core}}(n\ell) = \frac{i/4\pi}{|\langle 0|n\rangle|^2} \sum_a \sum_{jk} \oint \left\{ \frac{(e_k - e_j)(e_a - 2e_k + e_j)}{e_a - e_j} \left[{}^n_a | V |^n_j \right] \ln \frac{Z^2}{2|e_a - e_k|} \langle j|r|k\rangle \cdot \langle k|p|a\rangle + \text{c.c.} \right\} , \qquad (26.81)$$

$$U_{(1)}(n\ell) = \frac{1/2\pi}{|\langle 0|n\rangle|^2} \sum_a \left\{ \left\langle a \left| p^2 \right| a \right\rangle \left[{}^n_a | V |^n_a \right] - \left[{}^n_{(a)'} | V |^n_{(a)'} \right] - \left(\left[{}^{(b)'}_a | V |^a_{(b)'} \right] + \text{c.c.} \right) \delta_{nb} \right\} , \qquad (26.82)$$

$$U_{(2)}(n\ell) = \frac{i/2\pi}{|\langle 0|n\rangle|^2} \sum_a \sum_{k<q} \oint \left\{ \frac{(2e_a - e_k - e_q)}{e_q - e_k} \left[{}^n_q | V |^n_k \right] \left(\ln \left| \frac{e_a - e_q}{e_a - e_k} \right| + 2 \right) \langle a|p|q\rangle \cdot \langle k|p|a\rangle + \text{c.c.} \right\} , \qquad (26.83)$$

$$U_{\text{core}}^{so}(n\ell) = \frac{3/16\pi}{|\langle 0|n\rangle|^2} \sum_{aj} \oint \left\{ \frac{\delta_{\ell_a \ell_j}}{e_a - e_j} \left[{}^n_a | V |^n_j \right] \left\langle j \left| \frac{1}{r^3} \right| a \right\rangle C_\ell + \text{c.c.} \right\} , \qquad (26.84)$$

$$K^C(n\ell) = \frac{1}{|\langle 0|n\rangle|^2} \sum_a \left[{}^n_a \left| \delta^3(x-y) \right| {}^n_a \right] , \qquad (26.85)$$

$$K^L(n\ell) = \frac{7/2}{|\langle 0|n\rangle|^2|} \sum_a \left[{}^n_a \left| \frac{1}{4\pi} \nabla^2 \left(\frac{\ln(Z|x-y|) + \gamma}{|x-y|} \right) \right| {}^n_a \right] , \qquad (26.86)$$

where

$$U(n\ell) \equiv U_{(1)}(n\ell) + U_{(2)}(n\ell) , \qquad (26.87)$$

$$\langle r|(a)'\rangle \equiv \frac{d}{dr} \langle r|a\rangle , \qquad (26.88)$$

and γ is the Euler–Mascheroni constant. As in (26.27), x refers to the top row and y to the bottom row in the two-row expression in (26.86).

$L(n\ell)$, which is associated with the valence electron and the nuclear Coulomb potential, has the form of a hydrogenic BL, except that it is calculated with HF wave functions and energies. $L_{\text{core}}(n\ell)$ comes from BL terms associated with core electrons.

The expressions appearing in (26.80), (26.81), and (26.83) originate from the double commutator $[p \cdot [p, H]]$, which is then approximated by using the commutator $[r, H] \approx ip$. This is not an exact result

because the ee exchange term in the HF potential is neglected. One thus obtains [26.13]

$$\langle m | [p \cdot [p, H]] | n \rangle \qquad (26.89)$$
$$\approx i(e_n - 2e_k + e_m)(e_k - e_n) \langle m | p | k \rangle \cdot \langle k | r | n \rangle .$$

A less accurate approximation is [26.12]

$$4\pi Z \delta^3(r) \approx [p \cdot [p, H]] . \qquad (26.90)$$

Using the left-hand side of this equation instead of the approximation (26.89) to the right-hand side would lead to only s-state a, j and p-state k contributions in (26.80) and alternative forms of (26.81) and (26.83).

The major part of the contribution to the energy due to radiative corrections comes from $F_{v,h}(n, 0)$ (s-states), and numerical tests indicate that the principal effect in this term comes from the renormalization of the electron density at the coordinate origin due to electron shielding.

This reduction occurs because the shielded wave function is more spread out than the unshielded one. Thus, one can extend the above results semi-empirically to high Z (for which $F_{core}(n, \ell)$ and $F_{ee}(n, \ell)$ play a much smaller role because of their $1/Z$ dependence) by using the hydrogenic results [26.27] for high Z, i. e., replacing Z^4 for hydrogen by $Z(Z_{n,\text{eff}})^3$ for 1P/1H atoms (where $Z_{n,\text{eff}}$ is the shielded nuclear charge number, defined in (26.68), and Z is the unshielded nuclear charge number). The results obtained in this way are competitive with other evaluations of ΔE_n [26.28].

Finally, there is a correction to $F(n, \ell)$ for smaller Z when the integral equations for the self-energy and vacuum polarization contributions are solved more accurately than by iteration. These corrections play little role in s-state energies, but are somewhat more important in p-states for the hard core case (closed shells, $N = 2, 10$, etc.). They are expected to provide a much more significant contribution in the soft core case (closed *sub*shells, $N = 4, 12$, etc.).

The correction is based on the simpler approximation given in (26.90) of the more accurate (26.89). It is given by

$$\delta F(n, \ell) = \frac{1}{Z\langle \mathbf{0}|n\rangle^2} \sum_a \sum_j \left\{ \frac{\left[\begin{smallmatrix} n \\ a \end{smallmatrix} \middle| V \middle| \begin{smallmatrix} n \\ j \end{smallmatrix}\right]}{e_a - e_j} \left[\langle j|\mathcal{E}|a\rangle \right.\right.$$
$$\left.\left. - Z\mathcal{F}_{\text{v,h}}^{(0)} \langle j|\mathbf{0}\rangle \langle \mathbf{0}|a\rangle \right] + \text{c.c.} \right\},$$
(26.91)

where

$$\langle j|\mathcal{E}|a\rangle = Z\mathcal{F}_{\text{v,h}}^{(0)} \langle j|\mathbf{0}\rangle \langle \mathbf{0}|a\rangle$$
$$+ \sum_b \sum_k \left(\frac{\left[\begin{smallmatrix} j \\ b \end{smallmatrix} \middle| V \middle| \begin{smallmatrix} a \\ k \end{smallmatrix}\right]}{e_b - e_k} \left[\langle k|\mathcal{E}|b\rangle + \text{c.c.}\right] \right),$$
(26.92)

$$\mathcal{F}_{\text{v,h}}^{(o)} = \frac{4}{3}\{N(Z) + L\}.$$
(26.93)

The inhomogeneous term in (26.92) appears only for states $|j\rangle$ and $|a\rangle$ which are s-states. L in (26.93) is taken to be a constant, an approximation sufficient for the desired accuracy, and reflects the fact that $L(n, 0)$ for s-states is essentially constant as a function of radial quantum number, and is approximately the same for hydrogen and the HF approximation.

In order to obtain the correction $\delta F(n, \ell)$ of (26.91), it is necessary first to solve the coupled inhomogeneous linear equations of (26.92). While the sum $\sum_a$ over core states is always over a finite number of discrete states, the symbol $\sum_j$ denotes an infinite sum over discrete bound valence states and an integral over the continuum of such states. Indeed, expressions of this type occur throughout the GFA. They can be dealt with by the use of finite basis techniques, for example the B-spline approach [26.29, 30].

27. Quantum Electrodynamics

Quantum Electrodynamics (QED) is the underlying theory of atomic and molecular physics. Despite this generality, it is not necessary to use the full theory in most atomic physics problems. This is because in the nonrelativistic limit QED reduces to the Schrödinger equation, and the extra physics in QED is in general quite small, being suppressed by powers of the fine structure constant α. Given the difficulty of solving the Schrödinger equation with high accuracy in most atomic physics situations, these small corrections can usually be neglected. The theory is however needed to explain small deviations from the solution to the Schrödinger equation in simple systems, in particular a single electron in a constant magnetic field and few-electron atoms. Larger deviations occur for highly charged ions, and also for high-energy scattering of electrons and photons. We note that a rather extensive review of QED is available [27.1], and refer the reader interested in more details to that work. In addition, comparison with experiment is made by *Mohr* in Chapt. 28, and thus is done here only in selected cases.

Part B | 27

27.1 Covariant Perturbation Theory

QED combines relativity, electromagnetism, and quantum mechanics. As the first two theories were well understood when quantum mechanics was formulated, the development of the the fundamental equations of QED (after Dirac's introduction of his relativistic equation for the electron) took place rapidly, being in place in 1928 [27.2, 3]. However, it was recognized almost immediately that when higher order perturbation theory was considered, infinities associated with short wavelengths, known as ultraviolet divergences, were present, and that this apparently predicted infinite shifts in spectral lines. These difficulties were not overcome for two decades, but at that time improvements in calculational technology coupled with an understanding that the infinities could be grouped into renormalizations of the electron's mass, charge, and wave function and the photon's wave function, led to the modern form of QED.

A central object in this form of the theory is the *S*-matrix. To introduce it, we start with the Schrödinger equation,

$$i\hbar \frac{\partial}{\partial t} \Psi(t) = (H_0 + H_I)\Psi(t) \tag{27.1}$$

where H_0 is the Hamiltonian of free electrons and photons (although this can be easily generalized to include external potentials such as a nuclear Coulomb field), and H_I the electromagnetic interaction between them. These Hamiltonians follow from the Lagrangian density $\mathcal{L} = \mathcal{L}_0 + \mathcal{L}_1$, where

$$\mathcal{L}_0 = \bar{\psi}_0(\boldsymbol{x},t)\left(\gamma_\mu p^\mu - m_0\right)\psi_0(\boldsymbol{x},t)$$
$$- \frac{1}{4}F_{0\mu\nu}(\boldsymbol{x},t)F_0^{\mu\nu}(\boldsymbol{x},t) \tag{27.2}$$

and

$$\mathcal{L}_I = -e_0\bar{\psi}_0(\boldsymbol{x},t)\gamma_\mu\psi_0(\boldsymbol{x},t)A_0^\mu(\boldsymbol{x},t). \tag{27.3}$$

The 0 subscripts in the above emphasize that the fields and couplings are unrenormalized: renormalization will be discussed in the next section. In addition $\bar{\psi} p^\mu \psi$ is understood to represent $\frac{1}{2}i\bar{\psi}(\partial^\mu \psi) - \frac{1}{2}i(\partial^\mu \bar{\psi})\psi$, and gauge fixing terms have been suppressed. By making the unitary transformation

$$\Psi(t) \equiv e^{-iH_0 t/\hbar} \Phi(t) , \qquad (27.4)$$

which transforms from the Schrödinger to the interaction representation, and further defining the U matrix through

$$\Phi(t) = U(t, -\infty)\Phi(-\infty) , \qquad (27.5)$$

one finds an equation for this matrix

$$i\hbar \frac{\partial}{\partial t} U(t, -\infty) = \hat{H}_I(t) U(t, -\infty) \qquad (27.6)$$

where

$$\hat{H}_I(t) = e^{iH_0 t/\hbar} H_I e^{-iH_0 t/\hbar} . \qquad (27.7)$$

Solving this equation iteratively then gives for the S-matrix, defined as $S = U(\infty, -\infty)$,

$$S = \sum_{n=0}^{\infty} (-i)^n \frac{1}{n!} \int_{-\infty}^{\infty} dt_1 \cdots \int_{-\infty}^{\infty} dt_n$$
$$\times T\left[\hat{H}_1(t_1), \cdots \hat{H}_1(t_n)\right] , \qquad (27.8)$$

where T is the time ordering operator. An initial state consisting of free electrons, positrons, and photons will then have an amplitude to scatter into a final state with different momenta and perhaps different numbers of particles given by the S-matrix. This amplitude can be calculated using Wick's theorem, and the result conveniently represented by Feynman diagrams. Lowest order results of this procedure (tree approximation) describe processes such as electron scattering, electron–positron annihilation, etc. to fairly high precision. However, as mentioned above, when higher terms in the perturbation expansion are considered, diagrams containing closed loops are encountered that are formally infinite, and a renormalization program must be introduced.

27.2 Renormalization Theory and Gauge Choices

Before we discuss renormalization theory, we mention that QED has the same freedom to choose gauge as classical electromagnetism. We will discuss four gauges that have been used in QED calculations, though there is of course an arbitrary number. All of these gauges can be defined through the photon propagator in momentum space. If this is defined by

$$\int d^4x\, e^{-ik\cdot x} \langle 0|T[A_\mu(x) A_\nu(0)]|0\rangle \equiv -i\frac{G_{\mu\nu}(k)}{k^2} \qquad (27.9)$$

the Coulomb gauge is defined by

$$G_{00} = -\frac{k^2}{\mathbf{k}^2} ,$$
$$G_{ij} = -\left(\delta_{ij} - \frac{k_i k_j}{\mathbf{k}^2}\right) ,$$
$$G_{i0} = G_{0i} = 0 . \qquad (27.10)$$

While this gauge is particularly physical, with the G_{00} part directly corresponding to the instantaneous Coulomb interaction and the G_{ij} to magnetic interactions, it is relatively difficult to work with. For ease of calculation, the covariant gauges, defined by

$$G_{\mu\nu} = g_{\mu\nu} + \beta \frac{k_\mu k_\nu}{k^2} \qquad (27.11)$$

are useful, particularly the case $\beta = 0$, the Feynman gauge. Other values of β are $\beta = 2$, the Yennie gauge [27.4], and $\beta = -1$, the Landau gauge. The former has the advantage of controlling infrared divergences, and the latter of controlling ultraviolet divergences.

Two of these infinities are first encountered when the self-energy of a free electron is calculated in second order perturbation theory. In order to deal with finite quantities, we first must introduce a device to regulate the high-frequency range of the integrations. This can be done in a number of ways, among them Pauli–Villars regularization [27.5]. In this method one modifies the photon propagator to

$$1/q^2 \rightarrow 1/\left(q^2 - \lambda^2\right) - 1/\left(q^2 - \Lambda^2\right) , \qquad (27.12)$$

where λ is a photon mass that regulates infrared divergences and Λ an ultraviolet cutoff mass. In this case the self-energy operator is represented by the Feynman diagram of Fig. 27.1a, and is, using Feynman gauge,

$$\Sigma(p) = -ie^2 \int \frac{d^4k}{(2\pi)^4} \gamma_\mu \frac{1}{\not{p} - \not{k} - m_0} \gamma^\mu$$
$$\times \left(\frac{1}{k^2 - \lambda^2} - \frac{1}{k^2 - \Lambda^2}\right) . \qquad (27.13)$$
Fig. 27.1a–c Ultraviolet divergent one-loop Feynman diagrams

Combining the two denominators together with a Feynman parameter and carrying out the integration over k then leads to

$$\Sigma(p) = \delta m^{(2)} + B^{(2)}(\not{p} - m_0) + \Sigma_F(p) , \qquad (27.14)$$

where

$$\delta m^{(2)} = \frac{3\alpha m_0}{2\pi} [\ln(\Lambda/m_0) + 1/4] \qquad (27.15)$$

and

$$B^{(2)} = -\frac{\alpha}{2\pi} [\ln(\Lambda/m_0) + 2\ln(\lambda/m_0) + 9/4] . \qquad (27.16)$$

Σ_F will not be given here, but the important point is that it is ultraviolet finite. Thus the ultraviolet infinities of QED are isolated in the first two terms, which are of a very simple structure.

The next infinity is connected with the vertex function of Fig. 27.1b. This is defined by the equation

$$\Gamma_\mu = -\mathrm{i}e_0^3 \int \frac{\mathrm{d}^4 k}{(2\pi)^4} \gamma_\rho \frac{1}{\not{p} - \not{k} - m} \gamma_\mu$$
$$\times \frac{1}{\not{p}' - \not{k} - m} \gamma^\rho \left(\frac{1}{k^2 - \lambda^2} - \frac{1}{k^2 - \Lambda^2} \right) . \qquad (27.17)$$

While Γ_μ is a fairly complicated function, its ultraviolet divergent part is simply a multiple of γ_μ. When the electron momenta p and p' are equal and on shell, this integral can be evaluated to be

$$\Gamma_\mu = e_0 \gamma_\mu L^{(2)} \qquad (27.18)$$

where

$$L^{(2)} = \frac{\alpha}{2\pi} [\ln(\Lambda/m) + 2\ln(\lambda/m) + 9/4] . \qquad (27.19)$$

The fact that $L^{(2)} = -B^{(2)}$ is a consequence of the Ward identity [27.6].

The final infinity of second-order QED arises from the vacuum polarization diagram of Fig. 27.1c. The associated integral is

$$\Pi_{\mu\nu}(p) = -\mathrm{i}e^2 \int \frac{\mathrm{d}^4 k}{(2\pi)^4} \mathrm{Tr}$$
$$\times \left(\gamma_\mu \frac{1}{\not{p} + \not{k} - m_0} \gamma_\nu \frac{1}{\not{k} - m_0} \right) . \qquad (27.20)$$

In this case the integral cannot be regulated as before, since there is no photon propagator to modify. Instead one can subtract a similar integral with the electron mass replaced by M. Vacuum polarization is particularly sensitive to ultraviolet divergences, since the nominal order of the divergence is quadratic. However, gauge invariance requires $\Pi_{\mu\nu}(p)$ to have the structure $(p^2 g_{\mu\nu} - p_\mu p_\nu) \Pi(p^2)$, and if one considers only the $p_\mu p_\nu$ part of the vacuum polarization integral, the ultraviolet divergence is only logarithmic. This divergence is independent of the photon momentum p, and one can write

$$\Pi(p^2) = C^{(2)} + \Pi_{\text{finite}}(p^2) \qquad (27.21)$$

where

$$C^{(2)} = \frac{\alpha}{3\pi} \ln\left(M^2/m_0^2 \right) \qquad (27.22)$$

and

$$\Pi_{\text{finite}}(p^2) = -\frac{2\alpha}{\pi} \int_0^1 \mathrm{d}x \, x(1-x)$$
$$\times \ln\left[1 - x(1-x)p^2/m_0^2 \right] . \qquad (27.23)$$

The four infinite quantities encountered in second order perturbation theory are modified by higher order corrections, but no new divergent structures arise. The basic idea of renormalization is to note that these structures are already present in the lowest order Lagrangian. We now make the following definitions:

$$m = m_0 + \delta m , \qquad (27.24)$$
$$\psi(x) = Z_2^{-1/2} \psi_0(x) , \qquad (27.25)$$
$$A^\mu(x) = Z_3^{-1/2} A_0^\mu(x) , \qquad (27.26)$$

and

$$e = e_0 Z_1^{-1} Z_2 Z_3^{1/2} . \qquad (27.27)$$

These correspond to an additive renormalization of the electron mass and multiplicative renormalizations of the electron and photon wave functions and the electron charge. Rewriting the original bare Lagrangian in terms of these renormalized quantities then gives that Lagrangian without the 0 subscripts, plus the following counterterms:

$$\mathcal{L}_{CT1} = Z_2 \delta m \bar{\psi}(\boldsymbol{x}, t) \psi(\boldsymbol{x}, t) , \qquad (27.28)$$
$$\mathcal{L}_{CT2} = -e(Z_1 - 1) \bar{\psi}(\boldsymbol{x}, t) \gamma_\mu \psi(\boldsymbol{x}, t) A^\mu(\boldsymbol{x}, t) , \qquad (27.29)$$
$$\mathcal{L}_{CT3} = -\frac{1}{4}(Z_3 - 1) F_{\mu\nu}(\boldsymbol{x}, t) F^{\mu\nu}(\boldsymbol{x}, t) , \qquad (27.30)$$

and

$$\mathcal{L}_{CT4} = (Z_2 - 1)\bar{\psi}(\boldsymbol{x}, t)\left(\gamma_\mu p^\mu - m\right)\psi(\boldsymbol{x}, t) . \tag{27.31}$$

By choosing $Z_2 = 1 + B^{(2)}$, $Z_1 = 1 - L^{(2)}$, $\delta m = \delta m^{(2)}$, and $Z_3 = 1 - C^{(2)}$, these counterterms will precisely cancel the previously encountered divergences in second order. At this point we identify m and e as the experimentally determined mass and charge of the electron: as long as these are used, the radiative corrections discussed above have no effect for free electrons. However, when an electron undergoes scattering or is in the presence of an external magnetic or nuclear Coulomb field, the finite terms no longer vanish, and give rise to small corrections. We now turn to a discussion of these corrections.

27.3 Tests of QED in Lepton Scattering

The highest energy tests of QED come from scattering experiments at accelerators. While the dominant part of QED corrections for all the other tests discussed in this chapter involves electron and photon propagators close to the mass shell, scattering experiments involve propagators very far off the mass shell, which allows tests of the theory at very small distances. It is standard to parameterize possible deviations from the predictions of QED at these small distances by the introduction of form factors of the form

$$F(q^2) = 1 - \frac{q^2}{q^2 - \Lambda^2} \tag{27.32}$$

where q is photon momentum at an electron–photon vertex. In QED Λ is infinite and this form factor is unity even at very high q^2, but this can be tested in various scattering experiments. For example, Bhabha scattering, $e^+ e^- \rightarrow e^+ e^-$, has been accurately measured at high center of mass energy, $\sqrt{s} = 34.8\,\text{GeV}$, at TASSO [27.1, 7]. To compare with QED, very sizable radiative corrections must be carefully calculated, and at these energies electroweak effects involving the Z boson, while small, must also be considered. Although the accuracy of the experiments is not high compared with atomic physics measurements, being at the percent level, the good agreement with QED that is found allows lower limits on the cutoff $\Lambda > 500\,\text{GeV}$ to be placed. This corresponds to distances of under $10^{-16}\,\text{cm}$. It is of interest to compare this sensitivity with that available from atomic physics tests. The change in the photon propagator given above corresponds to a potential $e^{-\Lambda r}/r$. This would lead to an energy shift of a 2s electron in hydrogen of $46/\Lambda^2\,\text{kHz}$ with Λ in units of GeV. Thus even 1 kHz accuracy in the Lamb shift would only restrict $\Lambda > 7\,\text{GeV}$.

27.4 Electron and Muon *g* Factors

One of the successes of the Dirac equation is the prediction $g = 2$ for the electron. The leading correction to this result coming from QED is the Schwinger correction [27.8],

$$g = 2\left(1 + \frac{\alpha}{2\pi}\right) . \tag{27.33}$$

While in principle this is an external field problem, because of the weakness of laboratory magnetic fields, the correction can be related to Feynman diagrams with free propagators. To see the weakness we note that $eB/m_e^2 = 2.3 \times 10^{-14} B$ (Gauss). In extremely intense magnetic fields such as can be encountered in astrophysical situations, a bound state approach [27.9] should be used both for calculating energy shifts and the imaginary part of these shifts, which describe synchrotron radiation. An example of the more precise approach is Demeur's formula for the (real) energy shift of an electron in the lowest energy level

$$\Delta E = \frac{m\alpha}{2\pi}\left[-\frac{eB}{2m^2} + \left(\frac{eB}{m^2}\right)^2\left(\frac{4}{3}\ln\frac{m^2}{2eB} - \frac{13}{18}\right)\right.$$
$$+ \left(\frac{eB}{m^2}\right)^3\left(\frac{14}{3}\ln\frac{m^2}{2eB} - \frac{32}{5}\ln 2 + \frac{83}{90}\right)$$
$$\left. + \cdots\right]. \tag{27.34}$$

The second term could actually be seen at the present level of precision, but is spin-independent, and the third term is negligible. An interesting feature of the experiment is the effect of the conducting cavity, which must be understood to extract the correct value of $g - 2$ [27.1, 10].

After the initial verification of the Schwinger correction, experiments of increasing precision culminating in

the Penning trap measurements in Washington [27.11] have stimulated advances in theoretical calculations. These involve the evaluation of constants C_i defined by

$$a_e = C_1 \frac{\alpha}{\pi} + C_2 \left(\frac{\alpha}{\pi}\right)^2 + C_3 \left(\frac{\alpha}{\pi}\right)^3 + C_4 \left(\frac{\alpha}{\pi}\right)^4 + \cdots$$
(27.35)

where $a_e = (g - 2)/2$ is the anomalous magnetic moment of the electron. The computational effort involved in computing the coefficients C_i increases very rapidly with i, and the four loop calculation is the largest QED calculation ever carried out. The situation with regard to these calculations is as follows. After the calculation of the Schwinger correction, the next step was the evaluation of the seven Feynman diagrams of Fig. 27.2. A feature of the one-loop calculation, that it is ultraviolet finite, is no longer present at this level, and renormalizations of the self-mass, vertex, and wave function must be performed, although the latter two cancel by Ward's identity. When the calculation is carried out in Feynman gauge, each graph has an infrared divergence that must be regulated in some fashion, for example by giving the photon a small mass λ. This calculation was first correctly carried out by *Sommerfield* [27.12] and *Petermann* [27.13]. The result is

$$C_2 = \frac{197}{144} + \frac{\pi^2}{6}(0.5 - 3\ln 2) + 0.75\zeta(3)$$
(27.36)

where $\zeta(3) = 1.20205\ldots$ is the Riemann zeta function of argument 3. While each individual diagram is infrared divergent in Feynman gauge, *Adkins* [27.14] has used Yennie gauge [27.4] to recalculate the effect, free of infrared divergent terms. His results are given in Table 27.1.

The vacuum polarization graph of Fig. 27.2e plays an interesting role. While the result for C_2 given above
Table 27.1 Contributions to of C_2 in Yennie gauge

Graph	Value
a	$-\frac{1}{2}B^{(2)} - \frac{3}{16}$
b	$\frac{5}{4}\zeta(3) - \frac{5}{6}\pi^2 \ln 2 + \frac{5}{12}\pi^2 + \frac{7}{12}$
c	$-B^{(2)} - \frac{1}{2}\zeta(3) + \frac{1}{3}\pi^2 \ln 2 - \frac{29}{24}$
d	$B^{(2)} - \frac{9}{8}$
e	$-\frac{1}{3}\pi^2 + \frac{119}{36}$
Counterterm	$\frac{1}{2}B^{(2)}$

includes only the case where the intermediate particles in the loop are electrons, that loop can also involve any charged particle, such as the muon, pion, or tau. However, because all these particles are much heavier than the electron, which sets the energy scale of the Feynman integral, their effect is suppressed by the square of the mass ratio of the electron to their mass, and are thus quite small. Specifically, in units of 10^{-12}, the muon loop contributes 2.80, the tau loop 0.01, and hadrons 1.6(2). These act to increase C_2 by 0.00000082. We note in passing that the effect of the weak interactions enters in one loop, and contributes 0.05×10^{-12} to the electron $g - 2$ value and $195(10) \times 10^{-11}$ for the muon.

When the anomalous magnetic moment of the muon is considered the situation changes significantly. Firstly, the contribution of electrons in the loop is enhanced, since they are now relatively light particles, and the vacuum polarization loop behaves as a logarithm of the mass ratio. Specifically, the difference between the muon and electron $g - 2$ factors behaves as [27.15]

$$a_\mu - a_e = 1.094 \left(\frac{\alpha}{\pi}\right)^2 + 22.9 \left(\frac{\alpha}{\pi}\right)^3$$
$$+ 132.7 \left(\frac{\alpha}{\pi}\right)^4 + \cdots$$
(27.37)

These large coefficients arise primarily because the vacuum polarization loops involving electrons change the effective value of α to $\alpha/(1 - 2\alpha/3\pi \ln m_\mu/m_e)$. Note however that such logarithmic terms also arise from other sources, most notably the light-by-light scattering graphs that enter first in third order.

The second important change in the muon case is the significant role of strongly interacting particles in the loop. Fortunately, while our present inability to carry

Fig. 27.2a–e Two-loop Feynman diagrams contributing to $g - 2$

out high accuracy calculations of the strong interactions could in principle interfere with the interpretation of the muon $g - 2$ as a QED test, the bulk of this contribution can be related to the experimentally available cross-section for $e^+ e^-$ annihilation into hadrons [27.16]. It is also possible to use τ decay to determine the contribution [27.17]. At present the two methods are not in agreement, and this situation will have to be resolved before a possible discrepancy between theory and the most recent experiment [27.18] can be interpreted as indicating new physics. Specifically, if the τ data is used a 1.4 standard deviation difference exists, but if the $e^+ e^-$ data is used the discrepancy increases to 2.7 standard deviations.

The calculation of C_3 involves 72 Feynman graphs, although they can be grouped together into a smaller number of gauge invariant sets. As discussed in more detail in Chapt. 28, C_3 is now known analytically, removing an important source of numerical uncertainty. The evaluation of such high-order graphs requires an intricate set of subtractions to lead to finite answers, and provides a practical demonstration of the renormalizability of QED. The result for C_3 is

$$C_3 = 1.181\,241\,456\ldots \tag{27.38}$$

precision measurements of recoil in cesium [27.20, 21], which has achieved 7 ppb and has the potential of reaching 1 ppb. Another way to determine α involves the fine structure of helium, as will be discussed below.

Finally, the very large scale calculation of C_4, which is almost completely numerical, has been carried out by *Kinoshita* and *Lindquist* [27.19]. When their result,

$$C_4 = -1.509\,8(384)\,, \tag{27.39}$$

is compared with experiment, agreement is found, but the largest source of error is the uncertainty in the fine structure constant as determined from solid state physics. However, if one instead assumes the validity of QED, the situation can be turned around to determine a QED value of the fine structure constant. This is done by combining the experimental result [27.11]

$$a_{e^-} = 1\,159\,652\,188.4(4.3) \times 10^{-12}$$
$$a_{e^+} = 1\,159\,652\,187.9(4.3) \times 10^{-12} \tag{27.40}$$

with the previous formulas for the C coefficients (including the small vacuum polarization corrections for C_2 discussed above). The result is

$$\alpha_{\mathrm{QED}}^{-1} = 137.035\,992\,22(51)(48) \tag{27.41}$$

where the errors come from experiment and C_4 respectively. It would be of great interest to have another QED determination of the fine structure constant of comparable accuracy: a very promising approach involves

27.5 Recoil Corrections

Because of the smallness of the ratio of the electron mass to most nuclear masses, a reasonable approximation to atoms is to treat the nucleus as a source of a classical Coulomb and magnetic dipole field, which corresponds to the use of *Furry* representation [27.22]. In addition, the leading correction to this approximation can be accounted for by using the reduced mass in place of the electron mass. However, to calculate higher order terms consistently, one must treat a one-electron atom as a two-body system and an N-electron atom as a $N + 1$-body system. Shortly after the development of modern QED, a number of workers [27.23–25] developed two-body equations by considering the Green's function for electron–nucleus scattering, with the original equation known as the Bethe–Salpeter equation. Considered as a function of the total energy in the c.m. frame, this Green's function has poles at bound state energies. In practice an approximate Green's function is considered that has poles at either the Schrödinger or the Dirac energies, with reduced mass built in to some degree. Then

a perturbation theory is set up that allows corrections of higher order in α and m_e/m_N to be calculated in a systematic way.

While the treatment of recoil using various versions of the Bethe–Salpeter equation gives correct answers, its implementation is quite complicated. In recent years enormous progress has been made using the very different approach of effective field theory. One of the earliest uses of effective field theory was in QED [27.26], and we will refer to it as NRQED (nonrelativistic QED). Effective field theories have been used in many different areas of physics, and are useful whenever physics at one scale can be treated separately from physics at a widely different scale. Atomic physics is an ideal place for the use of effective field theory, as, for example, the scale of the Bohr radius, the basic atomic physics length scale, is separated from the electron Compton wavelength, which is characteristic of most QED effects, by two orders of magnitude. NRQED applies to both recoil and non-recoil QED corrections, and always has as its

starting point the well-understood Schrödinger equation. Relativistic effects, such as relativistic mass increase, magnetic interactions, or the Darwin term, are then included perturbatively. This requires cutoff methods to deal with higher orders of perturbation theory, where those operators lead to ultraviolet singular results. In addition, the short distance physics of QED is accounted for by adding in perturbations that involve delta functions or derivatives of delta functions, with coefficients determined by what is called a matching procedure, in which scattering calculations in full QED and in the effective field theory are forced to agree. This approach, which unfortunately has not yet been treated at textbook level, has had a very great impact on higher order QED calculations, with a number of higher order effects calculated in recent years using the technique.

To illustrate the method, we follow a treatment of Pachucki [27.27] in which the Dirac energies of hydrogen in the non-recoil limit are calculated to order $m\alpha^6$. While he treated the general case, for simplicity we consider here only the ground state energy, which has the Taylor expansion

$$E = mc^2 \left[1 - \frac{1}{2}(Z\alpha)^2 - \frac{1}{8}(Z\alpha)^4 - \frac{1}{16}(Z\alpha)^6 \right] ,$$
(27.42)

where we follow the convention of allowing for a general nuclear charge Z. The fine structure, as is well known, can be derived from perturbations associated with the relativistic mass increase and the Darwin term, with the spin–orbit interaction not contributing for s-states. While the contribution of these perturbations is finite in lowest order perturbation theory, they give rise to singularities when treated in second order. To see this, we give the momentum space version of second order perturbation theory,

$$E^{(2)} = \int \frac{\mathrm{d}^3 p \, \mathrm{d}^3 k \, \mathrm{d}^3 l \, \mathrm{d}^3 q}{(2\pi)^9} \phi_0(\boldsymbol{p}) V(\boldsymbol{p}, \boldsymbol{k})$$
$$\times G_R(\boldsymbol{k}, \boldsymbol{l}) V(\boldsymbol{l}, \boldsymbol{q}) \phi_0(\boldsymbol{q}) ,$$
(27.43)

where G_R is the reduced Coulomb Green's function. It can be expanded in terms of a free term, a one-potential term, and a many-potential term. The strongest singularities are associated with the free term,

$$G_R^0(\boldsymbol{k}, \boldsymbol{l}) = -\frac{(2\pi)^3 2m\delta^3(\boldsymbol{k}-\boldsymbol{l})}{k^2 + \gamma^2} ,$$
(27.44)

where $\gamma = mZ\alpha$. The Darwin term in momentum space is simply $V_D = \pi Z\alpha/2m^2$, and it is simple to see that when both V's in the expression for $E^{(2)}$ are Darwin terms and the free part of the Green's function is used

a linearly divergent integral results. This can be regulated by imposing a cutoff Λ on the magnitude of all momenta in the integral, in which case a simple calculation gives

$$E^{(2)}(\mathrm{DD0}) = -\frac{\Lambda(Z\alpha)^5}{4\pi} + \frac{m(Z\alpha)^6}{8} .$$
(27.45)

Linear divergences also exist when two relativistic mass increase (RMI) terms or Darwin-RMI cross terms are considered, but these terms happen to cancel.

To get a finite answer, the contribution of operators of intrinsic order $m(Z\alpha)^6$ must be considered. These operators can be obtained from consideration of the Bethe–Salpeter equation, but a great simplification of NRQED is the fact that they can also be obtained by considering free-particle scattering, where the complications of the bound state problem are not present. We illustrate this by considering electron scattering in a Coulomb potential created by a stationary charge $Z|e|$. In the Dirac theory this is given by

$$\frac{-4\pi Z\alpha}{|\boldsymbol{p}_2 - \boldsymbol{p}_1|^2} \bar{\psi}(\boldsymbol{p}_2) \gamma_0 \psi(\boldsymbol{p}_1)$$
$$= \frac{-4\pi Z\alpha}{|\boldsymbol{p}_2 - \boldsymbol{p}_1|^2} \left(1 - \frac{|\boldsymbol{p}_2 - \boldsymbol{p}_1|^2}{8m^2} \right.$$
$$\left. + \frac{6|\boldsymbol{p}_2 - \boldsymbol{p}_1|^2 \left(p_1^2 + p_2^2 \right) + 5 \left(p_2^2 - p_1^2 \right)^2}{128m^4} \right) .$$
(27.46)

In the above we have carried out a Taylor expansion to fourth order in the electron momenta and dropped spin–orbit terms. While this coincides with Schrödinger theory in lowest order, a set of extra terms exists in the Dirac case. To account for these, we modify the nonrelativistic theory by adding extra operators that make the theories agree. If the Taylor expansion is stopped in order p^2, we recognize the Darwin term already treated above, but to go to order $m(Z\alpha)^6$ the last terms must be treated. They are again linearly divergent, as are two other terms – one associated with the next term in RMI,

$$V_{\mathrm{RMI}} = -(2\pi)^3 \delta(\boldsymbol{k} - \boldsymbol{l}) \left(\frac{|\boldsymbol{k}|^4}{8m^3} - \frac{|\boldsymbol{k}|^6}{16m^5} \right)$$
(27.47)

and the other a term that can either be derived with a Foldy–Wouthuysen transformation or by comparing two-Coulomb photon scattering in the Dirac and Schrödinger theories. When combined, first order perturbation theory for these operators cancels out the linear divergence found above arising from second order perturbation theory, along with a logarithmic singularity, leaving a finite answer in agreement with the Dirac theory.

27.6 Fine Structure

The fine structure of hydrogenic atoms in the non-recoil limit is correctly described by the Dirac equation, which gives for a state of principal quantum number n and spin j $E_{nj} = m_e f(n, j)$, with

$$f(n, j) = \left(1 + \frac{(Z\alpha)^2}{(n - \beta)^2}\right)^{-1/2} . \tag{27.48}$$

Here

$$\beta \equiv j + \frac{1}{2} - \sqrt{\left(j + \frac{1}{2}\right)^2 - (Z\alpha)^2} , \tag{27.49}$$

which gives the expansion

$$E_{nj} = m \left\{1 - \frac{(Z\alpha)^2}{2n^2} - \frac{(Z\alpha)^4}{2n^3}\left(\frac{1}{j + \frac{1}{2}} - \frac{3}{4n}\right) + \cdots\right\} \tag{27.50}$$

With the use of the Bethe–Salpeter equation or NRQED one can include recoil corrections exactly to order $m(Z\alpha)^4$, and to this order

$$E = M + m_r[f(n, j) - 1] - \frac{m_r^2}{2M}[f(n, j) - 1]^2$$
$$+ \frac{(Z\alpha)^4 m_r^3}{2n^3 m_N^2}\left(\frac{1}{j + \frac{1}{2}} - \frac{1}{l + \frac{1}{2}}\right)(1 - \delta_{l0}) \tag{27.51}$$

The last term in this expression leads to a slight breaking of the degeneracy of the $2s_{1/2}$ and $2p_{1/2}$ states: this splitting is referred to as the Lamb shift. A larger breaking arises from the finite size of the nucleus, which in the nonrelativistic limit shifts s-states by

$$\Delta E_n(\text{finite size}) = \frac{2}{3n^3}(Z\alpha)^4 m_r^3 \langle r^2 \rangle . \tag{27.52}$$

A major issue for the Lamb shift in hydrogen is the disagreement between measurements at Stanford [27.28] and Mainz [27.29] of the charge radius of the proton. As discussed in Mohr's chapter, the 18 kHz difference creates difficulties in interpreting the experimental status of the Lamb shift. While assuming the validity of QED and completing all calculations that enter at the few kHz level may allow one to determine the proton charge radius independently, it is clearly highly desirable that a definitive electron-scattering experiment be carried out. A promising alternative resolution to the problem may come from measurements on muonic hydrogen undergoing at PSI. Because the scale of such atoms is two orders of magnitude smaller than hydrogen, the effect of proton size is greatly enhanced, and a measurement of the Lamb shift would then allow a very precise measurement of the proton charge radius.

The largest correction to the Lamb shift comes from the self-energy and vacuum polarization graphs previously introduced in Sect. 27.2, with the understanding that the free electron propagators are replaced by Dirac–Coulomb propagators. The self-energy diagram in Feynman gauge gives an energy shift

$$\Delta E_n(\text{SE}) = -ie^2 \int d^3r \, d^3r'$$
$$\times \int \frac{d^4k}{(2\pi)^4} \frac{e^{ik\cdot(r-r')}}{k^2 + i\epsilon} \bar{\psi}_n(r)$$
$$\times \gamma_\mu S_F(r, r'; E_n - k_0)\gamma^\mu \psi_n(r') \tag{27.53}$$

and the vacuum polarization a shift

$$\Delta E_n(\text{VP}) = -ie^2 \int d^3r \int d^3r'$$
$$\times \int \frac{d^3k}{(2\pi)^3} \int \frac{dE}{2\pi} \bar{\psi}_n(r)$$
$$\times \gamma_0 \psi_n(r) \frac{e^{ik\cdot(r-r')}}{k^2} \text{Tr}[\gamma^0 S_F(r', r'; E)] . \tag{27.54}$$

In both cases the counterterms discussed above are understood to be added. It is conventional to pull out the overall behavior in Z, α, and the principal quantum number n as follows:

$$\Delta E_n(\text{SE}) + \Delta E_n(\text{VP}) \equiv m\alpha \frac{(Z\alpha)^4}{\pi n^3} F_n(Z\alpha) . \tag{27.55}$$

The evaluation of the function $F_n(Z\alpha)$ is quite difficult. At low Z, a perturbative expansion to order $(Z\alpha)^2$ is available, and is expressed as

$$F_n(Z\alpha) = A_{40} + A_{41} \ln(Z\alpha)^{-2} + (Z\alpha)A_{50}$$
$$+ (Z\alpha)^2 \Big[A_{62} \ln^2(Z\alpha)^{-2}$$
$$+ A_{61} \ln(Z\alpha)^{-2} + A_{60} \Big]$$
$$+ \cdots \tag{27.56}$$

The constants A can be found in *Mohr*'s Chapt. 28. A_{40} contains a constant that must be obtained numerically,

known as the Bethe logarithm. It can be defined from a nonrelativistic limit of the Coulomb gauge version of (27.53), in which one carries out the integral over k_0 with Cauchy's theorem, keeping only the photon pole, makes the dipole approximation, and replaces α with $\boldsymbol{p}/m$. In that limit one has

$$\Delta E_n^{\text{NR}} = \frac{2e^2}{3m^2} \int_0^{\Lambda} \frac{\mathrm{d}^3 k}{2\omega(2\pi)^3} \sum_m \frac{|\boldsymbol{p}_{nm}|^2}{E_n - \omega - E_m},$$

(27.57)

where $\boldsymbol{p}_{nm} \equiv \langle n|\boldsymbol{p}|m\rangle$. Because negative energy states are not present, this expression diverges linearly with Λ. The Bethe logarithm is defined by subtracting $-1/\omega$ from the above denominator and carrying out the $\mathrm{d}^3 k$ integration, giving

$$\Delta E_n^{\text{NR}} = \frac{e^2}{6m^2\pi^2} \sum_m |\boldsymbol{p}_{nm}|^2 (E_m - E_n) \ln \frac{\Lambda}{|E_m - E_n|}$$

$$\equiv \frac{4m\alpha(Z\alpha)^4}{3\pi n^3} \ln\left(\frac{\Lambda}{k_0(n)\text{Ry}}\right).$$

(27.58)

Elegant high accuracy determinations of these quantities using Schwinger's Coulomb Green's function have been made [27.30, 31]. Reference [27.32] contains an extensive tabulation.

We next discuss recoil corrections to the Lamb shift. One recoil effect is the modification of the A constants by a factor $(m_r/m_e)^3$ (although part of A_{40} is modified instead by $(m_r/m_e)^2$). Another correction, similar to the Lamb shift but involving a photon exchanged between the electron and nucleus was first derived by *Salpeter* [27.25], and is given by

$$\Delta E_n = \frac{m_r^3}{m_e m_N} \frac{(Z\alpha)^5}{\pi n^3} \left[\frac{2}{3}\delta_{l0} \ln\left(\frac{1}{Z\alpha}\right) - \frac{8}{3}\ln k_0(n)\right.$$

$$- \frac{7}{3}a_n - \frac{1}{9}\delta_{l0} - \frac{2}{m_N^2 - m_e^2}\delta_{l0}$$

$$\left. \times \left(m_N^2 \ln \frac{m_e}{m_r} - m_e^2 \ln \frac{m_N}{m_r}\right)\right],$$

(27.59)

where $a_{1s} = -3 - \ln 4$, $a_{2s} = -9/2$, and $a_{2p} = -13/3$. Present research is concerned with corrections of order $\alpha^6 m_e^2/m_N$.

Finally we discuss the two-loop Lamb shift. The leading contribution is [27.33–35]

$$\Delta E_n(\text{two-loop}) = \frac{m\alpha^2(Z\alpha)^4}{\pi^2 n^3} H_n(Z\alpha)$$

(27.60)

where for s-states

$$H_n = -\frac{4358}{1296} - \frac{10}{27}\pi^2 + \frac{3}{2}\pi^2 \ln 2 - \frac{9}{4}\zeta(3)$$

(27.61)

and for non-s states

$$H_n = \left[\frac{197}{72} + \frac{\pi^2}{6} - \pi^2 \ln 2 + \frac{3}{2}\zeta(3)\right]\frac{C_{lj}}{2(2l+1)}$$

(27.62)

where $C_{lj} = 2(j-l)/(j+1/2)$. The $Z\alpha$ corrections to this quantity have been carried out [27.36, 37], and considerable progress has been made in calculating terms of order $(Z\alpha)^2$ [27.38], though a complete calculation of the constant in that order has not yet been carried out.

27.7 Hyperfine Structure

27.7.1 Muonium Hyperfine Splitting

After the electron $g - 2$, the best test of QED is afforded by ground state muonium hyperfine splitting. This is dominated by the Fermi splitting, which is given by

$$E_{\text{F}} = \frac{16}{3}\alpha^2 \frac{m_r^3}{m_e^2 m_\mu} cR_\infty$$

(27.63)

where m_r is the reduced mass. The leading correction to the Fermi splitting involves the electron and muon anomalous magnetic moment, which act to increase the splitting by a factor $(1 + a_e)(1 + a_\mu)$. It is convenient to split the remaining corrections into non-recoil and recoil parts. The non-recoil terms are given by

$$\Delta \nu_{\text{non-recoil}} = (1 + a_\mu)\left\{1 + a_e + \frac{3}{2}(Z\alpha)^2\right.$$

$$+ \alpha(Z\alpha)\left(\ln 2 - \frac{5}{2}\right)$$

$$- \frac{8\alpha(Z\alpha)^2}{3\pi}\ln(Z\alpha)$$

$$\times \left[\ln(Z\alpha) - \ln 4 + \frac{281}{480}\right]$$

$$+ \frac{\alpha(Z\alpha)^2}{\pi}[14.88 (0.29)]$$

$$\left. + \frac{\alpha^2(Z\alpha)}{\pi}D_1\right\} E_{\text{F}}.$$

(27.64)

A recent development has been the complete evaluation of D_1, which is a binding correction to the two-loop $g-2$ contribution, by *Kinoshita* and *Nio* [27.39], who found $D_1 = 0.82(4)$. Note also the constant 14.88 has changed from the previous value of 15.38 because of a new calculation of the vacuum polarization component, as discussed further in Mohr's chapter. Subtracting $\Delta\nu_{\text{non-recoil}}$ from experiment leaves 795 kHz to be accounted for by recoil. The present state of recoil corrections is given by

$$\Delta\nu_{\text{recoil}} = \left\{ -\frac{3Z\alpha}{\pi} \frac{m_{\text{e}} m_\mu}{m_\mu^2 - m_{\text{e}}^2} \ln\frac{m_\mu}{m_{\text{e}}} + \frac{(Z\alpha)^2 m_{\text{r}}^2}{m_{\text{e}} m_\mu} \right.$$
$$\times \left[-2\ln(Z\alpha) - 8\ln 2 + \frac{65}{18} \right]$$
$$+ \frac{\alpha(Z\alpha)}{\pi^2} \frac{m_{\text{e}}}{m_\mu} \left[-2\ln^2\frac{m_\mu}{m_{\text{e}}} + \frac{13}{12}\ln\frac{m_\mu}{m_{\text{e}}} \right.$$
$$+ \frac{21}{2}\zeta(3) + \frac{\pi^2}{6} + \frac{35}{9} + 2.15(14)$$
$$\left.\left. + \frac{\alpha}{\pi}\left(-\frac{4}{3}\ln^3\frac{m_\mu}{m_{\text{e}}} + \frac{4}{3}\ln^2\frac{m_\mu}{m_{\text{e}}} \right) \right] \right\} E_{\text{F}} .$$

(27.65)

The full power of modern forms of the Bethe–Salpeter equation was needed for the evaluation of the second term [27.40]. While these terms account for just the needed 795 kHz mentioned above, the relatively large uncertainty in the muon mass leads to an uncertainty in the Fermi splitting of 1.3 kHz, and further progress in muonium hyperfine splitting will need this uncertainty to be reduced.

27.7.2 Hydrogen Hyperfine Splitting

The situation in hydrogen hyperfine splitting is quite different from the muonium case because of the structure of the proton. The recoil corrections in (27.65) that involve $\ln m_\mu/m_{\text{e}}$ involve the offshell muon propagator. Because the muon is a pointlike particle, there is no uncertainty in the calculation. However, when it is replaced by a proton, two strong-interaction problems arise that limit the theoretical accuracy that can be attained. The first arises from the fact that the charge distribution of the proton modifies the hyperfine splitting. The fractional correction can be expressed in terms of the electric and magnetic form factors of the proton as follows:

$$\delta_p(\text{Zemach}) = \frac{2\alpha m_{\text{e}}}{\pi^2} \int \frac{\text{d}^3 p}{p^4}$$
$$\times \left(\frac{G_{\text{E}}(-p^2) G_{\text{M}}(-p^2)}{1 + \kappa} - 1 \right) ,$$

(27.66)

where κ is the anomalous magnetic moment of the proton. It contributes -38.72 ppm, with an error of 0.5 ppm coming from the uncertainty in the form factors. The second correction, δ_{recoil}, replaces the first term in $\Delta\nu_{\text{recoil}}$ discussed in muonium hfs. The logarithm of the ratio of the muon and electron masses in that expression arises from high internal momenta. In the case of hydrogen hfs, this is sensitive to details of the proton structure. The most recent evaluation of this quantity [27.41] gives a 5.68 ppm effect, which is smaller than the Zemach correction only because of cancellation of individual terms of comparable size. When these corrections are added to the the other QED corrections, theory agrees with experiment at under the 1 ppm level, with hadronic uncertainties of about 0.5 ppm. This limits the size of hadronic effects arising from the polarizability of the proton, which is known to be bounded in magnitude by 4 ppm from inelastic electron scattering data [27.42]. As with the case of the Lamb shift in hydrogen, further progress will require better understanding from either an experimental or theoretical approach of properties of the proton.

27.8 Orthopositronium Decay Rate

The decay rate of orthopositronium has been measured with increasing accuracy over the years, and has reached the level where corrections of order α^2 to the lowest order decay rate need to be considered. The most recent experiment [27.43] has determined

$$\Gamma_{\text{experiment}} = 7.0404(10)(8)\,\mu\text{s}^{-1} .$$

(27.67)

The lowest order rate is

$$\Gamma_0 = 2\frac{\pi^2 - 9}{9\pi} m\alpha^6 = 7.211\,1670(1)\,\mu\text{s}^{-1} ,$$

(27.68)

so that radiative corrections must be quite large, about 2.4%, to account for the difference. These radiative

corrections are conventionally written as

$$\Gamma_{\text{theory}} = \left[1 + A\frac{\alpha}{\pi} + \frac{\alpha^2}{3}\ln\alpha + B\left(\frac{\alpha}{\pi}\right)^2 - \frac{3\alpha^3}{2\pi}\ln^2\alpha \right.$$
$$\left. + C\frac{\alpha^3}{\pi}\ln\alpha + D\left(\frac{\alpha}{\pi}\right)^3 + \dots \right]\Gamma_0 .$$

$$(27.69)$$

The constant A was first correctly calculated in [27.44]. Analytic and numeric improvements to this work [27.45] have led to the present value of

$$A = -10.286\,606 \pm 0.000\,010 , \qquad (27.70)$$

which accounts for all but 0.1% of the difference between theory and experiment. The logarithmic term of order $\alpha^2\Gamma_0$ was determined by *Caswell* and *Lepage* [27.46] and the leading logarithmic term of order α^3

by *Karshenboim* [27.47, 48]. The coefficient of the non-leading logarithmic term in order α^3, C, has recently been determined, but is numerically insignificant. For quite some time a discrepancy appeared to be present between theory and experiment, because a set of experiments in both powders and vacuum appeared to require a very large coefficient B. However, when this constant was finally calculated [27.49], it was found to be

$$B = 45.06(26) , \qquad (27.71)$$

which is too small to explain the discrepancy. However, another experiment [27.50] was consistent with theory, and further work at Michigan led to the above result, which is in complete agreement with theory: there is at present no discrepancy in the decay rate of orthopositronium. We note also progress in the theory of the decay rate of parapositronium [27.51, 52], which is also consistent with experiment.

27.9 Precision Tests of QED in Neutral Helium

The Bethe–Salpeter equation mentioned above was developed in terms of an expansion of free electron and nuclear propagators. However, if these propagators are replaced with two electron propagators in an external Coulomb field, the formalism, while now more complicated, allows a rigorous treatment of helium in the non-recoil limit. This was carried out by *Araki* [27.53] and *Sucher* [27.54], and allowed theoretical predictions up to order $m\alpha^5$. However, the actual calculations are far more difficult because of the more complicated propagators. Firstly, the Schrödinger equation cannot be solved analytically, but rather numerically. However, the use of sophisticated Hylleras basis sets [27.55, 56], or the more recently introduced method of random exponents [27.57], leads to accuracies far beyond experimental precision. Secondly, the fine structure cannot be calculated analytically, but instead involves expectation values of operators that are somewhat singular: again the high-quality basis sets just mentioned allow the precision evaluation of this quantity [27.58, 59]. A third difficulty is the evaluation of the Lamb shift. In helium the analog of the Bethe logarithm discussed in connection with hydrogen is much more difficult to evaluate. However, significant progress has been made in recent years, with one approach using *Schwartz*'s [27.60] idea of using an integral representation of the numerator of the Bethe logarithm [27.61, 62]. An even more accurate and com-

putationally simpler approach has been developed by *Drake* and *Goldman* [27.63].

Most of the leading QED corrections in helium can be expressed in terms of expectation values of various operators $\langle O \rangle$, where

$$\langle O \rangle \equiv \int d^3 r_1 \, d^3 r_2 \phi_0^*(r_1, r_2) O(r_1, r_2) \phi_0(r_1, r_2) .$$

$$(27.72)$$

Explicitly, one has

$$H^{(4)} = \frac{\alpha}{\pi}\langle H_{\text{so}} \rangle + \frac{\alpha}{2\pi}\langle H_{\text{soo}} \rangle + \frac{\alpha}{\pi}\langle H_{\text{ss}} \rangle$$
$$+ \left(\frac{89}{15} + \frac{14}{3}\ln\alpha - \frac{20}{3}s_1 \cdot s_2 \right)\frac{\alpha^2}{m^2}\langle \delta(r_{12}) \rangle$$
$$+ \left(\frac{76}{45} - \frac{8}{3}\ln 2\alpha^2 \right)\frac{\alpha^2}{m^2}$$
$$\times [\langle Z\delta(r_1) + Z\delta(r_2) \rangle]$$
$$- \frac{14}{3}\frac{\alpha^2}{m^2}Q - \frac{2\alpha}{3\pi m^2}M .$$

$$(27.73)$$

Here

$$H_{\text{so}} = \frac{\alpha}{4m^2}\left\{ \frac{Z}{r_1^3}\sigma_1 \cdot L_1 + \frac{Z}{r_2^3}\sigma_2 \cdot L_2 \right.$$
$$\left. - \frac{1}{r_{12}^3}[\sigma_1 \cdot (r_{12} \times p_1)\sigma_2 \cdot (r_{12} \times p_2)] \right\} ,$$

$$(27.74)$$

$$H_{\mathrm{soo}} = \frac{\alpha}{2m^2}\left[\boldsymbol{\sigma}_1 \cdot \left(\frac{\boldsymbol{r}_{12}}{r_{12}^3}\times\boldsymbol{p}_2\right) + \boldsymbol{\sigma}_2 \cdot \left(\frac{\boldsymbol{r}_{12}}{r_{12}^3}\times\boldsymbol{p}_1\right)\right]$$

(27.75)

and

$$H_{\mathrm{ss}} = \frac{\alpha}{4m^2}\left\{\left[\frac{\boldsymbol{\sigma}_1 \cdot \boldsymbol{\sigma}_2 - 3\boldsymbol{\sigma}_1\cdot\hat{r}_{12}\boldsymbol{\sigma}_2\cdot\hat{r}_{12}}{r_{12}^3}\right]\right.$$
$$\left. - \frac{8\pi}{3}\boldsymbol{\sigma}_1\cdot\boldsymbol{\sigma}_2\delta^3(\boldsymbol{r}_{12})\right\}.$$

(27.76)

In the above, units in which $\hbar = c = 1$ are used. Then p and $1/r$ are of order $m\alpha$, and $H^{(4)}$ is of order $m\alpha^5$. The quantity Q is defined by

$$Q = \frac{1}{4\pi}\lim_{a\to 0}\left\langle\frac{1}{r_{12}^3(a)} + 4\pi\delta(\boldsymbol{r}_{12})[\gamma + \ln(a)]\right\rangle,$$

(27.77)

where $r_{12}(a)$ vanishes when $r_{12} < a$ and M is given by

$$M = \sum_n \left(E_n^0 - E^0\right)|\boldsymbol{P}_n|^2 \ln\frac{\left(E_n^0 - E^0\right)}{m\alpha^2}$$

(27.78)

where

$$\boldsymbol{P}_n = \int \mathrm{d}^3 r_1\,\mathrm{d}^3 r_2 \phi_n^*(\boldsymbol{r}_1,\boldsymbol{r}_2)(\boldsymbol{p}_1+\boldsymbol{p}_2)\phi_0(\boldsymbol{r}_1,\boldsymbol{r}_2)\,.$$

(27.79)

M can be written in terms of an expectation value if we define the Bethe logarithm $\ln k_0$ through

$$M \equiv \sum_n \left(E_n^0 - E^0\right)|\boldsymbol{P}_n|^2 \ln\frac{k_0}{m\alpha^2}\,.$$

(27.80)

Calculations of the next order, that is, those of order $m\alpha^6$, were carried out for triplet P states by *Douglas* and *Kroll* [27.64] some time ago, but extension of the method to S states has only recently become possible through the use of NRQED techniques: we note in particular a calculation of the 2^3S_1 state by *Pachucki* [27.65] and of the ground state by *Korobov* and *Yelkhovsky* [27.66]. An outstanding problem in QED is the completion of the extension of the fine structure calculation to order $m\alpha^7$. This latter calculation should allow an extraction of the fine structure constant from helium competitive to that obtained from electron $g-2$ [27.67]. Work on this problem using both a Bethe–Salpeter formalism [27.68] and NRQED [27.69] is ongoing.

27.10 QED in Highly Charged One-Electron Ions

Because the Lamb shift scales as Z^4 and energy levels as Z^2, the relative importance of this effect increases as one goes out along an isoelectronic sequence. In addition, the approach used in the previous section, which relies on an expansion in powers of $Z\alpha$, becomes inappropriate, and requires methods that do not use such an expansion. Such methods were introduced by *Wichmann* and *Kroll* [27.70] for vacuum polarization. They were extended to the more difficult self-energy calculation by *Brown* and others [27.71], and the first correct calculations using the method were carried out by *Desiderio* and *Johnson* [27.72]. The basic idea is first to carry out the $\mathrm{d}^3 k$ integration in (27.53) analytically, leaving an integration over $\mathrm{d}^3 r$, $\mathrm{d}^3 r'$, and k_0 of a product of the electron and photon propagators in coordinate space. If one then makes a partial wave expansion of these propagators, the angle integrations can be carried out, and the self-energy becomes a sum over partial waves of an integral over two radial coordinates and the photon energy, which integral is carried out numerically. While simple in principle, this method is numerically awkward because the parts of the self-energy that are ultraviolet divergent are not well described in coordinate space. To solve this prob-

lem, the parts of the self-energy that have this sensitivity, which are associated with the part of the electron propagator in which the electron propagates freely, or with a single interaction, can be separated out. These subtractions allowed the first high-accuracy calculation of the self-energy in Coulomb potentials by *Mohr* [27.73–75]. Later *Blundell* and *Snyderman* [27.76] used such subtractions in a purely numeric approach that allowed the treatment of non-Coulomb potentials, which must be used for the many-electron ions discussed in the next section. While the most accurate calculations have been carried out for the case of the Coulomb potential, the finite size of the nucleus cannot be neglected, particularly at high Z. This issue has recently been studied by several groups [27.77, 78], and is now well understood. The experimental status of QED in one-electron ions is discussed by Mohr in this volume. An important recent development has been the calculation of the two-loop Lamb shift using exact electron propagators. While so far carried out only for the ground state in the ranges $Z > 40$ [27.79] it should be straightforward, though computationally intensive, to extend the calculations both to excited states and to lower values of Z.

27.11 QED in Highly Charged Many–Electron Ions

The previous applications of QED have been concentrated on simple systems, the most complex being helium. However, slight modifications of the S-matrix approach to QED described in Sect. 27.1 allow the treatment of ions with any number of electrons. In practice, this does not necessarily allow progress, since diagrams of arbitrarily high order contribute at the level of 1 a.u. in the many-body problem. However, when the nuclear Coulomb field dominates the Coulomb fields of the electrons, a small parameter is available, the quantity $1/Z$. Physically this simply reflects the fact the the energy of repulsion of any pair of electrons is of the order of Z a.u., while the energy of attraction to the nucleus scales as Z^2 a.u.. This $1/Z$ expansion has been studied empirically in the context of many-body perturbation theory, and it can be seen that while diagrams involving two-photon interactions are important, those involving three photons are highly suppressed. Thus the possibility exists of putting the QED of highly charged ions on the same footing as, for example, the electron $g - 2$, in the sense that evaluation of a limited number of Feynman diagrams will allow precision tests of QED. However, while in principle one can start with the original Furry representation, in practice, particularly when larger numbers of electrons are present, it is better to start with non-Coulomb potentials that build in a major part of the electron screening present in the ion. For example, if one considers sodiumlike platinum ($Z = 78$), the valence electron should see a nuclear charge of around 68 because of the ten 'core' electrons. One potential that builds in this property is the so-called 'core-Hartree' potential [27.80], which is defined so that

$$V_{CH}(r) = V_{nuc}(r) + \sum_a (2j_a + 1)v_0(a, a; r) ,$$

(27.81)

where

$$v_0(a, a; r) \equiv \int_0^\infty dr' \frac{1}{r_>} \left[g_a^2(r') + f_a^2(r') \right]$$

(27.82)

with g_a and f_a the upper and lower radial components of the Dirac wavefunction for core state a. For sodium-like systems, a ranges over the 1s, 2s, $2p_{1/2}$, and $2p_{3/2}$ states. These states are solved for self consistently. The resulting potential gives results close to a full Dirac–Fock potential, but has the advantage of being local, which makes the connection with QED

transparent. Because as $r \to \infty$, $v_0(a, a; r) \to 1/r$, the long range behavior of this potential has the physically expected limit. It is very simple to modify the Furry representation to include this potential: one simply writes

$$H_0 = \int d^3r\psi^\dagger(r)[\alpha \cdot p + \beta m + V_{CH}(r)]\psi(r)$$

(27.83)

and

$$H_I = \int d^3r\psi^\dagger(r)[V_{nuc}(r) - V_{CH}(r)]\psi(r)$$
$$- e \int d^3r\psi^\dagger(r)\alpha \cdot A(r)\psi(r)$$
$$+ \frac{\alpha}{2} \int \frac{d^3r\,d^3r'}{|r - r'|}\psi^\dagger(r)\psi(r)\psi^\dagger(r')\psi(r') .$$

(27.84)

The only difference with the QED discussed in the previous section is the first term of H_I, which acts in a manner similar to the self-mass counterterm, though it is of course finite. However, when more than one electron is present, new types of Feynman diagram are encountered: a representative set of them is given in Fig. 27.3. There is an interesting connection between these diagrams and the many-body perturbation theory (MBPT) method of solving the many-electron Schrödinger equation. In this latter method the N-electron Hamiltonian is written $H = H_0 + V_C$, where

$$H_0 = \sum_{i=1}^{i=N} \left[\alpha_i \cdot p_i + \beta_i m - \frac{Z\alpha}{r_i} + U(r_i) \right]$$

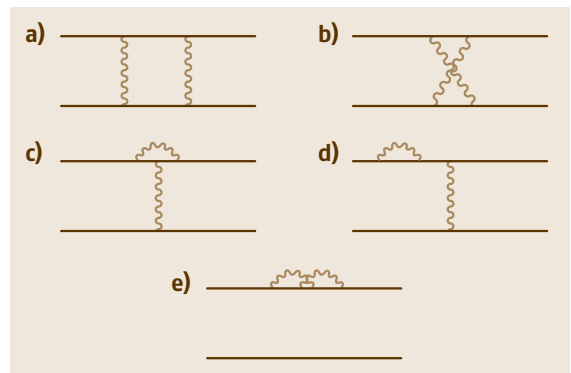
(27.85)


Fig. 27.3a–e Two-photon diagrams contributing to energy levels of highly charged ions

and

$$V_C = \frac{\alpha}{2} \sum_{ij} \frac{1}{|\boldsymbol{r}_i - \boldsymbol{r}_j|} - \sum_{i=1}^{i=N} U(r_i) \ . \tag{27.86}$$

Care must be taken when working with the relativistic version of the N-electron Schrödinger equation because of negative energy states, a point that has been emphasized by *Sucher* [27.81]. This problem shows up in MBPT in second order, where the associated energy shift for the ground state of an alkali atom with valence electron v in the case when U is the Hartree–Fock potential is

$$E^{(2)} = -\sum_{amn} \frac{g_{vamn}(g_{mnva} - g_{mnav})}{\epsilon_m + \epsilon_n - \epsilon_a - \epsilon_v}$$
$$+ \sum_{abm} \frac{g_{abmv}(g_{mvab} - g_{mvba})}{\epsilon_m + \epsilon_v - \epsilon_a - \epsilon_b} \ . \tag{27.87}$$

Here a and b range over the occupied core states, and m and n over excited states including in principle negative energy states. However, if they are included, the energy denominator in the first term of the above expression can vanish when m is a positive energy state and n negative energy, and vice versa. This problem can be avoided by restricting sums over excited states to positive energy states, but this procedure must be justified in the framework of QED. This can indeed be done [27.82], with the result that the use of MBPT with the positive energy restriction is justified, but negative energy state effects enter in a well-defined way, giving effects on the order of the Lamb shift.

To illustrate the present status of QED in highly charged many-electron ions, we consider the spectrum of sodium-like platinum. The transition energy between $3p_{3/2}$ and $3s_{1/2}$ has been measured [27.83] to be 653.44(7) eV. When MBPT is applied to this transition through second order, the answer depends slightly on the starting potential. The Hartree–Fock potential gives 659.56 eV, while the core-Hartree potential described above gives 659.59 eV. A modification of the core-Hartree potential in which the factor $2j_a + 1$ is reduced by 1 for the last core state give 659.57 eV. This spread of 0.03 eV gives a measure of the convergence of MBPT: it should be compared with a spread of 12 eV in lowest order and 0.4 eV in first order. Thus the difference with experiment of 6.1 eV that is to be explained by QED is reliable at the 0.1 eV level.

The QED calculations in highly charged ions are not as advanced as in the QED tests in simple neutral atoms. As discussed above, only in the last decade

have calculations of one-loop radiative corrections in non-Coulomb potentials begun to be carried out. In the case of the core-Hartree potential they give exactly the 6.1 eV required to explain the difference between MBPT and experiment. This is actually somewhat unfortunate, since the set of two-photon Feynman diagrams comprising the two-loop Lamb shift mentioned above, some of which are shown in Fig. 27.3, should be detectable. Specifically, scaling arguments indicate that they should contribute at the few tenths of an eV level, and it is likely the good agreement with experiment found above involves fortuitous calculations. The graph of Fig. 27.3a plays a particularly interesting role, since it can be shown to 'contain' $E^{(2)}$. Specifically, when both photons are Coulomb photons and the electron propagators are written in terms of a spectral representation, the fourth component of the internal momentum integration can be carried out with contour methods. When both propagators involve positive energy states, $E^{(2)}$ from MBPT is precisely reproduced, including of course the previously introduced ad hoc rule of having only positive energy states in intermediate sums. When one is positive and the other negative the undefined term discussed above could arise, but since in this case both poles are on the same side of the axis, the contribution vanishes. However, when both are negative, a contribution outside of MBPT, part of the QED effect, arises. It is of order $Z^3\alpha^3$ a.u., in other words $1/Z$ of the leading Lamb shift. For sodium-like platinum, this should enter at the 0.1 eV level. For this reason, to be sensitive to corrections beyond the one-loop Lamb shift, ever more precise experiments along with more sophisticated MBPT calculations are required.

In recent years considerable progress has been made in the evaluation of 'two-photon' physics in lithium-like ions. This physics involves not only the two-loop Lamb shift mentioned in the previous section, but also vertex corrections to one-photon exchange and a full QED treatment of the correlation effects discussed in the previous paragraph. These effects have been included in recent calculations [27.80, 84], and the extension to sodiumlike and other alkalilike ions should be straightforward. This latter development would be desirable, as new data on sodiumlike and copperlike uranium of extremely high accuracy has become available.

As this progress is made, the interesting prospect arises of extending the high-accuracy QED tests in simple neutral systems discussed in this review to more complicated many-electron ions, and eventually to all the neutral atoms in the periodic table.

28. Tests of Fundamental Physics

This chapter describes comparisons of precise measurements and theoretical predictions that provide tests of our knowledge of fundamental physics. The focus is on several quantitative tests of quantum electrodynamics (QED).

The basic formulation of the theory of QED and calculational methods are discussed in Chapt. 27. Here, only the end results of calculations are collected, numerically evaluated, and compared with the corresponding experiments. (All quoted uncertainties are meant to be approximately at the one standard deviation level.)

It should be remarked that QED theory and the fundamental constants that are employed in evaluating the theoretical expressions are intimately linked. Fundamental constants are discussed in Chapt. 1. Values of the constants needed for comparison of theory and experiment are generally determined by other comparisons of theory and experiment, so that only the consistency of a set of tests is checked. However, the fact that this overall consistency is maintained at a high level of precision and over a broad range of phenomena provides confidence that QED is sound despite mathematical shortcomings in its formulation.

Recent reviews that cover topics in this chapter are given in [28.1, 2]. Much of the content in this chapter is reprinted from [28.3]. Values of the fundamental constants used in calculations in this chapter are the 2002 CODATA recommended values [28.3].

28.1 Electron g−Factor Anomaly

The magnetic moment of any of the three charged leptons (e, μ, τ) is written as

$$\boldsymbol{\mu} = g\frac{e}{2m}\boldsymbol{s} \ , \tag{28.1}$$

where g is the g-factor of the particle, m is its mass, and $\boldsymbol{s}$ is its spin. In (28.1), e is the elementary charge and is positive. For the negatively charged leptons (e^-, μ^-, and τ^-) g is negative, and for the corresponding antiparticles (e^+, μ^+, and τ^+) g is positive. CPT invariance implies that the masses and absolute values of the g-factors are the same for each particle–antiparticle pair.

These leptons have eigenvalues of spin projection $s_z = \pm\hbar/2$, and in the case of the electron and positron

it is conventional to write, based on (28.1),

$$\mu_{\mathrm{e}} = \frac{g_{\mathrm{e}}}{2}\mu_{\mathrm{B}} \ , \tag{28.2}$$

where $\mu_{\mathrm{B}} = e\hbar/(2m_{\mathrm{e}})$ is the Bohr magneton.

For nucleons or nuclei with spin $\boldsymbol{I}$, the magnetic moment can be written as

$$\boldsymbol{\mu} = g\frac{e}{2m_{\mathrm{p}}}\boldsymbol{I} \ , \tag{28.3}$$

or

$$\mu = g\mu_N i \,. \tag{28.4}$$

In (28.4), $\mu_N = e\hbar/(2m_p)$ is the nuclear magneton, defined in analogy with the Bohr magneton, and i is the spin quantum number of the nucleus defined by $\mathbf{I}^2 = i(i+1)\hbar^2$ and $I_z = -i\hbar, \ldots, (i-1)\hbar, i\hbar$, where I_z is the spin projection. However, in some publications moments of nucleons are expressed in terms of the Bohr magneton with a corresponding change in the definition of the g-factor.

One of the most precise tests of QED is the comparison of theory and experiment for the electron magnetic moment anomaly; the current status of this comparison is given in this section.

The electron magnetic moment is proportional to

$$g_e = -2(1 + a_e) \,, \tag{28.5}$$

where the anomaly a_e characterizes the deviation of the g-factor from the Dirac value of $g_e(\mathrm{Dirac}) = -2$. Measurement of the anomaly by the University of Washington group has yielded values for the electron and positron given respectively by [28.4]

$$a_{e^-}(\exp) = 1\,159\,652\,188.4\,(4.3) \times 10^{-12} \,, \tag{28.6}$$

$$a_{e^+}(\exp) = 1\,159\,652\,187.9\,(4.3) \times 10^{-12} \,, \tag{28.7}$$

which yield the mean value

$$a_e(\exp) = 1\,159\,652\,188.3\,(4.2) \times 10^{-12} \,, \tag{28.8}$$

based on the analysis described in [28.1]. This analysis assumes that CPT invariance holds for the electron–positron system.

The same experiment has provided a precision comparison of the electron and positron g-factors

$$\left| \frac{g_{e^-}}{g_{e^+}} \right| = 1 + (0.5 \pm 2.1) \times 10^{-12} \,, \tag{28.9}$$

which provides a test of CPT invariance of the electron–positron system.

The theoretical expression for a_e may be written as

$$a_e(\mathrm{th}) = a_e(\mathrm{QED}) + a_e(\mathrm{weak}) + a_e(\mathrm{had}) \,, \tag{28.10}$$

where the terms denoted by QED, weak, and had account for the purely quantum electrodynamic, predominantly electroweak, and predominantly hadronic (that is, strong interaction) contributions to a_e, respectively. The QED contribution may be written as [28.5]

$$a_e(\mathrm{QED}) = A_1 + A_2(m_e/m_\mu) + A_2(m_e/m_\tau)$$
$$+ A_3(m_e/m_\mu, m_e/m_\tau) \,. \tag{28.11}$$

The term A_1 is mass independent and the other terms are functions of the indicated mass ratios. For these terms the lepton in the numerator of the mass ratio is the particle under consideration, while the lepton in the denominator of the ratio is the virtual particle that is the source of the vacuum polarization that gives rise to the term.

Each of the four terms on the right-hand side of (28.11) is expressed as a power series in the fine-structure constant α:

$$A_i = A_i^{(2)} \left(\frac{\alpha}{\pi}\right) + A_i^{(4)} \left(\frac{\alpha}{\pi}\right)^2 + A_i^{(6)} \left(\frac{\alpha}{\pi}\right)^3$$
$$+ A_i^{(8)} \left(\frac{\alpha}{\pi}\right)^4 + \cdots \,. \tag{28.12}$$

The fine-structure constant α is proportional to the square of the elementary charge e, and the order of a term containing $(\alpha/\pi)^n$ is $2n$ and its coefficient is called the $2n$th-order coefficient.

The second-order coefficient is known exactly, and the fourth- and sixth-order coefficients are known analytically in terms of readily evaluated functions:

$$A_1^{(2)} = \frac{1}{2} \tag{28.13}$$

$$A_1^{(4)} = -0.328\,478\,965\,579\ldots \tag{28.14}$$

$$A_1^{(6)} = 1.181\,241\,456\ldots \,. \tag{28.15}$$

A total of 891 Feynman diagrams give rise to the eighth-order coefficient $A_1^{(8)}$, and only a few of these are known analytically. However, in an effort begun in the 1970s, *Kinoshita* and collaborators have calculated $A_1^{(8)}$ numerically (for a summary of some of this work see [28.6, 7]). The value of $A_1^{(8)}$ used in the 1998 CODATA adjustment of the fundamental constants was $-1.5098\,(384)$ [28.1]. Recently an error in the program employed in the evaluation of a gauge-invariant 18 diagram subset of the 891 diagrams was discovered in the course of carrying out an independent calculation to check this value [28.8]. The corrected program together with improved precision in the numerical integration for all diagrams leads to the tentative value $A_1^{(8)} = -1.7366\,(60)$ [28.9], where the shift from the earlier value is predominately due to the correction of the error. As a result of this recent work, *Kinoshita* and *Nio* [28.8] report that the integrals from all 891 Feynman diagrams have now been verified by independent calculation and/or checked by analytic comparison with lower-order integrals. Nevertheless, because the precision of the numerical evaluation of some integrals is still being improved and a closer examination is being made

of the uncertainty of the numerical evaluation of other integrals, we retain the uncertainty estimate of the earlier reported value of $A_1^{(8)}$. This gives

$$A_1^{(8)} = -1.7366\,(384)\,. \tag{28.16}$$

The 0.0384 standard uncertainty of $A_1^{(8)}$ contributes a standard uncertainty to a_e(th) of $0.96 \times 10^{-9} a_e$, which may be compared to the $3.7 \times 10^{-9} a_e$ uncertainty of the experimental value (28.8). We also note that work is in progress on analytic calculations of eighth-order integrals. See, for example, *Laporta* [28.10] and *Mastrolia* and *Remiddi* [28.11].

Little is known about the tenth-order coefficient $A_1^{(10)}$ and higher-order coefficients. To evaluate the contribution to the uncertainty of a_e(th) due to lack of knowledge of $A_1^{(10)}$, we follow [28.1] to obtain $A_1^{(10)} = 0.0(3.8)$. Because the 3.8 standard uncertainty of $A_1^{(10)}$ contributes a standard uncertainty component to a_e(th) of only $0.22 \times 10^{-9} a_e$, the uncertainty contributions to a_e(th) from all other higher-order coefficients are assumed to be negligible.

The mass-dependent coefficients of possible interest and corresponding contributions to a_e(th), based on the 2002 CODATA recommended values of the mass ratios [28.3], are

$$A_2^{(4)}(m_e/m_\mu) = 5.197\,386\,70\,(27) \times 10^{-7}$$
$$\rightarrow 2.418 \times 10^{-9} a_e\,, \tag{28.17}$$

$$A_2^{(4)}(m_e/m_\tau) = 1.837\,63\,(60) \times 10^{-9}$$
$$\rightarrow 0.009 \times 10^{-9} a_e\,, \tag{28.18}$$

$$A_2^{(6)}(m_e/m_\mu) = -7.373\,941\,58\,(28) \times 10^{-6}$$
$$\rightarrow -0.080 \times 10^{-9} a_e\,, \tag{28.19}$$

$$A_2^{(6)}(m_e/m_\tau) = -6.5819\,(19) \times 10^{-8}$$
$$\rightarrow -0.001 \times 10^{-9} a_e\,, \tag{28.20}$$

where the standard uncertainties of the coefficients are due to the uncertainties of the mass ratios. However, the contributions are so small that the uncertainties of the mass ratios are negligible. It may also be noted that the contributions from $A_3^{(6)}(m_e/m_\mu, m_e/m_\tau)$ and all higher-order mass-dependent terms are negligible as well.

For the electroweak contribution we have

$$a_e(\text{weak}) = 0.0297\,(5) \times 10^{-12}$$
$$= 0.0256\,(5) \times 10^{-9} a_e\,, \tag{28.21}$$

as in [28.1].

The hadronic contribution is

$$a_e(\text{had}) = 1.671\,(19) \times 10^{-12}$$
$$= 1.441\,(17) \times 10^{-9} a_e\,, \tag{28.22}$$

and is the sum of the following three contributions: $a_e^{(4)}(\text{had}) = 1.875\,(18) \times 10^{-12}$ obtained by *Davier* and *Höcker* [28.12]; $a_e^{(6a)}(\text{had}) = -0.225\,(5) \times 10^{-12}$ given by *Krause* [28.13]; and $a_e^{(\gamma\gamma)}(\text{had}) = 0.0210\,(36) \times 10^{-12}$ obtained by multiplying the corresponding result for the muon given in [28.3] by the factor $(m_e/m_\mu)^2$, since $a_e^{(\gamma\gamma)}(\text{had})$ is assumed to vary approximately as m_μ^2. The contribution a_e(had), although larger than a_e(weak), is not yet of major significance.

Since the dependence on α of any contribution other than a_e(QED) is negligible, we obtain a convenient form for the function by combining terms in a_e(QED) that have like powers of α/π. This leads to the following summary of the above results:

$$a_e(\text{th}) = a_e(\text{QED}) + a_e(\text{weak}) + a_e(\text{had})\,, \tag{28.23}$$

where

$$a_e(\text{QED}) = C_e^{(2)}\left(\frac{\alpha}{\pi}\right) + C_e^{(4)}\left(\frac{\alpha}{\pi}\right)^2 + C_e^{(6)}\left(\frac{\alpha}{\pi}\right)^3$$
$$+ C_e^{(8)}\left(\frac{\alpha}{\pi}\right)^4 + C_e^{(10)}\left(\frac{\alpha}{\pi}\right)^5 + \cdots\,, \tag{28.24}$$

with

$$C_e^{(2)} = 0.5\,,$$
$$C_e^{(4)} = -0.328\,478\,444\,00\,,$$
$$C_e^{(6)} = 1.181\,234\,017\,,$$
$$C_e^{(8)} = -1.7366\,(384)\,,$$
$$C_e^{(10)} = 0.0\,(3.8)\,, \tag{28.25}$$

and where

$$a_e(\text{weak}) = 0.030\,(1) \times 10^{-12} \tag{28.26}$$

and

$$a_e(\text{had}) = 1.671\,(19) \times 10^{-12}\,. \tag{28.27}$$

The standard uncertainty of a_e(th) from the uncertainties of the terms listed above, other than that due to α, is

$$u[a_e(\text{th})] = 1.15 \times 10^{-12} = 0.99 \times 10^{-9} a_e\,, \tag{28.28}$$

and is dominated by the uncertainty of the coefficient $C_e^{(8)}$.

We define an additive correction δ_e to a_e(th) to account for the lack of exact knowledge of a_e(th), and

hence the complete theoretical expression for the electron anomaly is

$$a_e(\alpha, \delta_e) = a_e(\text{th}) + \delta_e \,, \tag{28.29}$$

where all the uncertainty is associated with δ_e. The theoretical estimate of δ_e is zero and its standard uncertainty is $u[a_e(\text{th})]$:

$$\delta_e = 0.0\,(1.1) \times 10^{-12} \,. \tag{28.30}$$

Equating the theoretical expression with $a_e(\text{exp})$ given in (28.8) yields

$$\alpha^{-1}(a_e) = 137.035\,998\,80\,(52) \,. \tag{28.31}$$

The uncertainty of $a_e(\text{th})$ is significantly smaller than the uncertainty of $a_e(\text{exp})$, and thus the uncertainty of this inferred value of α is determined mainly by the uncertainty of $a_e(\text{exp})$. This result has the smallest uncertainty of any value of alpha currently available.

This result compares favorably with the value

$$\alpha^{-1}(\text{recoil}) = 137.036\,0001\,(11) \tag{28.32}$$

derived from the atomic recoil frequency shift of photons absorbed and emitted by cesium, as reviewed in [28.3].

28.2 Electron g-Factor in $^{12}C^{5+}$ and $^{16}O^{7+}$

For a ground-state hydrogenic ion $^A X^{(Z-1)+}$ with mass number A, atomic number (proton number) Z, nuclear spin quantum number $i = 0$, and g-factor $g_{e^-}(^A X^{(Z-1)+})$ in an applied magnetic flux density B, the ratio of the electron's spin-flip (often called precession) frequency $f_s = |g_{e^-}(^A X^{(Z-1)+})|(e\hbar/2m_e)B/h$ to the cyclotron frequency of the ion $f_c = (Z-1)eB/2\pi m(^A X^{(Z-1)+})$ in the same magnetic flux density is

$$\frac{f_s(^A X^{(Z-1)+})}{f_c(^A X^{(Z-1)+})} = -\frac{g_{e^-}(^A X^{(Z-1)+})}{2(Z-1)} \frac{A_r(^A X^{(Z-1)+})}{A_r(e)} \,, \tag{28.33}$$

where $A_r(X)$ is the relative atomic mass of particle X. If the frequency ratio f_s/f_c is determined experimentally with high accuracy, and $A_r(^A X^{(Z-1)+})$ of the ion is also accurately known, then this expression can be used to determine an accurate value of $A_r(e)$, assuming the bound-state electron g-factor can be calculated from QED theory with sufficient accuracy; or the g-factor can be determined if $A_r(e)$ is accurately known from another experiment. In fact, a broad program involving workers from a number of European laboratories has been underway since about the mid-1990s to measure the frequency ratio and calculate the g-factor for different ions, most notably (to date) $^{12}C^{5+}$ and $^{16}O^{7+}$. The measurements themselves are being performed at the GSI (Gesellschaft für Schwerionenforschung, Darmstadt, Germany) by GSI and University of Mainz researchers. Values reported are [28.14–16]

$$\frac{f_s(^{12}C^{5+})}{f_c(^{12}C^{5+})} = 4376.210\,4989\,(23) \tag{28.34}$$

and [28.16–18]

$$\frac{f_s(^{16}O^{7+})}{f_c(^{16}O^{7+})} = 4164.376\,1836\,(31) \,. \tag{28.35}$$

It should be noted that these two frequency ratios are correlated. Based on the detailed uncertainty budget of the two results [28.16], we find

$$r\left(\frac{f_s(^{12}C^{5+})}{f_c(^{12}C^{5+})}, \frac{f_s(^{16}O^{7+})}{f_c(^{16}O^{7+})}\right) = 0.035 \tag{28.36}$$

for the correlation coefficient.

We next consider the g-factor in (28.33) for an electron in the 1S state of hydrogen-like carbon 12 (atomic number $Z = 6$, nuclear spin quantum number $i = 0$) or in the 1S state of hydrogen-like oxygen 16 (atomic number $Z = 8$, nuclear spin quantum number $i = 0$) within the framework of relativistic bound-state theory. The measured quantity is the transition frequency between the two Zeeman levels of the atom in an externally applied magnetic field.

The energy of a free electron with spin projection s_z in a magnetic flux density B in the z direction is

$$E_{s_z} = -g_{e^-}\frac{e}{2m_e}s_z B \,, \tag{28.37}$$

and hence the spin-flip energy difference is

$$\Delta E = -g_{e^-}\mu_B B \,. \tag{28.38}$$

(In keeping with the definition of the g-factor in Sect. 28.1 the quantity g_{e^-} is negative.) The analogous expressions for the ions considered here are

$$\Delta E_b(X) = -g_{e^-}(X)\mu_B B \,, \tag{28.39}$$

which defines the bound-state electron g-factor in the case where there is no nuclear spin, and where X is either $^{12}C^{5+}$ or $^{16}O^{7+}$.

The main theoretical contributions to $g_{e^-}(X)$ can be categorized as follows:

- Dirac (relativistic) value g_D;
- radiative corrections Δg_{rad};
- recoil corrections Δg_{rec};
- nuclear size corrections Δg_{ns}.

Thus we write

$$g_{e^-}(X) = g_D + \Delta g_{rad} + \Delta g_{rec} + \Delta g_{ns} + \cdots ,$$
(28.40)

where terms accounting for other effects are assumed to be negligible at the current level of uncertainty of the relevant experiments (relative standard uncertainty $u_r \approx 6 \times 10^{-10}$). These theoretical contributions are discussed in the following paragraphs; numerical results are summarized in Tables 28.1, 28.2.

Breit [28.19] obtained the exact value

$$g_D = -\frac{2}{3}\left[1 + 2\sqrt{1-(Z\alpha)^2}\right]$$
$$= -2\left[1 - \frac{1}{3}(Z\alpha)^2 - \frac{1}{12}(Z\alpha)^4\right.$$
$$\left. - \frac{1}{24}(Z\alpha)^6 + \cdots\right]$$
(28.41)

from the Dirac equation for an electron in the field of a fixed point charge of magnitude Ze, where the only uncertainty is that due to the uncertainty in α.

The radiative corrections may be written as

$$\Delta g_{rad} = -2\left[C_e^{(2)}(Z\alpha)\left(\frac{\alpha}{\pi}\right)\right.$$
$$\left. + C_e^{(4)}(Z\alpha)\left(\frac{\alpha}{\pi}\right)^2 + \cdots\right],$$
(28.42)

where the coefficients $C_e^{(2n)}(Z\alpha)$, corresponding to n virtual photons, are slowly varying functions of $Z\alpha$. These coefficients are defined in direct analogy with the corresponding coefficients for the free electron $C_e^{(2n)}$ given in Sect. 28.1 so that

$$\lim_{Z\alpha \to 0} C_e^{(2n)}(Z\alpha) = C_e^{(2n)} .$$
(28.43)

The coefficient $C_e^{(2)}(Z\alpha)$ has been calculated to second order in $Z\alpha$ by *Grotch* [28.20] who finds

$$C_e^{(2)}(Z\alpha) = C_e^{(2)} + \frac{1}{12}(Z\alpha)^2 + \cdots$$
$$= \frac{1}{2} + \frac{1}{12}(Z\alpha)^2 + \cdots .$$
(28.44)

This result has been confirmed by *Faustov* and *Close* [28.21] and *Osborn* [28.22], as well as by others.

The terms listed in (28.44) do not provide a value of $C_e^{(2)}(Z\alpha)$ which is sufficiently accurate at the level of uncertainty of the current experimental results. However, *Yerokhin* [28.23, 24] have recently calculated numerically the self-energy contribution $C_{e,SE}^{(2)}(Z\alpha)$ to the coefficient to all orders in $Z\alpha$ over a wide range of Z. These results are in general agreement with, but are more accurate than, the earlier results of *Beier* et al. [28.25] and *Beier* [28.26]. Other calculations of the self energy have been carried out by *Persson* [28.27]; *Blundell* et al. [28.28]; and *Goidenko* [28.29]. For $Z = 6$ and $Z = 8$ the calculation of *Yerokhin* et al. [28.23] gives

$$C_{e,SE}^{(2)}(6\alpha) = 0.500\,183\,609\,(19)$$
$$C_{e,SE}^{(2)}(8\alpha) = 0.500\,349\,291\,(19) ,$$
(28.45)

where we have converted their quoted result to conform with our notation convention, taking into account the value of α employed in their calculation.

Table 28.1 Theoretical contributions and total for the g-factor of the electron in hydrogenic carbon 12 based on the 2002 recommended values of the constants

Contribution	Value	Source (Eq.)
Dirac g_D	$-1.998\,721\,354\,39\,(1)$	(28.41)
$\Delta g_{SE}^{(2)}$	$-0.002\,323\,672\,45\,(9)$	(28.45)
$\Delta g_{VP}^{(2)}$	$0.000\,000\,008\,51$	(28.49)
$\Delta g^{(4)}$	$0.000\,003\,545\,74\,(16)$	(28.53)
$\Delta g^{(6)}$	$-0.000\,000\,029\,62$	(28.54)
$\Delta g^{(8)}$	$0.000\,000\,000\,10$	(28.55)
Δg_{rec}	$-0.000\,000\,087\,64\,(1)$	(28.56, 28.58)
Δg_{ns}	$-0.000\,000\,000\,41$	(28.60)
$g_{e^-}(^{12}C^{5+})$	$-2.001\,041\,590\,16\,(18)$	(28.61)

Table 28.2 Theoretical contributions and total for the g-factor of the electron in hydrogenic oxygen 16 based on the 2002 recommended values of the constants

Contribution	Value	Source (Eq.)
Dirac g_D	$-1.997\,726\,003\,06\,(2)$	(28.41)
$\Delta g_{SE}^{(2)}$	$-0.002\,324\,442\,15\,(9)$	(28.45)
$\Delta g_{VP}^{(2)}$	$0.000\,000\,026\,38$	(28.49)
$\Delta g^{(4)}$	$0.000\,003\,546\,62\,(42)$	(28.53)
$\Delta g^{(6)}$	$-0.000\,000\,029\,62$	(28.54)
$\Delta g^{(8)}$	$0.000\,000\,000\,10$	(28.55)
Δg_{rec}	$-0.000\,000\,117\,02\,(1)$	(28.56, 28.58)
Δg_{ns}	$-0.000\,000\,001\,56\,(1)$	(28.60)
$g_{e^-}(^{16}O^{7+})$	$-2.000\,047\,020\,31\,(43)$	(28.61)

The lowest-order vacuum-polarization correction is conveniently considered as consisting of two parts. In one the vacuum polarization loop modifies the interaction between the bound electron and the Coulomb field of the nucleus, and in the other the loop modifies the interaction between the bound electron and the external magnetic field. The first part, sometimes called the "wave function" correction, has been calculated numerically by *Beier* et al. [28.25], with the result (in our notation)

$$C_{e,VPwf}^{(2)}(6\alpha) = -0.000\,001\,840\,3431\,(43)\,,$$
$$C_{e,VPwf}^{(2)}(8\alpha) = -0.000\,005\,712\,028\,(26)\,. \quad (28.46)$$

Each of these values is the sum of the Uehling potential contribution and the higher-order Wichmann–Kroll contribution, which were calculated separately.

The values in (28.46) are consistent with the result of an evaluation of the correction in powers of $Z\alpha$. Terms to order $(\alpha/\pi)(Z\alpha)^7$ have been calculated for the Uehling potential contribution [28.30–32]; and an estimate of the leading order $(\alpha/\pi)(Z\alpha)^6$ term of the Wichmann–Kroll contribution has been given by *Karshenboim* et al. [28.32] based on a prescription of *Karshenboim* [28.30]. To the level of uncertainty of interest here, the values from the power series are the same as the numerical values in (28.46). (Note that for the Wichmann–Kroll term, the agreement between the power-series results and the numerical results is improved by an order of magnitude if an additional term in the power series for the energy level [28.33] used in Karshenboim's prescription is included.)

For the second part of the lowest-order vacuum polarization correction, sometimes called the "potential" correction, *Beier* et al. [28.25] found that the Uehling potential contribution is zero. They also calculated the Wichmann–Kroll contribution numerically over a wide range of Z. Their value at low Z is very small and only an uncertainty estimate of 3×10^{-10} in g is given because of poor convergence of the partial wave expansion. The reduction in uncertainty (by a factor of 30 for carbon) employed by *Beier* et al. [28.14] for this term, based on the assumption that it is of the order of $(\alpha/\pi)(Z\alpha)^7$, is not considered here, because the reference quoted for this estimate [28.32] does not explicitly discuss this term. *Yerokhin* et al. [28.23] obtained numerical values for this contribution for carbon and oxygen by a least-squares fit to the values of *Beier* et al. [28.25] at higher Z.

Subsequently, *Karshenboim* and *Milstein* [28.34] analytically calculated the Wichmann–Kroll contribution

to the potential correction to lowest order in $Z\alpha$. Their result in our notation is

$$C_{e,VPp}^{(2)}(Z\alpha) = \frac{7\pi}{432}(Z\alpha)^5 + \cdots . \quad (28.47)$$

This result, together with the numerical values from *Beier* [28.26], yields

$$C_{e,VPp}^{(2)}(6\alpha) = 0.000\,000\,007\,9595\,(69)\,,$$
$$C_{e,VPp}^{(2)}(8\alpha) = 0.000\,000\,033\,235\,(29)\,, \quad (28.48)$$

which are used in the present analysis. We obtained these results by fitting a function of the form $[a+bZ\alpha+c(Z\alpha)^2](Z\alpha)^5$ to the point in (28.47) and two values of the complete function calculated by [28.26] (separated by about 10 calculated values) and evaluating the fitted function at $Z = 6$ or 8. This was done for a range of pairs of points from [28.26], and the results in (28.48) are the apparent limit of the values as the lower Z member of the pair used in the fit approaches either 6 or 8 as appropriate. (This general approach is described in more detail in [28.35].)

The total one-photon vacuum polarization coefficients are given by the sum of (28.46) and (28.48):

$$C_{e,VP}^{(2)}(6\alpha) = C_{e,VPwf}^{(2)}(6\alpha) + C_{e,VPp}^{(2)}(6\alpha)$$
$$= -0.000\,001\,832\,384\,(11)\,;$$
$$C_{e,VP}^{(2)}(8\alpha) = C_{e,VPwf}^{(2)}(8\alpha) + C_{e,VPp}^{(2)}(8\alpha)$$
$$= -0.000\,005\,678\,793\,(55)\,. \quad (28.49)$$

The total for the one-photon coefficient $C_e^{(2)}(Z\alpha)$, given by the sum of (28.45) and (28.49), is

$$C_e^{(2)}(6\alpha) = C_{e,SE}^{(2)}(6\alpha) + C_{e,VP}^{(2)}(6\alpha)$$
$$= 0.500\,181\,777\,(19)\,,$$
$$C_e^{(2)}(8\alpha) = C_{e,SE}^{(2)}(8\alpha) + C_{e,VP}^{(2)}(8\alpha)$$
$$= 0.500\,343\,613\,(19)\,, \quad (28.50)$$

where in this case, following *Beier* et al. [28.25], the uncertainty is simply the sum of the individual uncertainties in (28.45) and (28.49). The total one-photon contribution $\Delta g^{(2)}$ to the g-factor is thus

$$\Delta g^{(2)} = -2C_e^{(2)}(Z\alpha)\left(\frac{\alpha}{\pi}\right)$$
$$= -0.002\,323\,663\,93\,(9) \quad \text{for } Z = 6$$
$$= -0.002\,324\,415\,77\,(9) \quad \text{for } Z = 8\,.$$
$$(28.51)$$

The separate one-photon self energy and vacuum polarization contributions to the g-factor are given in Tables 28.1, 28.2.

Evaluations by *Eides* and *Grotch* [28.36] using the Bargmann–Michel–Telegdi equation and by *Czarnecki* et al. [28.37] using an effective potential approach yield

$$C_e^{(2n)}(Z\alpha) = C_e^{(2n)}\left(1 + \frac{(Z\alpha)^2}{6} + \cdots\right) \qquad (28.52)$$

as the leading binding correction to the free electron coefficients $C_e^{(2n)}$ for any n. For $n = 1$, this result was already known, as is evident from (28.44). We include this correction for the two-photon term, that is, for $n = 2$, which gives

$$
\begin{aligned}
C_e^{(4)}(Z\alpha) &= C_e^{(4)}\left(1 + \frac{(Z\alpha)^2}{6} + \cdots\right) \\
&= -0.328\,583\,(14) \quad \text{for } Z = 6 \\
&= -0.328\,665\,(39) \quad \text{for } Z = 8 ,
\end{aligned}
$$
$$(28.53)$$

here $C_e^{(4)} = -0.328\,478\,444\ldots$. The uncertainty is due to uncalculated terms and is obtained by assuming that the unknown higher-order terms for $n = 2$, represented by the dots in (28.52), are the same as the higher-order terms for $n = 1$ as can be deduced by comparing the numerical results given in (28.50) to (28.44). This is the same general approach as that employed by *Beier* et al. [28.14].

The three-photon term is calculated in a similar way but the uncertainty due to uncalculated higher-order terms is negligible:

$$
\begin{aligned}
C_e^{(6)}(Z\alpha) &= C_e^{(6)}\left(1 + \frac{(Z\alpha)^2}{6} + \cdots\right) \\
&= 1.1816\ldots \quad \text{for } Z = 6 \\
&= 1.1819\ldots \quad \text{for } Z = 8 ,
\end{aligned}
\qquad (28.54)
$$

where $C_e^{(6)} = 1.181\,234\ldots$. For the four-photon correction, at the level of uncertainty of current interest, only the free-electron coefficient is necessary:

$$C_e^{(8)}(Z\alpha) \approx C_e^{(8)} = -1.7366\,(384) . \qquad (28.55)$$

The preceding corrections Δg_D and Δg_{rad} are based on the approximation that the nucleus of the hydrogenic atom has an infinite mass. The recoil correction to the bound-state g-factor associated with the finite mass of the nucleus is denoted by Δg_{rec}, which we write here as the sum $\Delta g_{rec}^{(0)} + \Delta g_{rec}^{(2)}$ corresponding to terms that are zero- and first-order in α/π, respectively. For $\Delta g_{rec}^{(0)}$, we have

$$
\begin{aligned}
\Delta g_{rec}^{(0)} = &\left[-(Z\alpha)^2 + \frac{(Z\alpha)^4}{3\left[1 + \sqrt{1 - (Z\alpha)^2}\right]^2} \right. \\
&\left. - (Z\alpha)^5 P(Z\alpha) \right] \frac{m_e}{m_N} + \mathcal{O}\left(\frac{m_e}{m_N}\right)^2
\end{aligned}
$$

$$
\begin{aligned}
&= -0.000\,000\,087\,71\,(1)\ldots \quad \text{for } Z = 6 \\
&= -0.000\,000\,117\,11\,(1)\ldots \quad \text{for } Z = 8 ,
\end{aligned}
$$
$$(28.56)$$

where m_N is the mass of the nucleus. The mass ratios, obtained from the 2002 CODATA adjustment, are $m_e/m(^{12}C^{6+}) = 0.000\,045\,7275\ldots$ and $m_e/m(^{16}O^{8+}) = 0.000\,034\,3065\ldots$. In (28.56), the first term in the brackets was calculated by *Grotch* [28.38]. Shortly thereafter, this term and higher-order terms were obtained by *Grotch* [28.39], *Hegstrom* [28.40], *Faustov* [28.21], *Close* and *Osborn* [28.22], and *Grotch* and *Hegstrom* [28.41] (see also *Hegstrom* [28.42] and *Grotch* [28.20]). The second and third terms in the brackets were calculated by *Shabaev* and *Yerokhin* [28.43] based on the formulation of *Shabaev* [28.44] (see also *Yelkhovski* [28.45]). Shabaev and Yerokhin have numerically evaluated the function $P(Z\alpha)$ over a wide range of Z, with the result $P(6\alpha) = 10.493\,95\,(1)$ for hydrogenic carbon and $P(8\alpha) = 9.300\,18\,(1)$ for hydrogenic oxygen.

An additional term of the order of the mass ratio squared has been considered by various authors. Earlier calculations of this term for atoms with a spin one-half nucleus, such as muonium, have been done by *Close* and *Osborn* [28.22] and *Grotch* and *Hegstrom* [28.41] (see also *Eides* and *Grotch* [28.36]). Their result for this term is

$$(1 + Z)(Z\alpha)^2 \left(\frac{m_e}{m_N}\right)^2 . \qquad (28.57)$$

Eides and *Grotch* [28.36], *Eides* [28.46] find that this correction to the g-factor is independent of the spin of the nucleus, so (28.57) gives the correction for carbon and oxygen, as well as atoms with a spin one-half nucleus. On the other hand, *Martynenko* and *Faustov* [28.47, 48] find that the correction of this order depends on the spin of the nucleus and give a result with the factor $1 + Z$ replaced by $Z/3$ for a spin zero nucleus. In view of

this discrepancy, we include a contribution to $\Delta g_{\text{rec}}^{(0)}$ in (28.56) that is the average of the two quoted results with an uncertainty of half of the difference between them.

For $\Delta g_{\text{rec}}^{(2)}$, we have

$$\Delta g_{\text{rec}}^{(2)} = \frac{\alpha}{\pi} \frac{(Z\alpha)^2}{3} \frac{m_e}{m_N} + \cdots$$
$$= 0.000\,000\,000\,06 \ldots \text{ for } Z = 6$$
$$= 0.000\,000\,000\,09 \ldots \text{ for } Z = 8 , \quad (28.58)$$

There is a small correction to the bound-state g-factor due to the finite size of the nucleus:

$$\Delta g_{\text{ns}} = \frac{8}{3} (Z\alpha)^4 \left(\frac{R_N}{\lambdabar_C} \right)^2 + \cdots , \quad (28.59)$$

where R_N is the bound-state nuclear rms charge radius and $\lambdabar_C$ is the Compton wavelength of the electron divided by 2π. In (28.59), the term shown is the nonrelativistic approximation given by *Karshenboim* [28.30]. This term and the dominant relativistic correction have been calculated by *Glazov* and *Shabaev* [28.49]. We take $R_N = 2.4705\,(23)$ fm and $R_N = 2.6995\,(68)$ from the compilation of *Angeli* [28.50] for the values of the ^{12}C and ^{16}O nuclear radii, respectively, which, based on *Glazov* and *Shabaev* [28.49], yields

$$\Delta g_{\text{ns}} = -0.000\,000\,000\,41 \quad \text{for } ^{12}\text{C} ,$$
$$\Delta g_{\text{ns}} = -0.000\,000\,001\,56\,(1) \quad \text{for } ^{16}\text{O} . \quad (28.60)$$

The theoretical value for the g-factor of the electron in hydrogenic carbon 12 or oxygen 16 is the sum of the individual contributions discussed above and summarized in Tables 28.1 and 28.2:

$$g_{e^-}(^{12}\text{C}^{5+}) = -2.001\,041\,590\,16\,(18)$$
$$g_{e^-}(^{16}\text{O}^{7+}) = -2.000\,047\,020\,31\,(43) . \quad (28.61)$$

We define $g_C(\text{th})$ to be the sum of g_D as given in (28.41), the term $-2(\alpha/\pi)C_e^{(2)}$, and the numerical values of the remaining terms in (28.40) as given in Table 28.1 without the uncertainties. The standard uncertainty of $g_C(\text{th})$ from the uncertainties of these latter terms is

$$u[g_C(\text{th})] = 1.8 \times 10^{-10} = 9.0 \times 10^{-11} |g_C(\text{th})| . \quad (28.62)$$

The uncertainty in $g_C(\text{th})$ due to the uncertainty in α enters primarily through the functional dependence of g_D and the term $-2(\alpha/\pi)C_e^{(2)}$ on α. Therefore this particular component of uncertainty is not explicitly included in

$u[g_C(\text{th})]$, but it is included in Tables 28.1 and 28.2. To take the uncertainty $u[g_C(\text{th})]$ into account we employ as the theoretical expression for the g-factor

$$g_C(\alpha, \delta_C) = g_C(\text{th}) + \delta_C , \quad (28.63)$$

where the input value of the additive correction δ_C is taken to be zero and its standard uncertainty is $u[g_C(\text{th})]$:

$$\delta_C = 0.0\,(1.8) \times 10^{-10} . \quad (28.64)$$

Analogous considerations apply for the g-factor in oxygen:

$$u[g_O(\text{th})] = 4.3 \times 10^{-10} = 2.2 \times 10^{-10} |g_O(\text{th})| \quad (28.65)$$

$$g_O(\alpha, \delta_O) = g_O(\text{th}) + \delta_O \quad (28.66)$$
$$\delta_O = 0.0\,(4.3) \times 10^{-10} . \quad (28.67)$$

Since the uncertainties of the theoretical values of the carbon and oxygen g-factors arise primarily from the same sources, the quantities δ_C and δ_O are highly correlated. Their covariance is

$$u(\delta_C, \delta_O) = 741 \times 10^{-22} , \quad (28.68)$$

which corresponds to a correlation coefficient of $r(\delta_C, \delta_O) = 0.95$.

The theoretical value of the ratio of the two g-factors, which is relevant to the following discussion, is

$$\frac{g_{e^-}(^{12}\text{C}^{5+})}{g_{e^-}(^{16}\text{O}^{7+})} = 1.000\,497\,273\,23\,(13) , \quad (28.69)$$

where the covariance is taken into account in calculating the uncertainty, and for this purpose includes the contribution due to the uncertainty in α.

Finally, we consider evaluation of the mass ratio in (28.33) by applying the relation for the relative atomic mass $A_r(^AX)$ of a neutral atom ^AX in terms of the relative atomic mass of an ion of the atom formed by the removal of n electrons, which is given by

$$A_r(^AX) = A_r(^AX^{n+}) + nA_r(e)$$
$$- \frac{E_b(^AX) - E_b(^AX^{n+})}{m_u c^2} . \quad (28.70)$$

Here A is the mass number, Z is the atomic number (proton number), $E_b(^AX)/m_u c^2$ is the relative-atomic-mass equivalent of the total binding energy of the Z electrons of the atom, $E_b(^AX^{n+})/m_u c^2$ is the relative-atomic-mass-equivalent of the binding energy of the $^AX^{n+}$ ion, and m_u is the atomic mass constant.

From (28.33) and (28.70), we have

$$\frac{f_s\left(^{12}C^{5+}\right)}{f_c\left(^{12}C^{5+}\right)} = -\frac{g_{e-}\left(^{12}C^{5+}\right)}{10A_r(e)}$$

$$\times \left[12 - 5A_r(e) + \frac{E_b\left(^{12}C\right) - E_b\left(^{12}C^{5+}\right)}{m_u c^2} \right], \tag{28.71}$$

which is the equation for the $^{12}C^{5+}$ frequency-ratio. Evaluation of this expression using the result for $f_s\left(^{12}C^{5+}\right)/f_c\left(^{12}C^{5+}\right)$ in (28.34), the theoretical result for $g_{e-}\left(^{12}C^{5+}\right)$ in Table 28.1, and the relevant binding energies from [28.3], yields

$$A_r(e) = 0.000\,548\,579\,909\,31\,(29), \tag{28.72}$$

a result that is consistent with the University of Washington result [28.51], but has about a factor of four smaller uncertainty.

Similarly, we have

$$\frac{f_s\left(^{16}O^{7+}\right)}{f_c\left(^{16}O^{7+}\right)} = -\frac{g_{e-}\left(^{16}O^{7+}\right)}{14A_r(e)} A_r\left(^{16}O^{7+}\right) \tag{28.73}$$

with

$$A_r\left(^{16}O\right) = A_r\left(^{16}O^{7+}\right) + 7A_r(e)$$

$$- \frac{E_b\left(^{16}O\right) - E_b\left(^{16}O^{7+}\right)}{m_u c^2}, \tag{28.74}$$

which are the equations for the oxygen frequency ratio and $A_r\left(^{16}O\right)$, respectively. The first expression,

evaluated using the result for $f_s\left(^{16}O^{7+}\right)/f_c\left(^{16}O^{7+}\right)$ in (28.35) and the theoretical result for $g_{e-}\left(^{16}O^{7+}\right)$ in Table 28.2, in combination with the second expression, evaluated using the value of $A_r\left(^{16}O\right)$ from the *University of Washington group* [28.52, 53] and the relevant binding energies from [28.3], yields

$$A_r(e) = 0.000\,548\,579\,909\,57\,(43), \tag{28.75}$$

a value that is consistent with both the *University of Washington* value [28.51] and the value in (28.72) obtained from $f_s\left(^{12}C^{5+}\right)/f_c\left(^{12}C^{5+}\right)$.

As a consistency test, it is of interest to compare the experimental and theoretical values of the ratio of $g_{e-}\left(^{12}C^{5+}\right)$ to $g_{e-}\left(^{16}O^{7+}\right)$ [28.54]. The main reason is that the experimental value of the ratio is only weakly dependent on the value of $A_r(e)$. The theoretical value of the ratio is given in (28.69) and takes into account the covariance of the two theoretical values. The experimental value of the ratio can be obtained by combining (28.34) to (28.36), (28.71), (28.73), and (28.74), and using the 2002 CODATA recommended value for $A_r(e)$. (Because of the weak dependence of the experimental ratio on $A_r(e)$, the value used is not at all critical.) The result is

$$\frac{g_{e-}\left(^{12}C^{5+}\right)}{g_{e-}\left(^{16}O^{7+}\right)} = 1.000\,497\,273\,70\,(90), \tag{28.76}$$

in agreement with the theoretical value in (28.69).

28.3 Hydrogen and Deuterium Atoms

This section gives a brief survey of the theory of the energy levels of hydrogen and deuterium relevant to measurements of transition frequencies. Although information to completely determine the theoretical values for the energy levels is provided, results that are included in [28.1, 2] are given with minimal discussion, and the emphasis is on recent results. For brevity, reference to most historical works is not included.

The theoretical data provided here are confined to that needed to evaluate the theoretical values of the precisely measured transition frequencies in hydrogen and deuterium summarized in [28.3].

It should be noted that the theoretical values of the energy levels of different states of hydrogen and deuterium are highly correlated. For example, for S states, the uncalculated terms are primarily of the form of

an unknown common constant divided by n^3. This fact is taken into account by calculating covariances between energy levels in addition to the uncertainties of the individual levels as discussed in detail in Sect. 28.3.12. To provide the information needed to calculate the covariances, where necessary we distinguish between components of uncertainty that are proportional to $1/n^3$, denoted by u_0, and components of uncertainty that are essentially random functions of n, denoted by u_n.

Theoretical values of the energy levels of hydrogen and deuterium atoms are determined mainly by the Dirac eigenvalue, QED effects such as self energy and vacuum polarization, and nuclear size and motion effects. We consider each of these contributions in turn.

28.3.1 Dirac Eigenvalue

The binding energy of an electron in a static Coulomb field (the external electric field of a point nucleus of charge Ze with infinite mass) is determined predominantly by the Dirac eigenvalue

$$E_D = \left(1 + \frac{(Z\alpha)^2}{(n-\delta)^2}\right)^{-1/2} m_e c^2 , \qquad (28.77)$$

where n is the principal quantum number,

$$\delta = |\kappa| - \left[\kappa^2 - (Z\alpha)^2\right]^{1/2} , \qquad (28.78)$$

and κ is the angular momentum-parity quantum number ($\kappa = -1, 1, -2, 2, -3$ for $S_{1/2}$, $P_{1/2}$, $P_{3/2}$, $D_{3/2}$, and $D_{5/2}$ states, respectively). States with the same principal quantum number n and angular momentum quantum number $j = |\kappa| - \frac{1}{2}$ have degenerate eigenvalues. The nonrelativistic orbital angular momentum is given by $l = |\kappa + \frac{1}{2}| - \frac{1}{2}$. (Although we are interested only in the case where the nuclear charge is e, we retain the atomic number Z in order to indicate the nature of various terms.)

Corrections to the Dirac eigenvalue that approximately take into account the finite mass of the nucleus m_N are included in the more general expression for atomic energy levels, which replaces (28.77) [28.55, 56]:

$$\begin{aligned}
E_M = Mc^2 &+ [f(n,j) - 1]m_r c^2 \\
&- [f(n,j) - 1]^2 \frac{m_r^2 c^2}{2M} \\
&+ \frac{1 - \delta_{l0}}{\kappa(2l+1)} \frac{(Z\alpha)^4 m_r^3 c^2}{2n^3 m_N^2} + \cdots ,
\end{aligned} \qquad (28.79)$$

where

$$f(n,j) = \left[1 + \frac{(Z\alpha)^2}{(n-\delta)^2}\right]^{-1/2} , \qquad (28.80)$$

$M = m_e + m_N$, and $m_r = m_e m_N / (m_e + m_N)$ is the reduced mass.

28.3.2 Relativistic Recoil

Relativistic corrections to (28.79) associated with motion of the nucleus are considered relativistic-recoil corrections. The leading term, to lowest order in $Z\alpha$

and all orders in m_e/m_N, is [28.56, 57]

$$\begin{aligned}
E_S = \frac{m_r^3}{m_e^2 m_N} &\frac{(Z\alpha)^5}{\pi n^3} m_e c^2 \\
\times \Bigg\{ &\frac{1}{3} \delta_{l0} \ln(Z\alpha)^{-2} - \frac{8}{3} \ln k_0(n,l) - \frac{1}{9} \delta_{l0} - \frac{7}{3} a_n \\
&- \frac{2}{m_N^2 - m_e^2} \delta_{l0} \left[m_N^2 \ln\left(\frac{m_e}{m_r}\right) - m_e^2 \ln\left(\frac{m_N}{m_r}\right) \right] \Bigg\} ,
\end{aligned} \qquad (28.81)$$

where

$$\begin{aligned}
a_n = -2 &\left[\ln\left(\frac{2}{n}\right) + \sum_{i=1}^{n} \frac{1}{i} + 1 - \frac{1}{2n} \right] \delta_{l0} \\
&+ \frac{1 - \delta_{l0}}{l(l+1)(2l+1)} .
\end{aligned} \qquad (28.82)$$

To lowest order in the mass ratio, higher-order corrections in $Z\alpha$ have been extensively investigated; the contribution of the next two orders in $Z\alpha$ can be written as

$$\begin{aligned}
E_R = \frac{m_e}{m_N} &\frac{(Z\alpha)^6}{n^3} m_e c^2 \\
&\times \left[D_{60} + D_{72} Z\alpha \ln^2 (Z\alpha)^{-2} + \cdots \right] ,
\end{aligned} \qquad (28.83)$$

where for $nS_{1/2}$ states [28.58, 59]

$$D_{60} = 4 \ln 2 - \frac{7}{2} \qquad (28.84)$$

and for states with $l \geq 1$ [28.60–62]

$$D_{60} = \left(3 - \frac{l(l+1)}{n^2}\right) \frac{2}{(4l^2 - 1)(2l+3)} . \qquad (28.85)$$

(As usual, the first subscript on the coefficient refers to the power of $Z\alpha$ and the second subscript to the power of $\ln(Z\alpha)^{-2}$.) The next coefficient in (28.83) has been calculated recently with the result [28.63, 64]

$$D_{72} = -\frac{11}{60\pi} \delta_{l0} . \qquad (28.86)$$

The relativistic recoil correction used here is based on (28.81) to (28.86). Numerical values for the complete contribution of (28.83) to all orders in $Z\alpha$ have been obtained by *Shabaev* et al. [28.65]. While these results are in general agreement with the values given by the power series expressions, the difference between them for S states is about three times larger than expected (based on the uncertainty quoted by *Shabaev* et al. [28.65] and the estimated uncertainty of the truncated power series

which is taken to be one-half the contribution of the term proportional to D_{72}, as suggested by *Eides* et al. [28.2]). This difference is not critical, and we allow for the ambiguity by assigning an uncertainty for S states of 10% of the contribution given by (28.83). This is sufficiently large that the power series value is consistent with the numerical all-order calculated value. For the states with $l \geq 1$, we assign an uncertainty of 1% of the contribution in (28.83). The covariances of the theoretical values are calculated by assuming that the uncertainties are predominately due to uncalculated terms proportional to $(m_e/m_N)/n^3$.

28.3.3 Nuclear Polarization

Another effect involving specific properties of the nucleus, in addition to relativistic recoil, is nuclear polarization. It arises from interactions between the electron and nucleus in which the nucleus is excited from the ground state to virtual higher states.

For hydrogen, the result that we use for the nuclear polarization is [28.66]

$$E_P(H) = -0.070\,(13)\,h\frac{\delta_{l0}}{n^3}\,\text{kHz}\,. \tag{28.87}$$

Larger values for this correction have been reported by *Roedenfelder* [28.67], *Martynenko* and *Faustov* [28.68], but apparently they are based on an incorrect formulation of the dispersion relations [28.2, 66].

For deuterium, to a good approximation, the polarizability of the nucleus is the sum of the proton polarizability, the neutron polarizability [28.69], and the dominant nuclear structure polarizability [28.70], with the total given by

$$E_P(D) = -21.37\,(8)\,h\frac{\delta_{l0}}{n^3}\,\text{kHz}\,. \tag{28.88}$$

We assume that this effect is negligible in states of higher l.

28.3.4 Self Energy

The second order (in e, first order in α) level shift due to the one-photon electron self energy, the lowest-order radiative correction, is given by

$$E_{SE}^{(2)} = \frac{\alpha}{\pi}\frac{(Z\alpha)^4}{n^3}F(Z\alpha)m_e c^2\,, \tag{28.89}$$

where

$$\begin{aligned}
F(Z\alpha) &= A_{41}\ln(Z\alpha)^{-2} + A_{40} + A_{50}(Z\alpha)\\
&\quad + A_{62}(Z\alpha)^2\ln^2(Z\alpha)^{-2}\\
&\quad + A_{61}(Z\alpha)^2\ln(Z\alpha)^{-2}\\
&\quad + G_{SE}(Z\alpha)(Z\alpha)^2\,,
\end{aligned} \tag{28.90}$$

with [28.71]

$$A_{41} = \frac{4}{3}\delta_{l0}$$

$$A_{40} = -\frac{4}{3}\ln k_0(n, l) + \frac{10}{9}\delta_{l0}$$
$$\quad - \frac{1}{2\kappa(2l+1)}(1 - \delta_{l0})$$

$$A_{50} = \left(\frac{139}{32} - 2\ln 2\right)\pi\delta_{l0}$$

$$A_{62} = -\delta_{l0}$$

$$\begin{aligned}
A_{61} &= \left[4\left(1 + \frac{1}{2} + \cdots + \frac{1}{n}\right) + \frac{28}{3}\ln 2 - 4\ln n\right.\\
&\quad \left. - \frac{601}{180} - \frac{77}{45n^2}\right]\delta_{l0}\\
&\quad + \left(1 - \frac{1}{n^2}\right)\left(\frac{2}{15} + \frac{1}{3}\delta_{j\frac{1}{2}}\right)\delta_{l1}\\
&\quad + \frac{96n^2 - 32l(l+1)}{3n^2(2l-1)(2l)(2l+1)(2l+2)(2l+3)}\\
&\quad \times (1 - \delta_{l0})\,.
\end{aligned} \tag{28.91}$$

Selected Bethe logarithms $\ln k_0(n, l)$ that appear in (28.91) are given in Table 28.3 [28.72].

The function $G_{SE}(Z\alpha)$ in (28.90) gives the higher-order contribution (in $Z\alpha$) to the self energy, and values for $G_{SE}(\alpha)$ are listed in Table 28.4. For the states with $n = 1$ and $n = 2$, the values in the table are based on direct numerical evaluations by *Jentschura* et al. [28.73, 74], and the values for the 3S and 4S states are from *Jentschura* and *Mohr* [28.75]. The remaining values of $G_{SE}(\alpha)$ are based on the

low-Z limit of this function, $G_{SE}(0) = A_{60}$, in the cases where it is known, together with extrapolations of the results of complete numerical calculations of $F(Z\alpha)$ (28.90) at higher Z [28.76, 77]. There is a long history of calculations of A_{60} [28.2], leading up to the accurate values of A_{60} for the 1S and 2S states obtained by *Pachucki* [28.73, 78–80]. Values for P and D states have been reported subsequently by *Jentschura* and *Pachucki* [28.62], *Jentschura* et al. [28.81, 82]. Extensive numerical evaluations of $F(Z\alpha)$ at higher Z, which in turn yield values for $G_{SE}(Z\alpha)$, have been done by *Mohr* [28.83], *Mohr* and *Kim* [28.84], *Indelicato* and *Mohr* [28.85], *Le Bigot* [28.86].

The dominant effect of the finite mass of the nucleus on the self energy correction is taken into account by multiplying each term of $F(Z\alpha)$ by the reduced-mass factor $(m_r/m_e)^3$, except that the magnetic moment term $-1/[2\kappa(2l+1)]$ in A_{40} is instead multiplied by the factor $(m_r/m_e)^2$. In addition, the argument $(Z\alpha)^{-2}$ of the logarithms is replaced by $(m_e/m_r)(Z\alpha)^{-2}$ [28.56].

The uncertainty of the self energy contribution to a given level arises entirely from the uncertainty of $G_{SE}(\alpha)$ listed in Table 28.4 and is taken to be entirely of type u_n.

28.3.5 Vacuum Polarization

The second-order vacuum-polarization level shift, due to the creation of a virtual electron–positron pair in the exchange of photons between the electron and the nucleus, is

$$E_{VP}^{(2)} = \frac{\alpha}{\pi} \frac{(Z\alpha)^4}{n^3} H(Z\alpha) m_e c^2 \,, \tag{28.92}$$

where the function $H(Z\alpha)$ is divided into the part corresponding to the Uehling potential, denoted here by $H^{(1)}(Z\alpha)$, and the higher-order remainder $H^{(R)}(Z\alpha) = H^{(3)}(Z\alpha) + H^{(5)}(Z\alpha) + \cdots$, where the superscript denotes the order in powers of the external field. The

individual terms are expanded in a power series in $Z\alpha$ as

$$H^{(1)}(Z\alpha) = V_{40} + V_{50}(Z\alpha) + V_{61}(Z\alpha)^2 \ln(Z\alpha)^{-2}$$
$$+ G_{VP}^{(1)}(Z\alpha)(Z\alpha)^2 \,, \tag{28.93}$$

$$H^{(R)}(Z\alpha) = G_{VP}^{(R)}(Z\alpha)(Z\alpha)^2 \,, \tag{28.94}$$

with

$$V_{40} = -\frac{4}{15}\delta_{l0} \,,$$

$$V_{50} = \frac{5}{48}\pi\delta_{l0} \,,$$

$$V_{61} = -\frac{2}{15}\delta_{l0} \,. \tag{28.95}$$

The part $G_{VP}^{(1)}(Z\alpha)$ arises from the Uehling potential, and is readily calculated numerically [28.76, 87]; values are given in Table 28.5. The higher-order remainder $G_{VP}^{(R)}(Z\alpha)$ has been considered by *Wichmann* and *Kroll*, and the leading terms in powers of $Z\alpha$ are [28.33, 88, 89]

$$G_{VP}^{(R)}(Z\alpha) = \left(\frac{19}{45} - \frac{\pi^2}{27}\right)\delta_{l0}$$
$$+ \left(\frac{1}{16} - \frac{31\pi^2}{2880}\right)\pi(Z\alpha)\delta_{l0} + \cdots \,. \tag{28.96}$$

Higher-order terms omitted from (28.96) are negligible.

In a manner similar to that for the self energy, the leading effect of the finite mass of the nucleus is taken into account by multiplying (28.92) by the factor $(m_r/m_e)^3$ and including a multiplicative factor of (m_e/m_r) in the argument of the logarithm in (28.93).

There is also a second-order vacuum polarization level shift due to the creation of virtual particle pairs other than the e^-e^+ pair. The predominant contribution for nS states arises from $\mu^+\mu^-$, with the leading term being [28.90, 91]

$$E_{\mu VP}^{(2)} = \frac{\alpha}{\pi} \frac{(Z\alpha)^4}{n^3} \left(-\frac{4}{15}\right) \left(\frac{m_e}{m_\mu}\right)^2 \left(\frac{m_r}{m_e}\right)^3 m_e c^2 \,. \tag{28.97}$$

Table 28.5 Values of the function $G_{VP}^{(1)}(\alpha)$

n	$S_{1/2}$	$P_{1/2}$	$P_{3/2}$	$D_{3/2}$	$D_{5/2}$
1	$-0.618\,724$				
2	$-0.808\,872$	$-0.064\,006$	$-0.014\,132$		
3	$-0.814\,530$				
4	$-0.806\,579$	$-0.080\,007$	$-0.017\,666$		$-0.000\,000$
6	$-0.791\,450$				$-0.000\,000$
8	$-0.781\,197$			$-0.000\,000$	$-0.000\,000$
12				$-0.000\,000$	$-0.000\,000$

The next order term in the contribution of muon vacuum polarization to nS states is of relative order $Z\alpha m_e/m_\mu$ and is therefore negligible. The analogous contribution $E_{\tau VP}^{(2)}$ from $\tau^+\tau^-$ (-18 Hz for the 1S state) is also negligible at the level of uncertainty of current interest.

For the hadronic vacuum polarization contribution, we take the result given by *Friar* et al. [28.92] that utilizes all available e^+e^- scattering data:

$$E_{\text{had VP}}^{(2)} = 0.671\,(15) E_{\mu VP}^{(2)} , \qquad (28.98)$$

where the uncertainty is of type u_0.

The muonic and hadronic vacuum polarization contributions are negligible for P and D states.

28.3.6 Two-Photon Corrections

Corrections from two virtual photons, of order α^2, have been calculated as a power series in $Z\alpha$:

$$E^{(4)} = \left(\frac{\alpha}{\pi}\right)^2 \frac{(Z\alpha)^4}{n^3} m_e c^2 F^{(4)}(Z\alpha) , \qquad (28.99)$$

where

$$\begin{aligned}
F^{(4)}(Z\alpha) &= B_{40} + B_{50}(Z\alpha) + B_{63}(Z\alpha)^2 \ln^3(Z\alpha)^{-2} \\
&\quad + B_{62}(Z\alpha)^2 \ln^2(Z\alpha)^{-2} \\
&\quad + B_{61}(Z\alpha)^2 \ln(Z\alpha)^{-2} + B_{60}(Z\alpha)^2 \\
&\quad + \cdots .
\end{aligned} \qquad (28.100)$$

The leading term B_{40} is well known:

$$\begin{aligned}
B_{40} &= \left[\frac{3\pi^2}{2}\ln 2 - \frac{10\pi^2}{27} - \frac{2179}{648} - \frac{9}{4}\zeta(3)\right]\delta_{l0} \\
&\quad + \left[\frac{\pi^2\ln 2}{2} - \frac{\pi^2}{12} - \frac{197}{144} - \frac{3\zeta(3)}{4}\right]\frac{1-\delta_{l0}}{\kappa(2l+1)} .
\end{aligned} \qquad (28.101)$$

The second term has been calculated by *Eides* and *Shelyuto* [28.93], *Pachucki* [28.94], *Eides* et al. [28.90], *Pachucki* [28.95] with the result

$$B_{50} = -21.5561\,(31)\delta_{l0} . \qquad (28.102)$$

The next coefficient, as obtained by *Karshenboim* [28.96], *Yerokhin* [28.97], *Manohar* and *Stewart* [28.98], *Pachucki* [28.99], is

$$B_{63} = -\frac{8}{27}\delta_{l0} . \qquad (28.103)$$

For S states the coefficient B_{62} has been found to be

$$\begin{aligned}
B_{62} &= \frac{16}{9}\left[\frac{71}{60} - \ln 2 + \gamma + \psi(n)\right. \\
&\quad \left. - \ln n - \frac{1}{n} + \frac{1}{4n^2}\right] ,
\end{aligned} \qquad (28.104)$$

where $\gamma = 0.577\ldots$ is Euler's constant and ψ is the psi function [28.100]. The difference $B_{62}(1) - B_{62}(n)$ was calculated by *Karshenboim* [28.101] and confirmed by *Pachucki* [28.99] who also calculated the n-independent additive constant. For P states the calculated value is [28.101]

$$B_{62} = \frac{4}{27}\frac{n^2-1}{n^2} . \qquad (28.105)$$

This result has been confirmed by *Jentschura* and *Nándori* [28.102] who also show that for D and higher angular momentum states $B_{62} = 0$.

The single-logarithm coefficient B_{61} for S states has been given as [28.99]

$$\begin{aligned}
B_{61} &= \frac{39751}{10800} + \frac{4N(n)}{3} + \frac{55\pi^2}{27} - \frac{616\ln 2}{135} \\
&\quad + \frac{3\pi^2\ln 2}{4} + \frac{40\ln^2 2}{9} - \frac{9\zeta(3)}{8} \\
&\quad + \left(\frac{304}{135} - \frac{32\ln 2}{9}\right) \\
&\quad \times \left[\frac{3}{4} + \gamma + \psi(n) - \ln n - \frac{1}{n} + \frac{1}{4n^2}\right] ,
\end{aligned} \qquad (28.106)$$

where $N(n)$ is a term that was numerically evaluated for the 1S state by *Pachucki* [28.99]. *Jentschura* [28.103] has evaluated $N(n)$ for excited S states with $n = 2$ to $n = 8$, has made an improved evaluation for $n = 1$, and has given an approximate fit to the calculated results in order to extend them to higher n. Values of the function $N(n)$ for the states of interest here are given in Table 28.6. There are no results yet for P or D states for B_{61}. Based on the relative magnitude of A_{61} for the S, P, and D states, we take as uncertainties $u_n(B_{61}) = 5.0$ for P states and $u_n(B_{61}) = 0.5$ for D states.

Recent work indicates that there may be an additional contribution to B_{61} and/or B_{60} [28.104, 105]. The effect of such a contribution would be to change the S-state energy levels by an amount that is likely to be less than half the uncertainty of the nuclear size correction due to uncertainty in the rms radius of the nucleus.

The two-loop Bethe logarithm b_L, which is expected to be the dominant part of the no-log term B_{60}, has been calculated for the 1S and 2S states by *Pachucki* and *Jentschura* [28.106] who obtained

$$b_L = -81.4\,(3) \quad \text{1S state} \tag{28.107a}$$
$$b_L = -66.6\,(3) \quad \text{2S state}. \tag{28.107b}$$

An additional contribution for S states,

$$b_M = \frac{10}{9}N, \tag{28.108}$$

was derived by *Pachucki* [28.99], where N is given in Table 28.7 as a function of the state n. These contributions can be combined to obtain an estimate for the coefficient B_{60} for S states:

$$B_{60} = b_L + \frac{10}{9}N + \cdots, \tag{28.109}$$

where the dots represent uncalculated contributions to B_{60} which are at the relative level of 15% [28.106]. In order to obtain an approximate value for B_{60} for S states

with $n \geq 3$, we employ a simple extrapolation formula,

$$b_L = a + \frac{b}{n}, \tag{28.110}$$

with a and b fitted to the 1S and 2S values of b_L, and we include a component of uncertainty $u_0(b_L) = 5.0$. The results for b_L, along with the total estimated values of B_{60} for S states, are given in Table 28.7. For P states, there is a calculation of fine-structure differences [28.107], but because of the uncertainty in B_{61} for P states, we do not include this result. We assume that for both the P and D states, the uncertainty attributed to B_{61} is sufficiently large to account for the uncertainty in B_{60} and higher-order terms as well.

As in the case of the order α self-energy and vacuum-polarization contributions, the dominant effect of the finite mass of the nucleus is taken into account by multiplying each term of the two-photon contribution by the reduced-mass factor $(m_r/m_e)^3$, except that the magnetic moment term, the second line of (28.101), is instead multiplied by the factor $(m_r/m_e)^2$. In addition, the argument $(Z\alpha)^{-2}$ of the logarithms is replaced by $(m_e/m_r)(Z\alpha)^{-2}$.

28.3.7 Three-Photon Corrections

The leading contribution from three virtual photons is assumed to have the form

$$E^{(6)} = \left(\frac{\alpha}{\pi}\right)^3 \frac{(Z\alpha)^4}{n^3} m_e c^2 \left[C_{40} + C_{50}(Z\alpha) + \cdots\right], \tag{28.111}$$

in analogy with (28.99) for two photons. The level shifts of order $(\alpha/\pi)^3(Z\alpha)^4 m_e c^2$ that contribute to C_{40} can be characterized as the sum of a self-energy correction, a magnetic-moment correction, and a vacuum polarization correction. The self-energy correction arises from the slope of the Dirac form factor, and it has recently been calculated by *Melnikov* and *Ritbergen* [28.108]

Table 28.6 Values of N

n	N
1	17.855 672 (1)

6	9.031 832 (1)
8	8.697 639 (1)

Table 28.7 Values of b_L and B_{60}

n	b_L	B_{60}
1	−81.4 (3)	−61.6 (9.2)
2	−66.6 (3)	−53.2 (8.0)
3	−61.7 (5.0)	−50.1 (9.0)
4	−59.2 (5.0)	−48.4 (8.8)
6	−56.7 (5.0)	−46.7 (8.6)
8	−55.5 (5.0)	−45.8 (8.5)

who obtained

$$
\begin{aligned}
E_{\mathrm{SE}}^{(6)} = \left(\frac{\alpha}{\pi}\right)^3 \frac{(Z\alpha)^4}{n^3} m_e c^2 \Bigg(&-\frac{868 a_4}{9} + \frac{25\zeta(5)}{2} \\
&-\frac{17\pi^2\zeta(3)}{6} - \frac{2929\zeta(3)}{72} - \frac{217\ln^4 2}{54} \\
&-\frac{103\pi^2\ln^2 2}{270} + \frac{41671\pi^2\ln 2}{540} + \frac{3899\pi^4}{6480} \\
&-\frac{454979\pi^2}{9720} - \frac{77513}{46656} \Bigg)\delta_{l0} ,
\end{aligned}
\tag{28.112}
$$

where ζ is the Riemann zeta function and $a_4 = \sum_{n=1}^{\infty} 1/(2^n n^4) = 0.517\,479\,061\ldots$. The magnetic-moment correction comes from the known three-loop electron anomalous magnetic moment [28.109], and is given by

$$
\begin{aligned}
E_{\mathrm{MM}}^{(6)} = \left(\frac{\alpha}{\pi}\right)^3 \frac{(Z\alpha)^4}{n^3} m_e c^2 \Bigg(&-\frac{100 a_4}{3} + \frac{215\zeta(5)}{24} \\
&-\frac{83\pi^2\zeta(3)}{72} - \frac{139\zeta(3)}{18} - \frac{25\ln^4 2}{18} \\
&+\frac{25\pi^2\ln^2 2}{18} + \frac{298\pi^2\ln 2}{9} + \frac{239\pi^4}{2160} \\
&-\frac{17101\pi^2}{810} - \frac{28259}{5184} \Bigg)\frac{1}{\kappa(2l+1)} ,
\end{aligned}
\tag{28.113}
$$

and the vacuum-polarization correction is [28.110, 111]

$$
\begin{aligned}
E_{\mathrm{VP}}^{(6)} = \left(\frac{\alpha}{\pi}\right)^2 \frac{(Z\alpha)^4}{n^3} m_e c^2 \Bigg(&-\frac{8135\zeta(3)}{2304} + \frac{4\pi^2\ln 2}{15} \\
&-\frac{23\pi^2}{90} + \frac{325805}{93312} \Bigg)\delta_{l0} .
\end{aligned}
\tag{28.114}
$$

The total for C_{40} is

$$
\begin{aligned}
C_{40} = \Bigg(&-\frac{568 a_4}{9} + \frac{85\zeta(5)}{24} \\
&-\frac{121\pi^2\zeta(3)}{72} - \frac{84071\zeta(3)}{2304} - \frac{71\ln^4 2}{27} \\
&-\frac{239\pi^2\ln^2 2}{135} + \frac{4787\pi^2\ln 2}{108} + \frac{1591\pi^4}{3240} \\
&-\frac{252251\pi^2}{9720} + \frac{679441}{93312} \Bigg)\delta_{l0} \\
&+\Bigg(-\frac{100 a_4}{3} + \frac{215\zeta(5)}{24} \\
&-\frac{83\pi^2\zeta(3)}{72} - \frac{139\zeta(3)}{18} - \frac{25\ln^4 2}{18} \\
&+\frac{25\pi^2\ln^2 2}{18} + \frac{298\pi^2\ln 2}{9} + \frac{239\pi^4}{2160} \\
&-\frac{17101\pi^2}{810} - \frac{28259}{5184} \Bigg)\frac{1-\delta_{l0}}{\kappa(2l+1)} .
\end{aligned}
\tag{28.115}
$$

An uncertainty in the three-photon correction is assigned by taking $u_0(C_{50}) = 30\delta_{l0}$ and $u_n(C_{63}) = 1$, where C_{63} is defined by the usual convention.

The dominant effect of the finite mass of the nucleus is taken into account by multiplying C_{40} in (28.115) by the reduced-mass factor $(m_r/m_e)^3$ for $l = 0$ or by the factor $(m_r/m_e)^2$ for $l \neq 0$.

The contribution from four photons is expected to be of order

$$
\left(\frac{\alpha}{\pi}\right)^4 \frac{(Z\alpha)^4}{n^3} m_e c^2 ,
\tag{28.116}
$$

which is about 10 Hz for the 1S state and is negligible at the level of uncertainty of current interest.

28.3.8 Finite Nuclear Size

At low Z, the leading contribution due to the finite size of the nucleus is

$$
E_{\mathrm{NS}}^{(0)} = \mathcal{E}_{\mathrm{NS}}\delta_{l0} ,
\tag{28.117}
$$

with

$$
\mathcal{E}_{\mathrm{NS}} = \frac{2}{3} \left(\frac{m_r}{m_e}\right)^3 \frac{(Z\alpha)^2}{n^3} m_e c^2 \left(\frac{Z\alpha R_N}{\lambdabar_C}\right)^2 ,
\tag{28.118}
$$

where R_N is the bound-state root-mean-square (rms) charge radius of the nucleus and $\lambdabar_C$ is the Compton wavelength of the electron divided by 2π. The leading higher-order contributions have been examined by *Friar* [28.112], *Friar* and *Payne* [28.113], *Karshenboim* [28.114] (see also *Mohr* [28.115], *Borisoglebski* and *Trofimenko* [28.89]). The expressions that we employ to evaluate the nuclear size correction are the same as those discussed in more detail in [28.1].

For S states the leading and next-order corrections are given by

$$
\begin{aligned}
E_{\mathrm{NS}} = \mathcal{E}_{\mathrm{NS}} \Bigg\{ &1 - C_\eta \frac{m_r}{m_e} \frac{R_N}{\lambdabar_C} Z\alpha - \Bigg[\ln\left(\frac{m_r}{m_e} \frac{R_N}{\lambdabar_C} \frac{Z\alpha}{n}\right) \\
&+\psi(n)+\gamma - \frac{(5n+9)(n-1)}{4n^2} - C_\theta \Bigg](Z\alpha)^2 \Bigg\} ,
\end{aligned}
\tag{28.119}
$$

where C_η and C_θ are constants that depend on the details of the assumed charge distribution in the nucleus. The values used here are $C_\eta = 1.7\,(1)$ and $C_\theta = 0.47\,(4)$ for hydrogen or $C_\eta = 2.0\,(1)$ and $C_\theta = 0.38\,(4)$ for deuterium.

For the $P_{1/2}$ states in hydrogen the leading term is

$$
E_{\mathrm{NS}} = \mathcal{E}_{\mathrm{NS}} \frac{(Z\alpha)^2(n^2-1)}{4n^2} .
\tag{28.120}
$$

28.3.9 Nuclear–Size Correction to Self Energy and Vacuum Polarization

In addition to the direct effect of finite nuclear size on energy levels, its effect on the self energy and vacuum polarization contributions must also be considered. This same correction is sometimes called the radiative correction to the nuclear-size effect.

For the self energy, the additional contribution due to the finite size of the nucleus is [28.116–119]

$$E_{\mathrm{NSE}} = \left(4\ln 2 - \frac{23}{4}\right)\alpha(Z\alpha)\mathcal{E}_{\mathrm{NS}}\delta_{l0} \,, \qquad (28.121)$$

and for the vacuum polarization it is [28.117, 120, 121]

$$E_{\mathrm{NVP}} = \frac{3}{4}\alpha(Z\alpha)\mathcal{E}_{\mathrm{NS}}\delta_{l0} \,. \qquad (28.122)$$

For the self-energy term, higher-order size corrections for S states [28.118] and size corrections for P states have been calculated [28.103, 122], but these corrections are negligible for the current work, and are not included. The D-state corrections are assumed to be negligible.

28.3.10 Radiative–Recoil Corrections

The dominant effect of nuclear motion on the self energy and vacuum polarization has been taken into account by including appropriate reduced-mass factors. The additional contributions beyond this prescription are termed radiative-recoil effects with leading terms given by

$$
\begin{aligned}
E_{\mathrm{RR}} = {} & \frac{m_{\mathrm{r}}^3}{m_{\mathrm{e}}^2 m_{\mathrm{N}}}\frac{\alpha(Z\alpha)^5}{\pi^2 n^3}m_{\mathrm{e}}c^2\delta_{l0} \\
& \times\left[6\zeta(3) - 2\pi^2\ln 2 + \frac{35\pi^2}{36} - \frac{448}{27}\right. \\
& \left. + \frac{2}{3}\pi(Z\alpha)\ln^2(Z\alpha)^{-2} + \cdots\right] \,. \quad (28.123)
\end{aligned}
$$

The leading constant term in (28.123) is the sum of the analytic result for the electron-line contribution [28.123, 124] and the vacuum-polarization contribution [28.125, 126]. The log-squared term has been calculated by *Pachucki* and *Karshenboim* [28.63] and *Melnikov* and *Yelkhovski* [28.64].

For the uncertainty, we take a term of order $(Z\alpha)\ln(Z\alpha)^{-2}$ relative to the square brackets in (28.123) with numerical coefficients 10 for u_0 and 1 for u_n. These coefficients are roughly what one would expect for the higher-order uncalculated terms.

28.3.11 Nucleus Self Energy

An additional contribution due to the self energy of the nucleus has been given by *Pachucki* [28.126]:

$$
\begin{aligned}
E_{\mathrm{SEN}} = {} & \frac{4Z^2\alpha(Z\alpha)^4}{3\pi n^3}\frac{m_{\mathrm{r}}^3}{m_{\mathrm{N}}^2}c^2 \\
& \times\left[\ln\left(\frac{m_{\mathrm{N}}}{m_{\mathrm{r}}(Z\alpha)^2}\right)\delta_{l0} - \ln k_0(n,l)\right] \,.
\end{aligned}
$$
$$(28.124)$$

This correction has also been examined by *Eides* et al. [28.2], who consider how it is modified by the effect of structure of the proton. The structure effect leads to an additional model-dependent constant in the square brackets in (28.124).

To evaluate the nucleus self-energy correction, we use (28.124) and assign an uncertainty u_0 that corresponds to an additive constant of 0.5 in the square brackets for S states. For P and D states, the correction is small and its uncertainty, compared to other uncertainties, is negligible.

28.3.12 Total Energy and Uncertainty

The total energy E_{nLj}^X of a particular level (where $L = \mathrm{S}, \mathrm{P}, \dots$ and $X = \mathrm{H}, \mathrm{D}, \dots$) is the sum of the various contributions listed above plus an additive correction δ_{nLj}^X that accounts for the uncertainty in the theoretical expression for E_{nLj}^X. Our theoretical estimate of the value of δ_{nLj}^X for a particular level is zero with a standard uncertainty of $u\!\left(\delta_{nLj}^X\right)$ equal to the square root of the sum of the squares (rss) of the individual uncertainties of the contributions, since, as they are defined above, the contributions to the energy of a given level are independent. (Components of uncertainty associated with the fundamental constants are not explicitly shown here.) Thus we have for the square of the uncertainty, or variance, of a particular level

$$u^2(\delta_{nLj}^X) = \sum_i \frac{u_{0i}^2(XLj) + u_{ni}^2(XLj)}{n^6} \,, \qquad (28.125)$$

where the individual values $u_{0i}(XLj)/n^3$ and $u_{ni}(XLj)/n^3$ are the components of uncertainty from each of the contributions, labeled by i, discussed above. [The factors of $1/n^3$ are isolated so that $u_{0i}(XLj)$ is explicitly independent of n.]

Table 28.8 Measured transition frequencies ν in hydrogen

Authors	Laboratory	Frequency interval	Reported value ν/kHz
Hagley and *Pipkin* 28.127	Harvard Univ.	$\nu_H(2S_{1/2} - 2P_{3/2})$	9 911 200 (12)
Lundeen and *Pipkin* 28.128	Harvard Univ.	$\nu_H(2P_{1/2} - 2S_{1/2})$	1 057 845.0 (9.0)
Newton et al. 28.129	Univ. Sussex	$\nu_H(2P_{1/2} - 2S_{1/2})$	1 057 862 (20)

The covariance of any two δs follows from (F7) of Appendix F of [28.1]. For a given isotope X, we have

$$u\left(\delta^X_{n_1 L j}, \delta^X_{n_2 L j}\right) = \sum_i \frac{u^2_{0i}(XLj)}{(n_1 n_2)^3} , \qquad (28.126)$$

which follows from the fact that $u(u_{0i}, u_{ni}) = 0$ and $u(u_{n_1 i}, u_{n_2 i}) = 0$ for $n_1 \neq n_2$. We also set

$$u\left(\delta^X_{n_1 L_1 j_1}, \delta^X_{n_2 L_2 j_2}\right) = 0 , \qquad (28.127)$$

if $L_1 \neq L_2$ or $j_1 \neq j_2$. For covariances between δs for hydrogen and deuterium, we have for states of the same n

$$u\left(\delta^H_{nLj}, \delta^D_{nLj}\right) = \sum_{i=i_c} \frac{u_{0i}(HLj)u_{0i}(DLj) + u_{ni}(HLj)u_{ni}(DLj)}{n^6} , \qquad (28.128)$$

and for $n_1 \neq n_2$

$$u\left(\delta^H_{n_1 L j}, \delta^D_{n_2 L j}\right) = \sum_{i=i_c} \frac{u_{0i}(HLj)u_{0i}(DLj)}{(n_1 n_2)^3} , \qquad (28.129)$$

where the summation is over the uncertainties common to hydrogen and deuterium. In most cases, the uncertainties can in fact be viewed as common except for a known multiplicative factor that contains all of the mass dependence. We assume

$$u\left(\delta^H_{n_1 L_1 j_1}, \delta^D_{n_2 L_2 j_2}\right) = 0 , \qquad (28.130)$$

if $L_1 \neq L_2$ or $j_1 \neq j_2$. These covariances correspond to correlation coefficients as large as 0.991.

Since the transitions between levels are measured in frequency units (Hz), in order to apply the above equations for the energy level contributions we divide the theoretical expression for the energy difference ΔE of the transition by the Planck constant h to convert it to a frequency. Further, we replace the group of constants $\alpha^2 m_e c^2 / 2h$ in $\Delta E/h$ by cR_∞ to calculate the uncertainties.

28.3.13 Transition Frequencies Between Levels with $n = 2$

As an indication of the consistency of the theory summarized above and the experimental data, we list values of the transition frequencies between levels with $n = 2$ in hydrogen. These results are based on a variation of the 2002 least-squares adjustment in which the measurements of these particular transitions are not included [28.1]. The calculated values are

$$\nu_H(2P_{1/2} - 2S_{1/2}) = 1\,057\,844.5\,(2.6)\ \text{kHz} ,$$
$$\nu_H(2S_{1/2} - 2P_{3/2}) = 9\,911\,197.1\,(2.6)\ \text{kHz} ,$$
$$\nu_H(2P_{1/2} - 2P_{3/2}) = 10\,969\,041.57\,(89)\ \text{kHz} . \qquad (28.131)$$

These results compare favorably with the most recent experimental values given in Table 28.8.

In addition, in He$^+$, a recent experimental value of the Lamb shift is $\mathcal{S} = 14\,041.13\,(17)$ MHz [28.130], and the current theoretical value is $\mathcal{S} = 14\,041.474\,(42)$ MHz [28.131].

29. Parity Nonconserving Effects in Atoms

Until 1957 the invariance of the laws of physics under the process of parity inversion was assumed to hold. The concept of this invariance has its origin in atomic physics, where Laporte introduced it to explain certain aspects of the iron spectrum. The underlying theory of atomic structure, quantum electrodynamics (QED), is an example of a theory that has this invariance. However, it was shown in 1957 that weak interaction processes are not invariant under parity inversion. At that time the only known weak interactions were charge changing and thus did not affect the spectrum of a stable atom. However, if charge conserving, or neutral weak interactions exist, these can lead to

parity nonconserving (PNC) processes in atoms. These include electric dipole transitions between states of the same parity and optical rotation.

It is now well established that such interactions do exist, and are mediated by the Z boson. Unfortunately, because of the extremely small ratio of the energy scale of atoms to the Z mass, PNC processes in atoms must be correspondingly small. In 1974, however, the *Bouchiats* [29.1], in a paper that laid the foundation for the field, showed that parity nonconserving (PNC) transitions in heavy atoms with atomic number Z were enhanced by a factor of Z^3. While still very small, this effect has been observed in a variety of heavy atoms, specifically cesium ($Z = 55$) [29.2–4], thallium ($Z = 81$) [29.5,6], lead ($Z = 82$) [29.7], and bismuth ($Z = 83$) [29.8]. The accurate calculation of the electronic structure of such atoms is of course a very challenging atomic physics problem, and such calculations must be carried out before the experiments can be interpreted in terms of particle physics. This problem is not present for hydrogen, but experimental problems have impeded progress in this direction.

At the time of the Bouchiats's paper, the question of whether or not neutral currents existed was an important problem in weak interaction physics, and even a qualitative observation of atomic PNC would have been of great interest. However, now that neutral currents are well established, what now has become the most important aspect of atomic PNC is the precise measurement of the effect. This is because of the present

intense interest in possible modifications of the standard model. While this model, described in more detail in the next section, is extremely successful, it is incomplete in some ways, in particular, in the way particle masses are treated. In the standard model, for example, the mystery of the fermion mass spectrum is simply transferred to another mystery of the sizes of Yukawa coupling constants that couple Higgs fields to fermions. It is hoped that some deviation from the standard model will be uncovered, generally referred to as 'new physics', that will provide a hint as to a more satisfactory theory. At the present time, since all standard model predictions are in agreement with experiment at the few percent level, the hoped for deviation will be small; and for this reason high precision experiments combined with calculations of similar accuracy are needed. For this reason atomic PNC, while apparently a somewhat esoteric branch of atomic physics, actually is involved with one of the most central problems of the field, the accurate solution of the Schrödinger equation for many-electron atoms. We will describe an approach to this fundamental problem below.

Another weak interaction effect important in atomic physics has to do with CP noninvariance. While the weak interactions are not invariant under parity inversion (P), until 1964 it appeared that they were invariant under the simultaneous operations of P and charge con-

jugation (C), or CP. In 1964, however, measurements of the neutral K meson system showed that CP invariance is slightly broken. While this does not directly affect atomic physics, it has been suggested that this still incompletely explained breaking in the quark sector may have a counterpart in the lepton sector, which could have, as a consequence, a nonvanishing electron electric dipole moment (edm). This opens the possibility of using precise atomic experiments to search for such an effect. In this case, as with 'ordinary' PNC, a calculation of atomic structure is necessary. The requirements of precision are not as important in this case, as the simple detection of a non-zero atomic edm would be a discovery of importance comparable to the detection of CP noninvariance in the kaon system. Because of limitations of space, we do not discuss this interesting field further, referring the interested reader to the review of the subject given in [29.9].

29.1 The Standard Model

The Standard Model is the present theory of the strong, weak, and electromagnetic interactions. We are concerned with the part of the standard model that unifies the weak and electromagnetic interactions, which is referred to as the electroweak theory. This theory involves the interactions of leptons and quarks with four vector bosons, the photon (A), a heavy neutral partner of the photon (Z), and two charged bosons (W$^+$, W$^-$). Interactions involving the photon conserve parity, while interactions between the other bosons do not. The neutral currents affecting atomic PNC are described by the following Lagrangian:

$$L = -e \sum_i q_i \bar{\psi}_i \gamma_\mu \psi_i A^\mu - \frac{e}{\sin 2\theta_W}$$
$$\times \sum_i \bar{\psi}_i \gamma_\mu (V_i - A_i \gamma_5) \psi_i Z^\mu , \qquad (29.1)$$

where i ranges over three types of fermions, the electron $\left(q_e = -1, V_e = -\frac{1}{2} + 2\sin^2\theta_W, A_e = -\frac{1}{2}\right)$, the up quark $\left(q_u = \frac{2}{3}, V_u = \frac{1}{2} - \frac{4}{3}\sin^2\theta_W, A_u = \frac{1}{2}\right)$, and the down quark $\left(q_d = -\frac{1}{3}, V_d = -\frac{1}{2} + \frac{2}{3}\sin^2\theta_W, A_d = -\frac{1}{2}\right)$. The weak angle θ_W is a fundamental parameter of the standard model and is discussed further below.

The physics in the above Lagrangian that leads to atomic PNC is the exchange of a virtual Z, either between a quark in the nucleus and an electron, or between two electrons, though calculations of the latter effect show it to be negligible [29.10]. PNC arises when the Z matrix element is a vector on the nucleus and an axial vector on the electron ($V_N A_e$), or vice versa ($A_N V_e$). The dominant PNC contribution comes from the former case, because all the quarks contribute coherently. The latter case, however, cannot be neglected and is discussed further below. Because the nuclear current is of vector nature, one can introduce a conserved charge, the weak charge Q_W,

$$Q_W = 2Z(2V_u + V_d) + 2N(V_u + 2V_d) . \qquad (29.2)$$

Here Z is the number of protons and N the number of neutrons. Putting in the above values of V_u and V_d then gives

$$Q_W = Z(1 - 4\sin^2\theta_W) - N . \qquad (29.3)$$

It would appear that the dependence of Q_W on the weak angle would allow its determination from atomic PNC. While this can be done, it is important to note that the above discussion has been at the tree level. One of the most important features of the electroweak theory is that radiative corrections can be calculated. These corrections enter at the percent level, and must be included for an accurate interpretation of experiments sensitive to electroweak effects. Until recently, of the parameters affecting the electroweak theory only the fine structure constant and the muon decay rate were known with high precision, leaving the weak angle a free parameter. However, now that the Z mass has been measured with very high precision, it is now possible to use that measurement to determine θ_W, and to then predict a large set of radiatively corrected electroweak processes, including atomic PNC [29.11]. While there is still some sensitivity to the top quark and Higgs masses, as discussed further below, using the Z mass allows the prediction for cesium of, assuming a Higgs mass of 100 GeV,

$$Q_W = -73.20(0.13) . \qquad (29.4)$$

Therefore, the importance of atomic PNC for fundamental physics is not so much its ability to determine the weak angle, but rather the fact that the standard model makes a definite prediction for the size of the effect, and any disagreement indicates new physics; and conversely, agreement to within a given precision puts limits on new physics.

29.2 PNC in Cesium

We concentrate on PNC in cesium because it is the simplest atom in which the effect has been measured. This is because it consists of a single electron outside a closed xenonlike core which is relatively unpolarizable. This should be contrasted with, for example, thallium. While thallium nominally also consists of one $6p_{1/2}$ electron outside a closed core, part of that core is a filled $6s_{1/2}^2$ subshell. It is quite easy to polarize the outer subshell, so that one really has three electrons outside a closed core. This leads to distinctly poorer convergence properties of many-body perturbation theory, the theoretical method used for these calculations, and consequently less accurate atomic theory predictions. Similar considerations apply to lead and bismuth. The PNC transition in cesium that has been studied is $6s_{1/2} \rightarrow 7s_{1/2}$, and accurate measurements have been made in *Paris* [29.2] and *Boulder* [29.3, 4]. Cesium is a 55 electron atom with a nucleus consisting of 78 neutrons and 55 protons with nuclear spin $I = 7/2$. The total angular momentum of atomic s-states is then $F = 3$ or $F = 4$. Both of the transitions, $6s_{1/2}(F = 4) \rightarrow 7s_{1/2}(F = 3)$ and $6s_{1/2}(F = 3) \rightarrow 7s_{1/2}(F = 4)$, have been measured, allowing the isolation of PNC effects that depend on the spin of the nucleus. The bulk of atomic PNC comes from the timelike contribution of the $(V_N A_e)$ exchange discussed in the previous section, and can be described by the effective Hamiltonian

$$H_W = \frac{G_F}{\sqrt{8}} Q_W \rho_{nuc}(r)\gamma_5 . \tag{29.5}$$

Here $\rho_{nuc}(r)$ is a weighted average of the neutron and proton distributions in the nucleus, which leads to nuclear structure uncertainties that will be discussed below. Using this Hamiltonian, a large scale calculation [29.10] leads to the prediction for the nuclear-spin-independent part of the PNC transition

$$E_{PNC} = -0.905(9) \times 10^{-11} i|e|a_0(-Q_W/N) . \tag{29.6}$$

Here the unknown Q_W has been factored out and divided by its approximate value $-N$. This result is in good agreement with independent MBPT calculations of the Novosibirsk [29.12] and Göteborg [29.13] groups. When this is compared with the experimental measurement [29.3, 4]

$$E_{PNC}^{exp} = -0.8374(67) \times 10^{-11} i|e|a_0 , \tag{29.7}$$

there results a prediction for Q_W of

$$Q_W = -72.17(0.58)[0.72] , \tag{29.8}$$

where the first error is experimental and the second theoretical. The spacelike part of $(V_N A_e)$ exchange and the timelike part of $(A_N V_e)$ exchange are negligible, but the spacelike part of the latter gives a nuclear spin-dependent effect that will be discussed below. Also discussed below is an interesting nuclear physics source of PNC known as the *anapole* moment [29.14], which arises from photon exchange with weak radiative corrections on the nuclear vertex. This effect enters at the several percent level, but in a way that can be subtracted out as will be described below.

29.3 Many–Body Perturbation Theory

While there are a variety of ways of solving the many-electron Schrödinger equation, the most accurate treatments of cesium PNC are based on many-body perturbation theory (MBPT). In MBPT, the Hamiltonian is broken up into $H = H_0 + V_C$, where

$$H_0 = \sum_{i=1}^{N} \left[\boldsymbol{\alpha}_i \cdot \boldsymbol{p}_i + \beta_i m + U(r_i) \right] \tag{29.9}$$

and

$$V_C = \frac{1}{2} \sum_{ij} \frac{\alpha}{|\boldsymbol{r}_i - \boldsymbol{r}_j|} - \sum_{i=1}^{N} \left[\frac{Z\alpha}{r_i} + U(r_i) \right] . \tag{29.10}$$

The starting potential $U(r)$ is generally chosen to be a frozen core Hartree–Fock (HF) potential. This model of the atom is rather inaccurate: valence removal energies disagree with experiment by about 10%, and matrix elements of the hyperfine operator by about 40%. Thus it is essential for accurate calculations to include the effects of V_C as fully as possible. MBPT proceeds by expanding the many-body wave function and the energy in powers of V_C. While going to second order in V_C improves agreement with experiment to the percent level for energies and the few percent level for matrix elements [29.15], more powerful methods that sum infinite classes of MBPT contributions are needed for higher ac-

curacy, and we turn to a description of these *all order* methods.

If the frozen-core HF wave function is denoted by Ψ_0, all-order *singles–doubles* methods add to it a correction $\Delta\Psi$ with either one or two orbitals in the HF wave function excited:

$$
\delta\Psi = \bigg(\sum_{am} \rho_{ma} a_m^\dagger a_a + \sum_{abmn} \rho_{mnab} a_m^\dagger a_n^\dagger a_a a_b
$$
$$
+ \sum_m \rho_{mv} a_m^\dagger a_v + \sum_{amn} \rho_{mnav} a_m^\dagger a_n^\dagger a_a a_v \bigg) \Psi_0 .
$$
(29.11)

The terms on the first line of (29.11) describe single and double excitations of the closed core, while those on the second line describe single and double excitations of the atom where the valence orbital is also excited. Substituting (29.11) into the Schrödinger equation, one obtains a set of coupled equations for the expansion coefficients that can be found in [29.16]. The first and second iterations of the equations for the expansion coefficients leads to results that are identical to first- and second-order perturbation theory. In third-order perturbation theory, terms associated with triple excitations contribute to the energy. These terms have no counterpart in the iterative solution to the equations under consideration.

To account for such terms, it is necessary to add to $\Delta\Psi$ a triple-excitation correction of the specific form:

$$
\Delta\Psi = \bigg(\sum_{abcmnr} \rho_{mnrabc} a_n^\dagger a_m^\dagger a_r^\dagger a_a a_b a_c
$$
$$
+ \sum_{abmnr} \rho_{mnrabv} a_n^\dagger a_m^\dagger a_r^\dagger a_a a_b a_v \bigg) \Psi_0 .
$$
(29.12)

Such a term enters in two ways. First, there are a set of equations giving the triple-excitation coefficients in terms of the single-, double-, and triple-excitation coefficients. Second, the triple-excitation coefficients enter on the right-hand side of the equations for the single- and double-excitation coefficients. Solving for the triple-excitation coefficients in terms of the singles and doubles (ignoring the triples on the right-hand sides of these equations), one can use them on the right-hand sides of the equations for the singles. This procedure leads to equations which, when iterated to third order, include all of the terms from MBPT. However, the triples also modify the the doubles equation, and this more computationally demanding step has not yet been implemented. As the effects of this modification enter first in fourth-order MBPT, the calculation is complete through third order, but still misses some fourth-order contributions. Nevertheless, the method is accurate enough to predict PNC to 1%. Greater accuracy is expected when the doubles equation is modified, which should lead to a calculation complete through fourth order, and work on this problem is in progress.

29.4 PNC Calculations

The above discussion of MBPT allows the calculation on cesium to be accurate to a few tenths of percent for energies and under one percent for 'ordinary' matrix elements [29.16], and thus should allow a calculation of similar accuracy for PNC. To calculate such transitions, one modifies H_0 by adding the weak-interaction h_W to the HF potential. This approach leads to a generalization of the single-particle states in which each state acquires an opposite-parity admixture, that is,

$$
\phi_k \to \phi_k + \tilde{\phi}_k .
$$
(29.13)

Thus, for example, each $s_{1/2}$ orbital will pick up a small $p_{1/2}$ state admixture. One can then calculate a PNC transition along the lines of a parity allowed transition calculation, simply replacing each orbital occuring in the MBPT formulas in turn with its opposite parity admixture. Details of this approach can be found in [29.10].

There are a number of smaller effects that must be considered when the 1% level of accuracy is reached. The first stems from the fact that the Z couples to the density of up and down quarks, which in turn is related to the density of protons and neutrons in the cesium nucleus. While experimental data is available on the charge distribution [29.17], the neutron distribution is available only theoretically. While this uncertainty can be shown to be unimportant for Cs^{133} [29.10], there has been interest in looking at PNC in several different isotopes with the aim of taking ratios and greatly reducing atomic physics uncertainties. However, the neutron distribution in different nuclei is more uncertain, and taking the ratio enhances the nuclear physics uncertainty. This issue has been addressed recently by *Chen* and *Vogel* [29.18], who estimate the nuclear physics uncertainties to be smaller than the anticipated experimental error.

The next small effect is the interaction between the nuclear axial-vector current and the electron vector current from Z exchange. In the limit of nonrelativistic nucleon motion, this interaction is given by the spin-dependent Hamiltonian

$$h_{\mathrm{W}}^{(2)} = -\frac{G}{\sqrt{2}} K_2 \frac{\kappa - 1/2}{I(I+1)} \boldsymbol{\alpha} \cdot \boldsymbol{I} \rho(r) \ . \qquad (29.14)$$

Here, $\kappa = 4$, $I = 7/2$ and $K_2 \simeq -0.05$ for the valence proton of ^{133}Cs. Additionally, parity violation in the nucleus leads to a parity-violating nuclear moment, the anapole moment mentioned above, that couples electromagnetically to the atomic electrons. The anapole–electron interaction is described by a Hamilto-nian similar to (29.14), with K_2 replaced by $-\kappa/(\kappa - 1/2)K_a$, where $K_a = 0.24 - 0.33$ is determined from nuclear model calculations [29.19]. Linear combinations of amplitudes for different $F \to F'$ transitions can be used to isolate either the spin-dependent or spin-independent parts of the interaction. The final smaller effects are Z exchange between the electrons, which as mentioned above turns out to be negligible, and the inclusion of the Breit interaction. While the original estimate of the latter was a small 0.2% effect, included in (29.6), this turned out to be an underestimate, one of a number of unexpectedly large contributions found in recent years, as discussed in the next section.

29.5 Recent Developments

The Breit interaction was reexamined by *Derevianko* [29.20] and found to be significantly larger than the 0.2% mentioned above. The 0.6% includes the effects of negative energy states, which are enhanced in the context of PNC. This was followed by the discovery of a number of effects that contributed at the several tenths of a percent level, with theory and experiment going into and out of agreement with one another as each effect was found. At present the situation has stabilized, and, as will be discussed in the next section, no discrepancy with the standard model is present. In the past eight years, the principal developments have been the discovery of a surprisingly large two-loop radiative correction associated with vacuum polarization [29.21, 22], recalculation of the atomic physics part of the calculation [29.23], which, however, only reduced the theoretical error bar, an independent measurement of the polarizability of cesium [29.24], and the discovery that the self-energy radiative correction, which in lowest order is $-\alpha/2\pi$, and is included in the radiative corrections to Q_{W} presented in [29.11], is strongly enhanced by binding corrections starting at order $Z\alpha$ [29.25–27]. When taken together, these different effects tend to cancel, so the qualitative picture of agreement with the standard model remains correct.

29.6 Comparison with Experiment

We can now make use of the above analysis to extract the value of the weak charge Q_{W} from experiment. The PNC amplitudes measured by *Wieman* et al. [29.3, 4] are

$$\frac{\Im(E_{\mathrm{PNC}})}{\beta} = \begin{cases} -1.6349(80) & F = 4 \to 3 \\ -1.5576(77) & F = 3 \to 4 \end{cases} \qquad (29.15)$$

in units of mV/cm. The quantity β is the vector part of the Stark induced polarizability for the $6s \to 7s$ transition in cesium. This quantity has also been calculated with an accuracy of better than 1% using the all-order techniques outlined above, giving $\beta = 27.00(20)a_0^3$. We note that this quantity can also be obtained from experiment, but at present two recent experiments [29.3, 4, 24] are in disagreement, so we use the number ob-tained from theory. Eliminating the spin-dependence from (29.15), by taking an appropriate linear combination and using the theoretical value for β, one finds

$$\Im\left(E_{\mathrm{PNC}}^{\mathrm{exp}}\right) = -0.8252(184)[61]10^{-11}|e|a_0 \ , \qquad (29.16)$$

where the the first error is from experiment and the second from theory. Combining this result with our calculation of the spin-independent amplitude given in (29.6), we obtain

$$Q_{\mathrm{W}} = -72.17(0.58)[0.72] \ . \qquad (29.17)$$

Alternatively, taking the opposite linear combination to eliminate the spin-independent terms in (29.15), we

obtain the value

$$K_a - (\kappa - 1/2)/\kappa K_2 = 0.72 \pm 0.10 \qquad (29.18)$$

for the constant governing the spin-dependent interaction.

Radiative corrections to the weak charge Q_W incorporating a parameterization of new physics beyond the standard model have been worked out by *Marciano* and *Rosner* [29.11], who find

$$Q_W\left(^{133}Cs_{55}\right) = -73.20 - 0.8S - 0.005T \pm 0.13 , \qquad (29.19)$$

assuming the values $m_t = 140\,\text{GeV}$ for the top quark mass and $m_H = 100\,\text{GeV}$ for the Higgs particle mass. The parameters S and T in (29.19) are associated partly with deviations of the top quark and Higgs masses from their assumed values and partly with new physics beyond the standard model. In the absence of new physics, the small factor multiplying T makes this prediction very insensitive to the top quark mass. Unfortunately, both the experimental and theoretical errors are presently too large to make atomic PNC in cesium a precision test of the standard model. However, there are two features of cesium PNC that even at the present accuracy lead to particle physics implications. The first is the fact that large positive values of S, such as can arise in technicolor theories [29.28], will lead to disagreement of theory and experiment in cesium PNC. The second is the effect of extra Z bosons, which is not accounted for in (29.19). Exchange of new Z's can be shown to be strongly constrained by atomic PNC [29.29]. Perhaps more interesting is the possibility of having entirely new physics that has not been thought of. Since new physics affects different weak interaction tests differently, it is important to have as many such tests as possible. The value of atomic PNC tests will increase when the next stage of accuracy is reached, at which time atomic physics will have a significant role in precision tests of the standard model.

30. Atomic Clocks and Constraints on Variations of Fundamental Constants

Fundamental constants play an important role in modern physics, being landmarks that designate different areas. We call them constants, however, as long as we only consider minor variations with the cosmological time/space scale, their constancy is an experimental fact rather than a basic theoretical principle. Modern theories unifying gravity with electromagnetic, weak, and strong interactions, or even the developing quantum gravity itself often suggest such variations.

Many parameters that we call *fundamental constants*, such as the electron charge and mass [30.1, 2], are actually not truly fundamental constants but effective parameters which are affected by renormalization or the presence of matter [30.3]. Living in a changing universe we cannot expect that matter will affect these parameters the same way during any given cosmological epoch. An example is the inflationary model of the universe which states that in a very early epoch the universe experienced a phase transition which, in particular, changed a vacuum average of the so-called Higgs field which determines the electron mass. The latter was zero before this transition and reached a value close or equal to the present value after the transition.

The problem of variations of constants has many facets and here we discuss aspects related to atomic clocks and precision frequency

measurements. Other related topics may be found in [30.4].

Laboratory searches for a possible time variation of fundamental physical constants currently consist of two important parts: (i) one has to measure a certain physical quantity at two different moments of time that are separated by at least a few years; (ii) one has to be able to interpret the result in terms of fundamental constants. The latter is a strong requirement for a cross comparison of different results.

The measurements which may be performed most accurately are frequency measurements; and thus, frequency standards or atomic clocks will be in-

volved in most of the laboratory searches. Frequency metrology has shown great progress in the last decade and will continue to do so for some time. The constraints on the variations of the fundamental constants obtained in this manner are, so far, somewhat weaker than those from other methods (astrophysics, geochemistry), but still competitive with them. In contrast to other methods, however, frequency measurements allow a very clear interpretation of the final results and a transparent evaluation procedure, making them less vulnerable to systematic

errors. While there is still potential for improvement, the basic details of the method have been recently fixed.

The most advanced atomic clocks are discussed in Sect. 30.1. They are realized with many-electron atoms and their frequency cannot be interpreted in terms of fundamental constants. However, a much simpler problem needs to be solved: to interpret their variation in terms of fundamental constants. This idea is discussed in Sect. 30.2. The current laboratory constraints on the variations of the fundamental constants are summarized in Sect. 30.3.

30.1 Atomic Clocks and Frequency Standards

Frequency standards are important tools for precision measurements and serve various purposes which, in turn, have different requirements that must be satisfied. In particular, it is not necessary for a frequency standard to reproduce a frequency which is related to a certain atomic transition although it may be expressed in its terms. A well known example is the hydrogen maser, where the frequency is affected by the wall shift which may vary with time [30.5]. For the study of time variations of fundamental constants it is necessary to use standards similar to a primary caesium clock. In this case, any deviation of its frequency from the unperturbed atomic transition frequency should be known (within a known uncertainty) because this is a necessary requirement for being a 'primary' standard.

From the point of view of fundamental physics, the hydrogen maser is an artefact quite similar, in a sense, to the prototype of the kilogram held at the Bureau International des Poids et Mesures (BIPM) in Paris. Both artefacts are somehow related to fundamental constants (e.g., the mass of the prototype can be expressed in terms of the nucleon masses and their number) but they also have a kind of residual classical-physics flexibility which allows their properties to change. In contrast, standards similar to the caesium clock have a frequency (or other property) that is determined by a certain natural constant which is not flexible, being of pure quantum origin. It may change only if the fundamental constants are changing.

In Sect. 30.3, results obtained with caesium and rubidium fountains, a hydrogen beam, ultracold calcium clouds, and trapped ions of ytterbium and mercury are discussed. While caesium and rubidium clocks operate in the radio frequency domain, most of the other standards listed above rely on optical transitions.

30.1.1 Caesium Atomic Fountain

Caesium clocks are the most accurate primary standards for time and frequency [30.6]. The hyperfine splitting frequency between the $F = 3$ and $F = 4$ levels of the $^2S_{1/2}$ ground state of the ^{133}Cs atom at 9.192 GHz has been used for the definition of the SI second since 1967. In a so-called caesium fountain (Fig. 30.1), a dilute cloud of laser cooled caesium atoms at a temperature of about $1\,\mu$K is launched upwards to initiate a free parabolic flight with an apogee at about 1 m above the cooling zone. A microwave cavity is mounted near the lower endpoints of the parabola and is traversed by the atoms twice – once during ascent, once during descent – so that Ramsey's method of interrogation with separated oscillatory fields [30.5] can be realized. The total interrogation time being on the order of 0.5 s, a resonance linewidth of 1 Hz is achieved, about a factor of 100 narrower than in traditional devices using a thermal atomic beam from an oven. Selection and detection
Fig. 30.1 Schematic of an atomic fountain clock

of the hyperfine state is performed via optical pumping and laser induced resonance fluorescence. In a carefully controlled setup, a relative uncertainty slightly below 1×10^{-15} can be reached in the realization of the resonance frequency of the unperturbed Cs atom. The averaging time that is required to reach this level of uncertainty is on the order of 10^4 s. One limiting effect that contributes significantly to the systematic uncertainty of the caesium fountain is the frequency shift due to cold collisions between the atoms. In this respect, a fountain frequency standard based on the ground state hyperfine frequency of the ^{87}Rb atom at about 6.835 GHz is more favorable, since its collisional shift is lower by more than a factor of 50 for the same atomic density. With the caesium frequency being fixed by definition in the SI system, the ^{87}Rb frequency is therefore presently the most precisely measured atomic transition frequency [30.7].

30.1.2 Single-Ion Trap

An alternative to interrogating atoms in free flight, and a possibility to obtain practically unlimited interaction time, is to store them in a trap. Ions are well suited because they carry electric charge and can be trapped in radio frequency ion traps (Paul traps [30.8]) that provide confinement around a field-free saddle point of an electric quadrupole potential. This ensures that the internal level structure is only minimally perturbed by the trap. Combined with laser cooling it is possible to reach the so-called Lamb–Dicke regime where the linear Doppler shift is eliminated. A single ion, trapped in an ultrahigh vacuum is conceptually a very simple system that allows good control of systematic frequency shifts [30.9]. The use of the much higher, optical reference frequency allows one to obtain a stability that is superior to microwave frequency standards, although only a single ion is used to obtain a correction signal for the reference oscillator.
Fig. 30.2 Double resonance scheme applied in single-ion-trap frequency standards

A number of possible reference optical transitions with a natural linewidth of the order of 1 Hz and below are available in different ions, such as Yb$^+$ [30.10] and Hg$^+$ [30.11, 12]. These ions possess a useful level system, where both a dipole-allowed transition and a forbidden reference transition of the optical clock can be driven with two different lasers from the ground state (Fig. 30.2). The dipole transition is used for laser cooling and for the optical detection of the ion via its resonance fluorescence. If a second laser excites the ion to the metastable upper level of the reference transition, the fluorescence disappears and every single excitation can thus be detected with practically hundred percent efficiency as a dark period in the fluorescence signal.

Using these techniques and a femtosecond laser frequency comb generator (see Sect. 30.1.5) for the link to primary caesium clocks, the absolute frequencies of the transitions $^2S_{1/2} \to {}^2D_{5/2}$ in ^{199}Hg$^+$ at 1065 THz and $^2S_{1/2} \to {}^2D_{3/2}$ in ^{171}Yb$^+$ at 688 THz have been measured with relative uncertainties of only 9×10^{-15}. It is believed that single-ion optical frequency standards offer the potential to ultimately reach the 10^{-18} level of relative accuracy.

A similar double resonance technique can be employed if the reference transition is in the microwave domain and a number of accurate measurements of hyperfine structure intervals in trapped ions has been performed. In particular, the HFS interval in ^{171}Yb$^+$ has been measured several times [30.13–15] and can be used to obtain constraints on temporal variations.

30.1.3 Laser-Cooled Neutral Atoms

Optical frequency standards have been developed with free laser-cooled neutral atoms, most notably of the alkaline-earth elements that possess narrow intercombination transitions. The atoms are collected in a magneto-optical trap, are then released and interogated by a sequence of laser pulses to realize a frequency-sensitive Ramsey–Bordé atom interferometer [30.16]. Of these systems, the one based on the $^1S_0 \to {}^3P_1$ intercombination line of ^{40}Ca at 657 nm has reached the lowest relative uncertainty so far (about 2×10^{-14}) [30.11, 12, 17, 18]. Limiting factors in the uncertainty of these standards are the residual linear Doppler effect and phase front curvature of the laser beams that excite the ballistically expanding atom cloud. It has therefore been proposed to confine the atoms in an optical lattice, i. e., in the array of interference maxima produced by several intersecting, red-detuned laser beams [30.19]. The detuning of the

trapping laser could be chosen such that the light shift it produces in the ground and excited state of the reference transition are equal, and therefore it would produce no shift of the reference frequency. This approach is presently being investigated and may be applied to the very narrow (mHz natural linewidth) $^1S_0 \rightarrow {}^3P_0$ transitions in neutral strontium, ytterbium, or mercury.

30.1.4 Two-Photon Transitions and Doppler-Free Spectroscopy

The linear Doppler shift of an absorption resonance can also be avoided if a two-photon excitation is induced by two counterpropagating laser beams. A prominent example that has been studied with high precision is the two-photon excitation of the $^1S \rightarrow {}^2S$ transition in atomic hydrogen. The precise measurement of this frequency is of importance for the determination of the Rydberg constant and as a test of quantum electrodynamics (QED). Hydrogen atoms are cooled by collisions in a cryogenic nozzle and interact with a standing laser-wave of 243 nm wavelength inside a resonator. Since the atoms are not as cold as in laser cooled samples, a correction for the second order Doppler effect is performed. The laser excitation is interrupted periodically and the excited atoms are detected in a time resolved manner so that their velocity can be examined. An accuracy of about 2×10^{-14} has been obtained in absolute frequency measurements with a transportable caesium fountain [30.20, 21].

30.1.5 Optical Frequency Measurements

In recent years, the progress in stability and accuracy of optical frequency standards has been impressive; and there is belief that in the future an optical clock may supersede the microwave clocks because the optical oscillators offer a much higher number of periods in a given time. In addition, some systematic effects, such as the Zeeman effect, have an absolute order of magnitude that does not scale with the transition frequency, and consequently is relatively less important at higher transition frequencies. A long-standing problem, however, was the precise conversion of an optical frequency to the microwave domain, where frequencies can be counted electronically in order to establish a time scale or can easily be compared in a phase coherent way.

This problem has recently been solved by the so-called femtosecond laser frequency comb generator [30.22]. Briefly, a mode-locked femtosecond laser
Fig. 30.3 Frequency comb generated from femtosecond laser pulses

produces, in the frequency domain, a comb of equally spaced optical frequencies f_n (Fig. 30.3) that can be written as $f_n = n f_r + f_{ceo}$ (with $f_{ceo} < f_r$), where f_r is the pulse repetition rate of the laser, the mode number n is a large integer (of order 10^5), and f_{ceo} (carrier-envelope-offset) is a shift of the whole comb that is produced by group velocity dispersion in the laser. The repetition rate f_r can easily be measured with a fast photodiode. In order to determine f_{ceo}, the comb is broadened in a nonlinear medium so that it covers at least one octave. Now the second harmonic of mode n from the "red" wing of the spectrum, at frequency $2(n f_r + f_{ceo})$, can be mixed with mode $2n$ from the "blue" wing, at frequency $2n f_r + f_{ceo}$, and f_{ceo} is obtained as a difference frequency. In this way, the precise relation between the two microwave frequencies f_r and f_{ceo} and the numerous optical frequencies f_n is known. The setup can now be used for an absolute optical frequency measurement by referencing f_r and f_{ceo} to a microwave standard and recording the beat note between the optical frequency f_o to be measured and the closest comb frequency f_n. Vice versa, the setup may work as an optical clockwork, for example, by adjusting f_{ceo} to zero and by stabilizing one comb line f_n to f_o so that f_r is now an exact subharmonic to order n of f_o. The precision of these transfer schemes has been investigated and was found to be so high that it will not limit the performance of optical clocks for the foreseeable future.

30.1.6 Limitations on Frequency Variations

The frequency standards described above have been succesfully developed and their accuracy has been improved

Table 30.1 Limits on possible time variation of frequencies of different transitions in SI units. Here $\delta f/f$ is the fractional uncertainty of the most accurate measurement of the frequency f

Atom, transition	f GHz	$\delta f/f$ (10^{-15})	$\Delta f/\Delta t$ (Hz/yr)	Ref.
H, Opt	2 466 061	14	-8 ± 16	[30.20, 21]
Ca, Opt	455 986	13	-4 ± 5	[30.17, 18]
Rb, HFS	6.835	1	$(0 \pm 5) \times 10^{-6}$	[30.7]
Yb$^+$, Opt	688 359	9	-1 ± 3	[30.23]
Yb$^+$, HFS	12.642	73	$(4 \pm 4) \times 10^{-4}$	[30.13–15]
Hg$^+$, Opt	1 064 721	9	0 ± 7	[30.11, 12]

in the last decade. This progress, as a consequence, has led to certain constraints on the possible variations of the fundamental constants. Considering frequency varia-

tions, one has to have in mind that not only the numerical value but also the units may vary. For this reason, one needs to deal with dimensionless quantities which are unit-independent. During the last decade, a number of transition frequencies were measured in the corresponding SI unit, the hertz (see Table 30.1). These dimensional results are actually related to dimensionless quantities since a frequency measurement in SI is a measurement with respect to the caesium hyperfine interval

$$\{f\} = 9\,192\,631\,770 \cdot \frac{f}{f_{\mathrm{HFS}}(\mathrm{Cs})} , \tag{30.1}$$

where $\{f\}$ stands for the numerical value of the frequency f. (Most absolute frequency measurements have been realized as a direct comparison with a primary caesium standard.) In Sect. 30.3, in order to simplify notation, this symbol for the numerical value is dropped.

30.2 Atomic Spectra and their Dependence on the Fundamental Constants

30.2.1 The Spectrum of Hydrogen and Nonrelativistic Atoms

The hydrogen atom is the simplest atom and one can easily calculate the leading contribution to different kinds of transitions in its spectrum [30.24, 25], such as the gross, fine, and hyperfine structure. The scaling behavior of these contributions with the values of the Rydberg constant R_∞, the fine structure constant α, and the magnetic moments of proton and Bohr magneton is clear. The results for some typical hydrogenic transitions are

$$f(2\mathrm{p} \to 1\mathrm{s}) \simeq \frac{3}{4} c R_\infty ,$$

$$f\left(2\mathrm{p}_{3/2} - 2\mathrm{p}_{1/2}\right) \simeq \frac{1}{16} \alpha^2 c R_\infty ,$$

$$f_{\mathrm{HFS}}(1\mathrm{s}) \simeq \frac{4}{3} \alpha^2 \frac{\mu_{\mathrm{p}}}{\mu_{\mathrm{B}}} c R_\infty . \tag{30.2}$$

In the nonrelativistic approximation, the basic frequencies and the fine and hyperfine structure intervals of all atomic spectra have a similar dependence on the fundamental constants. The presence of a few electrons and a nuclear charge of $Z \neq 1$ makes theory more complicated and introduces certain multiplicative numbers but involves no new parameters. The importance of this scaling for a search for the variations was first pointed out in [30.26] and was applied to astrophysical

data. Similar results may be presented for molecular transitions (electronic, vibrational, rotational and hyperfine) [30.27], however, up to now no measurement with molecules has been performed at a level of accuracy that is competitive with atomic transitions. They have been used only in a search for variations of constants in astrophysical observations [30.28].

30.2.2 Hyperfine Structure and the Schmidt Model

The atomic hyperfine structure

$$f_{\mathrm{NR}}(\mathrm{HFS}) = \mathrm{const}\,\alpha^2 \frac{\mu}{\mu_{\mathrm{B}}} c R_\infty \tag{30.3}$$

involves nuclear magnetic moments μ which are different for different nuclei; thus, a comparison of the constraints on the variations of nuclear magnetic moments has a reduced value. To compare them, one may apply the Schmidt model [30.3, 29], which predicts all the magnetic moments of nuclei with an odd number of nucleons (odd value of atomic number A) in terms of the proton and neutron g-factors, g_{p} and g_{n}, respectively, and the nuclear magneton only. Unfortunately, the uncertainty of the calculation within the Schmidt model is quite high (usually from 10% to 50%). The Schmidt model, being a kind of ab initio model, only allows for improvements which, unfortunately, involve some effective phenomenological parameters. This would not

really improve the situation, but return us to the case where there are too many possibly varying independent parameters. A comparison of the Schmidt values to the actual data is presented for caesium, rubidium, and ytterbium in Table 30.2.

30.2.3 Atomic Spectra: Relativistic Corrections

A theory based on the leading nonrelativistic approximation may not be accurate enough. Any atomic frequency can be presented as

$$f = f_{NR}\, F_{rel}(\alpha)\ ,   (30.4)$$

where the first (nonrelativistic) factor is determined by a scaling similar to the hydrogenic transitions (30.2). The second factor stands for relativistic corrections which vanish at $\alpha = 0$; and thus, $F_{rel}(0) = 1$.

The importance of relativistic corrections for the hyperfine structure was first emphasized in [30.30]. Relativistic many-body calculations for various transitions have been performed in [30.31–36]. A typical accuracy is about 10%. Some results are summarized in Tables 30.2 and 30.3, where we list the relative sensitivity of the relativistic factors F_{rel} to changes in α,

$$\kappa = \frac{\partial \ln F_{rel}}{\partial \ln \alpha}\ .   (30.5)$$

Note that the relativistic corrections in heavy atoms are proportional to $(Z\alpha)^2$ because of the singularity of relativistic operators. Due to this, the corrections rapidly increase with the nuclear charge Z.

The signs and magnitudes of κ are explained by a simple estimate of the relativistic correction. For example, an approximate expression for the relativistic correction factor for the hyperfine structure of an s-wave electron in an alkali-like atom is [30.30]

$$F_{rel}(\alpha) = \frac{1}{\sqrt{1-(Z\alpha)^2}} \cdot \frac{1}{1-(4/3)(Z\alpha)^2}$$
$$\simeq 1 + \frac{11}{6}(Z\alpha)^2\ .$$

Table 30.2 Magnetic moments and relativistic corrections for atoms involved in microwave standards. The relativistic sensitivity κ is defined in Sect. 30.2.3. Here μ is an actual value of the nuclear magnetic moment, μ_N is the nuclear magneton, and μ_S stands for the Schmidt value of the nuclear magnetic moment; the nucleon g factors are $g_p/2 \simeq 2.79$ and $g_n/2 \simeq -1.91$

Z	Atom	μ/μ_N	μ_S/μ_N	μ/μ_S	κ
37	^{87}Rb	2.75	$g_p/2+1$	0.74	0.34
55	^{133}Cs	2.58	$7/18 \cdot (10-g_p)$	1.50	0.83
70	^{171}Yb$^+$	0.49	$-g_n/6$	0.77	1.5

Table 30.3 Limits on possible time variation of the frequencies of different transitions and their sensitivity to variations in α due to relativistic corrections

Atom, transition	$\partial f / f \partial t$	κ
H, $1s - 2s$	$-3.2(63) \times 10^{-15}$ yr^{-1}	0.00
^{40}Ca, ^{1}S$_0 - ^3$P$_1$	$-8(11) \times 10^{-15}$ yr^{-1}	0.03
^{171}Yb$^+$, ^{2}S$_{1/2} - ^2$D$_{3/2}$	$-1.2(44) \times 10^{-15}$ yr^{-1}	0.9
^{199}Hg$^+$, ^{2}S$_{1/2} - ^2$D$_{5/2}$	$-0.2(70) \times 10^{-15}$ yr^{-1}	-3.2

A similar rough estimation for the energy levels may be performed for the gross structure:

$$E = -\frac{Z_a^2 mc^2 \alpha^2}{2n_*^2}\left(1 + \frac{(Z\alpha)^2}{n_*}\frac{1}{j+1/2}\right)\ .   (30.6)$$

Here j is the electron angular momentum, n_* is the effective value of the principle quantum number (which determines the nonrelativistic energy of the electron), and Z_a is the charge "seen" by the valence electron – it is 1 for neutral atoms, 2 for singly charged ions, etc. This equation tells us that κ, for the excitation of the electron from the orbital j to the orbital j', has a different sign for $j > j'$ and $j < j'$. The difference of sign between the sensitivities of the ytterbium and mercury transitions in Table 30.3 reflects the fact that in Yb$^+$ a 6s-electron is excited to the empty 5d-shell, while in Hg$^+$ a hole is created in the filled 5d-shell if the electron is excited to the 6s-shell.

30.3 Laboratory Constraints on Time the Variations of the Fundamental Constants

Logarithmic derivatives (30.5) appear since we are looking for a variation of the constants in relative units. In other words, we are interested in a determination of, e.g., $\Delta\alpha/\alpha\Delta t$ while the input data of interest are related to $\Delta f/f\Delta t$. Their relation takes the form

$$\frac{\partial \ln f}{\partial t} = \frac{\partial \ln f_{NR}}{\partial t} + \kappa \frac{\partial \ln \alpha}{\partial t}\ .   (30.7)$$

If one compares transitions of the same type – gross structure, fine structure – the first term cancels.

30.3.1 Constraints from Absolute Optical Measurements

Absolute frequency measurements offer the possibility to compare a number of optical transitions with frequencies f_{NR}, which scale as cR_∞, with the caesium hyperfine structure. One can rewrite (30.7) as

$$\frac{\partial \ln f_{opt}}{\partial t} = \frac{\partial \ln cR_\infty}{\partial t} + \kappa \frac{\partial \ln \alpha}{\partial t} , \qquad (30.8)$$

where dimensional quantities, such as frequency and the Rydberg constant, are stated in SI units (30.1). This equation may be used in different ways. For example, in Fig. 30.4 we plot experimental data for $\partial \ln f_{opt}/\partial t$ as a function of the sensitivity κ and derive a model-independent constraint on the variation of the fine structure constant

$$\frac{\partial \ln \alpha}{\partial t} = \left(-0.3 \pm 2.0 \times 10^{-15}\right) \, y^{-1} \qquad (30.9)$$

and the numerical value of the Rydberg frequency cR_∞ (Table 30.4) in the SI unit of Hertz. The latter is of great metrological importance, being related to a common drift of optical clocks with respect to a caesium clock, i.e., to the definition of the SI second. The SI definition of the metre is unpractical and so, in practice, the optical wavelengths of reference lines calibrated against the caesium standard are used to determine the SI metre [30.37].

The constraints on the variations of α and cR_∞ are correlated and the standard uncertainty ellipse, defined as

$$\sum_i \frac{1}{u_i^2} \left(\frac{\partial \ln f_i}{\partial t} - \frac{\partial \ln \mathrm{Ry}}{\partial t} - \kappa_i \frac{\partial \ln \alpha}{\partial t} \right)^2 = 1 + \chi^2_{min} ,$$

is presented in Fig. 30.5. Here we sum over all available data: $\partial \left(\ln f_i\right)/\partial t$ is the central value of the observed drift rate, u_i its 1σ uncertainty, and χ^2_{min} the minimized χ^2 of the fit.

Table 30.4 Model-independent laboratory constraints on the possible time variations of natural constants

X	$\partial \ln X/\partial t$
α	$(-0.3 \pm 2.0) \times 10^{-15} \, \mathrm{yr}^{-1}$
$\{cR_\infty\}$	$(-2.1 \pm 3.1) \times 10^{-15} \, \mathrm{yr}^{-1}$
μ_{Cs}/μ_B	$(3.0 \pm 6.8) \times 10^{-15} \, \mathrm{yr}^{-1}$
μ_{Rb}/μ_{Cs}	$(-0.2 \pm 1.2) \times 10^{-15} \, \mathrm{yr}^{-1}$
μ_{Yb}/μ_{Cs}	$(3 \pm 3) \times 10^{-14} \, \mathrm{yr}^{-1}$

The numerical value of the Rydberg constant, from the point of view of fundamental physics, can be expressed in terms of the caesium hyperfine interval in atomic units and its variation may be expressed in terms of the variations of α and μ_{Cs}/μ_B. A constraint for the latter is presented in Table 30.4.

30.3.2 Constraints from Microwave Clocks

A model-independent comparison of different HFS transitions is not simple because their nonrelativistic contributions f_{NR} are not the same, but involve different magnetic moments. Applying (30.9) to experimental data, one can obtain constraints on the relative variations of the magnetic moments of Rb, Cs, and Yb (Table 30.4).
Fig. 30.4 Frequency variations versus their sensitivity κ.
Fig. 30.5 Constraints on the time variations of the fine structure constant α and the numerical value of the Rydberg constant. The preliminary data on Ca are not included

30.3.3 Model-Dependent Constraints

In order to gain information on constants more fundamental than the nuclear magnetic moments, any further evaluation of the experimental data should involve the Schmidt model, which is far from perfect. Model-dependent constraints are summarized in Table 30.5.

The nucleon g factors, in their turn, depend on a dimensionless fundamental constant m_q / Λ_{QCD}, where m_q is the quark mass and Λ_{QCD} is the quantum chromodynamic (QCD) scale. A study of this dependence may supply us with deep insight into the possible variations of the more fundamental properties of Nature

Table 30.5 Model-dependent laboratory constraints on possible time variations of fundamental constants. The uncertainties here do not include uncertainties from the application of the Schmidt model

X	$\partial \ln X / \partial t$
m_e/m_p	$(2.9 \pm 6.2) \times 10^{-15}\ \mathrm{yr}^{-1}$
μ_p/μ_e	$(2.9 \pm 5.8) \times 10^{-15}\ \mathrm{yr}^{-1}$
g_p	$(-0.1 \pm 0.5) \times 10^{-15}\ \mathrm{yr}^{-1}$
g_n	$(3 \pm 3) \times 10^{-14}\ \mathrm{yr}^{-1}$

(see [30.31, 32] for details). This approach is promising, but its accuracy needs to be better understood.

30.4 Summary

The results collected in Tables 30.4 and 30.5 are competitive with data from other searches and have a more reliable interpretation. The results from astrophysical searches and the study of the samarium resonance from Oklo data claim higher sensitivity (see, e.g., [30.4]), however, they are more difficult to interpret. We have, for example, not assumed any hierarchy in variation rates or that some constants stay fixed while others vary, as it is done in the study of the position of the Oklo resonance. The evaluation presented here is transparent, and any particular calculation or measurement can be checked. In contrast, the astrophysical data show significant results only after an intensive statistical evaluation.

The laboratory searches involving atomic clocks have definitely shown progress and in a few years we expect an increase in the accuracy of these clocks, an increase in the number of different kinds of frequency standards (e.g., optical Sr, Sr$^+$, In$^+$ standards and a microwave Hg$^+$ standard are being tried now), and indeed an increase in the time separation between accurate experiments, since it is now typically only $2-3$ years. An optical clock based on a nuclear transition in Th-229 is also under consideration [30.38]. Such a clock would offer different sensitivity to systematic effects, as well as to variations of different fundamental constants.

Laboratory searches are not necessarily limited to experiments with metrological accuracy. An example of a high-sensitivity search with a relatively low accuracy is the study of the dysprosium atom for a determination of the splitting between the $4f^{10} 5d\, 6s$ and $4f^9 5d^2 6s$ states, which offers a great sensitivity value of $\kappa \simeq 5.7 \times 10^8$ [30.36].

Variations of constants on the cosmological time scale can be expected but the magnitude, as well as other details, is unclear. Because of a broad range of options there is a need for the development of as many different searches as possible, and the laboratory search for variations is an attractive opportunity to open up a way that could lead to new physics.

Part C Molecules

31. Molecular Structure

Molecular structure is a reflection of the Born–Oppenheimer separation of electronic and nuclear motion, which is in turn a consequence of the large difference between the electron and nuclear masses. One consequence of this separation is the concept of a potential energy surface for nuclear motion created by the faster moving electrons. Corollaries include equilibrium structures, transition states, and reaction paths which are the foundation of the description of molecular structure and reactivity. However the Born–Oppenheimer approximation is not uniformly applicable and its breakdown results in perturbations in molecular spectra, radiationless decay, and nonadiabatic chemical reactions.

There are many issues that can be addressed in a discussion of molecular structure, including the structure and bonding of individual classes of molecules, computational and/or experimental techniques used to determine or infer molecular structure, the accuracy of those methods, etc. In an effort to provide a broad view of the essential aspects of molecular structure, this Chapter considers issues in molecular structure from a theoretical/computational perspective using the Born–Oppenheimer approximation as the point of origin. Rather than providing a compendium of results, this chapter will explain how issues in molecular structure are investigated and how the questions that can be addressed reflect the available methodology. Even with these restrictions the scope of this topic remains enormous and precludes a detailed presentation of any one issue. Thus the abbreviated discussions in this work are supplemented by ample references to the literature.

Several aspects of potential energy surfaces and their relation to molecular structure will be considered: (i) the electronic structure techniques used to determine a single point on a potential energy surface, and the interactions that couple the electronic states in question, (ii) the local properties of potential energy surfaces, in particular equilibrium structures and rovibrational

levels that provide the link to experimental inferences concerning molecular structure, (iii) global chemistry deduced from potential energy surfaces including reaction mechanisms and reaction paths and (iv) phenomena resulting from the nonadiabatic interactions that couple potential energy surfaces.

Part C | 31

31.1 Concepts

31.1.1 Nonadiabatic Ansatz: Born–Oppenheimer Approximation

Basic Quantities

The total Hamiltonian for electronic and nuclear motion in the space fixed coordinate frame, in atomic units, is

$$
H^{\mathrm{eN}}(\boldsymbol{r}, \boldsymbol{R}) = \sum_{\alpha=1}^{N} \frac{-1}{2M_\alpha} \nabla_\alpha^2 + H^{\mathrm{e}}(\boldsymbol{r}; \boldsymbol{R})
$$
$$
\equiv T^{\mathrm{nuc}} + H^{\mathrm{e}}(\boldsymbol{r}; \boldsymbol{R}) , \tag{31.1}
$$

where $\boldsymbol{R}$ denotes the $3N$ nuclear coordinates, with $\boldsymbol{R} = (\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_N)$, $\boldsymbol{R}_i = (X_i, Y_i, Z_i)$, $\boldsymbol{r}$ denotes the $3M$ electronic coordinates 2using similar conventions, T^{nuc} is the nuclear kinetic energy operator and $H^{\mathrm{e}}(\boldsymbol{r}, \boldsymbol{R})$ is the total electronic Hamiltonian taken as

$$
H^{\mathrm{e}}(\boldsymbol{r}; \boldsymbol{R}) = H^0(\boldsymbol{r}; \boldsymbol{R}) + H^{\mathrm{rel}}(\boldsymbol{r}; \boldsymbol{R}) . \tag{31.2}
$$

Here $H^0(\boldsymbol{r}; \boldsymbol{R})$ is the nonrelativistic Born–Oppenheimer Hamiltonian

$$
H^0(\boldsymbol{r}; \boldsymbol{R}) = -\frac{1}{2} \sum_{i=1}^{M} \nabla_i^2 - \sum_{K,i} \frac{Z_K}{|\boldsymbol{R}_k - \boldsymbol{r}_i|}
$$
$$
+ \frac{1}{2} \sum_{i \neq j}^{M} \frac{1}{|\boldsymbol{r}_i - \boldsymbol{r}_j|} + \frac{1}{2} \sum_{K \neq L}^{N} \frac{Z_K Z_L}{|\boldsymbol{R}_K - \boldsymbol{R}_L|} , \tag{31.3}
$$

and $H^{\mathrm{rel}}(\boldsymbol{r}; \boldsymbol{R})$ is the relativistic contribution to the electronic Hamiltonian, for light atoms conventionally treated within the Breit–Pauli approximation [31.1] and discussed further in Sect. 31.3.2. Note that in (31.3) the nuclear kinetic energy is absent, so that only the $\boldsymbol{r}_i$ are dynamical variables in (31.2) and (31.3). Using the Born–Huang approach [31.2] to the Born–Oppenheimer approximation, the total wave function $\Psi_L^{\mathrm{eN}}(\boldsymbol{r}, \boldsymbol{R})$ is expanded in a basis of electronic states, $\Psi_I^{\mathrm{e}}(\boldsymbol{r}; \boldsymbol{R})$. The total wave function for the system thus has the form

$$
\Psi_L^{\mathrm{eN}}(\boldsymbol{r}, \boldsymbol{R}) = \sum_{I} \Psi_I^{\mathrm{e}}(\boldsymbol{r}; \boldsymbol{R}) \beta_I^L(\boldsymbol{R}) . \tag{31.4}
$$

Equation (31.4) is valid for any complete set of electronic states depending parametrically on nuclear coordinates. The parametrical dependence of $\Psi_I^{\mathrm{e}}(\boldsymbol{r}; \boldsymbol{R})$ on $\boldsymbol{R}$, denoted by the semicolon, reflects the fact that the $\boldsymbol{R}$ are not dynamical variables in (31.2) and (31.3). As a practical matter it is necessary to make a particular choice of $\Psi_I^{\mathrm{e}}(\boldsymbol{r}; \boldsymbol{R})$ in order to limit the size of the expansion in electronic states. An adiabatic electronic state is

an eigenfunction of $H^{\mathrm{e}}(\boldsymbol{r}; \boldsymbol{R})$ for fixed $\boldsymbol{R}$. A particularly useful choice of adiabatic state, denoted by $\Psi_I^0(\boldsymbol{r}; \boldsymbol{R})$, employs $H^0(\boldsymbol{r}; \boldsymbol{R})$ rather than the full $H^{\mathrm{e}}(\boldsymbol{r}, \boldsymbol{R})$. These electronic wave functions satisfy

$$
H^0(\boldsymbol{r}; \boldsymbol{R}) \Psi_I^0(\boldsymbol{r}; \boldsymbol{R}) = E_I^0(\boldsymbol{R}) \Psi_I^0(\boldsymbol{r}; \boldsymbol{R}) . \tag{31.5}
$$

The $\Psi_I^0(\boldsymbol{r}; \boldsymbol{R})$ are determined up to a geometry dependent phase. This phase is usually chosen such that the $\Psi_I^0(\boldsymbol{r}; \boldsymbol{R})$ are real. This assumption is acceptable except in the situation where there is a conical intersection on the potential energy surface in question. In that case, the real-valued $\Psi_I^0(\boldsymbol{r}; \boldsymbol{R})$ changes sign when a closed loop surrounding the conical intersection point is traversed, that is, $\Psi_I^0(\boldsymbol{r}; \boldsymbol{R})$ is not single-valued [31.3]. This geometric or *Berry* [31.4] phase condition has consequences in such phenomena as the dynamic Jahn–Teller effect [31.5, 6] but will not be addressed in detail in this review.

As a consequence of the parametric dependence of $\Psi_I^0(\boldsymbol{r}; \boldsymbol{R})$ on $\boldsymbol{R}$, $E_I^0(\boldsymbol{R})$ becomes a function of $\boldsymbol{R}$ and is referred to as the nonrelativistic Born–Oppenheimer potential energy surface for reasons discussed below. Approaches based on (31.5) are most appropriate for molecular systems with only light atoms. However with the use of pseudopotential techniques [31.7], formally equivalent approaches can be developed for heavier systems (Sect. 31.3.2).

Inserting (31.4) into the time independent Schrödinger equation $\left[H^{\mathrm{eN}}(\boldsymbol{r}; \boldsymbol{R}) - E \right] \Psi^{\mathrm{eN}}(\boldsymbol{r}; \boldsymbol{R}) = 0$ and taking the inner product with the electronic basis state $\Psi_I^0(\boldsymbol{r}; \boldsymbol{R})$ gives the following system of coupled equations for the rovibronic functions $\beta_I^L(\boldsymbol{R})$ [31.8, 9]:

$$
\left[T^{\mathrm{nuc}} + E_I^0(\boldsymbol{R}) - E \right] \beta_I(\boldsymbol{R})
$$
$$
= -\sum_{J} \left(\tilde{K}^{IJ}(\boldsymbol{R}) + H_{IJ}^{\mathrm{BP}}(\boldsymbol{R}) \right.
$$
$$
\left. - \sum_{\alpha=1}^{N} \left\{ \frac{1}{2M_\alpha} \left[\boldsymbol{f}_\alpha^{IJ}(\boldsymbol{R}) \cdot \nabla_\alpha + \nabla_\alpha \cdot \boldsymbol{f}_\alpha^{IJ}(\boldsymbol{R}) \right] \right\} \right)
$$
$$
\times \beta_J(\boldsymbol{R}) , \tag{31.6}
$$

where the state label L on β_I^L has been suppressed, and

$$
\boldsymbol{f}_\alpha^{IJ}(\boldsymbol{R}) \equiv \left[f_{X_\alpha}^{IJ}(\boldsymbol{R}), f_{Y_\alpha}^{IJ}(\boldsymbol{R}), f_{Z_\alpha}^{IJ}(\boldsymbol{R}) \right] , \tag{31.7}
$$

$$
\tilde{K}^{JI}(\boldsymbol{R}) = \sum_{W,\alpha} \frac{1}{2M_\alpha} \tilde{k}_{W_\alpha W_\alpha}^{JI}(\boldsymbol{R}) , \tag{31.8}
$$

$$
f_{W_\alpha}^{JI}(\boldsymbol{R}) = \left\langle \Psi_J^0(\boldsymbol{r}; \boldsymbol{R}) \left| \frac{\partial}{\partial W_\alpha} \Psi_I^0(\boldsymbol{r}; \boldsymbol{R}) \right. \right\rangle_{\boldsymbol{r}} , \tag{31.9}
$$

$$\tilde{k}_{W_\alpha W'_\beta}^{JI} = \left\langle \frac{\partial}{\partial W_\alpha} \Psi_J^0(r; R) \middle| \frac{\partial}{\partial W'_\beta} \Psi_I^0(r; R) \right\rangle_r ,$$

$$(31.10)$$

with $W = X, Y, Z, \alpha = 1 \cdots N$. The subscript r on the matrix elements in (31.9–31.10) denotes integration over all electronic coordinates and the final ∇_α in (31.6) acts on both $f_\alpha^{IJ}(R)$ and $\beta_J(R)$. While this representation may not be optimal for a treatment of the nuclear dynamics, since it employs a space fixed frame representation, it is adequate for the present development as it clearly displays the origins of the Born–Oppenheimer approximation and its breakdown.

Modifications to the Nonrelativistic Born–Oppenheimer Potential Energy Surface

When the interstate couplings on the right-hand side of (31.6) can be neglected, the nuclear motion is governed by the effective potential given by $V^I(R) \equiv E_I^e(R) + \tilde{K}^{II}(R) \equiv E_I^0(R) + H_{II}^{BP}(R) + \tilde{K}^{II}(R)$ and the Born–Oppenheimer approximation is valid. Here it is assumed that $f_\alpha^{II}(R) = 0$, a sufficient condition for which is that the $\Psi_I^0(r; R)$ are chosen real-valued [see discussion following (31.5)]. $E_I^0(R)$ is generally the principal R-dependent contribution to $V^I(R)$. $H_{II}^{BP}(R)$ is referred to as the relativistic contribution to the nonrelativistic Born–Oppenheimer potential energy surface and is discussed further in Sect. 31.3.2. The contribution $\tilde{K}^{II}(R)$ is referred to as the adiabatic correction. Unlike $E_I^0(R)$ and $H_{IJ}^{BP}(R)$, which are independent of mass, $\tilde{K}^{II}(R)$ is mass dependent (31.8 and 31.10). It has been computed from first principles [31.10–12] and inferred from experiments [31.13, 14] principally for diatomic systems.

31.1.2 Born–Oppenheimer Potential Energy Surfaces and Their Topology

$E_I^0(R)$ is the main focus of this chapter. There have been several recent reviews of ground state ($I = 1$) potential energy surfaces [31.15, 16].

Equilibrium structures (stable or metastable species) represent local minima on $E_I^0(R)$, that is $g_{W_\alpha}^I(R) \equiv \partial E_I^0(R)/\partial W_\alpha = 0$ for all W_α at $R = R^e$. There may be several equilibrium structures for a given set of nuclei; for example the atoms H, C and N form stable molecules HCN and HNC. Saddle points or transition states, extrema on $E_I^0(R)$ with one negative eigenvalue of the *Hessian matrix* $F^I(R)$, whose elements are defined by $F_{W_\alpha W_\beta}^I(R) \equiv \partial^2 E_I^0(R)/\partial W_\alpha \partial W_\beta$, represent mountain passes separating the various equilibrium structures

and the asymptotes – values of R corresponding to isolated molecular fragments. This situation is illustrated in Fig. 31.1.

Reaction paths [31.17] connect the asymptotes, minima, and saddle points. They can best be defined as the steepest descent paths from a transition state structure down to local minima [31.17], although methods for walking uphill (shallowest ascent path) [31.18] also exist. Unlike equilibrium structures and saddle points which are independent of the choice of coordinate system used to represent R, the reaction path is coordinate system dependent. The intrinsic reaction coordinate [31.17], the reaction coordinate in mass weighted cartesian coordinates $R_i \rightarrow R_i M_i$, is most frequently used (Sect. 31.4.4)

These features of the potential energy surfaces and their determination will be discussed further below. Their determination consists of two parts: (i) the level of treatment, i.e., the electronic structure technique used to determine $E_I^0(R)$ and (ii) the characterization of the features of $E_I^0(R)$, i.e., minima, saddle points, and reaction paths [31.19, 20] at the level of treatment chosen. In this chapter, only fully ab initio levels of treatment are considered [31.21, 22].

31.1.3 Classification of Interstate Couplings: Adiabatic and Diabatic Bases

Intersurface couplings, shown on the right-hand side of (31.6), result in the breakdown of the single potential energy surface Born–Oppenheimer approximation. Within the Born–Huang ansatz such a nonadiabatic process is interpreted in terms of motion on more than one Born–Oppenheimer potential energy surface [31.8]. From (31.6), it is seen that there are three types of matrix elements coupling the electronic states, $\tilde{K}^{IJ}(R)$, $H^{BP IJ}(R)$ and $f^{IJ}(R)$. Two of these couplings, $\tilde{K}^{IJ}(R)$
Fig. 31.1 Schematic representation of a transition state and reaction path connecting two minima

and $f^{IJ}(\boldsymbol{R})$ arise from the nuclear kinetic energy operator T^{nuc}, while the third coupling arises from the Breit–Pauli interaction H^{BP}. This classification of the intersurface interactions is a consequence of the choice of the adiabatic electronic states through (31.5). Other choices of $\Psi_I^0(\boldsymbol{r}; \boldsymbol{R})$, most notably the diabatic electronic states [31.23–27], are possible.

In the adiabatic state basis, $H^0(\boldsymbol{r}; \boldsymbol{R})$ is diagonal and in the absence of relativistic effects, intersurface couplings originate exclusively from the derivative coupling terms in (31.9) and (31.10). The diabatic basis seeks to 'transfer' the intersurface coupling from these derivative operators to a potential term analogous in form to $H_{IJ}^{\text{BP}}(\boldsymbol{R})$. The diabatic basis, $\Psi_I^{0-d}(\boldsymbol{r}; \boldsymbol{R})$, is a unitary transformation of the adiabatic electronic basis, defined such that [31.24]

$$f_{R_\alpha}^{JI,d} \equiv \left\langle \Psi_J^{0-d}(\boldsymbol{r}; \boldsymbol{R}) \left| \frac{\partial}{\partial R_\alpha} \Psi_I^{0-d}(\boldsymbol{r}; \boldsymbol{R}) \right\rangle_{\boldsymbol{r}} = 0 \right.$$

(31.11)

where R_α is an internal coordinate. For polyatomic systems ($N > 2$), rigorous diabatic bases do not exist [31.27] and approximate diabatic bases are sought [31.27–30]. A discussion of this issue can be found in [31.31].

31.1.4 Surfaces of Intersection of Potential Energy Surfaces

The intersurface couplings are most effective in promoting a nonadiabatic process when $|V^I(\boldsymbol{R}) - V^J(\boldsymbol{R})|$ is small for some J on the right-hand side of (31.6), so

that

$$E_I^e(\boldsymbol{R}) + \tilde{K}^{II}(\boldsymbol{R}) - \left[E_J^e(\boldsymbol{R}) + \tilde{K}^{JJ}(\boldsymbol{R}) \right]$$
$$\equiv \Delta E_{IJ}^0(\boldsymbol{R}) + \Delta E_{IJ}^{\text{BP}}(\boldsymbol{R}) + \Delta K_{IJ}(\boldsymbol{R})$$

(31.12)

is small. Here

$$\Delta E_{IJ}^0(\boldsymbol{R}) \equiv E_I^0(\boldsymbol{R}) - E_J^0(\boldsymbol{R}); ,$$ (31.13)

$$\Delta K_{IJ}(\boldsymbol{R}) \equiv \tilde{K}^{II}(\boldsymbol{R}) - \tilde{K}^{JJ}(\boldsymbol{R}) ,$$ (31.14)

$$\Delta E_{IJ}^{\text{BP}}(\boldsymbol{R}) \equiv H_{II}^{\text{BP}}(\boldsymbol{R}) - H_{JJ}^{\text{BP}}(\boldsymbol{R}) .$$ (31.15)

Since in general $\Delta K_{IJ}(\boldsymbol{R})$ is quite small, and for the low atomic number systems considered here H_{II}^{BP} is itself small, we are led to consider regions of nuclear coordinate space for which the magnitude of $\Delta E_{IJ}^0(\boldsymbol{R})$ is small, referred to as avoided intersections when $\Delta E_{IJ}^0(\boldsymbol{R}) \neq 0$ and as conical and Renner-type [31.32] intersections when $\Delta E_{IJ}^0(\boldsymbol{R}) = 0$. The set of $\boldsymbol{R}$ for which $\Delta E_{IJ}^0(\boldsymbol{R}) = 0$, the noncrossing rule, was first discussed in 1929 by *von Neumann* and *Wigner* [31.33]. The rule states that for diatomic systems, crossings between two potential energy curves of the same symmetry are not possible (actually, are extremely rare), whereas for polyatomic systems, potential energy surface intersections are allowed. Mathematically the noncrossing rule is expressed in terms of the dimensions of a surface, the surface of intersection, on which a set of conditions can be satisfied [31.3, 34]. For electronic states of the same symmetry (neglecting electron spin degeneracy), the dimension of the surface of conical intersection is $K - 2$, where K is the number of internal nuclear degrees of freedom. For states of different spin symmetry, the dimension of the surface of intersection is $K - 1$.

31.2 Characterization of Potential Energy Surfaces

This section is concerned with the determination of the approximate solution of (31.5). For this purpose it is frequently convenient to re-express $H^0(\boldsymbol{r}; \boldsymbol{R})$ in second quantized [31.35] form as

$$H^0(\boldsymbol{r}; \boldsymbol{R}) = \sum_{i,j} h_{ij} a_i^\dagger a_j + \frac{1}{2} \sum_{i,j,k,l} (il|jk) a_i^\dagger a_j^\dagger a_k a_l ,$$

(31.16)

where h_{ij} and $(il|jk)$ are standard abbreviations [31.36] for the one electron (kinetic energy and nuclear–electron attraction) and two electron (electron–electron repulsion) integrals respectively, and $a_i^\dagger$ and a_i are the fermion creation and destruction operators. The integrals and the creation and destruction operators are

defined in terms of a basis of one electron functions, usually molecular spin-orbitals $\phi_i \gamma_i$, $\gamma_i = \alpha$ or β. Thus

$$h_{ij}(\boldsymbol{R}) = \left\langle \phi_i(\boldsymbol{r}_k)\gamma_i \left| -\frac{1}{2}\nabla_k^2 \right.\right.$$
$$\left. - \sum_K \frac{Z_K}{|\boldsymbol{R}_K - \boldsymbol{r}_k|} \left| \phi_j(\boldsymbol{r}_k)\gamma_j \right\rangle_{\boldsymbol{r}_k} \right.$$

(31.17)

$$(ij|kl) = \left\langle \phi_i(\boldsymbol{r}_m)\gamma_i \phi_j(\boldsymbol{r}_m)\gamma_j \left| \frac{1}{|\boldsymbol{r}_m - \boldsymbol{r}_n|} \right.\right.$$
$$\left. \times \left| \phi_k(\boldsymbol{r}_n)\gamma_k \phi_l(\boldsymbol{r}_n)\gamma_l \right\rangle_{\boldsymbol{r}_m, \boldsymbol{r}_n} \right. .$$

(31.18)

Equation (31.18) is referred to as the Mulliken notation [31.37] for a two-electron integral. It differs from the frequently used [31.36] bra-ket representation $\langle ij|kl\rangle = (ik|jl)$. The molecular orbitals $\phi_i(r_j; R)$ are in turn expanded in terms of a basis set of atom-centered functions [31.38], $\chi(r_j; R)$, with $\phi_i(r_j; R) = \sum_{P=1}^{L} \chi_P(r_j; R) T_{P,i}(R)$. Note that here we have distinguished between a spin-orbital $\phi_i(r_j; R)\gamma_i$ and a molecular orbital $\phi_i(r_j; R)$, but we will follow the usual convention of allowing the functions in (31.17) and (31.18) to be molecular orbitals or spin-orbitals with the use being clear from the context.

Since $H^0(r; R)$ is independent of electron spin, it can also be written in terms of the $\tilde{E}_{pq}$, spin-averaged excitation operators [31.39], where $\tilde{E}_{pq} = \sum_{\gamma} a_{p\gamma}^{\dagger} a_{q\gamma}$, p, q label orbitals and $\gamma = \alpha, \beta$ so that

$$
H^0(r; R) = \sum_{i,j} h_{ij} \tilde{E}_{ij}
$$
$$
+ \frac{1}{2} \sum_{i,j,k,l} (ij|kl) \tilde{E}_{ij} \tilde{E}_{kl} - \delta_{jk} \tilde{E}_{il} .
$$

(31.19)

The $\tilde{E}_{pq}$ satisfy $\tilde{E}_{ij}, \tilde{E}_{kl}] = \tilde{E}_{il}\delta_{jk} - \tilde{E}_{kj}\delta_{il}$ as a consequence of the commutation relations for the $a_i^{\dagger}$ and a_i and are generators of the unitary group [31.40], (Chapt. 4). This observation allows the powerful machinery of the unitary group to be applied to the evaluation of $E_I^0(R)$ [31.41] (Sect. 31.1.2).

The determination of $E_I^0(R)$ involves two steps; (i) the determination of the molecular orbitals $\phi_i(r_j; R)$, and (ii) sometimes simultaneously, the determination of the approximate wave function $\Psi_I^0(r; R)$.

Wave functions discussed in this section are constructed from functions that are antisymmetrized products of spin-orbitals $\phi_i(r_j; R)\gamma_i$

$$
\Psi_I^0(r; R) = \mathcal{A} \prod_{i=1}^{M} \phi_i(r_j; R)\gamma_i ,
$$

(31.20)

where $\gamma_i = \alpha$ or β. The antisymmetrizer $\mathcal{A}$ is required to take into account the Fermi statistics of the electrons. The wave function in (31.20) is referred to as a Slater determinant and is an eigenfunction of M_s, the z-component of total electron spin. A linear combination of Slater determinants that is also an eigenfunction of S^2 is referred to as a configuration state function (CSF) [31.42]. Equation (31.20) corresponds to a particular distribution of electrons in the orbitals $\phi_i(r_j; R)$. This distribution is referred to as an electron configuration.

In principle, it is possible to learn everything about the topology of a potential energy surface from the pointwise evaluation of $E_I^0(R)$. In practice however, the determination of topological features, including location of equilibrium structures, saddle points and reaction paths, characterization of quadratic and anharmonic force fields [31.43], and even the evaluation of derivative couplings [31.44], has benefitted immensely from techniques in which the energy gradient $g^I(R)$ or higher derivatives are determined directly from knowledge of the wave function at the R in question. These analytic derivative techniques, i.e., techniques that do not use divided difference differentiation, have been actively developed since their first introduction [31.45].

The techniques most commonly used to calculate $E_I^0(R)$ and its derivatives are described below.

31.2.1 The Self–Consistent Field (SCF) Method

The SCF Energy
In this most basic treatment, the electronic wave function Ψ_I^{0-SCF} is taken as a single Slater determinant or a single CSF. The spin-orbitals are determined to give an extremum of the energy functional $\langle \Psi_I^{0-SCF}(r; R)|H^0(r; R)|\Psi_I^{0-SCF}(r; R)\rangle_r$. This gives rise to the self-consistent field conditions. For restricted closed shell wave functions [31.46], defined by the conditions

$$
\Psi_I^{0-RSCF}(r; R)
$$
$$
= \mathcal{A} \prod_{i=1}^{L} \phi_{2i}(r_{2i}; R)\alpha\phi_{2i+1}(r_{2i+1}; R)\beta \quad (31.21)
$$

with $\phi_{2i}(r_j; R) = \phi_{2i-1}(r_j; R)$, $i = 1, \ldots, L$ and $2L = M$, the SCF equations are

$$
\varepsilon_{ri} = h_{ri} + \sum_{j \in \{j_{occ}\}} 2(ir|jj) - (ij|rj) = 0 \quad (31.22)
$$

for ϕ_i, ϕ_r occupied and virtual orbitals, respectively. Here, occupied orbitals j_{occ} are those occurring in the orbital product in (31.21), and the remainder of the orbitals are referred to as virtual orbitals. The solution to (31.22) is referred to as the canonical SCF solution, provided the orbitals satisfy the SCF equations

$$
F\phi_i = \lambda_i \phi_i , \quad (31.23)
$$

where the Fock operator F is defined by $F_{ri} = \varepsilon_{ri}$ and $\lambda_i = \varepsilon_{ii}$. The corresponding electronic energy is $E_I^0(\boldsymbol{R}) \equiv E_I^{0-\text{SCF}}(\boldsymbol{R}) = \sum_{j \in \{j_{\text{occ}}\}} (\varepsilon_{jj} + h_{jj})$.

SCF Energy Derivatives

The derivative of $E_i^{0-\text{SCF}}(\boldsymbol{R})$ can be expanded through third order using analytic gradient techniques [31.47, 48], and through fourth order using divided differences and more recently using analytic derivative techniques [31.43]. The ability to evaluate the energy derivatives or force field through fourth order is important in the determination of vibrational properties of molecules, as discussed in Sect. 31.4.2.

Direct SCF

The range of molecular systems accessible to treatment at the SCF level has been expanded considerably by the introduction of the direct SCF methods [31.49]. In this method, none of the two-electron integrals in the χ basis $(pq|rs)$ are stored during the iterative solution of (31.22) and (31.23). Since the number of such integrals grows as $L^4/8$, direct SCF procedures avoid the 'L^4-storage bottleneck', enabling SCF wave functions to be determined for systems with more than 100 atoms and basis sets with more than 1000 functions. (If all the $L^4/8$ integrals were stored on disk this basis would require ≈ 1000 gigabytes).

31.2.2 Electron Correlation: Wave Function Based Methods

Wave functions more accurate than SCF wave functions are obtained by including the effects of electron correlation. The correlation energy is defined as $E_I^{\text{corr}}(\boldsymbol{R}) \equiv E_I^0(\boldsymbol{R}) - E_I^{0-\text{SCF}}(\boldsymbol{R})$. Methods for the determination of $E_I^{\text{corr}}(\boldsymbol{R})$ are commonly classified as single reference or mulitreference methods. In single reference methods, an SCF wave function $\Psi_I^{0-\text{SCF}}(\boldsymbol{r}; \boldsymbol{R})$ given by (31.20) is improved. In multireference methods, the starting point is the space spanned by a set of terms like (31.20). This space is referred to as the reference space and the functions in the space as the reference configurations. Sometimes the molecular orbitals $\boldsymbol{\phi}(\boldsymbol{r}_i; \boldsymbol{R})$ for the reference space are the SCF orbitals of a single reference configuration calculation, but more often the $\boldsymbol{\phi}(\boldsymbol{r}_i; \boldsymbol{R})$ are chosen to satisfy multiconfigurational self-consistent field (MCSCF) equations [31.50–53].

Single Reference Methods
Second Order Møller–Plesset Perturbation Theory (MP2). In this approach [31.54], the solutions of the SCF equations are used to determine $E_I^0(\boldsymbol{R})$ to second order as

$$E_I^{0-\text{MP2}}(\boldsymbol{R}) = E_I^{0-\text{SCF}}(\boldsymbol{R})$$
$$- \frac{1}{4} \sum_{a,b,i,j} \frac{(ab||ij)^2}{\lambda_a + \lambda_b - \lambda_i - \lambda_j}, \tag{31.24}$$

where i, j denote occupied orbitals, a, b denote virtual orbitals, and

$$(ab||ij) = (ai|bj) - (aj|bi) = \langle ab|ij \rangle - \langle ab|ji \rangle .$$

Both gradients of $E_I^{0-\text{MP2}}(\boldsymbol{R})$ and direct implementations of MP2 [31.37, 55] are currently available. Higher order perturbation theories, also in common use, are discussed in the context of coupled cluster methods which are considered next.

Coupled Cluster Method. Perhaps the most reliable method currently available for characterizing near equilibrium properties of moderately sized molecules is the coupled cluster approach [31.56–60] (Chapt. 5). In this approach, the exact wave function is written as a unitary transformation of a reference wave function $\Phi_0(\boldsymbol{r}; \boldsymbol{R})$ [usually, but not necessarily, the SCF wave function $\Phi_0(\boldsymbol{r}; \boldsymbol{R}) = \Psi_I^{0-\text{SCF}}(\boldsymbol{r}; \boldsymbol{R})$],

$$\Psi_I^{0-\text{CC}} = \exp(T)\Phi_0 . \tag{31.25}$$

where T is an excitation operator defined as

$$T = \sum_p T_p ; \tag{31.26}$$

with

$$T_p = \frac{1}{p!^2} \sum_{i,j,k,\dots,a,b,c} t_{ijk\cdots}^{abc\cdots} a_a^\dagger a_b^\dagger a_c^\dagger a_i a_j a_k , \tag{31.27}$$

where i, j, k denote occupied orbitals in Φ_0 and a, b, c denote virtual orbitals. Thus

$$\Psi_I^{0-\text{CC}} = \Phi_0 + \sum_{i,a} t_i^a \Phi_i^a + \frac{1}{4} \sum_{i,j,a,b} t_{ij}^{ab} \Phi_{ij}^{ab} + \cdots , \tag{31.28}$$

where Φ_i^a, Φ_{ij}^{ab} are single and double excitations from Φ_0, and it is the amplitudes t that must be determined. Wave functions of the form in (31.25–31.28) have the important property referred to as size consistency [31.60] or size extensivity [31.59]. Consider N noninteracting helium atoms. The electronic wave

function for the ith helium atom in the natural orbital basis [31.61] can be written as $\Psi_i = [1 + T_2(i)]\phi_0(i)$, so that the N atom electronic wave function becomes

$$
\Psi = \prod_i \Psi_i = \prod_i [1 + T_2(i)]\Phi_0
$$

$$
= \left[\exp \sum_i T_2(i) \right] \Phi_0 = \exp(T_2)\Phi_0 \qquad (31.29)
$$

Thus this exponential type of solution scales properly with the number of particles.

To obtain the amplitudes $\boldsymbol{t}$, define $H_N = H^0 - \langle \Phi_0 | H^0 | \Phi_0 \rangle$, $E_I^{0-\text{CC}} = \Delta E_I^{0-\text{CC}} + \langle \Phi_0 | H^0 | \Phi_0 \rangle \equiv \Delta E_I^{0-\text{CC}} + E_I^{0-0}$, $P = |\Phi_0\rangle\langle\Phi_0|$ and $Q = 1 - P$. Then, inserting (31.25–31.28) into (31.5) gives the energy (31.30) and amplitude (31.31) equations, which define the coupled cluster approach:

$$
\Delta E_I^{0-\text{CC}} = \langle \Phi_0 | \tilde{H}_N | \Phi_0 \rangle , \qquad (31.30)
$$

$$
\langle \Phi_{ijk\cdots}^{abc\cdots} | \tilde{H}_N | \Phi_0 \rangle = 0 \text{ for all } \Phi_{ijk\cdots}^{abc\cdots} , \qquad (31.31)
$$

where

$$
\tilde{H}_N = \exp(-T) H_N \exp(T)
$$

$$
= -E_I^{0-0} + \exp(-T) H^0 \exp(T) . \qquad (31.32)
$$

To appreciate the nature of these equations, consider the approximation $T = T_2$ constructed from SCF orbitals [31.36, 59], referred to as the coupled cluster doubles (CCD) level. At this level the energy equation becomes

$$
E_I^{0-\text{CCD}} = \langle \Phi_0 | \exp(-T_2) H^0 \exp(T_2) | \Phi_0 \rangle
$$

$$
= \langle \Phi_0 | H^0 T_2 | \Phi_0 \rangle + E_I^{0-0}
$$

$$
= E_I^{0-0} + \frac{1}{4} \sum_{i,j,r,s} \Phi_0 H^0 a_r^\dagger a_s^\dagger a_i a_j \Phi_0 t_{ij}^{rs}
$$

$$
= E_I^{0-0} + \frac{1}{4} \sum_{i,j,r,s} (rs||ij) t_{ij}^{rs} \qquad (31.33)
$$

for i, j occupied and r, s virtual orbitals. The amplitude equations become

$$
\langle \Phi_{ij}^{rs} | \exp(-T_2) H^0 \exp(T_2) | \Phi_0 \rangle
$$

$$
= \langle \Phi_{ij}^{rs} | \left(1 - T_2 + \frac{1}{2} T_2^2 \right) H^0
$$

$$
\times \left(1 + T_2 + \frac{1}{2} T_2^2 \right) | \Phi_0 \rangle
$$

$$
= 0 \qquad (31.34)
$$

which reduces (after considerable commutator algebra) [31.36] to

$$
(\lambda_r + \lambda_s - \lambda_i - \lambda_j) t_{ij}^{rs} =
$$

$$
- (rs||ij) - \sum_{p>q} (rs||pq) t_{ij}^{pq} - \sum_{k>l} (kl||ij) t_{kl}^{rs}
$$

$$
+ \sum_{k,p} \left[(ks||jp) t_{ik}^{rp} - (kr||jp) t_{ik}^{sp} \right.
$$

$$
\left. - (ks||ip) t_{jk}^{rp} + (kr||ip) t_{jk}^{sp} \right]
$$

$$
- \sum_{k>l; p>q} (kl||pq) \left[t_{ij}^{pq} t_{kl}^{rs} - 2 \left(t_{ij}^{rp} t_{kl}^{sq} + t_{ij}^{sq} t_{kl}^{rp} \right) \right.
$$

$$
\left. - 2 \left(t_{ik}^{rs} t_{jl}^{pq} + t_{ik}^{pq} t_{jl}^{rs} \right) + 4 \left(t_{ik}^{rp} t_{jl}^{sq} + t_{ik}^{sq} t_{jl}^{rp} \right) \right] .
$$

$$
(31.35)
$$

The solution to (31.35) is obtained iteratively. The first iteration gives $t_{ij}^{rs} = -(rs||ij)/(\lambda_r + \lambda_s - \lambda_i - \lambda_j)$, which when inserted into (31.33) gives (31.24), i.e., the MP2 result. If the quadratic terms in (31.35) are neglected, then the second iteration gives the third order Møller–Plesset (MP3) result [31.36]. The result of iterating (31.35) to convergence gives the CCD result.

Of the levels of coupled cluster treatments in current use, those including T_1, T_2, T_3, and T_4 in (31.25) provide the most reliable results [31.62–66].

Multireference Methods

Single reference methods provide probably the most powerful tools for treating near-equilibrium properties of ground electronic state systems. In other instances, such as the study of electronically excited states, determination of global potential energy surfaces and for systems with multiple open shells such as diradicals, multireference techniques are found to be extremely useful. In the multireference techniques discussed below, the wave function is written as

$$
\Psi_I^{0-\text{MRF}}(\boldsymbol{r}; \boldsymbol{R}) = \sum_\alpha c_\alpha^{\text{I}} \psi_\alpha(\boldsymbol{r}; \boldsymbol{R}) \qquad (31.36)
$$

where $\psi_\alpha(\boldsymbol{r}; \boldsymbol{R})$ is a CSF. This expansion is usually referred to as a configuration interaction (CI) expansion, and the coefficients $\boldsymbol{c}^{\text{I}}(\boldsymbol{R})$ are referred to as CI coefficients [31.42]. Since (31.36) does not involve the exponential ansatz, it is not automatically size extensive. In the description of these wave functions, it is useful to generalize the notion of occupied and virtual orbitals to inactive, active, and virtual orbitals, where, referring to the CSF's defining the reference space, inactive orbitals are fully occupied in all CSFs, virtual orbitals are not oc-

cupied in any CSF and the active orbitals are (partially) occupied in at least one CSF.

Most multireference techniques begin with the determination of a multiconfigurational self-consistent field (MCSCF) wave function or state averaged MCSCF (SA-MCSCF) wave function [31.50–53, 67]. This approach is capable of describing the internal or static correlation energy, the part of the correlation energy that leads to sizeable separation of two electrons in a pair, and near-degeneracy effects. A particularly robust type of MCSCF wave function, the complete active space (CAS) [31.68–70] wave function, includes in (31.36) all CSFs arising from the distribution of the available electrons among the active orbitals. Note that a CAS wave function is size consistent.

The remaining part of the correlation energy, the dynamic correlation, describes the two-electron cusp, i. e., the regions of space for which two electrons experience the singularity in the Coulomb potential. Empirically, it has been shown [31.71] that wave functions capable of providing chemically accurate descriptions of the dynamic correlation can be obtained by augmenting the MCSCF or reference wave function with all CSFs that differ by at most two molecular orbitals, double excitations (31.28) from those of the reference space. Such wave functions are generally referred to as multireference single and double excitation configuration interaction (MR-SDCI) wave functions. First (second) order wave functions [31.72] include all single (single and double) excitations relative to a CAS reference space.

Multiconfigurational Self–Consistent Field (MCSCF) Theory. In the MCSCF approximation, a wave function $\Psi_I^{0-\mathrm{MCSCF}}(r; R) = \sum_\alpha c_\alpha^I \psi_\alpha(r; R)$ of the form in (31.36) is to be determined. In this procedure, both the molecular orbitals $\phi(r_j; R)$ and $c^I(R)$ are determined from the requirement that

$$
\begin{aligned}
E_I^{0-\mathrm{MCSCF}} \\
= \left\langle \Psi_I^{0-\mathrm{MCSCF}}(r; R) \middle| H^0 \middle| \Psi_I^{0-\mathrm{MCSCF}}(r; R) \right\rangle_r ,
\end{aligned}
\tag{31.37}
$$

be a minimum. In a popular variant, the state averaged MCSCF (SA-MCSCF) [31.50–53] procedure, the average energy functional

$$
\begin{aligned}
E^{0-\mathrm{SA-MCSCF}} = \sum_{I=2}^K w_I \left\langle \Psi_I^{0-\mathrm{MCSCF}}(r; R) \middle| H^0 \middle| \right. \\
\left. \times \Psi_I^{0-\mathrm{MCSCF}}(r; R) \right\rangle_r ,
\end{aligned}
\tag{31.38}
$$

where the weight vector $w = (w_1, w_2, \dots, w_K)$ has only positive elements, is minimized. This procedure should be compared with the multireference CI approach described below in which a predetermined set of molecular orbitals is used.

The optimum molecular orbitals and CI coeffients can be written as unitary transformations of an initial set of such quantities, i. e.,

$$
\Psi_I^{0-\mathrm{MCSCF}} = \exp(\gamma) \exp(\Delta) \Phi_I^0 ,
\tag{31.39}
$$

where

$$
\gamma = \sum_{i,s} \gamma_{s,i} a_s^\dagger a_i , \quad \Delta = \sum_{n,l} \Delta_{l,n} \middle| \Phi_l^0 \middle\rangle \middle\langle \Phi_n^0 \middle| ,
\tag{31.40}
$$

and γ, Δ are general anti-Hermitian matrices. Since $m_{i,j} = -m_{j,i} \equiv m_{ij}$ for $m = \gamma$, Δ, the upper triangle of m forms a vector $\vec{m}$ that enumerates the independent parameters of m. The MCSCF or SA-MCSCF equations can be succinctly formulated by inserting (31.39) into (31.37) or (31.38), expanding the commutators to second order and requiring $\partial E / \partial m_{ij} = 0$ [31.36]. The result provides a system of Newton-Raphson equations that can be solved iteratively for the γ, Δ [31.52, 53, 67, 73].

Multireference Configuration Interaction Theory: The MR–SDCI Method. In multireference configuration interaction theory, the wave function is again of the form $\Psi_I^{0-\mathrm{MRCI}}(r; R) = \sum_\alpha c_\alpha^I(R) \psi_\alpha(r; R)$, but now CSFs involving the large space of virtual orbitals are included. In this approach the CI coefficients are found for a predetermined set of molecular orbitals. The CSF expansions at the MR-SDCI level become quite large (1–10 million CSFs is routine), and even larger expansions are tractable using specialized methods. The c^I satisfy the usual matrix equation

$$
\left(H^0 - E_I^0 \right) c^I = 0 ,
\tag{31.41}
$$

where

$$
\begin{aligned}
H_{\alpha\beta}^0 &= \langle \psi_\alpha | H^0 | \psi_\beta \rangle \\
&= \sum_{i,j} A_{ij}^{\alpha\beta} h_{ij} + \sum_{i,j,k,l} A_{ijkl}^{\alpha\beta} (ij|kl) .
\end{aligned}
\tag{31.42}
$$

It is the computationally elegant solution of (31.41) for large expansions that is the essence of modern MR-SDCI methods.

Because of the large dimension of the CSF space, it is not possible (or even desirable) to find all the solutions of (31.41). The few lowest eigenstates and eigenvalues can be found [31.74] using an iterative direct CI

procedure [31.75] in which a subspace is generated sequentially from the residual defined at the kth iteration by

$$\sigma_\mu^{(k)} = \sum_\nu \left(H_{\mu\nu}^0 - E^{(k-1)}\delta_{\mu\nu} \right) c_\nu^{(k-1)}, \qquad (31.43)$$

where for simplicity of notation, the state index I is suppressed. The computationally demanding step in this procedure is the efficient evaluation of the $A_{ijkl}^{\alpha\beta} = \langle \psi_\alpha | \tilde{E}_{ij}\tilde{E}_{kl} - \delta_{jk}\tilde{E}_{il} | \psi_\beta \rangle$. Key to the efficiency of this evaluation is the factorization formally achieved by

$$\langle \psi_\alpha | \tilde{E}_{ij}\tilde{E}_{kl} | \psi_\beta \rangle = \sum_m \langle \psi_\alpha | \tilde{E}_{ij} | \psi_m \rangle \langle \psi_m | \tilde{E}_{kl} | \psi_\beta \rangle .$$

$$(31.44)$$

Using unitary group techniques, this apparently intractable summation can be used to express the $A_{ijkl}^{\mu\nu}$ as a simple finite product [31.76].

Contracted CI and Complete Active Space Perturbation Theory (CASPT2). The direct approach outlined above makes treatment of large MR-SDCI expansions possible. However, as the size of the reference space grows, the CSF space in the MR-SDCI expansion may become intractably large, particularly if the full second-order wave function is used. To avoid this bottleneck, the reference CSFs may be selected from the active space, and perturbation theory may be used to select CSFs involving orbitals in the virtual space [31.42]. The use of selection procedures complicates the implementation of 'direct' techniques although recently progress in selected direct CI procedures has been reported [31.77–79]. Alternatively, new techniques have been developed that avoid this selection procedure. In these approaches, the MCSCF wave function itself is used as the reference wave function for CI or perturbation theory techniques. The use of a reference wave function rather than a reference space considerably reduces the size of the CSF space to be handled. In this approach, one of the principal computational complications is that the excited functions are not necessarily mutually orthogonal. Two computational procedures currently in wide use, known as contracted CI [31.80–83] and CASPT2 [31.84, 85], are based on this approach.

The CASPT2 method is a computationally efficient variant of second order perturbation theory in which the reference wave function is a CAS-MCSCF wave function and thus may itself contain tens of thousands of CSFs. In this case the full multireference CI problem would be intractable owing to the large space of double

excitations. A similar approach is adopted in the contracted CI method, in that the excitations are defined in terms of a general MCSCF reference wave function $\Psi_I^{0-\text{MRF}}$ rather than the reference space as in the MR-SDCI methods described above.

31.2.3 Electron Correlation: Density Functional Theory

The approaches in Sect. 31.1.1 and 31.1.2 can be referred to as wave function based approaches in the sense that determination of $E_I^0(\mathbf{R})$ is accompanied by the determination of the corresponding electronic wave function $\Psi_I^0(\mathbf{r}; \mathbf{R})$. An alternative approach is known as density functional theory (DFT) [31.86]. The ultimate goal of DFT is the determination of total densities and energies without the determination of wave functions, as in the Thomas–Fermi approximation. DFT is based on the Hohenberg–Kohn Theorem [31.87], which states that the total electronic density can be considered to be the independent variable in a multi-electron theory (see also Chapt. 20). Computationally viable approaches exploit the Kohn and Sham formulation [31.88], which introduces molecular orbitals as an intermediate device.

The essential features of the Kohn–Sham (KS) theory [31.86] are as follows [31.89]. Assume that the real N-electron system for a particular arrangement of the nuclei $\mathbf{R}$ has a total electron density $\rho(\mathbf{r}; \mathbf{R})$. Consider a system of N independent noninteracting electrons subject to a one-body potential V_0 with total density $\rho^0(\mathbf{r}; \mathbf{R})$ such that $\rho(\mathbf{r}; \mathbf{R}) = \rho^0(\mathbf{r}; \mathbf{R})$. The corresponding independent particle orbitals, the Kohn–Sham orbitals $\phi_i^{\text{KS}}(\mathbf{r}_j; \mathbf{R})$, satisfy a Hartree–Fock-like equation

$$\left(-\frac{1}{2}\nabla^2 + V_0 - \varepsilon_i \right) \phi_i^{\text{KS}} = 0 \qquad (31.45)$$

with

$$\rho^0(\mathbf{r}; \mathbf{R}) = \sum_i |\phi_i^{\text{KS}}|^2 . \qquad (31.46)$$

The relation between the energy of the ideal system and that of the true system $E^{0-\text{DFT}}(\mathbf{R})$ is obtained from the adiabatic connection formula [31.89].

In order to determine $E^{0-\text{DFT}}(\mathbf{R})$, functions ϕ_i^{KS} are required, which in turn means that V_0, the Kohn–Sham noninteracting one-body potential, must be determined. V_0 is written as (31.3)

$$V_0 = V_{\text{e–N}} + V_{\text{Coul}} + V_{\text{xc}} \qquad (31.47)$$

where V_{Coul} is the Coulomb interaction corresponding to the electron density, $V_{\text{e–N}}$ is the electron-nuclear at-

traction interaction and V_{xc} is the exchange-correlation density. The effect of (31.47) is to isolate from V_0 the straightforward contributions V_{Coul} and V_{e-N}, and transfers our ignorance to the remaining portion V_{xc}. Although, by the Hohenberg–Kohn theorem V_{xc} must exist, its determination remains the challenge of modern density functional theory, which currently uses approximate functional forms. These approximate treatments of V_{xc} are quite useful in practice, and for large systems, DFT offers a promising alternative to wave function based methods.

Through (31.45), the KS approach is formally similar to SCF theory, although the Kohn–Sham theory is in principle exact. This formal similarity is exploited in the evaluation of the derivative $E^{0-DFT}(\boldsymbol{R})$ [31.90].

31.2.4 Weakly Interacting Systems

When attempting to describe weak chemical interactions such as van der Waals or dispersion forces, the techniques outlined in Sect. 31.2.2 must be modified somewhat. These modifications arise from the finiteness, and hence incompleteness, of the basis (the set $\boldsymbol{\chi}$)

used to describe the molecular orbitals. Assume that the interaction of two molecules A and B is to be determined. Consider the description of molecule A as the distance between A and B decreases from infinity. The atom centered basis functions on molecule B augment those on molecule A, lowering its energy, independent of any physical interaction. This computational artifact serves to overestimate the interaction energy, and is known as the basis set superposition error [31.91, 92]. In chemically bonded systems where interaction energies are large, it is of negligible importance. However in weakly bonded systems for which the interaction energies may be on the order of 10 to 100 cm^{-1}, the basis set superpostion error can be significant.

The basis set superposition error can be reduced by the counterpoise correction [31.93, 94]. In this approach, the interaction energy is evaluated directly as

$$E_I^{0-int}(\boldsymbol{R}) = E_I^0(\boldsymbol{R}) - \left[E_I^{0-A}(\boldsymbol{R}) + E_I^{0-B}(\boldsymbol{R}) \right],$$
(31.48)

where $E_I^{0-A}(\boldsymbol{R})$ and $E_I^{0-B}(\boldsymbol{R})$, the energies of A and B respectively, are evaluated in the full basis.

31.3 Intersurface Interactions: Perturbations

The existence of interstate interactions can lead to 'unexpected' shifts in spectral lines as well as predissociation of the states themselves [31.95]. These situations are illustrated in Fig. 31.2a,b which present the $1, 2, 3\,^3\Pi_g$ potential energy curves for Al_2 and the corresponding derivative couplings $\boldsymbol{f}^{IJ}(\boldsymbol{R})$ respectively. The derivative couplings were evaluated using the method described in Sect. 31.3.1. In this molecule, derivative couplings between the $2, 3\,^3\Pi_g$ states are responsible for the perturbations in the vibrational levels of the bound $2, 3\,^3\Pi_g$ states. Derivative couplings of these states with the $1\,^3\Pi_g$ state causes predissociation of all levels in the $2, 3\,^3\Pi_g$ manifold [31.96].

Section 31.1 describes two classes of interstate matrix elements that can lead to these nonadiabatic phenomena, the derivative coupling matrix elements in (31.7–31.10) and H_{IJ}^{rel}, which is usually treated for low Z systems within the Breit–Pauli approximation. An illustration of a nonadiabatic process induced by H^{rel} is provided in Sect. 31.5. A key issue in the treatment of the electronic structure aspects of these phenomena is the reliable evaluation of the interstate matrix elements. The interstate interactions are usually of most interest in regions of nuclear coordinate space far removed from

the equlibrium nuclear configuration. Thus it is desirable to evaluate these interactions using multireference CI wave functions which (Sect. 31.1) are well suited for use in these regions of coordinate space. The evaluation of nonadiabatic interactions, based on SA-MCSCF/CI wave functions, is discussed below.

31.3.1 Derivative Couplings

From (31.9–31.11), two classes of matrix elements are required, $\tilde{k}_{W_\alpha W_\beta}^{JI}(\boldsymbol{R})$ and $f_{W_\alpha}^{JI}(\boldsymbol{R})$. In fact, techniques to evaluate both of these exist [31.44]. However, it is common to approximate $\tilde{k}_{W_\alpha W_\beta}^{JI}(\boldsymbol{R})$ by

$$\tilde{k}_{W_\alpha W_\beta'}^{JI}(\boldsymbol{R}) = \sum_M \left\langle \frac{\partial}{\partial W_\alpha} \Psi_J^0(\boldsymbol{r}; \boldsymbol{R}) \middle| \Psi_M^0(\boldsymbol{r}; \boldsymbol{R}) \right\rangle_{\boldsymbol{r}}$$
$$\times \left\langle \Psi_M^0(\boldsymbol{r}; \boldsymbol{R}) \middle| \frac{\partial}{\partial W_\beta'} \Psi_I^0(\boldsymbol{r}; \boldsymbol{R}) \right\rangle_{\boldsymbol{r}}$$
$$= \sum_M f_{W_\alpha}^{MJ} f_{W_\beta'}^{MI}.$$
(31.49)

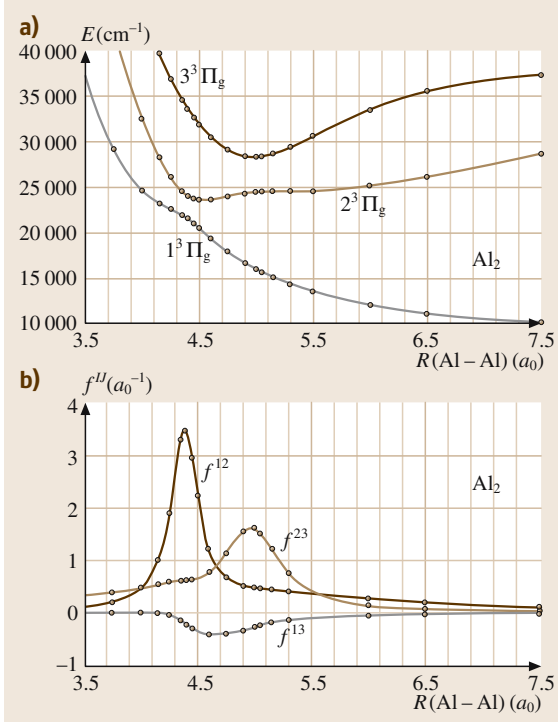
with the (in principle infinite) summation over states truncated to reflect only the states explicitly treated in the


Fig. 31.2 (a) Adiabatic potential energy curves for the 1, 2, 3 $^3\Pi_g$ states of Al_2 from [31.96]. **(b)** Derivative couplings $F^{Ij}(\boldsymbol{R})$ for $(I, J) = 1, 3\,^3\Pi_g$, 1, 2 $^3\Pi_g$ and 2, 3 $^3\Pi_g$ from [31.96]

nonadiabatic dynamics. Thus it is sufficient to discuss the determination of $f_{W_\alpha}^{JI}(\boldsymbol{R})$.

The use of analytic derivative theory [31.97, 98] greatly improves the computational efficiency of evaluating $f_{W_\alpha}^{JI}(\boldsymbol{R})$ relative to the earlier divided difference techniques [31.99]. The key ideas are given below. In this presentation, the standard, real-valued normalization is used. Additional contributions owing to the geometric phase, if required, must be evaluated separately as they do not follow from the electronic Schrödinger equation at a single point [31.100].

Differentiation of the $\Psi_I^0(\boldsymbol{r}; \boldsymbol{R})$ defined in (31.36) gives:

$$\frac{\partial}{\partial W_\alpha}\Psi_I^0(\boldsymbol{r}; \boldsymbol{R}) = \sum_\lambda \left\{ \left[\frac{\partial}{\partial W_\alpha}c_\lambda^I(\boldsymbol{R}) \right] \psi_\lambda(\boldsymbol{r}; \boldsymbol{R}) \right.$$
$$\left. + c_\lambda^I(\boldsymbol{R}) \left[\frac{\partial}{\partial W_\alpha}\psi_\lambda(\boldsymbol{r}; \boldsymbol{R}) \right] \right\} . \tag{31.50}$$

Thus $f_{W_\alpha}^{JI}(\boldsymbol{R})$, consists of two terms

$$f_{W_\alpha}^{JI}(\boldsymbol{R}) = {}^{CI}f_{W_\alpha}^{JI}(\boldsymbol{R}) + {}^{CSF}f_{W_\alpha}^{JI}(\boldsymbol{R}) , \tag{31.51}$$

where the CI contribution is given by

$$^{CI}f_{W_\alpha}^{JI}(\boldsymbol{R}) = \sum_\lambda c_\lambda^J(\boldsymbol{R}) \left[\frac{\partial}{\partial W_\alpha}c_\lambda^I(\boldsymbol{R}) \right] , \tag{31.52}$$

and the CSF contribution has the form

$$^{CSF}f_{W_\alpha}^{JI}(\boldsymbol{R})$$
$$= \sum_{\lambda,\mu} c_\lambda^J(\boldsymbol{R}) \left\langle \psi_\lambda(\boldsymbol{r}; \boldsymbol{R}) \left| \frac{\partial}{\partial W_\alpha}\psi_\mu^I(\boldsymbol{r}; \boldsymbol{R}) \right\rangle_{\boldsymbol{r}} c_\mu^I(\boldsymbol{R}) . \right.$$
$$\tag{31.53}$$

Evaluation of $^{CSF}f_{W_\alpha}^{JI}(\boldsymbol{R})$ is straightforward using analytical derivative techniques [31.101], so that the remainder of the discussion focusses on $^{CI}f_{W_\alpha}^{JI}(\boldsymbol{R})$. From (31.52), it would appear that the derivative of the CI coefficients $\partial/\partial W_\alpha c_\lambda^I(\boldsymbol{R}) \equiv V_{W_\alpha,\lambda}^I(\boldsymbol{R})$ would be required to evaluate $^{CI}f_{W_\alpha}^{JI}(\boldsymbol{R})$. This is quite costly and is in fact not necessary, since only the projection onto the state $\Psi_J^0(\boldsymbol{r}; \boldsymbol{R})$ is required. Equation (31.52) for $^{CI}f_{W_\alpha}^{JI}(\boldsymbol{R})$ can be recast in a form similar to that of $\boldsymbol{g}^I(\boldsymbol{R})$. This transformation of (31.52) enables the explicit determination of $V_{W_\alpha}^I(\boldsymbol{R})$ to be avoided, and is the key to the efficient use of analytic gradient techniques in the evaluation of $\boldsymbol{f}^{JI}(\boldsymbol{R})$.

Differentiating (31.41) with respect to W_α gives

$$\left[\boldsymbol{H}^0 - E_I^0(\boldsymbol{R}) \right] V_{W_\alpha}^I(\boldsymbol{R})$$
$$= -\left\{ \frac{\partial}{\partial W_\alpha} \left[\boldsymbol{H}^0 - E_I^0(\boldsymbol{R}) \right] \right\} c^I(\boldsymbol{R}) . \tag{31.54}$$

Taking the inner product of (31.54) with $c^J(\boldsymbol{R})$ gives

$$^{CI}f_{W_\alpha}^{JI}(\boldsymbol{R}) \equiv c^J(\boldsymbol{R})^\dagger V_{W_\alpha}^I(\boldsymbol{R}) \tag{31.55}$$

$$= \Delta E_{IJ}^0(\boldsymbol{R})^{-1} c^J(\boldsymbol{R})^\dagger \frac{\partial \boldsymbol{H}^0(\boldsymbol{R})}{\partial W_\alpha} c^I(\boldsymbol{R}) \tag{31.56}$$

$$\equiv \Delta E_{IJ}^0(\boldsymbol{R})^{-1} h_{W_\alpha}^{JI}(\boldsymbol{R}) . \tag{31.57}$$

Observe that (31.56) and (31.57) are not the Hellmann–Feynman theorem [31.101, 102] (Chapt. 51), to which they bear a formal resemblance, since it is not the Hamiltonian operator $H^0(\boldsymbol{r}; \boldsymbol{R})$ but rather the Hamiltonian matrix $\boldsymbol{H}^0(\boldsymbol{R})$ that is being differentiated. Since the energy gradient has the form [31.44]

$$\frac{\partial}{\partial W_\alpha}E_I^0(\boldsymbol{R}) = c^I(\boldsymbol{R})^\dagger \frac{\partial \boldsymbol{H}^0(\boldsymbol{R})}{\partial W_\alpha} c^I(\boldsymbol{R}) , \tag{31.58}$$

its relation to $^{CI}f_{W_\alpha}^{JI}(\boldsymbol{R})$ is clear. This identification is the key step in the evaluation of $^{CI}f_{W_\alpha}^{JI}(\boldsymbol{R})$ using analytic gradient techniques [31.97, 98].

31.3.2 Breit–Pauli Interactions

For light systems, it is possible to introduce relativistic effects using the Breit–Pauli approximation [31.1], in which the four component Dirac description of a single electron is replaced by a two component (α, β) description. The $H^e(\boldsymbol{r}; \boldsymbol{R})$ becomes [31.1, 103]

$$H^e(\boldsymbol{r}; \boldsymbol{R}) = H^0(\boldsymbol{r}; \boldsymbol{R}) + H^{rel}(\boldsymbol{r}; \boldsymbol{R}) , \qquad (31.59)$$

where, in parallel with (31.4–31.13) for the atomic case, the relativistic correction $H^{rel} = \sum_{k=1}^3 H^k(\boldsymbol{r}; \boldsymbol{R})$ can be divided into spin-dependent (SD) and spin-independent (SI) parts, plus an external field interaction term H^{ext}. These are given by

$$H^1 = H^{SD} \equiv H^{so} + H^{soo} + H^{ss} , \qquad (31.60)$$

$$H^2 = H^{SI} \equiv H^{mass} + H^D + H^{ssc} + H^{oo} , \qquad (31.61)$$

$$H^3 = H^{ext} , \qquad (31.62)$$

where, in atomic units,

$$H^{so} = \frac{\alpha^2}{2} \sum_{K,i} \frac{Z_K(\boldsymbol{r}_i - \boldsymbol{R}_K) \times \boldsymbol{p}_i \cdot \boldsymbol{s}_i}{|\boldsymbol{r}_i - \boldsymbol{R}_K|^3} , \qquad (31.63)$$

$$H^{soo} = -\frac{\alpha^2}{2} \sum_{i \neq j} \frac{\boldsymbol{r}_{ij} \times \boldsymbol{p}_i \cdot (\boldsymbol{s}_i + 2\boldsymbol{s}_j)}{|\boldsymbol{r}_{ij}|^3} , \qquad (31.64)$$

$$H^{ss} = \alpha^2 \sum_{i<j} \left[\frac{\boldsymbol{s}_i \cdot \boldsymbol{s}_j}{|\boldsymbol{r}_{ij}|^3} - \frac{3(\boldsymbol{r}_{ij} \cdot \boldsymbol{s}_i)(\boldsymbol{r}_{ij} \cdot \boldsymbol{s}_j)}{|\boldsymbol{r}_{ij}|^5} \right] , \qquad (31.65)$$

$$H^{mass} = -\frac{\alpha^2}{8} \sum_i p_i^4 , \qquad (31.66)$$

$$H^D = -\frac{\alpha^2}{8} \left[\sum_{K,i} Z_K \nabla_i^2 |\boldsymbol{r}_i - \boldsymbol{R}_K|^{-1} - \sum_{i \neq j} \nabla_i^2 |\boldsymbol{r}_{ij}|^{-1} \right] , \qquad (31.67)$$

$$H^{ssc} = -\frac{8\pi\alpha^2}{3} \sum_{i<j} (\boldsymbol{s}_i \cdot \boldsymbol{s}_j) \delta(\boldsymbol{r}_{ij}) , \qquad (31.68)$$

$$H^{oo} = -\frac{\alpha^2}{4} \left(\sum_{j \neq i} \frac{\boldsymbol{p}_i \cdot \boldsymbol{p}_j}{|\boldsymbol{r}_{ij}|} - \frac{\boldsymbol{r}_{ij} \cdot [\boldsymbol{r}_{ij} \cdot \boldsymbol{p}_j]\boldsymbol{p}_i}{|\boldsymbol{r}_{ij}|^3} \right) , \qquad (31.69)$$

$$H^{ext} = \frac{\alpha^2}{2} \sum_i \boldsymbol{E}(\boldsymbol{r}_i) \times \boldsymbol{p}_i \cdot \boldsymbol{s}_i + \frac{i\alpha^2}{4} \sum_i \boldsymbol{E}(\boldsymbol{r}_i) \cdot \boldsymbol{p}_i + 2\mu \sum_i \mathcal{H}(\boldsymbol{r}_i) \cdot \boldsymbol{s}_i , \qquad (31.70)$$

$\boldsymbol{E}(\boldsymbol{r})$ and $\mathcal{H}(\boldsymbol{r})$ are electric and magnetic fields, and $\mu = e\hbar/(2m_e)$ is the Bohr magneton. The physical significance of these terms is discussed is Sect. 21.1. One of the most important consequences of these relativistic effects is that total electron spin is no longer a good quantum number as it is in $H^0(\boldsymbol{r}; \boldsymbol{R})$. The term H^{SD} couple states corresponding to distinct eigenvalues of S^2 and lead to the nonadiabatic effects that are the subject of this section.

The Breit–Pauli approximation is most useful for light atoms, but the approximation breaks down when Z becomes large [31.104–106]. One of the principal effects omitted in a treatment which includes only H^{SD} is the relativistic contraction of the molecular orbitals [31.107] due to the mass-velocity operator (H^{mass}), an effect whose importance increases with Z. Several approaches exist which attempt to correct this situation while retaining the spirit and simplifications of the Breit–Pauli approximation. The first of these is the relativistic effective core potential (ECP) approximation [31.108–111]. In this approach, the results of an atomic Dirac–Fock calculation [31.112] are used to replace innermost or core electrons of a given atom with (i) an effective one electron potential that modifies the electron-nuclear attraction term in H^0 and (ii) an effective one electron spin-orbit operator, so that

$$H^e(\boldsymbol{r}; \boldsymbol{R}) \rightarrow H^{e-ECP}(\boldsymbol{r}; \boldsymbol{R})$$
$$= H^{0-ECP}(\boldsymbol{r}; \boldsymbol{R}) + H^{so-ECP}(\boldsymbol{r}; \boldsymbol{R}) . \qquad (31.71)$$

The formal similarity between H^{e-ECP} and $H^e(\boldsymbol{r}; \boldsymbol{R})$ results in a similar phenomenological interpretation of relativistically induced nonadiabatic processes. Applications of this approach have been reviewed [31.107, 113].

A second approach includes all electrons explicitly, and uses H^{SD} as defined above. The relativistic contraction of the core electrons is included by using a variational one-component spin-free approximation [31.114, 115] to the no-pair Hamiltonian [31.116] at the orbital optimization stage. The variational nature of the approximation provides advantages over the use of the H^{mass} term. Applications of this approach to the spectra of CuH and NiH have been reported [31.117, 118].

In order to evaluate $H_{IJ}^{SD}(\boldsymbol{R})$, it is necessary to specify the molecular orbitals to be used to construct the $\Psi_I^0(\boldsymbol{r}; \boldsymbol{R})$. The choice of molecular orbitals is dictated by the following considerations. Matrix elements of H^{SD} between different states are required. The molecular orbitals appropriate for one state may not be appropriate for the description of the second state. Two approaches are available to handle this situation. In one approach, distinct sets of (mutually nonorthogonal) molecular orbitals are used to describe each state [31.119]. This permits a more compact description of the spaces in question. However in this case one is required to evaluate the matrix element of a two electron operator H^{soo} and/or H^{ss} in a nonorthogonal molecular orbital basis, an imposing computational task. This significantly limits the size of the CSF space which is tractable. The alternative approach is to use a common orthonormal basis balanced between the two spaces in question, and to use larger CSF spaces [31.120–122]. The use of a common orthonormal basis decreases significantly the computational effort required to evaluate the matrix elements. A symbolic matrix element method [31.123] has been applied to H^{SD}, as described in the review [31.124].

31.3.3 Surfaces of Intersection

The preceding subsections have considered what must be calculated in order to characterize an electronically nonadiabatic process. As noted in Sect. 31.1, it is also necessary to consider where in nuclear coordinate space electronic nonadiabaticity is important. Nonadiabatic processes are important in regions of close approach of the potential energy surfaces with regions of surface intersections being of preeminent interest. Until recently, these surfaces of intersection were determined by indirect methods, i.e., the potential energy surfaces were characterized, and then the surface of intersection was determined. This made the determination of these surfaces of intersection a computationally daunting task. However, computational advances have made it possible to determine these surfaces of intersection directly, i.e., without prior determination of the individual potential energy surfaces. This point is discussed next.

A point on the surface of conical intersection of two states of the same symmetry, subject to a set of geometric equality constraints of the form $C_i(\boldsymbol{R}) = 0$, $i = 1, \ldots, m$, is determined from the Newton–Raphson equations [31.125]

$$-\begin{pmatrix} \boldsymbol{Q}^{IJ}(\boldsymbol{R}, \boldsymbol{\xi}, \boldsymbol{\lambda}) & \boldsymbol{g}^{IJ}(\boldsymbol{R}) & \boldsymbol{h}^{IJ}(\boldsymbol{R}) & \boldsymbol{k}(\boldsymbol{R}) \\ \boldsymbol{g}^{IJ}(\boldsymbol{R})^\dagger & 0 & 0 & \boldsymbol{0} \\ \boldsymbol{h}^{IJ}(\boldsymbol{R})^\dagger & 0 & 0 & \boldsymbol{0} \\ \boldsymbol{k}(\boldsymbol{R})^\dagger & \boldsymbol{0}^\dagger & \boldsymbol{0}^\dagger & \boldsymbol{0} \end{pmatrix} \begin{pmatrix} \delta\boldsymbol{R} \\ \delta\xi_1 \\ \delta\xi_2 \\ \delta\boldsymbol{\lambda} \end{pmatrix}$$
$$= \begin{pmatrix} \boldsymbol{g}^I(\boldsymbol{R}) + \xi_1 \boldsymbol{g}^{IJ}(\boldsymbol{R}) + \xi_2 \boldsymbol{h}^{IJ}(\boldsymbol{R}) + \sum_{i=1}^m \lambda_i \boldsymbol{k}^i(\boldsymbol{R}) \\ \Delta E_{IJ}(\boldsymbol{R}) \\ 0 \\ \boldsymbol{C}(\boldsymbol{R}) \end{pmatrix}$$
$$(31.72)$$

where $\delta\boldsymbol{R} = \boldsymbol{R}' - \boldsymbol{R}$, $\delta\boldsymbol{\lambda} = \boldsymbol{\lambda}' - \boldsymbol{\lambda}$, $\delta\boldsymbol{\xi} = \boldsymbol{\xi}' - \boldsymbol{\xi}$, $g_\alpha^{IJ}(\boldsymbol{R}) \equiv \partial\Delta E_{IJ}(\boldsymbol{R})/\partial R_\alpha$, $k_\alpha^i(\boldsymbol{R}) \equiv \partial C_i(\boldsymbol{R})/\partial R_\alpha$, $h_\alpha^{IJ}(\boldsymbol{R}) \equiv \boldsymbol{c}^{I\,\dagger}(\boldsymbol{R})\boldsymbol{H}^0(\boldsymbol{R})/\partial R_\alpha \boldsymbol{c}^J(\boldsymbol{R})$, $\boldsymbol{\xi}$ and $\boldsymbol{\lambda}$ are Lagrange multipliers, and $\boldsymbol{Q}^{IJ}(\boldsymbol{R}, \boldsymbol{\xi}, \boldsymbol{\lambda})$ is a matrix of second derivatives [31.125]. For two states of different symmetry, the analogue of (31.72) is used with the terms related to ξ_2 omitted [31.126]. The excellent performance of this algorithm has been documented [31.125, 127].

Equations (31.72) can be motivated as follows. $\boldsymbol{R}^c$ is sought so that $E_I^0(\boldsymbol{R})$ is minimized subject to the constraints $E_I^0(\boldsymbol{R}) = E_J^0(\boldsymbol{R})$ and $\boldsymbol{C}(\boldsymbol{R}) = 0$. The key is to impose the first of these constraints, noting that at each step in the Newton–Raphson procedure, $\boldsymbol{c}^I(\boldsymbol{R})$ and $\boldsymbol{c}^J(\boldsymbol{R})$ are eigenvectors. Equation (31.72) are the Newton-Raphson equations corresponding to the Lagrangian function [31.128]

$$L_{IJ}(\boldsymbol{R}, \boldsymbol{\xi}, \boldsymbol{\lambda}) = E_I(\boldsymbol{R}) + \xi_1 \Delta E_{IJ}(\boldsymbol{R})$$
$$+ \xi_2 H_{IJ}(\boldsymbol{R}) + \sum_{k=1}^M \lambda_k C_k(\boldsymbol{R}),$$
$$(31.73)$$

provided that the gradient of $H_{IJ}^0(\boldsymbol{R})$ is interpreted as a change in $\boldsymbol{H}^0(\boldsymbol{R})$ within the subspace spanned by $\boldsymbol{c}^I(\boldsymbol{R})$ and $\boldsymbol{c}^J(\boldsymbol{R})$. This can be derived from quasidegenerate perturbation theory and understood as follows. Assume for convenience that $m = 0$, i.e., there are no geometrical constraints.

Consider an $\boldsymbol{R}$ for which (31.72) is not satisfied. The 2×2 matrix $\boldsymbol{H}(\boldsymbol{R})$ with matrix elements $H_{KL}(\boldsymbol{R})$, $K, L \in \{I, J\}$ becomes at $\boldsymbol{R} + \delta\boldsymbol{R}$

$$H_{IJ}(\boldsymbol{R} + \delta\boldsymbol{R})$$
$$= \boldsymbol{c}^{I\,\dagger}(\boldsymbol{R})\left(\boldsymbol{H}(\boldsymbol{R}) + \sum_\alpha \frac{\partial \boldsymbol{H}(\boldsymbol{R})}{\partial R_\alpha} \delta R_\alpha \right) \boldsymbol{c}^J(\boldsymbol{R}),$$
$$(31.74)$$

$H(R)$ is diagonal but nondegenerate at R, i. e.,

$$H(R) = \begin{pmatrix} E_I^0(R) - E_J^0(R) & 0 \\ 0 & 0 \end{pmatrix} . \tag{31.75}$$

From (31.74) at $R^c = R + \delta R$, $H(R^c)$ becomes, to first order, ignoring an irrelevant uniform shift of the diagonal elements,

$$H(R^c) = \begin{pmatrix} \Delta E_{IJ}(R) + g^{IJ\dagger} \cdot \delta R & h^{IJ\dagger} \cdot \delta R \\ h^{IJ\dagger} \cdot \delta R & 0 \end{pmatrix} . \tag{31.76}$$

Thus (31.72) is seen to be the requirement that $H(R^c)$ has degenerate eigenvalues, with eigenvectors $c^I(R)$ and $c^J(R)$. When (31.72) have been solved, $H_{IJ}(R^c)$ is diagonal and degenerate, $E_I(R^c)$ has been minimized, and $g^I(R^c) = 0$, except along directions contained in the two dimensional subspace spanned by $g^{IJ}(R^c)$ and $h^{IJ}(R^c)$.

From (31.76), it is these two directions which lift the degeneracy of $H(R^c)$. Equation (31.72) is also relevant to the reaction path in a nonadiabatic process as discussed in Sect. 31.4. A discussion of these points from an alternative perspective has been presented by *Radazos* et al. [31.129].

A solution to (31.72) is referred to as a conical intersection, although rigorously degenerate states cannot be obtained from a numerical procedure. If required, the existence of a conical intersection can be rigorously established by showing that the adiabatic wave functions undergo a change of sign when transported around a closed loop containing R^c in the plane defined by $g^{IJ}(R^c)$ and $h^{IJ}(R^c)$. This is the geometric or Berry phase criterion [31.130, 131]. It has been explicitly demonstrated for a conical intersection in O_3 by *Ruedenberg* and coworkers [31.132].

31.4 Nuclear Motion

31.4.1 General Considerations

The determination of the rovibrational spectrum of polyatomic systems from first principles is a problem of primary importance since it allows the determination of molecular forces and structure from spectral data. In the adiabatic case, the solution of (31.6)

$$\left[T^{\mathrm{nuc}}(R) + E_I^0(Q) - E_K \right] \beta_K(R) = 0 \tag{31.77}$$

is sought, where Q denotes a set of internal nuclear coordinates. The reliability of the solution of (31.77) reflects the accuracy of the Born–Oppenheimer potential energy surface $E_I^0(Q)$ appearing in that equation. The methods for determining $E_I^0(Q)$ were discussed in Sect. 31.2. Conversely, the determination of the E_K from spectroscopic measurements can be used to infer information concerning $E_I^0(Q)$. In either case, the accurate solution of (31.77) is requisite and this section is concerned with its solution.

The operator in (31.77) has a continuous spectrum since T^{nuc} includes translations of the nuclear center of mass (cm). An operator with a discrete spectrum is obtained by replacing the Hamiltonian in (31.77) with one in which the translation of the nuclear c.m. has been eliminated by transforming to the c.m. frame. In the center of mass frame, (31.77) has the general form [31.133]

$$\left[T^{\mathrm{vr}}(\mathbf{\Omega}, Q) + T^{\mathrm{vib}}(Q) + E_I^0(Q) - E_K \right] \beta(\mathbf{\Omega}, Q) = 0 \tag{31.78}$$

where $\mathbf{\Omega}$ are three rotational coordinates and T^{vr} and T^{vib} are the rotational and vibrational kinetic energy operators. In $T^{\mathrm{vr}}(\mathbf{\Omega}, \mathbf{Q})$ all the complexity associated with the coupling of nuclear and electronic angular momentum is buried. The determination of the appropriate form for (31.78) is by no means straightforward [31.134, 135], and treatment of the effects of multiple angular momentum is a complex problem in angular momentum algebra.

In diatomic systems, the vibrational problem involves only one internal coordinate and is straightforward. Angular momentum coupling is usually treated using Hund's case (a), (b), etc., or an intermediate case approach [31.95] with Van Vleck's reversed angular momentum commutation relations being helpful in analyzing the coupled angular momentum problem [31.134].

Polyatomic systems introduce new complications, since in addition to the increased dimensionality of the vibrational problem, internal and rotational coordinates interconvert for colinear arrangements of the nuclei; this is particularly relevant in triatomic systems. In addition, since the $C_{\infty v}$ point group has doubly degenerate representations at collinear geometries, electronic

state degeneracies may arise (the Renner–Teller effect) [31.32,136,137], further complicating the analysis. Techniques associated with the description of triatomic systems involving coupled angular momentum and electronic degeneracy are illustrated in Sect. 31.4.3.

More generally, (31.78) can be rewritten as

$$\left[T^{\mathrm{vr}}(\boldsymbol{\Omega}, \boldsymbol{Q}^{\mathrm{e}}) + T^{\mathrm{vib}}(\boldsymbol{Q}) + E_I^{\mathrm{sep}}(\boldsymbol{Q}) - E_K\right]\beta(\boldsymbol{R})$$
$$= -\Delta T^{\mathrm{vr}}(\boldsymbol{\Omega}, \boldsymbol{Q})\beta(\boldsymbol{R}) - \Delta E_I^0(\boldsymbol{Q}) , \quad (31.79)$$

where

$$\Delta T^{\mathrm{vr}}(\boldsymbol{\Omega}, \boldsymbol{Q}) \equiv T^{\mathrm{vr}}(\boldsymbol{\Omega}, \boldsymbol{Q}) - T^{\mathrm{vr}}(\boldsymbol{\Omega}, \boldsymbol{Q}^{\boldsymbol{e}}) , \quad (31.80)$$
$$\Delta E_I^0(\boldsymbol{Q}) \equiv E_I^0(\boldsymbol{Q}) - E_I^{\mathrm{sep}}(\boldsymbol{Q}) , \quad (31.81)$$

$\boldsymbol{Q}^{\mathrm{e}}$ is an equilibrium structure, and $E_I^{\mathrm{sep}}(\boldsymbol{Q})$ is a separable function of the normal coordinates. In this case, the solution to the left-hand side of (31.79) can be factorized into a rotational part and a vibrational part [31.138] according to

$$\psi_I^J = \sum_K k_K^J D_{K0}^J(\theta, \chi) \prod_i \alpha_{l_i}(Q_i) \quad (31.82)$$

where D_{K0}^J is a symmetric top wave function [31.139], and $\alpha_j(Q_i)$ is a pure vibrational wave function, e.g., harmonic oscillator function, for the ith internal normal coordinate. It is in this approximation that the notion of a molecule rotating and vibrating about a fixed molecular structure is achieved. In this case, E_K is just the sum of the pure rotational and vibrational energies. These rigid rotator-vibrator solutions then form the basis for the inclusion of the effects of the right-hand side using, for example, perturbation theory [31.140]. They can also be used as a basis for a nonperturbative treatment (Sect. 31.4.2).

The classic treatments of (31.77) [31.141–144] have been periodically revisited [31.134, 145]. In these investigations, the contributions of electronic angular momentum to this Hamiltonian were frequently suppressed [31.144] so that these treatments are appropriate to totally symmetric electronic states. *Van Vleck* [31.134] has shown how the effects of electronic angular momentum can be incorporated into these treatments.

For nonlinear polyatomic systems, the Hamiltonian in (31.78) can be transformed to the Eckart or body fixed frame in which the reference axis is a body fixed axis oriented along the principal moments of inertia [31.146], although other choices of the body fixed axes are possible [31.147]. The principal moments of inertia represent the eigenvectors of the inertial tensor

matrix I_{ij}, $i, j = x, y, z$, where [31.144]

$$I_{xx} = \sum_i M_i(\boldsymbol{R}_i^{\mathrm{e}} \cdot \boldsymbol{R}_i^{\mathrm{e}} - X_i^{\mathrm{e}} X_i^{\mathrm{e}}) , \quad (31.83)$$

$$I_{xy} = -\sum_i M_i(X_i^{\mathrm{e}} Y_i^{\mathrm{e}}) , \quad (31.84)$$

and cyclic permutations, and $\boldsymbol{R}^{\mathrm{e}}$ denotes an equilibrium structure. The Hamiltonian determined by this procedure is referred to as the Watson Hamiltonian [31.145], and is widely used in discussing the rovibrational spectrum of nonlinear polyatomic molecules in singlet electronic states. Treatments of the Watson Hamiltonian are mentioned in Sect. 31.4.2. For linear molecules, an alternative treatment is required since there is one fewer overall rotational coordinate and one more internal coordinate [31.138].

31.4.2 Rotational–Vibrational Structure

Various approaches to the solution of (31.79) exist. The principal issues, which are interrelated, are (i) the range of nuclear configurations over which $E_I^0(\boldsymbol{Q})$ is known, (ii) the coordinate system used to express the internal coordinates, and (iii) particularly in larger systems, the number of modes or internal coordinates retained in the calculations (Sect. 31.4.3). With regard to point (i), two approaches are currently in use. The force field method uses a power series expansion of $E_I^0(\boldsymbol{Q})$ about $E_I^0(\boldsymbol{Q}^{\mathrm{e}})$, that is (using the Einstein summation convention)

$$E_I^0(\boldsymbol{Q}) = E_I^0(\boldsymbol{Q}^{\mathrm{e}}) + \frac{1}{2}\frac{\partial^2 E_I^0(\boldsymbol{Q}^{\mathrm{e}})}{\partial Q_i \partial Q_j}\Delta Q_i \Delta Q_j$$
$$+ \frac{1}{6}\frac{\partial^3 E_I^0(\boldsymbol{Q}^{\mathrm{e}})}{\partial Q_i \partial Q_j \partial Q_k}\Delta Q_i \Delta Q_j \Delta Q_k \quad (31.85)$$

together with perturbation theory to determine spectroscopic constants. In this approach, the force fields [the partial derivatives in (31.85) are usually evaluated directly with the aid of analytic gradient techniques (Sect. 31.2). Since the expansion of $E_I^0(\boldsymbol{Q})$ is truncated, the results are not independent of the coordinate system used. For example, significant differences in the description of Fermi-resonance parameters [31.148, 149] in rectilinear and curvilinear coordinates [31.150] have been reported.

Alternatively, $E_I^0(\boldsymbol{Q})$ can be represented by a grid of points around $\boldsymbol{Q}^{\mathrm{e}}$. In the most reliable calculations reported to date, $E_I^0(\boldsymbol{Q})$ is determined using the coupled cluster techniques discussed in Sect. 31.2. Then (31.79) can be solved in a basis analogous to

ψ_l^J in (31.82). This approach is frequently referred to as the vibrational CI problem [31.151]. The reliability of the results depends to a considerable extent on the basis functions and coordinate system used to describe the problem. Considerable success has been reported for a technique in which the Watson Hamiltonian and harmonic oscillator functions are used to solve (31.79) [31.151, 152].

31.4.3 Coupling of Electronic and Rotational Angular Momentum in Weakly Interacting

An understanding of the molecular structure of the weakly bound compounds of noble gas atoms and diatomic molecules provides important insights into the nature of chemical bonding. The inference of structural data from spectroscopic observations is an important aspect of this problem. In this subsection, a theoretical framework for understanding the spectroscopy of these systems is outlined as an illustration of the methods used to treat coupling of electronic and nuclear angular momentum in weakly interacting triatomic molecular systems. Detailed discussion of this class of problems can be found in [31.153–155].

As an example, consider the rovibronic structure of a noble gas-diatom complex Rg-AB, in either its $^1\Sigma^+$ or $^1\Pi$ states (which may be closely spaced). Note that degeneracy of the $^1\Pi$ state will only persist for collinear geometries of the triatom system. The rovibrational wave functions can be expanded in a product basis of functions describing (i) the rovibronic structure of AB and (ii) the relative motion (vibrational and end-over-end rotation) of Rg and AB. Since total angular momentum J and its space fixed projections M are good quantum numbers, the rovibronic wave function can be expanded as

$$\Psi^{JM} = \frac{1}{R} \sum_{vj\Omega l\varepsilon v} C_{j\Omega l\varepsilon v}^{JM}(R) \\ \times |\psi_{\text{Rg}}\rangle |v_{Ij}\rangle |Ij\Omega\varepsilon, l; JM\rangle , \quad (31.86)$$

where ψ_{Rg} is the ground state wave function for the noble gas atom, l denotes the angular momentum associated with the end-over-end motion, and v, j, ε and I denote respectively the vibrational, angular momentum (electronic + rotational), e/f symmetry index and state label of the electronic state of the AB molecule in Hund's case (a) basis. The angular momentum coupling algebra noted above is reflected in the definition of

$|Ij\Omega\varepsilon, l; JM\rangle$, which is

$$|Ij\Omega\varepsilon, l; JM\rangle \\ = \sum_{m_j m_l} \langle jm_j lm_l | JM\rangle Y_{lm_l}(\theta, \phi) \psi_{Ijm_j\Omega\varepsilon}(\beta, \alpha) , \quad (31.87)$$

where θ, ϕ and β, α are the polar and azimuthal angles for the line connecting the noble gas atom to the center of mass of the diatom and the diatom axis, respectively, and $\langle \cdots | \cdots \rangle$ is a Clebsch–Gordan coefficient [31.156] (Chapt. 2). The $\psi_{Ijm_j\Omega\varepsilon}$ are defined in turn by [31.95]

$$\psi_{Ijm_j\Omega\varepsilon} = \left(\frac{2J+1}{8\pi}\right)^{1/2} \\ \times \Big[D_{m_j,\Omega}^j(\alpha, \beta, 0)^* |I^{2S+1}\Lambda^+(\Sigma)\rangle \\ + \varepsilon D_{m_j,-\Omega}^j(\alpha, \beta, 0)^* |I^{2S+1}\Lambda^-(-\Sigma)\rangle \Big] \quad (31.88)$$

or

$$\psi_{Ijm_j\Omega\varepsilon} = \left(\frac{2J+1}{4\pi}\right)^{1/2} \\ \times D_{m_j,0}^j(\alpha, \beta, 0)^* |I^{2S+1}\Lambda(\Sigma)\rangle \quad (31.89)$$

when $\Lambda = \Sigma = 0$, where the electronic state has term symbol $I^{2S+1}\Lambda$ with $\Omega = \Lambda + \Sigma$.

The $\boldsymbol{C}^{JM}(\boldsymbol{R})$ satisfy the usual close coupled equations [31.157, 158] Sect. 47.1.1

$$\left[\left(\frac{-1}{2\mu} \frac{d^2}{dR^2} + \frac{l(l+1)}{2\mu R^2} \right) \boldsymbol{I} - \frac{\boldsymbol{k}^2}{2\mu} + \boldsymbol{V}(r) \right] \boldsymbol{C}^{JM}(r) \\ = 0 , \quad (31.90)$$

where $l(l+1)$ and $\boldsymbol{k}^2/2\mu$ designate the diagonal matrices of orbital angular momentum and asymptotic net scattering energy of individual channels. $\boldsymbol{V}(R)$ represents the matrix elements of $H^{\text{e}}(\boldsymbol{r}; \boldsymbol{R})$ in the vibronic basis defined in (31.86–31.89). It is built from terms of the form

$$\langle Y_{lm} D_{m_j\Omega}^{j\,*} v_{Ij} | \langle \psi_{\text{Rg}} I^{2S+1}\Lambda | H^{\text{e}}(\boldsymbol{r}; \boldsymbol{R}) \\ \times |\psi_{\text{Rg}} I'^{2S'+1}\Lambda'\rangle_{\boldsymbol{r}} |v_{I'j'} Y_{l'm'} D_{m_j'\Omega'}^{j'\,*}\rangle \\ \equiv \langle Y_{lm} D_{m_j\Omega}^{j\,*} v_{Ij} | H_{II'}^{\text{e}}(R, \tilde{\beta}, r) | Y_{l'm'} D_{m_j'\Omega'}^{j'\,*} v_{I'j'}\rangle . \quad (31.91)$$

The angle $\tilde{\beta}$ is the polar angle of the diatom with respect to the atom-diatom axis. The angular integrations on the

right-hand side of (31.91) are accomplished by expanding the angular dependence of $H_{II'}^e$ in d-matrices and using angular momentum coupling algebra [31.158]. $H_{II'}^e$ gives the interaction potential of the ground state noble gas atom and the $I^{2S+1}\Lambda$ state of AB. It represents the potential coupling in the diabatic basis $\psi_{Rg}|I^{2S+1}\Lambda\rangle$. These matrix elements are derived from the corresponding adiabatic potential energy surfaces, determined using the techniques of Sect. 31.2. Since the van der Waals interaction is weak, the counterpoised method discussed in Sect. 31.2.4 should be used. When only one electronic state of a given symmetry is involved (point group C_s in the case of a triatom), the adiabatic and diabatic potentials are taken as equal. This is the case if, for example, only the $^1\Pi$ state of AB is considered. When more than one electronic state of a given sysmmetry is involved, for example, when both $^1\Pi$ and $^1\Sigma^+$ electronic states of AB are included, the adiabatic potentials are used to determine the diabatic state potentials using an approximate adiabatic $\rightarrow$ diabatic state transformation [31.159, 160].

The solution to (31.90) can be obtained by either variational methods or by direct integration [31.153]. Results for Ar-OH [31.161], Ar-BH [31.155], and Ar-CH [31.162], based on potential energy surfaces determined from multireference contracted CI wave functions, are encouraging. In these studies, the r-dependence of the potential energy surfaces was neglected.

31.4.4 Reaction Path

The rovibrational spectrum reflects the molecular structure in the vicinity of an equilibrium structure of the molecule. However a chemical reaction samples a much broader range of molecular structures. The evolution of molecular structure can be characterized by the reaction path, which represents a minimum energy path along the potential energy surface connecting the reactants and products. The reaction path Hamiltonian [31.163, 164] enables dynamical aspects of a chemical reaction to be inferred from a characterization of the reaction path.

The reaction path $\boldsymbol{R}(s)$ on potential energy surface $E_I^0(\boldsymbol{R})$ is the curve in mass weighted Cartesian coordinates given parametrically in terms of the arc length s and is defined as that solution to the differential equation

$$\frac{d\boldsymbol{R}}{ds} = \boldsymbol{g}^I / \sqrt{\boldsymbol{g}^{I\dagger}\boldsymbol{g}^I} \equiv \boldsymbol{R}'(s) \tag{31.92}$$

which approaches the saddle point from below [31.17, 165], where the arc length is given by

$$ds^2 = \sum_{i=1}^N dR_i^2 . \tag{31.93}$$

At each point s, $\boldsymbol{R}(s)$ represents the molecular structure in terms of $3N$ mass weighted Cartesian coordinates. (In this subsection, the notation suppresses the difference between Cartesian and mass weighted Cartesian coordinates.)

The reaction path can be obtained by integrating (31.92). Integration begins at the saddle point along the direction of the single negative eigenvalue of $\boldsymbol{F}^I$, which is related to the reaction path curvature $d\boldsymbol{R}^2/ds^2$, by

$$\frac{d\boldsymbol{R}^2}{ds^2} \equiv \frac{d\boldsymbol{R}'}{ds} = \left[\boldsymbol{F}^I\boldsymbol{R}' - \left(\boldsymbol{R}'^{\dagger}\boldsymbol{F}^I\boldsymbol{R}'\right)\boldsymbol{R}'\right] \bigg/ \sqrt{\boldsymbol{g}^{I\dagger}\boldsymbol{g}^I} . \tag{31.94}$$

Thus integration of (31.92) gives the steepest descent path from the saddle point. This integration requires, in principle, only knowledge of the energy gradient, $\boldsymbol{g}^I(\boldsymbol{R})$, which is readily available using analytic gradient techniques (see Sect. 31.2). This approach works quite well when the reaction path is used only to investigate the topology of a potential energy surface. However if quantities such as the curvature are desired, procedures that follow the reaction path more closely are required. Such procedures require higher derivatives of the energy, as fully discussed in [31.165].

In a nonadiabatic process, the reaction path necessarily involves more than one potential energy surface. In the case of nonadiabatic reactions involving avoided intersections, the reaction path is difficult to define since the propensity for an intersurface transition spreads out over a range of nuclear coordinates. However, for nonadiabatic reactions that proceed though a surface of intersection of two potential energy surfaces, the reaction path passes through the minimum energy point on the surface of intersection of the two potential energy surfaces [31.166]. An example of such a process is provided in Sect. 31.5. The minimum energy point on the surface of intersection satisfies (31.72) with no geometric constraints. For a spin-forbidden reaction, the solution of (31.72) yields $\boldsymbol{g}^I\boldsymbol{R} + \xi_1\boldsymbol{g}^{IJ}(\boldsymbol{R}) = 0$, so that $\boldsymbol{g}^I(\boldsymbol{R}) = \xi_1/(1+\xi_1)\boldsymbol{g}^J(\boldsymbol{R})$, i.e., the gradients on the two surfaces are either parallel or anti-parallel depending on the value of ξ_1. The relationship between the gradients in the vicinity

of an intersection of two states of the same symmetry is not as simple. The wave functions are not differentiable at a point of intersection. In the vicinity of the point of intersection, the condition $g^I(R) + \xi_1 g^{IJ}(R) + \xi_2 h^{IJ}(R) \approx 0$ holds, so that $g^I(R)$ and $g^J(R)$ will not be simply related. Finally, note that the adiabatic correction, defined in Sect. 31.1, is large (and positive) in the vicinity of the conical intersection, so that the nuclear wave function exhibits a node at this point.

31.5 Reaction Mechanisms: A Spin–Forbidden Chemical Reaction

This section presents an example to illustrate how the ideas outlined in the preceding sections can be used to obtain a mechanistic description of a chemical reaction which could not be deduced on intuitive grounds. Considered here is the ground state reaction

$$CH(X\,^2\Pi) + N_2(X\,^1\Sigma_g^+) \rightarrow HCN_2(1\,^2A'')$$
$$\rightarrow HCN_2(1\,4A'') \rightarrow HCN(X\,^1\Sigma^+) + N(^4S),$$
(31.95)
which is of considerable importance in the chemistry of planetary atmospheres [31.168, 169] and hydrocarbon flames, having been suggested as the initial step in the production of prompt or Fenimore NO [31.169–172]. However, because the reaction is spin-forbidden, its importance has been questioned.

The reaction will be interpreted in terms of the intermediate complex model [31.173, 174]. In this model, the reaction can occur despite a small probability for intersystem crossing by repeatedly traversing the 2A''–4A'' surface of intersection. The repeated traversals result from a local minimum on the 2A'' potential energy surface. This mechanism is operative for the spin-forbidden oxygen quenching reactions [31.173, 174]

$$O(^1D) + N_2(X\,^1\Sigma_g^+) \rightarrow N_2O^*$$
$$\rightarrow O(^3P) + N_2(X^1\Sigma_g^+),$$
(31.96)

$$O(^1D) + CO(X\,^1\Sigma^+) \rightarrow CO_2^*$$
$$\rightarrow O(^3P) + CO(X^1\Sigma^+),$$
(31.97)
which are important in the chemistry of the atmosphere.

To demonstrate the feasibility of reaction (31.95) as an intermediate complex assisted chemical reaction it is necessary to (i) determine the energetically relevant portion of the doublet-quartet surface of intersection, (ii) determine the spin-orbit interaction coupling the doublet and quartet surfaces, (iii) characterize a local minimum on the doublet surface from which the surface of intersection is accessible, (iv) characterize a path from the reactant channel to this region, and (v) determine the exit channel path on the quartet surface. The results of electronic structure calculations at the MR-CI level, addressing these points [31.167, 175–178] are summarized below.

Local Extrema on the 2A''–4A'' Surface of Intersection. Points in the 2A''–4A'' surface of intersection were determined from the solution to (31.72) [31.126, 175]. The minimum energy point on the surface of intersection, labelled $\mathcal{C}_{\text{mex}}^{C_{2v}}$, has approximate C_{2v} symmetry, and is shown in Fig. 31.3. It is the region of this crossing point that must be accessed from the doublet surface.
Fig. 31.3a–c Key bond distances in Å for **(a)** $R_{\text{min}}^{\text{dative}}(CH) = 1.082$, $R_{\text{min}}^{\text{dative}}(CN^1) = 1.340$, $R_{\text{min}}^{\text{dative}}(N^1N^2) = 1.143$; **(b)** $R_{\text{min}}^{C_{2v}}(CH) = 1.071$, $R_{\text{min}}^{C_{2v}}(CN^1) = 1.311$; $R_{\text{min}}^{C_{2v}}(N^1N^2) = 1.735$; $R_{\text{mex}}^{C_{2v}}(CH) = 1.076$, $R_{\text{mrex}}^{C_{2v}}(CN^1) = 1.3$, $R_{\text{mex}}^{C_{2v}}(N^1N^2) = 2.221$; **(c)** $R_{\text{TS}}^c(CH) = 1.093$, $R_{\text{TS}}^c(CN^1) = 1.515$, $R_{\text{TS}}^c(N^1N^2) = 1.214$. The notation is as defined in Sect. 31.5. The *dashed line* in structure **(c)** indicates that H is out of the plane of the paper. **(a)**, **(b)** after [31.124], **(c)** after [31.167]

The Spin–Orbit Interaction. In the double group corresponding to C_s symmetry, the $4A''$ and $2A''$ wave functions each carry degenerate irreducible representations, Kramer's doublets [31.179]. The following pairs of nonrelativistic zeroth-order wave functions can be used to span these degenerate representations (i) $\Psi^0[2A''(\frac{1}{2})]$, $\Psi^0[2A''(-\frac{1}{2})]$, (ii) $i\Psi^0[4A''(\frac{1}{2})]$, $i\Psi^0[4A''(-\frac{1}{2})]$, and (iii) $i\Psi^0[4A''(\frac{3}{2})]$, $i\Psi^0[4A''(-\frac{3}{2})]$, where the M_s value has been given parenthetically. In this case, all nonvanishing matrix elements connecting the components of the $4A''$ and $2A''$ states can be expressed in terms of the single real-valued matrix element [31.139]

$$H^{\text{so}}(4A'', 2A'')$$
$$\equiv \left\langle i\Psi^0\left[4A''\left(\frac{3}{2}\right)\right]\middle|H^{\text{so}}\middle|\Psi^0\left[2A''\left(\frac{1}{2}\right)\right]\right\rangle, \quad (31.98)$$

which was found to be $\approx 12.5\,\text{cm}^{-1}$ [31.126, 175] in the vicinity of the minimum energy crossing point determined above.

Local Extrema on the 2A'' Potential Energy Surface. Two local minima on the $2A''$ potential energy surface have been found [31.175–177]. The local minimum configuration labeled $\mathcal{C}_{\text{min}}^{\text{dative}}$ pictured in Fig. 31.3 represents a datively bonded structure in which N_2 donates a pair of electrons to the empty $CH(1\pi)$ orbital. This can be thought of as a reactant channel structure, since the N–N and C–H bond lengths are similar to those in the isolated molecules. This point on the $2A''$ potential energy surface is stable by 20.2 kcal/mol relative to the doublet asymptote in the reactant channel. The second minimum on the $2A''$ potential energy surface is also pictured in Fig. 31.3 and is seen to have C_{2v} symmetry. This configuration point, denoted $\mathcal{C}_{\text{min}}^{C_{2v}}$, is stable by 22.3 kcal/mol relative to the doublet asymptote in the reactant channel. Note that $\mathcal{C}_{\text{min}}^{C_{2v}}$ and $\mathcal{C}_{\text{mex}}^{C_{2v}}$ differ only in the length of the N–N bond.

Reaction Path. From the above data it might appear that both the $\mathcal{C}_{\text{min}}^{C_{2v}}$ and $\mathcal{C}_{\text{min}}^{\text{dative}}$ structures are involved in the mechanism of reaction (31.95). However, the energy of the transition state connecting these two minima is quite large [31.177], so that the reaction path avoids $\mathcal{C}_{\text{min}}^{\text{dative}}$ [31.167]. The true reaction path involves $\mathcal{C}_{\text{min}}^{C_{2v}}$, $\mathcal{C}_{\text{mex}}^{C_{2v}}$, and a reactant channel transition state $\mathcal{C}_{\text{TS}}^{c}$ that connects $\mathcal{C}_{\text{min}}^{C_{2v}}$ and the reactant channel species $CH + N_2$. $\mathcal{C}_{\text{TS}}^{c}$ is also pictured
Fig. 31.4 Reaction path for $CH(X^2\Pi) + N_2(X^1\Sigma_g^+) \rightarrow$ $HCN(X^1\Sigma^+) + N(^4S)$ after [31.167]. Energy scale, which is approximate, is in kcal/mol

in Fig. 31.3. It involves the nonplanar cis- approach of HC to N_2 [31.167]. The total reaction path is presented in Fig. 31.4 [31.178]. Note that following intersystem crossing, the system encounters a final transition state before proceeding to the spin-forbidden products.

From this qualitative analysis, a bimodal picture of the reaction of ground state CH with N_2 emerges. $CH(^2\Pi)$ can be removed by either (i) forming a complex $\mathcal{C}_{\text{min}}^{\text{dative}}$ which is stabilized by a third body collision or (ii) forming the spin-forbidden products with the reaction mechanism indicated in Fig. 31.4. This mechanism has been deduced entirely from the computational results cited above. The key computational findings responsible for this mechanism are (i) the existence and geometrical relationship between $\mathcal{C}_{\text{min}}^{C_{2v}}$ and $\mathcal{C}_{\text{mex}}^{C_{2v}}$, (ii) the large barrier separating $\mathcal{C}_{\text{min}}^{\text{dative}}$ and $\mathcal{C}_{\text{min}}^{C_{2v}}$, and (iii) the entrance channel path across $\mathcal{C}_{\text{TS}}^{c}$ to $\mathcal{C}_{\text{min}}^{C_{2v}}$.

Since there is apparently no or little barrier to forming $\mathcal{C}_{\text{min}}^{\text{dative}}$ [31.177], at low temperatures CH will be removed exclusively by this process at a rate with a small or negative temperature dependence, indicating a barrierless reaction. At higher temperatures, the rate constant is expected to exhibit a more usual Arrhenius type behavior as the spin-forbidden channel can be accessed [31.180]. These expectations are consistent with previous low temperature measurements [31.169, 181] and high temperature shock tube results [31.172, 182, 183]. The above reaction path for the spin-forbidden reaction has been used in a two internal coordinate model for reaction (31.95) [31.180] that also supports the proposed description of this reaction.

31.6 Recent Developments

Added by Mark M. Cassar. If the motion of nuclei within a molecule causes more than one Born-Oppenheimer potential energy surface to intersect, then nonadiabatic transitions become an essential process in molecular dynamics. These transitions are at the heart of many biological processes, such as light harvesting by plants [31.184, 185], which depends on electronic excitation transfer, and a host of processes in the upper atmosphere. In recent years, it has become apparent that conical intersections (see Sect. 31.3.3 for a definition) of two states of the same symmetry are a fundamental element of electronically nonadiabatic phenomena [31.186]. As an example, conical intersections can facilitate transitions from upper to lower electronic states. Transitions of this nature provide efficient pathways to lower electronic states, and are thus amenable to experimental study (e.g., through dissociation products of photoexcitation [31.187]).

Although points of conical intersection, which are not individual but form seams, can be located in a straightfoward manner, finding points of minimum energy has proved more difficult. This difficulty has been attributed to the erratic behavior of the parameters used in the search algorithm. This seemingly intrinsic problem which would preclude extrapolation – a consequence of the singular nature of the intersection itself – has been avoided through the use of extrapolatable functions [31.188]. This recent work introduces functions that vary smoothly (i. e., are well-behaved) as one moves along the intersection seam, and hence allow the use of extrapolation techniques.

The study of conical intersections has also been extended to include three-state intersections and first-order relativistic effects. Accidental conical intersections (i. e., those not required by symmetry arguments) of three states of the same symmetry, which may provide an efficient mechanism for radiationless decay, have been shown to exist [31.189]. Spin-orbit effects are essential for the proper description of the nuclear dynamics in molecules containing an odd number of electrons [31.190]. The topography of conical intersections changes in this case, requiring the development of new algorithms [31.191].

32. Molecular Symmetry and Dynamics

Molecules are aggregates of two or more nuclei bound by at least one electron. The nuclei of most stable molecules can be imagined to be points in a more or less rigid body whose relative positions are constrained by an electronic bonding potential. This potential depends strongly upon the electronic state as described in Chapt. 31. Most of this discussion is about stable molecules in their electronic ground state. In Sect. 32.6 some comments are made about molecules with excited, or "loose", parts.

32.1 Dynamics and Spectra of Molecular Rotors

Motions that stretch or compress the bonds are called vibrational motions, and give rise to spectral resonances in the infrared region of the spectrum. Typical fundamental vibrational quanta (ν_0) lie between $80\,\mathrm{cm}^{-1}$ (the lowest $GeBr_4$ mode) and $3020\,\mathrm{cm}^{-1}$ (the highest CH_4 mode). (A $1000\,\mathrm{cm}^{-1}$ wave has a wavelength of $10\,\mu\mathrm{m}$ and a frequency defined by the speed of light: $29.979\,2458\,\mathrm{THz}$.) Vibrational amplitudes are usually tiny since zero-point motions or vibrations involving one or two quanta ($\nu = 0, 1, 2, \dots$) are constrained by the steep bonding potential to less than a few percent of the bond lengths, but high overtones may lead to dissociation, i.e., molecular breakup.

Overall rotation of molecules in free space is unconstrained, and gives rise to far-infrared or microwave pure rotational transitions or sidebands on top of vibrational spectra. Typical rotational quanta ($2B$) lie between $0.18\,\mathrm{cm}^{-1}$ ($5.4\,\mathrm{GHz}$) for SF_6 and $10.6\,\mathrm{cm}^{-1}$ for CH_4. Individual molecules are free to rotate or translate as a whole while undergoing tiny but usually rapid vibrations. Vibrating molecules may be thought of as tumbling collections of masses held together by 'springs' (the electronic vibrational potential or force field), and are called semirigid rotors. The coupling of rotational and vibrational motion is called rovibrational coupling and includes centrifugal and Coriolis coupling, which will be introduced in Sect. 32.6.

This discussion of molecular dynamics and spectra mainly involves molecular rotation and properties of rotationally excited molecules, particularly those with high rotational quantum number $J = 10$–200. However, the discussion also applies to molecules in excited vibrational states, and even certain cases of molecules in excited electronic states. The analysis of vibronic (vibrational-electronic), rovibrational (rotation–vibration), or rovibronic (all three) types of excitation can be very complicated [32.1–5] and is beyond the scope of this article, but these problems can all benefit from the elementary considerations described here.

32.1.1 Rigid Rotors

As a first approximation, and for the purposes of discussing basic molecular dynamics and spectra, one may ignore vibrations and model stable molecules as 'stick-and-ball' structures or rigid rotors. Then the Hamiltonian has just three terms:

$$H = A J_x^2 + B J_y^2 + C J_z^2 \; . \tag{32.1}$$

Here $\{J_x, J_y, J_z\}$ are rotational angular momentum operators, and the rotational constants are half the inverses of the principal moments of inertia I_α of the body:

$$A = \frac{1}{2I_x} \; , \quad B = \frac{1}{2I_y} \; , \quad C = \frac{1}{2I_z} \; . \tag{32.2}$$

This implies that the J-coordinate system being used is a special one fixed to the rotor's body and aligned to its principal axes, an elementary body, or Eckart, frame.

Many molecules, particularly all diatomic molecules, have two of these rotational constants equal, say, $A = B$. Such rotors are called symmetric tops, and their Hamiltonian can be written in terms of the square of the total angular momentum $\boldsymbol{J} \cdot \boldsymbol{J}$ and one other body component J_z as

$$
\begin{aligned}
H &= B J_x^2 + B J_y^2 + C J_z^2 \\
&= B J_x^2 + B J_y^2 + B J_z^2 + (C - B) J_z^2 \\
&= B \boldsymbol{J} \cdot \boldsymbol{J} + (C - B) J_z^2
\end{aligned}
\tag{32.3}
$$

This gives a simple formula for the symmetric top rotational energy levels in terms of the quantum numbers J for the total angular momentum and K for the body z-component:

$$E(J, K) = B J(J + 1) + (C - B) K^2 \tag{32.4}$$

However, this eigenvalue formula may be a little too simple, since it hides the structure of the eigenstates or eigenfunctions. Indeed, the full Schrödinger angular differential equation based upon the Hamiltonian (32.1) is more lengthy. One should remember that H is written in a rotating body coordinate frame that must be connected to a star-fixed, or laboratory, frame in order to get the full theory.

32.1.2 Molecular States Inside and Out

Rotor angular momentum eigenfunctions can be expressed as continuous linear combinations of rotor angular position states $|\alpha\beta\gamma\rangle$ defined by Euler angles of the lab azimuth α, the polar angle β of body z-axis, and the body azimuth, or 'gauge twist', γ. The eigenfunctions are,

$$
\left| \begin{matrix} J \\ MK \end{matrix} \right\rangle = \frac{\sqrt{2J+1}}{8\pi^2} \int\limits_0^{2\pi} \mathrm{d}\alpha \int\limits_0^\pi \sin\beta \, \mathrm{d}\beta
$$
$$
\times \int\limits_0^{2\pi} \mathrm{d}\gamma \, D_{MK}^{J}{}^*(\alpha\beta\gamma) |\alpha\beta\gamma\rangle \; , \tag{32.5}
$$

where the rotor wave functions $D_{MK}^{J}{}^*$ are just the conjugates of the Wigner rotation matrices described in Sect. 32.3.1, and row and column indices M and K, respectively, are the lab and body components of the angular momentum [32.5–7].

An important feature of polyatomic molecules is that their angular momentum states have two kinds of azimuthal quantum numbers. In addition to the usual lab component of momentum M associated with the lab coordinate α (α and β are usually labeled φ and ϑ), there is a body component K associated with the Euler coordinate γ, the body azimuthal angle of the laboratory Z-axis relative to the body z-axis.

The physics of atomic or diatomic angular momentum states has no internal or "body" structure, so the quantum number K is always zero. Unless one sets $K = 0$, the energy formula (32.4) blows up for a point particle because z-inertia for a point is zero and C is infinite. Also, the dimension of the angular momentum state multiplet of a given J is larger than the usual $(2J + 1)$ found in atomic or diatomic molecular physics. In polyatomic rotors, the number of states for each J is $(2J + 1)^2$, since both quantum numbers M and K range between $-J$ and $+J$.

A further important feature is that the molecular rotor wave functions contain, as a special ($K = 0$) case, all

the usual atomic spherical harmonics Y_m^ℓ complete with correct normalization and phase, since

$$\sqrt{4\pi} Y_m^\ell(\varphi\vartheta) = D_{m0}^\ell(\varphi\vartheta\cdot)^* \sqrt{2\ell+1} \ . \qquad (32.6)$$

This is part of a powerful symmetry principle: group representations are quantum wave functions, and symmetry analysis is an extension of Fourier analysis – not just for translations as in Fourier's original work, but for any group of symmetry operations. The usual Fourier coefficients e^{ikx} are replaced by the D functions in the rotational Fourier transform embodied by (32.5).

Molecular rotational analysis displays another important but little known aspect of symmetry analysis in general. For every group of symmetry operations, such as the external lab-based rotations familiar to atomic physics, there is an independent dual group of internal or body-based operations. The external symmetry of the environment or laboratory is independent of the internal symmetry of the molecular body, and all the operations of one commute with all those of the other. The molecular rotation group is thus written as an outer product $R(3)_{LAB} \otimes R(3)_{BODY}$ of the external and internal parts, and the degeneracy associated with this group's representations for a single J is $(2J+1)^2$ as mentioned above. It is a special $\otimes$-product, however, since the J-number is shared.

The inversion or parity operator $I(\mathbf{r} \to -\mathbf{r})$ can be defined to be the same for both lab and body frames. Including I with the rotational group $R(3)$ gives the orthogonal group $O(3) = R(3) \otimes \{\mathbf{1}, \mathbf{I}\}$. If parity is conserved (e.g., no weak neutral currents), the fundamental molecular orthogonal group is $O(3)_{LAB} \otimes O(3)_{BODY}$.

How this symmetry breaks down and which levels split depends upon both the perturbative laboratory environment and the internal molecular structure. A spherical top Hamiltonian is (32.1) with $A = B = C$. This has a full $O(3)_{BODY}$ (spherical) symmetry since it is just $B\mathbf{J} \cdot \mathbf{J}$. Given that the rotor is in an $O(3)_{LAB}$ laboratory (empty space), the original symmetry $O(3)_{LAB} \otimes O(3)_{BODY}$ remains intact and the $(2J+1)^2$ degeneracy is to be expected. However, a symmetric rotor in a lab vacuum has its internal symmetry broken down to $O(2)_{BODY}$ if $A = B \neq C$, and the energies given by (32.4) consist of internal quantum singlets for $K = 0$ and $\pm K$ doublets for $K \neq 0$. But each of these levels still has a lab degeneracy of $(2J+1)$ if $O(3)_{LAB}$ is still in effect. So the $(2J+1)^2$ level degeneracies are each split into multiplets of degeneracy $(2J+1)$ and $2(2J+1)$ for $K = 0$ and $K \neq 0$, respectively. The resulting levels are often labeled $\Sigma, \Pi, \Delta, \Phi, \Gamma, \ldots$ in a somewhat inap-propriate analogy with the atomic s, p, d, f, g, ... labels of Bohr model electronic orbitals.

Only by perturbing the lab environment can one reduce the $O(3)_{LAB}$ symmetry and split the M degeneracies. For example, a uniform electric field would reduce the $O(3)_{LAB}$ to an $O(2)_{LAB}$, giving Stark splittings which consist of external quantum singlets for $M = 0$ and $\pm M$ doublets for $M \neq 0$. A uniform magnetic field would reduce the $O(3)_{LAB}$ to an $R(2)_{LAB}$, giving Zeeman splittings into external quantum singlets for each M. The analogy between atomic external field splitting and internal molecular rotational structure splitting is sometimes a useful one and will be used later.

32.1.3 Rigid Asymmetric Rotor Eigensolutions and Dynamics

The general case for the rigid rotor Hamiltonian (32.1) has three unequal principal moments of inertia ($A \neq B \neq C$). This is called the rigid asymmetric top Hamiltonian, and provides a first approximation for modeling rotation of low symmetry molecules, such as H_2O. Also, a number of properties of its eigensolutions are shared by more complicated systems. The dynamics of an asymmetric top is quite remarkable, as demonstrated by tossing a tennis racquet in the air, flat side up. The corresponding quantum behavior of such a molecule is also nontrivial.

Given the total angular momentum J, one may construct a $(2J+1)$-dimensional matrix representation of H using standard matrix elements of the angular momentum operators J_x, J_y, and J_z, as given in Chapt. 2. The H matrix connects states with $(2J+1)$-different body quantum numbers $K(-J \leq K \leq J)$, but the matrix is independent of the lab quantum numbers M, so there are $(2J+1)$ identical H matrices; one for each value of the lab quantum number $M(-J \leq K \leq J)$.

A plot of the 21 eigenvalues of (32.1) for $J = 10$ is shown in Fig. 32.1. Here, the constants are set to $A = 0.2\,\mathrm{cm}^{-1}$ and $C = 0.6\,\mathrm{cm}^{-1}$, while B is varied between $B = A$, which corresponds to a prolate symmetric top (an elongated cylindrical object) and $B = C$, which corresponds to an oblate symmetric top (a flattened cylindrical object or discus). For all B values between those of A and C, the object is asymmetric.

The left hand end $\left(A = B = 0.2\,\mathrm{cm}^{-1}, \quad C = 0.6\,\mathrm{cm}^{-1}\right)$ of the plot in Fig. 32.1 corresponds to a prolate symmetric top. The symmetric top level spectrum is given by (32.4). It consists of a lowest singlet state corresponding to $K = 0$ and an ascending quadratic ladder of doublets corresponding to $K = \pm 1, \pm 2, \ldots, \pm J$.
Fig. 32.1 $J = 10$ eigenvalue plot for symmetric rigid rotors. ($A = 0.2$, $C = 0.6 \, \text{cm}^{-1}$ $A < B < C$). Prolate and oblate RE surfaces are shown

The right hand end $\left(A = 0.2 \, \text{cm}^{-1}, \, B = C = 0.6 \, \text{cm}^{-1}\right)$ of the plot corresponds to an oblate symmetric top with a descending quadratic ladder of levels, the $K = 0$ level being highest. Also, the internal K-axis of quantization switches from the body z-axis for $(A = B = 0.2 \, \text{cm}^{-1}$, $C = 0.6 \, \text{cm}^{-1})$ to the body x-axis for $(A = 0.2 \, \text{cm}^{-1}$, $B = C = 0.6 \, \text{cm}^{-1})$. Note that the lab M-degeneracy is invisible here, but exists nevertheless.

For intermediate values of B, one has an asymmetric top level structure and, strictly speaking, no single axis of quantization. As a result, the eigenlevel spectrum is quite different. A detailed display of asymmetric top levels for the case $\left(A = 0.2 \, \text{cm}^{-1}, \, B = 0.4 \, \text{cm}^{-1}, \, C = 0.6 \, \text{cm}^{-1}\right)$ is given at the bottom of Fig. 32.2. They are shown to correspond to semiclassical orbits discussed in Sect. 32.2. This example is the most asymmetric top, since parameter B has a value midway between the symmetric top limits of $B = A$ and $B = C$.

The twenty-one $J = 10$ asymmetric top levels are arranged into roughly ten asymmetry doublets and one singlet. This resembles the symmetric top levels except that doublets are split by varying amounts, and the singlet is isolated from the other levels in the middle of the band instead of being crowded at the top or bottom. The doublet splittings are magnified in circles drawn next to the levels, and these indicate that the splitting decreases quasi-exponentially with each doublet's separation from the central singlet.

An asymmetric doublet splitting is also called superfine structure and can be viewed as the result of a dynamic tunneling process in a semiclassical model of rotation [32.8–10]. Such a model clarifies the classical-quantum correspondence for polyatomic rovibrational dynamics in general. It can also help to derive simple approximations for eigenvalues and eigenvectors.

32.2 Rotational Energy Surfaces and Semiclassical Rotational Dynamics

A semiclassical model of molecular rotation can be based upon what is called a rotational energy surface (RES) [32.7–14]. Examples of RES for an asymmetric top are shown in Fig. 32.2, and for prolate and oblate symmetric tops in Fig. 32.1. Each surface is a radial plot of the classical energy derived from the Hamil-

tonian (32.1) as a function of the polar direction of the classical angular momentum J-vector in the body frame. The magnitude of J is fixed for each surface. Note that the J-vector in the lab frame is a classical constant of the motion if there are no external perturbations. However, J may gyrate considerably in the moving body frame,
Fig. 32.2 $J = 10$ rotational energy surface and related level spectrum for an asymmetric rigid rotator $\left(A = 0.2,\ B = 0.4,\ C = 0.6\,\mathrm{cm}^{-1}\right)$

but its magnitude $|J|$ stays the same in all frames for free rotation.

An RES differs from what is called a constant energy surface (CES), which is obtained by simply plotting $E = H = $ const. in J-space using (32.1). A rigid rotor CES is an ellipsoid covering a range of $|J|$ values at a single energy. An RE surface, on the other hand, is a spherical harmonic plot at a single $|J|$ value for a range of energies. The latter is more appropriate for spectroscopic studies of fine structure, since one value of the rotational quantum number J corresponds to a multiplet of energy levels or transitions. An RES also shows loci of high and low energy rotations. Also, it has roughly the same shape as the body it represents, i. e., an RES is long in the direction that the corresponding molecule is long (but vice-versa for CES).

For a freely rotating molecule, the laboratory components of the classical total angular momentum J are constant. If one chooses to let J define the lab Z-axis, then the direction of the J-vector in the body frame is given by polar and body azimuthal coordinates β and γ, which are the second and third Euler angles, respectively. (It is conventional to use the negatives $-\beta$ and $-\gamma$ as polar coordinates, but this will not be necessary here.) Then the body components of the J-vector are written as

$$\left(J_x = |J| \sin \beta \cos \gamma , \quad J_y = |J| \sin \beta \sin \gamma , \right.$$
$$\left. J_z = |J| \cos \beta \right) , \tag{32.7}$$

where the magnitude of the quantum value $|J| = \sqrt{J(J+1)} \cong J + \frac{1}{2}$.

Substituting this into the Hamiltonian (32.1) gives an expression for the general rigid rotor RES radius in polar coordinates:

$$E(\beta, \gamma) = \langle H \rangle = J(J+1)$$
$$\times \left[\sin^2 \beta \left(A \cos^2 \gamma + B \sin^2 \gamma \right) + C \cos^2 \beta \right] . \tag{32.8}$$

The prolate symmetric top $(A = B < C)$ expression

$$E(\beta) = \langle H \rangle = J(J+1) \left[B + (C - B) \cos^2 \beta \right] \tag{32.9}$$

is independent of azimuthal angle γ. The 3-dimensional plots of these expressions are shown in Figs. 32.1 and 32.2.

The RES have topography lines of constant energy $(E = $ const.) that are the intersection of an RES (constant $|J|$) with spheres of constant energy. The topography lines are allowed classical paths of the angular momentum J-vector in the body frame, since these paths conserve both energy and momentum.

The trajectories in these figures are special ones. They are the quantizing trajectories for total angular momentum $J = 10$. For the prolate symmetric top, the quantizing trajectories have integral values for the body z-component K of angular momentum. According to the Dirac vector model, angular momentum vectors trace out a cone of altitude K and slant height $|J| = \sqrt{J(J+1)}$. The quantizing polar angles Θ_k^J are given by

$$\Theta_K^J = \cos^{-1} \frac{K}{\sqrt{J(J+1)}} \tag{32.10}$$
$$(K = J, J-1, \cdots, -J) .$$

These are the latitude angles of the paths on the RES in Fig. 32.1 for $K = 10, 9, 8, \ldots, -10$. (For the oblate RES, the angles are relative to the x-axis.) If $\beta = \left(\Theta_K^J \right)$ is substituted into the symmetric top RES (32.9), the result is

$$E\left(\Theta_K^J \right) = J(J+1)B + (C - B) K^2 , \tag{32.11}$$

which is precisely the symmetric top eigenvalue (32.4). The quantizing paths are circles lying at the intersections of the Dirac angular momentum cones and the RES. The angle $\left(\Theta_K^J \right)$ is a measure of the angular momentum uncertainty ΔJ_x or ΔJ_y transverse to the z-axis of quantization. Clearly, $K = \pm J$ states have minimum uncertainty.

For the asymmetric top, the classical paths that conserve both $|J|$ and E are one of two types. First, there are those pairs of equal-energy orbits that go around the hills on the plus or minus end of the body z-axis, which correspond to the $\pm K$ pairs of levels in the upper half of the level spectrum drawn in Fig. 32.2. Then there are the pairs of levels belonging to the equal-energy orbits in either of the two valleys surrounding the body x-axis, which are associated with the pairs of levels in the lower half of the level spectrum. Different eigensolutions occupy different geography.

The upper pairs of paths are seen to be distorted versions of the prolate top orbits seen on the left-hand side of Fig. 32.1, while the lower pairs are distorted versions of the oblate top orbits seen on the right-hand side of Fig. 32.1. The distortion makes J_z deviate from a constant K-value and corresponds to K-mixing in the quantum states. This also shows that more than one axis of quantization must be considered; the prolate-like paths are based on the z-axis, while the oblate-like paths belong to the body x-axis.

The two types of orbits, x and y, are separated by what is called a separatrix curve, which crosses the sad-

dle points on either side of the body y-axis. In the example shown in Fig. 32.2, the separatrix is associated with a single level which separates the upper and lower energy doublets. The doublets that are closer to the separatrix level are split more than those which are farther away. Apart from the splitting, the energy levels can be obtained by generalized Bohr quantization of the classical paths on the RES. The quantization condition is,

$$\int J_z \, d\gamma = K , \tag{32.12a}$$

where

$$J_z = \sqrt{\frac{J(J+1)\left(C \cos^2 \gamma + B \sin^2 \gamma\right) - E}{\left(C \cos^2 \gamma + B \sin^2 \gamma\right) - A}} \tag{32.12b}$$

follows from (32.7) and (32.8). The resulting E_K-values are obtained by iteration.

The doublet, or superfine, splitting is a quantum effect which may be associated with tunneling between orbits that would have had equal energies E_K in the purely classical or semiclassical model. Approximate tunneling rates are obtained from integrals over the saddle point between each pair of equal-energy quantizing paths. The K-th rate, or amplitude, is,

$$S_K = \nu_K \, e^{-P_K} , \tag{32.13}$$

where

$$P_K = \tag{32.14}$$
$$i \int_{\gamma-}^{\gamma+} d\gamma \sqrt{\frac{J(J+1)\left(C \cos^2 \gamma + B \sin^2 \gamma\right) - E_K}{\left(C \cos^2 \gamma + B \sin^2 \gamma\right) - A}}$$

is the saddle path integral between the points of closest approach, $\gamma+$ and $\gamma-$, and ν_K is the classical precession frequency or quantum level spacing around energy level E_K. Since there are two tunneling paths, the amplitude S_K is doubled in a tunneling Hamiltonian matrix for the K-th semiclassical doublet of z and $-z = \bar{z}$ paths:

$$\langle H \rangle_K = \begin{pmatrix} E_K & 2S_K \\ 2S_K & E_K \end{pmatrix} \begin{array}{c} |z\rangle \\ |\bar{z}\rangle \end{array} . \tag{32.15}$$

The resulting tunneling energy eigensolutions are given in Table 32.1.

A- or B-states correspond to symmetric and antisymmetric combinations of waves localized on the two semiclassical paths. Rotational symmetry is considered in Sect. 32.3.

The total doublet splitting is $4S_K$, and decreases exponentially with the saddle path integral (32.14). The superfine A–B splittings in Fig. 32.2 are seen to range from several GHz near the separatrix down to only 26 kHz for the highest-K doublets at the band edges.

Meanwhile, the typical interdoublet level spacing or classical precessional frequency is about 150 GHz for the $J = 10$ levels shown in Fig. 32.2. This K-level spacing is called rotational fine structure splitting, and is also present in the symmetric top case. (The superfine splitting of the symmetric top doublets is exactly zero, since they have $O(2)_{BODY}$ symmetry if $A = B$ or $B = C$. In this case, all tunneling amplitudes cancel.)

The classical precession of $\boldsymbol{J}$ in the body frame follows a "left-hand rule" similar to what meteorologists use to determine Northern Hemisphere cyclonic rotation. A left "thumbs-down" or "low" has counterclockwise precession as does an oblate rotor valley, but a prolate RES "high" supports clockwise motion just like a weather "high".

Finally, consider the spacing between adjacent J-levels, which is called rotational structure, in a spectrum. This spacing is

$$E(J, K) - E(J-1, K) = 2BJ , \tag{32.16}$$

according to the symmetric top energy formulas (32.4). For the example just treated, $2BJ$ is about $10 \, \text{cm}^{-1}$ or 300 GHz. This corresponds to the actual rotation frequency of the body. It is the only kind of rotational dynamics or spectrum that is possible for a simple diatomic rotor. A diatomic molecule, however, can have internal electronic or nuclear spin rotation, which gives an additional fine structure as discussed later [32.1,6,15].

To summarize, polyatomic molecules can be expected to exhibit all three types of rotational motion and spectra (from faster to slower): rotational, precessional, and precessional tunneling. These are related to three kinds of spectral structure (from coarser to finer spectra): rotational structure, fine structure, and superfine structure, respectively. Again, this neglects internal rotational and spin effects, which can have abnormally strong rotational resonance coupling due to the superfine structure [32.9,16]. Examples of this are discussed at the end of this chapter.

Table 32.1 Tunneling energy eigensolutions

Eigenvectors	$|z\rangle$	$|\bar{z}\rangle$	Eigenvalues
$|A\rangle$	1	1	$E^A(K) = E_K + 2S_K$
$|B\rangle$	1	-1	$E^B(K) = E_K - 2S_K$

32.3 Symmetry of Molecular Rotors

Molecular rotational symmetry is most easily introduced using examples of rigid rotors. Molecular rotor structures may have more or less internal molecular symmetry, depending on how their nuclei are positioned relative to one another in the body frame. A molecule's rotational symmetry is described by one of the elementary rotational point symmetry groups. These are the n-fold axial cyclic groups C_n and polygonal dihedral groups $D_n (n = 1, 2, \dots)$, the tetrahedral group T, the cubic-octahedral group O, or the icosahedral group Y. All other point groups, such as C_{nv}, T_d, and O_h, are a combination of an elementary point group with the inversion operation $I(r \rightarrow -r)$. Each of these groups consist of operations which leave at least one point (origin) of a structure fixed while mapping identical atoms or nuclei into each other in such a way that the appearance of the structure is unchanged. The point groups are subgroups of the nuclear permutation groups [32.17].

In other words, molecular symmetry is based upon one of the most fundamental properties of atomic physics: the absolute identity of all atoms or, more precisely, nuclei of a given atomic number Z and mass number A. It is the identity of the so-called 'elementary' electronic and nucleonic constituent particles that underlies the symmetry.

The Pauli principle states that all half-integer spin particles are antisymmetrized with every other one of their kind in the universe. The Pauli–Fermi antisymmetrization principle and the related Bose–Einstein symmetrization principle determine much of molecular symmetry and dynamics, just as the Pauli exclusion principle is fundamental to electronic structure.

32.3.1 Asymmetric Rotor Symmetry Analysis

For an asymmetric rigid rotor, any rotation which interchanges $x-$, $y-$, or z-axes of the body cannot possibly be a symmetry, since all three axes are assumed to have different inertial constants. This restricts one to consider only 180° rotations about the body axes, and these are the elements of the rotor groups C_2 and D_2.

The two symmetry types for C_2 are even (denoted A or 0_2) and odd (denoted B or 1_2) with respect to a 180° rotation. For D_2, which is just $C_2 \otimes C_2$, the four

symmetry types are even-even (denoted A_1), even-odd (denoted A_2), odd-even (denoted B_1), and odd-odd (denoted B_2) with respect to 180° rotations about the y- and x-axes, respectively. (The z-symmetry is determined by a product of the other two since $R_z = R_x R_y$.) This is summarized in the character Tables 32.2 and 32.3.

The RES for the rigid rotor shown in Fig. 32.2 is invariant under 180° rotations about each of the three body axes. Therefore, its Hamiltonian symmetry is D_2 and its quantum eigenlevels must correspond to one of the four types listed under D_2 in Table 32.3. The D_2 symmetry labels are called rotational (or in general rovibronic) species of the molecular state. The species label the symmetry of a quantum wave function associated with a pair of C_2 symmetric semiclassical paths.

The classical J-paths come in D_2 symmetric pairs, but each individual classical J-path on the rigid rotor RES has a C_2 symmetry which is a subgroup of D_2. Each path in the valley around the x-axis is invariant under just the 180° rotation around the x-axis. This is $C_2(x)$ symmetry. The other member of its pair that goes around the negative x-axis also has this local $C_2(x)$ symmetry. The combined pair of paths has the full D_2 symmetry but classical mechanics does not permit occupation of two separate paths. Multiple path occupation is a completely quantum effect.

Similarly, each individual J-path on the hill around the z-axis is invariant under just the 180° rotation around the z-axis, so it has $C_2(z)$ symmetry as does the equivalent path around the negative z-axis. Only the separatrix has the full D_2 symmetry, since its pairs are linked up on the y-axis to form the boundary between the x and z paths. No J-paths encircle the unstable y-axis since it is a saddle point.

Each classical J-path near the x- or z-axis belongs to a particular K-value through the semiclassical quantization conditions (32.12). Depending upon whether the K-value is even (0_2) or odd (1_2), the corresponding K-doublet is correlated with a pair of D_2 species as shown in the columns of the correlation tables in Fig. 32.3. These three correlation tables give the axial

Table 32.2 Character table for symmetry group C_2

Fig. 32.3 Tables of correlations between D_2 symmetry species and the even (0_2) and odd (I_2) symmetric species of subgroups $C_2(x)$, $C_2(y)$, and $C_2(z)$

180° rotational symmetry of each D_2 species for rotation near each body axis x, y and z, respectively, but only the stable rotation axes x and z support stable path doublets for this Hamiltonian (32.1).

For example, consider the $K = 10$ paths which lie lowest in the x-axis valleys. Since $K = 10$ is even (0_2),

it is correlated with an A_1 and B_1 superfine doublet [see the 0_2 column of the $C_2(x)$ table]. On the high end near the z-axis hilltop, $K = 10$ gives rise to an A_1 and B_2 doublet [see the 0_2 column of the $C_2(z)$ table]. All the doublets in Fig. 32.2 may be assigned in this way.

32.4 Tetrahedral–Octahedral Rotational Dynamics and Spectra

The highest symmetry rigid rotor is the *spherical top* for which the three inertial constants are equal $(A = B = C)$. The spherical top Hamiltonian

$$H = B\mathbf{J} \cdot \mathbf{J}$$

has the full $R(3)_{\text{LAB}} \otimes R(3)_{\text{BODY}}$ symmetry. With inversion parity, the symmetry is $O(3)_{\text{LAB}} \otimes O(3)_{\text{BODY}}$. In any case, the J-levels are $(2J+1)^2$-fold degenerate. The resulting $BJ(J+1)$ energy expression is the first approximation for molecules which have regular polyhedral symmetry of, for example, a tetrahedron (CF_4), cube (C_6H_6), octahedron (SF_6), dodecahedron or icosahedron ($C_{20}H_{20}$, $B_{12}H_{12}$, or C_{60}). Rigid regular

polyhedra have isotropic or equal inertial constants and rotate just like they were perfectly spherical distributions of mass.

However, no molecule can really have spherical $O(3)_{\text{BODY}}$ symmetry; even molecules of the highest symmetry contain a finite number of nuclear mass points, and therefore have a finite internal point symmetry. Evidence of octahedral or tetrahedral symmetry shows up in fine structure splittings analogous to those for asymmetric tops. However, spherical top fine structure is due to symmetry breaking caused by anisotropic or tensor rotational distortion. To discuss this, one needs to consider what are called semirigid rotors.

Part C | 32.4

32.4.1 Semirigid Octahedral Rotors and Centrifugal Tensor Hamiltonians

The lowest order tensor centrifugal distortion perturbation has the same form for both tetrahedral and octahedral molecules. It is simply a sum of fourth powers of angular momentum operators given in the third term below. The first two terms are the scalar rotor energy and scalar centrifugal energy.

$$H = B\,|J|^2 + D\,|J|^4 + 10 t_{044}$$
$$\times \left[J_x^4 + J_y^4 + J_z^4 - (3/5) J^4 \right]. \quad (32.17)$$

The tensor term includes the scalar $(3/5) J^4$ to preserve the center of gravity of the tensor level splitting. This type of semirigid rotor Hamiltonian was first used in the study of methane (CH_4) spectra [32.18].

The scalar terms do not reduce the symmetry or split the levels. The tensor term (t_{044}) breaks the molecular symmetry from $O(3)_{LAB} \otimes O(3)_{BODY}$ to the lower symmetry subgroup $O(3)_{LAB} \otimes T_{dBODY}$, or $O(3)_{LAB} \otimes O_{hBODY}$, and splits the $(2J+1)^2$-fold degeneracy into intricate fine structure patterns which are analogous to cubic crystal field splitting of atomic orbitals. The first calculations of the tensor spectrum were done by direct numerical diagonalization [32.18–21]. As a result, many of the subtle symmetry properties were missed. The semiclassical analysis [32.22] described in the following Sections exposes these properties.

32.4.2 Octahedral and Tetrahedral Rotational Energy Surfaces

By substituting in (32.7) and plotting the energy as a function of body polar angles β and γ, an RES is obtained, two views of which are shown in Fig. 32.4. Here the tensor term is exaggerated in order to exhibit the topography clearly. (In ($n = 0$) SF_6, the t_{044} coefficient is only about 5.44 Hz, while the rotational constant is $B = 0.09\,\text{cm}^{-1}$. The t_{244} coefficient of ($n = 1$) SF_6 is much greater.)

A positive tensor coefficient ($t_{a44} > 0$) gives an octahedral shaped RES, as shown in Fig. 32.4. This is appropriate for octahedral molecules since they are least susceptible to distortion by rotations around the x-, y-, and z-axes containing the strong radial bonds. Thus the rotational energy is highest for a J-vector near one of six body axes $(\pm 1, 0, 0)$, $(0, \pm 1, 0)$, or $(0, 0, \pm 1)$, i.e., one of the six RES hills in Fig. 32.4.

However, if the J-vector is set in any of the eight interaxial directions $(\pm 1, \pm 1, \pm 1)$, the centrifugal force

will more easily bend the weaker angular bonds, raise the molecular inertia, and lower the rotational energy. This accounts for the eight valleys on the RES in Fig. 32.4.

A negative tensor coefficient ($t_{a44} < 0$) gives a cubic shaped RES. This is usually appropriate for cubic and tetrahedral molecules, since they are most susceptible to distortion by rotations around the x-, y-, and z-axes which lie between the strong radial bonds on the cubic diagonals. Instead of six hills and eight valleys, one finds six valleys and eight hills on the cubic RES. Both freon CF_4 and cubane C_8H_8 are examples of this type of topology.

Note that a semirigid tetrahedral rotor may have the same form of rotational Hamiltonian and RE surface as a cubic rotor. The four tetrahedral atomic sites are in the same directions as four of the eight cubic sites. The other four cubic sites form an inverted tetrahedron of the same shape.

If only tetrahedral symmetry were required, the Hamiltonian could contain a third order tensor of the form $J_x J_y J_z$. However, pure rotational Hamiltonians must also satisfy time-reversal symmetry: the energy for each J must be the same as for $-J$, and thus rotational sense should not matter. This symmetry excludes all odd powers of J. Simple rotor RES have inversion symmetry even if their molecules do not. Compound rotors containing spins or other rotors may have "lopsided" pairs of RES as shown in Sect. 32.6.

32.4.3 Octahedral and Tetrahedral Rotational Fine Structure

An example of rotational fine structure for angular momentum quantum number $J = 30$ is shown in Fig. 32.4. The levels consist mainly of clusters of levels belonging to the octahedral symmetry species A_1, A_2, E, T_1, or T_2. The characters of these species are given in Table 32.4. (The tetrahedral T_d group has a similar table where T_1 and T_2 are often labeled F_1 and F_2).

The first column gives the dimension or degeneracy of each species; A_1, A_2, are singlets, E is a doublet,

Table 32.4 Character table for symmetry group O

O	0°	120°	180°	90°	180°
A_1	1	O 1	1	1	1
A_2	1	1	1	−1	−1
E	2	−1	2	0	0
T_1	3	0	−1	1	−1
T_2	3	0	−1	−1	1
Fig. 32.4 $J = 10$ rotational energy surface related level spectrum for a semirigid octahedral or thetrahedral rotor

while T_1 and T_2 are triplets. These species form two clusters (A_1, T_1, T_2, A_2) and (T_2, E, T_1) on the low end of the spectrum and six clusters (T_1, T_2), (A_2, T_2, E), (T_1, T_2), (E, T_1, A_1), (T_1, T_2), and (A_2, T_2, E) on

the upper part of the spectrum. (See the right-hand side of Fig. 32.4). Note that the total dimension or (near) degeneracy for each of the two lower clusters is eight: $(1+3+3+1)$ and $(3+2+3)$, while the upper clusters each have a six-fold (near) degeneracy: $(3+3)$, $(1+3+2)$, etc.

Each of the two lower eight-fold clusters can be associated with semiclassical quantizing paths in an RES valley as shown in Fig. 32.4. The eight-fold dimension or (near) degeneracy occurs because each quantizing path is repeated eight times – once in each of the eight identical valleys. Similarly, the six-fold cluster dimension occurs because there are six identical hills, and each quantizing path is repeated six times around the surface.

The majority of the paths lie on the hills because the hills are bigger than the valleys. The hills subtend a half angle of 35.3° to the separatrix, while the valleys only have 19.5°. To estimate the number of paths or clusters in hills or valleys, the angular momentum cone angles for $J = 30$ may be calculated using (32.10). The results are displayed in Fig. 32.5. The results are consistent with the spectrum in Fig. 32.4. Only the two highest K-values of $K = 29, 30$ have cones small enough to fit in the valleys, but the six states of $K = 25-30$ can all fit onto the hills.

The angular momentum cone formula also provides an estimate for each level cluster energy. The estimates become more and more accurate as K increases (approaching J), while the uncertainty angle Θ_K^J decreases. Paths for higher K are more nearly circular and therefore more nearly correspond to symmetric top quantum states of pure K. The paths on octahedral RE surfaces are more nearly circular for a given K than are those on the asymmetric top RE surface, and so the octahedral rotor states can be better approximated by those of a symmetric top.

Fig. 32.5 $J = 30$ angular momentum cone half angles and octahedral cutoffs
