These two quotes define fairly well the path that econophysics tries to follow. They both insist on the fact that one should begin by focusing on simple phenomena even if at first sight they have little practical implications. In what follows we will develop this point but first of all we must address a question which comes to the mind of all persons who hear about econophysics for the first time, namely:

“Why should physicists have something to say about economic and social phenomena. Admittedly, biology can benefit from physics because of the means of observation [e. g. exploration of protein molecules by X-ray scattering] that it provides, but there are no similar needs in economics.”

I have heard this question asked repeatedly by many of my colleagues. In my answer I usually emphasize that what matters is more the method of investigation than the phenomena by themselves. I stress that applying to the social sciences the experimental methodology invented by physicists and chemists would mark a great progress. However, with the benefit of insight, I realize that these answers may have appeared far fetched and unconvincing to many of my listeners. A better and more factual claim is to observe that over the past century several of the most renowned economists and sociologists were in fact econophysicists in the sense defined in the glossary. Indeed, back in the nineteenth century, the only way to get a decent mathematical training was to study astronomy, engineering,

mathematics or physics. When such people entered the social sciences this led to two kinds of approaches which we may designate as econophysics and economathematics (see Sect. “Glossary”). In the first category one may mention the astronomer Adolphe Quételet (1796–1874), Clément Juglar (1819–1905) educated as a medical doctor, Vilfredo Pareto (1848–1923) educated as an engineer, the mathematician Louis Bachelier (1870–1946), the physicist Elliott Montroll (1916–1983), the mathematician Benoît Mandelbrot (1924–). In the second category one may mention Léon Walras (1834–1910) who was educated as an engineer, the astronomer Simon Newcomb (1835–1905), the physicist Maurice Allais (1911–).

Of course, if the economic discipline had been highly successful there would be little need for an alternative approach. However, great doubts have been expressed by some of the most renowned economists about the attainments of their discipline. We have already cited Schumpeter’s opinion on this matter. In addition one may mention the judgments of Vassily Leontief, Anna Schwartz, Lawrence Summers or the thesis developed in a recent book by Masanao Aoki and Hiroshi Yoshikawa.

- Leontief and Schwartz emphasized that the present organization of economic research discourages observational research. In Schwartz’s words [12]¹

“The main disincentive to improve the handling and use of data is that the profession withholds recognition to those who devote their energies to measurement. Someone who introduces an innovation in econometrics, by contrast, will win plaudits.”

- The assessment made by Summers in a paper published in 1991 is well summarized by its title: “The scientific illusion of empirical macroeconomics”.
- In their book, Aoki and Yoshikawa (p. 25 in [1]) point out that the representative agent assumption which is supposed to provide a connection between micro- and macroeconomics is fundamentally flawed because it neglects both social variability and stochastic fluctuations. It may be true that in recent years a greater emphasis has been put on the issue of heterogeneity. Yet, is this the right way to tackle the problem? A model is a simplification of reality anyway, so if it is not tenable to use loosely defined representative agents, an alternative solution may be to focus on sharply defined agent’s

¹Leontief (p. xi in [3]) has even stronger words: “The methods used to maintain intellectual discipline in this country’s most influential economics departments can occasionally remind one of those employed by the Marines to maintain discipline on Parris Island [a training camp of US Marines].”

attitudes. For instance, whereas without further specification home buyers may not be well defined as a useful category, the behavior of investors during the final phases of speculative price peaks may be sufficiently recurrent to make up for a well defined category.

Introduction

What are the main characteristics of econophysics? In what follows we will try to summarize some basic principles. Each of them will be illustrated by one or several studies performed by econophysicists over the past decade. Although the wording that we use is fairly personal, we believe that fundamentally these principles are shared by many econophysicists. In the course of more than a decade, econophysics has become a big tree with many branches. Obviously it is impossible to describe all of them if only because the knowledge and understanding of the present author is limited. He apologizes in advance for his limitations and for the fact that the present selection is by necessity fairly subjective.

The Primacy of Observation

Econophysics started around 1995 in sync with the creation of huge computerized databases giving minute by minute transactions on financial markets such as the New York stock market, the dollar-yen exchange rate, the forward interest rates or providing individual income data for millions of people. It may be estimated that between 1995 and 2005 about two thirds of the papers published by econophysicists aimed at deriving *regularity rules* from such databases. Let us illustrate this point by the case of income data. Since Pareto's work we know that the distribution of high incomes can be described by a power law with an exponent α comprised between 1 and 1.5. With databases comprising millions of income data one can get high accuracy estimates for α and observe how α changes as the result of economic booms or stock market crashes. It turns out that α decreases during booms and increases in the wake of stock market collapses [6].

Other empirical investigations were carried out in the past decades. We list some of them below. The list is arranged by topic and by research teams.

- Stock transactions, (i) Boston University: see publications involving G. Stanley. (ii) CEA (i. e. Commissariat à l'Énergie Atomique which means Institute for Atomic Research) and "Science-Finance": see publications involving J.P. Bouchaud. (iii) Nice University and UCLA: see publications involving D. Sornette. (iv) University of Warsaw: see publications involving J. Kertesz.
- Forward interest rates, Singapore University: see publications involving B. Baaquie.
- Exchange rates, Zurich: see publications involving M. Dacorogna.

To many physicists the statement that observation is supreme could seem self evident. In economics, however, such a statement represents a revolution. We already mentioned the fact that observation is a neglected topic in economics. As a matter of fact, before econophysics started it was impossible to publish a paper which would identify *regularity rules* without at the same time providing a model².

Investigating One Effect at a Time

In most natural phenomena different effects occur simultaneously. For instance, if one leaves a glass of cold water in the sun, the water will of course get warmer but if one looks at the mechanisms which are implied this involves many different effects: interaction of light and water, interaction of light and glass, conduction of heat, creation of convection currents between layers of water which are at different temperatures, and so on. One of the main challenges of physics was to identify these effects and to study them separately. Similarly, most social phenomena involve different effects; thus, one of the main tasks of the social sciences should be to disentangle and decompose complex phenomena into simple effects. In principle this is easier to do in physics than in the social sciences because one can change experimental conditions fairly easily. However, history shows that the main obstacle are conceptual. The previous phenomenon involves the transformation of one form of energy (light) into other forms of energy and it is well known that it took centuries for a clear understanding of these processes to emerge. In order to convince the reader that the same approach can be used in the social sciences we briefly describe a specific case.

Suicide is commonly considered as a phenomenon which is due to many factors. One of them is the strength of the marital bond. How can we isolate that factor? Of course, it is impossible to isolate it completely but one can at least make it so predominant that other factors become negligible. To achieve that objective, we consider a population in which the number of males is much larger than

²In what economists call "empirical econometrics" the researcher necessarily must provide a multivariate econometric model which means that even before he analyses the data he already knows the theory which rules the phenomenon. Moreover, all factors whether they have a weak or a strong impact are treated on the same footing. As we will see in the next point this has important implications.

the number of females. Such a population will necessarily have a large proportion of bachelors and therefore will be an ideal testing ground to study the role of the marital bond. Where can we find populations with a large excess of men? Almost all populations of immigrants are characterized by an excess of males. It turns out that due to specific circumstances, this imbalance was particularly large in the population of Chinese people living in the United States. By the end of the 19th century there were about 27 Chinese men for one Chinese woman³.

What makes the present principle important? Unless one is able to estimate the impact of each factor separately, one will never gain a *lasting* understanding. It is important to understand why. Let us for a moment return to the previous experiment. In the econometric approach one would conduct multivariate regressions of the temperature as a function of various (pre-conceived) parameters such as the volume of the liquid, the thickness of the glass and so on. Now suppose we wish to predict what happens when water is replaced by black ink. As a result of greater light absorption temperature differentials will be larger and convection currents will be stronger. The fact that many effects change at the same time will make the multivariate estimates irrelevant. Unless one has an understanding of the various individual effects it will be impossible to make any sound prediction. To sum up, any major change in business and social conditions will invalidate the previously accepted econometric models. This explains why the econometric approach fails to ensure that knowledge grows in a cumulative way.

What Guidance Can Physics Provide?

One can recall that the experimental methodology pioneered by researchers such as Tycho Brahe (1546–1601), Johannes Kepler (1571–1630) or Galileo (1564–1642) marked the beginning of modern physics. Two centuries later, that methodology was adapted to the exploration of the living world by people such as Claude Bernard (1813–1878), Louis Pasteur (1822–1895) and Gregor Mendel (1822–1884). In a sense it is a paradox that this method has been used successfully for the understanding of living organisms but has not yet gained broad acceptance in the social sciences for it can be argued with good reason that living organisms are more complex systems than are states or societies⁴. In short, applying the experimental method-

³For more details about this case, see [9].

⁴We will not develop this point here but it can be observed that a bacteria or a cell contains thousands of different proteins which interact in various ways. In the same line of thought one may recall that living organisms have been around for several billions years whereas

ology to the social sciences is a move which seems both natural and long overdue. Actually, serious efforts were made in this direction by social scientists such as Emile Durkheim (1858–1917) or Vilfredo Pareto (1848–1923) but this route seems to have been sidetracked in the second half of the 20th century.

Can we use the mathematical framework of physics in the investigation of social phenomena? This approach has been tried with some success by renowned econophysicists such as Belal Baaquie and coworkers (2004, 2007) and Jean-Philippe Bouchaud and coworkers [2,4]. In those cases the success must probably be attributed to the fact that the methods of theoretical physics which were used could be formulated in a purely mathematical way which did not rely on any physical concepts such as energy, momentum or temperature. As we do not yet know how these notions should be transposed to social systems, it seems impossible to apply the formalism of statistical mechanics to social phenomena⁵.

Our claim that the experimental methodology of physics can be used to explore social phenomena must be substantiated by explaining how it is possible to carry out “experiments” in social phenomena. This is the purpose of the next section.

How Cross-National Observations Can Be Used to Test the Role of Different Factors

Nowadays when a solid state physicist wants to measure, say, the interaction between ultraviolet light and a crystal of germanium, the experiment involves little uncertainties. That is so because this field of physics is already well understood. On the contrary, in the case of new and not well understood phenomena there is considerable uncertainty about the specific conditions of the experimental set up. In the two years after Léon Foucault demonstrated the Foucault pendulum experiment, at least twenty physicists tried to repeat it. Some succeeded while others did not. Indeed the experimental conditions, e. g. the length of the pendulum or the nature of the suspension wire, ensuring that the Foucault effect will be observed were not well understood.

societies appeared less than 100,000 years ago and states less than 10,000 years ago.

⁵It could be argued that one is free to define “social energy” in the way which one wishes. However, one should remember that the notion of energy is pivotal in physics only because it is ruled by (experimentally proved) conservation laws, such as the equivalence between heat and mechanical energy demonstrated by James Joule. Naturally, prior to defining a “social temperature”, it would seem natural to define a herd- or swarm-temperature describing aggregated populations of bacteria, insects or animals. As far as we know, no operational definition of this kind has yet been proposed.

It is only through various attempts with different settings that a better understanding progressively emerged. For instance it was realized that by using a pendulum of great length one would be able to reduce two undesirable effects (i) the sensitivity of the pendulum to exogenous noise⁶ (ii) the Poiseux effect which generates a rotation of the oscillation plane which interferes with the Foucault effect.

Few (if any) sociological phenomena are well understood which means that social researchers are basically in the same situation as those physicists in the years 1851–1852 who tried to observe the Foucault effect⁷. As an illustration suppose we wish to know if the publication of a specific type of news has an effect on the number of suicides⁸. Such an observation depends upon many parameters: the nature of the news and the amount of attention that it receives, the time interval (days, weeks or months?) between the publication of the news and the occurrence of the suicides. In addition one does not know if there will be an increase or a decrease in the number of suicides, if men will be more or less affected than women, and so on. All these questions can in principle be answered by conducting many observations in different countries and in different periods of time. In other words, if we are sufficiently determined, patient and tenacious and if we can get access to the statistical data that are needed, we should be able to disentangle and unravel the phenomenon under consideration in the same way as experimenters have been able to determine how the Foucault effect can be observed.

How Vested Interests May Affect the Accessibility and Reliability of Social Data

So far we have emphasized the similarities between natural and social phenomena but there are also some stumbling blocks which are specific to the social sciences. One of them is the fact that some data may have been altered or swept under the carpet by some sort of ideological, political or social bias, pressure or interference. Needless to say, extreme care must be exercised in such cases before making use of the data.

As an illustration, suppose that an econophysicist or a sociologist wants to study episodes of military occupation of one country by another. Such episodes are of

⁶Indeed, it is when the speed of the pendulum goes through zero that it is particularly sensitive to external perturbations; increasing the length of the pendulum reduces the number of oscillations in a given time interval and therefore the drift due to noise.

⁷As a more recent and even less understood case, one can mention the physicists who keep on trying to observe the cold fusion effect.

⁸This question is connected to what is known in sociology as the Werther effect; for more details see the papers written by Phillips (in particular [7]) and Chap. 3 in [9].

particular interest from a sociological perspective because they bring about strong interactions and can serve to probe the characteristics of a society. Moreover, because armies display many similarities no matter their country of origin, such episodes offer a set of *controlled experiments*. Naturally, in order to be meaningful the comparison must rely on trustworthy accounts for each of the episodes. Unfortunately, it turns out that in many cases only scant and fairly unreliable information is available. Consider for instance the occupation of Iceland by British and American forces during World War II. Among all occupation episodes this one was particularly massive with troops representing 50% of the population of Iceland prior to the occupation. The same proportion in a country such as Japan would have meant 30 million occupation troops that is 60 times more than the peak number of 500,000 reached at the end of 1945. Quite understandably for such a high density of troops, there were many incidents with the population of Iceland⁹; yet, it is difficult to find detailed evidence. Due to the paucity of data a superficial investigation would easily lead to the conclusion that there were in fact only few incidents. It does not require much imagination to understand why this information has not been released. The fact that in a general way all countries whatsoever are reluctant to recognize possible misconduct of their military personnel explains why the information is still classified in British and American archives. Because Iceland and the United States became close allies after 1945, one can also understand that the Icelandic National Archive is reluctant to release information about these incidents. The same observation also applies (and for the same reasons) to the occupation of Japan, 1946–1951; for more details see Roehner pp. 90–98 in [9] and [10]. Naturally, similar cases abound. Due to a variety of reasons well-meaning governments, archivists and statistical offices keep sensitive files closed to social scientists. Most often it is in fact sufficient to catalog sensitive file units in a fairly obscure way. The plain effect is that the information will not be found except perhaps by pure luck, a fairly unlikely prospect in big archives.

How Can Exogenous Factors be Taken into Account?

This question is not specific to social phenomena, it is also of importance in physics. As a matter of fact, in astronomy

⁹According to a report that Prime Minister Hermann Jonasson sent to the American Headquarters, there were 136 incidents between troops and Icelanders during the period between July 1941 (arrival of the American troops) and April 1942 (Hunt 1966) in Reykjavik alone. Unfortunately, no copy of this report seems to be available at the National Archives of Iceland.

it provides a powerful method for observing objects that cannot be observed directly. Thus, we know the existence of exoplanets only from the perturbing effect which they have on the position of the star around which they move. However, for social phenomena the problem of exogenous factors is much more serious because (i) they may not be known to observers (ii) even once they are identified it is very difficult to correct the data in a reliable way. One of the main pitfalls in the modeling of socio-economic phenomena is to explain them through endogenous mechanisms while they are in fact due to exogenous factors. The following examples make clear that this difficulty exists for many phenomena, whether they belong to the financial, economic or social sphere.

- In their paper of 2005 about consensus formation and shifts in opinion Michard and Bouchaud confront their theory to two classes of social phenomena: (i) the diffusion of cell phones (ii) the diffusion of birth rate patterns. In the first case it is clear that advertising campaigns may have played an important role. Of course, one could argue that these campaigns were part of the endogenous diffusion process. However, this argument does not hold for big telecom companies (e.g. Vodafone) which operate in many countries. In such cases the decision about the magnitude of the advertising campaigns are taken by the board of the company which means that such campaigns can hardly be considered as endogenous effects. Similarly, birth rates depend upon exogenous factors. For instance the length of time spent in higher education has an effect on the average age of marriage and the later has an effect on birth rates.
- On 21 July 2004 the share price of Converium, a Swiss reinsurance company listed on the New York Stock Exchange dropped 50%. Was this fall the result of an avalanche effect due to a movement of panic among investors? In fact, the most likely explanation is that it was the consequence of a decision taken by the board of Fidelity International, a major investment fund and one of the main shareholders of Converium. Indeed in a statement issued by Converium on August 3, 2004 it was announced that Fidelity had reduced its holdings from 9.87% to 3.81%. In other words, it would be completely irrelevant to explain such a fall through a herd effect model or through any other endogenous mechanism (more details can be found in [8]). Similar conclusions apply to corporate stock buybacks, as well as to mergers, acquisitions, buyouts and takeovers; in all these cases decisions taken by a few persons (the average board of directors has nine members) may trigger substantial changes in share prices. How should such effects be taken into account by stock market models?
- At the end of 2004 and in the first months of 2005 British housing prices began to decline after having risen rapidly during several years. Yet after May 2005, they suddenly began to pick up again at an annual rate of about 10%. This resurgence was particularly intriguing because at the same time US housing prices began to decline. To what factor should this unexpected rise be attributed? Most certainly this was the market response to a plan introduced by the Chancellor of the Exchequer Gordon Brown in late May (The Economist May 28, 2005). Under this plan which aimed at propping up house prices new buyers would benefit from a zero-interest loan for 12% of the price. In addition, the government would cover all losses incurred by banks as a result of possible bankruptcies of borrowers (at least so long as prices did not fall by more than 12%). It appears that the plan indeed propped up the market. Consequently, in order to confront the predictions of any model (e.g. see Richmond's paper which was published in 2007) with observation the impact of this plan effect must first be taken out of the picture.
- The same difficulty is also encountered in socio-political phenomena. Here is an illustration. On 5 October 2000, in protest against the publication of the results of the presidential election there was a huge mass demonstration in Belgrade which involved thousands of people from the provinces who were transported to the federal capital by hundreds of buses. It clearly showed that president Milosevic was no longer in control of the police and army and lead to his retirement from the political scene. Thus, what NATO air strikes (24 March-11 June 1999¹⁰) had not been able to achieve was accomplished by one night of street demonstrations. What was the part of exogenous factors in this event? Although in many similar cases it is very difficult to know what really happened, in this specific case a partial understanding is provided by a long article published in the New York Times¹¹. In this article

¹⁰It can be noted that similarly to what would happen in 2003 for the invasion of Iraq, these air strikes were carried out without the authorization of the United Nations Security Council.

¹¹New York Times, Sunday 26 November 2000, Magazine Section, p. 43, 7705 words; the article by Roger Cohen is entitled: "Who really brought down Milosevic". What makes this account particularly convincing is the fact that it was preceded by another article entitled: "US anti-Milosevic plan faces major test at polls" which appeared on September 23, 2000 (p. 6, 1150 words); this article described the way Milosevic would be removed from power two weeks *before* the events. The article makes clear that the course of events would be the same no matter what the results of the election would be.

we learn that several American organizations belonging to the intelligence network supported, financed and trained Serbian opposition groups. For instance the article mentions the Albert Einstein Foundation, the International Republican Institute, the National Endowment for Democracy, the US Agency for International Development. Although the amount of the total financial support is not known, the New York Times article says that it exceeded \$ 28 million. The plan comprised two facets: the organization of demonstrations on the one hand and the infiltration of the army and police on the other hand in order to undermine their loyalty and convince them to remain passive during the demonstrations. According to the article this second facet remains classified. With an exogenous interference of such a magnitude, it would clearly be meaningless to describe this upheaval as a purely endogenous process. Moreover, the fact that we have only partial knowledge about the exogenous forces makes it very difficult (if not altogether impossible) to come up with a satisfactory description. It should also be noted that the influence of these groups did not disappear overnight after October 4, which means that the subsequent history of Serbia must also take them into account at least to some extent.

Future Directions

In this article we have described the challenges and obstacles to which one is confronted in trying to understand socio-economic phenomena. In parallel we have shown that the econophysics approach has many assets. One of them which has not yet been mentioned is the fact that econophysicists are not subject to the rigid barriers which exist between various fields and subfields of the human sciences. Thus, if it turns out that in order to explain an economic phenomena one needs to understand a social effect, econophysicists would have no problem in shifting from one field to another. There is another historical chance that we have not mentioned so far, namely the development of the Internet. In the past decade 1997–2007 the amount of information to which one has access has increased tremendously. Electronic catalogs of major libraries or of national archives, indexes of newspaper, search engines on the Internet, searchable databases of books, all these innovations contributed to give the researcher easy access to information sources that have never been available before. In particular it has become fairly easy to find cross-national data. Thus, social scientists and econophysicists are in a better position than ever for carrying out the kind of comparative studies that we called for in this article.

Glossary

Probability density $P(x)$ is defined so that the probability of finding a random variable x in the interval from x to $x + dx$ is equal to $P(x) dx$.

Cumulative probability $C(x)$ is defined as the integral $C(x) = \int_x^\infty P(x) dx$. It gives the probability that the random variable exceeds a given value x .

The Boltzmann–Gibbs distribution gives the probability of finding a physical system in a state with the energy ε . Its probability density is given by the exponential function (1).

The Gamma distribution has the probability density given by a product of an exponential function and a power-law function, as in (9).

The Pareto distribution has the probability density $P(x) \propto 1/x^{1+\alpha}$ and the cumulative probability $C(x) \propto 1/x^\alpha$ given by a power law. These expressions apply only for high enough values of x and do not apply for $x \rightarrow 0$.

The Lorenz curve was introduced by American economist Max Lorenz to describe income and wealth inequality. It is defined in terms of two coordinates $x(r)$ and $y(r)$ given by (19). The horizontal coordinate $x(r)$ is the fraction of the population with income below r , and the vertical coordinate $y(r)$ is the fraction of income this population accounts for. As r changes from 0 to ∞ , x and y change from 0 to 1, parametrically defining a curve in the (x, y) -plane.

The Gini coefficient G was introduced by the Italian statistician Corrado Gini as a measure of inequality in a society. It is defined as the area between the Lorenz curve and the straight diagonal line, divided by the area of the triangle beneath the diagonal line. For perfect equality (everybody has the same income or wealth) $G = 0$, and for total inequality (one person has all income or wealth, and the rest have nothing) $G = 1$.

The Fokker–Planck equation is the partial differential equation (22) that describes evolution in time t of the probability density $P(r, t)$ of a random variable r experiencing small random changes Δr during short time intervals Δt . It is also known in mathematical literature as the Kolmogorov forward equation. The diffusion equation is an example of the Fokker–Planck equation.

Definition of the Subject

Econophysics is an interdisciplinary research field applying methods of statistical physics to problems in economics and finance. The term “econophysics” was first introduced by the prominent theoretical physicist Eu-

gene Stanley in 1995 at the conference *Dynamics of Complex Systems*, which was held in Calcutta (now known as Kolkata) as a satellite meeting to the STATPHYS-19 conference in China [1,2]. The term appeared in print for the first time in the paper by Stanley et al. [3] in the proceedings of the Calcutta conference. The paper presented a manifesto of the new field, arguing that “behavior of large numbers of humans (as measured, e. g., by economic indices) might conform to analogs of the scaling laws that have proved useful in describing systems composed of large numbers of inanimate objects” [3]. Soon the first econophysics conferences were organized: *International Workshop on Econophysics*, Budapest, 1997 and *International Workshop on Econophysics and Statistical Finance*, Palermo, 1998 [2], and the book *An Introduction to Econophysics* [4] was published.

The term “econophysics” was introduced by analogy with similar terms, such as “astrophysics”, “geophysics”, and “biophysics”, which describe applications of physics to different fields. Particularly important is the parallel with biophysics, which studies living creatures, which still obey the laws of physics. It should be emphasized that econophysics does not literally apply the laws of physics, such as Newton’s laws or quantum mechanics, to humans, but rather uses mathematical methods developed in statistical physics to study statistical properties of complex economic systems consisting of a large number of humans. So, it may be considered as a branch of applied theory of probabilities. However, statistical physics is distinctly different from mathematical statistics in its focus, methods, and results.

Originating from physics as a quantitative science, econophysics emphasizes quantitative analysis of large amounts of economic and financial data, which became increasingly available with the massive introduction of computers and the Internet. Econophysics distances itself from the verbose, narrative, and ideological style of political economy and is closer to **econometrics** in its focus. Studying mathematical models of a large number of interacting economic agents, econophysics has much common ground with the **agent-based modeling and simulation**. Correspondingly, it distances itself from the representative-agent approach of traditional economics, which, by definition, ignores statistical and heterogeneous aspects of the economy.

Two major directions in econophysics are applications to finance and economics. Observational aspects are covered in the article ► [Econophysics, Observational](#). The present article, ► [Econophysics, Statistical Mechanics Approach to](#), concentrates primarily on statistical distributions of money, wealth, and income among interacting economic agents.

Another direction related to econophysics has been advocated by the theoretical physicist Serge Galam since the early 1980s under the name “**sociophysics**” [5], with the first appearance of the term in print in [6]. It echoes the term *physique sociale* proposed in the nineteenth century by Auguste Comte, the founder of sociology. Unlike econophysics, the term “sociophysics” did not catch on when first introduced, but it is coming back with the popularity of econophysics and active promotion by some physicists [7,8,9]. While the principles of both fields have a lot in common, econophysics focuses on the narrower subject of economic behavior of humans, where more quantitative data are available, whereas sociophysics studies a broader range of social issues. The boundary between econophysics and sociophysics is not sharp, and the two fields enjoy a good rapport [10]. A more detailed description of the historical development is presented in Sect. “[Historical Introduction](#)”.

Historical Introduction

Statistical mechanics was developed in the second half of the nineteenth century by James Clerk Maxwell, Ludwig Boltzmann, and Josiah Willard Gibbs. These physicists believed in the existence of atoms and developed mathematical methods for describing their statistical properties, such as the probability distribution of velocities of molecules in a gas (the Maxwell–Boltzmann distribution) and the general probability distribution of states with different energies (the Boltzmann–Gibbs distribution). There are interesting connections between the development of statistical physics and statistics of social phenomena, which were recently brought up by the science journalist Philip Ball [11,12].

Collection and study of “social numbers”, such as the rates of death, birth, and marriage, has been growing progressively since the seventeenth century (see Chap. 3 in [12]). The term “statistics” was introduced in the eighteenth century to denote these studies dealing with the civil “states”, and its practitioners were called “statists”. Popularization of social statistics in the nineteenth century is particularly accredited to the Belgian astronomer Adolphe Quetelet. Before the 1850s, statistics was considered an empirical arm of political economy, but then it started to transform into a general method of quantitative analysis suitable for all disciplines. It stimulated physicists to develop statistical mechanics in the second half of the nineteenth century.

Rudolf Clausius started development of the kinetic theory of gases, but it was James Clerk Maxwell who made a decisive step of deriving the probability distribu-

tion of velocities of molecules in a gas. Historical studies show (see Chap. 3 in [12]) that, in developing statistical mechanics, Maxwell was strongly influenced and encouraged by the widespread popularity of social statistics at the time. This approach was further developed by Ludwig Boltzmann, who was very explicit about its origins (see p. 69 in [12]):

“The molecules are like individuals, ... and the properties of gases only remain unaltered, because the number of these molecules, which on the average have a given state, is constant.”

In his book *Populäre Schriften* from 1905 [13], Boltzmann praises Josiah Willard Gibbs for systematic development of statistical mechanics. Then, Boltzmann says (cited from [14]):

“This opens a broad perspective if we do not only think of mechanical objects. Let’s consider to apply this method to the statistics of living beings, society, sociology and so forth.”

(The author is grateful to Michael E. Fisher for bringing this quote to his attention.)

It is worth noting that many now-famous economists were originally educated in physics and engineering. Vilfredo Pareto earned a degree in mathematical sciences and a doctorate in engineering. Working as a civil engineer, he collected statistics demonstrating that distributions of income and wealth in a society follow a power law [15]. He later became a professor of economics at Lausanne, where he replaced Léon Walras, also an engineer by education. The influential American economist Irving Fisher was a student of Gibbs. However, most of the mathematical apparatus transferred to economics from physics was that of Newtonian mechanics and classical thermodynamics [16]. It culminated in the neoclassical concept of mechanistic equilibrium where the “forces” of supply and demand balance each other. The more general concept of statistical equilibrium largely eluded mainstream economics.

With time, both physics and economics became more formal and rigid in their specializations, and the social origin of statistical physics was forgotten. The situation is well summarized by Philip Ball (see p. 69 in [12]):

“Today physicists regard the application of statistical mechanics to social phenomena as a new and risky venture. Few, it seems, recall how the process originated the other way around, in the days when physical science and social science were the twin siblings of a mechanistic philosophy and when it was

not in the least disreputable to invoke the habits of people to explain the habits of inanimate particles”.

Some physicists and economists attempted to connect the two disciplines during the twentieth century. The theoretical physicist Ettore Majorana argued in favor of applying the laws of statistical physics to social phenomena in a paper published after his mysterious disappearance [17]. The statistical physicist Elliott Montroll co-authored the book *Introduction to Quantitative Aspects of Social Phenomena* [18]. Several economists applied statistical physics to economic problems [19,20,21,22]. An early attempt to bring together the leading theoretical physicists and economists at the Santa Fe Institute was not entirely successful [23]. However, by the late 1990s, the attempts to apply statistical physics to social phenomena finally coalesced into the robust movements of econophysics and sociophysics, as described in Sect. “Definition of the Subject”.

The current standing of econophysics within the physics and economics communities is mixed. Although an entry on econophysics has appeared in the *New Palgrave Dictionary of Economics* [24], it is fair to say that econophysics is not accepted yet by mainstream economics. Nevertheless, a number of open-minded, nontraditional economists have joined this movement, and the number is growing. Under these circumstances, econophysicists have most of their papers published in physics journals. The journal *Physica A: Statistical Mechanics and Its Applications* emerged as the leader in econophysics publications and has even attracted submissions from some bona fide economists. The mainstream physics community is generally sympathetic to econophysics, although it is not uncommon for econophysics papers to be rejected by *Physical Review Letters* on the grounds that “it is not physics”. There are regular conferences on econophysics, such as *Applications of Physics in Financial Analysis* (sponsored by the European Physical Society), *Nikkei Econophysics Symposium*, and *Econophysics Colloquium*. Econophysics sessions are included in the annual meetings of physical societies and statistical physics conferences. The overlap with economics is the strongest in the field of agent-based simulation. Not surprisingly, the conference series WEHIA/ESHIA, which deals with heterogeneous interacting agents, regularly includes sessions on econophysics.

Statistical Mechanics of Money Distribution

When modern econophysics started in the middle of the 1990s, its attention was primarily focused on analysis of financial markets. However, three influential pa-

pers [25,26,27], dealing with the subject of money and wealth distributions, were published in 2000. They started a new direction that is closer to economics than finance and created an expanding wave of follow-up publications. We start reviewing this subject with [25], whose results are the most closely related to the traditional statistical mechanics in physics.

The Boltzmann–Gibbs Distribution of Energy

The fundamental law of equilibrium statistical mechanics is the Boltzmann–Gibbs distribution. It states that the probability $P(\varepsilon)$ of finding a physical system or subsystem in a state with the energy ε is given by the exponential function

$$P(\varepsilon) = ce^{-\frac{\varepsilon}{T}}, \quad (1)$$

where T is the temperature, and c is a normalizing constant [28]. Here we set the Boltzmann constant k_B to unity by choosing the energy units for measuring the physical temperature T . Then, the expectation value of any physical variable x can be obtained as

$$\langle x \rangle = \frac{\sum_k x_k e^{-\frac{\varepsilon_k}{T}}}{\sum_k e^{-\frac{\varepsilon_k}{T}}}, \quad (2)$$

where the sum is taken over all states of the system. Temperature is equal to the average energy per particle: $T \sim \langle \varepsilon \rangle$, up to a numerical coefficient of the order of 1.

Equation (1) can be derived in different ways [28]. All derivations involve the two main ingredients: statistical character of the system and conservation of energy ε . One of the shortest derivations can be summarized as follows. Let us divide the system into two (generally unequal) parts. Then, the total energy is the sum of the parts, $\varepsilon = \varepsilon_1 + \varepsilon_2$, whereas the probability is the product of probabilities, $P(\varepsilon) = P(\varepsilon_1)P(\varepsilon_2)$. The only solution of these two equations is the exponential function (1).

A more sophisticated derivation, proposed by Boltzmann himself, uses the concept of entropy. Let us consider N particles with total energy E . Let us divide the energy axis into small intervals (bins) of width $\Delta\varepsilon$ and count the number of particles N_k having energies from ε_k to $\varepsilon_k + \Delta\varepsilon$. The ratio $N_k/N = P_k$ gives the probability for a particle having the energy ε_k . Let us now calculate the multiplicity W , which is the number of permutations of the particles between different energy bins such that the occupation numbers of the bins do not change. This quantity is given by the combinatorial formula in terms of the factorials

$$W = \frac{N!}{N_1!N_2!N_3!\dots}. \quad (3)$$

The logarithm of multiplicity of called the entropy $S = \ln W$. In the limit of large numbers, the entropy per particle can be written in the following form using the Stirling approximation for the factorials:

$$\frac{S}{N} = - \sum_k \frac{N_k}{N} \ln \left(\frac{N_k}{N} \right) = - \sum_k P_k \ln P_k . \quad (4)$$

Now we would like to find what distribution of particles between different energy states has the highest entropy, i. e. the highest multiplicity, provided that the total energy of the system, $E = \sum_k N_k \varepsilon_k$, has a fixed value. Solution of this problem can be easily obtained using the method of Lagrange multipliers [28], and the answer gives the exponential distribution (1).

The same result can be derived from the **ergodic theory**, which says that the many-body system occupies all possible states of a given total energy with equal probabilities. Then it is straightforward to show [29,30] that the probability distribution of the energy of an individual particle is given by (1).

Conservation of Money

The derivations outlined in Sect. “[The Boltzmann–Gibbs Distribution of Energy](#)” are very general and use only the statistical character of the system and the conservation of energy. So, one may expect that the exponential Boltzmann–Gibbs distribution (1) may apply to other statistical systems with a conserved quantity.

The economy is a big statistical system with millions of participating agents, so it is a promising target for applications of statistical mechanics. Is there a conserved quantity in economy? Drăgulescu and Yakovenko [25] argue that such a conserved quantity is money m . Indeed, the ordinary economic agents can only receive money from and give money to other agents. They are not permitted to “manufacture” money, e. g., to print dollar bills. When one agent i pays money Δm to another agent j for some goods or services, the money balances of the agents change as follows:

$$\begin{aligned} m_i &\rightarrow m'_i = m_i - \Delta m , \\ m_j &\rightarrow m'_j = m_j + \Delta m . \end{aligned} \quad (5)$$

The total amount of money of the two agents before and after the transaction remains the same,

$$m_i + m_j = m'_i + m'_j , \quad (6)$$

i. e., there is a local conservation law for money. The rule (5) for the transfer of money is analogous to the transfer of energy from one molecule to another in molecular

collisions in a gas, and (6) is analogous to conservation of energy in such collisions.

Addressing some misunderstandings developed in economic literature [31,32,33,34], we should emphasize that, in the model of [25], the transfer of money from one agent to another happens voluntarily, as a payment for goods and services in a market economy. However, the model only keeps track of money flow, and does not keep track of what kinds of goods and service are delivered. One reason for this is that many goods, e. g., food and other supplies, and most services, e. g., getting a haircut or going to a movie, are not tangible and disappear after consumption. Because they are not conserved and also because they are measured in different physical units, it is not very practical to keep track of them. In contrast, money is measured in the same unit (within a given country with a single currency) and is conserved in transactions, so it is straightforward to keep track of money flow.

Unlike ordinary economic agents, a central bank or a central government can inject money into the economy. This process is analogous to an influx of energy into a system from external sources, e. g., the Earth receives energy from the Sun. Dealing with these situations, physicists start with an idealization of a closed system in thermal equilibrium and then generalize to an open system subject to an energy flux. As long as the rate of money influx from central sources is slow compared with relaxation processes in the economy and does not cause hyperinflation, the system is in quasi-stationary statistical equilibrium with slowly changing parameters. This situation is analogous to heating a kettle on a gas stove slowly, where the kettle has a well-defined, but slowly increasing temperature at any moment of time.

Another potential problem with conservation of money is debt. This issue is discussed in more detail in Sect. “[Models with Debt](#)”. As a starting point, Drăgulescu and Yakovenko [25] first considered simple models, where debt is not permitted. This means that money balances of agents cannot go below zero: $m_i \geq 0$ for all i . Transaction (5) takes place only when an agent has enough money to pay the price, $m_i \geq \Delta m$, otherwise the transaction does not take place. If an agent spends all the money, the balance drops to zero $m_i = 0$, so the agent cannot buy any goods from other agents. However, this agent can still produce goods or services, sell them to other agents, and receive money for them. In real life, cash balance dropping to zero is not at all unusual for people who live from paycheck to paycheck.

The conservation law is the key feature for the successful functioning of money. If the agents were permitted to “manufacture” money, they would be printing money

and buying all goods for nothing, which would be a disaster. The physical medium of money is not essential, as long as the conservation law is enforced. Money may be in the form of paper cash, but today it is more often represented by digits in computerized bank accounts. The conservation law is the fundamental principle of accounting, whether in the single-entry or in the double-entry form. More discussion of banks and debt is given in Sect. “Models with Debt”.

The Boltzmann–Gibbs Distribution of Money

Having recognized the principle of money conservation, Drăgulescu and Yakovenko [25] argued that the stationary distribution of money should be given by the exponential Boltzmann–Gibbs function analogous to (1):

$$P(m) = ce^{\frac{-m}{T_m}}. \quad (7)$$

Here c is a normalizing constant, and T_m is the “money temperature”, which is equal to the average amount of money per agent: $T = \langle m \rangle = M/N$, where M is the total money, and N is the number of agents.

To verify this conjecture, Drăgulescu and Yakovenko [25] performed agent-based computer simulations of money transfers between agents. Initially all agents were given the same amount of money, say, \$ 1000. Then, a pair of agents (i, j) were randomly selected, the amount Δm was transferred from one agent to another, and the process was repeated many times. Time evolution of the probability distribution of money $P(m)$ can be seen in computer animation videos at the Web pages [35,36]. After a transitory period, money distribution converges to the stationary form shown in Fig. 1. As expected, the distribution is very well fitted by the exponential function (7).

Several different rules for Δm were considered in [25]. In one model, the amount transferred was fixed to a constant $\Delta m = 1\$$. Economically, it means that all agents were selling their products for the same price $\Delta m = 1\$$. Computer animation [35] shows that the initial distribution of money first broadens to a symmetric, Gaussian curve, characteristic for a diffusion process. Then, the distribution starts to pile up around the $m = 0$ state, which acts as the impenetrable boundary, because of the imposed condition $m \geq 0$. As a result, $P(m)$ becomes skewed (asymmetric) and eventually reaches the stationary exponential shape, as shown in Fig. 1. The boundary at $m = 0$ is analogous to the ground-state energy in statistical physics. Without this boundary condition, the probability distribution of money would not reach a stationary state. Computer animation [35,36] also shows how the entropy of money distribution, defined as $S/N =$

Econophysics, Statistical Mechanics Approach to, Figure 1 Stationary probability distribution of money $P(m)$ obtained in agent-based computer simulations. *Solid curves*: fits to the Boltzmann–Gibbs law (7). *Vertical lines*: the initial distribution of money. (Reproduced from [25])

$-\sum_k P(m_k) \ln P(m_k)$, grows from the initial value $S = 0$, when all agents have the same money, to the maximal value at the statistical equilibrium.

While the model with $\Delta m = 1$ is very simple and instructive, it is not very realistic, because all prices are taken to be the same. In another model considered in [25], Δm in each transaction is taken to be a random fraction of the average amount of money per agent, i. e., $\Delta m = \nu(M/N)$, where ν is a uniformly distributed random number between 0 and 1. The random distribution of Δm is supposed to represent the wide variety of prices for different products in the real economy. It reflects the fact that agents buy and consume many different types of products, some of them simple and cheap, some sophisticated and expensive. Moreover, different agents like to consume these products in different quantities, so there is variation in the amounts Δm paid, even though the unit price of the same product is constant. Computer simulation of this model produces exactly the same stationary distribution (7) as in the first model. Computer animation for this model is also available on the Web page [35].

The final distribution is universal despite different rules for Δm . To amplify this point further, Drăgulescu and Yakovenko [25] also considered a toy model, where Δm was taken to be a random fraction of the average amount of money of the two agents: $\Delta m = \nu(m_i + m_j)/2$. This model produced the same stationary distribution (7) as the other two models.

The pairwise models of money transfer are attractive in their simplicity, but they represent a rather prim-

itive market. The modern economy is dominated by big firms, which consist of many agents, so Drăgulescu and Yakovenko [25] also studied a model with firms. One agent at a time is appointed to become a “firm”. The firm borrows capital K from another agent and returns it with interest hK , hires L agents and pays them wages W , manufactures Q items of a product, sells them to Q agents at price R , and receives profit $F = RQ - LW - hK$. All of these agents are randomly selected. The parameters of the model are optimized following a procedure from economics textbooks [37]. The aggregate demand–supply curve for the product is used in the form $R(Q) = v/Q^\eta$, where Q is the quantity consumers would buy at price R , and η and v are some parameters. The production function of the firm has the traditional Cobb–Douglas form: $Q(L, K) = L^\chi K^{1-\chi}$, where χ is a parameter. Then the profit of the firm F is maximized with respect to K and L . The net result of the firm activity is a many-body transfer of money, which still satisfies the conservation law. Computer simulation of this model generates the same exponential distribution (7), independently of the model parameters. The reasons for the universality of the Boltzmann–Gibbs distribution and its limitations are discussed from a different perspective in Sect. “Additive Versus Multiplicative Models”.

Well after paper [25] appeared, Italian econophysicists [38] found that similar ideas had been published earlier in obscure journals in Italian by Eleonora Beninati [39,40]. They proposed calling these models the Beninati–Drăgulescu–Yakovenko game [41]. The Boltzmann distribution was independently applied to social sciences by Jürgen Mimkes using the Lagrange principle of maximization with constraints [42,43]. The exponential distribution of money was also found in [44] using a Markov chain approach to strategic market games. A long time ago, Benoit Mandelbrot observed (see p. 83 in [45]):

“There is a great temptation to consider the exchanges of money which occur in economic interaction as analogous to the exchanges of energy which occur in physical shocks between gas molecules”.

He realized that this process should result in the exponential distribution, by analogy with the barometric distribution of density in the atmosphere. However, he discarded this idea, because it does not produce the Pareto power law, and proceeded to study the stable Lévy distributions. Ironically, the actual economic data, discussed in Sect. “Empirical Data on Money and Wealth Distributions” and “Empirical Data on Income Distribution”, do show the exponential distribution for the majority of the population. Moreover, the data have finite variance, so the

stable Lévy distributions are not applicable because of their infinite variance.

Models with Debt

Now let us discuss how the results change when debt is permitted. Debt may be considered as negative money. When an agent borrows money from a bank (considered here as a big reservoir of money), the cash balance of the agent (positive money) increases, but the agent also acquires a debt obligation (negative money), so the total balance (net worth) of the agent remains the same, and the conservation law of total money (positive and negative) is satisfied. After spending some cash, the agent still has the debt obligation, so the money balance of the agent becomes negative. Any stable economic system must have a mechanism preventing unlimited borrowing and unlimited debt. Otherwise, agents can buy any products without producing anything in exchange by simply going into unlimited debt. The exact mechanisms of limiting debt in the real economy are complicated and obscured. Drăgulescu and Yakovenko [25] considered a simple model where the maximal debt of any agent is limited by a certain amount m_d . This means that the boundary condition $m_i \geq 0$ is now replaced by the condition $m_i \geq -m_d$ for all agents i . Setting interest rates on borrowed money to be zero for simplicity, Drăgulescu and Yakovenko [25] performed computer simulations of the models described in Sect. “The Boltzmann–Gibbs Distribution of Money” with the new boundary condition. The results are shown in Fig. 2. Not surprisingly, the stationary money distribution again has an exponential shape, but now with the new boundary condition at $m = -m_d$ and the higher money temperature $T_d = m_d + M/N$. By allowing agents to go into debt up to m_d , we effectively increase the amount of money available to each agent by m_d . So, the money temperature, which is equal to the average amount of effectively available money per agent, increases. A model with nonzero interest rates was also studied in [25].

We see that debt does not violate the conservation law of money, but rather modifies boundary conditions for $P(m)$. When economics textbooks describe how “banks create money” or “debt creates money” [37], they count only positive money (cash) as money, but do not count liabilities (debt obligations) as negative money. With such a definition, money is not conserved. However, if we include debt obligations in the definition of money, then the conservation law is restored. This approach is in agreement with the principles of double-entry accounting, which records both assets and debts. Debt obligations are as real as positive cash, as many borrowers painfully real-

 Stationary distributions of money with and without debt. The debt is limited to $m_d = 800$. Solid curves: fits to the Boltzmann-Gibbs laws with the “temperatures” $T = 1800$ and $T = 1000$. (Reproduced from [25])

ized in their experience. A more detailed study of positive and negative money and bookkeeping from the point of view of econophysics is presented in a series of papers by the physicist Dieter Braun [46,47,48].

One way of limiting the total debt in the economy is the so-called required reserve ratio r [37]. Every bank is required by law to set aside a fraction r of the money deposited with the bank, and this reserved money cannot be loaned further. If the initial amount of money in the sys-

Econophysics, Statistical Mechanics Approach to, Figure 3
 The stationary distribution of money for the required reserve ratio $r = 0.8$. The distribution is exponential for positive and negative money with different “temperatures” T_+ and T_- , as illustrated by the inset on log-linear scale. (Reproduced from [49])

tem (the money base) is M_0 , then with loans and borrowing the total amount of positive money available to the agents increases to $M = M_0/r$, where the factor $1/r$ is called the money multiplier [37]. This is how “banks create money”. Where does this extra money come from? It comes from the increase of the total debt in the system. The maximal total debt is equal to $D = M_0/r - M_0$ and is limited by the factor r . When the debt is maximal, the total amounts of positive, M_0/r , and negative, $M_0(1-r)/r$, money circulate between the agents in the system, so there are effectively two conservation laws for each of them [49]. Thus, we expect to see the exponential distributions of positive and negative money characterized by two different temperatures: $T_+ = M_0/rN$ and $T_- = M_0(1-r)/rN$. This is exactly what was found in computer simulations in [49], shown in Fig. 3. Similar two-sided distributions were also found in [47].

Proportional Money Transfers and Saving Propensity

In the models of money transfer considered thus far, the transferred amount Δm is typically independent of the money balances of agents. A different model was introduced in the physics literature earlier [50] under the name multiplicative asset exchange model. This model also satisfies the conservation law, but the amount of money transferred is a fixed fraction γ of the payer’s money in (5):

$$\Delta m = \gamma m_i . \tag{8}$$

The stationary distribution of money in this model, shown in Fig. 4 with an exponential function, is close, but not exactly equal, to the Gamma distribution:

$$P(m) = cm^\beta e^{-\frac{m}{T}} . \tag{9}$$

Equation (9) differs from (7) by the power-law prefactor m^β . From the Boltzmann kinetic equation (discussed in more detail in Sect. “Additive Versus Multiplicative Models”), Ispolatov et al. [50] derived a formula relating the parameters γ and β in (8) and (9):

$$\beta = \frac{-1 - \ln 2}{\ln(1 - \gamma)} . \tag{10}$$

When payers spend a relatively small fraction of their money $\gamma < 1/2$, (10) gives $\beta > 0$, so the low-money population is reduced and $P(m \rightarrow 0) = 0$, as shown in Fig. 4.

Later, Thomas Lux brought to the attention of physicists [32] that essentially the same model, called the inequality process, had been introduced and studied much earlier by the sociologist John Angle [51,52,53,54,55], see also the review [56] for additional references. While Ispolatov

Econophysics, Statistical Mechanics Approach to, Figure 4
Stationary probability distribution of money in the multiplicative random exchange model (8) for $\gamma = 1/3$. Solid curve: the exponential Boltzmann-Gibbs law. (Reproduced from [25])

latov et al. [50] did not give much justification for the proportionality law (8), Angle [51] connected this rule with the surplus theory of social stratification [57], which argues that inequality in human society develops when people can produce more than necessary for minimal subsistence. This additional wealth (surplus) can be transferred from original producers to other people, thus generating inequality. In the first paper by Angle [51], the parameter γ was randomly distributed, and another parameter, δ , gave a higher probability of winning to the agent with a higher money balance in (5). However, in the following papers, he simplified the model to a fixed γ (denoted as ω by Angle) and equal probabilities of winning for higher- and lower-balance agents, which makes it completely equivalent to the model of [50]. Angle also considered a model [55,56] where groups of agents have different values of γ , simulating the effect of education and other “human capital”. All of these models generate a Gamma-like distribution, well approximated by (9).

Another model with an element of proportionality was proposed in [26]. (This paper originally appeared as a follow-up preprint cond-mat/0004256 to the preprint cond-mat/0001432 of [25].) In this model, the agents set aside (save) some fraction of their money λm_i , whereas the rest of their money balance $(1 - \lambda)m_i$ becomes available for random exchanges. Thus, the rule of exchange (5) becomes

$$\begin{aligned} m'_i &= \lambda m_i + \xi(1 - \lambda)(m_i + m_j), \\ m'_j &= \lambda m_j + (1 - \xi)(1 - \lambda)(m_i + m_j). \end{aligned} \quad (11)$$

Here the coefficient λ is called the saving propensity, and the random variable ξ is uniformly distributed between 0 and 1. It was pointed out in [56] that, by the change of notation $\lambda \rightarrow (1 - \gamma)$, (11) can be transformed to the same form as (8), if the random variable ξ takes only discrete values 0 and 1. Computer simulations [26] of the model (11) found a stationary distribution close to the Gamma distribution (9). It was shown that the parameter β is related to the saving propensity λ by the formula $\beta = 3\lambda/(1 - \lambda)$ [38,58,59,60]. For $\lambda \neq 0$, agents always keep some money, so their balances never go to zero and $P(m \rightarrow 0) = 0$, whereas for $\lambda = 0$ the distribution becomes exponential.

In the subsequent papers by the Kolkata school [1] and related papers, the case of random saving propensity was studied. In these models, the agents are assigned random parameters λ drawn from a uniform distribution between 0 and 1 [61]. It was found that this model produces a power-law tail $P(m) \propto 1/m^2$ at high m . The reasons for stability of this law were understood using the Boltzmann kinetic equation [60,62,63], but most elegantly in the mean-field theory [64]. The fat tail originates from the agents whose saving propensity is close to 1, who hoard money and do not give it back [38,65]. An interesting matrix formulation of the problem was presented in [66]. Patriarca et al. [67] studied the relaxation rate in the money transfer models. Drăgulescu and Yakovenko [25] studied a model with taxation, which also has an element of proportionality. The Gamma distribution was also studied for conservative models within a simple Boltzmann approach in [68] and using much more complicated rules of exchange in [69,70].

Additive Versus Multiplicative Models

The stationary distribution of money (9) for the models of Sect. “Proportional Money Transfers and Saving Propensity” is different from the simple exponential formula (7) found for the models of Sect. “The Boltzmann-Gibbs Distribution of Money”. The origin of this difference can be understood from the Boltzmann kinetic equation [28,71]. This equation describes time evolution of the distribution function $P(m)$ due to pairwise interactions:

$$\begin{aligned} \frac{dP(m)}{dt} &= \iint \{ -f_{[m,m'] \rightarrow [m-\Delta, m'+\Delta]} P(m) P(m') \\ &+ f_{[m-\Delta, m'+\Delta] \rightarrow [m,m']} P(m - \Delta) \cdot P(m' + \Delta) \} dm' d\Delta. \end{aligned} \quad (12)$$

Here $f_{[m,m'] \rightarrow [m-\Delta, m'+\Delta]}$ is the probability of transferring money Δ from an agent with money m to an agent

with money m' per unit time. This probability, multiplied by the occupation numbers $P(m)$ and $P(m')$, gives the rate of transitions from the state $[m, m']$ to the state $[m - \Delta, m' + \Delta]$. The first term in (12) gives the depopulation rate of the state m . The second term in (12) describes the reverse process, where the occupation number $P(m)$ increases. When the two terms are equal, the direct and reverse transitions cancel each other statistically, and the probability distribution is stationary: $dP(m)/dt = 0$. This is the principle of detailed balance.

In physics, the fundamental microscopic equations of motion of particles obey time-reversal symmetry. This means that the probabilities of the direct and reverse processes are exactly equal:

$$f_{[m, m'] \rightarrow [m - \Delta, m' + \Delta]} = f_{[m - \Delta, m' + \Delta] \rightarrow [m, m']}. \quad (13)$$

When (13) is satisfied, the detailed balance condition for (12) reduces to the equation $P(m)P(m') = P(m - \Delta)P(m' + \Delta)$, because the factors f cancel out. The only solution of this equation is the exponential function $P(m) = c \exp(-m/T_m)$, so the Boltzmann–Gibbs distribution is the stationary solution of the Boltzmann kinetic equation (12). Notice that the transition probabilities (13) are determined by the dynamical rules of the model, but the equilibrium Boltzmann–Gibbs distribution does not depend on the dynamical rules at all. This is the origin of the universality of the Boltzmann–Gibbs distribution. It shows that it may be possible to find out the stationary distribution without knowing details of the dynamical rules (which are rarely known very well), as long as the symmetry condition (13) is satisfied.

The models considered in Sect. “The Boltzmann–Gibbs Distribution of Money” have the time-reversal symmetry. The model with the fixed money transfer Δ has equal probabilities (13) of transferring money from an agent with balance m to an agent with balance m' and vice versa. This is also true when Δ is random, as long as the probability distribution of Δ is independent of m and m' . Thus, the stationary distribution $P(m)$ is always exponential in these models.

However, there is no fundamental reason to expect time-reversal symmetry in economics, so (13) may be not valid. In this case, the system may have a nonexponential stationary distribution or no stationary distribution at all. In model (8), the time-reversal symmetry is broken. Indeed, when an agent i gives a fixed fraction γ of his money m_i to an agent with balance m_j , their balances become $(1 - \gamma)m_i$ and $m_j + \gamma m_i$. If we try to reverse this process and appoint an agent j to be the payer and

to give the fraction γ of her money, $\gamma(m_j + \gamma m_i)$, to agent i , the system does not return to the original configuration $[m_i, m_j]$. As emphasized by Angle [56], the payer pays a deterministic fraction of his money, but the receiver receives a random amount from a random agent, so their roles are not interchangeable. Because the proportional rule typically violates the time-reversal symmetry, the stationary distribution $P(m)$ in multiplicative models is typically not exactly exponential.¹ Making the transfer dependent on the money balance of the payer effectively introduces a Maxwell’s demon into the model. That is why the stationary distribution is not exponential, and, thus, does not maximize entropy (4). Another view on the time-reversal symmetry in economic dynamics is presented in [72].

These examples show that the Boltzmann–Gibbs distribution does not hold for any conservative model. However, it is universal in a limited sense. For a broad class of models that have time-reversal symmetry, the stationary distribution is exponential and does not depend on the details of the model. Conversely, when the time-reversal symmetry is broken, the distribution may depend on the details of the model. The difference between these two classes of models may be rather subtle. Deviations from the Boltzmann–Gibbs law may occur only if the transition rates f in (13) explicitly depend on the agent’s money m or m' in an asymmetric manner. Drăgulescu and Yakovenko [25] performed a computer simulation where the direction of payment was randomly selected in advance for every pair of agents (i, j) . In this case, money flows along directed links between the agents: $i \rightarrow j \rightarrow k$, and the time-reversal symmetry is strongly violated. This model is closer to the real economy, where one typically receives money from an employer and pays it to a grocery store. Nevertheless, the Boltzmann–Gibbs distribution was found in this model, because the transition rates f do not explicitly depend on m and m' and do not violate (13).

In the absence of detailed knowledge of real microscopic dynamics of economic exchanges, the semiuniversal Boltzmann–Gibbs distribution (7) is a natural starting point. Moreover, the assumption of [25] that agents pay the same prices Δm for the same products, independent of their money balances m , seems very appropriate for the modern anonymous economy, especially for purchases over the Internet. There is no particular empirical evidence for the proportional rules (8) or (11). However, the differ-

¹However, when Δm is a fraction of the total money $m_i + m_j$ of the two agents, the model is time-reversible and has an exponential distribution, as discussed in Sect. “The Boltzmann–Gibbs Distribution of Money”.

ence between the additive (7) and multiplicative (9) distributions may be not so crucial after all. From the mathematical point of view, the difference is in the implementation of the boundary condition at $m = 0$. In the additive models of Sect. “[The Boltzmann–Gibbs Distribution of Money](#)”, there is a sharp cutoff of $P(m)$ at $m = 0$. In the multiplicative models of Sect. “[Proportional Money Transfers and Saving Propensity](#)”, the balance of an agent never reaches $m = 0$, so $P(m)$ vanishes at $m \rightarrow 0$ in a power-law manner. At the same time, $P(m)$ decreases exponentially for large m for both models.

By further modifying the rules of money transfer and introducing more parameters in the models, one can obtain even more complicated distributions [73]. However, one can argue that parsimony is the virtue of a good mathematical model, not the abundance of additional assumptions and parameters, whose correspondence to reality is hard to verify.

Statistical Mechanics of Wealth Distribution

In the econophysics literature on exchange models, the terms “money” and “wealth” are often used interchangeably; however, economists emphasize the difference between these two concepts. In this section, we review the models of wealth distribution, as opposed to money distribution.

Models with a Conserved Commodity

What is the difference between money and wealth? One can argue [25] that wealth w_i is equal to money m_i plus the other property that an agent i has. The latter may include durable material property, such as houses and cars, and financial instruments, such as stocks, bonds, and options. Money (paper cash, bank accounts) is generally liquid and countable. However, the other property is not immediately liquid and has to be sold first (converted into money) to be used for other purchases. In order to estimate the monetary value of property, one needs to know the price p . In the simplest model, let us consider just one type of property, say, stocks s . Then the wealth of an agent i is given by the formula

$$w_i = m_i + ps_i. \quad (14)$$

It is assumed that the price p is common for all agents and is established by some kind of market process, such as an auction, and may change in time.

It is reasonable to start with a model where both the total money $M = \sum_i m_i$ and the total stock $S = \sum_i s_i$ are

conserved [74,75,76]. The agents pay money to buy stock and sell stock to get money, and so on. Although M and S are conserved, the total wealth $W = \sum_i w_i$ is generally not conserved, because of the price fluctuation [75] in (14). This is an important difference from the money transfer models of Sect. “[Statistical Mechanics of Money Distribution](#)”. Here the wealth w_i of an agent i , not participating in any transactions, may change when transactions between other agents establish a new price p . Moreover, the wealth w_i of an agent i does not change after a transaction with an agent j . Indeed, in exchange for paying money Δm , agent i receives the stock $\Delta s = \Delta m/p$, so her total wealth (14) remains the same. In principle, the agent can instantaneously sell the stock back at the same price and recover the money paid. If the price p never changes, then the wealth w_i of each agent remains constant, despite transfers of money and stock between agents.

We see that redistribution of wealth in this model is directly related to price fluctuations. One mathematical model of this process was studied in [77]. In this model, the agents randomly change preferences for the fraction of their wealth invested in stocks. As a result, some agents offer stock for sale and some want to buy it. The price p is determined from the market-clearing auction matching supply and demand. Silver et al. [77] demonstrated in computer simulations and proved analytically using the theory of Markov processes that the stationary distribution $P(w)$ of wealth w in this model is given by the Gamma distribution, as in (9). Various modifications of this model [32], such as introducing monopolistic coalitions, do not change this result significantly, which shows the robustness of the Gamma distribution. For models with a conserved commodity, Chatterjee and Chakrabarti [75] found the Gamma distribution for a fixed saving propensity and a power law tail for a distributed saving propensity.

Another model with conserved money and stock was studied in [78] for an artificial stock market where traders follow different investment strategies: random, momentum, contrarian, and fundamentalist. Wealth distribution in the model with random traders was found have a power-law tail $P(w) \sim 1/w^2$ for large w . However, unlike in most other simulation, where all agents initially have equal balances, here the initial money and stock balances of the agents were randomly populated according to a power law with the same exponent. This raises the question whether the observed power-law distribution of wealth is an artifact of the initial conditions, because equilibration of the upper tail may take a very long simulation time.

Models with Stochastic Growth of Wealth

Although the total wealth W is not exactly conserved in the models considered in Sect. “[Models with a Conserved Commodity](#)”, W nevertheless remains constant on average, because the total money M and stock S are conserved. A different model for wealth distribution was proposed in [27]. In this model, time evolution of the wealth w_i of an agent i is given by the stochastic differential equation

$$\frac{dw_i}{dt} = \eta_i(t)w_i + \sum_{j(\neq i)} J_{ij}w_j - \sum_{j(\neq i)} J_{ji}w_i, \quad (15)$$

where $\eta_i(t)$ is a Gaussian random variable with mean $\langle \eta \rangle$ and variance $2\sigma^2$. This variable represents growth or loss of wealth of an agent due to investment in stock market. The last two terms describe transfer of wealth between different agents, which is taken to be proportional to the wealth of the payers with the coefficients J_{ij} . So, the model (15) is multiplicative and invariant under the scale transformation $w_i \rightarrow Zw_i$. For simplicity, the exchange fractions are taken to be the same for all agents: $J_{ij} = J/N$ for all $i \neq j$, where N is the total number of agents. In this case, the last two terms in (15) can be written as $J(\langle w \rangle - w_i)$, where $\langle w \rangle = \sum_i w_i/N$ is the average wealth per agent. This case represents a “mean-field” model, where all agents feel the same environment. It can be easily shown that the average wealth increases in time as $\langle w \rangle_t = \langle w \rangle_0 e^{(\langle \eta \rangle + \sigma^2)t}$. Then, it makes more sense to consider the relative wealth $\tilde{w}_i = w_i/\langle w \rangle_t$. Equation (15) for this variable becomes

$$\frac{d\tilde{w}_i}{dt} = (\eta_i(t) - \langle \eta \rangle - \sigma^2)\tilde{w}_i + J(1 - \tilde{w}_i). \quad (16)$$

The probability distribution $P(\tilde{w}, t)$ for the stochastic differential equation (16) is governed by the Fokker-Planck equation:

$$\frac{\partial P}{\partial t} = \frac{\partial [J(\tilde{w} - 1) + \sigma^2 \tilde{w}]P}{\partial \tilde{w}} + \sigma^2 \frac{\partial}{\partial \tilde{w}} \left(\tilde{w} \frac{\partial (\tilde{w}P)}{\partial \tilde{w}} \right). \quad (17)$$

The stationary solution ($\partial P/\partial t = 0$) of this equation is given by the following formula:

$$P(\tilde{w}) = c \frac{e^{-J/\sigma^2 \tilde{w}}}{\tilde{w}^2 \sigma^2}. \quad (18)$$

The distribution (18) is quite different from the Boltzmann-Gibbs (7) and Gamma (9) distributions. Equation (18) has a power-law tail at large \tilde{w} and a sharp cut-off at small \tilde{w} . Equation (15) is a version of the generalized Lotka-Volterra model, and the stationary distribution (18)

was also obtained in [79,80]. The model was generalized to include negative wealth in [81].

Bouchaud and Mézard [27] used the mean-field approach. A similar result was found for a model with pairwise interaction between agents in [82]. In this model, wealth is transferred between the agents using the proportional rule (8). In addition, the wealth of the agents increases by the factor $1 + \zeta$ in each transaction. This factor is supposed to reflect creation of wealth in economic interactions. Because the total wealth in the system increases, it makes sense to consider the distribution of relative wealth $P(\tilde{w})$. In the limit of continuous trading, Slanina [82] found the same stationary distribution (18). This result was reproduced using a mathematically more involved treatment of this model in [83]. Numerical simulations of the models with stochastic noise η in [69,70] also found a power-law tail for large w .

Let us contrast the models discussed in Sect. “[Models with a Conserved Commodity](#)” and “[Models with Stochastic Growth of Wealth](#)”. In the former case, where money and commodity are conserved and wealth does not grow, the distribution of wealth is given by the Gamma distribution with an exponential tail for large w . In the latter models, wealth grows in time exponentially, and the distribution of relative wealth has a power-law tail for large \tilde{w} . These results suggest that the presence of a power-law tail is a nonequilibrium effect that requires constant growth or inflation of the economy, but disappears for a closed system with conservation laws.

Reviews of the models discussed were also given in [84,85]. Because of lack of space, we omit discussion of models with wealth condensation [27,50,86,87,88], where a few agents accumulate a finite fraction of the total wealth, and studies of wealth distribution on networks [89,90,91,92]. Here we discuss the models with long-range interaction, where any agent can exchange money and wealth with any other agent. A local model, where agents trade only with the nearest neighbors, was studied in [93].

Empirical Data on Money and Wealth Distributions

It would be very interesting to compare theoretical results for money and wealth distributions in various models with empirical data. Unfortunately, such empirical data are difficult to find. Unlike income, which is discussed in Sect. “[Data and Models for Income Distribution](#)”, wealth is not routinely reported by the majority of individuals to the government. However, in many countries, when a person dies, all assets must be reported for the purpose of inheritance tax. So, in principle, there exist good statis-

Econophysics, Statistical Mechanics Approach to, Figure 5

Cumulative probability distribution of net wealth in the UK shown on log–log and log–linear (*inset*) scales. Points represent the data from the Inland Revenue, and solid lines are fits to the exponential (Boltzmann–Gibbs) and power (Pareto) laws. (Reproduced from [95])

tics of wealth distribution among dead people, which, of course, is different from the wealth distribution among living people. Using an adjustment procedure based on the age, gender, and other characteristics of the deceased, the UK tax agency, the Inland Revenue, reconstructed the wealth distribution of the whole population of the UK [94]. Figure 5 shows the UK data for 1996 reproduced from [95]. The figure shows the cumulative probability $C(w) = \int_w^\infty P(w')dw'$ as a function of the personal net wealth w , which is composed of assets (cash, stocks, property, household goods, etc.) and liabilities (mortgages and other debts). Because statistical data are usually reported at nonuniform intervals of w , it is more practical to plot the cumulative probability distribution $C(w)$ rather than its derivative, the probability density $P(w)$. Fortunately, when $P(w)$ is an exponential or a power-law function, then $C(w)$ is also an exponential or a power-law function.

The cumulative probability distribution in Fig. 5 is plotted on a log–log scale, where a straight line represents a power-law dependence. The figure shows that the distribution follows a power law $C(w) \propto 1/w^\alpha$ with exponent $\alpha = 1.9$ for wealth greater than about £100,000. The inset in Fig. 5 shows the data on log–linear scale, where the straight line represents an exponential dependence. We observe that below £100,000 the data are well fitted by the exponential distribution $C(w) \propto \exp(-w/T_w)$ with the effective “wealth temperature” $T_w = £60,000$, (which corresponds to the median wealth of £41,000). So, the dis-

tribution of wealth is characterized by the Pareto power law in the upper tail of the distribution and the exponential Boltzmann–Gibbs law in the lower part of the distribution for the great majority (about 90%) of the population. Similar results are found for the distribution of income, as discussed in Sect. “Data and Models for Income Distribution”. One may speculate that the wealth distribution in the lower part is dominated by distribution of money, because the corresponding people do not have other significant assets, so the results of Sect. “Statistical Mechanics of Money Distribution” give the Boltzmann–Gibbs law. On the other hand, the upper tail of the wealth distribution is dominated by investment assets, where the results of Sect. “Models with Stochastic Growth of Wealth” give the Pareto law. The power law was studied by many researchers for the upper-tail data, such as the Forbes list of the 400 richest people [96,97], but much less attention was paid to the lower part of the wealth distribution. Curiously, Abdul-Magd [98] found that the wealth distribution in ancient Egyptian society was consistent with (18).

For direct comparison with the results of Sect. “Statistical Mechanics of Money Distribution”, it would be very interesting to find data on the distribution of money, as opposed to the distribution of wealth. Making a reasonable assumption that most people keep most of their money in banks, one can approximate the distribution of money by the distribution of balances on bank accounts. (Balances on all types of bank accounts, such as checking, saving, and money manager, associated with the same person should be added up.) Despite imperfections (people may have accounts with different banks or not keep all their money in banks), the distribution of balances on bank accounts would give valuable information about the distribution of money. The data for a big enough bank would be representative of the distribution in the whole economy. Unfortunately, it has not been possible to obtain such data thus far, even though it would be completely anonymous and not compromise the privacy of bank clients.

Measuring the probability distribution of money would be very useful, because it determines how much people can, in principle, spend on purchases without going into debt. This is different from the distribution of wealth, where the property component, such as house, car, or retirement investment, is effectively locked up and, in most cases, is not easily available for consumer spending. So, although wealth distribution may reflect the distribution of economic power, the distribution of money is more relevant for consumption. Money distribution can be useful for determining prices that maximize revenue of a manufacturer [25]. If a price p is set too high, few people can afford it, and, if a price is too low, the sales revenue is

small, so the optimal price must be in-between. The fraction of the population who can afford to pay the price p is given by the cumulative probability $C(p)$, so the total sales revenue is proportional to $pC(p)$. For the exponential distribution $C(p) = \exp(-p/T_m)$, the maximal revenue is achieved at $p = T_m$, i. e., at the optimal price equal to the average amount of money per person [25]. Indeed, the prices of mass-market consumer products, such as computers, electronics goods, and appliances, remain stable for many years at a level determined by their affordability to the population, whereas the technical parameters of these products at the same price level improve dramatically owing to technological progress.

Data and Models for Income Distribution

In contrast to money and wealth distributions, a lot more empirical data are available for the distribution of income r from tax agencies and population surveys. In this section, we first present empirical data on income distribution and then discuss theoretical models.

Empirical Data on Income Distribution

Empirical studies of income distribution have a long history in the economics literature [99,100,101]. Following the work by Pareto [15], much attention was focused on the power-law upper tail of the income distribution and less on the lower part. In contrast to more complicated functions discussed in the literature, Drăgulescu and Yakovenko [102] introduced a new idea by demonstrating that the lower part of income distribution can be well fitted with a simple exponential function $P(r) = c \exp(-r/T_r)$ characterized by just one parameter, the “income temperature” T_r . Then it was recognized that the whole income distribution can be fitted by an exponential function in the lower part and a power-law function in the upper part [95,103], as shown in Fig. 6. The straight line on the log–linear scale in the inset of Fig. 6 demonstrates the exponential Boltzmann–Gibbs law, and the straight line on the log–log scale in the main panel illustrates the Pareto power law. The fact that income distribution consists of two distinct parts reveals the two-class structure of American society [104,105]. Coexistence of the exponential and power-law distributions is known in plasma physics and astrophysics, where they are called the “thermal” and “superthermal” parts [106,107,108]. The boundary between the lower and upper classes can be defined as the intersection point of the exponential and power-law fits in Fig. 6. For 1997, the annual income separating the two classes was about \$120,000. About 3% of the popula-

tion belonged to the upper class, and 97% belonged to the lower class.

Silva and Yakovenko [105] studied time evolution of income distribution in the USA during 1983–2001 on the basis of data from the Internal Revenue Service (IRS), the government tax agency. The structure of the income distribution was found to be qualitatively the same for all years, as shown in Fig. 7. The average income in nominal dollars approximately doubled during this time interval. So, the horizontal axis in Fig. 7 shows the normalized income r/T_r , where the “income temperature” T_r was obtained by fitting of the exponential part of the distribution for each year. The values of T_r are shown in Fig. 7. The plots for the 1980s and 1990s are shifted vertically for clarity. We observe that the data points in the lower-income part of the distribution collapse on the same exponential curve for all years. This demonstrates that the shape of the income distribution for the lower class is extremely stable and does not change in time, despite the gradual increase of the average income in nominal dollars. This observation suggests that the lower-class distribution is in statistical, “thermal” equilibrium.

On the other hand, Fig. 7 shows that the income distribution in the upper class does not rescale and significantly changes in time. Silva and Yakovenko [105] found that the exponent α of the power law $C(r) \propto 1/r^\alpha$ decreased from 1.8 in 1983 to 1.4 in 2000. This means that the upper tail became “fatter”. Another useful parameter is the total in-

Cumulative probability distribution of tax returns plotted on log-log scale versus r/T_r (the annual income r normalized by the average income T_r in the exponential part of the distribution). The IRS data points are for 1983–2001, and the *columns of numbers* give the values of T_r for the corresponding years. (Reproduced from [105])

come of the upper class as the fraction f of the total income in the system. The fraction f increased from 4% in 1983 to 20% in 2000 [105]. However, in 2001, α increased and f decreased, indicating that the upper tail was reduced after the stock market crash at that time. These results indicate that the upper tail is highly dynamical and not stationary. It tends to swell during the stock market boom and shrink during the bust. Similar results were found for Japan [109,110,111,112].

Although relative income inequality within the lower class remains stable, the overall income inequality in the USA has increased significantly as a result of the tremendous growth of the income of the upper class. This is illustrated by the Lorenz curve and the Gini coefficient shown in Fig. 8. The Lorenz curve [99] is a standard way of representing income distribution in the economics literature.

It is defined in terms of two coordinates $x(r)$ and $y(r)$ depending on a parameter r :

$$\begin{aligned}
 x(r) &= \int_0^r P(r') dr', \\
 y(r) &= \frac{\int_0^r r' P(r') dr'}{\int_0^\infty r' P(r') dr'}.
 \end{aligned}
 \tag{19}$$

The horizontal coordinate $x(r)$ is the fraction of the population with income below r , and the vertical coordinate $y(r)$ is the fraction of the income this population accounts for. As r changes from 0 to ∞ , x and y change from 0 to 1 and parametrically define a curve in the (x, y) -plane.

Figure 8 shows the data points for the Lorenz curves in 1983 and 2000, as computed by the IRS [113]. Drăgulescu and Yakovenko [102] analytically derived the Lorenz curve

Econophysics, Statistical Mechanics Approach to, Figure 8
 Lorenz plots for income distribution in 1983 and 2000. The data points are from the IRS [113], and the theoretical curves represent (20) with f from Fig. 7. Inset: The closed circles are the IRS data 113 for the Gini coefficient G , and the open circles show the theoretical formula $G = (1 + f)/2$. (Reproduced from [105])

formula $y = x + (1 - x) \ln(1 - x)$ for a purely exponential distribution $P(r) = c \exp(-r/T_r)$. This formula is shown by the red line in Fig. 8 and describes the 1983 data reasonably well. However, for 2000, it is essential to take into account the fraction f of income in the upper tail, which modifies the Lorenz formula as follows [103,104,105]:

$$y = (1 - f)[x + (1 - x) \ln(1 - x)] + f\Theta(x - 1). \quad (20)$$

The last term in (20) represent the vertical jump of the Lorenz curve at $x = 1$, where a very small percentage of the population in the upper class accounts for a substantial fraction f of the total income. The blue curve representing (20) fits the 2000 data in Fig. 8 very well.

The deviation of the Lorenz curve from the straight diagonal line in Fig. 8 is a certain measure of income inequality. Indeed, if everybody had the same income, the Lorenz curve would be a diagonal line, because the fraction of income would be proportional to the fraction of the population. The standard measure of income inequality is the so-called Gini coefficient $0 \leq G \leq 1$, which is defined as the area between the Lorenz curve and the diagonal line, divided by the area of the triangle beneath the diagonal line [99]. Time evolution of the Gini coefficient, as computed by the IRS [113], is shown in the inset of Fig. 8. Drăgulescu and Yakovenko [102] derived analytically the result that $G = 1/2$ for a purely exponential distribution.

In the first approximation, the values of G shown in the inset of Fig. 8 are indeed close to the theoretical value $1/2$. If we take into account the upper tail using (20), the formula for the Gini coefficient becomes $G = (1 + f)/2$ [105]. The inset in Fig. 8 shows that this formula is a very good fit to the IRS data for the 1990s using the values of f deduced from Fig. 7. The values $G < 1/2$ for the 1980s cannot be captured by this formula, because the Lorenz data points are slightly above the theoretical curve for 1983 in Fig. 8. Overall, we observe that income inequality has been increasing for the last 20 years, because of swelling of the Pareto tail, but decreased in 2001 after the stock market crash.

Thus far we have discussed the distribution of individual income. An interesting related question is the distribution $P_2(r)$ of family income $r = r_1 + r_2$, where r_1 and r_2 are the incomes of spouses. If individual incomes are distributed exponentially $P(r) \propto \exp(-r/T_r)$, then

$$P_2(r) = \int_0^r dr' P(r') P(r - r') = cr \exp(-r/T_r), \quad (21)$$

where c is a normalization constant. Figure 9 shows that (21) is in good agreement with the family income distribution data from the US Census Bureau [102]. In (21), we assumed that incomes of spouses are uncorrelated. This simple approximation is indeed supported by the scatter plot of incomes of spouses shown in Fig. 10. Each family is represented in this plot by two points (r_1, r_2) and (r_2, r_1) for symmetry. We observe that the density of points is approximately constant along the lines of constant family in-

Econophysics, Statistical Mechanics Approach to, Figure 9

Econophysics, Statistical Mechanics Approach to, Figure 10 Scatter plot of the spouses' incomes (r_1, r_2) and (r_2, r_1) based on the data from the Panel Study of Income Dynamics (PSID). (Reproduced from [103])

come $r_1 + r_2 = \text{const}$, which indicates that incomes of spouses are approximately uncorrelated. There is no significant clustering of points along the diagonal $r_1 = r_2$, i. e., no strong positive correlation of spouses' incomes.

The Gini coefficient for the family income distribution (21) was calculated in [102] as $G = 3/8 = 37.5\%$. Figure 11 shows the Lorenz quintiles and the Gini coefficient for 1947–1994 plotted from the US Census Bureau data. The solid line, representing the Lorenz curve calculated from (21), is in good agreement with the data. The systematic deviation for the top 5% of earners results from the upper tail, which has a less pronounced effect on family income than on individual income, because of income averaging in the family. The Gini coefficient, shown in the inset of Fig. 11, is close to the calculated value of 37.5%. Moreover, the average G for the developed capitalist countries of North America and western Europe, as determined by the World Bank [103], is also close to the calculated value of 37.5%.

Income distribution has been examined in econophysics papers for different countries: Japan [68,109,110,111,112,114,115,116], Germany [117,118], the UK [68,85,116,117,118], Italy [118,119,120], the USA [117,121], India [97], Australia [91,120,122], and New Zealand [68,116]. The distributions are qualitatively similar to the results presented in this section. The upper tail follows a power law and comprises a small fraction of the pop-

Econophysics, Statistical Mechanics Approach to, Figure 11 Lorenz plot for family income calculated from (21), compared with the US Census data points. *Inset:* The US Census data points for the Gini coefficient for families, compared with the theoretically calculated value $3/8=37.5\%$. (Reproduced from [102])

ulation. To fit the lower part of the distribution, the use of exponential, Gamma, and log-normal distributions was reported in different papers. Unfortunately, income distribution is often reported by statistical agencies for households, so it is difficult to differentiate between one-earner and two-earner income distributions. Some papers reported the use of interpolating functions with different asymptotic behavior for low and high incomes, such as the Tsallis function [116] and the Kaniadakis function [118]. However, the transition between the lower and upper classes is not smooth for the US data shown in Figs. 6 and 7, so such functions would not be useful in this case. The special case is income distribution in Argentina during the economic crisis, which shows a time-dependent bimodal shape with two peaks [116].

Theoretical Models of Income Distribution

Having examined the empirical data on income distribution, let us now discuss theoretical models. Income r_i is the influx of money per unit time to an agent i . If the money balance m_i is analogous to energy, then the income r_i would be analogous to power, which is the energy flux per unit time. So, one should conceptually distinguish between the distributions of money and income. While money is regularly transferred from one agent to another in pairwise

transactions, it is not typical for agents to trade portions of their income. Nevertheless, indirect transfer of income may occur when one employee is promoted and another demoted, while the total annual budget is fixed, or when one company gets a contract, whereas another one loses it, etc. A reasonable approach, which has a long tradition in the economics literature [123,124,125], is to treat individual income r as a stochastic process and study its probability distribution. In general, one can study a Markov process generated by a matrix of transitions from one income to another. In the case where income r changes by a small amount Δr over a time period Δt , the Markov process can be treated as income diffusion. Then one can apply the general Fokker–Planck equation [71] to describe evolution in time t of the income distribution function $P(r, t)$ [105]:

$$\begin{aligned} \frac{\partial P}{\partial t} &= \frac{\partial}{\partial r} \left[AP + \frac{\partial(BP)}{\partial r} \right], \\ A &= -\frac{\langle \Delta r \rangle}{\Delta t}, \quad B = \frac{\langle (\Delta r)^2 \rangle}{2\Delta t}. \end{aligned} \quad (22)$$

The coefficients A and B in (22) are determined by the first and second moments of income changes per unit time. The stationary solution $\partial_t P = 0$ of (22) obeys the following equation with the general solution:

$$\begin{aligned} \frac{\partial(BP)}{\partial r} &= -AP, \\ P(r) &= \frac{c}{B(r)} \exp \left(-\int^r \frac{A(r')}{B(r')} dr' \right). \end{aligned} \quad (23)$$

For the lower part of the distribution, it is reasonable to assume that Δr is independent of r , i. e., the changes of income are independent of income itself. This process is called additive diffusion [105]. In this case, the coefficients in (22) are constants A_0 and B_0 . Then (23) gives the exponential distribution $P(r) \propto \exp(-r/T_r)$, with the effective income temperature $T_r = B_0/A_0$. Notice that a meaningful stationary solution (23) requires that $A > 0$, i. e., $\langle \Delta r \rangle < 0$. The coincidence of this result with the Boltzmann–Gibbs exponential law (1) and (7) is not accidental. Indeed, instead of considering pairwise interaction between particles, one can derive (1) by considering energy transfers between a particle and a big reservoir, as long as the transfer process is “additive” and does not involve a Maxwell–demon-like discrimination. Stochastic income fluctuations are described by a similar process. So, although money and income are different concepts, they may have similar distributions, because they are governed by similar mathematical principles. It was shown explicitly in [25,82,83] that the models of pairwise money transfer can be described in a certain limit by the Fokker–Planck equation.

On the other hand, for the upper tail of the income distribution, it is reasonable to expect that $\Delta r \propto r$, i. e., income changes are proportional to income itself. This is known as the proportionality principle of Gibrat [123], and the process is called multiplicative diffusion [105]. In this case, $A = ar$ and $B = br^2$, and (23) gives the power-law distribution $P(r) \propto 1/r^{\alpha+1}$, with $\alpha = 1 + a/b$.

Generally, lower-class income comes from wages and salaries, where the additive process is appropriate, whereas upper-class income comes from bonuses, investments, and capital gains, calculated in percentages, where the multiplicative process applies [126]. However, the additive and multiplicative processes may coexist. An employee may receive a cost-of-living rise calculated in percentages (the multiplicative process) and a merit rise calculated in dollars (the additive process). In this case, we have $A = A_0 + ar$ and $B = B_0 + br^2 = b(r_0^2 + r^2)$, where $r_0^2 = B_0/b$. Substituting these expressions into (23), we find

$$P(r) = c \frac{e^{-\left(\frac{r_0}{r}\right) \arctan\left(\frac{r}{r_0}\right)}}{\left[1 + \left(\frac{r}{r_0}\right)^2\right]^{\frac{1+a}{2b}}}. \quad (24)$$

The distribution (24) interpolates between the exponential law for low r and the power law for high r , because either the additive or the multiplicative process dominates in the corresponding limit. The crossover between the two regimes takes place at $r \sim r_0$, where the additive and multiplicative contributions to B are equal. The distribution (24) has three parameters: the “income temperature” $T_r = A_0/B_0$, the Pareto exponent $\alpha = 1 + a/b$, and the crossover income r_0 . It is a minimal model that captures the salient features of the empirical income distribution shown in Fig. 6. A mathematically similar, but more economically oriented model was proposed in [114,115], where labor income and asset accumulation are described by the additive and multiplicative processes correspondingly. A general stochastic process with additive and multiplicative noise was studied numerically in [127], but the stationary distribution was not derived analytically. A similar process with discrete time increments was studied by Kesten [128]. Recently, a formula similar to (24) was obtained in [129].

To verify the multiplicative and additive hypotheses empirically, it is necessary to have data on income mobility, i. e., the income changes Δr of the same people from one year to another. The distribution of income changes $P(\Delta r|r)$ conditional on income r is generally not available publicly, although it can be reconstructed by researchers at the tax agencies. Nevertheless, the multiplicative hypothesis for the upper class was quantitatively verified

in [111,112] for Japan, where tax identification data is published for the top taxpayers.

The power-law distribution is meaningful only when it is limited to high enough incomes $r > r_0$. If all incomes r from 0 to ∞ follow a purely multiplicative process, then one can change to a logarithmic variable $x = \ln(r/r_*)$ in (22) and show that it gives a Gaussian time-dependent distribution $P_t(x) \propto \exp(-x^2/2\sigma^2 t)$ for x , i. e., the log-normal distribution for r , also known as the Gibrat distribution [123]. However, the width of this distribution increases linearly in time, so the distribution is not stationary. This was pointed out by Kalecki [124] a long time ago, but the log-normal distribution is still widely used for fitting income distribution, despite this fundamental logical flaw in its justification. In a classic paper, Champernowne [125] showed that a multiplicative process gives a stationary power-law distribution when a boundary condition is imposed at $r_0 \neq 0$. Later, this result was rediscovered by econophysicists [130,131]. In our (24), the exponential distribution of the lower class effectively provides such a boundary condition for the power law of the upper class. Notice also that (24) reduces to (18) in the limit $r_0 \rightarrow 0$, which corresponds to purely multiplicative noise $B = br^2$.

There are alternative approaches to income distribution in the economics literature. One of them, proposed by Lydall [132], involves social hierarchy. Groups of people have leaders, who have leaders of a higher order, and so on. The number of people decreases geometrically (exponentially) with the increase of the hierarchical level. If individual income increases by a certain factor (i. e., multiplicatively) when moving to the next hierarchical level, then income distribution follows a power law [132]. However, the original argument of Lydall can be easily modified to produce an exponential distribution. If individual income increases by a certain amount, i. e., income increases linearly with the hierarchical level, then income distribution is exponential. The latter process seems to be more realistic for moderate incomes below \$100,000. A similar scenario is the Bernoulli trials [133], where individuals have a constant probability of increasing their income by a fixed amount. We see that the deterministic hierarchical models and the stochastic models of additive and multiplicative income mobility represent essentially the same ideas.

Other Applications of Statistical Physics

Statistical physics was applied to a number of other subjects in economics. Because of lack of space, only two such topics are briefly discussed in this section.

Economic Temperatures in Different Countries

As discussed in Sect. “Empirical Data on Money and Wealth Distributions” and “Empirical Data on Income Distribution”, the distributions of money, wealth, and income are often described by exponential functions for the majority of the population. These exponential distributions are characterized by the parameters T_m , T_w , and T_r , which are mathematically analogous to temperature in the Boltzmann–Gibbs distribution (1). The values of these parameters, extracted from the fits of the empirical data, are generally different for different countries, i. e., different countries have different economic “temperatures”. For example, Drăgulescu and Yakovenko [95] found that the US income temperature was 1.9 times higher than the UK income temperature in 1998 (using the exchange rate of dollars to pounds at that time). Also, there was $\pm 25\%$ variation between income temperatures of different states within the USA. [95].

In physics, a difference of temperatures allows one to set up a thermal machine. In was argued in [25] that the difference of money or income temperatures between different countries allows one to extract profit in international trade. Indeed, as discussed at the end of Sect. “Empirical Data on Money and Wealth Distributions”, the prices of goods should be commensurate with money or income temperature, because otherwise people cannot afford to buy those goods. So, an international trading company can buy goods at a low price T_1 in a “low-temperature” country and sell them at a high price T_2 in a “high-temperature” country. The difference of prices $T_2 - T_1$ would be the profit of the trading company. In this process, money (the analog of energy) flows from the “high-temperature” to the “low-temperature” country, in agreement with the second law of thermodynamics, whereas products flow in the opposite direction. This process very much resembles what is going on in the global economy now. In this framework, the perpetual trade deficit of the USA is the consequence of the second law of thermodynamics and the difference of temperatures between the USA and “low-temperature” countries, such as China. Similar ideas were developed in more detail in [134,135], including a formal Carnot cycle for international trade.

The statistical physics approach demonstrates that profit originates from statistical nonequilibrium (the difference of temperatures), which exists in the global economy. However, it does not answer the question what is the origin of this difference. By analogy with physics, one would expect that the money flow should reduce the temperature difference and, eventually, lead to equilibration

of temperatures. In physics, this situation is known as the “thermal death of the universe”. In a completely equilibrated global economy, it would be impossible to make profit by exploiting differences of economic temperatures between different countries. Although globalization of the modern economy does show a tendency toward equilibration of living standards in different countries, this process is far from straightforward, and there are many examples contrary to equilibration. This interesting and timely subject certainly requires further study.

Society as a Binary Alloy

In 1971, Thomas Schelling [136] proposed the now-famous mathematical model of segregation. He considered a lattice, where the sites can be occupied by agents of two types, e.g., blacks and whites in the problem of racial segregation. He showed that if the agents have some probabilistic preference for the neighbors of the same type, the system spontaneously segregates into black and white neighborhoods. This mathematical model is similar to the so-called Ising model, which is a popular model for studying phase transitions in physics. In this model, each lattice site is occupied by a magnetic atom, whose magnetic moment has only two possible orientations, up or down. The interaction energy between two neighboring atoms depends on whether their magnetic moments point in the same or in the opposite directions. In physics language, the segregation found by Schelling represents a phase transition in this system.

Another similar model is the binary alloy, a mixture of two elements which attract or repel each other. It was noticed in [137] that the behavior of actual binary alloys is strikingly similar to social segregation. In the following papers [42,138], this mathematical analogy was developed further and compared with social data. Interesting concepts, such as the coexistence curve between two phases and the solubility limit, were discussed in this work. The latter concept means that a small amount of one substance dissolves in another up to some limit, but phase separation (segregation) develops for higher concentrations. Recently, similar ideas were rediscovered in [139,140,141]. The vast experience of physicists in dealing with phase transitions and alloys may be helpful for practical applications of such models [142].

Future Directions, Criticism, and Conclusions

The statistical models described in this review are quite simple. It is commonly accepted in physics that theoretical models are not intended to be photographic copies of

reality, but rather to be caricatures, capturing the most essential features of a phenomenon with a minimal number of details. With only few rules and parameters, the models discussed in Sect. “[Statistical Mechanics of Money Distribution](#)”, “[Statistical Mechanics of Wealth Distribution](#)”, and “[Data and Models for Income Distribution](#)” reproduce spontaneous development of stable inequality, which is present in virtually all societies. It is amazing that the calculated Gini coefficients, $G = 1/2$ for individuals and $G = 3/8$ for families, are actually very close to the US income data, as shown in Figs. 8 and 11. These simple models establish a baseline and a reference point for development of more sophisticated and more realistic models. Some of these future directions are outlined below.

Future Directions

Agents with a Finite Lifespan The models discussed in this review consider immortal agents who live forever, like atoms. However, humans have a finite lifespan. They enter the economy as young people and exit at an old age. Evolution of income and wealth as functions of age is studied in economics using the so-called overlapping-generations model. The absence of the age variable was one of the criticisms of econophysics by the economist Paul Anglin [31]. However, the drawback of the standard overlapping-generations model is that there is no variation of income and wealth between agents of the same age, because it is a representative-agent model. It would be best to combine stochastic models with the age variable. Also, to take into account inflation of average income, (22) should be rewritten for relative income, in the spirit of (17). These modifications would allow one to study the effects of demographic waves, such as baby boomers, on the distributions of income and wealth.

Agent-Based Simulations of the Two-Class Society

The empirical data presented in Sect. “[Empirical Data on Income Distribution](#)” show quite convincingly that the US population consists of two very distinct classes characterized by different distribution functions. However, the theoretical models discussed in Sect. “[Statistical Mechanics of Money Distribution](#)” and “[Statistical Mechanics of Wealth Distribution](#)” do not produce two classes, although they do produce broad distributions. Generally, not much attention has been paid in the agent-based literature to simulation of two classes. One exception is [143], in which spontaneous development of employers and employees classes from initially equal agents was simulated [36]. More work in this direction would be certainly desirable.

Access to Detailed Empirical Data A great amount of statistical information is publicly available on the Internet, but not for all types of data. As discussed in Sect. “[Empirical Data on Money and Wealth Distributions](#)”, it would be very interesting to obtain data on the distribution of balances on bank accounts, which would give information about the distribution of money (as opposed to wealth). As discussed in Sect. “[Theoretical Models of Income Distribution](#)”, it would be useful to obtain detailed data on income mobility, to verify the additive and multiplicative hypotheses for income dynamics. Income distribution is often reported as a mix of data on individual income and family income, when the counting unit is a tax return (joint or single) or a household. To have a meaningful comparison with theoretical models, it is desirable to obtain clean data where the counting unit is an individual. Direct collaboration with statistical agencies would be very useful.

Economies in Transition Inequality in developed capitalist countries is generally quite stable. The situation is very different for former socialist countries making a transition to a market economy. According to the World Bank data [103], the average Gini coefficient for family income in eastern Europe and the former Soviet Union jumped from 25% in 1988 to 47% in 1993. The Gini coefficient in the socialist countries before the transition was well below the equilibrium value of 37.5% for market economies. However, the fast collapse of socialism left these countries out of market equilibrium and generated a much higher inequality. One may expect that, with time, their inequality will decrease to the equilibrium value of 37.5%. It would be very interesting to trace how fast this relaxation takes place. Such a study would also verify whether the equilibrium level of inequality is universal for all market economies.

Relation to Physical Energy The analogy between energy and money discussed in Sect. “[Conservation of Money](#)” is a formal mathematical analogy. However, actual physical energy with low entropy (typically in the form of fossil fuel) also plays a very important role in the modern economy, as the basis of current human technology. In view of the looming energy and climate crisis, it is imperative to find realistic ways for making a transition from the current “disposable” economy based on “cheap” and “unlimited” energy and natural resources to a sustainable one. Heterogeneity of human society is one of the important factors affecting such a transition. Econophysics, at the intersection of energy, entropy, economy, and statistical physics, may play a useful role in this quest [144].

Criticism from Economists

As econophysics is gaining popularity, some criticism has appeared from economists [31], including those who are closely involved with the econophysics movement [32,33,34]. This reflects a long-standing tradition in economic and social sciences of writing critiques on different schools of thought. Much of the criticism is useful and constructive and is already being accommodated in econophysics work. However, some criticism results from misunderstanding or miscommunication between the two fields and some from significant differences in scientific philosophy. Several insightful responses to the criticism have been published [145,146,147]; see also [7,148]. In this section, we briefly address the issues that are directly related to the material discussed in this review.

Awareness of Previous Economics Literature One complaint of [31,32,33,34] is that physicists are not well aware of the previous economics literature and either rediscover known results or ignore well-established approaches. To address this issue, it is useful to keep in mind that science itself is a complex system, and scientific progress is an evolutionary process with natural selection. The sea of scientific literature is enormous, and nobody knows it all. Recurrent rediscovery of regularities in the natural and social world only confirms their validity. Independent rediscovery usually brings a different perspective, broader applicability range, higher accuracy, and better mathematical treatment, so there is progress even when some overlap with previous results exists. Physicists are grateful to economists for bringing relevant and specific references to their attention. Since the beginning of modern econophysics, many old references have been uncovered and are now routinely cited.

However, not all old references are relevant to the new development. For example, Gallegati et al. [33] complained that the econophysics literature on income distribution ignores the so-called Kuznets hypothesis [149]. The Kuznets hypothesis postulates that income inequality first rises during an industrial revolution and then decreases, producing an inverted-U-shaped curve. Gallegati et al. [33] admitted that, to date, the large amount of literature on the Kuznets hypothesis is inconclusive. Kuznets [149] mentioned that this hypothesis applies to the period from colonial times to the 1970s; however, the empirical data for this period are sparse and not very reliable. The econophysics literature deals with reliable volumes of data for the second half of the twentieth century, collected with the introduction of computers. It is not clear what is the definition of industrial revolution

and when exactly it starts and ends. The chain of technological progress seems to be continuous (steam engine, internal combustion engine, cars, plastics, computers, Internet), so it is not clear where the purported U-curve is supposed to be placed in time. Thus, the Kuznets hypothesis appears to be, in principle, unverifiable and unfalsifiable. The original paper by Kuznets [149] actually does not contain any curves, but it has one table filled with made-up, imaginary data! Kuznets admits that he has “neither the necessary data nor a reasonably complete theoretical model” (p. 12 in [149]). So, this paper is understandably ignored by the econophysics community. In fact, the data analysis for 1947–1984 shows amazing stability of income distribution [150], consistent with Fig. 11. The increase of inequality in the 1990s resulted from growth of the upper class relative to the lower class, but the relative inequality within the lower class remains very stable, as shown in Fig. 7.

Reliance on Visual Data Analysis Another complaint of [33] is that econophysicists favor graphic analysis of data over the formal and “rigorous” testing prescribed by mathematical statistics, as favored by economists. This complaint goes against the trend of all sciences to use increasingly sophisticated data visualization for uncovering regularities in complex systems. The thick IRS publication 1304 [151] is filled with data tables, but has virtually no graphs. Despite the abundance of data, it gives a reader no idea about income distribution, whereas plotting the data immediately gives insight. However, intelligent plotting is the art with many tools, which not many researchers have mastered. The author completely agrees with Gallegati et al. [33] that too many papers mindlessly plot any kind of data on a log–log scale, pick a finite interval, where any smooth curved line can be approximated by a straight line, and claim that there is a power law. In many cases, replotting the same data on a log–linear scale converts a curved line into a straight line, which means that the law is actually exponential.

Good visualization is extremely helpful in identifying trends in complex data, which can then be fitted to a mathematical function; however, for a complex system, such a fit should not be expected with infinite precision. The fundamental laws of physics, such as Newton’s law of gravity or Maxwell’s equations, are valid with enormous precision. However, the laws in condensed matter physics, uncovered by experimentalists with a combination of visual analysis and fitting, usually have much lower precision, at best 10% or so. Most of these laws would fail the formal criteria of mathematical statistics. Nevertheless these approximate laws are enormously useful in practice, and ev-

eryday devices engineered on the basis of these laws work very well for all of us.

Because of the finite accuracy, different functions may produce equally good fits. Discrimination between the exponential, Gamma, and log-normal functions may not be always possible [122]. However, the exponential function has fewer fitting parameters, so it is preferable on the basis of simplicity. The other two functions can simply mimic the exponential function with a particular choice of the additional parameters [122]. Unfortunately, many papers in mathematical statistics introduce too many fitting parameters into complicated functions, such as the generalized beta distribution mentioned in [33]. Such overparameterization is more misleading than insightful for data fitting.

Quest for Universality Gallegati et al. [33] criticized physicists for trying to find universality in economics data. They also seemed to equate the concepts of power law, scaling, and universality. These are three different, albeit overlapping, concepts. Power laws usually apply only to a small fraction of data at the high ends of various distributions. Moreover, the exponents of these power laws are usually nonuniversal and vary from case to case. Scaling means that the shape of a function remains the same when its scale changes. However, the scaling function does not have to be a power-law function. A good example of scaling is shown in Fig. 7, where income distributions for the lower class collapse on the same exponential line for about 20 years of data. We observe amazing universality of income distribution, unrelated to a power law. In a general sense, the diffusion equation is universal, because it describes a wide range of systems, from dissolution of sugar in water to a random walk in the stock market.

Universalities are not easy to uncover, but they form the backbone of regularities in the world around us. This is why physicists are so interested in them. Universalities establish the first-order effect, and deviations represent the second-order effect. Different countries may have somewhat different distributions, and economists often tend to focus on these differences. However, this focus on details misses the big picture that, in the first approximation, the distributions are quite similar and universal.

Theoretical Modeling of Money, Wealth, and Income

It was pointed out in [31,33,34] that many econophysics papers confuse or misuse the terms for money, wealth, and income. It is true that terminology is sloppy in many papers and should be refined. However, the terms in [25,26] are quite precise, and this review clearly distinguishes between these concepts in Sect. “Statistical Mechanics of Money Distribution”, “Statistical Mechanics of Wealth

Distribution”, and “Data and Models for Income Distribution”.

One contentious issue is about conservation of money. Gallegati et al. [33] agree that “transactions are a key economic process, and they are necessarily conservative”, i. e., money is indeed conserved in transactions between agents. However, Anglin [31], Gallegati et al. [33], and Lux [34] complain that the models of conservative exchange do not consider production of goods, which is the core economic process and the source of economic growth. Material production is indeed the ultimate goal of an economy, but it does not violate conservation of money by itself. One can grow coffee beans, but nobody can grow money on a money tree. Money is an artificial economic device that is designed to be conserved. As explained in Sect. “Statistical Mechanics of Money Distribution”, the money transfer models implicitly assume that money in transactions is voluntarily paid for goods and services generated by production for the mutual benefit of the parties. In principle, one can introduce a billion variables to keep track of every coffee bean and other product of the economy. What difference would it make for the distribution of money? Despite the claims in [31,33], there is no contradiction between models of conservative exchange and the classic work of Adam Smith and David Ricardo. The difference is only in the focus: We keep track of money, whereas they keep track of coffee beans, from production to consumption. These approaches address different questions, but do not contradict each other. Because money constantly circulates in the system as payment for production and consumption, the resulting statistical distribution of money may very well not depend on what exactly is produced and in what quantities.

In principle, the models with random transfers of money should be considered as a reference point for developing more sophisticated models. Despite the totally random rules and “zero intelligence” of the agents, these models develop well-characterized, stable, and stationary distributions of money. One can modify the rules to make the agents more intelligent and realistic and see how much the resulting distribution changes relative to the reference one. Such an attempt was made in [32] by modifying the model of [77] with various more realistic economic ingredients. However, despite the modifications, the resulting distributions were essentially the same as in the original model. This example illustrates the typical robustness and universality of statistical models: Modifying details of microscopic rules does not necessarily change the statistical outcome.

Another misconception, elaborated in [32,34], is that the money transfer models discussed in Sect. “Statistical

Mechanics of Money Distribution” imply that money is transferred by fraud, theft, and violence, rather than voluntarily. One should keep in mind that the catchy labels “theft-and-fraud”, “marriage-and-divorce”, and “yard-sale” were given to the money transfer models by the journalist Brian Hayes [152] in a popular article. Econophysicists who originally introduced and studied these models do not subscribe to this terminology, although the early work of Angle [51] did mention violence as one source of redistribution. In the opinion of the author, it is indeed difficult to justify the proportionality rule (8), which implies that agents with high balances pay proportionally greater amounts in transactions than agents with low balances. However, the additive model of [25], where money transfers Δm are independent of money balances m_i of the agents, does not have this problem. As explained in Sect. “The Boltzmann–Gibbs Distribution of Money”, this model simply means that all agents pay the same prices for the same product, although prices may be different for different products. So, this model is consistent with voluntary transactions in a free market.

McCauley [145] argued that conservation of money is violated by credit. As explained in Sect. “Models with Debt”, credit does not violate conservation law, but creates positive and negative money without changing net worth. Negative money (debt) is as real as positive money. McCauley [145] claimed that money can be easily created with the tap of a computer key via credit. Then why would an employer not tap the key and double salaries, or a funding agency double research grants? Because budget constraints are real. Credit may provide a temporary relief, but sooner or later it has to be paid back. Allowing debt may produce a double-exponential distribution as shown in Fig. 3, but it does not change the distribution fundamentally.

As discussed in Sect. “Conservation of Money”, a central bank or a central government can inject new money into the economy. As discussed in Sect. “Statistical Mechanics of Wealth Distribution”, wealth is generally not conserved. As discussed in Sect. “Data and Models for Income Distribution”, income is different from money and is described by a different model (22). However, the empirical distribution of income shown in Fig. 6 is qualitatively similar to the distribution of wealth shown in Fig. 5, and we do not have data on money distribution.

Conclusions

The “invasion” of physicists into economics and finance at the turn of the millennium is a fascinating phenomenon. The physicist Joseph McCauley proclaims that “Econo-

physics will displace economics in both the universities and boardrooms, simply because what is taught in economics classes doesn't work" [153]. Although there is some truth in his arguments [145], one may consider a less radical scenario. Econophysics may become a branch of economics, in the same way as games theory, psychological economics, and now agent-based modeling became branches of economics. These branches have their own interests, methods, philosophy, and journals. The main contribution from the infusion of new ideas from a different field is not in answering old questions, but in raising new questions. Much of the misunderstanding between economists and physicists happens not because they are getting different answers, but because they are answering different questions.

The subject of income and wealth distributions and social inequality was very popular at the turn of another century and is associated with the names of Pareto, Lorenz, Gini, Gibrat, and Champernowne, among others. Following the work by Pareto, attention of researchers was primarily focused on the power laws. However, when physicists took a fresh, unbiased look at the empirical data, they found a different, exponential law for the lower part of the distribution. The motivation for looking at the exponential law, of course, came from the Boltzmann–Gibbs distribution in physics. Further studies provided a more detailed picture of the two-class distribution in a society. Although social classes have been known in political economy since Karl Marx, the realization that they are described by simple mathematical distributions is quite new. Demonstration of the ubiquitous nature of the exponential distribution for money, wealth, and income is one of the new contributions produced by econophysics.

Glossary

Boson peak The Boson peak is an excess of low frequency modes observed in glasses, as manifested, for example, in inelastic neutron scattering data. In rigidity percolation the Boson peak is related to the number of floppy modes.

Constraint Edges in a graph constrain the degrees of freedom of the nodes in the graph. If edges are independent, each edge acts as one constraint.

Degrees of freedom In d dimensions a point object has d degrees of freedom, while a body has $d(d + 1)/2$ degrees of freedom due to rotations and translations.

Floppy mode A floppy mode is a deformation of a structure which is soft and in ideal models is treated as a zero energy deformation.

Generic rigidity A network is generic if none of its edges are dependent due to the particular geometric arrangement of the nodes in the network. With high probability random networks are generic, while regular lattices are non-generic.

Isostatic network An isostatic network is rigid but has no redundant bonds. Isostatic networks are marginally rigid as removal of any edge induces a floppy mode. Ideal generic granular media are isostatic at jamming.

Redundant bond A redundant bond is not essential to the rigidity of a structure. Generic networks which contain redundant bonds are overconstrained and internally stressed.

Rigidity percolation threshold The rigidity threshold marks the transition from floppy networks which have zero elastic moduli to rigid networks with finite elastic moduli.

Definition of the Subject

Materials or structures with sufficiently low connectivity are floppy and have very low elastic moduli, while at high connectivity they are rigid and have relatively high elastic moduli. Elastic percolation networks describe the transition from floppy to rigid that occurs as the network

connectivity increases. The percolative geometry and elastic behavior near percolation are of particular interest. Conventional percolative geometries describe some experimental systems however the elastic critical behavior falls into several different universality classes. Moreover, distinct percolative geometries occur in systems with only central forces or which have soft torsional forces and in these cases both the geometry and elastic behavior may be distinct from conventional percolation. Granular media manifest a further distinct elastic percolation network, with the concept of an isostatic network underlying elastic behavior near jamming. This rich fundamental research framework is relevant to an enormous range of materials of scientific and technical interest [79], including physical and chemical gels [84,87], semiflexible networks in biology [6,42], proteins [79], chalcogenide glasses [10,79] and granular media [85]. This brief review outlines the broad underlying principles common to these diverse systems.

Introduction

Many materials exhibit a sharp change in elastic behavior as the degree of interconnection in the material is increased. One well studied example is the gel transition, in which a liquid becomes a gel (solid) as the number of short-range crosslinks increases [18,28,73,84,87]. A similar behavior occurs in epoxies where a polymer melt is irreversibly crosslinked by addition of crosslinking agents to form a stiff, hard solid [18,28,72,73,84]. Crosslinking can be invoked using a variety of stimuli, including chemical, microwave or thermal methods, given the appropriate precursors. Vulcanization in rubber formation is another example. Following the work by de Gennes [17], there has been considerable debate about the elastic scaling behavior occurring near the gelation point. Semiflexible rod networks in biology, including actin filaments in the cell and F filaments in blood clots, [6,42] are also gels. Moreover, paper is composed of cellulose rods and their crosslinking is critical to their mechanical performance [1]. As elucidated in Sects. “[Idealized Experiments](#)”–“[Granular Media](#)” the ideas of floppy modes and network rigidity are useful in understanding the elastic behavior of these materials, particularly near the gel point.

Elastic percolation is richer than conductivity percolation in that transmission of stress is a vector process while transmission of current only requires simple connectivity. Nevertheless, in some cases simple connectivity is sufficient to enable transmission of stress, while in others a more highly connected structure is required [67,79]. At the engineering level, the reasons for these distinctions have been known at least since the time of Maxwell [48],

though explicit models to elucidate the various types of elastic percolation processes in disordered media were only developed in the early 1980's [24,41]. Chalcogenide glasses, for example $Se_{1-x}Ge_x$, are miscible and provide a unique system in which to study the effect of increasing the crosslinking of low coordination networks. Selenium is relatively floppy as it is two-fold coordinated, while germanium is tetrahedrally bonded and rigid [59,78]. Though computational studies of these glasses indicate critical behavior near average co-ordination $r_c = 2.4$ [32], the experimental consensus is for rather smooth elastic moduli near threshold, presumably due to rounding effects such as dihedral forces or entropic elasticity. Nevertheless quantities such as the number of floppy modes in the Boson peak [40] and Raman scattering [26], do have a clear experimental signature near r_c .

The jamming transition of hard particles is different than the examples listed above as hard core repulsion provides a strong resistance to compression while there is no resistance to extension [2,30,55,85]. However in colloidal gels where there is a weak attractive potential, the behavior may be restored to that of rigidity percolation. Even in the absence of these attractive terms, some of the ideas of rigidity percolation are very useful in granular media, particularly the idea of an isostatic network [21,55]. In this picture, the onset of rigidity in a granular packing occurs at a stress free isostatic critical point. By considering systems with soft repulsive potentials, the elastic behavior in

compression can be described by deviations from this critical point, as evident in recent large scale computational studies [57]. Experiments generally support the idea of an isostatic critical point [30,46,85].

The onset of elastic percolation can be determined by making realistic models and by studying their response to an applied stress. This strategy is important, however a deeper understanding has emerged through combinatorial methods which identify constraints that reduce the number of floppy modes [38,52,59,78]. These constraint counting methods enable determination of the ability of a structure or graph to transmit stress, as developed by Maxwell for engineering structures [48] (see Fig. 1). Understanding of stress bearing geometries enables a broader view of elasticity percolation, unifying a broad range of experimental examples and elucidating the aspects which are universal and those that are not. It also enables unification of perspectives from several disciplines (as illustrated in Fig. 1), including engineering, mathematics, material science, physics and more recently biological physics. Algorithms and concepts developed in the graph theory and topology communities have proved particularly rich [34,43,83]. These methods and their relation to elastic percolation are surveyed in Sect. "Exact Algorithms and Percolative Geometries". Constraint counting methods also enable an exact analysis on Bethe lattices [22] which demonstrate that rigidity percolation is often first order (see Sect. "Exact Solution on Bethe Lattices"). From

a

b

Elastic Percolation Networks, Figure 1

Constraint counting methods are similar at the scale of bridges or atoms. a Maxwell asked how many beams are required to make engineering structures rigid. Triangulation is the standard method for ensuring enough central force bonds (rods or beams) are available to support a load, as illustrated by the Cairo Mississippi River bridge from www.bridgehunter.com. b Phillips [59] asked how many higher co-ordination atoms are required to make a random network rigid, for example a structure such as silica from www.phys.uu.nl/~Barkema. Dohler et al. [20] showed that Maxwell counting implies that in bond-bending networks rigidity sets in when the average co-ordination is $r_c = 2.4$

Elastic Percolation Networks, Figure 2

Examples of networks which have just enough connectivity to be rigid. These structures are called **isostatic** and are stress free. They have a finite elastic constant and no floppy modes. **a** When central forces, bond angle forces and dihedral terms are all important (all three terms in Eq. (1) or (2)). **b** When dihedral terms are not important (only the first two terms in Eq. (1) or (2) are important). **c** When only central forces are important (only the first term in (1) or (2))

a theoretical perspective, replica symmetry breaking is not required in solving the rigidity percolation problem on Bethe lattices, though the system is frustrated [22,64].

There are several different types of elastic percolation, depending on the interaction energy, as illustrated by considering standard force fields, such as the CHARMM [12], AMBER [82] and the Dreiding [49] potentials. They contain three short range terms in their potential energy expressions, with a common form being,

$$E = K_b \sum_{\text{bonds}} (b - b_0)^2 + K_\theta \sum_{\text{angles}} (\theta - \theta_0)^2 + K_\phi \sum_{\text{torsions}} (1 + \cos(n\phi - \phi_0)). \quad (1)$$

The first term in this expression describes the energy required to change the length of a nearest neighbor bond and is a central force term, while the second and third terms provide a restoring force when bond angles or dihedral (torsion) angles are deformed. For the arguments that follow we only need to be able to divide the energy into three terms so that,

$$E = E_{\text{bonds}} + E_{\text{angles}} + E_{\text{torsions}}. \quad (2)$$

Even long-range non-bonded interaction terms can be represented using this type of model, by adding further neighbor bonds. The theoretical problem is then: Given a graph or network where the nodes interact with a potential such as Eq. (1), what is the elastic response? Where is the rigidity percolation threshold located as we increase the average connectivity of the network? How many floppy modes are there?

The most interesting geometric aspect of elastic percolation is that the geometry which can support a stress

depends on the forces which are important, so that three different cases are illustrated by considering Eq. (1): (i) If all terms in Eq. (1) are important so that, $K_b \sim K_\theta \sim K_\phi$, the underlying geometry is the same as connectivity percolation as any connected network transmits stress (see Fig. 2a); (ii) If only the first two terms are important (i. e. $K_b \sim K_\theta \gg K_\phi$) then the underlying geometry is a special sort of rigidity percolation which can be solved using efficient combinatorial methods (see Fig. 2b). This applies to many Chalcogenide glasses as well as to many polymers and proteins, and is often called the bond-bending case; (iii) The hardest case is when only central force terms are present (i. e. $K_b \gg K_\theta, K_\phi$) in three dimensions (see Fig. 2c). This problem is called the central force rigidity problem and has no rigorous combinatorial characterization, so that we have to resort to direct simulations or approximations. Note that in two dimensions the torsional term is absent and the central force rigidity percolation problem can be solved using combinatorial methods [34,37,50].

It is intuitively evident that as the number of connections in a network increases, the system becomes more rigid or constrained. This intuitive observation is the basis of constraint counting methods introduced by James Clerk Maxwell in 1864 [48], who asked the question: “how many edges are required to make a graph internally rigid, so that it can support an applied stress?” He made the following simple constraint counting argument for three dimensional systems. Consider the case of central forces (only the first term in Eq. (1)) and a set of “ n ” nodes connected by “ b ” bonds. Each node has three degrees of freedom, its three translations. If a graph is internally rigid, it still has six degrees of freedom due to its global translations and rotations. Maxwell then stated that the minimal

number of bonds required to make a central force system rigid is given by the relation,

$$b = 3n - 6. \quad (3)$$

The example in Fig. 2c has $n = 5$ and $b = 9$ and so it satisfies this “Maxwell counting” condition. Maxwell counting is not exact but it provides a useful mean field model for most rigidity problems. It can also be applied to connectivity percolation, but it is a much poorer approximation in that case.

In 1970, Laman [43] proved a theorem showing that for a restricted class of rigidity problems, namely planar graphs, a Maxwell counting calculation on subgraphs can be used to infer the rigidity of a graph. This revived interest in combinatorial rigidity and several methods for implementing his theorem were developed, with Hendrickson’s [34] bond-testing procedure yielding the highly efficient algorithms in use today. Extensions of Laman’s theorem to body-bar networks and the conjecture of its extension to molecular frameworks [36,83] have yielded practical algorithms for a wide range of macromolecular systems and other networks. Maxwell’s work is also important in engineering where truss networks are analogous to central force systems and have a variety of applications (see e.g. Fig. 1a).

Basic Theoretical Concepts

Maxwell Counting in Random Networks

Maxwell counting [59,78] provides a quick, and frequently quite accurate, estimate of the number of floppy modes and the rigidity threshold. For example, consider bond-diluted triangular lattices where a fraction p of bonds are present. Following Thorpe [78], an unconstrained or flexible degree of freedom is called a floppy mode so that the number of floppy modes, F , remaining in a diluted triangular lattice is,

$$F = 2N - \frac{1}{2}pzN + R, \quad (4)$$

where N is the number of nodes in the lattice $z = 6$ is the coordination number of the lattice and R is the number of redundant bonds. In this expression $2N$ is the number of degrees of freedom in the absence of any bonds, while $pzN/2$ is the number of bonds in the network. Maxwell counting sets $R = 0$ so that every bond added to the lattice reduces the number of floppy modes by one. Redundant bonds are not essential for the rigidity of a structure, though they do increase the elastic moduli and they may also induce internal stresses in rigidity percolation problems. A comparison of the simplest examples of redundant

Elastic Percolation Networks, Figure 3

The simplest subgraphs on a triangular lattice which contain a redundant bond (dashed). Connectivity case (left), $g = 2$ rigidity case (right). From article by C. Moukarzel and P. M. Duxbury in [79]

bonds occurring in connected and rigid clusters on a triangular lattice is presented in Fig. 3.

In Maxwell counting we make the mean field approximation that the number of redundant bonds is zero, and that the rigidity transition occurs when the number of floppy modes goes to zero. In that case, Eq. (4) predicts that the rigidity transition for bond diluted triangular lattices occurs at, $p_r = 2/3$. This is surprisingly accurate as large scale simulations using methods which count the number of redundant bonds exactly, determine the threshold $p_r = 0.6602(3)$ [38] which is within 1% of the Maxwell counting estimate. The percolation threshold for bond bending systems is the same as that for connectivity percolation which is known exactly for bond diluted triangular lattices, $p_c = 2 \sin(\pi/18) = .347 \dots$ It is then clear that the central-force rigidity threshold occurs at a much higher bond concentration than the connectivity threshold [24]. Note that the Maxwell estimate of the connectivity percolation threshold is found from $F = N - pzN/2$, yielding $p_c = 0.33$, which is a much poorer approximation than for the central force rigidity case. In general Maxwell counting is a good approximation to the percolation threshold for all rigidity problems studied so far, except for cases where the connectivity percolation geometry applies!

Though Maxwell counting is very useful, the fact that it ignores redundant bond makes it incomplete. A Bethe lattice approach [22,53], and field theory methods [56,64] provide more complete theories. These approaches and also simulations on certain two [51] and three dimensional lattices [15], e.g. body-centered-cubic lattices, have demonstrated that the rigidity percolation transition is frequently first order with a large jump in the infinite cluster probability at the rigidity threshold. In fully random

networks, the onset of an infinite rigid cluster and the onset of an internally stressed cluster occur at the same threshold. However, in several important cases, the infinite cluster is unstressed or isostatic which is believed to occur in granular media [55,57] due to repulsive terms and in chalcogenide glasses due to self-organization [9,80]. In these cases, a mixed transition may occur where a first order jump and a continuous singularity occur at the same threshold. This behavior was first observed in Bethe lattice models of rigidity percolation [53].

Elastic Behavior

In all random connectivity and rigidity percolation problems studied so far the elastic behavior is continuous near the rigidity threshold, even in cases where the infinite rigid cluster undergoes a first order jump [15,51,56]. However, the question remains open in models of granular media and in self-organizing glass systems where an isostatic critical point plays a role. Direct numerical studies of the elastic constants of bond diluted central force systems indicate that they are quite linear for $p > p_r$, except very near the rigidity threshold, and that mean field estimates of the elastic behavior are surprisingly accurate in these cases [24,25,70]. In contrast the elastic behavior of bond bending networks in three dimensions is non-linear over most of the concentration range (see Fig. 4). Nevertheless, in all cases, the number of floppy modes as a function of $r < r_c$ is close to linear as is consistent with the simple Maxwell estimate.

In ideal elastic percolation networks, the elastic behavior is singular with a behavior typical of a continuous sin-

Elastic Percolation Networks, Figure 4

Elastic behavior of glass models as a function of average site coordination using continuous random network models like that of Fig. 1b, from [32]

gularity, $(p - p_r)^T$. The value of the critical exponent T has been a matter of debate. There is general agreement that in cases where bond-bending terms are dominant, the critical exponent T is larger than the conductivity exponent t [41]. For example in two dimensional lattices with bond-bending terms, $t = 1.31(1)$ while $T = 3.96(3)$ [90]. It is also well accepted that continuum systems may exhibit non-universal critical behavior due to the occurrence of necks of varying size in continuum systems [23]. Moreover, even in the absence of continuum effects there are several different elasticity models, with three well studied cases being: gel models where entropic effects are important [17,62] and following de Gennes, $T \approx t$; bonding bending networks where $T \approx t + 2\nu$ [8,24,69,90] and; central force networks where the elastic critical behavior is close to the bond bending case [31,68], at least on regular lattices.

However, in connecting network geometry to elastic behavior in central force networks and in three dimensional networks without torsional forces, it is important to distinguish between generic networks and non-generic networks. This distinction is noticed in granular media where perfectly monodisperse spheres can form regular packings in two dimensions with average contact number six, while random packings, through jamming of regular or polydisperse spheres, have average contact number near four. The latter case is the generic case, while the former is the non-generic case. Non-generic systems are characterized by constraints which are degenerate and occur in the dynamical matrix as dependent equations. In network structures they can occur as special sets of parallel bonds or series combinations of bonds pointing in the same direction (see Sect. “Exact Algorithms and Percolative Geometries”). These configurations do not occur on random networks which are therefore generic. Regular lattices such as the triangular lattice are thus non-generic and the consequences of this on elasticity is still poorly understood.

Idealized Experiments

Idealized experiments have been carried out to test the prediction that, for a given geometric structure, the elastic moduli have different critical exponents than the those which apply to conductivity. A simple tabletop experiment to test this prediction was devised by Benguigui [7]. In his experiment, holes are drilled on a square grid in a metal sheet. The conductivity, σ and Young’s modulus, C , were measured as a function of the remaining metal, ϕ . From these experiments the elastic exponent $T \approx 3.5$, and conductivity exponent $t \approx 1.3$ were extracted, which are in agreement with theoretical expectations in two dimen-

sions, within the experimental uncertainty. Conductivity and elasticity measurements on sintered sub micron silver powder aggregates [19] yielded $t = 2.15(25)$ and $T = 3.8(5)$, which agree with theoretical calculations on bond-bending networks in three dimensions which predict $T = t + 2\nu$ [8] and with simulations [69]. To our knowledge there have been no idealized experiments on central force systems, or on systems without torsional forces in three dimensions.

Chalcogenide Glasses

Following Phillips and Thorpe [20,59,78], Maxwell counting for the number of floppy modes in the $Se_{1-x}Ge_x$ system proceeds as follows. Each atom has three degrees of freedom while each r -fold co-ordinated atom imposes $r/2$ central-force constraints and $2r - 3$ bond bending constraints on the network. A two fold Se atom then imposes two constraints while a four fold Ge atom imposes seven constraints. Here we assume that the torsional forces are negligible and the network is continuous with all atoms in one connected cluster. The Maxwell counting estimate for the number of floppy modes is then,

$$F = 3N - 2(1 - x)N - 7xN \quad (5)$$

where N is the number of atoms in the network and $r = 2$ for Se while $r = 4$ for Ge so that the average co-ordina-

tion of a glass is $r = 4x + 2(1 - x)$. Equation (5) indicates that the number of floppy modes is linear in x and goes to zero at $x_c = 0.2$, which corresponds to the critical average co-ordination $r_c = 2.4$ [20]. This critical co-ordination also applies when a fraction y of three-fold coordinated atoms are added to the model, as is relevant to the ternary $Se_{1-x-y}As_yGe_x$. In that case $F = 3N - 2(1 - x - y)N - 9yN/2 - 7xN$, and the average site coordination, $r = 2(1 - x - y) + 3y + 4x$. Of course torsional forces are non-zero in these materials and have to be considered in comparisons with experiment.

The prediction of critical coordination $r_c = 2.4$ in chalcogenide glasses stimulated a search for experimental signatures of rigidity percolation. Though early experiments indicated a singular behavior in the elastic constants near r_c , these results were later found to be due to experimental artifacts. Later experiments indicated that the elastic moduli of chalcogenides are smooth near r_c . However the number of floppy modes [40] and an appropriately defined asymptotic glass transition temperature [3] do clearly indicate a rigidity threshold. The number of floppy modes is manifested in inelastic neutron scattering data [40] where a strong low frequency peak, called the Boson peak, exists for $r < r_c$ (see Fig. 5). The number of modes in the Boson peak gives a measure of the number of floppy modes and the location of the peak provides an estimate of the dihedral forces in the material. Theo-

The intermediate phase observed in the derivative of the viscosity $d\eta/dT$ at T_g and in the non-reversible enthalpy ΔH_{nr} , from [9]

retical analysis of the dynamical response of glassy networks yields good agreement with this data [13]. Several other measurements, including Mössbauer spectra [11], Raman scattering [26], vibrational lifetimes [81], also support a critical value of r_c which is close to 2.4.

A stimulating, though still controversial, concept is the intermediate phase in chalcogenide glasses [9,10,80]. The intermediate phase lies between the traditional floppy and rigid phases and occurs by self-organization to avoid internal stress. There are then two co-ordination thresholds r_1 and r_2 , with the first heralding the onset of a rigid but stress-free network and the second the onset of a rigid but internally-stressed network [80]. The extent of the intermediate regime between r_1 and r_2 has been explored in a variety of models [80] and experimental support has come from studies of chalcogenide glasses over narrow composition regimes [9,10], as illustrated in Fig. 5b.

Constraint counting and rigidity concepts developed in chalcogenide glasses have been applied to a wide variety of covalently bonded materials, ranging from amorphous carbons to complex ternaries. Thermal effects along with local structural and chemical ordering often confound a simple interpretation of the data as a purely random rigidity percolation process, nevertheless rigidity and elastic percolation concepts are fundamental to much of the literature in this area [2,3,79,85].

Gels and Semiflexible Rod Networks

Soon after the development of percolation theory, gelation was recognized as a related process and the geometry of gels has been compared to percolation in many different systems [6,42,47,66,73,84,87,89]. Though percolation provides a useful framework for the description of the onset

of rigidity in gels, it is often difficult to access the critical regime [65].

Gels are ubiquitous in science, nature and technology though there is no consensus definition of what constitutes a gel. Nevertheless we are all familiar with gels, ranging from jelly to clay dispersions and to chemically crosslinked systems such as rubber and epoxies. Gelation may occur through physical or chemical crosslinking, or through a combination of both processes. Crosslinking is a short range concept and long range forces can sometimes be critical. Nevertheless a broad range of physical and chemical gels can be understood using rigidity concepts based on the change in structure as the crosslinking in a network increases. Even at the single molecule level it is sometimes reasonable to use rigidity percolation ideas to evaluate flexibility as a function of internal crosslinking, for example in proteins [63]. Colloidal gels with strong repulsive terms and weak short-range attractive interactions have many features in common with granular media, as described in the next section.

The original work on gels related the gelation point to connectivity percolation [73], while recent work relates the gel point in rod networks to rigidity percolation [33,35,44,45], as illustrated in Fig. 6. Maxwell counting in two dimensional rod networks [44] states that the number of floppy modes in a network with N rods connected by P pivots is given by,

$$F = 3N - 2P - 3. \quad (6)$$

There are three degrees of freedom per rod, two translations and one rotation, while each pivot removes two translational degrees of freedom from the two rods which it connects. The Maxwell counting estimate, found by set-

Elastic Percolation Networks, Figure 6

Elastic percolation of biofibers. **a, b** Two views of the actin filament network in a human cell, from [77]. The right panel is a schematic phase diagram of semiflexible rod networks, from [33]. The solid line is associated with a rigidity threshold in a random rod network. The mean distance between crosslinks or entanglements is l_c , and $c \approx 1/l_c$. L is the molecular weight of the semiflexible polymers and the rigidity threshold occurs at $L \approx 1/c$ which defines the sol-gel transition in this model

ting $F = 0$ in Eq. (6), for the onset of rigidity in these two dimensional rod networks is then $P_r/N = 3/2$, so that there are three pivot points on each rod. Connectivity percolation occurs at $P_c/N = 1$. Elastic models have been simulated and good agreement with Eq. (6) was found. However experimental gels exhibit correlations in local structure [87], and in the case of fibers orientational ordering and bundling [6,42]. Moreover the elastic behavior of crosslinks is difficult to quantify. These factors are particularly important for non-universal parameters such as the percolation or gelation threshold, and they strongly affect the non-linear response of gels.

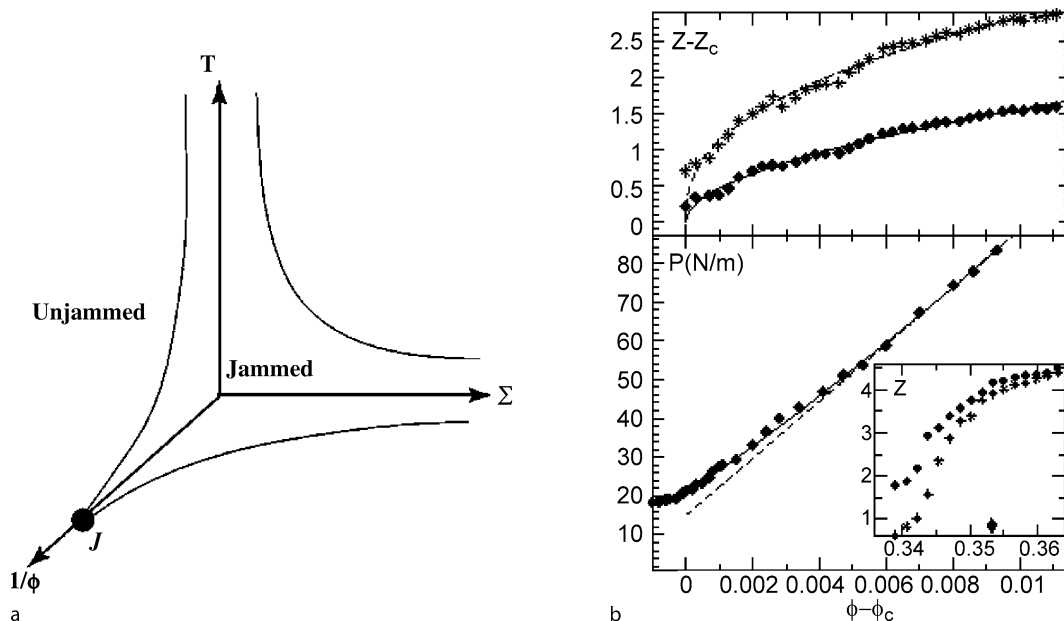

The elastic behavior near gelation is expected to be more universal provided long-range correlations in structure are absent. In a well known paper, de Gennes predicted that the elastic critical exponent, T , of gels should be the same as the conductivity exponent t [17]. However, as discussed in Sect. “Basic Theoretical Concepts” and elaborated upon in Sect. “Elastic Critical Behavior”, purely geometric models predict that the elasticity exponent is significantly larger than $t_{3D} = 2.01(1)$, and is well described by $T_{3D} = t_{3D} + 2\nu_{3D} = 3.77(3)$, where $\nu_{3D} = 0.88$ is the percolation correlation length exponent [8,24,41,69,90]. Over the years many experiments have measured T at the

gelation threshold, for example [4,29,47,65,84,87], with the consensus that $T = t$ in most gels as predicted by de Gennes. This issue will be discussed further in Sect. “Elastic Critical Behavior”.

Granular Media

Jamming occurs as the packing fraction or density of a colloidal or granular system increases. Though the relations between rigidity and jamming have been discussed for many years [30], it is only recently that the relationship has yielded to a clear quantitative analysis [2,55,57,85]. Alexander [2] discussed the presence of floppy modes or rattlers in granular systems and recent work has noted their relation to the Boson peak in glasses [86].

The presence of complex stress bearing networks has been imaged [30] and studied analytically and computationally and the relation to an isostatic network was noted by Moukarzel [55] who developed the idea of jamming as an isostatic critical point. Molecular dynamics simulations in systems with purely repulsive potentials provide a beautiful synthesis of the relations between rigidity, colloidal glasses and granular media [57] (see Fig. 7). These simulations demonstrate that the zero temperature jamming

Behavior of a theoretical and b experimental dense packings near jamming. a schematic of phase behavior found from simulations of purely repulsive models, from [57]. The jamming point J is an isostatic critical point. Σ is the applied shear stress, T is temperature and ϕ is packing fraction. b Behavior of the pressure, P and average co-ordination number $Z - Z_c$ on approach to jamming of photoelastic spheres. $\phi - \phi_c$ is the deviation from close packing, from [46]. In the top panel and in the inset, the diamonds exclude rattlers while the stars include them

point provides insight into the whole phase diagram and enables calculation of the way in which various properties approach zero on approach to jamming from above. These simulations avoid the non-generic critical point which is characteristic of the crystal phase of monodisperse packings, and instead focused upon non-crystalline random packing states which are characteristic of generic rigidity. The computed critical exponents for the shear modulus depend on the form of the repulsive potential but not on the spatial dimension. Later simulations suggest that the stress bearing backbone has a mixed behavior on approach to the jamming point, and its behavior is argued to be essentially the same as that observed in the Bethe lattice theory near an isostatic critical point [71]. Experiments on photoelastic spheres [46] are in general supportive of the physical picture emerging from these theoretical insights (see Fig. 7), including the idea of a jump in average coordination at the jamming point.

Exact Solution on Bethe Lattices

Maxwell counting provides a very useful mean field theory for the rigidity transition, nevertheless, it is not a complete theory as it ignores redundant bonds and does not provide a geometry for the rigidity percolation process. Moreover Maxwell counting predicts that the onset of rigidity occurs when all floppy modes are removed so that the whole network is in one giant isostatic cluster.

Bethe lattice theory is a more complete theory which resolves most of the problems with Maxwell counting methods, moreover it is simple and exactly solvable. In the following we describe the simplest Bethe lattice theory to illustrate the way in which the classic theory of connectivity percolation compares to rigidity percolation [27] and how Maxwell counting should be modified in light of the Bethe analysis. The extent of the intermediate phase [80] can also be simply calculated from the results of the Bethe lattice rigidity theory, as outlined at the end of this section.

The rigidity problem on Bethe lattices encompasses a wide range of different models [53], though here we focus on one generic case [22]. In d dimensions a point object has d degrees of freedom (d translations), while extended objects or bodies also have rotational modes and a total of $d(d+1)/2$ degrees of freedom. We define g as the number of degrees of freedom of a free or unbonded site, so that $g = 1$ corresponds to connectivity percolation, $g = d$ to point objects and $g = d(d+1)/2$ to bodies. A network with N sites (and no edges) has a total of $F = Ng$ degrees of freedom, or floppy (zero frequency) modes. Constraint counting notes that each time an *independent* edge is added to the network, the number floppy

modes is reduced by one, so that

$$F = Ng - E + R \quad (7)$$

where E is the number edges in the graph and R is the number of redundant edges. Note the additional term R on the right hand side. This term is key in understanding the relation between constraint counting and percolation, and in finding algorithms for rigidity percolation. An edge does not reduce the number of floppy modes if it is placed between two sites which are already mutually rigid, in which case this edge is redundant. The simplest examples of subgraphs containing a redundant bond on a triangular lattice are illustrated in Fig. 3 for the connectivity ($g = 1$) and $g = 2$ rigidity cases. Note that any one of the bonds in these structures could be labeled as the redundant one. However once any one of them is removed, all of the others are necessary to ensure the mutual rigidity of the structure. The set of all bonds which are mutually redundant form an overconstrained or stressed cluster. In rigidity theory each edge can be considered to be a central force spring, which means that there is a restoring force only in tension and compression. Then an overconstrained cluster of such springs (with random natural lengths) is internally stressed due to a redundant bond. In the connectivity case each bond is like a wire which can carry current or fluid flow. The simplest overconstrained cluster is then a loop which can support an internal eddy current. Rigid structures which contain no redundant bonds are minimally rigid or isostatic. In connectivity percolation isostatic structures are trees, whereas in ($g > 1$) rigidity percolation isostatic structures always contain many loops.

In percolation problems, we are interested in the asymptotic limit of very large graphs ($N \rightarrow \infty$), and it is more convenient to work with intensive quantities, so we define $f(p) = F/gN$ and $r(p) = 2R/gzN$, so that

$$f(p) = 1 - \frac{z}{2g}(p - r(p)) \quad (8)$$

where, on average, the number of edges is $E/N = zp/2$. $g * r(p)$ is the probability that a bond is redundant [22,38]. The number of floppy modes, $f(p)$, acts as a free energy for both connectivity and rigidity problems, so that if $\partial f(p)/\partial p$ undergoes a jump discontinuity, the transition is first order [22]. The behavior of this quantity is directly related to the probability that a bond is overconstrained P_{ov} via the relation,

$$\frac{\partial f}{\partial p} = -\frac{z}{2g}(1 - P_{ov}). \quad (9)$$

If the transition is second order, the second derivative $\partial^2 f/\partial p^2 \sim (p - p_c)^{-\alpha}$, where α is the specific heat exponent [38].

Elastic Percolation Networks, Figure 8
Dangling ends connected to a backbone (shaded). Connectivity case (left) and $g = 2$ rigidity case (right). Dangling ends don't contribute to current (left) or stress (right) which is applied in the vertical direction

The infinite cluster probability in rigidity problems is composed of the stress-bearing backbone plus dangling ends. Dangling ends are rigidly connected to the backbone but are not part of the stress bearing backbone. Examples of dangling ends in the connectivity and rigidity cases are illustrated in Fig. 8 for central force problems on the triangular lattice.

The quantities, $f(p)$, $\partial f(p)/\partial p$, $r(p)$, P_∞ , P_{ov} can be calculated exactly on Bethe lattices of general coordination z , where p is the bond probability of the Bethe lattice. The key quantity from which all the others is derived is the probability, T , that a site on a branch of a Bethe lattice is part of the infinite rigid cluster. This quantity has a steady state solution which is found from the equation,

$$T = \sum_{l=g}^{z-1} \binom{z-1}{l} (pT)^l (1-pT)^{z-1-l}, \quad (10)$$

where T is the probability that a site is connected to the infinite rigid cluster through one branch of the Bethe lattice. The case $g = 1$ recovers the well known Bethe lattice equation for connectivity percolation [27] while for general g , these equations are the same as those for k -core percolation on Bethe lattices [14], where $k = g + 1$. As illustrated in Fig. 9, the solutions to Eq. (10) depend sensitively on the value of g . The case $g = 1$ corresponds to connectivity percolation and shows a typical continuous behavior, while the case $g = 2$ is first order and is typical of all cases where $g > 1$. This means that central force percolation on random graphs is typically first order [22,54].

It is clearly seen from these figures that the rigidity transition is first order on Bethe lattices, while the connectivity transition is second order. We identify the point at which the stable solution becomes nonzero as p_s , the spinodal point, and in the connectivity case $p_s = p_c$ because the transition is second order.

Combining the stable solutions to branch probabilities, yields the infinite cluster probability of the Bethe lattice,

$$P_\infty = \sum_{l=g}^z \binom{z}{l} (pT)^l (1-pT)^{z-l}. \quad (11)$$

The other quantities of interest are found from the stable solution for T as follows. The probability that a bond is overconstrained is [22],

$$P_{ov} = T^2, \quad (12)$$

so that Eq. (9) yields,

$$\frac{\partial f}{\partial p} = -\frac{z}{2g}(1-T^2). \quad (13)$$

Elastic Percolation Networks, Figure 9

Elastic Percolation Networks, Figure 10

The order parameters, floppy modes and its derivative as a function of p for a typical connectivity percolation case $z = 3, g = 1$, and **b** a typical rigidity percolation case, $z = 6, g = 2$. The quantities plotted are $f(p)$ (dashed), $r(p)$ (dot dashed), $-df/dp$ (heavy dashed), P_{ov} (thin solid), P_{inf} (heavy solid). In the connectivity case we find $p_c = p_s$, while in rigidity cases $p_s < p_c$. For the rigidity case, $p_s = 0.605$ and $p_c = 0.655$, from article by C. Moukarzel and P. M. Duxbury in [79]

The probability that a bond is on the infinite cluster is,

$$P_{inf} = T^2 + 2TT_1. \quad (14)$$

where T_1 is the probability that a site has one degree of freedom and can also be found straightforwardly [22]. We also want to find the total number of redundant bonds $r(p)$ and the total number of floppy modes $f(p)$. In order to find these quantities, we integrate Eq. (13) and then use Eq. (7). However, the integration of Eq. (13) leads to one free constant. To determine this constant, for a lattice of co-ordination z , we impose the constraint [22],

$$r(1) = 1 - \frac{2g}{z}. \quad (15)$$

We then find that $r(p)$ approaches zero at a critical point p_c , which lies above p_s , for any $g > 1$, and that p_c is close to the Maxwell estimate $p_c = 2g/z$. Results for five key quantities found from Bethe lattice theory are presented in Fig. 10 for typical conductivity and rigidity percolation cases.

The Bethe lattice theory outlined above has been carefully compared with exact simulations of random graphs which demonstrate that it is exact [22]. This is a symmetric theory as the order parameter does not need to be described by a non-trivial distribution. The fact that this symmetric theory is exact [64] and yet applies to glassy systems such as granular media and rod networks is intriguing as replica symmetry breaking would be expected in those cases, as occurs in problems such as KSAT, spin glasses, and lattice gases. It is worth noting that the Bethe lattice Eqs. (10)–(11) are the same as the Bethe lattice equations for k -core percolation [14] which is also being

used as a simple model for granular media [71]. Extensions of the Bethe lattice theory to chalcogenide glasses have been carried out and provide a more complete theory than Maxwell counting [79].

Extension to the Intermediate Phase

In the intermediate phase [80], the network is dominated by a giant rigid but isostatic cluster. To generate such a cluster, we consider adding bonds to a graph, with the constraint that any redundant bond is not added to the network. As described in the next section this is how the exact constraint counting algorithms proceed, so computation of geometric structures which are stress free is straightforward using Hendrickson's bond testing procedure [34].

In the Bethe lattice solution, the onset of a metastable solution occurs at p_s , however this solution contains a number, $r(p_s)$, of redundant bonds. Since bonds are added randomly, the lowest threshold at which a stress-free percolating cluster can occur is $p_1 = p_s - r(p_s)$. In first order rigidity cases $r(p_s)$ is small, so to a good approximation $p_1 \approx p_s$. The upper limit of the intermediate phase is an isostatic network to which no more isostatic bonds can be added. This is just the Maxwell counting estimate, so $p_2 \approx p_m$. Calculation of p_1 and p_2 for other graphs and lattices can be carried out in a similar way, using the exact algorithms outlined in the next subsection. In second order cases however, $p_s = p_c$, so that $p_1 = p_c - r(p_c)$ and $p_2 = p_m$. In glasses, it is unlikely that all stress inducing bonds can be avoided so we expect the observed values of the intermediate regime to begin at $p > p_1$ and to end at $p < p_2$.

Exact Algorithms and Percolative Geometries

Exact constraint counting provides a procedure for figuring out if a structure can carry stress, without having to solve the elastic equations for the structure. The procedure is based on determining whether all internal degrees of freedom in the structure are fixed by the constraints. A small activity in this area has been ongoing for many years in the graph theory and topology branches of mathematics. The problem is called the graph rigidity problem and is a subset of the problem of graphic matroids. Laman's theorem in 1970 [43] provides the basis for practical algorithms and states that: A bar-joint graph in the plane is rigid *iff* it has no redundant bonds and $b = 2n - 3$, where b is the number of edges (bars) in the graph and n is the number of nodes. This is basically Maxwell counting (see Eq. (3)) in two dimensions, modified by the key requirement that there be no redundant bonds. Hendrickson [34] provided a practical algorithm which tests if a bond in a graph is redundant. In his algorithm, edges are added to the graph one at a time, and tested to see if they are redundant. If they are redundant, then they are not placed in the structure but are noted and stored elsewhere. In this way an isostatic graph obeying Maxwell counting is generated. A structure with no redundant bonds has the Maxwell counting value, $F = 2n - b - 3$, of floppy modes. The number of redundant bonds are also counted enabling a check of the relation Eq. (7). It is also possible to use this method to find the number of stressed bonds, as when a redundant bond is added to a network, an internally stressed cluster of bonds is generated. By cleverly adding a redundant bond across the whole network, this can also be used to identify the stressed backbone [37,50].

Laman's theorem has been extended to body-bar systems in arbitrary dimensions [75,76]. There is also a conjecture that it is exact for molecular frameworks which is

important in applications to chalcogenide glasses, polymers and proteins [36,83]. Molecular frameworks are systems where central forces and bond-bending terms are strong but torsional terms are neglected. However a key system where no combinatorial characterization is available is the central force rigidity problem in three dimensions where exceptions to Laman's theorem are known to exist, such as the famous double banana configuration of Fig. 11a.

A second issue, of significance to a variety of applications including granular media, is the issue of generic rigidity as compared to non-generic rigidity. The issue is illustrated in Fig. 11 where two examples of systems with two bodies and three bars in two dimensions are compared. In the generic rigidity case of Fig. 11c, the three bars have different lengths and are at different angles. Maxwell counting indicates that this system is rigid as there are three degrees of freedom per body and there are three bars. However the non-generic example in Fig. 11b is not rigid as the three bars are parallel enabling a shear distortion of the two bodies with respect to each other. The three bars, which are the constraints in this system, are not independent and this dependence is due to the particular way in which the bars are arranged. In this non-generic case, it is not sufficient to know only the connectivity of the graph as the particular geometry of the structure plays a key role. Clearly regular lattices and regular packings of granular media are non-generic while random lattices, polydisperse packings and random packings are typically generic. Combinatorial rigidity applies to generic cases so that disorder in some sense makes the generic problem more tractable.

To illustrate Hendrickson's redundant bond testing procedure, we consider percolation on diluted triangular lattices. The procedure applies to both rigidity and connectivity cases and it is useful to compare the way in which bond testing compares in the two cases. In the connectivity

Elastic Percolation Networks, Figure 11

Illustration of two key issues in combinatorial rigidity. **a** The double banana configuration which violates Laman's theorem and illustrates a difficulty in applying combinatorial rigidity to three dimensional central force networks. **b** Non-generic and **c** generic geometric structures. Laman's theorem and its extensions apply only to generic networks. The non-generic case depends on geometry and so a theory depending only on connectivity is insufficient. The probability of finding non-generic configurations in large random structures is negligible so generic rigidity applies

case Hendrickson's algorithm checks for loops. His redundant bond testing procedure is based on bipartite matching which is a well known problem in combinatorial optimization. It is implemented as follows [34,37,50]:

Start with an empty triangular lattice (no bonds) and assign to each node g degrees of freedom.

Then:

1. Randomly add a bond to the lattice.
2. Test whether this bond is redundant with respect to the bonds which are currently in the lattice.
3. If the bond is redundant *do not add it to the lattice*, but instead store its location in a different array.
4. Return to 1.

End

Step 2 is the key one and is implemented by matching constraints (bonds) to degrees of freedom, with the restriction that the number of constraints assigned to each node must be less than or equal to the number of degrees of freedom at a node ($g = 2$). It is natural to represent the assignment of constraints to nodes using arrows as illustrated in Fig. 12. When a new bond is added, we add $G + 1$ bonds to take account of the global translations and rotations of a body. For a triangular lattice a body has three degrees of freedom, so we add four bonds as indicated in the figure. Hendrickson noted that if the $G + 1$ added bonds can be matched to the degrees of freedom in the graph, then the bond is not redundant. However, if the arrows cannot be matched, added edge is *redundant*. Another useful way to think about the matching procedure is to consider associating pebbles with the degrees of freedom of the nodes in a graph. Then these pebbles may be placed on the edges of the graph with the constraint that they may only cover edges which enter the node. The matching of arrows to nodes then corresponds to placing pebbles on edges, with the constraint that pebbles can only sit on adjacent edges. The matching fails if it is not possible to cover all edges with pebbles [38]. A successful and a failed match are illustrated in Fig. 12 for a connectivity ($g = 1$) case and a rigidity ($g = 2$) case. Note that the bond that is being tested carries with it G additional copies which account for global degrees of freedom of a rigid cluster. In the connectivity case $G = 1$, while on central-force bar-joint networks in two dimensions $G = 3$.

When the bond test fails, the algorithm identifies all bonds which are overconstrained or stressed with respect to the redundant bond. This set of bonds is called a *Laman subgraph*. Note that if a redundant bond is already in

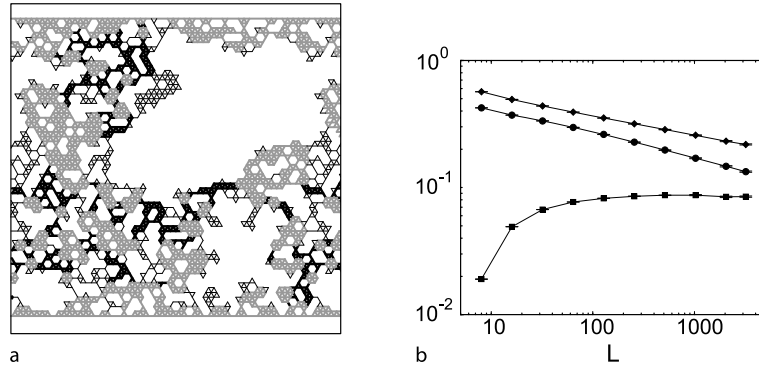

Elastic Percolation Networks, Figure 12

Examples of successful (top figures a and b) and failed (bottom figures, c and d) matches in the connectivity ($g = G = 1$, left figures, a and c) and joint-bar rigidity ($g = 2$, $G = 3$, right figures, b and d) cases on triangular lattices. AB is the new bond that is being tested. Each site has g degrees of freedom and therefore accepts at most g incoming arrows. Each new bond carries with it G auxiliary arrows, which must also be matched. If any of the arrows cannot be matched (dashed), the new bond is redundant. From article by C. Moukarzel and P. M. Duxbury in [79]

a graph, it is not possible to add a new bond and test its redundancy with this method. This is the reason that the algorithm proceeds by adding bonds one at a time starting with an empty lattice. Any error in testing the redundancy of a bond invalidates the rest of the addition sequence. However since this algorithm is an integer method there is no problem with roundoff. It is easy to see that the matching algorithm is quite efficient, however it requires quite a bit of effort to fully optimize these methods. A key step in this optimization procedure is to identify rigid clusters and to describe them in a more condensed way. Moukarzel [50] condenses rigid clusters to a body and hence renormalizes an original bar-joint network to an effective body-joint-bar network. Jacobs [37] instead uses a reduced bar-joint representation of rigid subgraphs. In either case the computational complexity is reduced significantly especially for $p > p_r$.

The geometry of rigidity percolation on a triangular lattice is presented in Fig. 13 [51]. Because of the fact that we add bonds one at a time until the percolation point is reached, it is possible to identify p_c or p_r exactly for

Elastic Percolation Networks, Figure 13

The geometry of rigidity percolation on site diluted triangular lattices. **a** The infinite-cluster geometry at threshold. *Dark wide lines* are cutting bonds, *wide lines* are non-critical backbone bonds (blobs) and *thin lines* are dangling ends. **b** The density of backbone bonds (circles), infinite cluster bonds (diamonds) and dangling bonds (squares) at p_r . A fit to the backbone density yields the exponent $P_B \approx L^{-\beta'/\nu}$, with $\beta' = 0.25(2)$. The dangling ends have not reached the asymptotic regime so it is not clear if the infinite cluster probability has either. Nevertheless, the transition is second order with correlation length exponent $\nu = 1.16(2)$ found from the finite size scaling of the number of cutting bonds and also from the scaling of finite size corrections to p_c [39,51,52], from [51]

each sample, and therefore measure the components of the spanning cluster exactly at p_c or p_r . This eliminates the error associated with measurements at fixed values of p , since estimated exponents are known to depend very sensitively on p . Just as in connectivity percolation, at p_r we identify three different types of bonds: *backbone bonds*, *dangling ends* and *cutting bonds*, as illustrated in Fig. 13a. These together form the *infinite cluster*. The cutting bonds are stressed (belong to the backbone), but they are “critical” because if one of them is removed, load is no longer transmitted across the infinite cluster.

In order to find the correlation length exponent, two relations were used [38,39,51,52]: the size dependence of the threshold behaves as $\delta p_c \sim L^{-1/\nu}$ and secondly, the number of cutting bonds varies as $n_c \sim L^{1/\nu}$, yielding $\nu = 1.16(2)$ [52] or $\nu = 1.20(3)$ [38]. Calculations on the rigidity of rod networks [44] find $\nu = 1.18(2)$. From data such as Fig. 13b the backbone density is found to decrease algebraically $P_B \sim L^{-\beta'/\nu}$, with $\beta' = 0.25 \pm 0.02$ [51,52,54]. It also appears that the infinite-cluster probability is decreasing algebraically, however that is difficult to reconcile with the behavior of the dangling ends which must also eventually decrease for this trend to be asymptotic.

Since it has a diverging correlation length, rigidity percolation on triangular lattices is second order, however first order cases do occur in two dimensions, for example a square network to which diagonals are added at random locations exhibits a strong first order transition, even though the elastic behavior remains continuous [51,56]. Moreover, simulations of central force networks in three

dimensions [15] demonstrate a strong first order transition, as illustrated in Fig. 14.

Elastic Critical Behavior

After a flurry of activity in the 1980’s and early 1990’s study of elastic critical exponents has diminished, nevertheless many issues remain unresolved. The distinction between bond-bending networks and central force networks was brought into sharp focus in the early 1980’s [24], moreover the distinction between the critical exponents describing conductivity and elasticity was emphasized [41]. Many studies were purely energetic, so that thermal effects were ignored. In contrast, de Gennes [17] early argument concerning the equivalence of the conductivity and elasticity exponents of gels relies on entropic springs. The effect of entropic terms has been simulated more recently, supporting the early analysis by de Gennes [60,61].

In two dimensional systems with bond-bending terms or in three dimensional systems with both bond-bending and torsion or dihedral terms (see Eq. (1)), elastic percolation occurs at the conductivity percolation threshold. In the absence of entropic terms, it is well established that in this case the elastic critical behavior, $E \sim (\delta p)^T$ is different than the conductivity critical behavior, $\sigma \sim (\delta p)^t$. E is the Young’s modulus while σ is the conductivity, and $\delta p = p - p_c$ with p_c the conductivity percolation threshold. T is the elastic critical exponent and t is the conductivity critical exponent. A variety of methods have been applied to the calculation of t and T in two and three dimensions, with the currently

Elastic Percolation Networks, Figure 14

The number of floppy modes (*top panel*). The infinite-cluster probability and stressed backbone probability (*bottom panel*) on bond diluted bcc lattices. The transition is strongly first order, though the elastic behavior appears to be continuous, from [15]

accepted values being $t_{2D} = 1.30(1)$, $t_{3D} = 2.01(2)$ and $T_{2D} = 3.96(4)$ [90]. In three dimensional bond-bending networks $T_{3D} \approx 3.75$ [69], and both of these elastic critical exponents are consistent with the relation $T = t + 2\nu$, which is claimed to be exact [8]. Here ν is the percolation critical exponent and $\nu_{2D} = 4/3$ and $\nu_{3D} = 0.88(1)$. It is worth noting that a model where hard inclusions are placed in a soft elastic background has a different behavior. The critical point is the point at which an infinite hard cluster percolates. On approach to this point from below, the elastic constant diverges $E \sim |\Delta p|^{-S}$. The analogous electrical problem consists of perfectly conducting inclusions in a finite conductivity matrix where $\sigma \sim |\Delta p|^{-s}$. In this case Bergman [8] argues that $s = S$. The lattice results quoted above require modification in the case of continuum systems, for example in cases where holes are

punched randomly in a sheet so that narrow necks of material can exist [23]. This case is non-universal in both the conductivity and elasticity cases, though the geometric exponents, such as ν , remain universal.

Elastic percolation on central force networks occurs at different thresholds than conductivity percolation on the same networks. Maxwell counting gives a good first approximation to the elastic percolation thresholds, however precise values can only be found by direct simulation. Direct simulations of central force networks in two and three dimensions have been quite controversial, however the consensus seems to be that the behavior in two dimensions close to criticality is in the bond-bending universality class described in the paragraph above [31]. However central force systems in three dimensions [68] exhibit a different behavior, with $T/\nu \approx 2.1$ for body centered cubic lattices, which is much smaller than the bond bending value $T/\nu \approx 4.4$. Moreover, the geometry of these systems is now known to exhibit a strong first order jump (see Fig. 14) in three dimensions [15].

The elastic behavior of bond-diluted central force systems is remarkably simple away from p_r and is well described by a simple linear relation found using effective medium theory [25]. The critical regime appears to be quite narrow in these central force models. It is also important to note that the results for p_r found from combinatorial methods apply to triangular lattices where the sites are randomly displaced from their regular locations to remove degeneracies. This may be the reason that geometric calculations of p_r on triangular lattices are higher 0.6603 [38] than values found from direct solution of elastic response on regular lattices where $p_r \sim 0.64$ [16]. A further complication is that elastic calculations on displaced lattices lead to a non-linear stiffening of the lattice as bonds which are nearly co-linear are brought into alignment by the applied stress and lead to a stiffening of the network [52].

In geometric models of rigidity, as described above and in Sect. “Exact Solution on Bethe Lattices”, the rigidity percolation threshold, p_r , lies above the connectivity percolation threshold, p_c . However in real materials there is usually a finite elastic modulus even in the regime $p_c < p < p_r$, which may arise through a variety of different effects. In polymers, proteins and chalcogenide glasses, the torsional forces are smaller but significant leading to the onset of elasticity at p_c rather than p_r . Moreover entropic effects may be significant even in ideal central force systems, so that thermal fluctuations lead to a finite elastic modulus for all $p > p_c$. This has been demonstrated in simple central force systems such as diluted square, triangular and cubic lattices [62]. This effect is even more pronounced in crosslinked polymeric systems, such as rubber,

where entropic rubber elasticity dominates [5,17,88]. In these systems the regime $p_c < p < p_r$ is extremely broad so that even heavily crosslinked flexible polymeric systems are in this regime. A further mechanism which leads to a reduction of the percolation threshold from that predicted by geometric rigidity is the presence of tension in the network [74], or if the natural length of the springs in the network is taken to zero. Moreover the elastic critical exponent observed in entropic systems and in systems in tension is usually quite close to the conductivity value, as first predicted by de Gennes in 1976 [5,17,88] and as observed in many experiments on gels (see Sect. “Gels and Semiflexible Rod Networks”).

Final Remarks and Future Directions

The relevance of rigidity percolation to granular media and to semiflexible polymer networks is now well established, though many issues remain unresolved. Ideal experiments to test the recent theoretical predictions will greatly clarify the extent to which current rigidity concepts are sufficient to describe these systems. The intermediate phase in chalcogenide glasses is a stimulating, and physically very natural, concept, that perhaps could be observed in large scale molecular dynamics simulations with realistic potentials of systems such as $Se_{1-x}Ge_x$. Presumably there is a dynamical lengthscale at which self-organization is possible, which limits the extent of the intermediate phase.

Graph combinatorial methods and direct elastic model simulations provide complementary information about the mechanical response of complex materials. The combinatorial methods however remain limited due to the absence of an exact combinatorial characterization of rigid structures in three dimensional central force networks. Moreover, the physical significance of banana configurations, as illustrated in Fig. 11a, remains unexplored and is an intriguing outstanding problem. The common occurrence of a strong first order jump in the infinite rigid cluster along with a continuous elastic behavior [15,51,56] is surprising and also largely unexplored.

Rigidity percolation is emerging as a geometric model for structural glasses [85]. Clearly thermal effects are critical in many applications of rigidity percolation so that models which treat both geometric and thermal effects are valuable. Molecular dynamics models provide insight into the interplay of geometry and temperature and warrant further study. In particular the evolution of the boson peak in model glasses as a function of geometry and temperature remains unexplored and would help resolve

contrasting models which emphasize either temperature effects [58] or geometric effects [85].

The role of generic as compared to non-generic configurations is critical to granular media and to the elasticity of lattices. Even the most basic questions remain unresolved, for example are the elastic exponents of regular lattices the same as the elastic exponents of random lattices with the same co-ordination? Is the elasticity of random generic networks inherently non-linear due to alignment of bonds under stress?

Nevertheless, rigidity percolation provides a useful model for a broad range of physical phenomena, significantly generalizing the connectivity percolation model. Combinatorial methods drawn from graph theory have greatly extended our understanding of rigidity, providing both practical tools as well as conceptual novelties including the distinction between generic and non-generic rigidity. The applications of related geometric methods to granular media and to semiflexible gels is extremely rich and are harbingers of a broader use of rigidity concepts in the analysis of the mechanical behavior of complex materials.

Glossary

Phylogenesis Indicates the variations of the genetic characteristics of a population of artificial agents throughout generations.

Ontogenesis Indicates the variations which occur in the phenotypical characteristics of an artificial agent (i. e. in the characteristics of the control system or of the body of the agent) while it interacts with the environment.

Embodied agent Indicates an artificial system (simulated or physical) which has a body (characterized by physical properties such as shape, dimension, weight, etc), actuators (e. g. motorized wheels, motorized articulated joints), and sensors (e. g. touch sensors or vision sensors). For a more restricted definition see the concluding section of the paper.

Situated agent Indicates an artificial system which is located in a physical environment (simulated or real) with which it interacts on the basis of the law of physics. For a more restricted definition see the concluding section of the paper.

Morphological computation Indicates the ability of the body of an agent (with certain specific characteristics) to control its interaction with the environment so to produce a given desired behavior.

Definition of the Subject

Adaptive behavior concerns the study of how organisms develop their behavioral and cognitive skills through a synthetic methodology which consists in designing artificial agents which are able to adapt to their environment autonomously. These studies are important both from a modeling point of view (i. e. for making progress in our understanding of intelligence and adaptation in natural beings) and from an engineering point of view (i. e. for making progresses in our ability to develop artefacts displaying effective behavioral and cognitive skills).

Introduction

Adaptive behavior research concerns the study of how organisms can develop behavioral and cognitive skills by adapting to the environment and to the task they have to fulfill autonomously (i. e. without human intervention). This goal is achieved through a synthetic methodology, i. e. through the synthesis of artificial creatures which: (i) have a body, (ii) are situated in an environment with which they interact, and (iii) have characteristics which vary during an adaptation process. In the rest of the paper we will use the term “agent” to indicate artificial creatures which possess the first two features described above and the term “adaptive agent” to indicate artificial creatures which also possess the third feature.

The agents and the environment might be simulated or real. In the former case the characteristics of agents’ body, motor, and sensory system, the characteristics of the environment, and the rules that regulate the interactions between all the elements are simulated on a computer. In the latter case, the agents consist of physical entities (mobile robots) situated in a physical environment with which they interact on the basis of the physical laws.

The adaptive process which regulates how the characteristics of the agents (and eventually of the environment change) might consist of a population-based evolutionary process and/or of a developmental/learning process. In the former case, the characteristics of the agents do not vary during their “lifetime” (i. e. during the time in which the agents interact with the environment) but phylogenetically, while individual agents “reproduce”. In the latter case, the characteristics of the agents vary ontogenetically, while they interact with the environment. The criteria which determine how variations are generated and/or

whether or not variations are retained can be task-dependent and/or task-independent, i. e. might be based on an evaluation of whether the variation increase or decrease agents’ ability to display a behavior which is adapted to the task/environment or might be based on task-independent criteria (i. e. general criteria which do not reward directly the exhibition of the requested skill).

The paper is organized as follows. In Sect. “**Introduction**” we briefly introduce the notion of *embodiment* and *situatedness* and their implications. In Sect. “**Embodiment and Situatedness**” we claim that behavior and cognition in embodied and situated adaptive agents should be characterized as a complex adaptive system. In Sect. “**Behavior and Cognition as Complex Adaptive Systems**” we briefly describe the methods which can be used to synthesize embodied and situated adaptive agents. Finally in Sect. “**Adaptive Methods**”, we draw our conclusions.

Embodiment and Situatedness

The notion of *embodiment* and *situatedness* has been introduced [8,9,12,34,48] to characterize systems (e. g. natural organism and robots) which have a physical body and which are situated in a physical environment with which they interact. In this and in the following sections we will briefly discuss the general implications of these two fundamental properties. This analysis will be further extended in the concluding section where we will claim on the necessity to distinguish between a weak and a strong notion of embodiment and situatedness.

One first important implication of being embodied and situated consists in the fact that these agents and their parts are characterized by their physical properties (e. g. weight, dimension, shape, elasticity etc.), are subjected to the laws of physics (e. g. inertia, friction, gravity, energy consumption, deterioration etc.), and interact with the environment through the exchange of energy and physical material (e. g. forces, sound waves, light waves etc.). Their physical nature also implies that they are quantitative in state and time [49]. The fact that these agents are quantitative in time implies, for example, that the joints which connect the parts of a robotic arm can assume any possible position within a given range. The fact that these agents are quantitative in time implies, for example, that the effects of the application of a force to a joint depend from the time duration of its application.

One second important implication is that the information measured by the sensors is not only a function of the environment but also of the relative position of the agent in the environment. This implies that the motor actions performed by an agent, by modifying the

agent/environmental relation or the environment, co-determine the agent sensory experiences.

One third important implication is that the information measured by the sensors provide information about the external environment which is egocentric (depends from the current position and the orientation of the agent in the environment), local (only provide information related to the local observable portion of the environment), incomplete (due to visual occlusion, for example), and subjected to noise. Similar characteristics apply to the motor actions produced by the agent's effectors.

It is important to notice that these characteristics do not only represent constraints but also opportunities to be exploited. Indeed, as we will see in the next section, the exploitation of some of these characteristics might allow embodied and situated agents to solve their adaptive problems through solutions which are robust and parsimonious (i. e. minimal) with respect to the complexity of the agent's body and control system.

Behavior and Cognition as Complex Adaptive Systems

In embodied and situated agents, behavioral and cognitive skills are dynamical properties which unfold in time and which arise from the interaction between agents' nervous system, body, and the environment [3,11,19,29,31] and from the interaction between dynamical processes occurring within the agents' control system, the agents' body, and within the environment [4,15,45]). Moreover, behavioral and cognitive skills typically display a multi-level and multi-scale organization involving bottom-up and top-down influences between entities at different levels of organization. These properties imply that behavioral and cognitive skills in embodied and situated agents can be properly characterized as complex adaptive systems [29].

These aspects and the complex system nature of behavior and cognition will be illustrated in more details in the next subsections also with the help of examples. The theoretical and practical implication of these aspects for developing artificial agents able to exhibit effective behavioral and cognitive skills will be discussed in the forthcoming sections.

Behavior and Cognition as Emergent Dynamical Properties

Behavior and cognition are dynamical properties which unfold in time and which emerge from high-frequency non-linear interactions between the agent, its body, and the external environment [11].

Embodied and Situated Agents, Adaptive Behavior in, Figure 1
A schematic representation of the relation between agent's control system, agent's body, and the environment. The behavioral and cognitive skills displayed by the agent are the emergent result of the bi-directional interactions (represented with *full arrows*) between the three constituting elements – agent's control system, agent's body, and environment. The *dotted arrows* indicate that the three constituting elements might be dynamical systems on their own. In this case, agents' behavioral and cognitive skills result of the dynamics originating from the agent/body/environmental interactions but also from the combination and the interaction between dynamical processes occurring within the agent's body, within the agent's control system, and within the environment (see Sect. "Embodiment and Situatedness")

At any time step, the environmental and the agent/environmental relation co-determine the body and the motor reaction of the agent which, in turn, co-determines how the environment and/or the agent/environmental relation vary. Sequences of these interactions, occurring at a fast time rate, lead to a dynamical process – behavior – which extends over significant larger time span than the interactions (Fig. 1).

Since interactions between the agent's control system, the agent's body, and the external environment are non-linear (i. e. small variations in sensory states might lead to significantly different motor actions) and dynamical (i. e. small variations in the action performed at time t might significantly impact later interactions at time $t+x$) the relation between the rules that govern the interactions and the behavioral and cognitive skills originating from the interactions tend to be very indirect. Behavioral and cogni-

Embodied and Situated Agents, Adaptive Behavior in, Figure 2
A schematization of the passive walking machine developed by McGeer [24]. The machine includes two passive knee joints and a passive hip joint

tive skills thus emerge from the interactions between the three foundational elements and cannot be traced back to any of the three elements taken in isolation. Indeed, the behavior displayed by an embodied and situated agent can hardly be predicted or inferred from an external observer even on the basis of a complete knowledge of the interacting elements and of the rules governing the interactions.

A clear example of how behavioral skill might emerge from the interaction between the agents' body and the environment is constituted by the passive walking machines developed in simulation by McGeer [24] – a two-dimensional bipedal machines able to walk down a four-degree slope with no motors and no control system (Fig. 2). The walking behavior arises from the fact that the physical forces resulting from gravity and from the collision between the machine and the slope produce a movement of the robot and the fact that robot's movements produce a variation of the agent-environmental relation which in turn produce a modification of the physical forces to which the machine will be subjected in the next time step. The sequence of by-directional effects between the robot's body and the environment can lead to a stable dynamical process – the walking behavior.

The type of behavior which arises from the robot/environmental interaction depends from the characteristics of the environment, the physics law which regulate the interaction between the body and the environment, and the characteristics of the body. The first two factors can be considered as fixed but the third factor, the body structure, can be adapted to achieve a given function. Indeed, in the case of this biped robot, the author carefully selected

Embodied and Situated Agents, Adaptive Behavior in, Figure 3
Left: The agent situated in the environment. The agent is a Khepera robot [26]. The environment consists of an arena of 60×35 cm containing cylindrical objects placed in a randomly selected location. *Right:* Angular trajectories of an evolved robot close to a wall (*top graph*) and to a cylinder (*bottom graph*). The picture was obtained by placing the robot at a random position in the environment, leaving it free to move for 500 time steps each lasting 100 ms, and recording its relative movements with respect to the two types of objects for distances smaller than 45 mm. The x-axis and the y-axis indicate the relative angle (in degrees) and distance (in mm) between the robot and the corresponding object. For sake of clarity, *arrows* are used to indicate the relative direction, but not the amplitude of movements

the leg length, the leg mass, and the foot size to obtain the desired walking behavior. In more general term, this example shows how the role of regulating the interaction between the robot and the environment in the appropriate way can be played not only but the control system but also from the body itself providing that the characteristics of the body has been shaped so to favor the exhibition of the desired behavior. This property, i. e. the ability of the body to control its interaction with the environment, has been named with the term “morphological computation” [35]. For related work which demonstrate how effective walking machines can be obtained by integrating passive walking techniques with simple control mechanisms, see [6,13,50]. For related works which show the role of elastic material and elastic actuators for morphological computing see [23,40].

To illustrate of how behavioral and cognitive skills might emerge from agent's body, agent's control system, and environmental interactions we describe a simple experiment in which a small wheeled robot situated in an arena surrounded by walls has been evolved to find and to remain close to a cylindrical object. The Khepera robot [26] is provided with eight infrared sensors and two motors controlling the two corresponding wheels (Fig. 3).

From the point of view of an external observer, solving this problem requires robots able to: (a) explore the environment until an obstacle is detected, (b) discriminate whether the obstacle detected is a wall or a cylindrical ob-

ject, and (c) approach or avoid objects depending on the object type. Some of these behaviors (e. g. the wall-avoidance behavior) can be obtained through simple control mechanisms but others require non trivial control mechanisms. Indeed, a detailed analysis of the sensory patterns experienced by the robot indicated that the task of discriminating the two objects is far from trivial since the two classes of sensory patterns experienced by robots close to a wall and close to cylindrical objects largely overlap.

The attempt to solve this problem through an evolutionary adaptive method (see Sect. “[Behavior and Cognition as Complex Adaptive Systems](#)”) in which the free parameters (i. e. the parameters which regulate the fine-grained interaction between the robot and the environment) are varied randomly and in which variations are retained or discarded on the basis on an evaluation of the overall ability of the robot (i. e. on the basis of the time spent by the robot close to the cylindrical object) demonstrated how adaptive robots can find solutions which are robust and parsimonious in term of control mechanisms [28]. Indeed, in all replications of these experiment, evolved robot solve the problem by moving forward, by avoiding walls, and by oscillating back and fourth and left and right close to cylindrical objects (Fig. 3, right). All these behaviors result from sequences of interactions between the robot and the environment mediated by four types of simple control rules which consist in: turning left when the right infrared sensors are activated, turning right when the left infrared sensors are activated, moving back when the frontal infrared sensors are activated, and moving forward when the frontal infrared sensors are not activated.

To understand how these simple control rules can produce the required behaviors and the required arbitration between behaviors we should consider that the same motor responses produce different effects on different agent/environmental situations. For example, the execution of a left-turning action close to a cylindrical object and the subsequent modification of the robot/object relative position produce a new sensory state which triggers a right-turning action. Then, the execution of the latter action and the subsequent modification of the robot/object relative position produce a new sensory state which triggers a left-turning action. The combination and the alternation of these left and right-turning actions over time produce an attractor in the agent/environmental dynamics (Fig. 3, right, bottom graph) which allows the robot to remain close to the cylindrical object. On the other hand the execution of a left-turning behavior close to a wall object and the subsequent modification of the robot/wall position produce a new sensory state which triggers the reiteration

of the same motor action. The execution of a sequence of left-turning action then leads to the avoidance of the object and to a modification of the robot/environmental relation which finally lead to a perception of a sensory state which trigger a move-forward behavior (Fig. 4, right, top graph).

Before concluding the description of this experiment, it is important to notice that, although the rough classification of the robot motor responses into four different types of actions is useful to describe the strategy with which these robots solve the problem qualitatively, the quantitative aspects which characterize the robot motor reactions (e. g. how sharply a robot turns given a certain pattern of activation of the infrared sensors) are crucial for determining whether the robot will be able to solve the problem or not. Indeed, small differences in the robot’s motor response tend to cumulate in time and might prevent the robot for producing successful behavior (e. g. might prevent the robot to produce a behavioral attractor close to cylindrical objects).

This experiment clearly exemplifies some important aspects which characterize all adaptive behavioral system, i. e. systems which are embodied and situated and which have been designed or adapted so to exploit the properties that emerge from the interaction between their control system, their body, and the external environment. In particular, it demonstrates how required behavioral and cognitive skills (i. e. object categorization skills) might emerge from the fine-grained interaction between the robot’s control system, body, and the external environment without the need of dedicated control mechanisms. Moreover, it demonstrates how the relation between the control rules which mediate the interaction between the robot body and the environment and the behavioral skills exhibited by the agents are rather indirect. This means, for example, that an external human observer can hardly predict the behaviors which will be produced by the robot, before observing the robot interacting with the environment, even on the basis of a complete description of the characteristics of the body, of the control rules, and of the environment.

Behavior and Cognition as Phenomena Originating from the Interaction Between Coupled Dynamical Processes

Up to this point we restricted our analysis to the dynamics originating from the agent’s control system, agents’ body, and environmental interactions. However, the body of an agent, its control system, and the environment might have their own dynamics (dotted arrows in Fig. 1). For the sake of clarity, we will refer to the dynami-

Embodied and Situated Agents, Adaptive Behavior in, Figure 4

Left: The e-puck robot developed at EPFL, Switzerland <http://www.e-puck.org/>. **Center:** The environment which have a size of 52 cm by 60 cm. The light produced by the light bulb located on the *left side* of the central corridor cannot be perceived from the other two corridors. **Right:** The motor trajectory produced by the robot during a complete lap of the environment

cal processes occurring within the agent control system, within the agent body, or within the environment as *internal dynamics* and to the dynamics originating from the agent/body/environmental interaction as *external dynamics*. In cases in which agents' body, agents' control system, or the environment have their own dynamics, behavior should be characterized as a property emerging from the combination of several coupled dynamical processes.

The existence of several concurrent dynamical processes represents an important opportunity for the possibility to exploit emergent features. Indeed, behavioral and cognitive skills might emerge not only from the external dynamics, as we showed in the previous section, but also from the internal dynamical processes or from the interaction between different dynamical processes.

As an example which illustrates how complex cognitive skills can emerge from the interaction between a simple agent/body/environmental dynamic and a simple agent's internal dynamic consider the case of a wheeled robot placed in a maze environment (Fig. 4) which has been trained to: (a) produce a wall-following behavior which allows the robot to periodically visit and re-visit all environmental areas, (b) identify a target object constituted by a black disk which is placed in a randomly selected position of the environment for a limited time duration, and (c) recognize the location in which the target object was previously found every time the robot re-visit the corresponding location [15].

The robot has infrared sensors (which provide information about nearby obstacles), light sensors (which provide information about the light gradient generated by the light bulb placed in the central corridor), ground sensors (which detect the color of the ground), two motors

(which control the desired speed of the two corresponding wheels), and one additional output units which should be turned on when the robot re-visit the environmental area in which the black disk was previously found. The robot's controller consists of a three layers neural network which includes a layer of sensory neurons (which encode the state of the corresponding sensors), a layer of motor neurons which encode the state of the actuators, and a layer of internal neurons which consist of leaky integrators operating at tuneable time scale [3,15]. The free parameters of the robot's neural controllers (i. e. the connection weights, and the time constant of the internal neurons which regulate the time rate at which this neurons change their state over time) were adapted through an evolutionary technique [31].

By analyzing the evolved robot the authors observed how they are able to generate a spatial representation of the environment and of their location in the environment while they are situated in the environment itself. Indeed, while the robot travel by performing different laps of the environment (see Fig. 4, right), the states of the two internal neurons converge on a periodic limit cycle dynamic in which different states correspond to different locations of the robot in the environment (Fig. 5).

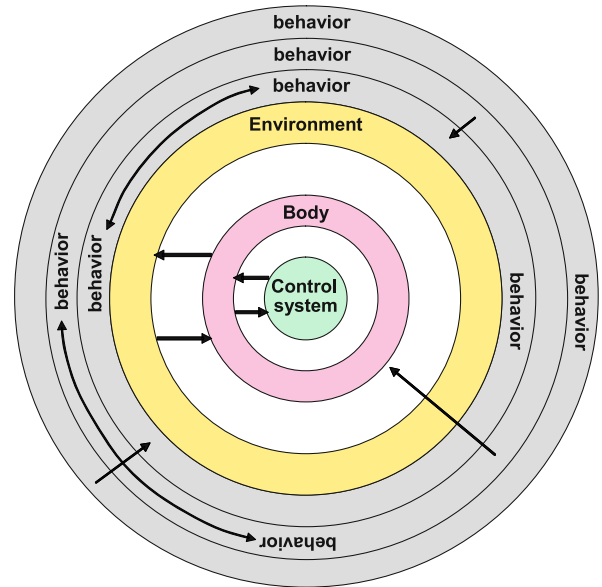

As we mentioned above, the ability to generate this form of representation which allow the robot to solve its adaptive problem originate from the coupling between a simple robot's internal dynamics and a simple robot/body/environmental dynamics. The former dynamics is characterized by the fact that the state of the two internal neurons tends to move slowly toward different fixed point attractors, in the robot's internal dynamics, which correspond to different type of sensory states exemplified in Fig. 5. The latter dynamics originate from the

Embodied and Situated Agents, Adaptive Behavior in, Figure 5
The state of the two internal neurons (i_1 and i_2) of the robot recorded for 330 s while the robot performs about 5 laps of the environment. The s , a , b , c , and d labels indicate the internal states corresponding to five different positions of the robot in the environment shown in Fig. 4. The other labels indicate the position of the fixed point attractors in the robot's internal dynamics corresponding to five types of sensory states experienced by the robot when it detects: a light in its frontal side (LF), a light on its rear side (LR), an obstacle on its right and frontal side (OFR), an obstacle on its right side (OR), no obstacles and no lights (NO)

fact that different types of sensory states last for different time durations and alternate with a given order while the robot move in the environment. The interaction between these two dynamical processes leads to a transient dynamics of agents' internal state which moves slowly toward the current fixed point attractor without never fully reaching it (thus preserving information about previously experienced sensory states, the time duration of these states, and the order with which they have been experienced). The coupling between the two dynamical processes originates from the fact that the free parameters which regulate the agent/environmental dynamics (e. g. the trajectory and the speed with which the robot moves in the environment) and the agent internal dynamics (e. g. the direction and the speed with which the internal neurons change their state) have been co-adapted and co-shaped during the adaptive process.

For related works which show how navigation and localization skills might emerge from the coupling between agent's internal and external dynamics, see [45]. For other works addressing other behavioral/cognitive capabilities see [4] for what concerns categorization, [16,41] for what concerns selective attention and [44] for what concern language and compositionality.

Embodied and Situated Agents, Adaptive Behavior in, Figure 6
A schematic representation of multi-level and multi-scale organization of behavior. The behaviors represented in the *inner circles* represent elementary behaviors which arise from fine-grained interactions between the control system, the body, and the environment, and which extend over limited time spans. The behaviors represented in the *external circles* represent higher level behaviors which arise from the combination and interaction between lower-level behaviors and which extend over longer time spans. The *arrows* which go from higher level behavior toward lower levels indicate the fact that the behaviors currently exhibited by the agents later affect the lower level behaviors and/or the fine-grained interaction between the constituting elements (agent's control system, agent's body, and the environment)

Behavior and Cognition as Phenomena with a Multi-Level and Multi-Scale Organization

Another fundamental feature that characterizes behavior is the fact that it is a multi-layer system with different levels of organizations extending at different time scales [2,19]. More precisely, as exemplified in Fig. 6, the behavior of an agent or of a group of agents involve both lower and higher level behaviors which extend for shorter or longer time spans, respectively. Lower level behaviors arise from few agent/environmental interactions and short term internal dynamical processes. Higher level behaviors, instead, arise from the combination and interaction of lower level behaviors and/or from long term internal dynamical processes.

The multi-level and multi-scale organization of agents' behavior play important roles: it is one of the factors which allow agents to produce functionally useful be-

Embodied and Situated Agents, Adaptive Behavior in, Figure 7

Left: Four robots assembled into a linear structure. **Right:** A simulation of the robots shown in the left part of the figure

havior without necessarily developing dedicated control mechanisms [8,9,29], it might favor the development of new behavioral and/or cognitive skills thanks to the recruitment of pre-existing capabilities [22], it allow agents to generalize their skills in new task/environmental conditions [29].

An exemplification of how the multi-level and multi-scale organization of behavior allow agents to generalize their skill in new environmental conditions is represented by the experiments carried out by Baldassarre et al. [2] in which the authors evolved the control system of a group of robots assembled into a linear structure (Fig. 7) for the ability to move in a coordinated manner and for the ability to display a coordinated light approaching behavior.

Each robot [27] consists of a mobile base (chassis) and a main body (turret) that can rotate with respect to the chassis along the vertical axis. The chassis has two drive mechanisms that control the two corresponding tracks and teathed wheels. The turret has one gripper, which allows robots to assemble together and to grasp objects, and a motor controlling the rotation of the turret with respect to the chassis. Robots are provided with a traction sensor, placed at the turret-chassis junction, that detects the intensity and the direction of the force that the turret exerts on the chassis (along the plane orthogonal to the vertical axis) and light sensors. Given that the orientations of individual robots might vary and given that the target light might be out of sight, robots need to coordinate to choose a common direction of movement and to change their direction as soon as one or few robots start to detect a light gradient.

Evolved individuals show the ability to negotiate a common direction of movement and by approaching light targets as soon as a light gradient is detected. By testing evolved robots in different conditions the authors observed that they are able to generalize their skills in new

conditions and also to spontaneously produce new behaviors which have not been rewarded during the evolutionary process. More precisely, groups of assembled robots display a capacity to generalize their skills with respect to the number of robots which are assembled together and to the shape formed by the assembled robots. Moreover, when the evolved controllers are embodied in eight robots assembled so to form a circular structure and situated in the maze environment shown in Fig. 8, the robots display an ability to collectively avoid obstacles, to rearrange their shape so to pass through narrow passages, and to explore the environment. The ability to display all these behavioral skills allow the robots to reach the light target even in large maze environments, i. e. even in environmental conditions which are rather different from the conditions that they experienced during the training process (Fig. 8).

By analyzing the behavior displayed by the evolved robots tested in the maze environment, a complex multi-level organization can be observed. The simpler behaviors that can be identified consist of low level individual behaviors which extend over short time spans:

1. A *move-forward behavior* which consists of the individuals' ability to move forward when the robot is coordinated with the rest of the team, is oriented toward the direction of the light gradient (if any), and does not collide with obstacles. This behavior results from the combination of: (a) a control rule which produces a move forward action when the perceived traction has a low intensity and when difference between the intensity of the light perceived on the left and the right side of the robot is low, and (b) the sensory effects of the execution of the move forward action selected mediated by the external environment which does not produce a variation of the state of the sensors until the conditions that should be satisfied to produce this behaviors hold.

Embodied and Situated Agents, Adaptive Behavior in, Figure 8
The behavior produced by eight robots assembled into a circular structure in a maze environment including walls and cylindrical objects (represented with gray lines and circles). The robots start in the central portion of the maze and reach the light target located in the bottom-left side of the environment (represented with an empty circle) by exhibiting a combination of coordinated-movement behaviors, collective obstacle-avoidance, and collective light-approaching behaviors. The irregular lines, that represent the trajectories of the individual robots, show how the shape of the assembled robots changes during motion by adapting to the local structure of the environment

2. A *conformistic behavior* which consists of the individuals' ability to conform its orientation with that of the rest of the team when the two orientations differ significantly. This behavior results from the combination of: (a) a control rule that makes the robot turns toward the direction of the traction when its intensity is significant, and (b) the sensory effects produced by the execution of this action mediated by the external environment that lead to a progressive reduction of the intensity of the traction until the orientation of the robot conform with the orientation of the rest of the group.
3. A *phototaxis behavior* which consists of the individuals' ability to orient toward the direction of the light target. This behavior results from the combination of: (a) a control rule that makes the robot turns toward the direction in which the intensity of the light gradient is higher, and (b) the sensory effects produced by the execution of this action mediated by the external environment that lead to a progressive reduction of the difference in the light intensity detected on the two side of the

robot until the orientation of the robot conforms with the direction of the light gradient.

4. An *obstacle-avoidance behavior* which consists of the individuals' ability to change direction of motion when the execution of a motor action produced a collision with an obstacle. This behavior results from the combination of: (a) the same control rule which lead to behavior #2 which make the robot turns toward the direction of the perceived traction (which in this case is caused by the collision with the obstacle while in the case of behavior #2 is caused by the forces exerted by the other assembled robots), and (b) the sensory effects produced by the execution of the turning action mediated by the external environment which make the robot turns until collisions do not prevent anymore the execution of a moving forward behavior.

The combination and the interaction between these three behaviors produce the following higher levels collective behaviors that extend over a longer time span:

5. A *coordinated-motion behavior* which consists in the ability of the robots to negotiate a common direction of movement and to keep moving along such direction by compensating further misalignments originating during motion. This behavior emerges from the combination and the interaction of the conformistic behavior (which plays the main role when robots are misaligned) and the move-forward behavior (which plays the main role when robots are aligned).
6. A *coordinated-light-approaching behavior* which consists in the ability of the robots to co-ordinately move toward a light target. This behavior emerges from the combination of the conformistic, the move-forward, and the phototaxis behaviors (which is triggered when the robots detect a light gradient). The relative importance of the three control rules which lead to the three corresponding behaviors depends both on the strength of the corresponding triggering condition (i. e. the extent of lack of traction forces, the intensity of traction forces, and the intensity of the light gradient, respectively) and on a priority relations among behaviors (i. e. the fact that the conformistic behavior tends to play a stronger role than the phototaxis behavior).
7. A *coordinated-obstacle-avoidance behavior* which consists in the ability of the robots to co-ordinately turn to avoid nearby obstacles. This behavior arises as the result of the combination of the obstacle avoidance-, the conformistic and the move-forward behaviors.

The combination and the interaction between these behaviors lead to the following higher levels collective behaviors that extend over still longer time spans:

8. A *collective-exploration-behavior* which consists in the ability of the robots to visit different area on the environment when the light target cannot be detected. This behavior emerges from the combination of the coordinated-motion behavior and the coordinate obstacle-avoidance behavior which ensures that the assembled robots can move in the environment without getting stuck and without entering into limit cycle trajectories.
9. A *shape-re-arrangement behavior* which consists in the ability of the assembled robots to dynamically adapt their shape to the current structure of the environment so to pass through narrow passages especially when the passages to be negotiated are in the direction of the light gradient. This behavior emerges from the combination and the interaction between coordinated motion and coordinated-light-approaching behaviors mediated by the effects produced by relative differences in motion between robots resulting from the execution of different motor actions and/or from differences in the collisions. The fact that the shape of the assembled robots adapt to the current environmental structure so to facilitate the overcoming of narrow passages can be explained by considering that collisions produce a modification of the shape which affect on particular the relative position of the colliding robots.

The combination and the interaction of all these behavior leads to a still higher level behavior:

10. A *collective-navigation-behavior* which consists in the ability of the assembled robots to navigate toward the light target by producing coordinated movements, exploring the environment, passing through narrow passages, and producing a coordinated-light-approaching behavior (Fig. 8).

This analysis illustrates two important mechanisms which explain the remarkable generalization abilities of these robots. The first mechanism consists in the fact that the control rules which regulate the interaction between the agents' and the environment so to produce certain behavioral skills in certain environmental conditions will produce different but related behavioral skills in other environmental conditions. In particular, the control rules which generate the behaviors #5 and #6 for which evolving robots have been evolved in an environment without obstacles also produce behavior #7 in an environment with obstacles. The second mechanism consists in the fact that the development of certain behaviors at a given level of organization which extend for a given time span will automatically lead to the exhibition of related higher-level

behaviors extending at longer time spans which originate from the interactions from the former behaviors (even if these higher level behaviors have not being rewarded during the adaptation process). In particular, the combination and the interaction of behaviors #5, #6, and #7 (which have been rewarded during the evolutionary process or which arise from the same control rules which lead to the generation of rewarded behaviors) automatically lead to the production of behaviors #8, #9, and #10 (which have not been rewarded). Obviously, there no warranty that the new behaviors obtained as a result of these generalization processes will play useful functions. However, the fact that these behaviors are related to the other functional behavioral skills implies that the probabilities that these new behavior will play useful functions is significant.

In principle, these generalization mechanisms can also be exploited by agents during their adaptive process to generate behavioral skills which play new functionalities and which emerge from the combination and the interaction between pre-existing behavioral skills playing different functions.

On the Top-Down Effect from Higher to Lower Levels of Organization

In the previous sections we have discussed how the interactions between the agents' body, the agents' control system, and the environment lead to behavioral and cognitive skills and how such skills have a multi-level and multi-scale organization in which the interaction between lower-level skills lead to the emergence of higher-level skills. However, higher level skills also affect lower level skills up to the fine-grained interaction between the constituting elements (agents' body, agents' control system, and environment). More precisely, the behaviors which originate from the interaction between the agent and the environment and from the interaction between lower levels behaviors, later affect the lower levels behaviors and the interaction from which they originate. These bi-directional influences between different levels of organization can lead to circular causality [20] where high level processes act as independent entities which constraint the lower level processes from which they originate.

One of the most important effects of this top-down influences consists in the fact that the behavior exhibited by an agent constraint the type of sensory patterns that the agent will experience later on (i. e. constraint the fine-grained agent/environmental interactions which determine the behavior that will be later exhibited by the agent). Since the complexity of the problem faced by an

agent depends on the sensory information experienced by the agent itself, this top down influences can be exploited in order to turn hard problems into simple ones.

One neat demonstration of this type of phenomena is given by the experiments conducted by Marocco and Nolfi [32] in which a simulated finger robot with six degree of freedom provided with sensors of its joint positions and with rough touch sensors is asked to discriminate between cubic and spherical objects varying in size. The problem is not trivial since, in general terms, the sensory patterns experienced by the robot do not provide clear regularities for discriminating between the two types of objects. However, the type of sensory states which are experienced by the agent also depend on the behavior previously exhibited by the agent itself – agents exhibiting different behavior might face simpler or harder problems. By evolving the robots in simulation for the ability to solve this problem and by analyzing the complexity of the problem faced by robots of successive generations, the authors observed that the evolved robot manage to solve their adaptive problem on the basis of simple control rules which allow the robot to approach the object and to move following the surface of the object from left to right, independently from the object shape. The exhibition of this behavior in interaction with objects characterized by a smooth or irregular surface (in the case of spherical or cubic objects, respectively) ensures that the same control rules lead to two types of behaviors depending on the type of the object. These behaviors consist in following the surface of the object and then moving away from the object in the case of spherical objects, and in following the surface of the object by getting stuck in a corner in the case of cubic objects. The exhibition of these two behaviors allows the agent to experience rather different proprioceptors states as a consequence of having had interacted with spherical or cubic object which nicely encode the regularities which are necessary to differentiate the two types of objects.

For other examples which shows how adaptive agents can exploit the fact that behavioral and cognitive processes which arise from the interaction between lower-level behaviors or between the constituting elements later affect these lower level processes see [4,28,39].

Adaptive Methods

In this section we briefly review the methods through which artificial embodied and situated agents can develop their skill autonomously while they interact at different levels of organization with the environment and eventually with other agents. These methods are inspired by the adap-

tive process observed in nature: evolution, maturation, development, and learning.

We will focus in particular on self-organized adaptive methodologies in which the role of the experimenter/designer is reduced to the minimum and in which the agents are free to develop their strategy to solve their adaptive problems within a large number of potentially alternative solutions. This choice is motivated by the following considerations:

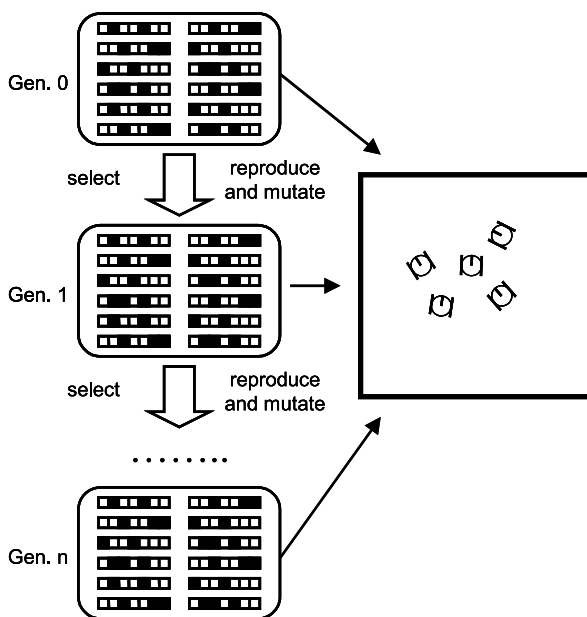

- (a) These methods allow agents to identify the behavioral and cognitive skills which should be possessed, combined, and integrated so to solve the given problem. In other words, these methods can come up with effective ways of decomposing the overall required skill into a collection of simpler lower levels skills. Indeed, as we showed in the previous section, evolutionary adaptive techniques can discover ways of decomposing the high-level requested skill into lower-levels behavioral and cognitive skills so find solutions which are effective and parsimonious thanks to the exploitation of properties emerging from the interaction between lower-levels processes and skills and thanks to the recruitment of previously developed skills for performing new functions. In other words, these methods release the designer from the burden of deciding how the overall skill should be divided into a set of simpler skills and how these skills should be integrated. More importantly, these methods can come up with solutions exploiting emergent properties which would be hard to design [17,31].
- (b) These methods allow agents to identify how a given behavioral and cognitive skill can be produced, i.e. the appropriate fine-grained characteristics of agents' body structure and control rules regulating the agent/environmental interaction. As for the previous aspect, the advantage of using adaptive techniques lies not only in the fact that the experimenter is released from the burden of designing the fine-grained characteristics of the agents but also in the fact that adaptation might prove more effective than human design due to the inability of an external observer to foresee the effects of large number of non-linear interactions occurring at different levels of organization.
- (c) These methods allow agents to adapt to variations of the task, of the environment, and of the social conditions.

Current approaches, in this respect, can be grouped into two families which will be illustrated in the following subsections and which include Evolutionary Robotics methods and Developmental Robotics methods.

Evolutionary Robotics Methods

Evolutionary Robotics [14,31] is a method which allow to create embodied and situated agents able to adapt to their task/environment autonomously through an adaptive process inspired by natural evolution [18] and, eventually, through the combination of evolutionary, developmental, and learning processes.

The basic idea goes as follows (Fig. 9). An initial population of different artificial genotypes, each encoding the control system (and possibly the morphology) of an agent, is randomly created. Each genotype is translated into a corresponding phenotype (i. e. a corresponding agent) which is then left free to act (move, look around, manipulate the environment etc.) while its performance (fitness) with respect to a given task is automatically evaluated. In cases in which this methodology is applied to collective behaviors, agents are evaluated in groups which might be heterogeneous or homogeneous (i. e. might consist of agents which differ not with respect to their genetic and phenotypic characteristics). The fittest individuals (those having higher fitness) are allowed to reproduce by generating copies of their genotype with the addition of

Embodied and Situated Agents, Adaptive Behavior in, Figure 9 A schematic representation of the evolutionary process. The stripes with black and white squares represent individual genotypes. The rectangular boxes indicate the genome of a population of a certain generation. The small robots placed inside the square on the right part of the figure represent a group of robots situated in an environment which interact with the environment and between themselves

changes introduced by some genetic operators (e. g., mutations, exchange of genetic material). This process is repeated for a number of generations until an individual or a group of individuals is born which satisfies the performance level set by the user.

The process that determines how a genotype (i. e. typically a string of binary values) is turned into a corresponding phenotype (i. e. a robot with a given morphology and control system) might consist of a simple one-to-one mapping or of a complex developmental process. In the former case, many of the characteristics of the phenotypical individual (e. g. the shape of the body, the number and position of the sensors and of the actuators, and in some case the architecture of the neural controller) are pre-determined and fixed and the genotype encodes a vector of free parameters (e. g. the connection weights of the neural controller [31]). In the latter case, the genotype might encode a set of rules that determine how the body structure and the control system of the individual growth during an artificial developmental processes. Through these type of indirect developmental mappings most of the characteristics of the phenotypical robot can be encoded in the genotype and subjected to the evolutionary adaptive process [31,36]. Finally, in some cases the adaptation process might involve both an evolutionary process that regulates how the characteristics of the robots vary phylogenetically (i. e. throughout generations) and a developmental/learning process which regulates how the characteristics of the robots vary ontogenetically (i. e. during the phase in which the robots act in the environment [30]).

Evolutionary methods can be used to allow agents to develop the requested behavioral and cognitive skills from scratch (i. e. starting from agents which do not have any behavioral or cognitive capability) or in an incremental manner (i. e. starting from pre-evolved robots which already have some behavioral capability which consists, for example, in the ability to solve a simplified version of the adaptive problem).

The fitness function which determines whether an individual will be reproduced or not might also include, in the addition to a component that score the performance of the agent with respect to a given task, additional task-independent components. These additional components, in fact, can lead to the development of behavioral skills which are not necessarily functional but which can favor the development of functional skills later on [37].

Evolutionary methods can allow agents to develop low-levels behavioral and cognitive skills which have been previously identified by the designer/experimenter, which might later be combined and integrated in order to realize the high-level requested skill, or directly to develop the

high-level requested skill. In the former case the adaptive process leads to the identification of the fine-grained features of the agent (e. g. number and type of sensors, body shape, architecture and connection weights of the neural controller) which by interacting between themselves and with the environment will produce the required skill. In the latter case, the adaptive process leads to the identification of the lower-levels skills (at different levels of organization) which are necessary to produce the required high-level skill, the identification of the way in which these lower levels skills should be combined and integrated, and (as for the former case) the identification of the fine grained features of the agent which, in interaction with the physical and social environment, will produce the required behavioral or cognitive skills.

Developmental Robotics Methods

Developmental Robotics [1,10,21], also known as *epigenetic robotics*, is a method for developing embodied and situated agents that adapt to their task/environment autonomously through processes inspired by biological developmental and learning processes.

Evolutionary and developmental robotics methods share the same fundamental assumptions but also present differences for what concerns the way in which they are realized and the type of situations in which they are typically applied. For what concerns the former aspect, unlike evolutionary robotics methods which operate on 'long' phylogenetic time scales, developmental methods typically operate on 'short' ontogenetic time scales. For what concerns the latter aspects, unlike evolutionary methods which are usually used to develop behavioral and cognitive skills from scratch, developmental methods are typically adopted to model the development of complex developmental and cognitive skills from simpler pre-existing skills which represents pre-requisites for the development of the required skills.

At the present stage, developmental robotics does not consist of a well defined methodology [1,21] but rather of a collection of approaches and methods often addressing complementary aspects which hopefully would be integrated in a single methodology in the future. Below briefly summarize some of the most important methodological aspects of the developmental robotics approach.

The Incremental Nature of the Developmental Process

Development should be characterized as an incremental process in which pre-existing structures and behavioral skills constitute important prerequisites and constraints for the development of more complex structures and be-

havioral skills and in which the complexity of the internal and external characteristics increases during developmental. One crucial aspect of developmental approach therefore consists in the identification of the initial characteristics and skills which should enable the bootstrapping of the developmental process: the layering of new skills on top of existing ones [10,25,38]. Another important aspect consists in shaping the developmental process so to ensure that the progressive increase in the complexity of the task matches the current competency of the system and so to drive the developmental process toward the progressive acquisition of the skills which represent the prerequisites for further developments. The progressive increase in complexity might concern not only the complexity of the task or of the required skills but also the complexity of single components of the robot/environmental interaction such as, for example, the number of freeze/unfreeze degrees of freedom [5].

The Social Nature of the Developmental Process

Development should involve social interaction with human subjects and with other developing robots. Social interactions (e. g. scaffolding, tutelage, mimicry, emulation, and imitation), in fact, play an important role not only for the development of social skills [7] but also as facilitators for the development of individual cognitive and behavioral skills [47]. Moreover, other types of social interactions (i. e. alignment processes or social games) might lead to the development of cognitive and/or behavioral skills which are generated by a collection of individuals and which could not be developed by a single individual robot [43].

Exploitation of the Interaction Between Concurrent Developmental Processes

Development should involve the exploitation of properties originating from the interaction and the integration of several co-occurring processes. Indeed, the co-development of different skills at the same time can favor the acquisition of the corresponding skills and of additional abilities arising from the combination and the integration of the developed skills. For example, the development of an ability to anticipate the sensory consequences of our own actions might facilitate the concurrent development of other skills such as categorical perception skills [46]. The development of an ability to pay attention to new situations (curiosity) and to look for new experiences after some time (boredom) might improve the learning of a given functional skill [33,42]. The co-development of behavioral and linguistic skills might favor the acquisition of the corresponding skills and the development of semantic combinatoriality skills Sugita and Tani [44].

Discussion and Conclusion

In this paper we described how artificial agents which are embodied and situated can develop behavioral and cognitive skills autonomously while they interact with their physical and social environment.

After having introduced the notion of embodiment and situatedness, we illustrated how the behavioral and cognitive skills displayed by adaptive agents can be properly characterized as complex system with multi-level and multi-scale properties resulting from a large number of interaction at different levels of organization and involving both bottom-up processes (in which the interaction between elements at lower levels of organization lead to higher levels properties) and top-down processes (in which properties at a certain level of organization later affect lower level properties or processes).

Finally, we briefly introduced the methods which can be used to synthesize adaptive embodied and situated agents.

The complex system nature of adaptive agents which are embodied and situated has important implications which constraint the organization of these systems and the dynamics of the adaptive process through which they develop their skills.

For what concerns the organization of these systems, it implies that agents' behavioral and/or cognitive skills (at any stage of the adaptive process) cannot be traced back to anyone of the three foundational elements (i. e. the body of the agents, the control system of the agents, and the environment) in isolation but should rather be characterized as properties which emerge from the interactions between these three elements and the interaction between behavioral and cognitive properties emerging from the former interactions at different levels of organizations. Moreover, it implies that 'complex' behavioral or cognitive skills might emerge from the interaction between simple properties or processes.

For what concerns agents' adaptive process, it implies that the development of new 'complex' skills does not necessarily require the development of new 'complex' morphological features or new 'complex' control mechanisms. Indeed, new 'complex' skills might arise from the addition of new 'simple' features or new 'simple' control rules which, in interaction with the pre-existing features and processes, might produce the required new behavioral or cognitive skills.

The study of adaptive behavior in artificial agents which has been reviewed in this paper has important implication both from an engineering point of view (i. e. for progressing in our ability to develop effective machines)

and from a modeling point of view (i. e. for understanding the characteristics of biological organisms).

In particular, from an engineering point of view, progresses in our ability to develop adaptive embodied and situated agents can lead to development of machines playing useful functionalities.

From a modeling point of view, progresses in our ability to model and analyze artificial adaptive agents can improve our understanding of the general mechanisms behind animal and human intelligence. For example, the comprehension of the complex system nature of behavioral and cognitive skills illustrated in this paper can allow us to better define the notion of embodiment and situatedness which represent two foundational concepts in the study of natural and artificial intelligence. Indeed, although possessing a body and being in a physical environment certainly represent a pre-requisite for considering an agent embodied and situated, a more useful definition of embodiment (or of truly embodiment) can be given in term of the extent to which a given agent exploits its body characteristics to solve its adaptive problem (i. e. the extent to which its body structure is adapted to the problem to be solved, or in other words, the extent to which its body performs morphological computation). Similarly, a more useful definition of situatedness (or truly situatedness) can be given in terms of the extent to which an agent exploits its interaction with the physical and social environment and the properties originating from this interaction to solve its adaptive problem. For sake of clarity we can refer to the former definition of the terms (i. e. possessing a physical body and being situated in a physical environment) as embodiment and situatedness as weak sense, and to the latter definition as embodiment and situatedness in a strong sense.

Glossary

Absolute temperature Denoted T .

Clausius entropy Also called *thermodynamic entropy*. Denoted S .

Boltzmann–Gibbs entropy Basis of Boltzmann–Gibbs statistical mechanics. This entropy, denoted S_{BG} , is *additive*. Indeed, for two probabilistically independent subsystems A and B , it satisfies $S_{BG}(A+B) = S_{BG}(A) + S_{BG}(B)$.

Nonadditive entropy It usually refers to the basis of nonextensive statistical mechanics. This entropy, denoted S_q , is *nonadditive* for $q \neq 1$. Indeed, for two probabilistically independent subsystems A and B , it satisfies $S_q(A+B) \neq S_q(A) + S_q(B)$ ($q \neq 1$). For historical reasons, it is frequently (but inadequately) referred to as *nonextensive entropy*.

q -logarithmic and q -exponential functions Denoted $\ln_q x$ ($\ln_1 x = \ln x$), and e_q^x ($e_1^x = e^x$), respectively.

Extensive system So called for historical reasons. A more appropriate name would be *additive system*. It is a system which, in one way or another, relies on or is connected to the (additive) Boltzmann–Gibbs entropy. Its basic dynamical and/or structural quantities are expected to be of the exponential form. In the sense of complexity, it may be considered a *simple system*.

Nonextensive system So called for historical reasons. A more appropriate name would be *nonadditive system*. It is a system which, in one way or another, relies on or is connected to a (nonadditive) entropy such as S_q ($q \neq 1$). Its basic dynamical and/or structural quantities are expected to asymptotically be of the power-law form. In the sense of complexity, it may be considered a *complex system*.

Definition of the Subject

Thermodynamics and statistical mechanics are among the most important formalisms in contemporary physics. They have overwhelming and intertwined applications in science and technology. They essentially rely on two basic concepts, namely *energy* and *entropy*. The mathematical expression that is used for the first one is well known to be *nonuniversal*; indeed, it depends on whether we are say in classical, quantum, or relativistic regimes. The second concept, and very specifically its connection with the microscopic world, has been considered during well over one century as essentially unique and *universal* as a physical concept. Although some mathematical generalizations of the entropy have been proposed during the last forty years, they have frequently been considered as mere practical expressions for disciplines such as cybernetics and control theory, with no particular physical interpretation. What we have witnessed during the last two decades is the growth, among physicists, of the belief that it is not necessarily so. In other words, the physical entropy would basically rely on the microscopic dynamical and structural properties of the system under study. For example, for systems microscopically evolving with strongly chaotic dynamics, the connection between the thermodynamical entropy and the thermostistical entropy would be the one

found in standard textbooks. But, for more complex systems (e. g., for weakly chaotic dynamics), it becomes either necessary, or convenient, or both, to extend the traditional connection. The present article presents the ubiquitous concept of entropy, useful even for systems for which no energy can be defined at all, within a standpoint reflecting a *nonuniversal* conception for the connection between the thermodynamic and the thermostistical entropies. Consequently, both the standard entropy and its recent generalizations, as well as the corresponding statistical mechanics, are here presented on equal footing.

Introduction

The concept of *entropy* (from the Greek $\epsilon\nu\ \tau\rho\epsilon\pi\omega$, *en trepo*, at turn, at transformation) was first introduced in 1865 by the German physicist and mathematician Rudolf Julius Emanuel Clausius, Rudolf Julius Emanuel in order to mathematically complete the formalism of classical thermodynamics [55], one of the most important theoretical achievements of contemporary physics. The term was so coined to make a parallel to *energy* (from the Greek $\epsilon\nu\epsilon\rho\gamma\omicron\varsigma$, *energos*, at work), the other fundamental concept of thermodynamics. Clausius connection was given by

$$dS = \frac{\delta Q}{T}, \quad (1)$$

where δQ denotes an infinitesimal transfer of heat. In other words, $1/T$ acts as an integrating factor for δQ . In fact, it was only in 1909 that thermodynamics was finally given, by the Greek mathematician Constantin Caratheodory, a logically consistent axiomatic formulation.

In 1872, some years after Clausius proposal, the Austrian physicist Ludwig Eduard Boltzmann introduced a quantity, that he noted H , which was defined in terms of microscopic quantities:

$$H \equiv \iiint f(\mathbf{v}) \ln[f(\mathbf{v})] \, d\mathbf{v}, \quad (2)$$

where $f(\mathbf{v})d\mathbf{v}$ is the number of molecules in the velocity space interval $d\mathbf{v}$. Using Newtonian mechanics, Boltzmann showed that, under some intuitive assumptions (*Stoßzahlansatz* or *molecular chaos hypothesis*) regarding the nature of molecular collisions, H does not increase with time. Five years later, in 1877, he identified this quantity with Clausius entropy through $-kH \equiv S$, where k is a constant. In other words, he established that

$$S = -k \iiint f(\mathbf{v}) \ln[f(\mathbf{v})] \, d\mathbf{v}, \quad (3)$$

later on generalized into

$$S = -k \iint f(\mathbf{q}, \mathbf{p}) \ln[f(\mathbf{q}, \mathbf{p})] \, d\mathbf{q} \, d\mathbf{p}, \quad (4)$$

where (\mathbf{q}, \mathbf{p}) is called the μ -*space* and constitutes the phase space (coordinate \mathbf{q} and momentum \mathbf{p}) corresponding to one particle.

Boltzmann's genius insight – the first ever mathematical connection of the macroscopic world with the microscopic one – was, during well over three decades, highly controversial since it was based on the hypothesis of the existence of atoms. Only a few selected scientists, like the English chemist and physicist John Dalton, the Scottish physicist and mathematician James Clerk Maxwell, and the American physicist, chemist and mathematician Josiah Willard Gibbs, believed in the reality of atoms and molecules. A large part of the scientific establishment was, at the time, strongly against such an idea. The intricate evolution of Boltzmann's lifelong epistemological struggle, which ended tragically with his suicide in 1906, may be considered as a neat illustration of Thomas Kuhn's *paradigm shift*, and the corresponding reaction of the scientific community, as described in *The Structure of Scientific Revolutions*. There are in fact two important formalisms in contemporary physics where the mathematical theory of probabilities enters as a central ingredient. These are statistical mechanics (with the concept of entropy as a functional of probability distributions) and quantum mechanics (with the physical interpretation of wave functions and measurements). In both cases, contrasting viewpoints and passionate debates have taken place along more than one century, and continue still today. This is no surprise after all. If it is undeniable that energy is a very deep and subtle concept, entropy is even more. Indeed, energy concerns the world of (microscopic) *possibilities*, whereas entropy concerns the world of the *probabilities* of those possibilities, a step further in epistemological difficulty.

In his 1902 celebrated book *Elementary Principles of Statistical Mechanics*, Gibbs introduced the modern form of the entropy for classical systems, namely

$$S = -k \int d\Gamma f(\mathbf{q}, \mathbf{p}) \ln[Cf(\mathbf{q}, \mathbf{p})], \quad (5)$$

where Γ represents the *full phase space* of the system, thus containing all coordinates and all momenta of its elementary particles, and C is introduced to take into account the finite size and the physical dimensions of the smallest admissible cell in Γ -space. The constant k is known today to be a universal one, called *Boltzmann constant*, and given by $k = 1.3806505(24) \times 10^{-23}$ Joule/Kelvin. The studies

of the German physicist Max Planck along Boltzmann and Gibbs lines after the appearance of quantum mechanical concepts, eventually led to the expression

$$S = k \ln W, \quad (6)$$

which he coined as *Boltzmann entropy*. This expression is carved on the stone of Boltzmann's grave at the Central Cemetery of Vienna. The quantity W is the total number of microstates of the system that are compatible with our macroscopic knowledge of it. It is obtained from Eq. (5) under the hypothesis of an uniform distribution or equal probabilities.

The Hungarian–American mathematician and physicist Johann von Neumann extended the concept of BG entropy in two steps – in 1927 and 1932 respectively –, in order to also cover quantum systems. The following expression, frequently referred to as the *von Neumann entropy*, resulted:

$$S = -k \operatorname{Tr} \rho \ln \rho, \quad (7)$$

ρ being the *density operator* (with $\operatorname{Tr} \rho = 1$).

Another important step was given in 1948 by the American electrical engineer and mathematician Claude Elwood Shannon. Having in mind the theory of digital communications he explored the properties of the discrete form

$$S = -k \sum_{i=1}^W p_i \ln p_i, \quad (8)$$

frequently referred to as *Shannon entropy* (with $\sum_{i=1}^W p_i = 1$). This form can be recovered from Eq. (5) for the particular case for which the phase space density $f(\mathbf{q}, \mathbf{p}) = \sum_{i=1}^W p_i \delta(\mathbf{q} - \mathbf{q}_i) \delta(\mathbf{p} - \mathbf{p}_i)$. It can also be recovered from Eq. (7) when ρ is diagonal. We may generically refer to Eqs. (5), (6), (7) and (8) as the *BG entropy*, noted S_{BG} . It is a measure of the disorder of the system or, equivalently, of our degree of ignorance or lack of information about its state. To illustrate a variety of properties, the discrete form (8) is particularly convenient.

Some Basic Properties

Non-negativity It can be easily verified that, in all cases, $S_{\text{BG}} \geq 0$, the zero value corresponding to *certainty*, i. e., $p_i = 1$ for one of the W possibilities, and zero for all the others. To be more precise, it is exactly so whenever S_{BG} is expressed either in the form (7) or in the form (8). However, this property of non-negativity may be no longer true if it is expressed in the form (5).

This violation is one of the mathematical manifestations that, at the microscopic level, the state of any physical system exhibits its quantum nature.

Expansibility Also $S_{\text{BG}}(p_1, p_2, \dots, p_W, 0) = S_{\text{BG}}(p_1, p_2, \dots, p_W)$, i. e., zero-probability events do not modify our information about the system.

Maximal value S_{BG} is maximized at equal probabilities, i. e., for $p_i = 1/W$, $\forall i$. Its value is that of Eq. (6). This corresponds to the Laplace *principle of indifference* or *principle of insufficient reason*.

Concavity If we have two arbitrary probability distributions $\{p_i\}$ and $\{p'_i\}$ for the same set of W possibilities, we can define the *intermediate* probability distribution $p''_i = \mu p_i + (1 - \mu) p'_i$ ($0 < \mu < 1$). It straightforwardly follows that $S_{\text{BG}}(\{p''_i\}) \geq \mu S_{\text{BG}}(\{p_i\}) + (1 - \mu) S_{\text{BG}}(\{p'_i\})$. This property is essential for thermodynamics since it eventually leads to *thermodynamic stability*, i. e., to *robustness* with regard to energy fluctuations. It also leads to the tendency of the entropy to attain, as time evolves, its maximal value compatible with our macroscopic knowledge of the system, i. e., with the possibly known values for the macroscopic constraints.

Lesche stability or experimental robustness B. Lesche introduced in 1982 [107] the definition of an interesting property, which he called *stability*. It reflects the *experimental robustness* that a physical quantity is expected to exhibit. In other words, similar experiments should yield similar numerical results for the physical quantities. Let us consider two probability distributions $\{p_i\}$ and $\{p'_i\}$, assumed to be close, in the sense that $\sum_{i=1}^W |p_i - p'_i| < \delta$, $\delta > 0$ being a small number. An entropic functional $S(\{p_i\})$ is said *stable* or *experimentally robust* if, for any given $\epsilon > 0$, a $\delta > 0$ exists such that $|S(\{p_i\}) - S(\{p'_i\})|/S_{\text{max}} < \epsilon$, where S_{max} is the maximal value that the functional can attain ($\ln W$ in the case of S_{BG}). This implies that $\lim_{\delta \rightarrow 0} \lim_{W \rightarrow \infty} (S(\{p_i\}) - S(\{p'_i\}))/S_{\text{max}} = 0$. As we shall see soon, this property is much stronger than it seems at first sight. Indeed, it provides a (necessary but not sufficient) criterion for classifying entropic functionals into physically admissible or not. It can be shown that S_{BG} is *Lesche-stable* (or *experimentally robust*).

Entropy production If we start the (deterministic) time evolution of a generic classical system from an arbitrarily chosen point in its Γ phase space, it typically follows a quite erratic trajectory which, in many cases, gradually visits the entire (or almost) phase space. By making partitions of this Γ -space, and counting the frequency of visits to the various cells (and related symbolic quantities), it is possible to define probabil-

ity sets. Through them, we can calculate a sort of time evolution of $S_{BG}(t)$. If the system is *chaotic* (sometimes called *strongly chaotic*), i. e., if its sensitivity to the initial conditions increases exponentially with time, then $S_{BG}(t)$ increases *linearly* with t in the appropriate asymptotic limits. This rate of increase of the entropy is called *Kolmogorov–Sinai entropy rate*, and, for a large class of systems, it coincides (*Pesin identity* or *Pesin theorem*) with the sum of the positive Lyapunov exponents. These exponents characterize the exponential divergences, along various directions in the Γ -space, of a small discrepancy in the initial condition of a trajectory.

It turns out, however, that the Kolmogorov–Sinai entropy rate is, in general, quite inconvenient for computational calculations for arbitrary nonlinear dynamical systems. In practice, another quantity is used instead [102], usually referred to as *entropy production per unit time*, which we note K_{BG} . Its definition is as follows. We first make a partition of the Γ -space into many W cells ($i = 1, 2, \dots, W$). In one of them, arbitrarily chosen, we randomly place M initial conditions (i. e., an *ensemble*). As time evolves, the occupancy of the W cells determines the set $\{M_i(t)\}$, with $\sum_{i=1}^W M_i(t) = M$. This set enables the definition of a probability set with $p_i(t) \equiv M_i(t)/M$, which in turn determines $S_{BG}(t)$. We then define the *entropy production per unit time* as follows:

$$K_{BG} \equiv \lim_{t \rightarrow \infty} \lim_{W \rightarrow \infty} \lim_{M \rightarrow \infty} \frac{S_{BG}(t)}{t}. \quad (9)$$

Up to date, no theorem guarantees that this quantity coincides with the Kolmogorov–Sinai entropy rate. However, many numerical approaches of various chaotic systems strongly suggest so. The same turns out to occur with what is frequently referred in the literature as a Pesin-like identity. For instance, if we have a one-dimensional dynamical system, its sensitivity to the initial conditions $\xi \equiv \lim_{\Delta x(0) \rightarrow 0} \Delta x(t)/\Delta x(0)$ is typically given by

$$\xi(t) = e^{\lambda t}, \quad (10)$$

where $\Delta x(t)$ is the discrepancy in the one-dimensional phase space of two trajectories initially differing by $\Delta x(0)$, and λ is the Lyapunov exponent ($\lambda > 0$ corresponds to *strongly sensitive to the initial conditions*, or *strongly chaotic*, and $\lambda < 0$ corresponds to *strongly insensitive to the initial conditions*). The so-called Pesin-like identity amounts, if $\lambda \geq 0$, to

$$K_{BG} = \lambda. \quad (11)$$

Additivity and extensivity If we consider a system $A + B$ constituted by two *probabilistically independent* subsystems A and B , i. e., if we consider $p_{ij}^{A+B} = p_i^A p_j^B$, we immediately obtain from Eq. (8) that

$$S_{BG}(A + B) = S_{BG}(A) + S_{BG}(B). \quad (12)$$

In other words, the BG entropy is *additive* [130]. If our system is constituted by N probabilistically independent identical subsystems (or *elements*), we clearly have $S_{BG}(N) \propto N$. It frequently happens, however, that the N elements are not exactly independent but only asymptotically so in the $N \rightarrow \infty$ limit. This is the usual case of many-body Hamiltonian systems involving only *short-range* interactions, where the concept of short-range will be focused in detail later on. For such systems, S_{BG} is only asymptotically additive, i. e.,

$$0 < \lim_{N \rightarrow \infty} \frac{S_{BG}(N)}{N} < \infty. \quad (13)$$

An entropy $S(\{p_i\})$ of a specific systems is said *extensive* if it satisfies

$$0 < \lim_{N \rightarrow \infty} \frac{S(N)}{N} < \infty, \quad (14)$$

where *no hypothesis at all* is made about the possible independence or weak or strong correlations between the elements of the system whose entropy S we are considering. Equation (13) amounts to say that the additive entropy S_{BG} is extensive for weakly correlated systems such as the already mentioned many-body short-range-interacting Hamiltonian ones. It is important to clearly realize that *additivity* and *extensivity* are independent properties. An additive entropy such as S_{BG} is extensive for simple systems such as the ones just mentioned, but it turns out to be nonextensive for other, more complex, systems that will be focused on later on. For many of these more complex systems, it is the nonadditive entropy S_q (to be analyzed later on) which turns out to be extensive for a non standard value of q (i. e., $q \neq 1$).

Boltzmann–Gibbs Statistical Mechanics

Physical systems (classical, quantum, relativistic) can be theoretically described in very many ways, through microscopic, mesoscopic, macroscopic equations, reflecting either stochastic or deterministic time evolutions, or even both types simultaneously. Those systems whose time evolution is completely determined by a well defined Hamiltonian with appropriate boundary conditions and ad-

missible initial conditions are the main purpose of an important branch of contemporary physics, named *statistical mechanics*. This remarkable *theory* (or *formalism*, as sometimes called), which for large systems satisfactorily matches classical thermodynamics, was primarily introduced by Boltzmann and Gibbs. The physical system can be in all types of situations. Two paradigmatic such situations correspond to *isolation*, and *thermal contact* with a large reservoir called *thermostat*. Their *stationary state* ($t \rightarrow \infty$) is usually referred to as *thermal equilibrium*. Both situations have been formally considered by Gibbs within his mathematical formulation of statistical mechanics, and they respectively correspond to the so-called *micro-canonical* and *canonical* ensembles (other ensembles do exist, such as the *grand-canonical* ensemble, appropriate for those situations in which the total number of elements of the system is not fixed; this is however out of the scope of the present article).

The stationary state of the micro-canonical ensemble is determined by $p_i = 1/W$ ($\forall i$, where i runs over all possible microscopic states), which corresponds to the extremization of S_{BG} with a single (and trivial) constraint, namely

$$\sum_{i=1}^W p_i = 1. \quad (15)$$

To obtain the stationary state for the canonical ensemble, the thermostat being at temperature T , we must (typically) add one more constraint, namely

$$\sum_{i=1}^W p_i E_i = U, \quad (16)$$

where $\{E_i\}$ are the energies of all the possible states of the system (i. e., eigenvalues of the Hamiltonian with the appropriate boundary conditions). The extremization of S_{BG} with the two constraints above straightforwardly yields

$$p_i = \frac{e^{-\beta E_i}}{Z} \quad (17)$$

$$Z \equiv \sum_{j=1}^W e^{-\beta E_j} \quad (18)$$

with the *partition function* Z , and the Lagrange parameter $\beta = 1/kT$. This is the celebrated *BG distribution* for thermal equilibrium (or *Boltzmann weight*, or *Gibbs state*, as also called), which has been at the basis of an enormous amount of successes (in fluids, magnets, superconductors, superfluids, Bose–Einstein condensation, conductors, chemical reactions, percolation, among many

other important situations). The connection with classical thermodynamics, and its Legendre-transform structure, occurs through relations such as

$$\frac{1}{T} = \frac{\partial S}{\partial U} \quad (19)$$

$$F \equiv U - TS = -\frac{1}{\beta} \ln Z \quad (20)$$

$$U = -\frac{\partial}{\partial \beta} \ln Z \quad (21)$$

$$C \equiv T \frac{\partial S}{\partial T} = \frac{\partial U}{\partial T} = -T \frac{\partial^2 F}{\partial T^2}, \quad (22)$$

where F , U and C are the *Helmholtz free energy*, the *internal energy*, and the *specific heat* respectively. The BG statistical mechanics historically appeared as the first connection between the microscopic and the macroscopic descriptions of the world, and it constitutes one of the cornerstones of contemporary physics. The Establishment resisted heavily before accepting the validity and power of Boltzmann's revolutionary ideas. In 1906 Boltzmann dramatically committed suicide, after 34 years that he had first proposed the deep ideas that we are summarizing here. At that early 20th century, few people believed in Boltzmann's proposal (among those few, we must certainly mention Albert Einstein), and most physicists were simply unaware of the existence of Gibbs and of his profound contributions. It was only half a dozen years later that the emerging new generation of physicists recognized their respective genius (thanks in part to various clarifications produced by Paul Ehrenfest, and also to the experimental successes related with Brownian motion, photoelectric effect, specific heat of solids, and black-body radiation).

On the Limitations of Boltzmann–Gibbs Entropy and Statistical Mechanics

Historical Background

As any other human intellectual construct, the applicability of the BG entropy, and of the statistical mechanics to which it is associated, naturally has restrictions. The understanding of present developments of both the concept of entropy, and its corresponding statistical mechanics, demand some knowledge of the historical background.

Boltzmann was aware of the relevance of the range of the microscopic interactions between atoms and molecules. He wrote, in his 1896 *Lectures on Gas Theory* [41], the following words:

When the distance at which two gas molecules interact with each other noticeably is vanishingly small relative to the average distance between a molecule

and its nearest neighbor—or, as one can also say, when the space occupied by the molecules (or their spheres of action) is negligible compared to the space filled by the gas—then the fraction of the path of each molecule during which it is affected by its interaction with other molecules is vanishingly small compared to the fraction that is rectilinear, or simply determined by external forces. [. . .] The gas is “ideal” in all these cases.

Also Gibbs was aware. In his 1902 book [88], he wrote:

In treating of the canonical distribution, we shall always suppose the multiple integral in equation (92) [the partition function, as we call it nowadays] to have a finite value, as otherwise the coefficient of probability vanishes, and the law of distribution becomes illusory. This will exclude certain cases, but not such apparently, as will affect the value of our results with respect to their bearing on thermodynamics. It will exclude, for instance, cases in which the system or parts of it can be distributed in unlimited space [. . .]. It also excludes many cases in which the energy can decrease without limit, as when the system contains material points which attract one another inversely as the squares of their distances. [. . .]. For the purposes of a general discussion, it is sufficient to call attention to the assumption implicitly involved in the formula (92).

The extensivity/additivity of S_{BG} has been challenged, along the last century, by many physicists. Let us mention just a few. In his 1936 *Thermodynamics* [82], Enrico Fermi wrote:

The entropy of a system composed of several parts is very often equal to the sum of the entropies of all the parts. This is true if the energy of the system is the sum of the energies of all the parts and if the work performed by the system during a transformation is equal to the sum of the amounts of work performed by all the parts. Notice that these conditions are not quite obvious and that in some cases they may not be fulfilled. Thus, for example, in the case of a system composed of two homogeneous substances, it will be possible to express the energy as the sum of the energies of the two substances only if we can neglect the surface energy of the two substances where they are in contact. The surface energy can generally be neglected only if the two substances are not very finely subdivided; otherwise, it can play a considerable role.

Laszlo Tisza wrote, in his *Generalized Thermodynamics* [178]:

The situation is different for the additivity postulate P a2, the validity of which cannot be inferred from general principles. We have to require that the interaction energy between thermodynamic systems be negligible. This assumption is closely related to the homogeneity postulate P d1. From the molecular point of view, additivity and homogeneity can be expected to be reasonable approximations for systems containing many particles, provided that the intermolecular forces have a short range character.

Corroborating the above, virtually all textbooks of quantum mechanics contain the mechanical calculations corresponding to a particle in a square well, the harmonic oscillator, the rigid rotator, a spin 1/2 in the presence of a magnetic field, and the Hydrogen atom. In the textbooks of statistical mechanics we can find the thermostatical calculations of all these systems . . . excepting the Hydrogen atom! Why? Because the long-range electron-proton interaction produces an energy spectrum which leads to a *divergent* partition function. This is but a neat illustration of the above Gibbs' alert.

A Remark on the Thermodynamics of Short- and Long-Range Interacting Systems

We consider here a simple d -dimensional classical fluid, constituted by many N point particles, governed by the Hamiltonian

$$\mathcal{H} = K + V = \sum_{i=1}^N \frac{p_i^2}{2m} + \sum_{i \neq j} V(r_{ij}), \quad (23)$$

where the potential $V(r)$ has, if it is attractive at short distances, no singularity at the origin, or an integrable singularity, and whose asymptotic behavior at infinity is given by $V(r) \sim -B/r^\alpha$ with $B > 0$ and $\alpha \geq 0$. One such example is the $d = 3$ Lennard–Jones fluid, for which $V(r) = A/r^{12} - B/r^6$ ($A > 0$), i. e., repulsive at short distances and attractive at long distances. In this case $\alpha = 6$. Another example could be Newtonian gravitation with a phenomenological short-distance cutoff (i. e., $V(r) \rightarrow \infty$ for $r \leq r_0$ with $r_0 > 0$). In this case, $\alpha = 1$. The full Γ -space of such a system has $2dN$ dimensions. The total potential energy is expected to scale (assuming a roughly homogeneous distribution of the particles) as

$$\frac{U_{\text{pot}}(N)}{N} \propto -B \int_1^\infty dr r^{d-1} r^{-\alpha}, \quad (24)$$

where the integral starts appreciably contributing above a typical cutoff, here taken to be unity. This integral is finite

[$= -B/(\alpha - d)$] for $\alpha/d > 1$ (*short-range interactions*), and diverges for $0 \leq \alpha/d \leq 1$ (*long-range interactions*). In other words, the energy cannot be *generically* characterized by Eq. (24), and we must turn onto a different and more powerful estimation. Given the *finiteness* of the size of the system, an appropriate one is, *in all cases*, given by

$$\frac{U_{\text{pot}}(N)}{N} \propto -B \int_1^{N^{1/d}} dr r^{d-1} r^{-\alpha} = -\frac{B}{d} N^{\alpha/d}, \quad (25)$$

where

$$N^{\alpha/d} \equiv \frac{N^{1-\alpha/d} - 1}{1 - \alpha/d} \sim \begin{cases} \frac{1}{\alpha/d - 1} & \text{if } \alpha/d > 1; \\ \ln N & \text{if } \alpha/d = 1; \\ \frac{N^{1-\alpha/d}}{1 - \alpha/d} & \text{if } 0 < \alpha/d < 1. \end{cases} \quad (26)$$

Notice that $N^{\alpha/d} = \ln_{\alpha/d} N$ where the q -log function $\ln_q x \equiv (x^{1-q} - 1)/(1 - q)$ ($x > 0$; $\ln_1 x = \ln x$) will be shown to play an important role later on. Satisfactorily enough, Eqs. (26) recover the characterization with Eq. (24) in the limit $N \rightarrow \infty$, but they have the great advantage of providing, for *finite* N , a *finite* value. This fact will be now shown to enable to properly scale the macroscopic quantities in the thermodynamic limit ($N \rightarrow \infty$), for all values of $\alpha/d \geq 0$.

Let us address the thermodynamical consequences of the microscopic interactions being short- or long-ranged. To present a slightly more general illustration, we shall assume from now on that our homogeneous and isotropic classical fluid is made by magnetic particles. Its Gibbs free energy is then given by

$$G(N, T, p, H) = U(N, T, p, H) - TS(N, T, p, H) + pV(N, T, p, H) - HM(N, T, p, H), \quad (27)$$

where (T, p, H) correspond respectively to the temperature, pressure and external magnetic field, V is the volume and M the magnetization. If the interactions are short-ranged (i. e., if $\alpha/d > 1$), we can divide this equation by N and then take the $N \rightarrow \infty$ limit. We obtain

$$g(T, p, H) = u(T, p, H) - Ts(T, p, H) + pv(T, p, H) - Hm(T, p, H), \quad (28)$$

where $g(T, p, H) \equiv \lim_{N \rightarrow \infty} G(N, T, p, H)/N$, and analogously for the other variables of the equation. If the interactions were instead long-ranged (i. e., if $0 \leq \alpha/d \leq 1$), all these quantities would be *divergent*, hence thermodynamically nonsense. Consequently, the generically correct

procedure, i. e. $\forall \alpha/d \geq 0$, must conform to the following lines:

$$\begin{aligned} \lim_{N \rightarrow \infty} \frac{G(N, T, p, H)}{NN^{\alpha/d}} &= \lim_{N \rightarrow \infty} \frac{U(N, T, p, H)}{NN^{\alpha/d}} \\ &- \lim_{N \rightarrow \infty} \frac{T}{N^{\alpha/d}} \frac{S(N, T, p, H)}{N} \\ &+ \lim_{N \rightarrow \infty} \frac{p}{N^{\alpha/d}} \frac{V(N, T, p, H)}{N} \\ &- \lim_{N \rightarrow \infty} \frac{H}{N^{\alpha/d}} \frac{M(N, T, p, H)}{N} \end{aligned} \quad (29)$$

hence

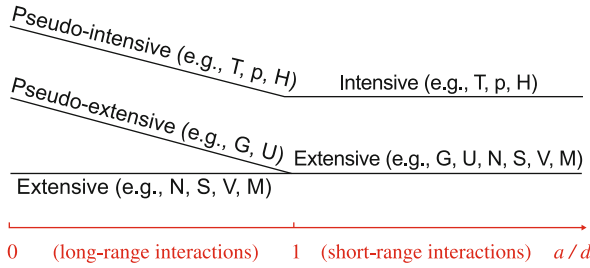

$$g(T^{\star}, p^{\star}, H^{\star}) = u(T^{\star}, p^{\star}, H^{\star}) - T^{\star} s(T^{\star}, p^{\star}, H^{\star}) + p^{\star} v(T^{\star}, p^{\star}, H^{\star}) - H^{\star} m(T^{\star}, p^{\star}, H^{\star}), \quad (30)$$

where the definitions of T^{\star} and all the other variables are self-explanatory (e. g., $T^{\star} \equiv T/N^{\alpha/d}$). In other words, in order to have *finite* thermodynamic equations of states, we must in general express them in the $(T^{\star}, p^{\star}, H^{\star})$ variables. If $\alpha/d > 1$, this procedure recovers the usual equations of states, and the usual *extensive* (G, U, S, V, M) and *intensive* (T, p, H) thermodynamic variables. But, if $0 \leq \alpha/d \leq 1$, the situation is more complex, and we realize that *three*, instead of the traditional *two*, classes of thermodynamic variables emerge. We may call them *extensive* (S, V, M, N), *pseudo-extensive* (G, U) and *pseudo-intensive* (T, p, H) variables. All the energy-type thermodynamical variables (G, F, U) give rise to pseudo-extensive ones, whereas those which appear in the usual Legendre thermodynamical pairs give rise to pseudo-intensive ones (T, p, H, μ) and extensive ones (S, V, M, N). See Figs. 1 and 2.

The possibly long-range interactions within Hamiltonian (23) refer to the *dynamical variables themselves*. There is another important class of Hamiltonians, where the possibly long-range interactions refer to the *coupling constants between localized dynamical variables*. Such is, for instance, the case of the following classical Hamiltonian:

$$\begin{aligned} \mathcal{H} = K + V &= \sum_{i=1}^N \frac{L_i^2}{2I} \\ &- \sum_{i \neq j} \frac{J_x s_i^x s_j^x + J_y s_i^y s_j^y + J_z s_i^z s_j^z}{r_{ij}^{\alpha}} \quad (\alpha \geq 0), \end{aligned} \quad (31)$$

where $\{L_i\}$ are the angular momenta, I the moment of inertia, $\{(s_i^x, s_i^y, s_i^z)\}$ are the components of classical rotators, (J_x, J_y, J_z) are coupling constants, and r_{ij} runs

Entropy, Figure 1

For long-range interactions ($0 \leq \alpha/d \leq 1$) we have three classes of thermodynamic variables, namely the pseudo-intensive (scaling with N^*), pseudo-extensive (scaling with NN^*) and extensive (scaling with N) ones. For short range interactions ($\alpha/d > 1$) the pseudo-intensive variables become intensive (independent from N), and the pseudo-extensive merge with the extensive ones, all being now extensive (scaling with N), thus recovering the traditional two textbook classes of thermodynamical variables

Entropy, Figure 2

The so-called extensive systems ($\alpha/d > 1$ for the classical ones) typically involve absolutely convergent series, whereas the so-called nonextensive systems ($0 \leq \alpha/d < 1$ for the classical ones) typically involve divergent series. The marginal systems ($\alpha/d = 1$ here) typically involve conditionally convergent series, which therefore depend on the boundary conditions, i.e., typically on the external shape of the system. Capacitors constitute a notorious example of the $\alpha/d = 1$ case. The model usually referred to in the literature as the Hamiltonian–Mean–Field (HMF) one lies on the $\alpha = 0$ axis ($\forall d > 0$). The model usually referred to as the d -dimensional α -XY model [19] lies on the vertical axis at abscissa d ($\forall \alpha \geq 0$)

over all distances between sites i and j of a d -dimensional lattice. For example, for a simple hypercubic lattice with unit crystalline parameter we have $r_{ij} = 1, 2, 3, \dots$ if $d = 1$, $r_{ij} = 1, \sqrt{2}, 2, \dots$ if $d = 2$, $r_{ij} = 1, \sqrt{2}, \sqrt{3}, 2, \dots$ if $d = 3$, and so on. For such a case, we have that

$$N^* \equiv \sum_{i=2}^N r_{1i}^{-\alpha}, \tag{32}$$

which has in fact the same asymptotic behaviors as indicated in Eq. (26). In other words, here again $\alpha/d > 1$ corresponds to short-range interactions, and $0 \leq \alpha/d \leq 1$ corresponds to long-range ones.

The correctness of the present generalized thermodynamical scalings has already been specifically checked in many physical systems, such as a ferrofluid-like model [97], Lennard–Jones-like fluids [90], magnetic systems [16,19,59,158], anomalous diffusion [66], percolation [85,144].

Let us mention that, for the $\alpha = 0$ models (i.e., mean field models), it is largely spread in the literature to divide by N the potential term of the Hamiltonian in order to make it extensive by force. Although mathematically admissible (see [19]), this is obviously very unsatisfactory in principle since it implies a microscopic coupling constant which depends on N . What we have described here is the thermodynamically proper way of eliminating the mathematical difficulties emerging in the models in the presence of long-range interactions.

Last but not least, we verify a point which is crucial for the developments here below, namely that the entropy S is expected to be extensive no matter the range of the interactions.

The Nonadditive Entropy S_q

Introduction and Basic Properties

The possibility was introduced in 1988 [183] (see also [42,112,157,182]) to generalize the BG statistical mechanics on the basis of an entropy S_q which generalizes S_{BG} . This entropy is defined as follows:

$$S_q \equiv k \frac{1 - \sum_{i=1}^W p_i^q}{q - 1} \quad (q \in \mathcal{R}; S_1 = S_{BG}). \tag{33}$$

For equal probabilities, this entropy takes the form

$$S_q = k \ln_q W \quad (S_1 = k \ln W), \tag{34}$$

where the q -logarithmic function has already been defined.

Remark With the same or different prefactor, this entropic form has been successively and independently introduced in many occasions during the last decades. J. Havrda and F. Charvat [92] were apparently the first to ever introduce this form, though with a different prefactor (adapted to binary variables) in the context of cybernetics and information theory. I. Vajda [207], further studied this form, quoting Havrda and Charvat. Z. Daroczy [74] rediscovered this form (he quotes neither Havrda–Charvat

nor Vajda). J. Lindhard and V. Nielsen [108] rediscovered this form (they quote none of the predecessors) through the property of entropic composability. B.D. Sharma and D.P. Mittal [163] introduced a two-parameter form which reproduces both S_q and Renyi entropy [145] as particular cases. A. Wehrl [209] mentions the form of S_q in p. 247, quotes Daroczy, but ignores Havrda–Charvat, Vajda, Lindhard–Nielsen, and Sharma–Mittal. Myself I rediscovered this form in 1985 with the aim of generalizing Boltzmann–Gibbs statistical mechanics, but quote none of the predecessors in the 1988 paper [183]. In fact, I started knowing the whole story quite a few years later thanks to S.R.A. Salinas and R.N. Silver, who were the first to provide me with the corresponding informations. Such rediscoveries can by no means be considered as particularly surprising. Indeed, this happens in science more frequently than usually realized. This point is lengthily and colorfully developed by S.M. Stigler [167]. In p. 284, a most interesting example is described, namely that of the celebrated *normal distribution*. It was first introduced by Abraham De Moivre in 1733, then by Pierre Simon de Laplace in 1774, then by Robert Adrain in 1808, and finally by Carl Friedrich Gauss in 1809, nothing less than 76 years after its first publication! This distribution is universally called *Gaussian* because of the remarkable insights of Gauss concerning the theory of errors, applicable in all experimental sciences. A less glamorous illustration of the same phenomenon, but nevertheless interesting in the present context, is that of Renyi entropy [145]. According to I. Csizsar [64], p. 73, the Renyi entropy had already been essentially introduced by Paul-Marcel Schutzenberger [161].

The entropy defined in Eq. (33) has the following main properties:

- (i) S_q is nonnegative ($\forall q$);
- (ii) S_q is expansive ($\forall q > 0$);
- (iii) S_q attains its maximal (minimal) value $k \ln_q W$ for $q > 0$ (for $q < 0$);
- (iv) S_q is concave (convex) for $q > 0$ (for $q < 0$);
- (v) S_q is Lesche-stable ($\forall q > 0$) [2];
- (vi) S_q yields a finite upper bound of the entropy production per unit time for a special value of q , whenever the sensitivity to the initial conditions exhibits an upper bound which asymptotically increases as a *power* of time. For example, many $D = 1$ nonlinear dynamical systems have a vanishing maximal Lyapunov exponent λ_1 and exhibit a sensitivity to the initial conditions which is (upper) bounded by

$$\xi = e_q^{\lambda_1 t}, \quad (35)$$

with $\lambda_q > 0$, $q < 1$, the q -exponential function e_q^x being the inverse of $\ln_q x$. More explicitly (see Fig. 3)

$$e_q^x \equiv \begin{cases} [1 + (1 - q)x]^{1/(1-q)} & \text{if } 1 + (1 - q)x > 0; \\ 0 & \text{otherwise.} \end{cases} \quad (36)$$

Such systems have a finite entropy production per unit time, which satisfies a q -generalized Pesin-like identity, namely, for the construction described in Sect. “Introduction”,

$$K_q \equiv \lim_{t \rightarrow \infty} \lim_{W \rightarrow \infty} \lim_{M \rightarrow \infty} \frac{S_q(t)}{t} = \lambda_q. \quad (37)$$

The situation is in fact sensibly much richer than briefly described here. For further details, see [27,28,29,30,93,116,117,146,147,148,149,150,151,152].

- (vii) S_q is nonadditive for $q \neq 1$. Indeed, for independent subsystems A and B , it can be straightforwardly proved

$$\frac{S_q(A + B)}{k} = \frac{S_q(A)}{k} + \frac{S_q(B)}{k} + (1 - q) \frac{S_q(A)}{k} \frac{S_q(B)}{k}, \quad (38)$$

or, equivalently,

$$S_q(A + B) = S_q(A) + S_q(B) + \frac{(1 - q)}{k} S_q(A) S_q(B), \quad (39)$$

which makes explicit that $(1 - q) \rightarrow 0$ plays the same role as $k \rightarrow \infty$. Property (38), occasionally referred to in the literature as *pseudo-additivity*, can be called *subadditivity* (*superadditivity*) for $q > 1$ ($q < 1$).

- (viii) $S_q = -k D_q \sum_{i=1}^W p_i^x |_{x=1}$, where the 1909 Jackson differential operator is defined as follows:

$$D_q f(x) \equiv \frac{f(qx) - f(x)}{qx - x} \quad (D_1 f(x) = df(x)/dx). \quad (40)$$

- (ix) An uniqueness theorem has been proved by Santos [159], which generalizes, for arbitrary q , that of Shannon [162].

Let us assume that an entropic form $S(\{p_i\})$ satisfies the following properties:

- (a)

$$S(\{p_i\}) \quad \text{is a continuous function of } \{p_i\}; \quad (41)$$

(b)

$S(p_i = 1/W, \forall i)$ monotonically increases with the total number of possibilities W ;
(42)

(c)

$$\frac{S(A+B)}{k} = \frac{S(A)}{k} + \frac{S(B)}{k} + (1-q) \frac{S(A)}{k} \frac{S(B)}{k}$$

if $p_{ij}^{A+B} = p_i^A p_j^B \forall (i, j)$, with $k > 0$;
(43)

(d)

$$S(\{p_i\}) = S(p_L, p_M) + p_L^q S(\{p_i/p_L\}) + p_M^q S(\{p_i/p_M\})$$

with $p_L \equiv \sum_{L \text{ terms}} p_i, p_M \equiv \sum_{M \text{ terms}} p_i (L + M = W)$,
and $p_L + p_M = 1$.
(44)

Then and only then [159] $S(\{p_i\}) = S_q(\{p_i\})$.

(x) Another (equivalent) uniqueness theorem was proved by Abe [1], which generalizes, for arbitrary q , that of Khinchin [100].

Let us assume that an entropic form $S(\{p_i\})$ satisfies the following properties:

(a)

$S(\{p_i\})$ is a continuous function of $\{p_i\}$;
(45)

(b)

$S(p_i = 1/W, \forall i)$ monotonically increases with the total number of possibilities W ;
(46)

(c)

$$S(p_1, p_2, \dots, p_W, 0) = S(p_1, p_2, \dots, p_W);$$

(47)

(d)

$$\frac{S(A+B)}{k} = \frac{S(A)}{k} + \frac{S(B|A)}{k} + (1-q) \frac{S(A)}{k} \frac{S(B|A)}{k}$$

where $S(A+B) \equiv S(\{p_{ij}^{A+B}\})$,

$$S(A) \equiv S\left(\left\{\sum_{j=1}^{W_B} p_{ij}^{A+B}\right\}\right),$$

and the conditional entropy

$$S(B|A) \equiv \frac{\sum_{i=1}^{W_A} (p_i^A)^q S(\{p_{ij}^{A+B}/p_i^A\})}{\sum_{i=1}^{W_A} (p_i^A)^q} \quad (k > 0)$$

(48)

Then and only then [1] $S(\{p_i\}) = S_q(\{p_i\})$.

Additivity Versus Extensivity of the Entropy

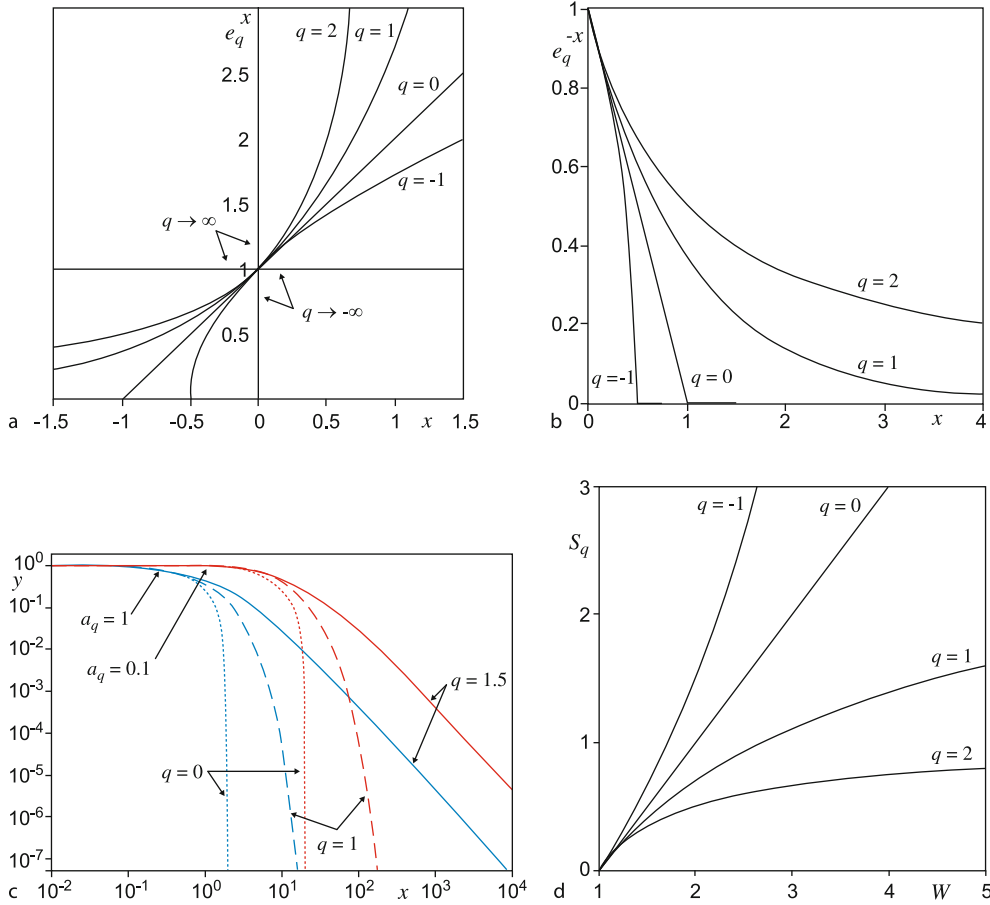

It is of great importance to distinguish *additivity* from *extensivity*. An entropy S is additive [130] if its value for a system composed by two independent subsystems A and B satisfies $S(A+B) = S(A) + S(B)$ (hence, for N independent equal subsystems or elements, we have $S(N) = NS(1)$). Therefore, S_{BG} is additive, and $S_q (q \neq 1)$ is nonadditive. A substantially different matter is whether a given entropy S is extensive for a given system. An entropy is extensive if and only if $0 < \lim_{N \rightarrow \infty} S(N)/N < \infty$. What matters for satisfactorily matching thermodynamics is extensivity *not* additivity. For systems whose elements are nearly independent (i. e., essentially weakly correlated), S_{BG} is extensive and S_q is nonextensive. For systems whose elements are strongly correlated in a special manner, S_{BG} is nonextensive, whereas S_q is extensive for a special value of $q \neq 1$ (and nonextensive for all the others).

Let us illustrate these facts for some simple examples of equal probabilities. If $W(N) \sim A\mu^N (A > 0, \mu > 1, \text{ and } N \rightarrow \infty)$, the entropy which is extensive is S_{BG} . Indeed, $S_{BG}(N) = k \ln W(N) \sim (\ln \mu)N \propto N$ (it is equally trivial to verify that $S_q(N)$ is nonextensive for any $q \neq 1$). If $W(N) \sim BN^\rho (B > 0, \rho > 0, \text{ and } N \rightarrow \infty)$, the entropy which is extensive is $S_{1-(1/\rho)}$. Indeed, $S_{1-(1/\rho)}(N) \sim k\rho B^{1/\rho} N \propto N$ (it is equally trivial to verify that $S_{BG}(N) \propto \ln N$, hence nonextensive). If $W(N) \sim C\mu^{N^\gamma} (C > 0, \mu > 1, \gamma \neq 1, \text{ and } N \rightarrow \infty)$, then $S_q(N)$ is nonextensive for any value of q . Therefore, in such a complex case, one must in principle refer to some other kind of entropic functional in order to match the extensivity required by classical thermodynamics.

Various nontrivial abstract mathematical models can be found in [113,160,186,198,199] for which $S_q (q \neq 1)$ is extensive. Moreover, a physical realization is also available now [60,61] for a many-body quantum Hamiltonian, namely the ground state of the following one:

$$\mathcal{H} = - \sum_{i=1}^{N-1} [(1+\gamma)S_i^x S_{i+1}^x + (1-\gamma)S_i^y S_{i+1}^y] - 2\lambda \sum_{i=1}^N S_i^z, \quad (49)$$

where λ is a transverse magnetic field, and (S_i^x, S_i^y, S_i^z) are Pauli matrices; for $|\gamma| = 1$ we have the Ising model, for $0 < |\gamma| < 1$, we have the anisotropic XY model, and, for $\gamma = 0$, we have the isotropic XY model. The two former share the same symmetry and consequently belong to the same critical universality class (the Ising uni-

Entropy, Figure 3

The q -exponential and q -logarithm functions in typical representations: **a** Linear-linear representation of e_q^x ; **b** Linear-linear representation of e_q^{-x} ; **c** Log-log representation of $y(x) = e_q^{-aqx}$, solution of $dy/dx = -aqy^q$ with $y(0) = 1$; **d** Linear-linear representation of $S_q = \ln_q W$ (value of the entropy for equal probabilities)

versality class, which corresponds to a so-called *central charge* $c = 1/2$), whereas the latter one belongs to a different universality class (the *XX* one, which corresponds to a central charge $c = 1$). At temperature $T = 0$ and $N \rightarrow \infty$, this model exhibits a second-order phase transition as a function of λ . For the Ising model, the critical value is $\lambda = 1$, whereas, for the *XX* model, the entire line $0 \leq \lambda \leq 1$ is critical. Since the system is at its ground state (assuming a vanishingly small magnetic field component in the $x - y$ plane), it is a *pure state* (i. e., its density matrix ρ_N is such that $\text{Tr} \rho_N^2 = 1, \forall N$), hence the entropy $S_q(N) (\forall q > 0)$ is strictly zero. However, the situation is drastically different for any L -sized block of the infinite chain. Indeed, $\rho_L \equiv \text{Tr}_{N-L} \rho_N$ is such that $\text{Tr} \rho_L^2 < 1$, i. e., it is a *mixed state*, hence it has a nonzero entropy. The block entropy $S_q(L) \equiv \lim_{N \rightarrow \infty} S_q(N, L)$ monotonically

increases with L for all values of q . And it does so *linearly* for

$$q = \frac{\sqrt{9 + c^2} - 3}{c}, \tag{50}$$

where c is the central charge which emerges in quantum field theory [54]. In other words, $0 < \lim_{L \rightarrow \infty} S_{(\sqrt{9+c^2}-3)/c}(L)/L < \infty$. Notice that q increases from zero to unity when c increases from zero to infinity; $q = \sqrt{37} - 6 \simeq 0.083$ for $c = 1/2$ (Ising model), $q = \sqrt{10} - 3 \simeq 0.16$ for $c = 1$ (isotropic *XY* model), $q = 1/2$ for $c = 4$ (dimension of space-time), and $q = (\sqrt{685} - 3)/26 \simeq 0.89$ for $c = 26$, related to string theory [89]. The possible physical interpretation of the limit $c \rightarrow \infty$ is still unknown, although it could correspond to some sort of mean field approach.

Nonextensive Statistical Mechanics

To generalize BG statistical mechanics for the canonical ensemble, we optimize S_q with constraint (15) and also

$$\sum_{i=1}^W P_i E_i = U_q, \quad (51)$$

where

$$P_i \equiv \frac{P_i^q}{\sum_{j=1}^W P_j^q} \quad \left(\sum_{i=1}^W P_i = 1 \right) \quad (52)$$

is the so-called *escort distribution* [33]. It follows that $p_i = P_i^{1/q} / \sum_{j=1}^W P_j^{1/q}$. There are various converging reasons for being appropriate to impose the energy constraint with the $\{P_i\}$ instead of with the original $\{p_i\}$. The full discussion of this delicate point is beyond the present scope. However, some of these intertwined reasons are explored in [184]. By imposing Eq. (51), we follow [193], which in turn reformulates the results presented in [71,183]. The passage from one to the other of the various existing formulations of the above optimization problem are discussed in detail in [83,193].

The entropy optimization yields, for the stationary state,

$$p_i = \frac{e^{-\beta_q(E_i - U_q)}}{\bar{Z}_q}, \quad (53)$$

with

$$\beta_q \equiv \frac{\beta}{\sum_{j=1}^W P_j^q}, \quad (54)$$

and

$$\bar{Z}_q \equiv \sum_i e^{-\beta_q(E_i - U_q)}, \quad (55)$$

β being the Lagrange parameter associated with the constraint (51). Equation (53) makes explicit that the probability distribution is, for fixed β_q , invariant with regard to the arbitrary choice of the zero of energies. The stationary state (or (meta)equilibrium) distribution (53) can be rewritten as follows:

$$p_i = \frac{e^{-\beta'_q E_i}}{Z'_q}, \quad (56)$$

with

$$Z'_q \equiv \sum_{j=1}^W e^{-\beta'_q E_j}, \quad (57)$$

and

$$\beta'_q \equiv \frac{\beta_q}{1 + (1 - q)\beta_q U_q}. \quad (58)$$

The form (56) is particularly convenient for many applications where comparison with experimental or computational data is involved. Also, it makes clear that p_i asymptotically decays like $1/E_i^{1/(q-1)}$ for $q > 1$, and has a cut-off for $q < 1$, instead of the exponential decay with E_i for $q = 1$.

The connection to thermodynamics is established in what follows. It can be proved that

$$\frac{1}{T} = \frac{\partial S_q}{\partial U_q}, \quad (59)$$

with $T \equiv 1/(k\beta)$. Also we prove, for the free energy,

$$F_q \equiv U_q - TS_q = -\frac{1}{\beta} \ln_q Z_q, \quad (60)$$

where

$$\ln_q Z_q = \ln_q \bar{Z}_q - \beta U_q. \quad (61)$$

This relation takes into account the trivial fact that, in contrast with what is usually done in BG statistics, the energies $\{E_i\}$ are here referred to U_q in (53). It can also be proved

$$U_q = -\frac{\partial}{\partial \beta} \ln_q Z_q, \quad (62)$$

as well as relations such as

$$C_q \equiv T \frac{\partial S_q}{\partial T} = \frac{\partial U_q}{\partial T} = -T \frac{\partial^2 F_q}{\partial T^2}. \quad (63)$$

In fact the entire Legendre transformation structure of thermodynamics is q -invariant, which is both remarkable and welcome.

A Connection Between Entropy and Diffusion

We review here one of the main common aspects of entropy and diffusion. We shall present on equal footing both the BG and the nonextensive cases [13,138,192,216]. Let us extremize the entropy

$$S_q = k \frac{1 - \int_{-\infty}^{\infty} d(x/\sigma) [\sigma p(x)]^q}{q - 1} \quad (64)$$

with the constraints

$$\int_{-\infty}^{\infty} dx p(x) = 1 \quad (65)$$

and

$$\langle x^2 \rangle_q \equiv \frac{\int_{-\infty}^{\infty} dx x^2 [p(x)]^q}{\int_{-\infty}^{\infty} dx [p(x)]^q} = \sigma^2, \tag{66}$$

$\sigma > 0$ being some fixed value having the same physical dimensions of the variable x . We straightforwardly obtain the following distribution:

$$p_q(x) = \begin{cases} \frac{1}{\sigma} \left[\frac{q-1}{\pi(3-q)} \right]^{1/2} \frac{\Gamma\left(\frac{1}{q-1}\right)}{\Gamma\left(\frac{3-q}{2(q-1)}\right)} \frac{1}{\left[1 + \frac{q-1}{3-q} \frac{x^2}{\sigma^2}\right]^{1/(q-1)}} & \text{if } 1 < q < 3; \\ \frac{1}{\sigma} \frac{1}{\sqrt{2\pi}} e^{-x^2/2\sigma^2} & \text{if } q = 1; \\ \frac{1}{\sigma} \left[\frac{1-q}{\pi(3-q)} \right]^{1/2} \frac{\Gamma\left(\frac{5-3q}{2(1-q)}\right)}{\Gamma\left(\frac{2-q}{1-q}\right)} \left[1 - \frac{1-q}{3-q} \frac{x^2}{\sigma^2}\right]^{1/(1-q)} & \text{for } |x| < \sigma [(3-q)/(1-q)]^{1/2}, \text{ and zero otherwise,} \\ & \text{if } q < 1. \end{cases} \tag{67}$$

These distributions are frequently referred to as q -Gaussians. For $q > 1$, they asymptotically have a power-law tail ($q \geq 3$ is not admissible because the norm (65) cannot be satisfied); for $q < 1$, they have a compact support. For $q = 1$, the celebrated Gaussian is recovered; for $q = 2$, the Cauchy–Lorentz distribution is recovered; finally, for $q \rightarrow -\infty$, the uniform distribution within the interval $[-1, 1]$ is recovered. For $q = \frac{3+m}{1+m}$, m being an integer ($m = 1, 2, 3, \dots$), we recover the Student’s t -distributions with m degrees of freedom [79]. For $q = \frac{n-4}{n-2}$, n being an integer ($n = 3, 4, 5, \dots$), we recover the so-called r -distributions with n degrees of freedom [79]. In other words, q -Gaussians are analytical extensions of Student’s t - and r -distributions. In some communities they are also referred to as the Barenblatt form. For $q < 5/3$, they have a finite variance which monotonically increases for q varying from $-\infty$ to $5/3$; for $5/3 \leq q < 3$, the variance diverges.

Let us now make a connection of the above optimization problem with diffusion. We focus on the following quite general diffusion equation:

$$\frac{\partial^\delta p(x, t)}{\partial t^\delta} = \frac{\partial}{\partial x} \left[\frac{\partial U(x)}{\partial x} p(x, t) \right] + D \frac{\partial^\alpha [p(x, t)]^{2-q}}{\partial |x|^\alpha} \tag{68}$$

$(0 < \delta \leq 1; 0 < \alpha \leq 2; q < 3; t \geq 0),$

with a generic nonsingular potential $U(x)$, and a generalized diffusion coefficient D which is positive (negative) for $q < 2$ ($2 < q < 3$). Several particular instances of this equation have been discussed in the literature (see [40,86,106,131,188] and references therein).

For example, the stationary state for $\alpha = 2, \forall \delta$, and any confining potential (i. e., $\lim_{|x| \rightarrow \infty} U(x) = \infty$) is given by [106]

$$p(x, \infty)_q = \frac{e_q^{-\beta [U(x)-U(0)]}}{Z}, \tag{69}$$

$$Z \equiv \int_{-\infty}^{\infty} dx e_q^{-\beta [U(x)-U(0)]}, \tag{70}$$

$$1/\beta \equiv kT \propto |D|, \tag{71}$$

which precisely is the distribution obtained within nonextensive statistical mechanics through extremization of S_q .

Also, the solution for $\alpha = 2, \delta = 1, U(x) = -k_1 x + \frac{k_2}{2} x^2$ ($\forall k_1$, and $k_2 \geq 0$), and $p(x, 0) = \delta(x)$ is given by [188]

$$p_q(x, t) = \frac{e_q^{-\beta(t)[x-x_M(t)]^2}}{Z_q(t)}, \tag{72}$$

$$\frac{\beta(t)}{\beta(0)} = \left[\frac{Z_q(0)}{Z_q(t)} \right]^2 \tag{73}$$

$$= \left[\left(1 - \frac{1}{K_2} e^{-t/\tau}\right) + \frac{1}{K_2} \right]^{-2/(3-q)}, \tag{74}$$

$$K_2 \equiv \frac{k_2}{2(2-q)D\beta(0)[Z_q(0)]^{q-1}}, \tag{75}$$

$$\tau \equiv \frac{1}{k_2(3-q)}, \tag{76}$$

$$x_M(t) \equiv \frac{k_1}{k_2} + \left[x_M(0) - \frac{k_1}{k_2} \right] e^{-k_2 t}. \tag{77}$$

In the limit $k_2 \rightarrow 0$, Eq. (73) becomes

$$Z_q(t) = \{ [Z_q(0)]^{3-q} + 2(2-q)(3-q)D\beta(0) [Z_q(0)]^2 t \}^{1/(3-q)}, \tag{78}$$

which, in the $t \rightarrow \infty$ limit, yields

$$\frac{1}{\beta(t)} \propto [Z_q(t)]^2 \propto t^{2/(3-q)}. \tag{79}$$

In other words, x^2 scales like t^γ , with

$$\gamma = \frac{2}{3-q}, \tag{80}$$

hence, for $q > 1$ we have $\gamma > 1$ (i. e., *superdiffusion*; in particular, $q = 2$ yields $\gamma = 2$, i. e., ballistic diffusion),

for $q < 1$ we have $\gamma < 1$ (i. e., *subdiffusion*; in particular, $q \rightarrow -\infty$ yields $\gamma = 0$, i. e., *localization*), and naturally, for $q = 1$, we obtain *normal diffusion*. Four systems are known for which results have been found that are consistent with prediction (79). These are the motion of *Hydra viridissima* [206], defect turbulence [73], simulation of a silo drainage [22], and molecular dynamics of a many-body long-range-interacting classical system of rotators ($\alpha - XY$ model) [143]. For the first three, it has been found $(q, \gamma) \simeq (3/2, 4/3)$. For the latter one, relation (79) has been verified for various situations corresponding to $\gamma > 1$.

Finally, for the particular case $\delta = 1$ and $U(x) = 0$, Eq. (68) becomes

$$\frac{\partial p(x, t)}{\partial t} = D \frac{\partial^\alpha [p(x, t)]^{2-q}}{\partial |x|^\alpha} \quad (0 < \alpha \leq 2; q < 3). \quad (80)$$

The diffusion constant D just rescales time t . Only two parameters are therefore left, namely α and q .

The linear case (i. e., $q = 1$) has two types of solutions: Gaussians for $\alpha = 2$, and Lévy- (or α -stable) distributions for $0 < \alpha < 2$. The case $\alpha = 2$ corresponds to the *Central Limit Theorem*, where the $N \rightarrow \infty$ attractor of the sums of N independent random variables with finite variance precisely is a Gaussian. The case $0 < \alpha < 2$ corresponds to the sometimes called *Levy-Gnedenko Central Limit Theorem*, where the $N \rightarrow \infty$ attractor of the sums of N independent random variables with infinite variance (and appropriate asymptotics) precisely is a Lévy distribution with index α .

The nonlinear case (i. e., $q \neq 1$) has solutions that are q -Gaussians for $\alpha = 2$, and one might conjecture that, similarly, interesting solutions exist for $0 < \alpha < 2$. Furthermore, in analogy with the $q = 1$ case, one expects corresponding q -generalized Central Limit Theorems to exist [187]. This is precisely what we present in the next Section.

Standard and q -Generalized Central Limit Theorems

The q -Product

It has been recently introduced (independently and virtually simultaneously) [43,125] a generalization of the product, which is called *q -product*. It is defined, for $x \geq 0$ and $y \geq 0$, as follows:

$$x \otimes_q y \equiv \begin{cases} [x^{1-q} + y^{1-q} - 1]^{1/(1-q)} & \text{if } x^{1-q} + y^{1-q} > 1; \\ 0 & \text{otherwise.} \end{cases} \quad (81)$$

It has, among others, the following properties: it recovers the *standard product* as a particular instance, i. e.,

$$x \otimes_1 y = xy; \quad (82)$$

it is *commutative*, i. e.,

$$x \otimes_q y = y \otimes_q x; \quad (83)$$

it is *additive under q -logarithm*, i. e.,

$$\ln_q(x \otimes_q y) = \ln_q x + \ln_q y \quad (84)$$

(whereas we remind that $\ln_q(xy) = \ln_q x + \ln_q y + (1 - q)(\ln_q x)(\ln_q y)$;

it has a $(2 - q)$ -*duality/inverse property*, i. e.,

$$1/(x \otimes_q y) = (1/x) \otimes_{2-q} (1/y); \quad (85)$$

it is *associative*, i. e.,

$$x \otimes_q (y \otimes_q z) = (x \otimes_q y) \otimes_q z = x \otimes_q y \otimes_q z = (x^{1-q} + y^{1-q} + z^{1-q} - 2)^{1/(1-q)}; \quad (86)$$

it admits *unity*, i. e.,

$$x \otimes_q 1 = x. \quad (87)$$

and, for $q \geq 1$, also a *zero*, i. e.,

$$x \otimes_q 0 = 0 \quad (q \geq 1). \quad (88)$$

The q -Fourier Transform

We shall introduce the q -Fourier transform of a quite generic function $f(x)$ ($x \in \mathcal{R}$) as follows [140,189,202,203,204,205]:

$$F_q[f](\xi) \equiv \int_{-\infty}^{\infty} dx e_q^{ix\xi} \otimes_q f(x) = \int_{-\infty}^{\infty} dx e_q^{ix\xi [f(x)]^{q-1}} f(x), \quad (89)$$

where we have primarily focused on the case $q \geq 1$. In contrast with the $q = 1$ case (standard Fourier transform), this integral transformation is *nonlinear* for $q \neq 1$. It has a remarkable property, namely that the q -Fourier transform of a q -Gaussian is another q -Gaussian:

$$F_q \left[N_q \sqrt{\beta} e_q^{-\beta x^2} \right] (\xi) = e_q^{-\beta_1 \xi^2}, \quad (90)$$

with

$$N_q \equiv \begin{cases} \left[\frac{q-1}{\pi} \right]^{1/2} \frac{\Gamma\left(\frac{1}{q-1}\right)}{\Gamma\left(\frac{3-q}{2(q-1)}\right)} & \text{if } 1 < q < 3, \\ \frac{1}{\sqrt{\pi}} & \text{if } q = 1, \\ \frac{3-q}{2} \left[\frac{1-q}{\pi} \right]^{1/2} \frac{\Gamma\left(\frac{3-q}{2(1-q)}\right)}{\Gamma\left(\frac{1}{1-q}\right)} & \text{if } q < 1, \end{cases} \quad (91)$$

and

$$q_1 = z(q) \equiv \frac{1+q}{3-q}, \quad (92)$$

$$\beta_1 = \frac{1}{\beta^{2-q}} \frac{N_q^{2(1-q)}(3-q)}{8}. \quad (93)$$

Equation (93) can be re-written as $\beta \sqrt{2-q} \beta_1^{1/\sqrt{2-q}} = [(N_q^{2(1-q)}(3-q))/8]^{1/\sqrt{2-q}} \equiv K(q)$, which, for $q = 1$, recovers the well known Heisenberg-uncertainty-principle-like relation $\beta\beta_1 = 1/4$.

If we iterate n times the relation $z(q)$ in Eq. (92), we obtain the following algebra:

$$q_n(q) = \frac{2q + n(1-q)}{2 + n(1-q)} \quad (n = 0, \pm 1, \pm 2, \dots), \quad (94)$$

which can be conveniently re-written as

$$\frac{2}{1-q_n(q)} = \frac{2}{1-q} + n \quad (n = 0, \pm 1, \pm 2, \dots). \quad (95)$$

(See Fig. 4). We easily verify that $q_n(1) = 1 (\forall n)$, $q_{\pm\infty}(q) = 1 (\forall q)$, as well as

$$\frac{1}{q_{n+1}} = 2 - q_{n-1}. \quad (96)$$

This relation connects the so called *additive duality* $q \rightarrow (2-q)$ and *multiplicative duality* $q \rightarrow 1/q$, frequently emerging in all types of calculations in the literature. Moreover, we see from Eq. (95) that multiple values of q are expected to emerge in connection with diverse properties of nonextensive systems, i. e., in systems whose basic entropy is the nonadditive one S_q . Such is the case of the so called *q-triplet* [185], observed for the first time in the magnetic field fluctuations of the solar wind, as it has been revealed by the analysis of the data sent to NASA by the spacecraft Voyager 1 [48].

Entropy, Figure 4
The q -dependence of $q_n(q) \equiv q_{2,n}(q)$

q-Independent Random Variables

Two random variables X [with density $f_X(x)$] and Y [with density $f_Y(y)$] having zero q -mean values (e. g., if $f_X(x)$ and $f_Y(y)$ are even functions) are said *q-independent*, with q_1 given by Eq. (92), if

$$F_q[X + Y](\xi) = F_q[X](\xi) \otimes_{q_1} F_q[Y](\xi), \quad (97)$$

i. e., if

$$\int_{-\infty}^{\infty} dz e^{iz\xi} \otimes_q f_{X+Y}(z) = \left[\int_{-\infty}^{\infty} dx e^{ix\xi} \otimes_q f_X(x) \right] \otimes_{(1+q)/(3-q)} \left[\int_{-\infty}^{\infty} dy e^{iy\xi} \otimes_q f_Y(y) \right], \quad (98)$$

with

$$\begin{aligned} f_{X+Y}(z) &= \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy h(x, y) \delta(x + y - z) \\ &= \int_{-\infty}^{\infty} dx h(x, z - x) \\ &= \int_{-\infty}^{\infty} dy h(z - y, y) \end{aligned} \quad (99)$$

where $h(x, y)$ is the joint density.

Clearly, q -independence means *independence* for $q = 1$ (i. e., $h(x, y) = f_X(x)f_Y(y)$), and implies a special correlation for $q \neq 1$. Although the full understanding of this correlation is still under progress, q -independence appears to be consistent with scale-invariance.

Entropy, Table 1

The attractors corresponding to the four basic cases, where the N variables that are being summed are q -independent (i. e., globally correlated) with $q_1 = (1 + q)/(3 - q)$; $\sigma_Q \equiv (\int_{-\infty}^{\infty} dx x^2 [f(x)]^Q)/(\int_{-\infty}^{\infty} dx [f(x)]^Q)$ with $Q \equiv 2q - 1$. The attractor for $(q, \alpha) = (1, 2)$ is a Gaussian $G(x) \equiv L_{1,2}$ (standard Central Limit Theorem); for $q = 1$ and $0 < \alpha < 2$, it is a Lévy distribution $L_\alpha \equiv L_{1,\alpha}$ (the so called Lévy-Gnedenko limit theorem); for $\alpha = 2$ and $q \neq 1$, it is a q -Gaussian $G_q \equiv L_{q,2}$ (the q -Central Limit Theorem; [203]); finally, for $q \neq 1$ and $0 < \alpha < 2$, it is a generic (q, α) -stable distribution $L_{q,\alpha}$ ([204,205]). See [140,189] for typical illustrations of the four types of attractors. The distribution $L_\alpha(x)$ remains, for $1 < \alpha < 2$, close to a Gaussian for $|x|$ up to about $x_c(1, \alpha)$, where it makes a crossover to a power-law. The distribution $G_q(x)$ remains, for $q > 1$, close to a Gaussian for $|x|$ up to about $x_c(q, 2)$, where it makes a crossover to a power-law. The distribution $L_{q,\alpha}(x)$ remains, for $q > 1$ and $\alpha < 2$, close to a Gaussian for $|x|$ up to about $x_c^{(1)}(q, \alpha)$, where it makes a crossover to a power-law (*intermediate regime*), which lasts further up to about $x_c^{(2)}(q, \alpha)$, where it makes a second crossover to another power-law (*distant regime*)

	$q = 1$ [independent]	$q \neq 1$ (i. e., $Q \neq 1$) [globally correlated]
$\sigma_Q < \infty$ ($\alpha = 2$)	$G(x)$ [with same σ_1 of $f(x)$]	$G_q(x) = G_{(3q_1-1)/(1+q_1)}(x)$ [with same σ_Q of $f(x)$] $G_q(x) \sim G(x)$ if $ x \ll x_c(q, 2)$ $G_q(x) \sim C_{q,2}/ x ^{2/(q-1)}$ if $ x \gg x_c(q, 2)$ for $q > 1$, with $\lim_{q \rightarrow 1} x_c(q, 2) = \infty$
$\sigma_Q \rightarrow \infty$ ($\alpha < 2$)	$L_\alpha(x)$ [with same $ x \rightarrow \infty$ behavior of $f(x)$] $L_\alpha(x) \sim G(x)$ if $ x \ll x_c(1, \alpha)$ $L_\alpha(x) \sim C_{1,\alpha}/ x ^{1+\alpha}$ if $ x \gg x_c(1, \alpha)$ with $\lim_{\alpha \rightarrow 2} q_c(1, \alpha) = \infty$	$L_{q,\alpha}(x)$ [with same $ x \rightarrow \infty$ behavior of $f(x)$] $L_{q,\alpha} \sim C_{q,\alpha}^{(intermediate)}/ x ^{\frac{2(1-q)-\alpha(3-q)}{2(q-1)}}$ if $x_c^{(1)}(q, \alpha) \ll x \ll x_c^{(2)}(q, \alpha)$ $L_{q,\alpha} \sim C_{q,\alpha}^{(distant)}/ x ^{\frac{1+\alpha}{1+\alpha(q-1)}}$ if $ x \gg x_c^{(2)}(q, \alpha)$

q -Generalized Central Limit Theorems

It is out of the scope of the present survey to provide the details of the complex proofs of the q -generalized central limit theorems. We shall restrict to the presentation of their structure. Let us start by introducing a notation which is important for what follows. A distribution is said (q, α) -stable distribution $L_{q,\alpha}(x)$ if its q -Fourier transform $L_{q,\alpha}(\xi)$ is of the form

$$L_{q,\alpha}(\xi) = a e_{q_1}^{-b|\xi|^\alpha}$$

$$[a > 0, b > 0, 0 < \alpha \leq 2, q_1 = (q + 1)/(3 - q)]. \tag{100}$$

Consistently, $L_{1,2}$ are Gaussians, $L_{1,\alpha}$ are Lévy distributions, and $L_{q,2}$ are q -Gaussians.

We are seeking for the $N \rightarrow \infty$ attractor associated with the sum of N identical and distinguishable random variables each of them associated with one and the same arbitrary symmetric distribution $f(x)$. The random variables are independent for $q = 1$, and correlated in a special manner for $q \neq 1$. To obtain the $N \rightarrow \infty$ invariant distribution, i. e. the attractor, the sum must be rescaled, i. e., divided by N^δ , where

$$\delta = \frac{1}{\alpha(2 - q)}. \tag{101}$$

For $(\alpha, q) = (2, 1)$, we recover the traditional $1/\sqrt{N}$ rescaling of Brownian motion. At the present stage, the theorems have been established for $q \geq 1$ and are summarized in Table 1. The case $q < 1$ is still open at the time at which these lines are being written. Two $q < 1$ cases have been preliminarily explored numerically in [124] and in [171]. The numerics seemed to indicate that the $N \rightarrow \infty$ limits would be q -Gaussians for both models. However, it has been analytically shown [94] that it is not exactly so. The limiting distributions numerically are amazingly close to q -Gaussians, but they are in fact different. Very recently, another simple scale-invariant model has been introduced [153], whose attractor has been analytically shown to be a q -Gaussian.

These $q \neq 1$ theorems play for the nonadditive entropy S_q and nonextensive statistical mechanics the same grounding role that the well known $q = 1$ theorems play for the additive entropy S_{BG} and BG statistical mechanics. In particular, interestingly enough, the ubiquity of Gaussians and of q -Gaussians in natural, artificial and social systems may be understood on equal footing.

Future Directions

The concept of entropy permeates into virtually all quantitative sciences. The future directions could therefore be very varied. If we restrict, however, to the evidence

Entropy, Figure 5
 Snapshot of a nongrowing dynamic network with $N = 256$ nodes (see details in [172], by courtesy of the author)

presently available, the main lines along which evolution occurs are:

Networks Many of the so-called scale-free networks, among others, systematically exhibit a *degree distribution* $p(k)$ (probability of a node having k links) which is of the form

$$p(k) \propto \frac{1}{(k_0 + k)^\gamma} \quad (\gamma > 0; k_0 > 0), \quad (102)$$

or, equivalently,

$$p(k) \propto e_q^{-k/\kappa} \quad (q \geq 1; \kappa > 0), \quad (103)$$

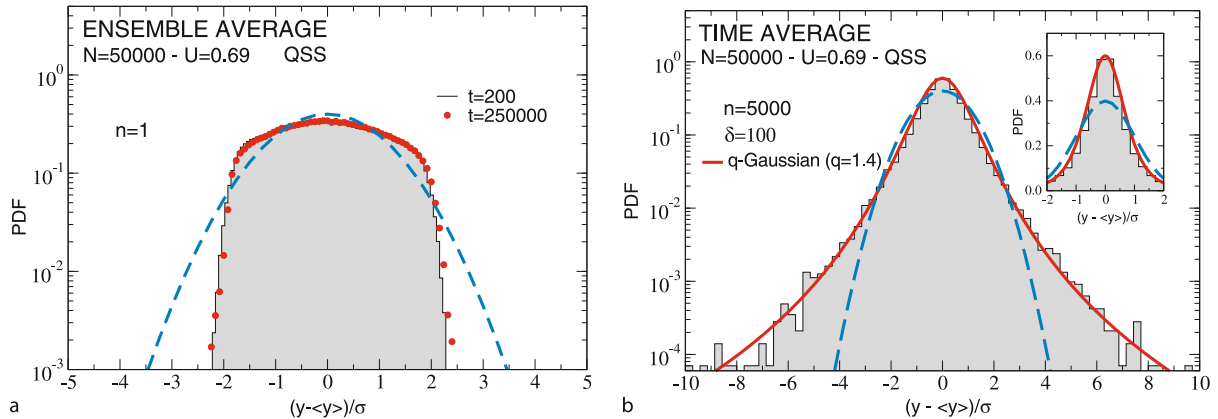

with $\gamma = 1/(q - 1)$ and $k_0 = \kappa/(q - 1)$ (see Figs. 5 and 6). This is not surprising since, if we associate to each link an “energy” (or *cost*) and to each node half of the “energy” carried by its links (the other half being associated with the other nodes to which any specific node is linked), the distribution of energies optimizing S_q precisely coincides with the degree distribution. If, for any reason, we consider k as the modulus of a d -dimensional vector \mathbf{k} , the optimization of the functional $S_q[p(\mathbf{k})]$ may lead to $p(k) \propto k^\eta e_q^{-k/\kappa}$, where k^η plays the role of a density of states, $\eta(d)$ being either zero (which reproduces Eq. (103)) or positive or negative. Several examples [12,39,76,91,165,172,173,212,213] already exist in the literature; in particular, the Barabasi–Albert universality class $\gamma = 3$ corresponds to $q = 4/3$. A deeper understanding of this connection might enable the sys-

 Nongrowing dynamic network: **a** Cumulative degree distribution for typical values for the number N of nodes; **b** Same data of **a** in the convenient representation *linear q -log versus linear* with $Z_q(k) \equiv \ln_q[P_q(> k)] \equiv ([P_q(> k)]^{1-q} - 1)/(1 - q)$ (the optimal fitting with a q -exponential is obtained for the value of q which has the highest value of the linear correlation r as indicated in the *inset*; here this is $q_c = 1.84$, which corresponds to the slope -1.19 in **a**). See details in [172,173]

tematic calculation of several meaningful properties of networks.

Nonlinear dynamical systems, self-organized criticality, and cellular automata Various interesting phenomena emerge in both low- and high-dimensional weakly chaotic deterministic dynamical systems, either dissipative or conservative. Among these phenomena we have the sensitivity to the initial conditions and the entropy production, which have been briefly addressed in Eq. (37) and related papers. But there is much more, such as relaxation, escape, glassy states, and distributions associated with the station-

Entropy, Figure 7

Distribution of velocities for the HMF model at the quasi-stationary state (whose duration appears to diverge when $N \rightarrow \infty$). The blue curves indicate a Gaussian, for comparison. See details in [137]

ary state [14,15,31,46,62,67,68,77,103,111,122,123,154,170,174,176,177,179]. Also, recent numerical indications suggest the validity of a dynamical version of the q -generalized central limit theorem [175]. The possible connections between all these various properties is still in its infancy.

Long-range-interacting many-body Hamiltonians

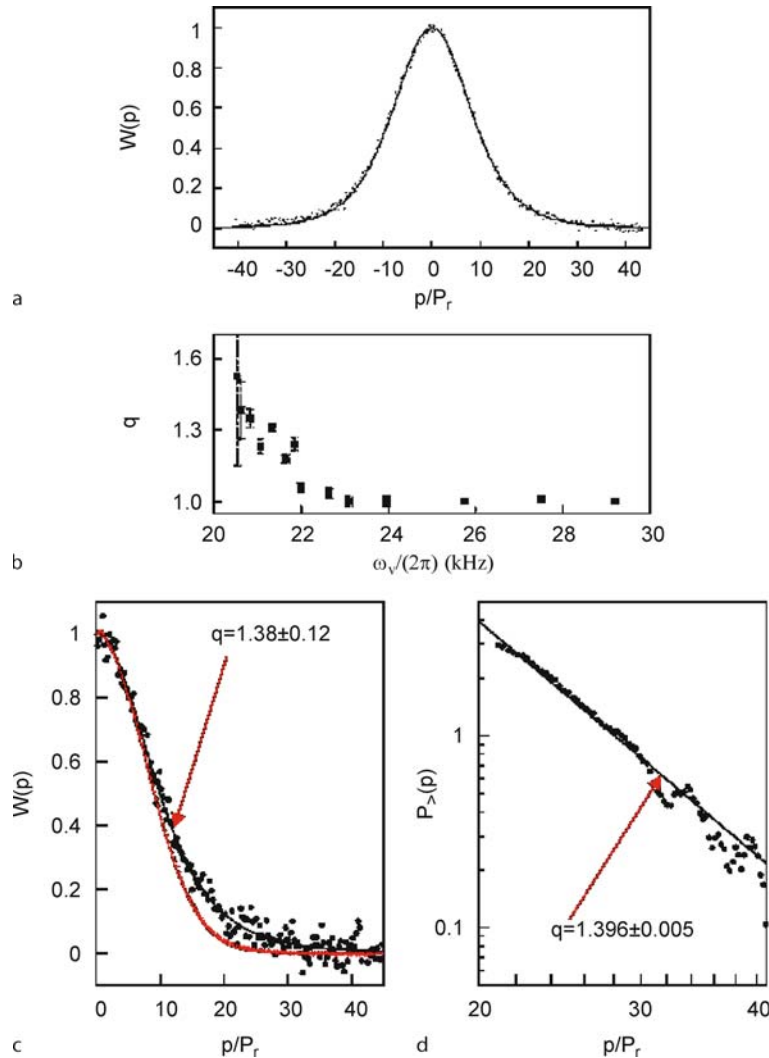

A wide class of long-range-interacting N -body classical Hamiltonians exhibits collective states whose Lyapunov spectrum has a maximal value that vanishes in the $N \rightarrow \infty$ limit. As such, they constitute natural candidates for studying whether the concepts derived from the nonadditive entropy S_q are applicable. A variety of properties have been calculated, through molecular dynamics, for various systems, such as Lennard-Jones-like fluids, XY and Heisenberg ferromagnets, gravitational-like models, and others. One or more long-standing quasi-stationary states (infinitely long-standing in the limit $N \rightarrow \infty$) are typically observed before the terminal entrance into thermal equilibrium. Properties such as distribution of velocities and angles, correlation functions, Lyapunov spectrum, metastability, glassy states, aging, time-dependence of the temperature in isolated systems, energy whenever thermal contact with a large thermostat at a given temperature is allowed, diffusion, order parameter, and others, are typically focused on. An ongoing debate exists, also involving Vlasov-like equations, Lynden-Bell statistics, among others. The breakdown of ergodicity that emerges in various situations makes the whole discussion rich and complex. The activity of the research nowadays in this area is illustrated in papers such as [21,26,45,53,56,57,63,104,119,121,

Entropy, Figure 8

Quantum Monte Carlo simulations in [81]: **a** Velocity distribution (superimposed with a q -Gaussian); **b** Index q (superimposed with Lutz prediction [110], by courtesy of the authors)

126,127,132,133,134,135,136,142,169,200]. A quite remarkable molecular-dynamical result has been obtained for a paradigmatic long-range Hamiltonian: the distribution of *time averaged* velocities sensibly differs from that found for the *ensemble-averaged* velocities, and has been shown to be numerically consistent with a q -Gaussian [137], as shown in Fig. 7. This result provides strong support to a conjecture made long ago: see Fig. 4 at p. 8 of [157].

Entropy, Figure 9

Experiments in [81]: **a** Velocity distribution (superimposed with a q -Gaussian); **b** Index q as a function of the frequency; **c** Velocity distribution (superimposed with a q -Gaussian; the red curve is a Gaussian); **d** Tail of the velocity distribution (superimposed with the asymptotic power-law of a q -Gaussian). [By courtesy of the authors]

Stochastic differential equations Quite generic Fokker–Planck equations are currently being studied. Aspects such as fractional derivatives, nonlinearities, space-dependent diffusion coefficients are being focused on, as well as their connections to entropic forms, and associated generalized Langevin equations [20,23,24,70,128,168,214]. Quite recently, computational (see Fig. 8) and experimental (see Fig. 9) verifications of Lutz’ 2003 prediction [110] have been exhibited [81], namely about the q -Gaussian form of the velocity distribution of cold atoms in dissipative optical lattices, with $q = 1 + 44E_R/U_0$ (E_R and U_0 being en-

ergy parameters of the optical lattice). These experimental verifications are in variance with some of those exhibited previously [96], namely double-Gaussians. Although it is naturally possible that the experimental conditions have not been exactly equivalent, this interesting question remains open at the present time. A hint might be hidden in the recent results [62] obtained for a quite different problem, namely the size distributions of avalanches; indeed, at a critical state, a q -Gaussian shape was obtained, whereas, at a noncritical state, a double-Gaussian was observed.

Quantum entanglement and quantum chaos The non-local nature of quantum physics implies phenomena that are somewhat analogous to those originated by classical long-range interactions. Consequently, a variety of studies are being developed in connection with the entropy S_q [3,36,58,59,60,61,155,156,195]. The same happens with some aspects of quantum chaos [11,180,210,211].

Astrophysics, geophysics, economics, linguistics, cognitive psychology, and other interdisciplinary applications Applications are available and presently searched in many areas of physics (plasmas, turbulence, nuclear collisions, elementary particles, manganites), but also in interdisciplinary sciences such astrophysics [38,47,48,49,78,84,87,101,109,129,196], geophysics [4,5,6,7,8,9,10,62,208], economics [25,50,51,52,80,139,141,197,215], linguistics [118], cognitive psychology [181], and others.

Global optimization, image and signal processing

Optimizing algorithms and related techniques for signal and image processing are currently being developed using the entropic concepts presented in this article [17,35,72,75,95,105,114,120,164,166,191].

Superstatistics and other generalizations The methods discussed here have been generalized along a variety of lines. These include Beck–Cohen superstatistics [32,34,65,190], crossover statistics [194,196], spectral statistics [201]. Also, a huge variety of entropies have been introduced which generalize in different manners the BG entropy, or even focus on other possibilities. Their number being nowadays over forty, we mention here just a few of them: see [18,44,69,98,99,115].

Glossary

Some of the following definitions refer to the “Notation” paragraph immediately below. Use *mpt* for ‘measure-preserving transformation’.

Measure space A *measure space* (X, \mathcal{X}, μ) is a set X , a *field* (that is, a σ -algebra) \mathcal{X} of subsets of X , and a countably-additive measure $\mu: \mathcal{X} \rightarrow [0, \infty]$. (We often just write (X, μ) , with the field implicit.) For a collection $\mathcal{C} \subset \mathcal{X}$, use $\text{Fld}(\mathcal{C}) \supset \mathcal{C}$ for the smallest field including \mathcal{C} . The number $\mu(B)$ is the “ μ -mass of B ”.

Measure-preserving map A *measure-preserving map* $\psi: (X, \mathcal{X}, \mu) \rightarrow (Y, \mathcal{Y}, \nu)$ is a map $\psi: X \rightarrow Y$ such that the inverse image of each $B \in \mathcal{Y}$ is in \mathcal{X} , and $\mu(\psi^{-1}(B)) = \nu(B)$. A (*measure-preserving*) *transformation* is a measure-preserving map $T: (X, \mathcal{X}, \mu) \rightarrow (X, \mathcal{X}, \mu)$. Condense this notation to $(T: X, \mathcal{X}, \mu)$ or $(T: X, \mu)$.

Probability space A *probability space* is a measure space (X, μ) with $\mu(X) = 1$; this μ is a *probability measure*. All our maps/transformations in this article are on probability spaces.

Factor map A *factor map*

$$\psi: (T: X, \mathcal{X}, \mu) \rightarrow (S: Y, \mathcal{Y}, \nu)$$

is a measure-preserving map $\psi: X \rightarrow Y$ which intertwines the transformations, $\psi \circ T = S \circ \psi$. And ψ is an *isomorphism* if – after deleting a nullset (a mass-zero set) in each space – this ψ is a bijection and ψ^{-1} is also a factor map.

Almost everywhere (a.e.) A measure-theoretic statement holds *almost everywhere*, abbreviated *a.e.*, if it holds off of a nullset. (Eugene Gutkin once remarked to me that the problem with Measure Theory is ... that you have to say “almost everywhere”, almost everywhere.) For example, $B \supset_{a.e.} A$ means that $\mu(B \setminus A)$ is zero. The *a.e.* will usually be implicit.

Probability vector A *probability vector* $\vec{v} = (v_1, v_2, \dots)$ is a list of non-negative reals whose sum is 1. We generally assume that probability vectors and partitions (see

below) have *finitely* many components. Write “*countable probability vector/partition*”, when finitely or denumerably many components are considered.

Partition A *partition* $P = (A_1, A_2, \dots)$ splits X into pairwise disjoint subsets $A_i \in \mathcal{X}$ so that the disjoint union $\bigsqcup_i A_i$ is all of X . Each A_i is an *atom* of P . Use $|P|$ or $\#P$ for the number of atoms. When P partitions a probability space, then it yields a probability vector \vec{v} , where $v_j := \mu(A_j)$. Lastly, use $P(x)$ to denote the P -atom that owns x .

Fonts We use the font $\mathcal{H}, \mathcal{E}, \mathcal{I}$ for *distribution-entropy, entropy* and the *information function*. In contrast, the script font $\mathcal{ABC} \dots$ will be used for collections of sets; usually subfields of \mathcal{X} . Use $\mathbb{E}(\cdot)$ for the (conditional) expectation operator.

Notation \mathbb{Z} = integers, \mathbb{Z}_+ = positive integers, and \mathbb{N} = natural numbers = $0, 1, 2, \dots$ (Some well-meaning folk use \mathbb{N} for \mathbb{Z}_+ , saying ‘*Nothing could be more natural than the positive integers*’. And this is why $0 \in \mathbb{N}$. Use $\lceil \cdot \rceil$ and $\lfloor \cdot \rfloor$ for the *ceiling* and *floor* functions; $\lfloor \cdot \rfloor$ is also called the “**greatest-integer function**”. For an interval $J := [a, b) \subset [-\infty, +\infty]$, let $[a \dots b)$ denote the *interval of integers* $J \cap \mathbb{Z}$ (with a similar convention for closed and open intervals). E. g., $(e \dots \pi) = (e \dots \pi) = \{3\}$.

For subsets A and B of the same space, Ω , use $A \subset B$ for inclusion and $A \subsetneq B$ for *proper* inclusion. The difference set $B \setminus A$ is $\{\omega \in B \mid \omega \notin A\}$. Employ A^c for the complement $\Omega \setminus A$. Since we work in a probability space, if we let $x := \mu(A)$, then a convenient convention is to have

$$x^c \text{ denote } 1 - x,$$

since then $\mu(A^c)$ equals x^c .

Use $A \Delta B$ for the *symmetric difference* $[A \setminus B] \cup [B \setminus A]$. For a collection $\mathcal{C} = \{E_j\}_j$ of sets in Ω , let the *disjoint union* $\bigsqcup_j E_j$ or $\bigsqcup(\mathcal{C})$ represent the union $\bigcup_j E_j$ and also assert that the sets are pairwise disjoint.

Use “ $\forall_{\text{large } n}$ ” to mean: “ $\exists n_0$ such that $\forall n > n_0$ ”. To refer to left hand side of an Eq. (20), use LHS(20); do analogously for RHS(20), the right hand side.

Definition of the Subject

The word ‘*entropy*’ (originally German, *Entropie*) was coined by Rudolf Julius Emanuel Clausius circa 1865 [2,3], taken from the Greek $\epsilon\nu\tau\rho\omicron\pi\alpha$, ‘*a turning towards*’. This article thus begins (*Prolegomenon*, “introduction”) and ends (*Exodos*¹, “the path out”) in Greek.

¹This is the Greek spelling.

Clausius, in his coinage, was referring to the thermodynamic notion in physics. Our focus in this article, however, will be the concept in measurable and topological dynamics. (Entropy in differentiable dynamics² would require an article by itself.) Shannon’s 1948 paper [6] on Information Theory, then Kolmogorov’s [4] and Sinai’s [7] generalization to dynamical systems, will be our starting point. Our discussion will be of the one-dimensional case, where the acting-group is \mathbb{Z} .

“My greatest concern was what to call it. I thought of calling it ‘*information*’, but the word was overly used, so I decided to call it ‘*uncertainty*’. John von Neumann had a better idea, he told me, ‘You should call it entropy, for two reasons. In the first place your uncertainty function goes by that name in statistical mechanics. In the second place, and more important, **nobody knows what entropy really is**, so in a debate you will always have the advantage.’” (Shannon as quoted in [59])

Entropy example: How many questions?

Imagine a dartboard, Fig. 1, split in five regions A, \dots, E with known probabilities. Blindfolded, you throw a dart at the board. What is the expected number V of Yes/No questions needed to ascertain the region in which the dart landed?

Solve this by always dividing the remaining probability in half. ‘*Is it A?*’ – if Yes, then $V = 1$. Else: ‘*Is it B or C?*’ – if Yes, then ‘*Is it B?*’ – if No, then the dart landed in C , and $V = 3$ was the number of questions. Evidently $V = 3$ also for regions B, D, E . Using “log” to denote base-2 logarithm³, the expected number of questions⁴ is thus

$$\begin{aligned} \mathbb{E}(V) &= \frac{1}{2} \cdot 1 + \frac{1}{8} \cdot 3 + \frac{1}{8} \cdot 3 + \frac{1}{8} \cdot 3 + \frac{1}{8} \cdot 3 \\ &= \sum_{j=0}^4 p_j \log \left(\frac{1}{p_j} \right) \stackrel{\text{note}}{=} 2. \end{aligned} \tag{1}$$

²For instance, see [15,18,24,25].

³In this paper, unmarked logs will be to base-2. In entropy theory, it does not matter much what base is used, but base-2 is convenient for computing entropy for messages described in bits. When using the natural logarithm, some people refer to the unit of information as a *nat*. In this paper, I have picked bits rather than nats.

⁴This is holds when each probability p is a reciprocal power of two. For general probabilities, the “expected number of questions” interpretation holds in a weaker sense: Throw N darts independently at N copies of the dartboard. Efficiently ask Yes/No questions to determine where *all* N darts landed. Dividing by N , then sending $N \rightarrow \infty$, will be the $p \log \left(\frac{1}{p} \right)$ sum of Eq. 1.

Entropy in Ergodic Theory, Figure 1

This dartboard is a probability space with a 5-set partition. The atoms have probabilities $\frac{1}{2}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}$. This probability distribution will be used later in Meshalkin’s example

Letting $\vec{v} := (\frac{1}{2}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8})$ be the probability vector, we can write this expectation as

$$\mathbb{E}(V) = \sum_{x \in \vec{v}} \eta(x).$$

Here, $\eta : [0, 1] \rightarrow [0, \infty)$ is the important function⁵

$$\eta(x) := x \log(1/x), \quad \text{so extending by continuity gives } \eta(0) = 0. \tag{2}$$

An interpretation of “ $\eta(x)$ ” is the number of questions needed to winnow down to an event of probability x .

Distribution Entropy

Given a probability vector \vec{v} , define its **distribution entropy** as

$$\mathcal{H}(\vec{v}) := \sum_{x \in \vec{v}} \eta(x). \tag{3}$$

This article will use the term **distropy** for ‘distribution entropy’, reserving the word **entropy** for the corresponding dynamical concept, when there is a notion of time involved. Getting ahead of ourselves, the *entropy* of a stationary process is the asymptotic average value that its distropy decays to, as we look at larger and larger finite portions of the process.

An equi-probable vector $\vec{v} := (\frac{1}{K}, \dots, \frac{1}{K})$ evidently has $\mathcal{H}(\vec{v}) = \log(K)$. On a probability space, the “**distropy of partition P**”, written $\mathcal{H}(P)$ or $\mathcal{H}(A_1, A_2, \dots)$ shall mean the distropy of probability vector $j \mapsto \mu(A_j)$.

A (finite) partition necessarily has finite distropy. A *countable* partition can have finite distropy, e.g.

⁵There does not seem to be a standard name for this function. I use η , since an uppercase η looks like an H , which is the letter that Shannon used to denote what I am calling distribution-entropy.

$\mathcal{H}(\frac{1}{2}, \frac{1}{4}, \frac{1}{8}, \dots) = 2$. One could also have infinite distropy: Consider a piece $B \subset X$ of mass $1/2^N$. Splitting B into 2^k many equal-mass atoms gives an η -sum of $2^k(k + N)/(2^k 2^N)$. Setting $k = k_N := 2^N - N$ makes this η -sum equal 1; so splitting the pieces of $X = \bigsqcup_{N=1}^{\infty} B_N$, with $\mu(B_N) = \frac{1}{2^N}$, yields an ∞ -distropy partition.

Function η

The $\eta(x) = x \log(1/x)$ function⁶ has vertical tangent at $x = 0$, maximum at $1/e$ and, when graphed in nats slope -1 at $x = 1$.

Consider partitions P and Q on the same space (X, μ) . Their **join**, written $P \vee Q$, has atoms $A \cap B$, for each pair $A \in P$ and $B \in Q$. They are **independent**, written $P \perp Q$ if $\mu(A \cap B) = \mu(A)\mu(B)$ for each A, B pair. We write $P \succcurlyeq Q$, and say that “**P refines Q**”, if each P -atom is a subset of some Q -atom. Consequently, each Q -atom is a union of P -atoms.

Recall, for δ a real number, our convention that δ^c means $1 - \delta$, in analogy with $\mu(B^c)$ equaling $1 - \mu(B)$ on a probability space.

Distropy Fact

For partitions P, Q, R on probability space (X, μ) :

- (a) $\mathcal{H}(P) \leq \log(\#P)$, with equality IFF P is an equi-mass partition.
- (b) $\mathcal{H}(Q \vee R) \leq \mathcal{H}(Q) + \mathcal{H}(R)$, with equality IFF $Q \perp R$.
- (c) For $\delta \in [0, \frac{1}{2}]$, the function $\delta \mapsto \mathcal{H}(\delta, \delta^c)$ is strictly increasing.
- (d) $R \preccurlyeq P$ implies $\mathcal{H}(R) \leq \mathcal{H}(P)$, with equality IFF $R \stackrel{a.e.}{=} P$.

Proof Use the strict concavity of $\eta(\cdot)$, together with Jensen’s inequality. □

Remark 1 Although we will not discuss it in this paper, most distropy statements remain true with ‘partition’ replaced by ‘countable partition of finite distropy’.

⁶Curiosity: Just in this paragraph we compute distropy in *nats*, that is, using natural logarithm. Given a small probability $p \in [0, 1]$ and setting $x := 1/p$, note that $\eta(p) = \frac{\log(x)}{x} \approx 1/\pi(x)$, where $\pi(x)$ denotes the number of prime numbers less-equal x . (This approximation is a weak form of the Prime Number Theorem.) Is there any actual connection between the ‘approximate distropy’ function $\mathcal{H}_\pi(\vec{p}) := \sum_{p \in \vec{p}} 1/\pi(1/p)$ and Number Theory, other than a coincidence of growth rate?

Entropy in Ergodic Theory, Figure 2

Using natural log, here are the graphs of: $\eta(x)$ in solid red, $\mathcal{H}(x, x^c)$ in dashed green, $1 - x$ in dotted blue. Both $\eta(x)$ and $\mathcal{H}(x, x^c)$ are strictly convex-down. The $1 - x$ line is tangent to $\eta(x)$ at $x = 1/e$

Entropy in Ergodic Theory, Figure 3

Using natural log: The graph of $\mathcal{H}(x_1, x_2, x_3)$ in barycentric coordinates; a slice has been removed, between $z = 0.745$ and $z = 0.821$. The three arches are copies of the distropy curve from Fig. 2.

Binomial Coefficients

The dartboard gave an example where distropy arises in a natural way. Here is a second example.

For a small $\delta > 0$, one might guess that the binomial coefficient $\binom{n}{\delta n}$ grows asymptotically (as $n \rightarrow \infty$) like $2^{\epsilon n}$, for some small ϵ . But what is the correct relation between ϵ and δ ?

Well, Stirling’s formula $n! \approx [n/e]^n$ gives

$$\frac{n!}{[\delta n]! [\delta^c n]!} \approx \frac{n^n}{[\delta n]^{[\delta n]} [\delta^c n]^{[\delta^c n]}}$$

$$= \frac{1}{[\delta \delta n] [\delta^c \delta^c n]} \quad (\text{recall } \delta^c = 1 - \delta).$$

Thus $\frac{1}{n} \log \binom{n}{\delta n} \approx \mathcal{H}(\delta, \delta^c)$. But by means of the above

distropy inequalities, we get an inequality true for *all* n , not just asymptotically.

Lemma 2 (Binomial Lemma) Fix a $\delta \in [0, \frac{1}{2}]$ and let $\mathbf{H} := \mathcal{H}(\delta, \delta^c)$. Then for each $n \in \mathbb{Z}_+$:

$$\sum_{j \in [0 \dots \delta n]} \binom{n}{j} \leq 2^{\mathbf{H}n}. \tag{4}$$

Proof Let $X \subset \{0, 1\}^n$ be the set of \vec{x} with

$$\#\{i \in [1 \dots n] \mid x_i = 1\} \leq \delta n.$$

On X , let P_1, P_2, \dots be the coordinate partitions; e.g. $P_7 = (A_7, A_7^c)$, where $A_7 := \{\vec{x} \mid x_7 = 1\}$. Weighting each point by $\frac{1}{|X|}$, the uniform distribution on X , gives that $\mu(A_7) \leq \delta$. So $\mathcal{H}(P_7) \leq \mathbf{H}$, by (c) in Sect. “Distropy Fact”.

Finally, the join $P_1 \vee \dots \vee P_n$ separates the points of X .

So

$$\log(\#X) = \mathcal{H}(P_1 \vee \dots \vee P_n)$$

$$\leq \mathcal{H}(P_1) + \dots + \mathcal{H}(P_n)$$

$$\leq \mathbf{H}n,$$

making use of (a),(b) in “Distropy Fact”. And $\#X$ equals LhS (4). \square

A Gander at Shannon’s Noisy Channel Theorem

We can restate the Binomial lemma using the *Hamming metric* on $\{0, 1\}^n$,

$$\text{Dist}(\vec{x}, \vec{y}) := \#\{i \in [1 \dots n] \mid x_i \neq y_i\}.$$

Use $\text{Bal}(\vec{x}, r)$ for the open radius- r ball centered at \vec{x} , and

$$\overline{\text{Bal}}(\vec{x}, r) := \{\vec{y} \mid \text{Dist}(\vec{x}, \vec{y}) \leq r\}$$

for the closed ball. The above lemma can be interpreted as saying that

$$|\overline{\text{Bal}}(\vec{x}, \delta n)| \leq 2^{\mathcal{H}(\delta, \delta^c)n}, \quad \text{for each } \vec{x} \in \{0, 1\}^n. \tag{5}$$

Corollary 3 Fix $n \in \mathbb{Z}_+$ and $\delta \in [0, \frac{1}{2}]$, and let

$$\mathbf{H} := \mathcal{H}(\delta, \delta^c).$$

Then there is a set $C \subset \{0, 1\}^n$, with $\#C \geq 2^{[1-\mathbf{H}]n}$, that is *strongly* δn -separated. I. e., $\text{Dist}(\vec{x}, \vec{y}) > \delta n$ for each distinct pair $\vec{x}, \vec{y} \in C$.

Noisy Channel

Shannon’s theorem says that a noisy channel has a **channel capacity**. Transmitting *above* this speed, there is a minimum error-rate (depending how much “*above*”) that no error-correcting code can fix. Conversely, one can transmit *below* – but arbitrarily close to – the channel capacity, and encode the data so as to make the error-rate less than any given ε . We use Corollary 3 to show the existence of such codes, in the simplest case where the noise⁷ is a binary independent-process (a “Bernoulli” process, in the language later in this article).

We have a channel which can pass one bit per second. Alas, there is a fixed noise-probability $\nu \in [0, \frac{1}{2})$ so that a bit in the channel is perturbed into the other value. Each perturbation is independent of all others. Let $\mathbf{H} := \mathcal{H}(\nu, \nu^c)$. The value $[1 - \mathbf{H}]$ bits-per-second is the **channel capacity** of this noise-afflicted channel.

Encoding/Decoding Encode using an “ k, n -block-code”; an injective map $F: \{0, 1\}^k \rightarrow \{0, 1\}^n$. The source text is split into consecutive k -bit blocks. A block $\vec{x} \in \{0, 1\}^k$ is encoded to $F(\vec{x}) \in \{0, 1\}^n$ and then sent through the channel, where it comes out perturbed to $\vec{\alpha} \in \{0, 1\}^n$. The *transmission rate* is thus k/n bits per second.

For this example, we fix a radius $r > 0$ to determine the decoding map,

$$D_r: \{0, 1\}^n \rightarrow \{Oops\} \sqcup \{0, 1\}^k .$$

We set $D_r(\vec{\alpha})$ to \vec{z} if there is a *unique* \vec{z} with $F(\vec{z}) \in \text{Bal}(\vec{\alpha}, r)$; else, set $D_r(\vec{\alpha}) := Oops$.

One can think of the noise as a $\{0, 1\}$ -independent-process, with $\text{Prob}(1) = \nu$, which is added mod-2 to the signal-process. Suppose we can arrange that the set $\{F(\vec{x}) \mid \vec{x} \in \{0, 1\}^k\}$ of codewords, is a strongly r -separated-set. Then

The probability that a block is mis-decoded is the probability, flipping a ν -coin n times that we get more than r many Heads. (6)

Theorem 4 (Shannon) Fix a noise-probability $\nu \in [0, \frac{1}{2})$ and let $\mathbf{H} := \mathcal{H}(\nu, \nu^c)$. Consider a rate $R < [1 - \mathbf{H}]$ and an $\varepsilon > 0$. Then $\forall_{\text{large } n}$ there exists a k and a code $F: \{0, 1\}^k \rightarrow \{0, 1\}^n$ so that: The F -code transmits bits at faster than R bits-per-second, and with error-rate $< \varepsilon$.

⁷The noise-process is assumed to be *independent* of the signal-process. In contrast, when the perturbation is highly dependent on the signal, then it is sometimes called **distortion**.

Proof Let $\mathbf{H}' := \mathcal{H}(\delta, \delta^c)$, where $\delta > \nu$ was chosen so close to ν that

$$\delta < \frac{1}{2} \quad \text{and} \quad 1 - \mathbf{H}' > R . \tag{7}$$

Pick a large n for which

$$\frac{k}{n} > R , \quad \text{where} \quad k := \lfloor [1 - \mathbf{H}']n \rfloor . \tag{8}$$

By Corollary 3, there is a strongly δn -separated-set $C \subset \{0, 1\}^n$ with $\#C \geq 2^{[1 - \mathbf{H}']n}$. So C is big enough to permit an injection $F: \{0, 1\}^k \rightarrow C$. Courtesy Eq. (6), the probability of a decoding error is that of getting more than δn many Heads in flipping a ν -coin n times. Since $\delta > \nu$, the Weak Law of Large Numbers guarantees – once n is large enough – that this probability is less than the given ε . □

The Information Function

Agree to use $\mathbf{P} = (A_1, \dots), \mathbf{Q} = (B_1, \dots), \mathbf{R} = (C_1, \dots)$ for partitions, and \mathcal{F}, \mathcal{G} for fields.

With \mathcal{C} a (finite or infinite) family of subfields of \mathcal{X} , their **join** $\bigvee_{\mathcal{G} \in \mathcal{C}} \mathcal{G}$ is the smallest field \mathcal{F} such that $\mathcal{G} \subset \mathcal{F}$, for each $\mathcal{G} \in \mathcal{C}$. A partition \mathbf{Q} can be interpreted also as a field; namely, the field of unions of its atoms. A join of denumerably many partitions will be interpreted as a field, but a join of *finitely* many, $\mathbf{P}_1 \vee \dots \vee \mathbf{P}_N$, will be viewed as a partition *or* as a field, depending on context.

Conditioning a partition \mathbf{P} on a positive-mass set B , let $\mathbf{P}|B$ be the probability vector $A \mapsto \frac{\mu(A \cap B)}{\mu(B)}$. Its distropy is

$$\mathcal{H}(\mathbf{P}|B) = \sum_{A \in \mathbf{P}} \log \left(\frac{1}{\mu(A \cap B)/\mu(B)} \right) \frac{\mu(A \cap B)}{\mu(B)} .$$

So conditioning \mathbf{P} on a *partition* \mathbf{Q} gives conditional distropy

$$\begin{aligned} \mathcal{H}(\mathbf{P}|\mathbf{Q}) &= \sum_{B \in \mathbf{Q}} \mathcal{H}(\mathbf{P}|B)\mu(B) \\ &= \sum_{A \in \mathbf{P}, B \in \mathbf{Q}} \log \left(\frac{1}{\mu(A \cap B)/\mu(B)} \right) \mu(A \cap B) . \end{aligned} \tag{9}$$

A “dartboard” interpretation of $\mathcal{H}(\mathbf{P}|\mathbf{Q})$ is

The expected number of questions to ascertain the \mathbf{P} -atom that a random dart $x \in X$ fell in, given that we are told its \mathbf{Q} -atom.

For a set $A \subset X$, use $\mathbf{1}_A : X \rightarrow \{0, 1\}$ for its *indicator function*; $\mathbf{1}_A(x) = 1$ IFF $x \in A$. The **information function** of partition P , a map $\mathcal{I}_P : X \rightarrow [0, \infty)$, is

$$\mathcal{I}_P := \sum_{A \in P} \log \left(\frac{1}{\mu(A)} \right) \mathbf{1}_A(\cdot). \tag{10}$$

The information function has been defined so that its expectation is the distropy of P ,

$$\mathbb{E}(\mathcal{I}_P) = \int_X \mathcal{I}_P(\cdot) d\mu = \mathcal{H}(P).$$

Conditioning on a Field

For a subfield $\mathcal{F} \subset \mathcal{X}$, recall that each function $g \in \mathbb{L}^1(\mu)$ has a *conditional expectation* $\mathbb{E}(g|\mathcal{F}) \in \mathbb{L}^1(\mu)$. It is the *unique* \mathcal{F} -measurable function with

$$\forall B \in \mathcal{F} : \int_B \mathbb{E}(g|\mathcal{F}) d\mu = \int_B g d\mu.$$

Returning to distropy ideas, use $\mu(A|\mathcal{F})$ for the **conditional probability** function; it is the conditional expectation $\mathbb{E}(\mathbf{1}_A|\mathcal{F})$. So the **conditional information function** is

$$\mathcal{I}_{P|\mathcal{F}}(x) := \sum_{A \in P} \log \left(\frac{1}{\mu(A|\mathcal{F}(x))} \right) \mathbf{1}_A(x). \tag{11}$$

Its integral

$$\mathcal{H}(P|\mathcal{F}) := \int \mathcal{I}_{P|\mathcal{F}} d\mu,$$

is the **conditional distropy** of P on \mathcal{F} .

When \mathcal{F} is the field of unions of atoms from some partition Q , then the number $\mathcal{H}(P|\mathcal{F})$ equals the $\mathcal{H}(P|Q)$ from Eq. (9).

Write $\mathcal{G}_j \nearrow \mathcal{F}$ to indicate that fields $\mathcal{G}_1 \subset \mathcal{G}_2 \subset \dots$ are nested, and that $\text{Fld}(\bigcup_1^\infty \mathcal{G}_j) = \mathcal{F}$, a.e. The Martingale Convergence Theorem (p. 103 in [20]) gives (c) below.

Conditional-Distropy Fact Consider partitions P, Q, R and fields \mathcal{F} and \mathcal{G}_j . Then

- (a) $0 \leq \mathcal{H}(P|\mathcal{F}) \leq \mathcal{H}(P)$, with equality IFF $P \stackrel{a.e.}{\subset} \mathcal{F}$, respectively, $P \perp \mathcal{F}$.
- (b) $\mathcal{H}(Q \vee R|\mathcal{F}) \leq \mathcal{H}(Q|\mathcal{F}) + \mathcal{H}(R|\mathcal{F})$.
- (c) Suppose $\mathcal{G}_j \nearrow \mathcal{F}$. Then $\mathcal{H}(P|\mathcal{G}_j) \searrow \mathcal{H}(P|\mathcal{F})$.
- (d) $\mathcal{H}(Q \vee R) = \mathcal{H}(Q|R) + \mathcal{H}(R)$.
- (d') $\mathcal{H}(Q \vee R_1|R_0) = \mathcal{H}(Q|R_1 \vee R_0) + \mathcal{H}(R_1|R_0)$.

Imagining our dartboard (Fig. 1) divided by superimposed partitions Q and R , equality (d) can be interpreted as saying: ‘You can efficiently discover where the dart landed

in both partitions, by first asking efficient questions about R , then – based on where it landed in R – asking intelligent questions about Q .’

Entropy of a Process

Consider a transformation $(T: X, \mu)$ and partition $P = (A_1, A_2, \dots)$. Each “time” n determines a partition $P_n := T^n P$, whose j th-atom is $T^{-n}(A_j)$. The **process** T, P refers to how T acts on the subfield $\bigvee_0^\infty P_n \subset \mathcal{X}$. (An alternative view of a process is as a stationary sequence V_0, V_1, \dots of random variables $V_n: X \rightarrow \mathbb{Z}_+$, where $V_n(x) := j$ because x is in the j th-atom of P_n .)

Write $\mathcal{E}(T, P)$ or $\mathcal{E}^T(P)$ for the “**entropy**” of the T, P process”. It is the limit of the **conditional-distropy-numbers**

$$c_n := \mathcal{H}(P_0|P_1 \vee P_2 \vee \dots \vee P_{n-1}).$$

This limit exists since $\mathcal{H}(P) = c_1 \geq c_2 \geq \dots \geq 0$.

Define the **average-distropy-number** $\frac{1}{n} h_n$, where

$$h_n := \mathcal{H}(P_0 \vee P_1 \vee \dots \vee P_{n-1}).$$

Certainly $h_n = c_n + \mathcal{H}(P_1 \vee \dots \vee P_{n-1}) = c_n + h_{n-1}$, since T is measure preserving. Induction gives $h_n = \sum_{j=1}^n c_j$. So the Cesàro averages $\frac{1}{n} h_n$ converge to the entropy.

Theorem 5 The entropy of process $(T, P: X, \mathcal{X}, \mu)$ equals

$$\begin{aligned} \lim_{n \rightarrow \infty} \frac{1}{n} \mathcal{H}(P_0 \vee \dots \vee P_{n-1}) \\ = \lim_{n \rightarrow \infty} \mathcal{H} \left(P_0 \middle| \bigvee_1^n P_j \right) = \mathcal{H} \left(P_0 \middle| \bigvee_1^\infty P_j \right). \end{aligned}$$

Both limits are non-increasing. The entropy $\mathcal{E}^T(P) \geq 0$, with equality IFF $P \subset \bigvee_1^\infty P_j$. And $\mathcal{E}^T(P) \leq \mathcal{H}(P)$, with equality IFF T, P is an independent process.

Generators

We henceforth only discuss *invertible* mpts, that is, when T^{-1} is itself an mpt. Viewing the atoms of P as “letters”, then, each $x \in X$ has a **T, P -name**

$$\dots x_{-2}x_{-1}x_0x_1x_2x_3 \dots,$$

where x_n is $P(T^n(x))$, the P -letter owning $T^n(x)$.

A partition P **generates** (the whole field) under $(T: X, \mu)$, if $\bigvee_{-\infty}^\infty T^n P =_\mu \mathcal{X}$. It turns out⁸ that

⁸I am now at liberty to reveal that our X has always been a **Lebesgue space**, that is, measure-isomorphic to an interval of \mathbb{R} to-

P generates IFF P *separates points*. That is, after deleting a (T -invariant) nullset, distinct points of X have distinct T, P -names.

A finite set $[1 \dots L]$ of integers, interpreted as an *alphabet*, yields the *shift space* $X := [1 \dots L]^{\mathbb{Z}}$ of doubly-infinite sequences $x = (\dots x_{-1}x_0x_1 \dots)$. The *shift* $T: X \rightarrow X$ acts on X by

$$T(x) := [n \mapsto x_{n+1}] .$$

The time-zero partition P separates points, under the action of the shift. This L -atom *time-zero partition* has $P(x) = P(y)$ IFF $x_0 = y_0$. So no matter what shift-invariant measure is put on X , the time-zero partition will generate under the action of T .

Time Reversibility

A transformation need not be isomorphic to its inverse. Nonetheless, the average-distropy-numbers show that $\mathcal{E}(T^{-1}, P) = \mathcal{E}(T, P)$; although this is not obvious from the conditioning-definition of entropy. Alternatively,

$$\begin{aligned} \mathcal{H} \left(P_0 \middle| \bigvee_1^n P_j \right) &= \mathcal{H}(P_0 \vee \dots \vee P_n) - \mathcal{H}(P_1 \vee \dots \vee P_n) \\ &= \mathcal{H}(P_{-n} \vee \dots \vee P_0) - \mathcal{H}(P_{-n} \vee \dots \vee P_{-1}) \\ &= \mathcal{H} \left(P_0 \middle| \bigvee_{-1}^{-n} P_j \right) . \end{aligned} \tag{12}$$

Bernoulli Processes

A probability vector $\vec{v} := (v_1, \dots, v_L)$ can be viewed as a measure on alphabet $[1 \dots L]$. Let $\mu_{\vec{v}}$ be the resulting product measure on $X := [1 \dots L]^{\mathbb{Z}}$, with T the shift on X and P the time-zero partition. The independent process $(T, P: X, \mu_{\vec{v}})$ is called, by ergodic theorists, a **Bernoulli process**. Not necessarily consistently, we tend to refer to the underlying *transformation* as a **Bernoulli shift**.

The $(\frac{1}{2}, \frac{1}{2})$ -Bernoulli and the $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ -Bernoulli have different process-entropies, but perhaps their underlying transformations are isomorphic? Prior to the Kol-

gether with countably many point-atoms (points with positive mass). The equivalence of *generating* and *separating* is a technical theorem, due to Rokhlin.

Assuming μ to be Lebesgue is not much of a limitation. For instance, if μ is a finite measure on any Polish space, then μ extends to a Lebesgue measure on the μ -completion of the Borel sets. To not mince words: All spaces are Lebesgue spaces unless you are actively looking for trouble.

mogorov–Sinai definition of entropy⁹ of a *transformation*, this question remained unanswered.

Entropy of a Transformation

The Kolmogorov–Sinai definition of the entropy of an mpt is

$$\mathcal{E}(T) := \sup\{\mathcal{E}^T(Q) \mid Q \text{ a partition on } X\} .$$

Certainly entropy is an isomorphism invariant – but is it useful? After all, the supremum of *distropies* of partitions is always infinite (on non-atomic spaces) and one might fear that the same holds for entropies. The key observation (re-stated in Lemma 8c and proved below) was this, from [4] and [7].

Theorem 6 (Kolmogorov–Sinai Theorem) *If P generates under T , then $\mathcal{E}(T) = \mathcal{E}(T, P)$.*

Thereupon the $(\frac{1}{2}, \frac{1}{2})$ and $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ Bernoulli-shifts are *not* isomorphic, since their respective entropies are $\log(2) \neq \log(3)$.

Wolfgang Krieger later proved a converse to the Kolmogorov–Sinai theorem.

Theorem 7 (Krieger Generator Theorem, 1970) *Suppose T ergodic. If $\mathcal{E}(T) < \infty$, then T has a generating partition. Indeed, letting K be the smallest integer $K > \mathcal{E}(T)$, there is a K -atom generator.¹⁰*

Proof See Rudolph [21], or § 5.1 in ► [Joinings in Ergodic Theory](#), where Krieger’s theorem is stated in terms of joinings. □

Entropy Is Continuous

Given *ordered* partitions $Q = (B_1, \dots)$ and $Q' = (B'_1, \dots)$, extend the shorter by null-atoms until $|Q| = |Q'|$. Let $Fat := \bigsqcup_j [B_j \cap B'_j]$; this set should have mass close to 1 if Q and Q' are almost the same partition. Define a new partition

$$Q \triangle Q' := \{Fat\} \sqcup \{B_i \cap B'_j \mid \text{with } i \neq j\} .$$

(In other words, take $Q \vee Q'$ and coalesce, into a single atom, all the $B_k \cap B'_k$ sets.) Topologize the space of parti-

⁹This is sometimes called *measure(-theoretic) entropy* or (perhaps unfortunately) *metric entropy*, to distinguish it from topological entropy. Tools known prior to entropy, such as *spectral* properties, did *not* distinguish the two Bernoulli-shifts; see ► [Spectral Theory of Dynamical Systems](#) for the definitions.

¹⁰It is an easier result, undoubtedly known much earlier, that every ergodic T has a *countable* generating partition – possibly of ∞ -distropy.

tions by saying¹¹ that $Q^{(L)} \rightarrow Q$ when $\mathcal{H}(Q \Delta Q^{(L)}) \rightarrow 0$. Then Lemma 8b says that process-entropy varies continuously with varying the partition.

Lemma 8 Fix a mpt $(T : X, \mu)$. For partitions P, Q, Q' , define $R := Q \Delta Q'$ and let $\delta := \mathcal{H}(R)$. Then

- (a) $|\mathcal{H}(Q) - \mathcal{H}(Q')| \leq \delta$. (Distropy varies continuously with the partition.)
- (b) $|\mathcal{E}^T(Q) - \mathcal{E}^T(Q')| \leq \delta$. (Process-entropy varies continuously with the partition.)
- (c) For all partitions $Q \subset \text{Fld}(T, P)$: $\mathcal{E}^T(Q) \leq \mathcal{E}^T(P)$.

Proof (of (a)) Evidently $Q' \vee R = Q' \vee Q = Q \vee R$. So $\mathcal{H}(Q') \leq \mathcal{H}(Q \vee R) \leq \mathcal{H}(Q) + \delta$. \square

Proof (of (b)) As above,

$$\mathcal{H}\left(\bigvee_1^N Q'_j\right) \leq \mathcal{H}\left(\bigvee_1^N Q_j\right) + \mathcal{H}\left(\bigvee_1^N R_j\right).$$

Sending $N \rightarrow \infty$ gives $\mathcal{E}^T(Q') \leq \mathcal{E}^T(Q) + \mathcal{E}^T(R)$. Finally, $\mathcal{E}^T(R) \leq \mathcal{H}(R)$ and so $\mathcal{E}^T(Q') \leq \mathcal{E}^T(Q) + \delta$. \square

Proof (of (c)) Let $K := |Q|$. Then there is a sequence of K -set partitions $Q^{(L)} \rightarrow Q$ with $Q^{(L)} \preceq \bigvee_{-L}^L P_\ell$. By above, $\mathcal{E}^T(Q^{(L)}) \rightarrow \mathcal{E}^T(Q)$, so showing that

$$\mathcal{E}^T\left(\bigvee_{-L}^L P_\ell\right) \stackrel{?}{\leq} \mathcal{E}^T(P)$$

will suffice. Note that

$$h_N := \mathcal{H}\left(\bigvee_{n=0}^{N-1} T^n \left(\bigvee_{-L}^L P_\ell\right)\right) = \mathcal{H}\left(\bigvee_{j=-L}^{N-1+L} P_j\right).$$

So $\frac{1}{N} h_N \leq \frac{1}{N} \mathcal{H}\left(\bigvee_0^{N-1} P_j\right) + \frac{1}{N} 2L\mathcal{H}(P)$. Now send $N \rightarrow \infty$. \square

Entropy Is Not Continuous

The most common topology placed on the space Ω of mpts is the *coarse topology*¹² that Halmos discusses in his “little red book” [14].

¹¹On the set of ordered K -set partitions (with K fixed) this convergence is the same as: $Q^{(L)} \rightarrow Q$ when $\mu(\text{Fat}(Q^{(L)}, Q)) \rightarrow 1$.

An alternative approach is the **Rokhlin metric**, $\text{Dist}(P, Q) := \mathcal{H}(P|Q) + \mathcal{H}(Q|P)$, which has the advantage of working for *un-ordered* partitions.

¹²i.e., $S_n \rightarrow T$ IFF $\forall A \in \mathcal{X} : \mu(S_n^{-1}(A) \Delta T^{-1}(A)) \rightarrow 0$; this is a metric-topology, since our probability space is countably generated. This can be restated in terms of the unitary operator U_T on $\mathbb{L}^2(\mu)$, where $U_T(f) := f \circ T$. Namely, $S_n \rightarrow T$ in the coarse topology IFF $U_{S_n} \rightarrow U_T$ in the strong operator topology.

The Rokhlin lemma (see p. 33 in [21]) implies that the isomorphism-class of *each* ergodic mpt is *dense* in Ω , (e.g., see p. 77 in [14]) disclosing that the $S \mapsto \mathcal{E}(S)$ map is ex-orbitantly discontinuous.

Indeed, the failure happens already for process-entropy with respect to a fixed partition. A Bernoulli process T, P has positive entropy. Take mpts $S_n \rightarrow T$, each isomorphic to an irrational rotation. Then each $\mathcal{E}(S_n, P)$ is zero, as shown in the later section “**Determinism and Zero-Entropy**”.

Further Results When \mathcal{F} is a T -invariant subfield, agree to use $T \upharpoonright_{\mathcal{F}}$ for “ T restricted to \mathcal{F} ”, which is a factor (see Glossary) of T . Transformations T and S are **weakly isomorphic** if each is isomorphic to a factor of the other.

The foregoing entropy tools make short shrift of the following.

Lemma 9 (Entropy Lemma) Consider T -invariant subfields \mathcal{G}_j and \mathcal{F} .

- (a) Suppose $\mathcal{G}_j \nearrow \mathcal{F}$. Then $\mathcal{E}T \upharpoonright_{\mathcal{G}_j} \nearrow \mathcal{E}(T \upharpoonright_{\mathcal{F}})$. In particular, $\mathcal{G} \subset \mathcal{F}$ implies that $\mathcal{E}(T \upharpoonright_{\mathcal{G}}) \leq \mathcal{E}(T \upharpoonright_{\mathcal{F}})$, so entropy is an invariant of weak-isomorphism.
- (b) $\mathcal{E}(T \upharpoonright_{\mathcal{G}_1 \vee \mathcal{G}_2 \vee \dots}) \leq \sum_j \mathcal{E}(T \upharpoonright_{\mathcal{G}_j})$.
And $\mathcal{E}(T, Q_1 \vee Q_2 \vee \dots) \leq \sum_j \mathcal{E}(T, Q_j)$.
- (c) For mpts $(S_j : Y_j, \nu_j)$: $\mathcal{E}(S_1 \times S_2 \times \dots) = \sum_j \mathcal{E}(S_j)$.
- (d) $\mathcal{E}(T^{-1}) = \mathcal{E}(T)$. More generally, $\mathcal{E}(T^n) = |n| \cdot \mathcal{E}(T)$.

Meshalkin’s Map

In the wake of Kolmogorov’s 1958 entropy paper, for two Bernoulli-shifts to be isomorphic one now knew that they had to have equal entropies. Meshalkin provided the first non-trivial example in 1959 [45].

Let $S : Y \rightarrow Y$ be the Bernoulli-shift over the “letter” alphabet $\{E, D, P, N\}$, with probability distribution $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$. The letters E, D, P, N stand for *Even, oDd, Positive, Negative*, and will be used to describe the code (isomorphism) between the processes.

Use $T : X \rightarrow X$ for the Bernoulli-shift over “digit” alphabet $\{0, +1, -1, +2, -2\}$, with probability distribution $(\frac{1}{2}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8})$. Both distributions $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$ and $(\frac{1}{2}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8})$ have distropy $\log(4)$.

After deleting invariant nullsets from X and Y , the construction will produce a measure-preserving isomorphism $\psi : X \rightarrow Y$ so that $T \circ \psi = \psi \circ S$.

The Code In X , consider this point x :

... 0 0 0 -1 0 0 +1 +2 -1 +1 0 ...

Regard each 0 as a left-parenthesis, and each non-zero as a right-parenthesis. Link them according to the legal way of matching parentheses, as shown in the top row, below:

0 0 0 -1 0 0 +1 +2 -1 +1 0
 P N N D P P D E D D ?

The leftmost 0 is linked to the rightmost +1, as indicated by the longest-overbar. The left/right-parentheses form a $(\frac{1}{2}, \frac{1}{2})$ -random-walk. Since this random walk is recurrent, every position in x will be linked (except for a nullset of points x).

Below each 0, write “P” or “N” as the 0 is linked to a positive or negative digit. And below the other digits, write “E” or “D” as the digit is even or odd. So the upper name in X is mapped to the lower name, a point $y \in Y$.

This map $\psi: X \rightarrow Y$ carries the upstairs $(\frac{1}{2}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8})$ distribution to $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$, downstairs. It takes some arguing to show that independence is preserved.

The inverse map ψ^{-1} views D and E as right-parentheses, and P and N as left. Above D, write the odd digit +1 or -1, as this D is linked to Positive or Negative.

Markov Shifts

A Bernoulli process T, P has independence $P_{(-\infty \dots 0]} \perp P_1$ whereas a **Markov process** is a bit less aloof:

The infinite Past $P_{(-\infty \dots 0]}$ doesn’t provide any more information about Tomorrow than Today did.

That is, the conditional distribution $P_1 | P_{(-\infty \dots 0]}$ equals $P_1 | P_0$. Equivalently,

$$\mathcal{H}(P_1 | P_0) = \mathcal{H}(P_1 | P_{(-\infty \dots 0]}) \stackrel{\text{note}}{=} \mathcal{E}(T, P). \tag{13}$$

The simplest non-trivial Markov process $(T, P: X, \mu)$ is over a two-letter alphabet $\{a, b\}$, and has transition graph Fig. 4, for some choice of transition probabilities s and c . The graph’s Markov matrix is

$$M = [m_{i,j}]_{i,j} = \begin{bmatrix} s & c \\ 1 & 0 \end{bmatrix},$$

where $c = 1 - s$, and $m_{i,j}$ denotes the probability of going from state i to state j .

If Today’s distribution on the two states is the probability-vector $\vec{v} := [p_a \ p_b]$, then Tomorrow’s is the product $\vec{v}M$. So a *stationary* process needs $\vec{v}M = \vec{v}$. This equation has the unique solution $p_a = \frac{1}{1+c}$ and $p_b = \frac{c}{1+c}$. An example of computing the probability of a word or

Entropy in Ergodic Theory, Figure 4

Call the transition probabilities $s := \text{Prob}(a \rightarrow a)$ for stay, and $c := \text{Prob } a \rightarrow b$ for change. These are non-negative reals, and $s + c = 1$

cylinder set; (see Sect. “The Carathéodory Construction” in **► Measure Preserving Systems**) in the process, is

$$\begin{aligned} \mu_s(\text{baaaba}) &= p_b m_{ba} m_{aa} m_{aa} m_{ab} m_{ba} \\ &= \frac{c}{1+c} \cdot 1 \cdot s \cdot s \cdot c \cdot 1. \end{aligned}$$

The subscript on μ_s indicates the dependence on the transition probabilities; let’s also mark the mpt and call it T_s . Using Eq. (13), the entropy of our Markov map is

$$\begin{aligned} \mathcal{E}(T_s) &= p_a \cdot \mathcal{H}(s, c) + p_b \cdot \underbrace{\mathcal{H}(1, 0)}_{=0} \\ &= \frac{-1}{1+c} \cdot [s \log(s) + c \log(c)]. \end{aligned} \tag{14}$$

Determinism and Zero-Entropy

Irrational rotations have zero-entropy; let’s reveal this in two different ways.

Equip $X := [0, 1)$ with “length” (Lebesgue) measure and wrap it into a circle. With “ \oplus ” denoting addition mod-1, have $T: X \rightarrow X$ be the rotation $T(x) := x \oplus \alpha$, where the rotation number α is irrational. Pick distinct points $y_0, z_0 \in X$, and let P be the partition whose two atoms are the intervals $[y_0, z_0)$ and $[z_0, y_0)$, wrapping around the circle.

The T -orbit of each point x is dense¹³ in X . In particular, y_0 has dense orbit, so P separates points – hence generates – under T . Our goal, thus, is $\mathcal{E}(T, P) \stackrel{?}{=} 0$.

Rotations are Deterministic

The forward T -orbit of each point is dense. This is true for y_0 , and so the *backward* T, P -name of each x actually tells us which point x is. I. e., $P \subset \bigvee_{-\infty}^{-1} T^n P$, which is our definition of “process T, P is **deterministic**”. Our P being finite, this determinism implies that $\mathcal{E}(T, P)$ is zero, by Theorem 5.

¹³Fix an $\varepsilon > 0$ and an $N > 1/\varepsilon$. Points $x, T(x), \dots, T^N(x)$ have some two at distance less than $\frac{1}{N}$; say, $\text{Dist}(T^i(x), T^j(x)) < \varepsilon$, for some $0 \leq i < j \leq N$. Since T is an isometry, $\varepsilon > \text{Dist}(x, T^k(x)) > 0$, where $k := j - i$. So the T^k -orbit of x is ε -dense.

Counting Names in a Rotation The $P_0 \vee \dots \vee P_{n-1}$ partition places n translates of points y_0 and of z_0 , cutting the circle into at most $2n$ intervals. Thus $\mathcal{H}(P_0 \vee \dots \vee P_{n-1}) \leq \log(2n)$. And $\frac{1}{n} \log(2n) \rightarrow 0$.

Alternatively, the below SMB-theorem implies, for an ergodic process T, P , that the number of length- n names is approximately $2^{\mathcal{E}(T,P) \cdot n}$, this, after discarding small mass from the space. But the growth of $n \mapsto 2n$ is sub-exponential and so, for our rotation, $\mathcal{E}(T, P)$ must be zero.

Theorem 10 (Shannon–McMillan–Breiman Theorem (SMB-Theorem)) Set $E := \mathcal{E}(T, P)$, where the tuple $(T, P: X, \mu)$ is an ergodic process. Then the average information function

$$\frac{1}{n} \mathcal{I}_{P_{[0..n]}}(x) \xrightarrow{n \rightarrow \infty} E, \quad \text{for a.e. } x \in X. \quad (15)$$

The functions $f_n := \mathcal{I}_{P_{[0..n]}}$ converge to the constant function E both in the \mathbb{L}^1 -norm and in probability.¹⁴

Proof See the texts of Karl Petersen (p. 261 in [20]), or Dan Rudolph (p. 77 in [21]). □

Consequences Recall that $P_{[0..n]}$ means $P_0 \vee P_1 \vee \dots \vee P_{n-1}$, where $P_j := T^j P$. As usual, $P_{[0..n]} \langle x \rangle$ denotes the $P_{[0..n]}$ -atom owning x .

Having deleted a nullset, we can restate Eq. (15) to now say that $\forall \varepsilon, \forall x, \forall \text{large } n$:

$$1/2^{[E+\varepsilon]n} \leq \mu(P_{[0..n]} \langle x \rangle) \leq 1/2^{[E-\varepsilon]n}. \quad (16)$$

This has the following consequence. Fixing a number $\delta > 0$, we consider any set with $\mu(B) \geq \delta$ and count the number of n -names of points in B . The SMB-Thm implies

$$\forall \varepsilon, \forall \text{large } n, \forall B \geq \delta : |\{n\text{-names in } B\}| \geq 2^{[E-\varepsilon]n}. \quad (17)$$

Rank-1 Has Zero-Entropy

There are several equivalent definitions for “rank-1 transformation”, several of which are discussed in the introduction of [28]. (See Chap. 6 in [13] as well as [51] and [27] for examples of stacking constructions.)

A **rank-1 transformation** $(T: X, \mu)$ admits a generating partition P and a sequence of Rokhlin stacks $S_n \subset X$, with heights going to ∞ , and with $\mu(S_n) \rightarrow 1$. Moreover, each of these Rokhlin stacks is P -monochromatic, that is, each level of the stack lies entirely in some atom of P .

Taking a stack of some height $2n$, let $B = B_n$ be the union of the bottom n levels of the stack. There are at most

n many length- n names starting in B_n , by monochromaticity. Finally, $\mu(B_n)$ is almost $\frac{1}{2}$, so is certainly larger than $\delta := \frac{1}{3}$. Thus Eq. (17) shows that our rank-1 T has zero entropy.

Cautions on Determinism’s Relation to Zero-Entropy

A finite-valued process T, P has zero-entropy iff $P \subset \bigvee_{-\infty}^{-1} P_j$. Iterating gives

$$\bigvee_0^{\infty} P_j \subset \bigvee_{-\infty}^{-1} P_j,$$

i. e., the future is measurable with respect to the past.

This was the case with the rotation, where a point’s past uniquely identified the point, thus telling us its future.

While determinism and zero-entropy mean the same thing for finite-valued processes, this fails catastrophically for real-valued (i. e., continuum-valued) processes, as shown by an example of the author’s. A stationary real-valued process $V = \dots V_{-1} V_0 V_1 V_2 \dots$ is constructed in [40] which is simultaneously

strongly deterministic: The two values V_0, V_1 determine all of V , future and past.

and **non-consecutively independent**. This latter means that for each bi-infinite increasing integer sequence $\{n_j\}_{j=-\infty}^{\infty}$ with no consecutive pair (always $1 + n_j < n_{j+1}$), then the list of random variables $\dots V_{n_{-1}} V_{n_0} V_{n_1} V_{n_2} \dots$ is an independent process.

Restricting the random variables to be countably-valued, how much of the example survives? Joint work with Kalikow [39] produced a countably-valued stationary V which is non-consecutively independent as well as deterministic. (Strong determinism is ruled out, due to cardinality considerations.) A side-effect of the construction is that V ’s time-reversal $n \mapsto V_{-n}$ is **not** deterministic.

The Pinsker–Field and K-Automorphisms

Consider the collection of **zero-entropy sets**,

$$\mathcal{Z} = \mathcal{Z}_T := \{A \in \mathcal{X} \mid \mathcal{E}(T, (A, A^c)) = 0\}. \quad (18)$$

Courtesy of Lemma 9b, \mathcal{Z} is a T -invariant field, and

$$\forall Q \subset \mathcal{Z}: \mathcal{E}(T, Q) = 0. \quad (19)$$

The **Pinsker field**¹⁵ of T is this \mathcal{Z} . It is maximal with respect to Eq. (19). Unsurprisingly, the **Pinsker factor** $T \upharpoonright_{\mathcal{Z}}$ has

¹⁴In engineering circles, this is called the Almost-everywhere equipartition theorem.

¹⁵Traditionally, this called the *Pinsker algebra* where, in this context, “algebra” is understood to mean “ σ -algebra”.

zero entropy, that is, $\mathcal{E}(T \upharpoonright_{\mathcal{Z}}) = 0$. A transformation T is said to have **completely-positive entropy** if it has no (non-trivial) zero-entropy factors. That is, its Pinsker field \mathcal{Z}_T is the trivial field, $\emptyset := \{\emptyset, X\}$.

K-Processes

Kolmogorov introduced the notion of a **K-process** or **Kolmogorov process**, in which the present becomes asymptotically independent of the distant past. The asymptotic past of the T, P process is called its **tail field**, where

$$\text{Tail}(T, P) := \bigcap_{M=1}^{\infty} \bigvee_{j=-\infty}^{-M} P_j .$$

This T, P is a K-process if $\text{Tail}(T, P) = \emptyset$. This turns out to be equivalent to what we might call a strong form of “sensitive dependence on initial conditions”: For each fixed length L , the distant future

$$\bigvee_{j \in (G \dots G+L]} P_j$$

becomes more and more independent of

$$\bigvee_{j \in (-\infty \dots 0]} P_j ,$$

as the gap $G \rightarrow \infty$.

A transformation T is a **Kolmogorov automorphism** if it possesses a generating partition P for which T, P is a K-process.

Here is a theorem that relates the “asymptotic forgetfulness” of $\text{Tail}(T, P) = \emptyset$, to the lack of determinism implied by having no zero-entropy factors (See Walters, [23], p. 113. Related results appear in Berg [44]).

Theorem 11 (Pinsker-Algebra Theorem) *Suppose P is a generating partition for an ergodic T . Then $\text{Tail}(T, P)$ equals \mathcal{Z}_T .*

Since \mathcal{Z}_T does not depend on P , this means that all generating partitions have the same tail field, and therefore K-ness of T can be detected from any generator.

Another non-evident fact follows from the above. The **future field** of T, P is defined to be $\text{Tail}(T^{-1}P)$. It is not obvious that if the present is independent of the distant past, then it is automatically independent of the distant future. (Indeed, the precise definitions are important; witness the *Cautions on determinism* section.) But since the entropy of a process, $\mathcal{E}(T, (A, A^c))$, equals the entropy of the time-reversed process $\mathcal{E}(T^{-1}, (A, A^c))$, it follows that \mathcal{Z}_T equals $\mathcal{Z}_{T^{-1}}$.

Ornstein Theory

In 1970, Don Ornstein [46] solved the long-standing problem of showing that entropy was a complete isomorphism-invariant of Bernoulli transformations; that is, that two independent processes with same entropy necessarily have the same underlying transformation. (Earlier, Sinai [52]) had shown that two such Bernoulli maps were **weakly isomorphic**, that is, each isomorphic to a factor of the other.)

Ornstein introduced the notion of a process being **finitely determined**, see [46] for a definition, proved that a transformation T was Bernoulli IFF it had a finitely-determined generator IFF every partition was finitely-determined with respect to T , and showed that entropy completely classified the finitely-determined processes up to isomorphism.

This seminal result led to a vast machinery for proving transformations to be Bernoulli, as well as classification and structure theorems [47,51,53]. Showing that the class of K-automorphisms far exceeds the Bernoulli maps, Ornstein and Shields produced in [48] an uncountable family of non-isomorphic K-automorphisms all with the same entropy.

Topological Entropy

Adler, Konheim and McAndrew, in 1965, published the first definition of *topological entropy* in the eponymous article [33]. Here, $T: X \rightarrow X$ is a continuous self-map of a compact topological space. The role of atoms is played by open sets. Instead of a finite partition, one uses a finite¹⁶ **open-cover** $\mathcal{V} = \{U_j\}_{j=1}^L$, i. e. each **patch** U_j is open, and their union $\bigcup(\mathcal{V}) = X$. (Henceforth, ‘cover’ means “open cover”.)

Let $\text{Card}(\mathcal{V})$ be the *minimum* cardinality over all sub-covers.

$$\text{Card}(\mathcal{V}) := \text{Min} \{ \# \mathcal{V}' \mid \mathcal{V}' \subset \mathcal{V} \text{ and } \bigcup(\mathcal{V}') = X \} ,$$

and let

$$\mathcal{H}(\mathcal{V}) = \mathcal{H}_{\text{top}}(\mathcal{V}) := \log(\text{Card}(\mathcal{V})) .$$

Analogous to the definitions for partitions, define

$$\mathcal{V} \vee \mathcal{W} := \{ V \cap W \mid V \in \mathcal{V} \text{ and } W \in \mathcal{W} \} ;$$

$$T\mathcal{V} := \{ T^{-1}(U) \mid U \in \mathcal{V} \}$$

$$\text{and } \mathcal{V}_{[0 \dots n]} := \mathcal{V}_0 \vee \mathcal{V}_1 \vee \dots \vee \mathcal{V}_{n-1} ;$$

$$\mathcal{W} \succcurlyeq \mathcal{V} , \text{ if each } \mathcal{W}\text{-patch is a subset of some } \mathcal{V}\text{-patch.}$$

¹⁶Because we only work on a compact space, we can omit “finite”. Some generalizations of topological entropy to non-compact spaces require that only *finite* open-covers be used [37].

The T, \mathcal{V} -entropy is

$$\begin{aligned} \mathcal{E}^T(\mathcal{V}) &= \mathcal{E}(T, \mathcal{V}) = \mathcal{E}_{\text{top}}(T, \mathcal{V}) \\ &:= \limsup_{n \rightarrow \infty} \frac{1}{n} \mathcal{H}_{\text{top}}(\mathcal{V}_{[0\dots n]}) . \end{aligned} \tag{20}$$

And the **topological entropy** of T is

$$\mathcal{E}_{\text{top}}(T) := \sup_{\mathcal{V}} \mathcal{E}_{\text{top}}(T, \mathcal{V}) , \tag{21}$$

taken over all open covers \mathcal{V} .

Thus \mathcal{E}_{top} counts, in some sense, the growth rate in the number of T -orbits of length n .

Evidently, topological entropy is an isomorphism invariant. Two continuous maps $T: X \rightarrow X$ and $S: Y \rightarrow Y$ are **topologically conjugate** (as *isomorphism* is called in this category) if there exists a homeomorphism $\psi: X \rightarrow Y$ with $\psi T = S\psi$.

Lemma 12 (Subadditive Lemma) *Consider a sequence $\mathbf{s} = (s_l)_1^\infty \subset [-\infty, \infty]$ satisfying $s_{k+l} \leq s_k + s_l$, for all $k, l \in \mathbb{Z}$. Then the following limit exists in $[-\infty, \infty]$, and $\lim_{n \rightarrow \infty} \frac{s_n}{n} = \inf_n \frac{s_n}{n}$.*

Topological entropy, or “**top ent**” for short, satisfies many of the relations of measure-entropy.

Lemma 13

(a) $\mathcal{V} \preceq \mathcal{W}$ implies

$$\mathcal{H}(\mathcal{V}) \leq \mathcal{H}(\mathcal{W}) \quad \text{and} \quad \mathcal{E}(T, \mathcal{V}) \leq \mathcal{E}(T, \mathcal{W}) .$$

(b) $\mathcal{H}(\mathcal{V} \vee \mathcal{W}) \leq \mathcal{H}(\mathcal{V}) + \mathcal{H}(\mathcal{W})$.

(c) $\mathcal{H}(T(\mathcal{V})) \leq \mathcal{H}(\mathcal{V})$, with equality if T is surjective. Also, $\mathcal{E}(T, \mathcal{V}) \leq \mathcal{H}(\mathcal{V})$.

(d) In Eq. (20), the $\lim_{n \rightarrow \infty} \frac{1}{n} \mathcal{H}(\mathcal{V}_{[0\dots n]})$ exists.

(e) Suppose T is a homeomorphism. Then

$$\mathcal{E}(T^{-1}, \mathcal{V}) = \mathcal{E}(T, \mathcal{V}) ,$$

for each cover \mathcal{V} . Consequently, $\mathcal{E}_{\text{top}}(T^{-1}) = \mathcal{E}_{\text{top}}(T)$.

(f) Suppose \mathcal{C} is a collection of covers such that: For each cover \mathcal{W} , there exists a $\mathcal{V} \in \mathcal{C}$ with $\mathcal{V} \preceq \mathcal{W}$. Then $\mathcal{E}_{\text{top}}(T)$ equals the supremum of $\mathcal{E}_{\text{top}}(T, \mathcal{V})$, just taken over those $\mathcal{V} \in \mathcal{C}$.

(g) For all $\ell \in \mathbb{N}$:

$$\mathcal{E}_{\text{top}}(T^\ell) = \ell \mathcal{E}_{\text{top}}(T) .$$

Proof (of (c)) Let $\mathcal{C} \preceq \mathcal{V}$ be a min-cardinality subcover. Then $T\mathcal{C}$ is a subcover of $T\mathcal{V}$. So $\text{Card } T\mathcal{V} \leq |T\mathcal{C}| = |\mathcal{C}|$.

As for entropy, inequality (b) and the foregoing give $\mathcal{H}(\mathcal{V}_{[0\dots n]}) \leq \mathcal{H}(\mathcal{V})n$. \square

Proof (of (d)) Set $s_n := \mathcal{H}(\mathcal{V}_{[0\dots n]})$. Then

$$s_{k+l} \leq s_k + \mathcal{H}(T^k(\mathcal{V}_{[0\dots l]})) \leq s_k + s_l ,$$

by (b) and (c), and so the Subadditive Lemma 12, applies. \square

Proof (of (g)) WLOG, $\ell = 3$. Given \mathcal{V} a cover, triple it to $\widehat{\mathcal{V}} := \mathcal{V} \cap T\mathcal{V} \cap T^2\mathcal{V}$; so

$$\bigvee_{j \in [0\dots 3N]} [T^3]^j(\widehat{\mathcal{V}}) = \bigvee_{i \in [0\dots 3N]} T^i(\mathcal{V}) .$$

Thus $\mathcal{H}(T^3, \widehat{\mathcal{V}}, N) = \mathcal{H}(T, \mathcal{V}, 3N)$, extending notation.

Part (d) and sending $N \rightarrow \infty$, gives $\mathcal{E}(T^3, \widehat{\mathcal{V}}) = 3\mathcal{H}(T, \mathcal{V})$.

Lastly, take covers such that

$$\mathcal{E}(T^3, \mathcal{C}^{(k)}) \rightarrow \mathcal{E}_{\text{top}}(T^3) \quad \text{and}$$

$$\mathcal{E}(T, \mathcal{D}^{(k)}) \rightarrow \mathcal{E}_{\text{top}}(T) ,$$

as $k \rightarrow \infty$. Define $\mathcal{V}^{(k)} := \mathcal{C}^{(k)} \vee \mathcal{D}^{(k)}$. Apply the above to $\mathcal{V}^{(k)}$, then send $k \rightarrow \infty$. \square

Using a Metric

From now on, our space is a compact metric space (X, d) .

Dinaburg [36] and Bowen [34,35], gave alternative, equivalent, definitions of topological entropy, in the compact metric-space case, that are often easier to work with than covers. Bowen gave a definition also when X is not compact¹⁷ (see [35] and Chap. 7 in [23]).

Metric Preliminaries An ε -ball-cover comprises finitely many balls, all of radius ε . Since our space is compact, every cover \mathcal{V} has a **Lebesgue number** $\varepsilon > 0$. I. e., for each $z \in X$, the $\text{Bal}(z, \varepsilon)$ lies entirely inside at least one \mathcal{V} -patch. (In particular, there is an ε -ball-cover which refines \mathcal{V} .) Let $\text{LEB}(\mathcal{V})$ be the supremum of the Lebesgue numbers. Courtesy of Lemma 13f we can

Fix a “universal” list $\mathcal{V}^{(1)} \preceq \mathcal{V}^{(2)} \preceq \dots$, with $\mathcal{V}^{(k)}$ a $\frac{1}{k}$ -ball-cover. For every $T: X \rightarrow X$, then, the $\lim_k \mathcal{E}(T, \mathcal{V}^{(k)})$ computes $\mathcal{E}_{\text{top}}(T)$.

¹⁷When X is not compact, the definitions need not coincide; e. g. [37]. And topologically-equivalent metrics, but which are not uniformly equivalent, may give the same T different entropies (see p. 171 in [23]).

An ε -Microscope Three notions are useful in examining a metric space (X, m) at scale ε . Subset $A \subset X$ is an ε -**separated-set**, if $m(z, z') \geq \varepsilon$ for all distinct $z, z' \in A$. Subset $F \subset X$ is ε -**spanning** if $\forall x \in X, \exists z \in F$ with $m(x, z) < \varepsilon$.

Lastly, a cover \mathcal{V} is ε -**small** if $\text{Diam}(U) < \varepsilon$, for each $U \in \mathcal{V}$.

You Take the High Road and I'll Take the Low Road

There are several routes to computing top-ent, some via maximization, others, minimization. Our foregoing discussion computed $\mathcal{E}_{\text{top}}(T)$ by a family of **sizes** $f_k(n) = f_k^T(n)$, depending on a parameter k which specifies the fineness of scale. (In Sect. "Metric Preliminaries", this k is an integer; in the original definition, an open cover.) Define two numbers:

$$\begin{aligned} \widehat{L}^f(k) &:= \limsup_{n \rightarrow \infty} \frac{1}{n} \log f_k(n) \quad \text{and} \\ \underline{L}^f(k) &:= \liminf_{n \rightarrow \infty} \frac{1}{n} \log f_k(n). \end{aligned} \tag{22}$$

Finally, let $\mathcal{E}^f(T) := \sup_k \widehat{L}^f(k)$. If the limit exists in Eq. (22) then agree to write $L^f(k)$ for the common value.

The A-K-M definition used the size $f_{\mathcal{V}}(n) := \text{Card}(\mathcal{V}_{[0 \dots n]})$, where

$$\text{Card}(\mathcal{W}) := \text{Minimum cardinality of a subcover from } \mathcal{W}.$$

Here are three metric-space sizes $f_{\varepsilon}(n)$:

$$\text{Sep}(n, \varepsilon) := \text{Maximum cardinality of a } d_{n-\varepsilon}\text{-separated set.}$$

$$\text{Spn}(n, \varepsilon) := \text{Minimum cardinality of a } d_{n-\varepsilon}\text{-spanning set.}$$

$$\text{Cov}(n, \varepsilon) := \text{Minimum cardinality of a } d_{n-\varepsilon}\text{-small cover.}$$

These use a list $(d_n)_{n=1}^{\infty}$ of progressively finer metrics on X , where

$$d_N(x, y) := \text{Max}_{j \in [0 \dots N]} d(T^j(x), T^j(y)).$$

Theorem 14 (All-Roads-Lead-to-Rome Theorem) Fix ε and let \mathcal{W} be any d - ε -small cover. Then

- (i) $\forall n$: $\text{Cov}(n, 2\varepsilon) \leq \text{Spn}(n, \varepsilon) \leq \text{Sep}(n, \varepsilon) \leq \text{Card}(\mathcal{W}_{[0 \dots n]})$.
- (ii) Take a cover \mathcal{V} and a $\delta < \text{LEB}(\mathcal{V})$. Then $\forall n$: $\text{Card}(\mathcal{V}_{[0 \dots n]}) \leq \text{Cov}(n, \delta)$.
- (iii) The limit $L^{\text{Cov}}(\varepsilon) = \lim_n \frac{1}{n} \log(\text{Cov}(n, \varepsilon))$ exists in $[0 \dots \infty)$.

(iv)

$$\mathcal{E}^{\text{Sep}}(T) = \mathcal{E}^{\text{Spn}}(T) = \mathcal{E}^{\text{Cov}}(T) = \mathcal{E}^{\text{Card}}(T) \stackrel{\text{by defn}}{=} \mathcal{E}_{\text{top}}(T).$$

Proof (of (i)) Take $F \subset X$, a min-cardinality $d_{n-\varepsilon}$ -spanning set. So $\bigcup_{z \in F} D_z = X$, where

$$D_z := d_n\text{-Bal}(z, \varepsilon) \stackrel{\text{note}}{=} \bigcap_{j=0}^{n-1} T^{-j} \left(\text{Bal}(T^j z, \varepsilon) \right).$$

This $\mathcal{D} := \{D_z\}_z$ is a cover, and it is $d_{n-2\varepsilon}$ -small. Thus $\text{Cov}(n, 2\varepsilon) \leq |\mathcal{D}| = |F|$.

For any metric, a *maximal* ε -separated-set is automatically ε -spanning; adjoin a putative unspanned point to get a larger separated set.

Let A be a max-cardinality $d_{n-\varepsilon}$ -separated set. Take \mathcal{C} , a min-cardinality subcover of $\mathcal{W}_{[0 \dots n]}$. For each $z \in A$, pick a \mathcal{C} -patch $C_z \ni z$. Could some pair $x, y \in A$ pick the same C ? Well, write $C = \bigcap_{j=0}^{n-1} T^{-j}(W_j)$, with each $W_j \in \mathcal{W}$. For every $j \in [0 \dots n)$, then,

$$d(T^j(x), T^j(y)) \leq \text{Diam}(W_j) < \varepsilon.$$

Hence $d_n(x, y) < \varepsilon$; so $x = y$. Accordingly, the $z \mapsto C_z$ map is injective, whence $|A| \leq |\mathcal{C}|$. \square

Proof (of (ii)) Choose a min-cardinality d_n - δ -small cover \mathcal{C} . For each $C \in \mathcal{C}$ and $j \in [0 \dots n)$, the d - $\text{Diam}(T^j C) < \delta$. So there is a \mathcal{V} -patch $V_{C,j} \supset T^j(C)$. Hence

$$\mathcal{V}_{[0 \dots n]} \stackrel{\text{note}}{\ni} \bigcap_{j=0}^{n-1} T^{-j}(V_{C,j}) \supset C.$$

Thus $\mathcal{V}_{[0 \dots n]} \preceq \mathcal{C}$. So

$$\text{Card}(\mathcal{V}_{[0 \dots n]}) \leq \text{Card}(\mathcal{C}) \leq |\mathcal{C}| = \text{Cov}(n, \delta). \quad \square$$

Proof (of (iii)) To upper-bound $\text{Cov}(k+l, \varepsilon)$ let \mathcal{V} and \mathcal{W} be min-cardinality ε -small covers, respectively, for metrics d_k and d_l . Then $\mathcal{V} \cap T^l(\mathcal{W})$ is a ε -small for d_{k+l} . Consequently $\text{Cov}(k+l, \varepsilon) \leq \text{Cov}(k, \varepsilon) \cdot \text{Cov}(l, \varepsilon)$. Thus $n \mapsto \log(\text{Cov}(n, \varepsilon))$ is subadditive. \square

Proof (of (iv)) Pick a \mathcal{V} from the list in Sect. "Metric Preliminaries", choose some $2\varepsilon < \text{LEB}(\mathcal{V})$ followed by an ε -small \mathcal{W} from Sect. "Metric Preliminaries". Pushing $n \rightarrow \infty$ gives

$$\begin{aligned} L^{\text{Card}}(\mathcal{V}) \leq L^{\text{Cov}}(2\varepsilon) &\leq \widehat{L}^{\text{Spn}}(\varepsilon) \leq \widehat{L}^{\text{Sep}}(\varepsilon) \leq L^{\text{Card}}(\mathcal{W}). \\ &\underline{L}^{\text{Spn}}(\varepsilon) \leq \underline{L}^{\text{Sep}}(\varepsilon) \end{aligned} \tag{23}$$

Now send \mathcal{V} and \mathcal{W} along the list in Sect. "Metric Preliminaries". \square

Pretension Topological entropy takes its values in $[0, \infty]$. A useful corollary of Eq. (23) can be stated in terms of any $\text{Distance}(\cdot, \cdot)$ which topologizes $[0, \infty]$ as a compact interval.

For each continuous $T: X \rightarrow X$ on a compact metric-space, the $\text{Distance}(\widehat{L}^{\text{Sep}}(\varepsilon), \underline{L}^{\text{Sep}}(\varepsilon))$ goes to zero as $\varepsilon \searrow 0$. Consequently, we can pretend that the

$$L^{\text{Sep}}(\varepsilon) = \lim_{n \rightarrow \infty} \frac{1}{n} \log(\text{Sep}(n, \varepsilon)) \quad (24)$$

limit exists, in arguments that subsequently send $\varepsilon \searrow 0$. Ditto for $L^{\text{Spn}}(\varepsilon)$.

This will be used during the proof of the **Variational Principle**. But first, here are two entropy computations which illustrate the efficacy in having several characterizations of topological entropy.

$\mathcal{E}_{\text{top}}(\text{Isometry}) = 0$ Suppose $(T: X, d)$ is a distance-preserving map of a compact metric-space. Fixing ε , a set is d_n - ε -separated IFF it is d - ε -separated. Thus $\text{Sep}(n, \varepsilon)$ does *not* grow with n . So each $\widehat{L}^{\text{Sep}}(\varepsilon)$ is zero.

Topological Markov Shifts Imagine ourselves back in the days when computer data is stored on large reels of fast-moving magnetic tape. One strategy to maximize the density of binary data stored is to *not* put timing-marks (which take up space) on the tape. This has the defect that when the tape-writer writes, say, 577 consecutive 1-bits, then the tape-reader may erroneously count 578 copies of 1. We sidestep this flaw by first encoding our data so as to avoid the 11⁵⁷⁷1 word, then writing to tape.

Generalize this to a finite alphabet Q and a finite list \mathcal{F} of disallowed Q -words. Extend each word to a common length $K + 1$; now $\mathcal{F} \subset Q^{K+1}$. The resulting “ K -step **TMS (topological Markov shift)**” is the shift on the set of doubly- ∞ Q -names having no substring in \mathcal{F} . In the above magnetic-tape example, $K = 576$. Making it more realistic, suppose that some string of zeros, say 00⁵⁷⁴0, is also forbidden¹⁸. Extending to length 577, we get $2^3 = 8$ new disallowed words of form 00⁵⁷⁴0 $b_1 b_2 b_3$.

We **recode** to a 1-step TMS (just called a **TMS** or a **subshift of finite type**) over the alphabet $P := Q^K$. Each outlawed Q -word $w_0 w_1 \dots w_K$ engenders a length-2 forbidden P -word $(w_0, \dots, w_{K-1})(w_1, \dots, w_K)$. The resulting TMS is topologically conjugate to the original K -step. The *allowed* length-2 words can be viewed as the edges in

Entropy in Ergodic Theory, Figure 5

Ignoring the labels on the edges, for the moment, the **Golden shift**, T , acts on the space of doubly-infinite paths through this graph. The space can be represented as a subset $X_{\text{Gold}} \subset \{a, b\}^{\mathbb{Z}}$, namely, the set of sequences with no two consecutive b letters.

a directed-graph and the set of points $x \in X$ is the set of doubly- ∞ paths through the graph. Once trivialities removed, this X is a Cantor set and the shift $T: X \rightarrow X$ is a homeomorphism.

The Golden Shift As the simplest example, suppose our magnetic-tape is constrained by the Markov graph, Fig. 5 that we studied measure-theoretically in Fig. 4.

We want to store the text of *The Declaration of Independence* on our magnetic tape. Imagining that English is a stationary process, we’d like to encode English into this Golden TMS as efficiently as possible. We seek a shift-invariant measure μ on X_{Gold} of *maximum entropy*, should such exist.

View $P = \{a, b\}$ as the time-zero partition on X_{Gold} ; that is, name $x = \dots x_{-1} x_0 x_1 x_2 \dots$, is in atom b IFF letter x_0 is “ b ”. Any measure μ gives conditional probabilities

$$\begin{aligned} \mu(a|a) &=: s, & \mu(b|a) &=: c, \\ \mu(a|b) &\stackrel{\text{note}}{=} 1, & \mu(b|b) &\stackrel{\text{note}}{=} 0. \end{aligned}$$

But recall, $\mathcal{E}(T) = \mathcal{H}(P_1|P_{[-\infty, \dots]}) \leq \mathcal{H}(P_1|P_0)$. So among all measures that make the conditional distribution $P|a$ equal (s, c) , the *unique* one maximizing entropy is the (s, c) -Markov-process. Its entropy, derived in Eq. (14), is

$$\begin{aligned} f(s) &:= \frac{1}{2-s} \mathcal{H}(s, 1-s) \\ &= \frac{-1}{2-s} [s \log(s) + (1-s) \log(1-s)]. \end{aligned} \quad (25)$$

Certainly $f(0) = f(1) = 0$, so f ’s maximum occurs at the (it turns out) *unique* point \widehat{s} where the derivative $f'(\widehat{s})$ equals zero. This $\widehat{s} = (-1 + \sqrt{5})/2$. Plugging in, the maximum entropy supportable by the Golden Shift is

$$\begin{aligned} \text{MaxEnt} &= \frac{2}{5 - \sqrt{5}} \left[\frac{-1 + \sqrt{5}}{2} \log \left(\frac{2}{-1 + \sqrt{5}} \right) \right. \\ &\quad \left. + \frac{3 - \sqrt{5}}{2} \log \left(\frac{2}{3 - \sqrt{5}} \right) \right]. \end{aligned} \quad (26)$$

¹⁸Perhaps the 0-bad-length, 574, is shorter than the 1-bad-length because, say, 0s take less tape-space than 1s and so – being written more densely – cause ambiguity sooner.

Exponentiating, the number of μ -typical n -names grows like G^n , where

$$G := \left[\frac{2}{-1 + \sqrt{5}} \frac{-1 + \sqrt{5}}{5 - \sqrt{5}} \right] \left[\frac{2}{3 - \sqrt{5}} \frac{3 - \sqrt{5}}{5 - \sqrt{5}} \right]. \tag{27}$$

This expression¹⁹ looks unpleasant to simplify – it isn’t even obviously an algebraic number – and yet topological entropy will reveal its familiar nature. This, because the Variational Principle (proved in the next section) says that the top-ent of a system is the supremum of measure-entropies supportable by the system.

Top-ent of the Golden Shift For a moment, let’s work more generally on an arbitrary subshift (a closed, shift-invariant subset) $X \subset Q^{\mathbb{Z}}$, where Q is a finite alphabet. Here, the transformation is always the shift – but the *space* is varying – so agree to refer to the top-ent as $\mathcal{E}_{\text{top}}(X)$. Let $\text{Names}_X(n)$ be the number of distinct words in the set $\{x \upharpoonright_{[0..n]} \mid x \in X\}$. Note that a metric inducing the product-topology on $Q^{\mathbb{Z}}$ is

$$d(x, x') := \frac{1}{1 + |m|}, \tag{28}$$

for the smallest $|m|$ with $x_m \neq x'_m$.

Lemma 15 *Consider a subshift X . Then the*

$$\lim_{n \rightarrow \infty} \frac{1}{n} \log(\text{Names}_X(n))$$

exists in $[0, \infty]$, and equals $\mathcal{E}_{\text{top}}(X)$.

Proof With $\varepsilon \in (0, 1)$ fixed, two n -names are d_n - ε -separated IFF they are not the same name. Hence $\text{Sep}(n, \varepsilon) = \text{Names}_X(n)$. \square

To compute $\mathcal{E}_{\text{top}}(X_{\text{Gold}})$, declare that a word is “golden” if it appears in some $x \in X_{\text{Gold}}$. Each $[n + 1]$ -golden word ending in a has form wa , where w is n -golden. An $[n + 1]$ -golden word ending in b , must end in ab and so has form wab , where w is $[n - 1]$ -golden. Summing up,

$$\begin{aligned} \text{Names}_{X_{\text{Gold}}}(n + 1) &= \text{Names}_{X_{\text{Gold}}}(n) + \text{Names}_{X_{\text{Gold}}}(n - 1). \end{aligned}$$

This is the Fibonacci recurrence, and indeed, these are *the* Fibonacci numbers, since $\text{Names}_{X_{\text{Gold}}}(0) = 1$ and $\text{Names}_{X_{\text{Gold}}}(1) = 2$. Consequently, we have that

$$\text{Names}_{X_{\text{Gold}}}(n) \sim \text{Const} \cdot \lambda^n,$$

¹⁹A popular computer-algebra-system was not, at least under my inexpert tutelage, able to simplify this. However, once top-ent gave the correct answer, the software *was* able to detect the equality.

where $\lambda = \frac{1 + \sqrt{5}}{2}$ is the Golden Ratio. So the sesquipedalian number G from Eq. (27) is simply λ , and $\mathcal{E}_{\text{top}}(X_{\text{Gold}}) = \log(\lambda)$.

Since $\log(\lambda) \approx 0.694$, each thousand bits written on tape (subject to the “no bb substrings” constraint) can carry at most 694 bits of information.

Top-ent of a General TMS A (finite) digraph G engenders a **TMS** $T: X_G \rightarrow X_G$, as well as a $\{0, 1\}$ -valued adjacency matrix $\mathbf{A} = \mathbf{A}_G$, where $a_{i,j}$ is the number of directed-edges from state i to j . (Here, each $a_{i,j}$ is 0 or 1.) The (i, j) -entry in power \mathbf{A}^n is automatically the number of length- n paths from i to j . Employing the matrix-norm $\|\mathbf{M}\| := \sum_{i,j} |m_{i,j}|$, then,

$$\|\mathbf{A}\|^n = \text{Names}_X(n).$$

Happily Gelfand’s formula (see 10.13 in [58] or [Spectral radius](#) in [60]) applies: *For an arbitrary (square) complex matrix,*

$$\lim_{n \rightarrow \infty} \|\mathbf{A}^n\|^{\frac{1}{n}} = \text{SpecRad}(\mathbf{A}). \tag{29}$$

This right hand side, the *spectral radius* of \mathbf{A} , means the maximum of the absolute values of \mathbf{A} ’s eigenvalues. So the top-ent of a **TMS** is thus the

$$\begin{aligned} \mathcal{E}_{\text{top}}(X_G) &= \text{SpecRad}(\mathbf{A}_G) \\ &:= \text{Max} \{ |e| \mid e \text{ is an eigenvalue of } \mathbf{A}_G \}. \end{aligned} \tag{30}$$

The (a, b) -adjacency matrix of Fig. 5 is

$$\begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix},$$

whose eigenvalues are λ and $\frac{1}{\lambda}$.

Labeling Edges Interpret $(s, c, 1)$ simply as edge-labels in Fig. 5. The set of doubly- ∞ paths can also be viewed as a subset $Y_{\text{Gold}} \subset \{s, c, 1\}^{\mathbb{Z}}$, and it too is a **TMS**. The shift on Y_{Gold} is conjugate (topologically isomorphic) to the shift on X_{Gold} , so they *a fortiori* have the same top-ent, $\log(\lambda)$. The $(s, c, 1)$ -adjacency matrix is

$$\begin{bmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 1 & 0 \end{bmatrix}.$$

Its $|\cdot|$ -largest eigenvalue is still λ , as it must.

Now we make a new graph. We modify Fig. 5 by manufacturing a total of two s -edges, seven c -edges, and three edges l_1, l_2, l_3 . Give these $2 + 7 + 3$ edges twelve *distinct* labels. We *could* compute the resulting **TMS**-entropy

from the corresponding 12×12 adjacency matrix. Alternatively, look at the (a, b)-adjacency matrix

$$A := \begin{bmatrix} 2 & 7 \\ 3 & 0 \end{bmatrix}.$$

The roots of its characteristic polynomial are $1 \pm \sqrt{22}$. Hence \mathcal{E}_{top} of this 12-symbol TMS is $\log(1 + \sqrt{22})$.

The Variational Principle

Let $\mathcal{M} := \mathcal{M}(X, d)$ be the set of Borel probability measures, and $\mathcal{M}(T) := \mathcal{M}(T: X, d)$ the set of T -invariant $\mu \in \mathcal{M}$. Assign

$$\text{EntSup}(T) := \sup \{ \mathcal{E}_{\mu}(T) \mid \mu \in \mathcal{M}(T) \}.$$

Theorem 16 (Variational principle (Goodson))
 $\text{EntSup}(T) = \mathcal{E}_{\text{top}}(T)$.

This says that top-ent is the top entropy – if there is a measure μ which realizes the supremum. There doesn't have to be. Choose a sequence of metric-systems $(S_k: Y_k, m_k)$ whose entropies *strictly* increase $\mathcal{E}_{\text{top}}(S_k) \nearrow L$ to some limit in $(0, \infty]$. Let $(S_{\infty}: Y_{\infty}, m_{\infty})$ be the identity-map on a 1-point space. Define a new system $(T: X, d)$, where $X := \bigsqcup_{k \in [1 \dots \infty]} Y_k$. Have $T(x) := S_k(x)$, for the unique k with $Y_k \ni x$. As for the metric, on Y_k let d be a scaled version of m_k , so that the d -Diam(Y_k) is less than $1/2^k$. Finally, for points in *distinct* components, $x \in Y_k$ and $z \in Y_{\ell}$, decree that $d(x, z) := |2^{-k} - 2^{-\ell}|$. Our T is continuous, and is a homeomorphism if each of the S_k is. Certainly $\mathcal{E}_{\text{top}}(T) = L > \mathcal{E}_{\text{top}}(S_k)$, for every $k \in [1 \dots \infty]$.

If L is *finite* then there is *no* measure μ of maximal entropy; for μ must give mass to *some* Y_k ; this pulls the entropy below L , since there are no compensatory components with entropy exceeding L .

In contrast, when $L = \infty$ then there is a maximal-entropy measure (put mass $1/2^j$ on some component Y_{k_j} , where $k_j \nearrow \infty$ swiftly); indeed, there are continuum-many maximal-entropy measures. *But* there is no ²⁰ *ergodic* measure of maximal entropy.

For a concrete $L = \infty$ example, let S_k be the shift on $[1 \dots k]^{\mathbb{Z}}$.

²⁰The ergodic measures are the extreme points of $\mathcal{M}(T)$; call them $\mathcal{M}_{\text{Erg}}(T)$. This $\mathcal{M}(T)$ is the set of barycenters obtained from Borel probability measures on $\mathcal{M}_{\text{Erg}}(T)$ (see [Krein-Milman theorem](#), [Choquet theory](#) in [60]). In this instance, what explains the failure to have an *ergodic* maximal-entropy measure? Let μ_k be an invariant ergodic measure on Y_k . These measures *do* converge to the one-point (ergodic) probability measure μ_{∞} on Y_{∞} . But the map $\mu \mapsto \mathcal{E}_{\mu}(T)$ is not continuous at μ_{∞} .

Topology on \mathcal{M} Let's arrange our tools for establishing the Variational Principle. The argument will follow Misiurewicz's proof, adapted from the presentations in [23] and [11].

Equip \mathcal{M} with the *weak-** topology.²¹ An $A \subset X$ is *μ -nice* if its topological boundary $\partial(A)$ is μ -null. And a *partition* is *μ -nice* if each atom is.

Proposition 17 *If $\alpha_L \rightarrow \mu$ and $A \subset X$ is μ -nice, then $\alpha_L(A) \rightarrow \mu(A)$.*

Proof Define operator $\mathcal{U}(D) := \limsup_L \alpha_L(D)$. It suffices to show that $\mathcal{U}(A) \leq \mu(A)$. For since A^c is μ -nice too, then $\mathcal{U}(A^c) \leq \mu(A^c)$. Thus $\lim_L \alpha_L(A)$ exists, and equals $\mu(A)$.

Because $C := \bar{A}$ is closed, the continuous functions $f_N \searrow \mathbf{1}_C$ pointwise, where

$$f_N(x) := 1 - \text{Min}(N \cdot d(x, C), 1).$$

By the Monotone Convergence theorem, then,

$$\int f_N d\mu \xrightarrow{N} \mu(C).$$

And $\mu(C) = \mu(A)$, since A is nice. Fixing N , then, it suffices to establish $\mathcal{U}(A) \leq \int f_N d\mu$. But f_N is continuous, so

$$\begin{aligned} \int f_N d\mu &= \limsup_{L \rightarrow \infty} \int f_N d\alpha_L \\ &\geq \limsup_{L \rightarrow \infty} \int \mathbf{1}_A d\alpha_L = \mathcal{U}(A). \quad \square \end{aligned}$$

Corollary 18 *Suppose $\alpha_L \rightarrow \mu$, and partition P is μ -nice. Then $\mathcal{H}_{\alpha_L}(P) \rightarrow \mathcal{H}_{\mu}(P)$.*

The *diameter* of partition P is $\text{Max}_{A \in P} \text{Diam}(A)$.

Proposition 19 *Take $\mu \in \mathcal{M}$ and $\varepsilon > 0$. Then there exists a μ -nice partition with $\text{Diam}(P) < \varepsilon$.*

Proof Centered at an x , the uncountably many balls $\{\text{Bal}(x, r) \mid r \in (0, \varepsilon)\}$ have disjoint boundaries. So all but countably many are μ -nice; pick one and call it B_x . Compactness gives a finite nice cover, say, $\{B_1, \dots, B_7\}$, at different centers. Then the partition $P := (A_1, \dots, A_7)$ is nice,²² where $A_k := B_k \setminus \bigcup_{j=1}^{k-1} B_j$. \square

Here is a consequence of Jensen's inequality.

²¹Measures $\alpha_L \rightarrow \mu$ IFF $\int f d\alpha_L \rightarrow \int f d\mu$, for each continuous $f: X \rightarrow \mathbb{R}$. This metrizable topology makes \mathcal{M} compact. Always, $\mathcal{M}(T)$ is a non-void compact subset (see [Measure Preserving Systems](#).)

²²For any two sets $B, B' \subset X$, the union $\partial B \cup \partial B'$ is a superset of the three boundaries $\partial(B \cup B')$, $\partial(B \cap B')$, $\partial(B \setminus B')$.

Lemma 20 (Distropy-Averaging Lemma) For $\mu, \nu \in \mathcal{M}$, a partition R , and a number $t \in [0, 1]$,

$$t\mathcal{H}_\mu(R) + t^c\mathcal{H}_\nu(R) \leq \mathcal{H}_{t\mu+t^c\nu}(R).$$

Strategy for $\text{EntSup}(T) \geq \mathcal{E}_{\text{top}}(T)$. Choose an $\varepsilon > 0$. For $L = 1, 2, 3, \dots$, take a maximal (L, ε) -separated-set $F_L \subset X$, then define

$$\mathbf{F} = \mathbf{F}_\varepsilon := \limsup_{L \rightarrow \infty} \frac{1}{L} \log(|F_L|).$$

Let $\varphi_L()$ be the equi-probable measure on F_L ; each point has weight $1/|F_L|$. The desired invariant measure μ will come from the Cesàro averages

$$\alpha_L := \frac{1}{L} \sum_{\ell \in [0..L)} T^\ell \varphi_L,$$

which get more and more invariant.

Lemma 21 Let μ be any weak-* accumulation point of the above $\{\alpha_L\}_1^\infty$. (Automatically, μ is T -invariant.) Then $\mathcal{E}_\mu(T) \geq \mathbf{F}$. Indeed, if Q is any μ -nice partition with $\text{Diam}(Q) < \varepsilon$, then $\mathcal{E}_\mu(T, Q) \geq \mathbf{F}$.

Tactics As usual, $Q_{[0..N)}$ means $Q_0 \vee Q_1 \vee \dots \vee Q_{N-1}$. Our goal is

$$\forall N: \quad \mathbf{F} \stackrel{?}{\leq} \frac{1}{N} \mathcal{H}_\mu(Q_{[0..N)}). \tag{31}$$

Fix N and $P := Q_{[0..N)}$, and a $\delta > 0$. It suffices to verify: $\forall_{\text{large } L} L \gg N$,

$$\frac{1}{L} \log(|F_L|) \stackrel{?}{\leq} \delta + \frac{1}{N} \mathcal{H}_{\alpha_L}(P), \tag{32}$$

since this and Corollary 17 will prove Eq. (31): Pushing $L \rightarrow \infty$ along the sequence that produced μ essentially sends LhS(32) to \mathbf{F} , courtesy Eq. (24). And RhS(32) goes to $\delta + \frac{1}{N} \mathcal{H}_\mu(P)$, by Corollary 17, since P is μ -nice. Descending $\delta \searrow 0$, hands us the needed Eq. (31).

Remark 22 The idea in the following proof is to mostly fill interval $[0..L)$ with N -blocks, starting with a offset $K \in [0..N)$. Averaging over the offset will create a Cesàro average over each N -block. Averaging over the N -blocks will allow us to compute distropy with respect to the averaged measure, α_L .

Proof (of Eq. (32)) Since L is frozen, agree to use φ for the φ_L probability measure.

Our d_L - ε -separated set F_L has at most *one* point in any given atom of $Q_{[0..L)}$, thereupon

$$\log(|F_L|) = \mathcal{H}_\varphi(Q_{[0..L)}).$$

Regardless of the “offset” $K \in [0..N)$, we can always fit $C := \lfloor \frac{L-N}{N} \rfloor$ many N -blocks into $[0..L)$. Denote by $\mathcal{G}(K) := [K..K + CN)$, this union of N -blocks, the **good** set of indices. Unsurprisingly, $\mathcal{B}(K) := [0..L) \setminus \mathcal{G}(K)$ is the **bad** index-set. Therefore,

$$\mathcal{H}_\varphi(Q_{[0..L)}) \leq \overbrace{\mathcal{H}_\varphi\left(\bigvee_{j \in \mathcal{B}(K)} Q_j\right)}^{\text{Bad}(K)} + \overbrace{\mathcal{H}_\varphi\left(\bigvee_{j \in \mathcal{G}(K)} Q_j\right)}^{\text{Good}(K)}. \tag{33}$$

Certainly $\text{Bad}(K) \leq 3N \log(|Q|)$. So

$$\frac{1}{NL} \sum_{K \in [0..N)} \text{Bad}(K) \leq \frac{3N}{L} \log(|Q|).$$

This is less than δ , since L is large. Applying $\frac{1}{NL} \sum_{K \in [0..N)}$ to Eq. (28) now produces

$$\frac{1}{L} \log(|F_L|) \leq \delta + \frac{1}{NL} \sum_K \text{Good}(K). \tag{34}$$

Note

$$\bigvee_{j \in \mathcal{G}(K)} T^j(Q) = \bigvee_{c \in [0..C) T^{K+cN}(P)}.$$

So

$$\text{Good}(K) \leq \sum_c \mathcal{H}_\varphi(T^{K+cN}P).$$

This latter, by definition, equals $\sum_c \mathcal{H}_{T^{K+cN}(\varphi)}(P)$. We conclude that

$$\begin{aligned} \frac{1}{NL} \sum_K \text{Good}(K) &\leq \frac{1}{NL} \sum_K \sum_c \mathcal{H}_{T^{K+cN}(\varphi)}(P) \\ &\leq \frac{1}{NL} \sum_{\ell \in [0..L)} \mathcal{H}_{T^\ell \varphi}(P), \end{aligned}$$

by adjoining a few translates of P ,

$$\leq \frac{1}{N} \mathcal{H}_{\alpha_L}(P),$$

by the Distropy-averaging lemma 18,

since α_L is the average $\frac{1}{L} \sum_\ell T^\ell \varphi$. Thus Eq. (34) implies Eq. (32), our goal. \square

Proof (of $\text{EntSup}(T) \leq \mathcal{E}_{\text{top}}(T)$) Fix a T -invariant μ . For partition $Q = (B_1, \dots, B_K)$, choose a compact set $A_k \subset B_k$ with $\mu(B_k \setminus A_k)$ small. (This can be done, since μ is automatically a regular measure [58].) Letting $D := [\bigsqcup_i A_i]^c$ and $P := (D, A_1, \dots, A_K)$, we can have made $\mathcal{H}(P|Q)$ as small as desired. Courtesy of Lemma 8b, then, we only need consider partitions of the form that P has.

Open-cover $\mathcal{V} = (U_1, \dots, U_K)$ has patches $U_k := D \cup A_k$. What atoms of, say, $P_{[0\dots 3]}$, can the intersection $U_9 \cap T^{-1}(U_2) \cap T^{-2}(U_5)$ touch? Only the eight atoms

$$(D \text{ or } A_9) \cap T^{-1}(D \text{ or } A_2) \cap T^{-2}(D \text{ or } A_5).$$

Thus $\#P_{[0\dots n]} \leq 2^n \cdot \#\mathcal{V}_{[0\dots n]}$. (Here, $\#()$ counts the number of non-void atoms/patches.) So

$$\begin{aligned} \frac{1}{n} \mathcal{H}_\mu(P_{[0\dots n]}) &\leq 1 + \frac{1}{n} \log(\#\mathcal{V}_{[0\dots n]}) \\ &\leq 1 + 1 + \mathcal{E}_{\text{top}}(T); \end{aligned}$$

this last inequality, when n is large. The upshot: $\mathcal{E}_\mu(T) \leq 2 + \mathcal{E}_{\text{top}}(T)$.

Applied to a power T^ℓ , this asserts that $\mathcal{E}_\mu(T^\ell) \leq 2 + \mathcal{E}_{\text{top}}(T^\ell)$. Thus

$$\mathcal{E}_\mu(T) \leq \frac{2}{\ell} + \mathcal{E}_{\text{top}}(T),$$

using Lemma 9d and using Lemma 13g. Now coax $\ell \rightarrow \infty$. □

Three Recent Results

Having given an survey of older results in measure-theoretic entropy and in topological entropy, let us end this survey with a brief discussion of a few recent results, chosen from many.

Ornstein–Weiss: Finitely-Observable Invariant

In a landmark paper [10], Ornstein and Weiss show that all “finitely observable” properties of ergodic processes are secretly entropy; indeed, they are continuous functions of entropy. This was generalized by Gutman and Hochman [9]; some of the notation below is from their paper.

Here is the setting. Consider an ergodic process, on a non-atomic space, taking on only finitely many values in \mathbb{N} ; let \mathcal{C} be some family of such processes. An **observation scheme** is a metric space (Ω, d) and a sequence of functions $\mathbf{S} = (S_n)_1^\infty$, where S_n maps $\mathbb{N} \times \dots \times \mathbb{N}$ into Ω . On a point $\vec{x} \in \mathbb{N}^\infty$, the scheme **converges** if

$$n \mapsto S_n(x_1, x_2, \dots, x_n) \tag{35}$$

converges in Ω . And on a particular process \mathcal{X} , say that \mathbf{S} **converges**, if \mathbf{S} converges on a.e. \vec{x} in \mathcal{X} .

A function $J: \mathcal{C} \rightarrow \Omega$ is isomorphism invariant if, whenever the underlying transformations of two processes $\mathcal{X}, \mathcal{X}' \in \mathcal{C}$ are isomorphic, then $J(\mathcal{X}) = J(\mathcal{X}')$. Lastly, say that \mathbf{S} “converges to J ”, if for each $\mathcal{X} \in \mathcal{C}$, scheme \mathbf{S} converges to the value $J(\mathcal{X})$.

The work of David Bailey [38], a student of Ornstein, produced an observation scheme for entropy. The Lempel–Ziv algorithm [43] was another entropy observer, with practical application.

Ornstein and Weiss provided entropy schemes in [41] and [42]. Their recent paper “Entropy is the only finitely-observable invariant” [10], gives a converse, a uniqueness result.

Theorem 23 (Ornstein, Weiss) *Suppose J is a finitely observable function, defined on all ergodic finite-valued processes. If J is an isomorphism invariant, then J is a continuous function of the entropy.*

Gutman–Hochman: Finitely-Observable Extension

Extending the Ornstein–Weiss result, Yonatan Gutman and Michael Hochman, in [9] proved that it holds even when the isomorphism invariant, J , is well-defined only on certain subclasses of the set of all ergodic processes. In particular they obtain the following result on three classes of zero-entropy transformations.

Theorem 24 (Gutman, Hochman) *Suppose $J()$ is a finitely observable invariant on one of the following classes:*

- (i) *The Kronecker systems; the class of systems with pure point spectrum.*
- (ii) *The zero-entropy mild mixing processes.*
- (iii) *The zero-entropy strong mixing processes.*

Then $J()$ is constant.

Entropy of Actions of Free Groups

Consider (G, \mathcal{G}) , a topological group and its Borel field (sigma-algebra). Let $\mathcal{X} \times \mathcal{X}$ be the field on $G \times X$ generated by the two coordinate-subfields. A map

$$\phi: G \times X \rightarrow X \tag{36}$$

is **measurable** if

$$\psi^{-1}(X) \subset \mathcal{G} \times X.$$

Use $\psi^g(x)$ for $\psi(g, x)$.

This map in Eq. (36) is a (measure-preserving) **group action** if $\forall g, h \in G: \psi^g \circ \psi^h = \psi^{gh}$, and each $\psi^g: X \rightarrow X$ is measure preserving.

This encyclopedia article has only discussed entropy for \mathbb{Z} -actions, i. e., when $G = \mathbb{Z}$. The ergodic theorem, our definition of entropy, and large parts of ergodic theory, involve taking averages (of some quantity of interest) over larger and larger “pieces of time”. In \mathbb{Z} , we typically use the intervals $I_n := [0 \dots n)$. When G is $\mathbb{Z} \times \mathbb{Z}$, we might average over squares $I_n \times I_n$.

The *amenable groups* are those which possess, in a certain sense, larger and larger averaging sets. Parts of ergodic theory have been carried over to actions of amenable groups, e. g. [49] and [55]. Indeed, much of the Bernoulli theory was extended to certain amenable groups by Ornstein and Weiss, [50].

The stereotypical example of a *non*-amenable group, is a free group (on more than one generator). But recently, Lewis Bowen [8] succeeded in extending the definition of entropy to actions of finite-rank free groups.

Theorem 25 (Lewis Bowen) *Let G be a finite-rank free group. Then two Bernoulli G -actions are isomorphic IFF they have the same entropy.*

The paper introduces a new isomorphism invariant, the “ f invariant”, and shows that, for Bernoulli actions, the f invariant agrees with entropy, that is, with the distropy of the independent generating partition.

Exodos

Ever since the pioneering work of Shannon, and of Kolmogorov and Sinai, entropy has been front and center as a major tool in Ergodic Theory. Simply *mentioning* all the substantial results in entropy theory would dwarf the length of this encyclopedia article many times over. And, as the above three results (cherry-picked out of many) show, Entropy shows no sign of fading away...

Glossary

Species richness the number of species per unit area; a synonym is species density.

Species abundance the number of individuals or amount of living biomass per species per unit area.

Per capita instantaneous growth rate the net number of new individuals produced by an average individual in a population at time t .

Deterministic chaos a pattern of change over time that is perfectly determined by initial conditions, but for which tiny changes in initial conditions result in divergences in the dynamics such that the pattern appears random.

Attractor a set of values (a point, a curve or higher – including a fractal – dimensional object) towards which a dynamic trajectory will move.

Basin of attraction the set of values from which any dynamic trajectory will move towards the same attractor.

Maximum entropy formalism a formal method for producing probability estimates that agree with certain constraints specifying available information about a system but that are otherwise maximally uninformative.

Maximally uninformative (or ignorance) prior a probability distribution that encodes the basic structure of a logical problem as given by the definition of the variable, but that contains no other information.

Definition of the Subject

An understanding of the determinants of biodiversity is an important goal of academic ecology and the protection

of biodiversity is an important goal in conservation. Biodiversity has two components: the number (or density) of species and the relative abundance of species. Both components vary over different spatial and temporal scales. The allocation of limiting resources to different species in an ecological community is reflected in the abundance of each species. The notion of a “community” in ecology (as in more general usages of this word) is poorly defined but will here mean the total number of organisms found within a fixed area of space (a site). Abundance is measured in different ways but the most exact measure is the total mass of living tissues (i. e. biomass) found in a given species at the site. Relative abundance is the proportional abundance of each species relative to the total abundance of all species at the site. The species “pool” is the set of species that can potentially disperse into the site, including those that are not found within the community because they have been excluded due either to biotic interactions or to an inability to survive the abiotic conditions of the site. The vector of abundances, $\mathbf{a} = \{a_i\}$, or relative abundances, $\mathbf{ra} = \{ra_i\}$, of each species in the species pool that is observed at the site is a description of the community structure. The change in this vector over time is a description of the community dynamics.

As such, community structure and dynamics are fundamental properties of ecological communities and relate to basic questions posed by ecologists: Which species will be found at a site? Which of these will be rare? Which species will dominate? How many species will be found? How is the flow of matter and energy through the organisms affected by community structure? How will the community structure change if the environmental conditions of the site change? Every one of these questions involves complex dynamics of large numbers of interactions of organisms. Because of this, answers to these questions will have to deal with this complexity. Most of the results that follow are based on plant communities, since these are the only ones that have been studied to date using entropy maximization, but animal communities will be discussed when looking at future directions. The answers to such questions have important applied implications for forestry, agriculture and conservation.

Introduction

Four aspects of ecological communities are obvious to even a casual observer of nature. First, the organisms found at any given site are distributed into different species. Second, the distribution of individuals and biomass, and therefore of resources, is not equal between species. It is not simply that some species are common and

some are rare, but that a small number of species in every community make up the majority of the biomass and most species in every community make up a minority of the biomass. Third, which species are common, which are rare, and which are absent, differ across sites having different physical (abiotic) environmental conditions. Fourth, which species are common, which are rare, and which are absent, change systematically at the same site over time following a major disturbance (i. e. ecological succession). Explaining and predicting these four properties of ecological communities is a major goal of ecological science.

Although much progress has been made at the empirical level, a general theoretical explanation of these properties with good predictive ability under field conditions is still largely missing despite almost a century of effort by influential theoretical ecologists. All of these theoretical efforts were based on dynamic models derived from population-level demography and based on an analogy with Newtonian mechanics. The purpose of this essay is to contrast this majority tradition in ecological modeling of communities with a more recent statistical mechanistic approach based on maximization of entropy or relative entropy.

Population dynamic models begin with two undeniable properties of any biological population. First, because each mature member of the population can potentially reproduce, population growth is a multiplicative process defining a geometric series. This is the first fundamental insight of Malthus that inspired Darwin [1] and Wallace [2] to propose the theory of evolution by natural selection: every biological population has the *potential* for exponential growth. If $n_i(t)$ is the number of individuals of species i alive at time t , then the per capita instantaneous growth rate at time t , $r_i(t)$, is defined as:

$$\frac{1}{n_i(t)} \frac{dn_i(t)}{dt} = r_i(t). \quad (1)$$

If $r_i(t)$ is constant over time then integration of Eq. (1) leads to exponential growth: $n_i(t) = n_i(0)e^{r_i t}$. Per capita growth rates can also be expressed as difference equations by an obvious modification of Eq. (1). The second undeniable property of any biological population is that exponential growth cannot persist indefinitely without resources becoming exhausted. For instance a single bacterium with a mass of 1 picogram that divides by binary fission once every 20 minutes would, if this rate of growth continued without interruption, produce offspring weighting the mass of the Earth in a little under two days. Therefore there must be a negative feedback such that $r_i(t)$ decreases in some fashion as population size, $n_i(t)$, increases. The simplest type of feedback leads to the well-known logistic (or Lotka–Volterra) equation, shown in Eq. (2). Lotka [3]

published his model in 1926 although the original idea is due to Pierre–François Verhulst [4]. Volterra [5] published the genesis of this model in 1926. Hutchinson [4] gives a good historical description of the origins of this equation.

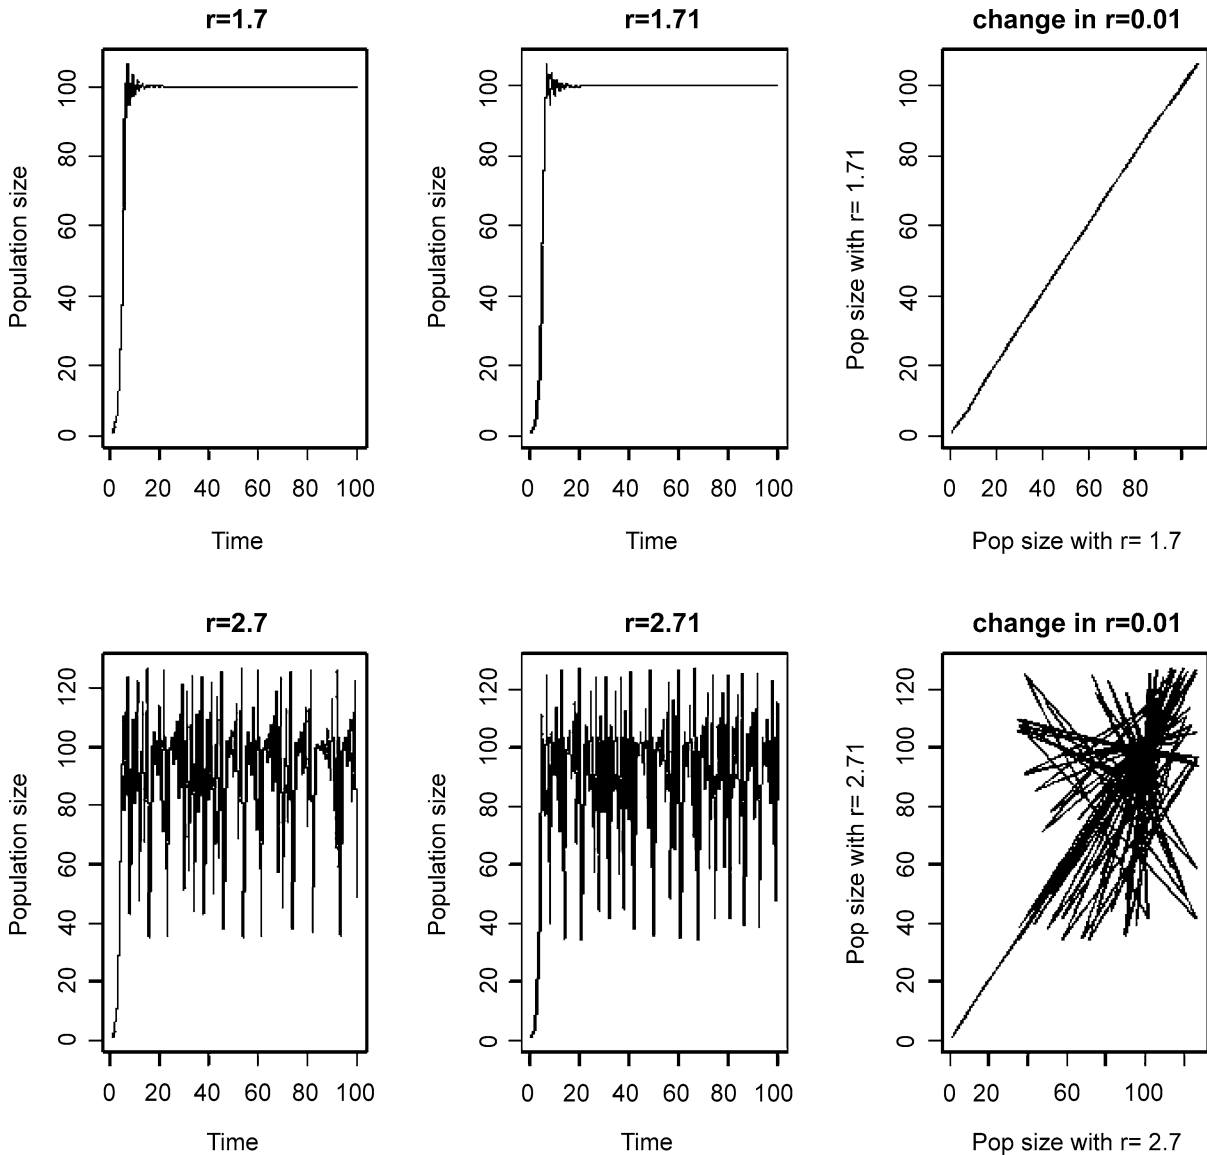

$$\frac{1}{n_i(t)} \frac{dn_i(t)}{dt} = r_i \left(\frac{K_i - \alpha_{ii} n_i(t)}{K_i} \right). \quad (2)$$

Here r_i is the maximum per capita growth rate, attained when $n_i \rightarrow 0$ and therefore when all competition disappears. K_i is the carrying capacity, attained when negative feedback reduces birth rates and increases death rates such that per capita birth and death rates are equal and leading to a constant population size with $r_i(t) = 0$. The coefficient α_{ii} (the per capita competition coefficient) is the amount by which each additional individual of species i decreases the per capita growth rate below the maximum (r_i). The extension to a community of S species leads to a system of simultaneous differential equation that are shown in Eq. (3), where the $S \times S$ matrix of competition coefficients is called the community competition matrix.

$$\frac{1}{n_i(t)} \frac{dn_i(t)}{dt} = r_i \left(\frac{K_i - \sum_{j=1}^S \alpha_{ij} n_j(t)}{K_i} \right). \quad (3)$$

Equation (3) has been modified in many ways, including the addition of time lags, of nonlinear terms, of replacing constants by stochastic terms [6], and replacing the generalized logistic equation by other feedback functions. A more recent modification has been to replace the phenomenological competition coefficients by a dynamic coupling of organisms having a population feedback following a Monod-type equation with an explicit description of dynamic changes in resource levels [7]. This essentially extends the demographic approach to resources as well as organisms. Despite this body of theoretical work, the ability of such demographically-based models to actually predict the structure and dynamics of real ecological communities under field conditions is very weak. In fact, even simplified multispecies communities of phytoplankton [8] or fruit flies reared under controlled laboratory conditions [9] are not well described by these equations despite their intuitive logic. Of course, given the large number of parameters that must be estimated in such models, they are not applicable to real ecological communities in practice.

Recent theoretical and empirical work, involving very simple one-species systems in controlled laboratory conditions, has suggested one reason why such demographic models have low predictive ability even in simplified sys-

Entropy Maximization and Species Abundance, Figure 1

Time series of the deterministic discrete logistic equation showing extreme sensitivity to initial conditions. *Top row:* Time series with the maximum per capita growth rate (r) set at either 1.7 or 1.71 and the relationship of population sizes at each time t . *Bottom row:* Time series with the maximum per capita growth rate (r) set at either 2.7 or 2.71 and the relationship of population sizes at each time t . Note that the same change in the maximum per capita growth rate ($\Delta = 0.01$) will produce changes in population sizes that are very small (*top right*) or very large and essentially random (*bottom right*)

tems. It has been known since May [10] that the simple logistic equation (Eq. (1)) can display deterministic chaos over some ranges of the three parameters (r , α , K). In fact, the basic structure of all such dynamic demographic models in ecology involves nonlinearity and feedback and these two properties are necessary for deterministic chaos. Thus, such models can be sensitive to initial conditions because of the presence of chaotic attractors in phase space.

To illustrate the problem, consider the logistic equation for a single population written as a difference equation: $N(t+1) = N(t) + N(t)r((K - N(t))/K)$. There are no random variables in this equation and, given the values of r , K and $N(0)$, the subsequent population sizes, $N(t)$, over time are completely deterministic and predictable. The first row of Fig. 1 (top row) shows, from left to right, the changes in population size over time when

$r = 1.7$, when $r = 1.71$ and the relationship between the population sizes at each time when comparing these two dynamics. We see the classic discrete version of the logistic equation and the tiny change (0.01) in the value of r is mirrored by the tiny change in the population sizes over time. The second row of Fig. 1 shows the same thing except that the values of r are 2.7 versus 2.71. The behavior of the population size over time looks completely random. More importantly, the same tiny change in r (0.01) results in trajectories of population size that rapidly diverge and that quickly become essentially independent. In other words, making an error of 0.01 in the estimation of the per capita growth rate would result in completely incorrect predictions of population size. Yet, if r were measured in a real field population, a difference of 0.01 would be far less than the measurement error even for a huge sample size. In such a case the population dynamics is, for all practical purposes, unpredictable. Depending on the equation and the part of parameter space that is being explored, even changes in parameter values of 10^{-6} can produce equally spectacular differences; this is an ecological example of Edward Lorenz' famous "butterfly effect" [11].

A good real-life example of this is the series of modeling and experimental studies described in Constantino et al. [12]. The experimental system was extremely simple: Flour beetles were grown over many generations in standardized containers in the laboratory. Each container received a fixed amount of food at regular intervals. Temperature, humidity and other environmental conditions are maintained at fixed values. A simple nonlinear dynamic model was developed to capture the essential elements of the population dynamics of this species under these carefully controlled conditions. An analysis of the model showed which areas of parameter space resulted in chaotic dynamics (as well as other dynamic properties) and the experimental conditions were then manipulated according to the model predictions in order to bring the measured parameters into these regions of parameter space. The experiments reproduced the various predictions of chaotic dynamics and showed that even very small differences in parameter values could quickly lead to dynamic trajectories that rapidly diverge and soon become indistinguishable from independent random variables.

These experimental results are very bad news for models attempting to model community assembly from this reductionist perspective of population dynamics. If even such a simplified system – a single species growing in controlled conditions in the laboratory – can exhibit such complicated dynamics, then it seems very likely that much more complicated systems, involving hundreds of competing species as well as their predators, prey, parasites and

pathogens existing in constantly fluctuating environmental conditions over many different temporal and spatial scales, will also show at least such complicated dynamics. If sensitivity to initial conditions, a signature of deterministic stochasticity, exists then it seems certain that accurate predictions are beyond the reach of such models in field conditions where parameter measurements are always estimated with a substantial degree of error.

These results, and the inherent difficulty in measuring the large number of parameter values required by dynamic demographic models, suggest that a new approach is needed to link properties of species to community structure.

Information Theory Basis of Entropy Maximization

Conceptually, the entire enterprise of modeling community structure is one of describing the relationship between macroscopic properties of communities (i.e. abundances of each species or the distribution of abundances) and microscopic properties of resource allocation when there are a large number of interacting entities. Stated in this way it is tempting to draw an analogy between, on the one hand, the patterns in ecological communities and the individuals that make up such communities and, on the other hand, the relationship between the macroscopic properties of a gas (pressure, volume, temperature) and the microscopic properties of individual molecules. Historically, the relationship between macroscopic properties of gases (for instance, temperature) and microscopic properties of molecules, for instance, the amount of kinetic and potential energy possessed by each one, was not obtained by solving a system of differential equations for the community of molecules, but rather by a statistical mechanistic approach based on macroscopic constraints [13,14]. Statistical mechanics tries to understand the macroscopic behavior of complex systems, involving large numbers of interacting microscopic components, from a probabilistic viewpoint. Although Boltzmann sought a dynamic explanation, this explanation was refuted by Jaynes [15]. More recent theoretical [16] and experimental studies [17] have confirmed Jaynes claim. Maxwell [14] saw that the second law of thermodynamics was a statistical, not a dynamic and deterministic, law; the seemingly deterministic behavior of macroscopic systems was due to the fact that such behavior was the most likely behavior by a very large margin.

Historically, Boltzmann derived his distribution from microstate counting arguments, but Gibbs [18] showed how this, and other distributions from statistical mechanics, could be derived by maximizing entropy subject to

certain physical constraints. As a way of illustration, consider N entities that can exist in one of S different states. The number of different ways (W) that these N entities can be distributed into these S states such that the macrostate distribution (i. e. the number n_i of entities expressing each state i) is the same is given by the multinomial formula (Eq. (4a)). Taking logarithms, applying Sterling's approximation ($\ln(x!) \approx x \ln(x) - x$ for large values of x), and re-expressing the numbers (n_i) as proportions ($p_i = n_i/N$), we get Shannon's information entropy (Eq. (4b)). We then see that maximizing the number of ways (W) that different microstates will produce the same macroscopic structure, consistent with certain physical constraints, is equivalent to maximizing the information entropy of $\mathbf{p} = \{p_i\}$ subject to these constraints. This link between counting microstates and entropy breaks down when the states vary continuously rather than being discrete with a fixed number, and a more general link is needed; this is explained below. In what follows we will attempt to develop a macroscopic description of ecological communities following this information theoretic approach to statistical mechanics. Although this approach began with Gibbs it was developed into its modern and generalized form, in the context of the Maximum Entropy Formalism, by Jaynes [19,20,21].

$$W = \frac{N!}{n_1!n_2!\dots n_S!} \quad (4a)$$

$$\frac{\ln(W)}{N} \approx H = - \sum_{i=1}^S p_i \ln(p_i) \quad (4b)$$

One begins by defining the average information content of a probability distribution using a Bayesian interpretation of probabilities, recognizing that the set of relative abundances $\mathbf{ra} = \{ra_i\}$ has the formal properties of a probability distribution. To emphasize this equivalence, we will express relative abundances as Bayesian probabilities $\mathbf{ra} = \{p_i\}$ where p_i is the probability that a unit of resource will be allocated to species i given certain information about macroscopic properties of the community. The uncertainty of the information contained in p_i is defined as $I_i = -\ln(p_i)$ and the average uncertainty of information content of a probability distribution, $\sum p_i I_i$, is the information (or Shannon) entropy (Eq. (4b)). For instance, if our available information is sufficient to perfectly predict which of S different states will be expressed by an entity before it happens, then we would have zero uncertainty, we would ascribe $p_i = 1$ to the correct state and ascribe $p_j = 0$ ($i \neq j$) to all others, and the Information entropy would be zero. If, on the other hand, our available information was simply that there are S different and

mutually exclusive states *and nothing else*, then we would ascribe $p_i = 1/S$ for all these states and the Information entropy would be maximal: $-\ln(S)$.

Equation (4b) is valid when the different possible states are discrete and fixed in number. A more general expression, valid for continuous states or when the number of states is not fixed, is the relative entropy expressed with reference to a maximally uninformative (or ignorance) prior probability distribution \mathbf{q} (Eq. (5)). The ignorance prior \mathbf{q} is chosen using transformation groups such that \mathbf{q} is invariant under changes in scale or location; this is equivalent to a scale-invariant measure on the probability space [21]. For a fixed number of unordered discrete states, \mathbf{q} is the discrete uniform distribution and, in this special case, the relative entropy (Eq. (5) equals the entropy (Eq. (4b)). The relative entropy is the negative of the Kullback-Leibler divergence [22] in Bayesian inference, which measures the divergence between two probability distributions (\mathbf{p}, \mathbf{q}).

$$\text{RH} = - \sum p_i \ln \left(\frac{p_i}{q_i} \right) \quad (5a)$$

$$\text{RH} = - \int p_i \ln \left(\frac{p_i}{q_i} \right) . \quad (5b)$$

The macroscopic constraints on the behavior of the system are expressed as linear functions of products of \mathbf{p} and traits of each of the i states (x_{ij}) in the form of j macroscopic constraints on means (Eq. (6)); examples will be given shortly.

$$\bar{X}_j = \sum x_{ij} p_i . \quad (6)$$

From basic axioms of inductive reasoning [21] we want to ascribe probability values (p_i) that agree with the information encoded in the constraint equations, but that do not imply any additional information beyond this available macroscopic information. In other words, they agree with what we know (the macroscopic constraints), but that is otherwise maximally uncertain (i. e. that doesn't assume further information for which we are lacking). Since Eqs. (4) and (5) each measure the average uncertainty of information content of \mathbf{p} , maximizing uncertainty subject to the constraints is equivalent to maximizing the (relative) entropy subject to the constraints. This is done using the method of Lagrange multipliers. We first specify our objective function (Q , Eq. (7)) which consists of the relative entropy (RH) plus each of the j constraint equations multiplied by its Lagrange multiplier (λ_j) and solve for the values of \mathbf{p} that maximize Q (Eq. (8)). The solution is a generalized exponential distribution (Eq. (9)). Analytical solutions to the values of λ are possible when there

are only a few constraint equations and numerical methods [23,24] are used for more complicated situations.

$$Q = RH + \lambda_0 \left(1 - \sum p_i\right) + \lambda_1 \left(\bar{X}_1 - \sum p_i x_{i1}\right) + \dots + \lambda_j \left(\bar{X}_j - \sum p_i x_{ij}\right) \quad (7)$$

$$\frac{\partial Q}{\partial p_i} = -(\ln p_i + 1) + \ln q_i - \lambda_0 - \sum_{j=1}^K x_{ij} \lambda_j = 0 \quad (8)$$

$$p_i = \frac{q_i e^{-\sum_{j=1}^K x_{ij} \lambda_j}}{\sum_i q_i e^{-\sum_{j=1}^K x_{ij} \lambda_j}} \quad (9)$$

The reason why entropy maximization works (when the correct physical constraints are identified) is that if the same macroscopic behavior arises every time we apply the same physical constraints, then these constraints must be sufficient in the explanation and the myriad complexities of the microscopic dynamics must be irrelevant: the overwhelming majority of microstates that are compatible with the macroscopic constraints look the same at the macroscopic level. At the macroscopic level it does not matter which of the macroscopically redundant microstates the system finds itself.

Fixed Species Pools: Predicting Community Composition

This section deals with the case in which the total number of species that can potentially arrive at a given site is known, as are the values of certain morphological, physiological or phenological traits of each species. This list of potential species is called the species pool. In this case, the goal is to predict the relative abundance of each of these species in the pool. A more general, but less precise problem arises when one does not know the number (and therefore the specific identity) of the species making up such a pool. This more general problem will be developed later.

Imagine a collection of genotypes possessing different values of some heritable morphological, physiological or phenological trait x . If different values of this trait cause differences in per capita growth rates of these genotypes then natural selection will result in increases in relative abundance of these genotypes according to the general replicator equation [25] of natural selection (Eq. (10)).

$$\frac{dp_i(t)}{dt} = p_i(t) (r_i(t) - \bar{r}(t)) \quad (10)$$

If we assume for simplicity that the relationship between per capita growth rates and the trait is linear plus a random error term (ε) with zero mean, i.e. $r_i(t) = a(t) + b(t) x_i + \varepsilon_i$, then the general replicator equation is:

$$\frac{dp_i(t)}{dt} = p_i(t) b(t) (x_i - \bar{X}(t)) \quad (11)$$

Equation (11), or more complicated versions if the relationship between per capita growth rates and traits is non-linear, defines a dynamic for community composition. The dynamics of such equations can be very complex, including the presence of chaotic attractors. However complex the dynamic might be, it is a function of the difference between the trait of each genotype, x_i , and the average trait value at a given time, $\bar{X}(t) = \sum p_i(t) X_i$. The trajectory of \bar{X} over time is a consequence of this dynamic and is constrained by it.

The breeder's equation of quantitative genetics (Eqs. (12a), (12b)), or its multivariate equivalent [26], gives the amount by which \bar{X} changes in one time unit (formally, before and after a single selection event). In this equation $h^2(t)$ is the heritability of the trait, varying between 1 (trait values are perfectly transmitted to offspring) and 0 (trait values are independent between parents and offspring) and $S(t)$ is the selection gradient at time t , i.e. the amount by which birth/death probabilities bias genotypes possessing different values of the trait. This equation therefore describes how the average trait value will behave in a given environment and is subject to natural selection. Because these average trait values change systematically over time and across different environmental conditions, they provide information about the trait distribution and are constraints (Eq. (6)). Therefore, if we know the values of these average trait values, and we know the trait values of each species, then we have the same formal mathematical problem as given in the Maximum Entropy Formalism.

$$\bar{X}(t+1) = h^2(t) S(t) + \bar{X}(t) \quad (12a)$$

$$\bar{X}(t) = \sum_{j=0}^t h^2(j) S(j) + \bar{X}(0) \quad (12b)$$

Natural selection, which describes the degree to which genotypes possessing particular traits in a given environmental setting have biased probabilities of reproduction and death, therefore represents a physical constraint on the dynamics of the system. We don't have to know the details of this dynamic so long as we can predict, or measure, these average trait values at the level of the entire community. Natural selection among potentially interbreeding genotypes (i.e. genotypes belonging

to the same species) leads to evolution as genotypes possessing the favored trait replace those of genotypes selected against. However, natural selection among genotypes that are reproductively isolated (i. e. genotypes belonging to different species) cannot lead to evolution since genes causing the particular phenotypic trait cannot be transmitted across the species barrier. In this case, natural selection leads to changes in the relative abundance of different species. In other words, natural selection among genotypes of different species leads to community assembly.

Before describing a field test of this statistical mechanistic approach, it is useful to look at a simple simulation. Consider a species pool consisting of six species, each species having one relevant trait whose value for species i is ($x_i = 1, 2, \dots, 6$). A neutral process of community assembly [27] would consist of each individual of each species having exactly the same probabilities of survival and reproduction irrespective of the trait value, so that any actual differences in population growth rates (i. e. $r_i(t)$, the per capita growth rates) are due purely to sampling fluctuations. We begin with 60 individuals per species and, in each generation, each species adds one new individual (reproduces) with a probability of $1/6$ and loses one existing individual (death) with a probability of $1/6$. Figure 2a shows the results of a simulation over 5000 generations and Fig. 2b shows the change in the average trait value (a community aggregated trait) over time in the community. Because probabilities of birth and death, and thus the effect of natural selection, are independent of the phenotypic trait, the average trait value fluctuates randomly. Notice that, since the trait value has no causal relationship to the probabilities of survival and reproduction and therefore does not constrain the population dynamics, the average trait value is very close to the value predicted by the maximally uninformative prior for this problem which is a discrete uniform distribution ($p_i = 1/6$). Using the average trait value at generation 5000 as a constraint and maximizing the entropy conditional on this average trait value gives, as expected, a maximum entropy distribution which is almost a discrete uniform distribution (Fig. 2c). In other words, since the phenotypic traits did not constrain the dynamics, the average trait value provided no new information that was not already present in the maximally uninformative prior.

Now, we repeat the simulation except that the probabilities of birth and death are functions of the trait x_i : larger values of x_i increase the probability of an individual of species i dying, while larger values of x_i decrease the probability of an individual of species i reproducing. Figure 3 shows the result of a typical simulation run.

Now, since there is a causal connection between the trait value and the probabilities of birth and death, these trait values constrain the population dynamics of each species and therefore the average trait value reflects the direction of natural selection as specified in the breeder's equation. Since natural selection favors individuals with low values of trait x , the average trait value (the community aggregated trait value) decreases over time. Since the trait constrains the dynamics, the average trait value provides information. Using the average trait value at the end of this simulation (generation 1000) and maximizing the entropy conditional on this average trait value correctly predicts the relative abundance of each species at this time (Fig. 3c).

It is possible to make these simulations much more complicated and realistic but the basic result is the same. If trait values are causally connected to probabilities of survival, reproduction, immigration and emigration then the population dynamics of the species will be constrained by them as specified in the general replicator equation (Eq. (11)) and the changes in these average trait values over time will be described by the breeder's equation or its multivariate version if (as there always is) there is more than one trait involved in determining fitness. In fact, since the general replicator equation is a mathematical expression of the notion of evolutionary fitness that links heritable phenotypic traits to probabilities of survival and reproduction relative to competing genotypes, such community average trait values are tracking the constraint of fitness over time and this is why they provide information on relative abundances.

An empirical example can be found in the context of secondary succession in an herbaceous plant community. Secondary succession is the well-known process of re-colonization and subsequent vegetation change following a major disturbance that kills off an existing plant community. A classic example is the pattern of vegetation change over time following abandonment of an agricultural field. If one lists the species and their relative abundances each year following abandonment in different regions and compares these lists then the patterns are unintelligible. Different species will be found in each list. On the other hand, if one lists the values of key morphological, physiological and phenological traits related to the ability of species to survive and reproduce that are found over time then very consistent patterns emerge. If one concentrates on the traits possessed by the more abundant species in each list over time, the patterns are even more consistent. Immediately following abandonment the common species will possess traits that allow them to rapidly colonize the newly opened space [28]. For instance, species

Entropy Maximization and Species Abundance, Figure 2

a An example of a neutral dynamic involving six species. Probabilities of birth and death are equal and all fluctuations in population numbers are due to sampling fluctuations. **b** Changes in the community averaged (aggregated) trait value over time that is produced by such a neutral dynamic. **c** Predicted relative abundances, given the community aggregated trait value at the end of the series, using the Maximum Entropy Formalism

having rapid growth rate and having small seeds, and especially seeds with appendages that allow for long distance dispersal, are very common. Species whose individuals produce large numbers of seeds are common since larger numbers of seeds increase the chances of some arriving at the site. Species adapted to sites having frequent large mortality events reproduce very rapidly following germination and this limits their size. Small plants that are required to

produce many seeds must further decrease the size of each one, and so on. Such ruderal species have physiologies that are adapted to quickly acquire available resources and allocate them to production rather than maintenance and this leads to a correlated series of traits (specific leaf area, maximum photosynthetic rate, tissue nutrient supplies, tissue turnover rates) that maximize production of new tissues over maintenance of existing ones [29,30]. As a vegetation

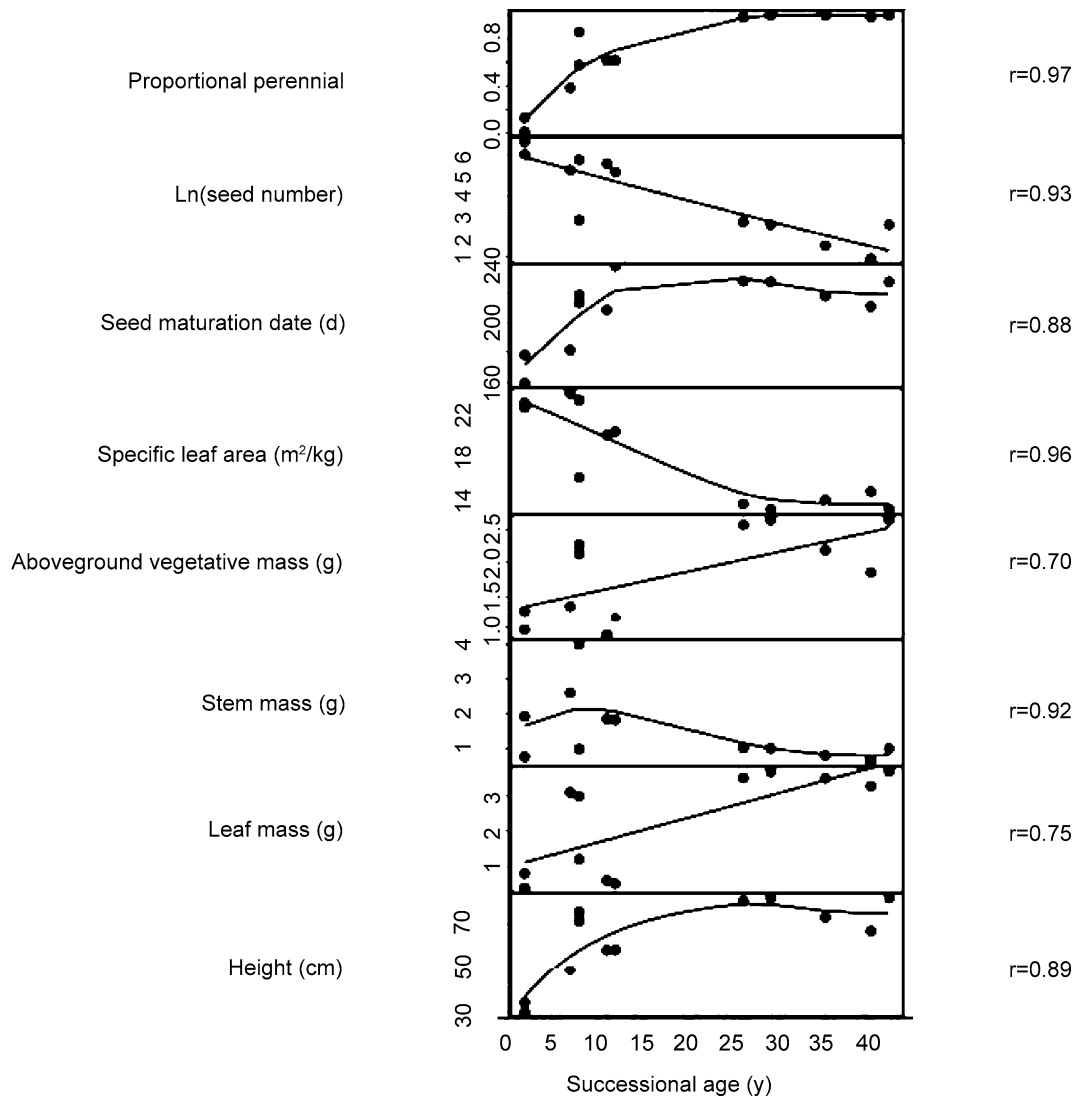

Entropy Maximization and Species Abundance, Figure 3

a An example of a dynamic involving six species in which one trait determines the differential probabilities of birth and death plus fluctuations in population numbers due to sampling fluctuations. **b** Changes in the community averaged (aggregated) trait value over time that is produced by such a dynamic. **c** Predicted relative abundances, given the community aggregated trait value at the end of the series, using the Maximum Entropy Formalism

cover develops, these ruderal species are replaced by a series of other species, larger and better able to competitively suppress those coming before, and this leads to changes in the suite of traits possessed by such species.

A recent structural equation model linking such plant traits to time following abandonment of vineyards in southern France was published by Vile et al. [31]. To test the ability of a maximum entropy approach to pre-

dicting secondary succession, Shipley et al. [32] used the same series of 10 sites. The sites varied from two to 42 years post-abandonment and estimates of the above-ground biomass of each species at each site were obtained from two $0.5 \times 0.5 \text{ m}^2$ quadrants in each. All were within a 4 km^2 distance and all had the same history of land use before abandonment. Using the 30 species in these that were more than transients in these 12 sites as the species

Entropy Maximization and Species Abundance, Figure 4

Each point represents the community aggregated value of the trait measured in one field, whose successional age (years since abandonment) is given on the ordinate. Lines are regression (cubic spline) smoothers. Also shown is the Pearson correlation between observed and predicted values. Figure taken from [32]

pool, and using eight traits measured on each of these 30 species, we calculated the community average (aggregated) values for each trait in each site. Figure 4 shows the results. As can be seen, there are clear systematic trends over time in these community averaged traits and these are consistent with trends reported by others.

If these traits are causally linked to fitness of these 30 species over this successional sequence then they will constrain the actual population dynamics as individual plants possessing different values of these traits immigrate into the sites, compete and reproduce. Using these eight com-

munity averaged trait values for each site, we then calculated the relative abundances assuming that these traits are sufficient to determine the population dynamics except for random sampling fluctuation. We did this by finding the distributions of relative abundance having maximum entropy after constraining them to agree with the community averaged traits. This was done using an algorithm published by Della Pietra et al. [24]. Figure 5 shows the result.

As can be seen, the predicted and observed values are close and highly significant. Clearly, there are prediction errors and this is probably be due to a combination of

Entropy Maximization and Species Abundance, Figure 5

Observed and predicted relative abundances of each of 30 species in each of 10 different fields. Predicted relative abundances were obtained by maximizing the entropy of the distribution of relative abundances for each field conditional on the eight community aggregated traits shown in Fig. 4

missing constraints (i. e. unmeasured traits that contribute to fitness), measurement error of the trait values and random demographic fluctuations due to the fact that the numbers of individuals per site are sufficiently small that probabilities of survival and reproduction and actual frequencies of survival and reproduction differ due to sampling effects.

Species Abundance Distributions

The previous section considered the case in which we know which species occur in the species pool and in which interest resides in predicting the relative abundance of each species given certain traits. In such a situation the number of species (i. e. states in which biomass can be allocated) is fixed. However, one can also imagine situations in which the number and identity of species in the species pool is unknown. In this case we cannot predict the abundance of any particular species but we do know the distribution of abundances of the species that are present. This leads to the species abundance distribution (SAD) which describes the probability that a species will have an abundance of n individuals.

The empirical study of species abundance distributions has a long history in ecology. The first known treatment was published in Japanese by Motomira [33], as cited in Hutchinson [4]. The proposed distribution was the geometric series (Eq. (13)). Corbet [34] published a species abundance distribution based on species of butterflies and this distribution, like all others since, shows that a few species are very common and most species are very rare. C.B. Williams had collected similar data for moths and so these two authors, in collaboration with the statistician and evolutionary theorist R.A. Fisher, put forward the log-series distribution (Eq. (14)) as a statistical description of the species abundance relationship [35]. Pueyo [36], applying a Taylor series expansion to the log-series distribution, found that small deviations from a log-series gave a bounded power law (Eq. (15)). F.W. Preston, working with birds, plotted the number of species having different numbers of individuals (i. e. abundance) by binning values on a logarithmic scale and showed that, in this form, the species abundance distribution was a log-normal distribution [37,38], although any variable that must be greater than zero and is strongly right-skewed will tend to show a curve similar to a log-normal distribution after binning.

More recently, so-called neutral models of population dynamics [27,39] have been shown to recreate these patterns. Neutral models assume that all species have equal fitnesses (thus probabilities of survival, reproduction and migration) and thus all changes in population size are due to sampling fluctuations. Hubbell [27], in particular, has proposed a slightly different SAD, the zero-sum multinomial. However, differentiating between these different distributions using empirical data has proved problematic because they are very similar over most of the range of observed values [40]. Even more problematic is that authors searching for specifically biological explanations for these patterns tend to ignore that such statistical patterns are commonly found in non-biological systems. Significantly for our purposes, Preston [41] noted the similarity of species abundance distributions and gas laws as well as the distribution of wealth. Limpert et al. [42] and Nekola and Brown [43] document other cases. If the patterns transcend ecology then the explanation for the patterns must also transcend ecology.

$$P(n) = \frac{\Psi}{n} \quad (13)$$

$$p(n) = \frac{\phi x^n}{n} = \frac{\phi (e^{-\beta})^n}{n} = \frac{\phi e^{-\beta n}}{n} \quad (14)$$

$$p(n) = \frac{\phi e^{-\beta_1 n}}{n \beta_2} \quad (15)$$

Very recently, two different groups have proposed that the common patterns of species abundance distributions can be more parsimoniously explained by the same statistical mechanistic approach as described above. The first hurdle in applying a maximum entropy approach to this area is to obtain the maximally uninformative prior. In the case of a fixed species pool the maximally uninformative prior is well-known: a discrete uniform distribution. However, when the number of species in the species pool is unknown and abundance is measured in numbers of individuals (a discrete variable) the prior is not clear. If abundance was measured as biomass, a continuous variable, then the maximally uninformative prior is known based on a consideration of invariance under transformations of scale and location [21] and is a Jeffrey's prior. Pueyo et al. [44], again based on a consideration of invariance under transformations of scale and location have shown that when abundance is measured as counts of individuals the same maximally uninformative prior is obtained: $q(n) = 1/n$.

The first constraint that one might propose is a limit on the total number of individuals (N) that can exist at a site, at least when averaged over time. This follows from

the fact that the total amount of resources within a fixed area is itself fixed but also follows from basic postulates of per capita growth, namely that as populations increase the increased competition for resources leads to a decrease in per capita reproductive rates and an increase in per capita death rates, until the per capita growth rate is zero. The second constraint is that the total number of species (S) that can exist at a site is also fixed, at least when averaged over time. This follows from the theory of island biogeography [45] where, as the available resources at a site decrease, the rate of introduction of new species decreases and the rate of local extinction of species already present increases, each due to increased competition. If we accept these two macroscopic constraints, then the average number of individuals per species must also be constrained (Eq. (16)).

$$\bar{n} = \frac{N}{S} \approx k_1. \quad (16)$$

To find the predicted proportion of species having abundance n in the community, and assuming that the only constraint acting on the system is to limit the average number of individuals per species (Eq. (16)), we must maximize the relative entropy conditional on this one constraint. In other words, find the values of \mathbf{p} that maximize Eq. (5a), subject to the constraint given in Eq. (16) plus the constraint on normalization ($\sum p_i = 1$). The solution, given in Eq. (17), is Fisher's log-series distribution where Z is a constant.

$$p_i = \frac{q_i e^{-\lambda_1 n_i}}{\sum_i q_i e^{-\lambda_1 n_i}} = \frac{e^{-\lambda_1 n_i}}{n_i Z}. \quad (17)$$

We know that, in any real ecological community, the process of community assembly involves a myriad of complicated interactions between the individuals of each species with each other and with those of other species plus the interactions of each with the physical properties of the environment. Equation (17) says that the statistical pattern of species relative abundance that was fit to empirical data by Fisher, Corbet and Williams is simply a consequence of two constraints: the total number of individuals at the site is (approximately) constant and the total number of species at the site is (approximately) constant. Equation (17) doesn't deny the existence of the complicated biological interactions that are involved in community assembly but does claim that these interactions are irrelevant with respect to the macroscopic pattern, *except* in how they constrain the total number of individuals and species. Pueyo et al. [44] call this an idiosyncratic model of community assembly: the exact process (or model) determining the abundance of species i is independent of the

process determining the abundance of every other species, therefore knowing the abundance of species i provides no information about the abundance of species j . Thus, from a macroscopic perspective, the abundances of each species at any point in time can be viewed as independent and identically distributed variables even though independent does not imply no interactions and identically distributed does not imply ecologically equivalent.

Can we imagine other macroscopic constraints that might exist in real communities? The per capita growth rate of species i over one small unit of time (Δt) is given as $r_i(t + \Delta t) = \ln(n_i(t + 1)) - \ln(n_i(t))$. If each species in the community is at a stable equilibrium by time t then $r_i(t) \approx 0$ for all species and so the following macroscopic constraint must hold:

$$\frac{\sum \ln(n(t + 1))}{S} = \frac{\sum \ln(n(t))}{S} = k_2. \quad (18)$$

Given the per capita growth rate describes exponential growth at time t , and since we are imagining a community

that is filled with individuals, it seems quite reasonable that Eq. (18) will hold; if it did not hold over any extended time then there would be huge swings in total biomass, and this is not observed. Maximizing the relative entropy conditional on the constraints in Eqs. (16) and (18), we recover the bounded power law of Pueyo [36], as given in Eq. (15).

Finally, we could imagine a case in which the community dynamics are such that the population trajectories are in a basin of attraction but in which random external perturbations result in total resource levels fluctuations around some average values so that the per capita growth rates, $r_i(t)$, are zero over a longer time scale but can randomly deviate from zero at any instant. The fact that the trajectories are in a basin of attraction means that there will be a constraint on how far the $r_i(t)$ values can deviate from zero and this will place a constraint on the variance of the $r_i(t)$ values and this would produce a bounded log-normal distribution when maximizing the relative entropy. Since this last constraint is quite speculative at this point, we won't explore this point further.

Entropy Maximization and Species Abundance, Figure 6

Distribution of abundances of tree species in a 50 hectare plot in Barro Colorado Island (Panama). Three theoretical curves, derived the maximization of relative entropy, are shown. The Geometric and Log-series curves are indistinguishable at this scale

To place these results in an empirical context, I have fit the geometric series of Motomura, the log-series of Fisher, and the bounded log-series of Pueyo to the extensive data set of tree species on Barro Colorado Island (Panama); these data come from the appendix of Volkov [46]. This data set consists of a complete census of each tree whose stem diameter at breast height is greater than 1 cm within a 50 hectare area [47]. The resulting curves are given in Eq. (19) and the result is shown in Fig. 6. The fitted curves for the geometric series and the log-series are not distinguishable and are not significantly different ($F_{1,1715} = 2.78$, $p = 0.10$) but the fitted curves for the log-series and the bounded log-series are highly significant ($F_{1,1715} = 534.43$, $p \ll 0.001$).

$$p_i = \frac{1}{933.32n} \quad (19a)$$

$$p_i = \frac{e^{-(4.263e-4)n}}{935.2n} \quad (19b)$$

$$p_i = \frac{e^{-(6.78e-3)n}}{1121n^{0.68}} \quad (19c)$$

Future Directions

Before discussing future directions, it is important to appreciate how little published work has been done in ecology using entropy maximization. Plank studied statistical mechanistic properties of the Lotka–Volterra equations [48,49,50]. A few studies have considered some theoretical aspects of entropy maximization in food webs [51, 52,53,54]. Levich and co-workers [55,56,57] applied entropy maximization to algal communities but without including maximally uninformative priors. Besides [44], discussed above, I am not aware of any other work in this area. Clearly, future directions are many and varied.

At a theoretical level it will be important to more precisely link the dynamics of natural selection and the allocation of energy and resources to individuals to microstate properties of communities. In this context Dewar's fluctuation theorem [58,59,60] might prove fruitful since it links entropy maximization with those dynamic trajectories of microstates that maximize the production of entropy. If possible this could open up a thermodynamic interpretation of community assembly and possibly even of evolution by natural selection.

Those few empirical results that have been obtained so far come from plant communities. In part, this is because it is easier to census plant communities, and therefore to get reasonably accurate determinations of abundance for all species present, but the main reason is probably idiosyncratic: the application of these ideas to ecology is very

recent and those very few ecologists who have explored them have been trained in plant ecology. The extension of these methods to animal communities is an obvious future direction. The use of constraints based on food webs seems particularly promising since such constraints can be linked to basic thermodynamic principles of energy transfer across trophic levels. As an example, homeotherms and poikilotherms have different basal metabolic rates and so the proportion of these two types of animals should constrain the length of food chains. Metabolic rate scales allometrically with body size [61] and so the average body size in a community should be constrained by the total amount of available energy and this, in turn, will be related to potential evapotranspiration (a function of average temperatures and precipitation). The ratio of predators to prey also scales with body size and so this might also serve as a constraint on the assembly of animal communities.

At an empirical level, it is clear that the success or failure of this approach resides in our ability to properly identify those physical constraints that actually control community dynamics and how such constraints might change as a function of environmental variables. This requires further work in order to make statistical inferences in the context of maximum entropy models and, especially, in detecting lack of fit. When the entities being allocated to different states are discrete and mutually independent and the states themselves are also discrete and fixed in number then the problem is a classical one. Given such assumptions then the statistic $-2N \sum p_i \ln p_i$ follows a chi-squared distribution with $N - k - 1$ degrees of freedom ($k =$ the number of constraints). However, such conditions rarely apply to ecological problems either because the sequential allocations are not mutually independent or because the total number (N) is unknown.

Roderick Dewar and Annabel Porté (INRA Centre de Bordeaux–Aquitaine, France) have been exploring other directions (pers. comm.). For instance, if we consider that the total amount of available resources (R) in an area is limited, that the organisms are using all of these resources, and that each species has a characteristic per capita rate of resource use, then the following constraint must hold: $\sum p_i r_i = R$. If this is combined with some well-known scaling laws in ecology relating body size with per capita resource use then, even without knowing the number of identity of species in a species pool, one can derive the species abundance distribution. Using the exponent of the Shannon entropy as an expression of the expected number of species, they explore how species richness (\hat{S} , the number of species per unit area) should vary as a function of R at different scales. At local spatial scales it is well known that \hat{S} has a so-called humped-back distribution [62] with

respect to productivity, and therefore R . At such local spatial scales, it is reasonable to consider R fixed and S (the number of species in the species pool) to be finite. At spatial scales large enough to include substantial variation in mean annual temperature and precipitation \hat{S} scales allometrically with potential evapotranspiration [63] and it is perhaps reasonable to consider R free. Can these contrasting patterns of biodiversity at different spatial scales be accounted for by a statistical mechanistic approach in which constraints on R and S change?

Glossary

Bernoulli shift Mathematical abstraction of the scenario in statistics or probability in which one performs repeated independent identical experiments.

Markov chain A probability model describing a sequence of observations made at regularly spaced time intervals such that at each time, the probability distribution of the subsequent observation depends only on the current observation and not on prior observations.

Measure-preserving transformation A map from a measure space to itself such that for each measurable subset of the space, it has the same measure as its inverse image under the map.

Measure-theoretic entropy A non-negative (possibly infinite) real number describing the complexity of a measure-preserving transformation.

Product transformation Given a pair of measure-preserving transformations: T of X and S of Y , the product transformation is the map of $X \times Y$ given by $(T \times S)(x, y) = (T(x), S(y))$.

Definition of the Subject

Many physical phenomena in equilibrium can be modeled as measure-preserving transformations. Ergodic theory is the abstract study of these transformations, dealing in particular with their long term average behavior.

One of the basic steps in analyzing a measure-preserving transformation is to break it down into its simplest possible components. These simplest components are its ergodic components, and on each of these components, the system enjoys the ergodic property: the long-term time

average of any measurement as the system evolves is equal to the average over the component. Ergodic decomposition gives a precise description of the manner in which a system can be split into ergodic components.

A related (stronger) property of a measure-preserving transformation is mixing. Here one is investigating the correlation between the state of the system at different times. The system is mixing if the states are asymptotically independent: as the times between the measurements increase to infinity, the observed values of the measurements at those times become independent.

Introduction

The term ergodic was introduced by Boltzmann [8,9] in his work on statistical mechanics, where he was studying Hamiltonian systems with large numbers of particles. The system is described at any time by a point of *phase space*, a subset of \mathbb{R}^{6N} where N is the number of particles. The configuration describes the 3-dimensional position and velocity of each of the N particles. It has long been known that the Hamiltonian (i. e. the overall energy of the system) is invariant over time in these systems. Thus, given a starting configuration, all future configurations as the system evolves lie on the same *energy surface* as the initial one.

Boltzmann's *ergodic hypothesis* was that the trajectory of the configuration in phase space would fill out the entire energy surface. The term ergodic is thus an amalgamation of the Greek words for work and path. This hypothesis then allowed Boltzmann to conclude that the long-term average of a quantity as the system evolves would be equal to its average value over the phase space.

Subsequently, it was realized that this hypothesis is rarely satisfied. The ergodic hypothesis was replaced in 1911 by the *quasi-ergodic hypothesis* of the Ehrenfests [17] which stated instead that each trajectory is dense in the energy surface, rather than filling out the entire energy surface. The modern notion of ergodicity (to be defined below) is due to Birkhoff and Smith [7]. Koopman [44] suggested studying a measure-preserving transformation by means of the associated isometry on Hilbert space, $U_T: L^2(X) \rightarrow L^2(X)$ defined by $U_T(f) = f \circ T$. This point of view was used by von Neumann [91] in his proof of the mean ergodic theorem. This was followed closely by Birkhoff [6] proving the pointwise ergodic theorem. An ergodic measure-preserving transformation enjoys the property that Boltzmann first intended to deduce from his hypothesis: that long-term averages of an observable quantity coincide with the integral of that quantity over the phase space.

These theorems allow one to deduce a form of independence on the average: given two sets of configurations A and B , one can consider the volume of the phase space consisting of points that are in A at time 0 and in B at time t . In an ergodic measure-preserving transformation, if one computes the average of the volumes of these regions over time, the ergodic theorems mentioned above allow one to deduce that the limit is simply the product of the volume of A and the volume of B . This is the weakest mixing-type property. In this article, we will outline a rather full range of mixing properties with ergodicity at the weakest end and the Bernoulli property at the strongest end.

We will set out in some detail the various mixing properties, basing our study on a number of concrete examples sitting at various points of this hierarchy. Many of the mixing properties may be characterized in terms of the Koopman operators operators mentioned above (i. e. they are *spectral properties*), but we will see that the strongest mixing properties are not spectral in nature.

We shall also see that there are connections between the range of mixing properties that we discuss and measure-theoretic entropy. In measure-preserving transformations that arise in practice, there is a correlation between strong mixing properties and positive entropy, although many of these properties are logically independent.

One important issue for which many questions remain open is that of higher-order mixing. Here, the issue is if instead of asking that the observations at two times separated by a large time T be approximately independent, one asks whether if one makes observations at more times, each pair suitably separated, the results can be expected to be approximately independent. This issue has an analogue in probability theory, where it is well-known that it is possible to have a collection of random variables that are pairwise independent, but not mutually independent.

Basics and Examples

In this article, except where otherwise stated, the measure-preserving transformations that we consider will be defined on probability spaces.

More specifically, given a measurable space (X, \mathcal{B}) and a probability measure μ defined on \mathcal{B} , a *measure-preserving transformation* of (X, \mathcal{B}, μ) is a \mathcal{B} -measurable map $T: X \rightarrow X$ such that $\mu(T^{-1}B) = \mu(B)$ for all $B \in \mathcal{B}$.

While this definition makes sense for arbitrary measures, not simply probability measures, most of the results and definitions below only make sense in the probability measure case. Sometimes it will be helpful to make the assumption that the underlying probability space is

a Lebesgue space (that is, the space together with its completed σ -algebra agrees up to a measure-preserving bijection with the unit interval with Lebesgue measure and the usual σ -algebra of Lebesgue measurable sets). Although this sounds like a strong restriction, in practice it is barely a restriction at all, as almost all of the spaces that appear in the theory (and all of those that appear in this article) turn out to be Lebesgue spaces. For a detailed treatment of the theory of Lebesgue spaces, the reader is referred to Rudolph's book [76]. The reader is referred also to the chapter on [► Measure Preserving Systems](#).

While many of the definitions that we shall present are valid for both invertible and non-invertible measure-preserving transformations, the strongest mixing conditions are most useful in the case of invertible transformations.

It will be helpful to present a selection of simple examples, relative to which we will be able to explore ergodicity and the various notions of mixing. These examples and the lemmas necessary to show that they are measure-preserving transformations as claimed may be found in the books of Petersen [64], Rudolph [76] and Walters [92]. More details on these examples can also be found in the chapter on [► Ergodic Theory: Basic Examples and Constructions](#).

Example 1 (Rotation on the circle) Let $\alpha \in \mathbb{R}$. Let $R_\alpha: [0, 1) \rightarrow [0, 1)$ be defined by $R_\alpha(x) = x + \alpha \pmod{1}$. It is straightforward to verify that R_α preserves the restriction of Lebesgue measure λ to $[0, 1)$ (it is sufficient to check that $\lambda(R_\alpha^{-1}(J)) = \lambda(J)$ for an interval J).

Example 2 (Doubling Map) Let $M_2: [0, 1) \rightarrow [0, 1)$ be defined by $M_2(x) = 2x \pmod{1}$. Again, Lebesgue measure is invariant under M_2 (to see this, one observes that for an interval J , $M_2^{-1}(J)$ consists of two intervals, each of half the length of J). This may be generalized in the obvious way to a map M_k for any integer $k \geq 2$.

Example 3 (Interval Exchange Transformation) The class of interval exchange transformations was introduced by Sinai [85]. An interval exchange transformation is the map obtained by cutting the interval into a finite number of pieces and permuting them in such a way that the resulting map is invertible, and restricted to each interval is an order-preserving isometry.

More formally, one takes a sequence of positive lengths $\ell_1, \ell_2, \dots, \ell_k$ summing to 1 and a permutation π of $\{1, \dots, k\}$ and defines $a_i = \sum_{j < i} \ell_j$ and $b_i = \sum_{\pi(j) < \pi(i)} \ell_j$ (again with $b_0 = 0$). The interval exchange transformation defined by (ℓ_1, \dots, ℓ_k) and π is the map $T: [0, 1) \rightarrow [0, 1)$ defined by $T|_{[a_i, a_{i+1})}(x) = x + (b_i - a_i)$. It is straightforward to check that any such interval exchange transformation preserves Lebesgue measure on the unit interval.

Example 4 (Bernoulli Shift) Let A be a finite set and fix a vector $(p_i)_{i \in A}$ of positive numbers that sum to 1. Let $A^{\mathbb{N}}$ denote the set of sequences of the form $x_0 x_1 x_2 \dots$, where $x_n \in A$ for each $n \in \mathbb{N}$ and let $A^{\mathbb{Z}}$ denote the set of bi-infinite sequences of the form $\dots x_{-2} x_{-1} \cdot x_0 x_1 x_2 \dots$ (the \cdot is a placeholder that allows us to distinguish (for example) between the sequences $\dots 01010 \cdot 10101 \dots$ and $\dots 10101 \cdot 01010 \dots$).

We define a map (the *shift map*) S on $A^{\mathbb{N}}$ by $(S(x))_n = x_{n+1}$ and define S on $A^{\mathbb{Z}}$ by the same formula. Note that S is invertible as a transformation on $A^{\mathbb{Z}}$ but non-invertible as a transformation on $A^{\mathbb{N}}$.

We need to equip $A^{\mathbb{N}}$ and $A^{\mathbb{Z}}$ with measures. This is done by defining the measure of a preferred class of sets, checking certain consistency conditions and appealing to the Kolmogorov extension theorem. Here the preferred sets are the *cylinder sets*. Given $m \leq n$ in the invertible case and a sequence $a_m \dots a_n$, we let $[a_m \dots a_n]_m^n$ denote $\{x \in A^{\mathbb{Z}}: x_m = a_m, \dots, x_n = a_n\}$ and define $\mu([a_m \dots a_n]_m^n) = p_{a_m} p_{a_{m+1}} \dots p_{a_n}$. This is then shown to uniquely define a measure μ on the σ -algebra of $A^{\mathbb{Z}}$ generated by the cylinder sets. It is immediate to see that for any cylinder set C , $\mu(S^{-1}C) = \mu(C)$, and it follows that S is a measure-preserving transformation of $(A^{\mathbb{Z}}, \mathcal{B}, \mu)$. The construction is exactly analogous in the non-invertible case. See the chapter on [► Measure Preserving Systems](#) or the books of Walters [92] or Rudolph [76] for more details of defining measures in these systems.

The class of Bernoulli shifts will play a distinguished role in what follows.

Example 5 (Markov Shift) The spaces $A^{\mathbb{N}}$ and $A^{\mathbb{Z}}$ are exactly as above, as is the shift map. All that changes is the measure.

To define a Markov shift, we need a stochastic matrix P (i. e. a matrix with non-negative entries whose rows sum to 1) with rows and columns indexed by A and a left eigenvector π for P with eigenvalue 1 with the property that the entries of π are non-negative and sum to 1. The existence of such an eigenvector is a consequence of the Perron–Frobenius theory of positive matrices. Provided that the matrix P is irreducible (for each a and a' in A , there is an $n > 0$ such that $P_{a, a'}^n > 0$), the eigenvector π is unique.

Given the pair (P, π) , one defines the measure of a cylinder set by $\mu([a_m \dots a_n]_m^n) = \pi_{a_m} P_{a_m a_{m+1}} \dots P_{a_{n-1} a_n}$ and extends μ as before to a probability measure on $A^{\mathbb{N}}$ or $A^{\mathbb{Z}}$.

Example 6 (Hard Sphere Gases and Billiards) We wish to model the behavior of a gas in a bounded region. We make the assumption that the gas consists of a large number N

of identical balls which move at constant velocity until two balls collide, whereupon they elastically swap momentum along the direction of contact. The phase space for this system is a region of \mathbb{R}^{6N} (with N 3-dimensional position vectors and N 3-dimensional velocity vectors). More abstractly, the system is equivalent to the motion of a single point particle in a region of $\mathbb{R}^M \times \mathbb{R}^M$ (with the first M -vector representing position and the second representing velocity). The system is constrained in that its position is required to lie in a bounded region S of \mathbb{R}^M with a piecewise smooth boundary. The system evolves by moving the position at a constant rate in the direction of the velocity vector until the point reaches ∂S , at which time the component of the velocity parallel to the normal to ∂S is reversed. This then defines a flow (i. e. a family of maps $(T_t)_{t \in \mathbb{R}}$ satisfying $T_{t+s} = T_t \circ T_s$) on the phase space. Since the magnitude of the velocity is conserved, it is convenient to restrict to flows with speed 1. This system is clearly the closest of the examples that we consider to the situation envisaged by Boltzmann. Perhaps not surprisingly, proofs of even the most basic properties for this system are much harder than those for the other examples that we consider.

We will need to make use of the concept of measure-theoretic isomorphism. Two measure-preserving transformations T of (X, \mathcal{B}, μ) and S of (Y, \mathcal{F}, ν) are *measure-theoretically isomorphic* (or just *isomorphic*) if there exist measurable maps $g: X \rightarrow Y$ and $h: Y \rightarrow X$ such that

1. $g \circ h$ and $h \circ g$ agree with the respective identity maps almost everywhere;
2. $\mu(g^{-1}F) = \nu(F)$ and $\nu(h^{-1}B) = \mu(B)$ for all $F \in \mathcal{F}$ and $B \in \mathcal{B}$; and
3. $S \circ g(x) = g \circ T(x)$ for μ -almost every x (or equivalently $T \circ h(y) = h \circ S(y)$ for ν -almost every y).

Measure-theoretic isomorphism is the basic notion of ‘sameness’ in ergodic theory. It is in some sense quite weak, so that systems may be isomorphic that feel very different (for example, as we discuss later, the time one map of a geodesic flow is isomorphic to a Bernoulli shift). For comparison, the notion of sameness in topological dynamical systems (topological conjugacy) is far stronger.

As an example of measure-theoretic isomorphism, it may be seen that the doubling map is isomorphic to the one-sided Bernoulli shift on $\{0, 1\}$ with $p_0 = p_1 = 1/2$ (the map g takes an $x \in [0, 1)$ to the sequence of 0’s and 1’s in its binary expansion (choosing the sequence ending with 0’s, for example, if x is of the form $p/2^n$) and the inverse map h takes a sequence of 0’s and 1’s to the point in $[0, 1)$ with that binary expansion.)

Given a measure-preserving transformation T of a probability space (X, \mathcal{B}, μ) , T is associated to an isometry of $L^2(X, \mathcal{B}, \mu)$ by $U_T(f) = f \circ T$. This operator is known as the *Koopman Operator*. In the case where T is invertible, the operator U_T is unitary. Two measure-preserving transformations T and S of (X, \mathcal{B}, μ) and (Y, \mathcal{F}, ν) are *spectrally isomorphic* if there is a Hilbert space isomorphism Θ from $L^2(X, \mathcal{B}, \mu)$ to $L^2(Y, \mathcal{F}, \nu)$ such that $\Theta \circ U_T = U_S \circ \Theta$. As we shall see below, spectral isomorphism is a strictly weaker property than measure-theoretic isomorphism.

Since in ergodic theory, measure-theoretic isomorphism is the basic notion of sameness, all properties that are used to describe measure-preserving systems are required to be invariant under measure-theoretic isomorphism (i. e. if two measure-preserving transformations are measure-theoretically isomorphic, the first has a given property if and only if the second does). On the other hand, we shall see that some mixing-type properties are invariant under spectral isomorphism, while others are not. If a property is invariant under spectral isomorphism, we say that it is a *spectral property*.

There are a number of mixing type properties that occur in the probability literature (α -mixing, β -mixing, ϕ -mixing, ψ -mixing etc.) (see Bradley’s survey [12] for a description of these conditions). Many of these are stronger than the Bernoulli property, and are therefore not preserved under measure-theoretic isomorphism. For this reason, these properties are not widely used in ergodic theory, although β -mixing turns out to be equivalent to the so-called *weak Bernoulli* property (which turns out to be stronger than the Bernoulli property that we discuss in this article – see Smorodinsky’s paper [87]) and α -mixing is equivalent to strong-mixing.

A basic construction (see the article on [► Ergodic Theory: Basic Examples and Constructions](#)) that we shall require in what follows is the product of a pair of measure-preserving transformations: given transformations T of (X, \mathcal{B}, μ) and S of (Y, \mathcal{F}, ν) , we define the *product transformation* $T \times S: (X \times Y, \mathcal{B} \otimes \mathcal{F}, \mu \times \nu)$ by $(T \times S)(x, y) = (Tx, Sy)$.

One issue that we face on occasion is that it is sometimes convenient to deal with invertible measure-preserving transformations. It turns out that given a non-invertible measure-preserving transformation, there is a natural way to uniquely associate an invertible measure-preserving transformation sharing almost all of the ergodic properties of the original transformation. Specifically, given a non-invertible measure-preserving transformation T of (X, \mathcal{B}, μ) , one lets $\bar{X} = \{(x_0, x_1, \dots): x_n \in X \text{ and } T(x_n) = x_{n-1} \text{ for all } n\}$, $\bar{\mathcal{B}}$

be the σ -algebra generated by sets of the form $\bar{A}_n = \{\bar{x} \in \bar{X} : x_n \in A\}$, $\bar{\mu}(\bar{A}_n) = \mu(A)$ and $\bar{T}(x_0, x_1, \dots) = (T(x_0), x_0, x_1, \dots)$. The transformation \bar{T} of $(\bar{X}, \bar{\mathcal{B}}, \bar{\mu})$ is called the *natural extension* of the transformation T of (X, \mathcal{B}, μ) (see the chapter on [Ergodic Theory: Basic Examples and Constructions](#) for more details). In situations where one wants to use invertibility, it is often possible to pass to the natural extension, work there and then derive conclusions about the original non-invertible transformation.

Ergodicity

Given a measure-preserving transformation $T: X \rightarrow X$, if $T^{-1}A = A$, then $T^{-1}A^c = A^c$ also. This allows us to decompose the transformation X into two pieces A and A^c and study the transformation T separately on each. In fact the same situation holds if $T^{-1}A$ and A agree up to a set of measure 0. For this reason, we call a set A *invariant* if $\mu(T^{-1}A \Delta A) = 0$.

Returning to Boltzmann's ergodic hypothesis, existence of an invariant set of measure between 0 and 1 would be a bad situation as his essential idea was that the orbit of a single point would 'see' all of X , whereas if X were decomposed in this way, the most that a point in A could see would be all of A , and similarly the most that a point in A^c could see would be all of A^c .

A measure-preserving transformation will be called *ergodic* if it has no non-trivial decomposition of this form. More formally, let T be a measure-preserving transformation of a probability space (X, \mathcal{B}, μ) . The transformation T is said to be ergodic if for all invariant sets, either the set or its complement has measure 0.

Unlike the remaining concepts that we discuss in this article, this definition of ergodicity applies also to infinite measure-preserving transformations and even to certain non-measure-preserving transformations. See Aaronson's book [1] for more information.

The following lemma is often useful:

Lemma 1 *Let (X, \mathcal{B}, μ) be a probability space and let $T: X \rightarrow X$ be a measure-preserving transformation. Then T is ergodic if and only if the only measurable functions f satisfying $f \circ T = f$ (up to sets of measure 0) are constant almost everywhere.*

For the straightforward proof, we notice that if the condition in the lemma holds and A is an invariant set, then $\mathbf{1}_A \circ T = \mathbf{1}_A$ almost everywhere, so that $\mathbf{1}_A$ is an a. e. constant function and so A or A^c is of measure 0. Conversely, if f is an invariant function, we see that for each α , $\{x: f(x) < \alpha\}$ is an invariant set and hence of measure 0

or 1. It follows that f is constant almost everywhere. We remark for future use that it is sufficient to check that the bounded measurable invariant functions are constant.

The following corollary of the lemma shows that ergodicity is a spectral property.

Corollary 2 *Let T be a measure-preserving transformation of the probability space (X, \mathcal{B}, μ) . Then T is ergodic if and only if 1 is a simple eigenvalue of U_T .*

The ergodic theorems mentioned earlier due to von Neumann and Birkhoff are the following (see also the chapter on [Ergodic Theorems](#)).

Theorem 3 (von Neumann Mean Ergodic Theorem [91]) *Let T be a measure-preserving transformation of the probability space (X, \mathcal{B}, μ) . For $f \in L^2(X, \mathcal{B}, \mu)$, let $A_N f = 1/N(f + f \circ T + \dots + f \circ T^{N-1})$. Then for all $f \in L^2(X, \mathcal{B}, \mu)$, $A_N f$ converges in L^2 to an invariant function f^* .*

Theorem 4 (Birkhoff Pointwise Ergodic Theorem [6]) *Let T be a measure-preserving transformation of the probability space (X, \mathcal{B}, μ) . Let $f \in L^1(X, \mathcal{B}, \mu)$. Let $A_N f$ be as above. Then for μ -almost every $x \in X$, $(A_N f(x))$ is a convergent sequence.*

Of these two theorems, the pointwise ergodic theorem is the deeper result, and it is straightforward to deduce the mean ergodic theorem from the pointwise ergodic theorem. The mean ergodic theorem was reproved very concisely by Riesz [71] and it is this proof that is widely known now. Riesz's proof is reproduced in Parry's book [63]. There have been many different proofs given of the pointwise ergodic theorem. Notable amongst these are the argument due to Garsia [23] and a proof due to Katznelson and Weiss [40] based on work of Kamae [35], which appears in a simplified form in work of Keane and Petersen [42].

If the measure-preserving transformation T is ergodic, then by virtue of Lemma 1, the limit functions appearing in the ergodic theorems are constant. One sees that the constant is simply the integral of f with respect to μ , so that in this situation $A_N f(x)$ converges to $\int f \, d\mu$ in norm and pointwise almost everywhere, thereby providing a justification of Boltzmann's original claim: for ergodic measure-preserving transformations, *time averages agree with spatial averages*. In the case where T is not ergodic, it is also possible to identify the limit in the ergodic theorems: we have $f^* = \mathbb{E}(f|\mathcal{I})$, where \mathcal{I} is the σ -algebra of T -invariant sets.

Note that the set on which the almost everywhere convergence in Birkhoff's theorem takes place depends on the L^1 function f that one is considering. Straightforward considerations show that there is no single full

measure set that works simultaneously for all L^1 functions. In the case where X is a compact metric space, it is well known that $C(X)$, the space of continuous functions on X with the uniform norm has a countable dense set, $(f_n)_{n \geq 1}$ say. If the invariant measure μ is ergodic, then for each n , there is a set B_n of measure 1 such that for all $x \in B_n$, $A_N f_n(x) \rightarrow \int f_n d\mu$. Letting $B = \bigcap_n B_n$, one obtains a full measure set such that for all n and all $x \in B$, $A_N f_n(x) \rightarrow \int f_n d\mu$. A simple approximation argument then shows that for all $x \in B$ and all $f \in C(X)$, $A_N f(x) \rightarrow \int f d\mu$. A point x with this property is said to be *generic* for μ . The observations above show that for an ergodic invariant measure μ , we have $\mu\{x: x \text{ is generic for } \mu\} = 1$.

If T is ergodic, but T^n is not ergodic for some n , then one can show that the space X splits up as A_1, \dots, A_d for some $d|n$ in such a way that $T(A_i) = A_{i+1}$ for $i < d$ and $T(A_d) = A_1$ with T^n acting ergodically on each A_i . The transformation T is *totally ergodic* if T^n is ergodic for all $n \in \mathbb{N}$. One can check that a non-invertible transformation T is ergodic if and only if its natural extension is ergodic.

The following lemma gives an alternative characterization of ergodicity, which in particular relates it to mixing.

Lemma 5 (Ergodicity as a Mixing Property) *Let T be a measure-preserving transformation of the probability space (X, \mathcal{B}, μ) . Then T is ergodic if and only if for all f and g in L^2 ,*

$$\frac{1}{N} \sum_{n=0}^{N-1} \langle f, g \circ T^n \rangle \rightarrow \langle f, 1 \rangle \langle 1, g \rangle.$$

In particular, if T is ergodic, then $(1/N) \sum_{n=0}^{N-1} \mu(A \cap T^{-n}B) \rightarrow \mu(A)\mu(B)$ for all measurable sets A and B .

Proof Suppose that T is ergodic. Then the left-hand side of the equality is equal to $\langle f, (1/N) \sum_{n=0}^{N-1} g \circ T^n \rangle$. The mean ergodic theorem shows that the second term converges in L^2 to the constant function with value $\int g d\mu = \langle g, 1 \rangle$, and the equality follows.

Conversely, if the equation holds for all f and g in L^2 , suppose that A is an invariant set. Let $f = g = \mathbf{1}_A$. Then since $g \circ T^n = \mathbf{1}_A$ for all n , the left-hand side is $\langle \mathbf{1}_A, \mathbf{1}_A \rangle = \mu(A)$. On the other hand, the right-hand side is $\mu(A)^2$, so that the equation yields $\mu(A) = \mu(A)^2$, and $\mu(A)$ is either 0 or 1 as required.

Taking $f = \mathbf{1}_A$ and $g = \mathbf{1}_B$ for measurable sets A and B gives the final statement. \square

We now examine the ergodicity of the examples presented above. Firstly, for the rotation of the circle, we claim that

the transformation is ergodic if and only if the ‘angle’ α is irrational. To see this, we argue as follows. If $\alpha = p/q$, then we see that $f(x) = e^{2\pi i q x}$ is a non-constant R_α -invariant function, and hence R_α is not ergodic. On the other hand, if α is irrational, suppose f is a bounded measurable invariant function. Since f is bounded, it is an L^2 function, and so f may be expressed in L^2 as a Fourier series: $f = \sum_{n \in \mathbb{Z}} c_n e_n$ where $e_n(x) = e^{2\pi i n x}$. We then see that $f \circ R_\alpha = \sum_{n \in \mathbb{Z}} e^{2\pi i n \alpha} c_n e_n$. In order for f to be equal in L^2 to $f \circ R_\alpha$, they must have the same Fourier coefficients, so that $c_n = e^{2\pi i n \alpha} c_n$ for each n . Since α is irrational, this forces $c_n = 0$ for all $n \neq 0$, so that f is constant as required.

The doubling map and the Bernoulli shift are both ergodic, although we defer proof of this for the time being, since they in fact have the strong-mixing property. A Markov chain with matrix P and vector π is ergodic if and only if for all i and j in A with $\pi_i > 0$ and $\pi_j > 0$, there exists an $n \geq 0$ with $P_{ij}^n > 0$. This follows from the ergodic theorem for Markov chains (which is derived from the Strong Law of Large Numbers) (see [18] for details). In particular, if the underlying Markov chain is irreducible, then the measure is ergodic.

In the case of interval exchange transformations, there is a simple necessary condition on the permutation for irreducibility, namely for $1 \leq j < k$, we do not have $\pi\{1, \dots, j\} = \{1, \dots, j\}$. Under this condition, Masure [49] and Veech [88] independently showed that for almost all values of the sequence of lengths $(\ell_i)_{1 \leq i \leq k}$, the interval exchange transformation is ergodic. (In fact they showed the stronger condition of *unique ergodicity*: that the transformation has no other invariant measure than Lebesgue measure. This implies that Lebesgue measure is ergodic, because if there were a non-trivial invariant set, then the restriction of Lebesgue measure to that set would be another invariant measure).

For the hard sphere systems, there are no results on ergodicity in full generality. Important special cases have been studied by Sinai [84], Sinai and Chernov [86], Krámli, Simányi and Szász [45], Simányi and Szász [81], Simányi [79,80] and Young [95].

Ergodic Decomposition

We already observed that if a transformation is not ergodic, then it may be decomposed into parts. Clearly if these parts are not ergodic, they may be further decomposed. It is natural to ask whether the transformation can be decomposed into ergodic parts, and if so what form does the decomposition take? In fact such a decomposition does exist, but rather than decompose the transforma-

tion, it is necessary to decompose the measure into ergodic pieces. This is known as ergodic decomposition.

The set of invariant measures for a measurable map T of a measurable space (X, \mathcal{B}) to itself forms a simplex. General functional analytic considerations (due to Choquet [14,15] – see also Phelps’ account [66] of this theory) mean that it is possible to write any member of the simplex as an integral-convex combination of the extreme points. Further, the extreme points of the simplex may be identified as precisely the ergodic invariant measures for T . It follows that any invariant probability measure μ for T may be uniquely expressed in the form

$$\mu(A) = \int_{M_{\text{erg}}(X, T)} \nu(A) \, d m(\nu),$$

where $M_{\text{erg}}(X, T)$ denotes the set of ergodic T -invariant measures on X and m is a measure on $M_{\text{erg}}(X, T)$.

We will give a proof of this theorem in the special case of a continuous transformation of a compact space. Our proof is based on the Birkhoff ergodic theorem and the Riesz Representation Theorem identifying the dual space of the space of continuous functions on a compact space as the set of bounded signed measures on the space (see Rudin’s book [75] for details). We include it here because this special case covers many cases that arise in practice, and because few of the standard ergodic theory references include a proof of ergodic decomposition. An exception to this is Rudolph’s book [76] which gives a full proof in the case that X is a Lebesgue space. This is based on a detailed development of the theory of these spaces and builds measures using conditional expectations. Kalikow’s notes [32] give a brief outline of a proof similar to that which follows. Oxtoby [62] also wrote a survey article containing much of the following (and much more besides).

Theorem 6 *Let X be a compact metric space, \mathcal{B} be the Borel σ -algebra, μ be an invariant Borel probability measure and T be a continuous measure-preserving transformation of (X, \mathcal{B}, μ) . Then for each $x \in X$, there exists an invariant Borel measure μ_x such that:*

1. For $f \in L^1(X, \mathcal{B}, \mu)$, $\int f \, d\mu = \int (\int f \, d\mu_x) \, d\mu(x)$;
2. Given $f \in L^1(X, \mathcal{B}, \mu)$, for μ -almost every $x \in X$, one has $A_N f(x) \rightarrow \int f \, d\mu_x$;
3. The measure μ_x is ergodic for μ -almost every $x \in X$.

Notice that conclusion (2) shows that μ_x can be understood as the distribution on the phase space “seen” if one starts the system in an initial condition of x . This interpretation of the measures μ_x corresponds closely with the ideas of Boltzmann and the Ehrenfests in the formulation

of the ergodic and quasi-ergodic hypotheses, which can be seen as demanding that μ_x is equal to μ for (almost) all x .

Proof The proof will be divided into 3 main steps: defining the measures μ_x , proving measurability with respect to x and proving ergodicity of the measures.

Step 1: Definition of μ_x

Given a function $f \in L^1(X, \mathcal{B}, \mu)$, Birkhoff’s theorem states that for μ -almost every $x \in X$, $(A_N f(x))$ is convergent. It will be convenient to denote the limit by $\tilde{f}(x)$. Let f_1, f_2, \dots be a sequence of continuous functions that is dense in $C(X)$. For each k , there is a set B_k of x ’s measure 1 for which $(A_n f_k(x))_{n=1}^\infty$ is a convergent sequence. Intersecting these gives a set B of full measure such that for $x \in B$, for each $k \geq 1$, $A_n f_k(x)$ is convergent. A simple approximation argument shows that for $x \in B$ and f an arbitrary continuous function, $A_n f(x)$ is convergent. Given $x \in B$, define a map $L_x: C(X) \rightarrow \mathbb{R}$ by $L_x(f) = \tilde{f}(x)$. This is a continuous linear functional on $C(X)$, and hence by the Riesz Representation Theorem there exists a Borel measure μ_x such that $\tilde{f}(x) = \int f \, d\mu_x$ for each $f \in C(X)$ and $x \in B$. Since $L_x(f) \geq 0$ when f is a non-negative function and $L_x(1) = 1$, the measure μ_x is a probability measure. Since $L_x(f \circ T) = L_x(f)$ for $f \in C(X)$, one can check that μ_x must be an invariant probability measure. For $x \notin B$, simply define $\mu_x = \mu$. Since B^c is a set of measure 0, this will not affect any of the statements that we are trying to prove.

Now for f continuous, we have $A_N f$ is a bounded sequence of functions with $A_N f(x)$ converging to $\int f \, d\mu_x$ almost everywhere and $\int A_N f \, d\mu = \int f \, d\mu$ since T is measure-preserving. It follows from the bounded convergence theorem that for $f \in C(X)$,

$$\int f \, d\mu = \int \left(\int f \, d\mu_x \right) \, d\mu(x). \tag{1}$$

Step 2: Measurability of $x \mapsto \mu_x(A)$

Lemma 7 *Let $C \in \mathcal{B}$ satisfy $\mu(C) = 0$. Then $\mu_x(C) = 0$ for μ -almost every $x \in X$.*

Proof Using regularity of Borel probability measures (see Rudin’s book [75] for details), there exist open sets $U_1 \supset U_2 \supset \dots \supset C$ with $\mu(U_k) < 1/k$. There exist continuous functions $g_{k,m}$ with $(g_{k,m}(x))_{m=1}^\infty$ increasing to $\mathbf{1}_{U_k}$ everywhere (e.g. $g_{k,m}(x) = \min(1, m \cdot d(x, U_k^c))$). By (1), we have $\int (\int g_{k,m} \, d\mu_x) \, d\mu(x) < 1/k$ for all k, m . Note that $\int g_{k,m} \, d\mu_x = \lim_{n \rightarrow \infty} \int A_n g_{k,m}(x)$ is a measurable function of x , so that using the monotone convergence theorem (taking the limit in m), $x \mapsto \int \mathbf{1}_{U_k} \, d\mu_x = \mu_x(U_k)$ is measurable and $\int (\int \mathbf{1}_{U_k} \, d\mu_x) \, d\mu(x) \leq 1/k$. We now see that $x \mapsto \lim_{k \rightarrow \infty} \mu_x(U_k) = \mu_x(\bigcap U_k)$

is also measurable, and by monotone convergence we see $\int \mu_x(\bigcap U_k) d\mu(x) = 0$. It follows that $\mu_x(\bigcap U_k) = 0$ for μ -almost every x . Since $\bigcap U_k \supset C$, the lemma follows. \square

Given a set $A \in \mathcal{B}$, let f_k be a sequence of continuous functions (uniformly bounded by 1) satisfying $\|f_k - \mathbf{1}_A\|_{L^1(\mu)} < 2^{-n}$, so that in particular $f_k(x) \rightarrow \mathbf{1}_A(x)$ for μ -almost every x . For each k , $x \mapsto \int f_k d\mu_x = \lim_{n \rightarrow \infty} A_n f_k(x)$ is a measurable function. By Lemma 7, for μ -almost every x , $f_k \rightarrow \mathbf{1}_A$ μ_x -almost everywhere, so that by the bounded convergence theorem $\lim_{k \rightarrow \infty} \int f_k d\mu_x = \mu_x(A)$ for μ -almost every x . Since the limit of measurable functions is measurable, it follows that $x \mapsto \mu_x(A)$ is measurable for any measurable set $A \in \mathcal{B}$.

This allows us to define a measure ν by $\nu(A) = \int \mu_x(A) d\mu(x)$. For a bounded measurable function f , we have $\int f d\nu = \int (\int f d\mu_x) d\mu(x)$. Since this agrees with $\int f d\mu$ for continuous functions by (1), it follows that $\mu = \nu$. Conclusion (1) of the theorem now follows easily.

Given $f \in L^1(X)$, we let (f_k) be a sequence of continuous functions such that $\|f_k - f\|_{L^1(\mu)}$ is summable. This implies that $\|f_k - f\|_{L^1(\mu_x)}$ is summable for μ -almost every x and in particular, $\int f_k d\mu_x \rightarrow \int f d\mu_x$ for almost every x . On the other hand, by the remark following the statement of Birkhoff's theorem, we have $\tilde{f}_k = \mathbb{E}(f_k | \mathcal{I})$ so that $\|\tilde{f} - \tilde{f}_k\|_{L^1(\mu)}$ is summable and $\tilde{f}_k(x) \rightarrow \tilde{f}(x)$ for μ -almost every x . Combining these two statements, we see that for μ -almost every x , we have

$$\tilde{f}(x) = \lim_{k \rightarrow \infty} \tilde{f}_k(x) = \lim_{k \rightarrow \infty} \int f_k d\mu_x = \int f d\mu_x.$$

This establishes conclusion (2) of the theorem.

Step 3: Ergodicity of μ_x

We have shown how to disintegrate the invariant measure μ as an integral combination of μ_x 's, and we have interpreted the μ_x 's as describing the average behavior starting from x . It remains to show that the μ_x 's are ergodic measures.

Fix for now a continuous function f and a number $0 < \epsilon < 1$. Since $A_n f(x) \rightarrow \tilde{f}(x)$ μ -almost everywhere, there exists an N such that $\mu\{x: |A_N f(x) - \tilde{f}(x)| > \epsilon/2\} < \epsilon^3/8$.

We now claim the following:

$$\mu\{x: \mu_x\{y: |\tilde{f}(y) - \int f d\mu_x| > \epsilon\} > \epsilon\} < \epsilon. \quad (2)$$

To see this, note that $\{y: |\tilde{f}(y) - \int f d\mu_x| > \epsilon\} \subset \{y: |\tilde{f}(y) - A_N f(y)| > \epsilon/2\} \cup \{y: |A_N f(y) - \tilde{f}(x)| > \epsilon/2\}$, so that if $\mu_x\{y: |\tilde{f}(y) - \int f d\mu_x| > \epsilon\} > \epsilon$, then either

$\mu_x\{y: |\tilde{f}(y) - A_N f(y)| > \epsilon/2\} > \epsilon/2$ or $\mu_x\{y: |A_N f(y) - \tilde{f}(x)| > \epsilon/2\} > \epsilon/2$. We show that the set of x 's satisfying each condition is small.

Firstly, we have $\epsilon^3/8 > \mu\{y: |\tilde{f}(y) - A_N f(y)| > \epsilon/2\} = \int \mu_x\{y: |\tilde{f}(y) - A_N f(y)| > \epsilon/2\} d\mu(x)$, so that $\mu\{x: \mu_x\{y: |\tilde{f}(y) - A_N f(y)| > \epsilon/2\} > \epsilon/2\} < \epsilon^2/4 < \epsilon/2$.

For the second term, given $c \in \mathbb{R}$, let $F_c(x) = |A_N f(x) - c|$ and $G(x) = F_{\tilde{f}(x)}(x)$. Note that

$$\int F_{\tilde{f}(x)}(y) d\mu_x(y) = \lim_{n \rightarrow \infty} A_n F_{\tilde{f}(x)}(x) = \lim_{n \rightarrow \infty} A_n G(x)$$

(using the facts that $y \mapsto F_{\tilde{f}(x)}(y)$ is a continuous function and that since $\tilde{f}(x)$ is an invariant function, $F_{\tilde{f}(x)}(T^k x) = G(T^k x)$). Since $\int G(x) d\mu(x) < \epsilon^3/8$, it follows that $\int F_{\tilde{f}(x)}(y) d\mu_x(y) \leq \epsilon^2/4$ except on a set of x 's of measure less than $\epsilon/2$. Outside this bad set, we have $\mu_x\{y: |A_N f(y) - \tilde{f}(x)| > \epsilon/2\} < \epsilon/2$ so that $\mu\{x: \mu_x\{y: |A_N f(y) - \tilde{f}(x)| > \epsilon/2\} > \epsilon/2\} < \epsilon/2$ as required.

This establishes our claim (2) above. Since $\epsilon > 0$ is arbitrary, it follows that for each $f \in C(X)$, for μ -almost every x , μ_x -almost every y satisfies $\tilde{f}(y) = \int f d\mu_x$. As usual, taking a countable dense sequence (f_k) in $C(X)$, it is the case that for all k and μ -almost every x , $\tilde{f}_k(y) = \int f_k d\mu_x$ μ_x -almost everywhere. Let the set of x 's with this property be D . We claim that for $x \in D$, μ_x is ergodic. Suppose not. Then let $x \in D$ and let J be an invariant set of μ_x measure between δ and $1 - \delta$ for some $\delta > 0$. Then by density of $C(X)$ in $L^1(\mu_x)$, there exists an f_k with $\|f_k - \mathbf{1}_J\|_{L^1(\mu_x)} < \delta$. Since $\mathbf{1}_J$ is an invariant function, we have $\tilde{\mathbf{1}}_J = \mathbf{1}_J$. On the other hand, \tilde{f}_k is a constant function. It follows that $\|\tilde{f}_k - \tilde{\mathbf{1}}_J\|_{L^1(\mu_x)} \geq \delta > \|f_k - \mathbf{1}_J\|_{L^1(\mu_x)}$. This contradicts the identification of the limit as a conditional expectation and concludes the proof of the theorem. \square

Mixing

As mentioned above, ergodicity may be seen as an independence on average property. More specifically, one wants to know whether in some sense $\mu(A \cap T^{-n} B)$ converges to $\mu(A)\mu(B)$ as $n \rightarrow \infty$. Ergodicity is the property that there is convergence in the Césaro sense. Weak-mixing is the property that there is convergence in the strong Césaro sense. That is, a measure-preserving transformation T is *weak-mixing* if

$$\frac{1}{N} \sum_{n=0}^{N-1} |\mu(A \cap T^{-n} B) - \mu(A)\mu(B)| \rightarrow 0 \quad \text{as } N \rightarrow \infty.$$

In order for T to be *strong-mixing*, we require simply $\mu(A \cap T^{-N}B) \rightarrow \mu(A)\mu(B)$ as $N \rightarrow \infty$. It is clear that strong-mixing implies weak-mixing and weak-mixing implies ergodicity.

If T^d is not ergodic (so that $T^{-d}A = A$ for some A of measure strictly between 0 and 1), then $|\mu(T^{-nd}A \cap A) - \mu(A)^2| = \mu(A)(1 - \mu(A))$, so that T is not weak-mixing.

An alternative characterization of weak-mixing is as follows:

Lemma 8 *The measure-preserving transformation T is weak-mixing if and only if for every pair of measurable sets A and B , there exists a subset J of \mathbb{N} of density 1 (i. e. $\#(J \cap \{1, \dots, N\})/N \rightarrow 1$) such that*

$$\lim_{n \rightarrow \infty, n \notin J} \mu(A \cap T^{-n}B) = \mu(A)\mu(B). \tag{3}$$

By taking a countable family of measurable sets that are dense (with respect to the metric $d(A, B) = \mu(A \Delta B)$) and taking a suitable intersection of the corresponding J sets, one shows that for a given weak-mixing measure-preserving transformation, there is a single set $J \subset \mathbb{N}$ such that (3) holds for *all* measurable sets A and B (see Petersen [64] or Walters [92] for a proof).

We show that an irrational rotation of the circle is not weak-mixing as follows: let $\alpha \in \mathbb{R} \setminus \mathbb{Q}$ and let A be the interval $[\frac{1}{4}, \frac{3}{4})$. There is a positive proportion of n 's in the natural numbers (in fact proportion 1/3) with the property that $|T^n(\frac{1}{2}) - \frac{1}{2}| < \frac{1}{6}$. For these n 's $\mu(A \cap T^{-n}A) > \frac{1}{3}$, so that in particular $|\mu(A \cap T^{-n}A) - \mu(A)\mu(A)| > \frac{1}{12}$. Clearly this precludes the required convergence to 0 in the definition of weak-mixing, so that an irrational rotation is ergodic but not weak-mixing. Since $R_\alpha^n = R_{n\alpha}$, the earlier argument shows that R_α^n is ergodic, so that R_α is totally ergodic.

On the other hand, we show that any Bernoulli shift is strong-mixing. To see this, let A and B be arbitrary measurable sets. By standard measure-theoretic arguments, A and B may each be approximated arbitrarily closely by a finite union of cylinder sets. Since if A' and B' are finite unions of cylinder sets, we have that $\mu(A' \cap T^{-n}B')$ is equal to $\mu(A')\mu(B')$ for large n , it is easy to deduce that $\mu(A \cap T^{-n}B) \rightarrow \mu(A)\mu(B)$ as required. Since the doubling map is measure-theoretically isomorphic to a one-sided Bernoulli shift, it follows that the doubling map is also strong-mixing.

Similarly, if a Markov Chain is irreducible (i. e. for any states i and j , there exists an $n \geq 0$ such that $P_{ij}^n > 0$) and aperiodic (there is a state i such that $\gcd\{n: P_{ii}^n > 0\} = 1$), then given any pair of cylinder sets A' and B' we have by standard theorems of Markov chains

$\mu(A' \cap T^{-n}B') \rightarrow \mu(A')\mu(B')$. The same argument as above then shows that an aperiodic irreducible Markov Chain is strong-mixing. On the other hand, if a Markov chain is periodic ($d = \gcd\{n: P_{ii}^n > 0\} > 0$), then letting $A = B = \{x: x_0 = i\}$, we have that $\mu(A \cap T^{-n}B) = 0$ whenever $d \nmid n$. It follows T^d is not ergodic, so that T is not weak-mixing.

Both weak- and strong-mixing have formulations in terms of functions:

Lemma 9 *Let T be a measure-preserving transformation of the probability space (X, \mathcal{B}, μ) .*

1. *T is weak-mixing if and only if for every $f, g \in L^2$ one has*

$$\frac{1}{N} \sum_{n=0}^{N-1} |\langle f, g \circ T^n \rangle - \langle f, 1 \rangle \langle 1, g \rangle| \rightarrow 0 \text{ as } N \rightarrow \infty.$$

2. *T is strong-mixing if and only if for every $f, g \in L^2$, one has*

$$\langle f, g \circ T^N \rangle \rightarrow \langle f, 1 \rangle \langle 1, g \rangle \text{ as } N \rightarrow \infty.$$

Using this, one can see that both mixing conditions are spectral properties.

Lemma 10 *Weak- and strong-mixing are spectral properties.*

Proof Suppose S is a weak-mixing transformation of (Y, \mathcal{F}, ν) and the transformation T of (X, \mathcal{B}, μ) is spectrally isomorphic to S by the Hilbert space isomorphism Θ . Then for $f, g \in L^2(X, \mathcal{B}, \mu)$, $\langle f, g \circ T^n \rangle_X - \langle f, 1 \rangle_X \langle 1, g \rangle_X = \langle \Theta(f), \Theta(g) \circ S^n \rangle_Y - \langle \Theta(f), \Theta(1) \rangle_Y \langle \Theta(1), \Theta(g) \rangle_Y$. Since 1 is an eigenfunction of U_T with eigenvalue 1, $\Theta(1)$ is an eigenfunction of U_S with an eigenvalue 1, so since S is ergodic, $\Theta(1)$ must be a constant function. Since Θ preserves norms, $\Theta(1)$ must have a constant value of absolute value 1 and hence $\langle f, g \circ T^n \rangle_X - \langle f, 1 \rangle_X \langle 1, g \rangle_X = \langle \Theta(f), \Theta(g) \circ S^n \rangle_Y - \langle \Theta(f), 1 \rangle_Y \langle 1, \Theta(g) \rangle_Y$. It follows from Lemma 9 that T is weak-mixing.

A similar proof shows that strong-mixing is a spectral property. \square

Both weak- and strong-mixing properties are preserved by taking natural extensions.

Recent work of Avila and Forni [4] shows that for interval exchange transformations of $k \geq 3$ intervals with the underlying permutation satisfying the non-degeneracy condition above, almost all divisions of the interval (with respect to Lebesgue measure on the $k - 1$ -dimensional simplex) lead to weak-mixing transformations. On the

other hand, work of Katok [36] shows that no interval exchange transformation is strong-mixing.

It is of interest to understand the behavior of the ‘typical’ measure-preserving transformation. There are a number of Baire category results addressing this. In order to state them, one needs a set of measure-preserving transformations and a topology on them. As mentioned earlier, it is effectively no restriction to assume that a transformation is a Lebesgue-measurable map on the unit interval preserving Lebesgue measure. The classical category results are then on the collection of invertible Lebesgue-measure preserving transformations of the unit interval. One topology on these is the ‘weak’ topology, where a sub-base is given by sets of the form $N(T, A, \epsilon) = \{S: \lambda(S(A)\Delta T(A)) < \epsilon\}$. With respect to this topology, Halmos [26] showed that a residual set (i. e. a dense G_δ set) of invertible measure-preserving transformations is weak-mixing (see also work of Alpern [3]), while Rokhlin [72] showed that the set of strong-mixing transformations is meagre (i. e. a nowhere dense F_σ set), allowing one to conclude that with respect to this topology, the typical transformation is weak- but not strong-mixing.

As often happens in these cases, even when a certain kind of behavior is typical, it may not be simple to exhibit concrete examples. In this case, a well-known example of a transformation that is weak-mixing but not strong-mixing was given by Chacon [13].

While on the face of it the formulation of weak-mixing is considerably less natural than that of strong-mixing, the notion of weak-mixing turns out to be extremely natural from a spectral point of view. Given a measure-preserving transformation T , let U_T be the Koopman operator described above. Since this operator is an isometry, any eigenvalue must lie on the unit circle. The constant function 1 is always an eigenfunction with eigenvalue 1. If T is ergodic and g and h are eigenfunctions of U_T with eigenvalue λ , then $g\bar{h}$ is an eigenfunction with eigenvalue 1, hence invariant, so that $g = Kh$ for some constant K . We see that for ergodic transformations, up to rescaling, there is at most one eigenfunction with any given eigenvalue.

If U_T has a non-constant eigenfunction f , then one has $|\langle U_T^n f, f \rangle| = \|f\|^2$ for each n , whereas by Cauchy–Schwartz, $|\langle f, 1 \rangle|^2 < \|f\|^2$. It follows that $|\langle U_T^n f, f \rangle - \langle f, 1 \rangle \langle 1, f \rangle| \geq c$ for some positive constant c , so that using Lemma 9, T is not weak-mixing.

Using the spectral theorem, the converse is shown to hold.

Theorem 11 *The measure-preserving transformation T is weak-mixing if and only if U_T has no non-constant eigenfunctions.*

Of course this also shows that weak-mixing is a spectral property. Equivalently, this says that the transformation T is weak-mixing if and only if the apart from the constant eigenfunction, the operator U_T has only continuous spectrum (that is, the operator has no other eigenfunctions). For a very nice and concise development of the part of spectral theory relevant to ergodic theory, the reader is referred to the Appendix in Parry’s book [63].

Using this theory, one can establish the following:

Theorem 12

1. T is weak-mixing if and only if $T \times T$ is ergodic;
2. If T and S are ergodic, then $T \times S$ is ergodic if and only if U_S and U_T have no common eigenvalues other than 1.

Proof The main factor in the proof is that the eigenvalues of $U_{T \times S}$ are precisely the set of $\alpha\beta$, where α is an eigenvalue of U_T and β is an eigenvalue of U_S . Further, the eigenfunctions of $U_{T \times S}$ with eigenvalue γ are spanned by eigenfunctions of the form $f \otimes g$, where f is an eigenfunction of U_T , g is an eigenfunction of U_S , and the product of the eigenvalues is γ .

Suppose that T is weak-mixing. Then the only eigenfunction is the constant function, so that the only eigenfunction of $U_{T \times T}$ is the constant function, proving that $T \times T$ is ergodic. Conversely, if U_T has an eigenvalue (so that $f \circ T = \alpha f$ for some non-constant f) then $f \otimes \bar{f}$ is a non-constant invariant function of $T \times T$ so that $T \times T$ is not ergodic.

For the second part, if U_S and U_T have a common eigenvalue other than 1 (say $f \circ T = \alpha f$ and $g \circ T = \alpha g$), then $f \otimes \bar{g}$ is a non-constant invariant function. Conversely, if $T \times S$ has a non-constant invariant function h , then h can be decomposed into functions of the form $f \otimes g$, where f and g are eigenfunctions of U_T and U_S respectively with eigenvalues α and β satisfying $\alpha\beta = 1$. Since the eigenvalues of S are closed under complex conjugation, we see that U_T and U_S have a common eigenvalue other than 1 as required. \square

For a measure-preserving transformation T , we let K be the subspace of L^2 spanned by the eigenfunctions of U_T . It is a remarkable fact that K may be identified as $L^2(X, \mathcal{B}', \mu)$ where \mathcal{B}' is a sub- σ -algebra of \mathcal{B} . The space K is called the *Kronecker factor* of T . The terminology comes from the fact that any sub- σ -algebra \mathcal{F} of \mathcal{B} gives rise to a factor mapping $\pi: (X, \mathcal{B}, \mu) \rightarrow (X, \mathcal{F}, \mu)$ with $\pi(x) = x$. By construction $L^2(X, \mathcal{B}', \mu)$ is the closed linear span of the eigenfunctions of T considered as a measure-preserving transformation of (X, \mathcal{B}', μ) . By the Discrete Spectrum Theorem of Halmos and von Neumann [27],

T acting on (X, \mathcal{B}', μ) is measure-theoretically isomorphic to a rotation on a compact group. This allows one to split $L^2(X, \mathcal{B}, \mu)$ as $L^2(X, \mathcal{B}', \mu) \oplus L^2_c(X, \mathcal{B}, \mu)$, where, as mentioned above the first part is the discrete spectrum part, spanned by eigenfunctions, and the second part is the continuous spectrum part, consisting of functions whose spectral measure is continuous. Since we have split L^2 into a discrete part and a continuous part, it is natural to ask whether the underlying transformation T can be split up in some way into a weak-mixing part and a discrete spectrum (compact group rotation) part, somewhat analogously to the ergodic decomposition. Unfortunately, there is no such decomposition available. However for some applications, for example to multiple recurrence (starting with the work of Furstenberg [20,21]), the decomposition of L^2 (possibly into more complicated parts) plays a crucial role (see the chapters on ► [Ergodic Theory: Recurrence](#) and ► [Ergodic Theory: Interactions with Combinatorics and Number Theory](#)).

For non-invertible measure-preserving transformations, the transformation is weak- or strong-mixing if and only if its natural extension has that property.

The understanding of weak-mixing in terms of the discrete part of the spectrum of the operator also extends to total ergodicity. T^m is ergodic if and only if T has no eigenvalues of the form $e^{2\pi i p/n}$ other than 1. From this it follows that an ergodic measure-preserving transformation T is totally ergodic if and only if it has no *rational spectrum* (i. e. no eigenvalues of the form $e^{2\pi i p/q}$ other than the simple eigenvalue 1).

An intermediate mixing condition between strong- and weak- mixing is that a measure-preserving transformation is *mild-mixing* if whenever $f \circ T^{n_i} \rightarrow f$ for an L^2 function f and a sequence $n_i \rightarrow \infty$, then f is a.e. constant. Clearly mild-mixing is a spectral property. If a transformation has an eigenfunction f , then it is straightforward to find a sequence n_i such that $f \circ T^{n_i} \rightarrow f$, so we see that mild-mixing implies weak-mixing. To see that strong-mixing implies mild-mixing, suppose that T is strong-mixing and that $f \circ T^{n_i} \rightarrow f$. Then we have $\int f \circ T^{n_i} \bar{f} \rightarrow \|f\|^2$. On the other hand, the strong mixing property implies that $\int f \circ T^{n_i} \bar{f} \rightarrow |\langle f, 1 \rangle|^2$. The equality of these implies that f is a.e. constant. Mild-mixing has a useful reformulation in terms of ergodicity of general (not necessarily probability) measure-preserving transformations: A transformation T is mild-mixing if and only if for every conservative ergodic measure-preserving transformation S , $T \times S$ is ergodic. See Furstenberg and Weiss' article [22] for further information on mild-mixing.

The strongest spectral property that we consider is that of having countable Lebesgue spectrum. While we

will avoid a detailed discussion of spectral theory in this article, this is a special case that can be described simply. Specifically, let T be an invertible measure-preserving transformation. Then T has countable Lebesgue spectrum if there is a sequence of functions f_1, f_2, \dots such that $\{1\} \cup \{U_T^n f_j: n \in \mathbb{Z}, j \in \mathbb{N}\}$ forms an orthonormal basis for $L^2(X)$.

To see that this property is stronger than strong-mixing, we simply observe that it implies that $\langle U_T^t U_T^n f_j, U_T^m f_k \rangle \rightarrow 0$ as $t \rightarrow \infty$. Then by approximating f and g by their expansions with respect to a finite part of the basis, we deduce that $\langle U_T^n f, g \rangle \rightarrow \langle f, 1 \rangle \langle 1, g \rangle$ as required. Since already strong-mixing is atypical from the topological point of view, it follows that countable Lebesgue spectrum has to be atypical. In fact, Yuzvinskii [96] showed that the typical invertible measure-preserving transformation has simple singular spectrum.

The property of countable Lebesgue spectrum is by definition a spectral property. Since it completely describes the transformation up to spectral isomorphism, there can be no stronger spectral properties. The remaining properties that we shall examine are invariant under measure-theoretic isomorphisms only.

An invertible measure-preserving transformation T of (X, \mathcal{B}, μ) is said to be K (for Kolmogorov) if there is a sub- σ -algebra \mathcal{F} of \mathcal{B} such that

1. $\bigcap_{n=1}^{\infty} T^{-n} \mathcal{F}$ is the trivial σ -algebra up to sets of measure 0 (i. e. the intersection consists only of null sets and sets of full measure).
2. $\bigvee_{n=1}^{\infty} T^n \mathcal{F} = \mathcal{B}$ (i. e. the smallest σ -algebra containing $T^n \mathcal{F}$ for all $n > 0$ is \mathcal{B}).

The K property has a useful reformulation in terms of entropy as follows: T is K if and only if for every non-trivial partition \mathcal{P} of X , the entropy of T with respect to the partition \mathcal{P} is positive: T has *completely positive entropy*. See the chapter on ► [Entropy in Ergodic Theory](#) for the relevant definitions. The equivalence of the K property and completely positive entropy was shown by Rokhlin and Sinai [74]. For a general transformation T , one can consider the collection of all subsets B of X such that with respect to the partition $\mathcal{P}_B = \{B, B^c\}$, $h(\mathcal{P}_B) = 0$. One can show that this is a σ -algebra. This σ -algebra is known as the *Pinsker σ -algebra*. The above reformulation allows us to say that a transformation is K if and only if it has a trivial Pinsker σ -algebra.

The K property implies countable Lebesgue spectrum (see Parry's book [63] for a proof). To see that K is not implied by countable Lebesgue spectrum, we point out that certain measure-preserving transformations derived from Gaussian systems (see for example the paper of Parry and

Newton [52]) have countable Lebesgue spectrum but zero entropy.

The fact that (two-sided) Bernoulli shifts have the K property follows from Kolmogorov's 0–1 law by taking $\mathcal{F} = \bigvee_{n=0}^{\infty} T^{-n}\mathcal{P}$, where \mathcal{P} is the partition into cylinder sets (see Williams's book [93] for details of the 0–1 law).

Although the K property is explicitly an invertible property, it has a non-invertible counterpart, namely exactness. A transformation T of (X, \mathcal{B}, μ) is *exact* if $\bigcap_{n=0}^{\infty} T^{-n}\mathcal{B}$ consists entirely of null sets and sets of measure 1. It is not hard to see that a non-invertible transformation is exact if and only if its natural extension is K.

The final and strongest property in our list is that of being measure-theoretically isomorphic to a Bernoulli shift. If T is measure-theoretically isomorphic to a Bernoulli shift, we say that T has the *Bernoulli property*. While in principle this could apply to both invertible and non-invertible transformations, in practice the definition applies to a large class of invertible transformations, but occurs comparatively seldom for non-invertible transformations. For this reason, we will restrict ourselves to a discussion of the Bernoulli property for invertible transformations (see however work of Hoffman and Rudolph [29] and Hecklen and Hoffman [28] for work on the one-sided Bernoulli property).

In the case of invertible Bernoulli shifts, Ornstein [53,58] developed in the early 1970s a powerful isomorphism theory, showing that two Bernoulli shifts are measure-theoretically isomorphic if and only if they have the same entropy. Entropy had already been identified as an invariant by Kolmogorov and Sinai [43,82], so this established that it was a complete invariant for Bernoulli shifts. Keane and Smorodinsky [41] gave a proof which showed that two Bernoulli shifts of the same entropy are isomorphic using a conjugating map that is continuous almost everywhere. With other authors, this theory was extended to show that the property of being isomorphic to a Bernoulli shift applied to a surprisingly large class of measure-preserving transformations (e. g. geodesic flows on manifolds of constant negative curvature (Ornstein and Weiss [60]), aperiodic irreducible Markov chains (Friedman and Ornstein [19]), toral automorphisms (Katznelson [39]) and more generally many Gibbs measures for hyperbolic dynamical systems (see the book of Bowen [11])).

Initially, it was conjectured that the properties of being K and Bernoulli were the same, but since then a number of measure-preserving transformations that are K but not Bernoulli have been identified. The earliest was due to Ornstein [55]. Ornstein and Shields [59] then provided an uncountable family of non-isomorphic K automorphisms.

Katok [37] gave an example of a smooth diffeomorphism that is K but not Bernoulli; and Kalikow [33] gave a very natural probabilistic example of a transformation that has this property (the T, T^{-1} process).

While in systems that one regularly encounters there is a correlation between positive entropy and the stronger mixing properties that we have discussed, these properties are logically independent (for example taking the product of a Bernoulli shift and the identity transformation gives a positive entropy transformation that fails to be ergodic; also, the zero entropy Gaussian systems with countable Lebesgue spectrum mentioned above have relatively strong mixing properties but zero entropy).

In many of the mixing criteria discussed above we have considered a pair of sets A and B and asked for asymptotic independence of A and B (so that for large n , A and $T^{-n}B$ become independent). It is natural to ask, given a finite collection of sets A_0, A_1, \dots, A_k , under what conditions $\mu(A_0 \cap T^{-n_1}A_1 \cap \dots \cap T^{-n_k}A_k)$ converges to $\prod_{j=0}^k \mu(A_j)$.

A measure-preserving transformation is said to be *mixing of order $k+1$* if for all measurable sets A_0, \dots, A_k ,

$$\lim_{n_1 \rightarrow \infty, n_{j+1} - n_j \rightarrow \infty} \mu(A_0 \cap T^{-n_1}A_1 \cap \dots \cap T^{-n_k}A_k) = \prod_{j=0}^k \mu(A_j).$$

An outstanding open question asked by Rokhlin [73] appearing already in Halmos' 1956 book [27] is to determine whether mixing (i. e. mixing of order 2) implies mixing of all orders. Kalikow [34] showed that mixing implies mixing of all orders for rank 1 transformations (existence of rank one mixing transformations having been previously established by Ornstein in [54]). Later Ryzhikov [77] used joining methods to establish the result for transformations with finite rank, and Host [30] also used joining methods to establish the result for measure-preserving transformations with singular spectrum, but the general question remains open.

It is not hard to show using martingale arguments that K automorphisms and hence all Bernoulli measure-preserving transformations are mixing of all orders.

For weak-mixing transformations, Furstenberg [21] has established the following *weak-mixing of all orders* statement: if a measure-preserving transformation T is weak-mixing, then given sets A_0, \dots, A_k , there is a subsequence J of the integers of density 0 such that

$$\lim_{n \rightarrow \infty, n \notin J} \mu(A_0 \cap T^{-n}A_1 \cap \dots \cap T^{-kn}A_k) = \prod_{i=0}^k \mu(A_i).$$

Bergelson [5] generalized this by showing that

$$\lim_{n \rightarrow \infty, n \notin J} \mu(A_0 \cap T^{-p_1(n)} A_1 \cap \dots \cap T^{-p_k(n)} A_k) = \prod_{i=0}^k \mu(A_i)$$

whenever $p_1(n), \dots, p_k(n)$ are non-constant integer-valued polynomials such that $p_i(n) - p_j(n)$ is unbounded for $i \neq j$. The method of proof of both of these results was a Hilbert space version of the van der Corput inequality of analytic number theory. Furstenberg's proof played a key role in his ergodic proof [20] of Szemerédi's theorem on the existence of arbitrarily long arithmetic progressions in a subset of the integers of positive density (see the chapter on [Ergodic Theory: Interactions with Combinatorics and Number Theory](#) for more information about this direction of study).

The conclusions that one draws here are much weaker than the requirement for mixing of all orders. For mixing of all orders, it was required that provided the gaps between $0, n_1, \dots, n_k$ diverge to infinity, one achieves asymptotic independence, whereas for these weak-mixing results, the gaps are increasing along prescribed sequences with regular growth properties.

It is interesting to note that the analogous question of whether mixing implies mixing of all orders is known to fail in higher-dimensional actions. Here, rather than a \mathbb{Z} action, in which there is a single measure-preserving transformation (so that the integer n acts on a point $x \in X$ by mapping it to $T^n x$), one takes a \mathbb{Z}^d action. For such an action, one has d commuting transformations T_1, \dots, T_d and a vector (n_1, \dots, n_d) acts on a point x by sending it to $T_1^{n_1} \dots T_d^{n_d} x$. Ledrappier [46] studied the following two-dimensional action. Let $X = \{x \in \{0, 1\}^{\mathbb{Z}^2} : x_v + x_{v+e_1} + x_{v+e_2} = 0 \pmod{2}\}$ and let $T_i(x)_v = x_{v+e_i}$. Since X is a compact Abelian group, it has a natural measure μ invariant under the group operations (the Haar measure). It is not hard to show that this system is mixing (i. e. given any measurable sets A and B , $\mu(A \cap T_1^{-n_1} T_2^{-n_2} B) \rightarrow \mu(A)\mu(B)$ as $\|(n_1, n_2)\| \rightarrow \infty$). Ledrappier showed that the system fails to be 3-mixing. Subsequently Masser [48] established necessary and sufficient conditions for similar higher-dimensional algebraic actions to be mixing of order k but not order $k + 1$ for any given k .

Hyperbolicity and Decay of Correlations

One class of systems in which the stronger mixing properties are often found is the class of smooth systems possessing uniform hyperbolicity (i. e. the tangent space to the manifold at each point splits into stable

and unstable subspaces $E^s(x)$ and $E^u(x)$ such that the $\|DT|_{E^s(x)}\| \leq a < 1$ for all x and $\|DT^{-1}|_{E^u(x)}\| \leq a$ and $DT(E_s(x)) = E_s(T(x))$ and $DT(E_u(x)) = E_u(T(x))$). In some cases similar conclusions are found in systems possessing non-uniform hyperbolicity. See Katok and Hasselblatt's book [38] for an overview of hyperbolic dynamical systems, as well as the chapter in this volume on [Smooth Ergodic Theory](#).

In the simple case of expanding piecewise continuous maps of the interval (that is, maps for which the absolute value of the derivative is uniformly bounded below by a constant greater than 1), it is known that if they are totally ergodic and topologically transitive (i. e. the forward images of any interval cover the entire interval), then provided that the map has sufficient smoothness (e. g. the map is C^1 and the derivative satisfies a certain additional summability condition), the map has a unique absolutely continuous invariant measure which is exact and whose natural extension is Bernoulli (see the paper of Góra [25] for results of this type proved under some of the mildest hypotheses). These results were originally established for maps that were twice continuously differentiable, and the hypotheses were progressively weakened, approaching, but never meeting, C^1 . Subsequent work of Quas [68,69] provided examples of C^1 expanding maps of the interval for which Lebesgue measure was invariant, but respectively not ergodic and not weak-mixing. Some of the key tools in controlling mixing in one-dimensional expanding maps that are absent in the C^1 case are bounded distortion estimates. Here, there is a constant $1 \leq C < \infty$ such that given any interval I on which some power T^n of T acts injectively and any sub-interval J of I , one has $1/C \leq (|T^n J|/|T^n I|)/(|J|/|I|) \leq C$. An early place in which bounded distortion estimates appear is the work of Rényi [70].

One important class of results for expanding maps establishes an exponential decay of correlations. Here, one starts with a pair of smooth functions f and g and one estimates $\int f \cdot g \circ T^n d\mu - \int f d\mu \int g d\mu$, where μ is an absolutely continuous invariant measure. If μ is mixing, we expect this to converge to 0. In fact though, in good cases this converges to 0 at an exponential rate for each pair of functions f and g belonging to a sufficiently smooth class. In this case, the measure-preserving transformation T is said to have exponential decay of correlations. See Liverani's article [47] for an introduction to a method of establishing this based on cones. Exponential decay of correlations implies in particular that the natural extension is Bernoulli.

Hu [31] has studied the situation of maps of the interval for which the derivative is bigger than 1 everywhere

except at a fixed point, where the local behavior is of the form $x \mapsto x + x^{1+\alpha}$ for $0 < \alpha < 1$. In this case, rather than exhibiting exponential decay of correlations, the map has polynomial decay of correlations with a rate depending on α .

In Young's survey [94], a variety of techniques are outlined for understanding the strong ergodic properties of non-uniformly hyperbolic diffeomorphisms. In her article [95], methods are introduced for studying many classes of non-uniformly hyperbolic systems by looking at suitably high powers of the map, for which the power has strong hyperbolic behavior. The article shows how to understand the ergodic behavior of these systems. These methods are applied (for example) to billiards, one-dimensional quadratic maps and Hénon maps.

Future Directions

Problem 1 (Mixing of all orders) Does mixing imply mixing of all orders? Can the results of Kalikow, Ryzhikov and Host be extended to larger classes of measure-preserving transformations? Thouvenot observed that it is sufficient to establish the result for measure-preserving transformations of entropy 0. This observation (whose proof is based on the Pinsker σ -algebra) was stated in Kalikow's paper [34] and is reproduced as Proposition 3.2 in recent work of de la Rue [16] on the mixing of all orders problem.

Problem 2 (Multiple weak-mixing) As mentioned above, Bergelson [5] showed that if T is a weak-mixing transformation, then there is a subset J of the integers of density 0 such that

$$\lim_{n \rightarrow \infty, n \notin J} \mu(A_0 \cap T^{-p_1(n)} A_1 \cap \dots \cap T^{-p_k(n)} A_k) = \prod_{i=0}^k \mu(A_i)$$

whenever $p_1(n), \dots, p_k(n)$ are non-constant integer-valued polynomials such that $p_i(n) - p_j(n)$ is unbounded for $i \neq j$. It is natural to ask what is the most general class of times that can replace the sequences $(p_1(n)), \dots, (p_k(n))$. In unpublished notes, Bergelson and Håland considered as times the values taken by a family of integer-valued generalized polynomials (those functions of an integer variable that can be obtained by the operations of addition, multiplication, addition of or multiplication by a real constant and taking integer parts (e.g. $g(n) = \lfloor \sqrt{2} \rfloor \pi n + \lfloor \sqrt{3} n \rfloor^2$)). They conjectured necessary and sufficient conditions for the analogue of Bergelson's weak-mixing polynomial ergodic theorem to hold, and proved the conjecture in certain cases.

In a recent paper of McCutcheon and Quas [50], the analogous question was addressed in the case where T is a mild-mixing transformation.

Problem 3 (Pascal adic transformation) Vershik [89,90] introduced a family of transformations known as the adic transformations. The underlying spaces for these transformations are certain spaces of paths on infinite graphs, and the transformations act by taking a path to its lexicographic neighbor. Amongst the adic transformations, the so-called Pascal adic transformation (so-called because the underlying graph resembles Pascal's triangle) has been singled out for attention in work of Petersen and others [2,10,51,65]. In particular, it is unresolved whether this transformation is weak-mixing with respect to any of its ergodic measures. Weak-mixing has been shown by Petersen and Schmidt to follow from a number-theoretic condition on the binomial coefficients [2,10].

Problem 4 (Weak Pinsker Conjecture) Pinsker [67] conjectured that in a measure-preserving transformation with positive entropy, one could express the transformation as a product of a Bernoulli shift with a system with zero entropy. This conjecture (now known as the *Strong Pinsker Conjecture*) was shown to be false by Ornstein [56,57]. Shields and Thouvenot [78] showed that the collection of transformations that can be written as a product of a zero entropy transformation with a Bernoulli shift is closed in the so-called \bar{d} -metric that lies at the heart of Ornstein's theory.

It is, however, the case that if $T: X \rightarrow X$ has entropy $h > 0$, then for all $h' \leq h$, T has a factor S with entropy h' (this was originally proved by Sinai [83] and reproved using the Ornstein machinery by Ornstein and Weiss in [61]). The *Weak Pinsker Conjecture* states that if a measure-preserving transformation T has entropy $h > 0$, then for all $\epsilon > 0$, T may be expressed as a product of a Bernoulli shift and a measure-preserving transformation with entropy less than ϵ .

Glossary

Dynamical system in its broadest sense, any set X , with a map $T: X \rightarrow X$. The classical example is: X is a set

whose points are the states of some physical system and the state x is succeeded by the state Tx after one unit of time.

Iteration repeated applications of the map T above to arrive at the state of the system after n units of time.

Orbit of x the forward images x, Tx, T^2x, \dots of $x \in X$ under iteration of T . When T is invertible one may consider the forward, backward or two-sided orbit of x .

Automorphism a dynamical system $T: X \rightarrow X$, where X is a measure space and T is an invertible map preserving measure.

Ergodic average if f is a function on X let $A_n f(x) = n^{-1} \sum_{i=0}^{n-1} f(T^i x)$; the average of the values of f over the first n points in the orbit of x .

Ergodic theorem an assertion that ergodic averages converge in some sense.

Mean ergodic theorem an assertion that ergodic averages converge with respect to some norm on a space of functions.

Pointwise ergodic theorem an assertion that ergodic averages $A_n f(x)$ converge for some or all $x \in X$, usually for a.e. x .

Stationary process a sequence (X_1, X_2, \dots) of random variables (real or complex-valued measurable functions) on a probability space whose joint distributions are invariant under shifting (X_1, X_2, \dots) to (X_2, X_3, \dots) .

Uniform distribution a sequence $\{x_n\}$ in $[0, 1]$ is uniformly distributed if for each interval $I \subset [0, 1]$, the time it spends in I is asymptotically proportional to the length of I .

Maximal inequality an inequality which allows one to bound the pointwise oscillation of a sequence of functions. An essential tool for proving pointwise ergodic theorems.

Operator any linear operator U on a vector space of functions on X , for example one arising from a dynamical system T by setting $Uf(x) = f(Tx)$. More generally any linear transformation on a real or complex vector space.

Positive contraction an operator T on a space of functions endowed with a norm $\|\cdot\|$ such that T maps positive functions to positive functions and $\|Tf\| \leq \|f\|$.

Definition of the Subject

Ergodic theorems are assertions about the long-term statistical behavior of a dynamical system. The subject arose out of Boltzmann's ergodic hypothesis which sought to equate the spatial average of a function over the set of

states in a physical system having a fixed energy with the time average of the function observed by starting with a particular state and following its evolution over a long time period.

Introduction

Suppose that (X, \mathcal{B}, μ) is a measure space and $T: (X, \mathcal{B}, \mu) \rightarrow (X, \mathcal{B}, \mu)$ is a measurable and measure-preserving transformation, that is $\mu(T^{-1}E) = \mu(E)$ for all $E \in \mathcal{B}$. One important motivation for studying such maps is that a Hamiltonian physical system (see the article by Petersen in this collection) gives rise to a one-parameter group $\{T_t : t \in \mathbb{R}\}$ of maps in the phase space of the system which preserve Lebesgue measure. The ergodic theorem of Birkhoff asserts that for $f \in L_1(\mu)$

$$\frac{1}{n} \sum_{i=0}^{n-1} f(T^i x) \quad (1)$$

converges a.e. and that if T is *ergodic* (to be defined shortly) then the limit is $\int f d\mu$. This may be viewed as a justification for Boltzmann's ergodic hypothesis that "space averages equal time averages". See Zund [214] for some history of the ergodic hypothesis. For physicists, then, the problem is reduced to showing that a given physical system is ergodic, which can be very difficult. However ergodic systems arise in many natural ways in mathematics. One example is rotation $z \mapsto \lambda z$ of the unit circle if λ is a complex number of modulus one which is not a root of unity. Another is the shift transformation on a sequence of i.i.d. random variables, for example a coin-tossing sequence. Another is an automorphism of a compact Abelian group. Often a transformation possesses an invariant measure which is not obvious at first sight. Knowledge of such a measure can be a very useful tool. See Petersen's article for more examples.

If (X, \mathcal{B}, μ) is a probability space and T is ergodic then Birkhoff's ergodic theorem implies that if A is a measurable subset of X then for almost every x , the frequency with which x visits A is asymptotically equal to $\mu(A)$, a very satisfying justification of intuition. For example, applying this to the coin-tossing sequence one obtains the *strong law of large numbers* which asserts that almost every infinite sequence of coin tosses has tails occurring with asymptotic frequency $\frac{1}{2}$. One also obtains Borel's theorem on normal numbers which asserts that for almost all $x \in [0, 1]$ each digit $0, 1, 2, \dots, 9$ occurs with limiting frequency $\frac{1}{10}$. The so-called *continued fraction transformation* $x \mapsto x^{-1} \pmod{1}$ on $(0, 1)$ has a finite invariant measure $\frac{dx}{1+x}$. (Throughout this article $x \pmod{1}$ denotes the

fractional part of x .) Applying Birkhoff's theorem then gives precise information about the frequency of occurrence of any $n \in \mathbb{N}$ in the continued fraction expansion of x , for a.e. x . See for example Billingsley [34].

These are the classical roots of the subject of ergodic theorems. The subject has evolved from these simple origins into a vast field in its own right, quite independent of physics or probability theory. Nonetheless it still has close ties to both these areas and has also forged new links with many other areas of mathematics.

Our purpose here is to give a broad overview of the subject in a historical perspective. There are several excellent references, notably the books of Krengel [135] and Tempelman [194] which give a good picture of the state of the subject at the time they appeared. There has been tremendous progress since then. The time is ripe for a much more comprehensive survey of the field than is possible here.

Many topics are necessarily absent and many are only glimpsed. For example this article will not touch on random ergodic theorems. See the articles [75,143] for some references on this topic.

I thank Mustafa Akcoglu, Ulrich Krengel, Michael Lin, Dan Rudolph and particularly Joe Rosenblatt and Vitaly Bergelson for many helpful comments and suggestions. I would like to dedicate this article to Mustafa Akcoglu who has been such an important contributor to the development of ergodic theorems over the past 40 years. He has also played a vital role in my mathematical development as well as of many other mathematicians. He remains a source of inspiration to me, and a valued friend.

Ergodic Theorems for Measure-Preserving Maps

Suppose (X, \mathcal{B}, μ) is a measure space. A (measure-preserving) *endomorphism* of (X, \mathcal{B}, μ) is a measurable mapping $T: X \rightarrow X$ such that $\mu(T^{-1}E) = \mu(E)$ for any measurable subset $E \subset X$. If T has a measurable inverse then one says that it is an *automorphism*. In this article the unqualified terms "endomorphism" or "automorphism" will always mean measure-preserving. T is called *ergodic* if for all measurable E one has

$$T^{-1}E = E \Rightarrow \mu(E) = 0 \quad \text{or} \quad \mu(E^c) = 0.$$

A very general class of examples comes from the notion of a *stationary stochastic process* in probability theory. A stochastic process is a sequence of measurable functions f_1, f_2, \dots on a probability space (X, \mathcal{B}, μ) taking values in a measurable space (Y, \mathcal{C}) . The *distribution* of the process, a measure ν on $Y^{\mathbb{N}}$, is defined as the image of μ under the

map $(f_1, f_2, \dots): X \rightarrow Y^{\mathbb{N}}$. ν captures all the essential information about the process $\{f_i\}$. In effect one may view any process $\{f_i\}$ as a probability measure on $Y^{\mathbb{N}}$. The process is said to be *stationary* if ν is invariant under the left shift transformation S on $Y^{\mathbb{N}}$, $S(y)(i) = y(i+1)$, that is S is an endomorphism of the probability space $(Y^{\mathbb{N}}, \nu)$.

From a probabilistic point of view the most natural examples of stationary stochastic processes are independent identically distributed processes, namely the case when ν is a product measure $\lambda^{\mathbb{N}}$ for some measure λ on (Y, \mathcal{C}) . More generally one can consider a stationary Markov process defined by transition probabilities on the state space Y and an invariant probability on Y . See for example Chap. 7 in [50], also Sect. "Pointwise Ergodic Theorems for Operators" below.

The first and most fundamental result about endomorphisms is the celebrated recurrence theorem of Poincaré [173]).

Theorem 1 *Suppose μ is finite, $A \in \mathcal{B}$ and $\mu(A) > 0$. Then for a.e. $x \in A$ there is an $n > 0$ such that $T^n x \in A$, in fact there are infinitely many such n .*

It may be viewed as an ergodic theorem, in that it is a qualitative statement about how x behaves under iteration of T . For a proof, observe that if $E \subset A$ is the measurable set of points which never return to A then for each $n > 0$ the set $T^{-n}E$ is disjoint from E . Applying T^{-m} one gets also $T^{-(n+m)}E \cap T^{-m}E = \emptyset$. Thus $E, T^{-1}E, T^{-2}E, \dots$ is an infinite sequence of disjoint sets all having measure $\mu(E)$ so $\mu(E) = 0$ since $\mu(X) < \infty$. Much later Kac [120] formulated the following quantitative version of Poincaré's theorem.

Theorem 2 *Suppose that $\mu(X) = 1$, T is ergodic and let $r_A x$ denote the time of first return to A , that is $r_A(x)$ is the least $n > 0$ such that $T^n x \in A$. Then*

$$\frac{1}{\mu(A)} \int_A r_A d\mu = \frac{1}{\mu(A)}, \quad (2)$$

that is, the expected value of the return time to A is $\mu(A)^{-1}$.

Koopman [131] made the observation that associated to an automorphism T there is a unitary operator $U = U_T$ defined on the Hilbert space $L_2(\mu)$ by the formula $Uf = f \circ T$. This led von Neumann [151] to prove his mean ergodic theorem.

Theorem 3 *Suppose \mathcal{H} is a Hilbert space, U is a unitary operator on \mathcal{H} and let P denote the orthogonal projection on the subspace of U -invariant vectors. Then for any $x \in \mathcal{H}$ one has*

$$\left\| \frac{1}{n} \sum_{i=0}^{n-1} U^i x - Px \right\| \rightarrow 0 \quad \text{as } n \rightarrow \infty. \quad (3)$$

Von Neumann's theorem is usually quoted as above but to be historically accurate he dealt with unitary operators indexed by a continuous time parameter.

Inspired by von Neumann's theorem Birkhoff very soon proved his pointwise ergodic theorem [35]. In spite of the later publication by von Neumann his result did come first. See [29,214] for an interesting discussion of the history of the two theorems and of the interaction between Birkhoff and von Neumann.

Theorem 4 *Suppose (X, \mathcal{B}, μ) is a measure space and T is an endomorphism of (X, \mathcal{B}, μ) . Then for any $f \in L_1 = L_1(\mu)$ there is a T -invariant function $g \in L_1$ such that*

$$A_n f(x) = \frac{1}{n} \sum_{i=0}^{n-1} f(T^i x) \rightarrow g(x) \quad \text{a.e.} \quad (4)$$

Moreover if μ is finite then the convergence also holds with respect to the L_1 norm and one has $\int_E g \, d\mu = \int_E f \, d\mu$ for all T -invariant subsets E .

Again this formulation of Birkhoff's theorem is not historically accurate as he dealt with a smooth flow on a manifold. It was soon observed that the theorem, and its proof, remain valid for an abstract automorphism of a measure space although the realization that T need not be invertible seems to have taken a little longer.

The notation $A_n f = A_n(T)f$ as above will occur often in the sequel. Whenever T is an endomorphism one uses the notation $Tf = f \circ T$ and with this notation $A_n(T) = \frac{1}{n} \sum_{i=0}^{n-1} T^i$. When the scalars (\mathbb{R} or \mathbb{C}) for an L_1 space are not specified the notation should be understood as referring to either possibility. In most of the theorems in this article the complex case follows easily from the real and any indications about proofs will refer to the real case.

Although von Neumann originally used spectral theory to prove his result, there is a quick proof, attributed to Riesz by Hopf in his 1937 book [100], which uses only elementary properties of Hilbert space. Let I denote the (closed) subspace of U -invariant vectors and I' the (usually not closed) subspace of vectors of the form $f - Uf$. It is easy to check that any vector orthogonal to I' must be in I , whence the subspace $I + I'$ is dense in \mathcal{H} . For any vector of the form $x = y + y'$, $y \in I$, $y' \in I'$ it is clear that $A_n x = \frac{1}{n} \sum_{i=0}^{n-1} U^i x$ converges to $y = Px$, since $A_n y = y$ and if $y' = z - Uz$ then the telescoping sum $A_n y' = n^{-1}(z - U^n z)$ converges to 0. This establishes the desired convergence for $x \in I + I'$ and it is easy to extend it to the closure of $I + I'$ since the operators A_n are contractions of \mathcal{H} ($\|A_n\| \leq 1$). Lorch [147] used a soft argument in a similar spirit to extend von Neumann's theorem

from the case of a unitary operator on a Hilbert space to that of an arbitrary linear contraction on any reflexive Banach space. Sine [188] gave a necessary and sufficient condition for the strong convergence of the ergodic averages of a contraction on an arbitrary Banach space.

Birkhoff's theorem has the distinction of being one of the most proved theorems of twentieth century mathematics. One approach to the pointwise convergence, parallel to the argument to argument just seen, is to find a dense subspace E of L_1 so that the convergence holds for all $f \in E$ and then try to extend the convergence to all $f \in L_1$ by an approximation argument. The first step is not too hard. For simplicity assume that μ is a finite measure. As in the proof of von Neumann's theorem the subspace E spanned by the T -invariant L_1 functions together with functions of the form $g - Tg$, $g \in L_1$, is dense in $L_1(\mu)$. This can be seen by using the Hahn–Banach theorem and the duality of L_1 and L_∞ . (Here one needs finiteness of μ to know that $L_\infty \subset L_1$.) The pointwise convergence of $A_n f$ for invariant f is trivial and for $f = g - Tg$ it follows from telescoping of the sum and the fact that $n^{-1}T^n g \rightarrow 0$ a.e. This last can be shown by using the Borel–Cantelli lemma. The second step, extending pointwise convergence, as opposed to norm convergence, for f in a dense subspace to all f in L_1 is a delicate matter, requiring a *maximal inequality*.

Roughly speaking a maximal inequality is an inequality which bounds the pointwise oscillation of $A_n f$ in terms of the norm of f . The now standard maximal inequality in the context of Birkhoff's theorem is the following, due to Kakutani and Yosida [209]. Birkhoff's proof of his theorem includes a weaker version of this result. Let $S_n f = nA_n f$, the n th partial sum of the iterates of f .

Theorem 5 *Given any real $f \in L_1$ let $A = \bigcup_{n \geq 1} \{S_n f \geq 0\}$. Then*

$$\int_A f \, d\mu \geq 0. \quad (5)$$

Moreover if one sets $Mf = \sup_{n \geq 1} A_n f$ then for any $\alpha > 0$

$$\mu\{Mf > \alpha\} \leq \frac{1}{\alpha} \|f\|_1 \quad (6)$$

A distributional inequality such as (6) will be referred to as a *weak L_1 inequality*. Note that (6) follows easily from (5) by applying (5) to $f - \alpha$, at least in the case when μ is finite. With the maximal inequality in hand it is straightforward to complete the proof of Birkhoff's theorem. For a real-valued function f let

$$\text{Osc } f = \limsup A_n f - \liminf A_n f. \quad (7)$$

$\text{Osc } f = 0$ a.e. if and only if $A_n f$ converges a.e. (to a possibly infinite limit). One has $\limsup A_n f \leq Mf \leq M|f|$ and by symmetry $\liminf A_n f \geq M|f|$, so $\text{Osc } f \leq 2M|f|$. To establish the convergence of $A_n f$ for a real-valued $f \in L_1$ let $\epsilon > 0$ and write $f = g + h$ with $g \in E$ (the subspace where convergence has already been established), $h \in L^1$ and $\|h\| < \epsilon$. Then since $\text{Osc } g = 0$ one has $\text{Osc } f = \text{Osc } h$. Thus for any fixed $\alpha > 0$, using (6)

$$\begin{aligned} \mu\{\text{Osc } f > \alpha\} &= \mu\{\text{Osc } h > \alpha\} \leq \mu\left\{Mh > \frac{\alpha}{2}\right\} \\ &\leq \frac{2\|h\|_1}{\alpha} < \frac{2\epsilon}{\alpha}. \end{aligned} \quad (8)$$

Since $\epsilon > 0$ was arbitrary one concludes that $\mu\{\text{Osc } f > \alpha\} = 0$ and since $\alpha > 0$ is arbitrary it follows that $\mu\{\text{Osc } f > 0\} = 0$, establishing the a.e. convergence. Moreover a simple application of Fatou's lemma shows that the limiting function is in L_1 , hence finite a.e.

There are many proofs of (5). Two of particular interest are Garsia's [89], perhaps the shortest and most mysterious, and the proof via the filling scheme of Chacón and Ornstein [61], perhaps the most intuitive, which goes like this. Given a function $g \in L_1$ write $g^+ = \max(g, 0)$, $g^- = g^+ - g$ and let $Ug = Tg^+ - g^-$. Interpretation: the region between the graph of g^+ and the X -axis is a sheaf of vertical spaghetti sticks, the intervals $[0, g^+(x)]$, x in X , and $-g^-$ is a hole. Now move the spaghetti (horizontally) by T and then let it drop (vertically) into the hole leaving a new hole and a new sheaf which are the negative and positive parts of Ug . Now let $E' = \bigcup_{n \geq 1} \{U^n f \geq 0\}$, the set of points x at which the hole is eventually filled after finitely many iterations of U .

The key point is that $E = E'$. Indeed if $S_n f(x) \geq 0$ for some n , then the total linear height of sticks over $x, Tx, \dots, T^{n-1}x$ is greater than the total linear depth of holes at these points. The only way that spaghetti can escape from these points is by first filling the hole at x , which shows $x \in E'$. Similar thinking shows that if $x \in E'$ and the hole at x is filled for the first time at time n then $S_n f(x) \geq 0$, so $x \in E$, and that all the spaghetti that goes into the hole at x comes from points $T^i x$ which belong to E' . This shows that $E = E'$ and that the part of the hole lying beneath E is eventually filled by spaghetti coming from $E' = E$. Thus the amount of spaghetti over E is no less than the size of the hole under E , that is $\int_E f d\mu \geq 0$.

Most proofs of Birkhoff's theorem use a maximal inequality in some form but a few avoid it altogether, for example [126,186]. It is also straightforward to deduce Birkhoff's theorem directly from a maximal inequality, as Birkhoff does, without first establishing convergence on a dense subspace. However the technique of proving

a pointwise convergence theorem by finding an appropriate dense subspace and a suitable maximal inequality has proved extremely useful, not only in ergodic theory.

Indeed, in some sense maximal inequalities are unavoidable: this is the content of the following principle proved already in 1926 by Banach. The principle has many formulations; the following one is a slight simplification of the one to be found in [135]. Suppose B is a Banach space, (X, \mathcal{B}, μ) is a finite measure space and let E denote the space of μ -equivalence classes of measurable real-valued functions on X . A linear map $T: B \rightarrow E$ is said to be *continuous in measure* if for each $\epsilon > 0$

$$\|x_n - x\| \rightarrow 0 \Rightarrow \mu\{|Tx_n - Tx| > \epsilon\} \rightarrow 0.$$

Suppose that T_n is a sequence of linear maps from B to E which are continuous in measure and let $Mx = \sup_n |T_n x|$. Of course if $T_n x$ converges a.e. to a finite limit then $Mx < \infty$ a.e.

Theorem 6 (Banach principle) *Suppose $Mx < \infty$ a.e. for each $x \in X$. Then there is a function $C(\lambda)$ such that $C(\lambda) \rightarrow 0$ as $\lambda \rightarrow \infty$ such that for all $x \in B$ and $\lambda > 0$ one has*

$$\mu\{Mx \geq \lambda\|x\|\} \leq C(\lambda). \quad (9)$$

Moreover the set of x for which $T_n x$ converges a.e. is closed in B .

The first chapter of Garsia's book [89] contains a nice introduction to the Banach principle.

It should be noted that, for general integrable f , Mf need not be in L^1 . However if $f \in L^p$ for $p > 1$ then Mf does belong to L^p and one has the estimate

$$\|Mf\|_p \leq \frac{p}{p-1} \|f\|_p. \quad (10)$$

This can be derived from (6) using also the (obvious) fact that $\|Mf\|_\infty \leq \|f\|_\infty$. Any such estimate on the norm of a maximal function will be called a *strong L_p* inequality. It also follows from (6) that if $\mu(X)$ is finite and $f \in L \log L$, that is $\int |f| \log^+ |f| d\mu < \infty$, then $Mf \in L^1$. In fact Ornstein [160] has shown that the converse of this last statement holds provided T is ergodic.

There is a special setting where one has uniform convergence in the ergodic theorem. Suppose T is a homeomorphism of a compact metric space X . By a theorem of Krylov and Bogoliouboff [138] there is at least one probability measure on the Borel σ -algebra of X which is invariant under T . T is said to be *uniquely ergodic* if there is only one Borel probability measure, say μ , invariant under T . It is easy to see that when this is the

case then T is an ergodic automorphism of (X, \mathcal{B}, μ) . As an example, if α is an irrational number then the rotation $z \mapsto e^{2\pi i \alpha} z$ is a uniquely ergodic transformation of the circle $\{|z| = 1\}$. Equivalently $x \mapsto x + \alpha \pmod 1$ is a uniquely ergodic map on $[0, 1]$. A quick way to see this is to show that the Fourier co-efficients $\hat{\mu}(n)$ of any invariant probability μ are zero for $n \neq 0$. The Jewett–Krieger theorem (see Jewett [109] and Krieger [137]) guarantees that unique ergodicity is ubiquitous in the sense that any automorphism of a probability space is measure-theoretically isomorphic to a uniquely ergodic homeomorphism. The following important result is due to Oxtoby [165]).

Theorem 7 *If T is uniquely ergodic, μ is its unique invariant probability measure and $f \in C(X)$ then the ergodic averages $A_n(f)$ converge uniformly to $\int f d\mu$.*

This result can be proved along the same lines as the proof given above of von Neumann’s theorem. In a nutshell, one uses the fact that the dual of $C_{\mathbb{R}}(X)$ is the space of finite signed measures on X and the unique ergodicity to show that functions of the form $f - f \circ T$ together with the invariant functions (which are just constant functions) span a dense subspace of $C(X)$.

A sequence $\{x_n\}$ in the interval $[0, 1]$ is said to be *uniformly distributed* if $\frac{1}{n} \sum_{i=1}^n f(x_i) \rightarrow \int_0^1 f(x) dx$ for any $f \in C[0, 1]$ (equivalently for any Riemann integrable f or for any $f = 1_I$ where I is any subinterval of $[0, 1]$). As a simple application of Theorem 7 one obtains the linear case of the following result of Weyl [202].

Theorem 8 *If α is irrational and $p(x)$ is any non-constant polynomial with integer coefficients then the sequence $\{p(n)\alpha \pmod 1\}$ is uniformly distributed.*

Furstenberg [84], see also [86], has shown that Weyl’s result, in full generality, can be deduced from the unique ergodicity of certain affine transformations of higher dimensional tori. For polynomials of degree $k > 1$ Weyl’s result is usually proved by inductively reducing to the case $k = 1$, using the following important lemma of van der Corput (see for example [139]).

Theorem 9 *Suppose that for each fixed $h > 0$ the sequence*

$$\{x_{n+h} - x_n \pmod 1\}_n$$

is uniformly distributed. Then $\{x_n\}$ is uniformly distributed.

When μ is infinite and T is ergodic the limiting function in Birkhoff’s theorem is 0 a.e. In 1937 Hopf [100] proved a generalization of Birkhoff’s theorem which is more meaningful in the case of an infinite invariant measure.

It is a special case of a later theorem of Hurewicz [105], which we will discuss first.

Suppose that (X, \mathcal{B}, μ) is a σ -finite measure space. If ν is another σ -finite measure on \mathcal{B} write $\nu \ll \mu$ (ν is *absolutely continuous* relative to μ) if $\mu(E) = 0$ implies $\nu(E) = 0$ and one writes $\nu \sim \mu$ if $\nu \ll \mu$ and $\mu \ll \nu$. Consider a *non-singular automorphism* $\tau: X \rightarrow X$, meaning that τ is measurable with a measurable inverse and that $\mu(E) = 0$ if and only if $\mu(\tau E) = 0$. In other words $\nu = \mu \circ \tau \sim \mu$. By the Radon–Nikodym theorem there is a function $\rho \in L_1(\mu)$ such that $\rho > 0$ a.e. and $\nu(E) = \int_E \rho d\mu$ for all measurable E . In order to obtain an associated operator T on L_1 which is an (invertible) isometry one defines

$$Tf(x) = \rho(x)f(\tau x). \tag{11}$$

The dual operator on L_∞ is then given by $T^*g = g \circ \tau^{-1}$.

If ν is a σ -finite measure equivalent to μ which is invariant under τ then the ergodic theory of τ can be reduced to the measure-preserving case using σ . The interesting case is when there is no such ν . It was an open problem for some time whether there is always an equivalent invariant measure. In 1960 Ornstein [163] gave an example of a τ which does not have an equivalent invariant measure. It is curious that, with hindsight, such examples were already known in the fifties to people studying von Neumann algebras.

For $f \in L_1$ let $S_n f = \sum_{i=0}^n T^i f$. τ is said to be *conservative* if there is no set E with $\mu(E) > 0$ such that $\tau^{-i} E, i = 0, 1, \dots$ are pairwise disjoint, that is if the Poincaré recurrence theorem remains valid. For example, the shift on \mathbb{Z} is not conservative. Hurewicz [105] proved the following ratio ergodic theorem.

Theorem 10 *Suppose τ is conservative, $f, g \in L_1$ and $g(x) > 0$ a.e. Then $S_n f/S_n g$ converges a.e. to a τ -invariant limit h . If τ is ergodic then $h = \frac{\int f d\mu}{\int g d\mu}$.*

In the case when μ is τ -invariant one has $Tf = f \circ \tau$. If μ is invariant and finite, taking $g = 1$ one recovers Birkhoff’s theorem. If μ is invariant and σ -finite then Hurewicz’s theorem becomes the theorem of Hopf alluded to earlier.

Wiener and Wintner [204] proved the following variant of Birkhoff’s theorem.

Theorem 11 (Wiener–Wintner) *Suppose T is an automorphism of a probability space (X, \mathcal{B}, μ) . Then for any $f \in L_1$ there is a subset $X' \subset X$ of measure one such that for each $x \in X'$ and $\lambda \in \mathbb{C}$ of modulus 1 the sequence $\frac{1}{n} \sum_{i=0}^{n-1} \lambda^i T^i f(x)$ converges.*

It is an easy consequence of the ergodic theorem that one has a.e. convergence for a given f and λ but the point here

is that the set on which the convergence occurs is independent of λ .

Generalizations to Continuous Time and Higher-Dimensional Time

A (measure-preserving) flow is a one-parameter group $\{T_t, t \in \mathbb{R}\}$ of automorphisms of (X, \mathcal{B}, μ) , that is $T_{t+s} = T_t T_s$, such that $T_t x$ is measurable as a function of (t, x) . It will always be implicitly assumed that the map $(t, x) \mapsto T_t x$ from $\mathbb{R} \times X$ to X is measurable. Theorem 4 generalizes to flows by replacing sums with integrals and this generalization follows without difficulty from Theorem 4. (As already observed this observation reverses the historical record.) Theorem 4 may be viewed as a theorem about the “discrete flow” $\{T_n = T^n : n \in \mathbb{Z}\}$. Wiener was the first to generalize Birkhoff’s theorem to families of automorphisms $\{T_g\}$ indexed by groups more general than \mathbb{R} or \mathbb{Z} .

A measure-preserving flow is an *action* of \mathbb{R} while a single automorphism corresponds to an action of \mathbb{Z} . A (measure-preserving) action of a group G is a homomorphism $T: g \mapsto T_g$ from G into the group of automorphisms of a measure space (X, \mathcal{B}, μ) (satisfying the appropriate joint measurability condition in case G is not discrete). Suppose now that $G = \mathbb{R}^k$ or \mathbb{Z}^k and T is an action of G on (X, \mathcal{B}, μ) . In the case of \mathbb{Z}^k an action amounts to an arbitrary choice of commuting maps $T_1, \dots, T_k, T_i = T(e_i)$ where e_i is the standard basis of \mathbb{Z}^k . In the case of \mathbb{R}^k one must specify k commuting flows.

Let m denote counting measure on G in case $G = \mathbb{Z}^k$ and Lebesgue measure in case $G = \mathbb{R}^k$. For any subset E of G with $m(E) < \infty$ let

$$A_E f(x) = \frac{1}{m(E)} \int_E f(T_g x) dm(g). \quad (12)$$

One may then ask whether $A_E f$ converges to a limit, either in the mean or pointwise, as E varies through some sequence of sets which “grow large” or, in case $G = \mathbb{R}^k$, “shrink to 0”. The second case is referred to as a *local ergodic theorem*. In the case of ergodic theorems at infinity the continuous and discrete theories are rather similar and often the continuous analogue of a discrete result can be deduced from the discrete result.

In Wiener [203] proved the following result for actions of $G = \mathbb{R}^k$ and ergodic averages over Euclidean balls $B_r = \{x \in \mathbb{R}^k : \|x\|_2 \leq r\}$.

Theorem 12 *Suppose T is an action of \mathbb{R}^k on (X, \mathcal{B}, μ) and $f \in L_1(\mu)$.*

- (a) *For $f \in L_1 \lim_{r \rightarrow \infty} A_{B_r} f = g$ exists a.e. If μ is finite the convergence also holds with respect to the L_1 -norm,*

g is T -invariant and $\int_I g d\mu = \int_I f d\mu$ for every T -invariant set I .

- (b) $\lim_{r \rightarrow 0} A_{B_r} f = f$ a.e.

The local aspect of Wiener’s theorem is closely related to the Lebesgue differentiation theorem, see for example Proposition 3.5.4 of [132], which, in its simplest form, states that for $f \in L^1(\mathbb{R}^k, m)$ one has a.e. convergence of $\frac{1}{m(B_r)} \int_{B_r} f(x+t) dt$ to $f(x)$ as $r \rightarrow 0$. The local ergodic theorem implies Lebesgue’s theorem, simply by considering the action of \mathbb{R}^k on itself by translation. In fact the local ergodic theorem can also be deduced from Lebesgue’s theorem by a simple application of Fubini’s theorem (see for example [135], Chap. 1, Theorem 2.4 in the case $k = 1$).

The key point in Wiener’s proof is the following weak L_1 maximal inequality, similar to (6).

Theorem 13 *Let $Mf = \sup_{r>0} |A_{B_r} f|$. Then one has*

$$\mu\{Mf > \alpha\} \leq \frac{C}{\alpha} \|f\|_1, \quad (13)$$

where C is a constant depending only on the dimension d . (In fact one may take $C = 3^d$.)

In the case when T is the action of \mathbb{R}^k on itself by translation (13) is the well-known maximal inequality for the Hardy–Littlewood maximal function ([132], Lemma 3.5.3). Wiener proves (13) by way of the following *covering lemma*. If B is a ball in \mathbb{R}^k let B' denote the concentric ball with three times the radius.

Theorem 14 *Suppose a compact subset K of \mathbb{R}^k is covered by a (finite) collection \mathcal{U} of open balls. Then there exist pairwise disjoint $B_i \in \mathcal{U}, i = 1, \dots, k$ such that $\bigcup_i B'_i$ covers K .*

To find the B_i it suffices to let B_1 be the largest ball in \mathcal{U} , then B_2 the largest ball which does not intersect B_1 and in general B_n the largest ball which does not intersect $\bigcup_{i=1}^{n-1} B_i$. Then it is not hard to argue that the B'_i cover K .

In general, a covering lemma is, roughly speaking, an assertion that, given a cover \mathcal{U} of a set K in some space (often a group), one may find a subcollection $\mathcal{U}' \subset \mathcal{U}$ which covers a substantial part of K and is in some sense efficient in that $\sum_{U \in \mathcal{U}'} 1_U \leq C$, C some absolute constant. Covering lemmas play an important role in the proofs of many maximal inequalities. See Sect. 3.5 of [132] for a discussion of several of the best-known classical covering lemmas.

As Wiener was likely aware, the same kind of covering argument easily leads to maximal inequalities and ergodic theorems for averages over “sufficiently regular” sets. For example, in the case of $G = \mathbb{Z}^k$ use the standard total order $<$ on G and for $n \in \mathbb{N}^k$ let $S_n = \{m \in \mathbb{Z}^k : 0 < m <$

n }. Let $e(n)$ denote the maximum value of n_i/n_j . Then one has the following result.

Theorem 15 For any $e > 0$ and any integrable f

$$\lim_{n \rightarrow \infty, e(n) < e} A_{S_n} f$$

exists a.e. and the limit is characterized by the same properties as in Theorem 12. Moreover there is a maximal inequality

$$\mu \left\{ \sup_{e(n) < e} |A_{S_n} f| > \alpha \right\} \leq \frac{C}{\alpha} \|f\|_1, \tag{14}$$

where C is a constant depending only on e and the dimension k .

If one does not impose a bound on $e(n)$ the a.e. convergence of $A_{S_n} f$ may fail for $f \in L_1$, (although it does hold for any increasing sequence of n 's by Theorem 30 below). Nonetheless Dunford [72] and independently Zygmund [215] showed that one does have unrestricted convergence if $f \in L_p$ for some $p > 1$, provided μ is finite. Let T_1, \dots, T_k be any k (possibly non-commuting!) automorphisms of a finite measure space (X, \mathcal{B}, μ) . For $n = (n_1, n_2, \dots, n_k)$ let $T_n = T_1^{n_1} \dots T_k^{n_k}$. (This is not an action of \mathbb{Z}^k unless the T_i commute with each other.) As before when $F \subset \mathbb{Z}^k$ is a finite subset write $A_F f = \frac{1}{|F|} \sum_{n \in F} T_n f$. Finally let $P_j f = \lim_n A_n(T_j) f$.

Theorem 16 For $f \in L_p$

$$\lim_{n \rightarrow \infty} A_{S_n} f = P_1 \dots P_k f \tag{15}$$

both a.e. and in L_p .

The proof of Theorem 16 uses repeated applications of Birkhoff's theorem and hinges on (10).

Somewhat surprisingly Hurewicz's theorem was not generalized to higher dimensions until the very recent work of Feldman [79]. In fact the theorem fails if one considers averages over the cube $[0, n - 1]^d$ in \mathbb{Z}^d . However Feldman was able to prove a suitably formulated generalization of Hurewicz's theorem for averages over symmetric cubes.

For $f \in L^1(\mathbb{R})$ the classical *Hilbert transform* is defined for a.e. t by

$$Hf(t) = \frac{1}{\pi} \lim_{\epsilon \rightarrow 0^+} \int_{|s| > \epsilon} \frac{f(t-s)}{s} ds \tag{16}$$

Let $H^* f(t) = \frac{1}{\pi} \sup_{\epsilon > 0} \left| \int_{|s| > \epsilon} \frac{f(t-s)}{s} ds \right|$, the corresponding maximal function. The proof that the limit (16) exists a.e. is based on the maximal inequality

$$m\{Hf > \lambda\} \leq \frac{C}{\lambda} \|f\|_1, \tag{17}$$

where C is an absolute constant. See Loomis [146] (1946) for a proof of (17) using real-variable methods. Cotlar [65] proved the existence of the following ergodic analogue of the Hilbert transform (actually for the n -dimensional Hilbert transform).

Theorem 17 Suppose $\{T_t\}$ is a measure-preserving flow on a probability space (X, \mathcal{B}, μ) and $f \in L^1$. Then

$$\lim_{\epsilon \rightarrow 0} \int_{\epsilon < t < \epsilon^{-1}} \frac{f(T_t x)}{t} dt \tag{18}$$

exists for a.a. x .

Motivated by Cotlar's result Calderón [54] proved a general *transfer principle* which allows one to transfer maximal inequalities and convergence theorems for functions of a real or integer variable to the ergodic setting. Although stated for functions on \mathbb{R} it applies equally well to \mathbb{R}^k or \mathbb{Z}^k . This principle subsumes Birkhoff's theorem, Wiener's theorem and Cotlar's result. For simplicity only a special case of Calderón's result, in the discrete case, will be stated here.

Let T be an automorphism of a probability space (X, \mathcal{B}, μ) , let m denote counting measure on \mathbb{Z} and suppose σ is a probability measure on \mathbb{Z} . For $g \in L_1(m)$ define $\sigma(g)(n) = \sum_{i \in \mathbb{Z}} \sigma(i) g(n+i)$. For $f \in L_1(\mu)$ let $\sigma(T)f = \sum_{i \in \mathbb{Z}} \sigma(i) T^i f$, which is easily seen to converge a.e. and in L_1 -norm. Given a fixed sequence σ_n of probabilities define $Mg = \sup_n \sigma_n g$ and $M(T)f = \sup_n \sigma_n(T)f$.

Theorem 18 (Calderón) Suppose there is a constant C such that

$$m\{Mg > \lambda\} < \frac{C}{\lambda} \|g\|_1 \quad \text{for all } g \in L_1(m). \tag{19}$$

Then one also has

$$\mu\{M(T)f > \lambda\} < \frac{C}{\lambda} \|f\|_1 \quad \text{for all } T \quad \text{and } g \in L_1(\mu). \tag{20}$$

In other words, in order to prove a maximal inequality for general T it suffices to prove it in case T is the shift map on the integers. The idea of transference could already be seen in Wiener's proof of the \mathbb{R}^n ergodic theorem. Transference principles in various forms of have become an important tool in the study of ergodic theorems. See Bellow [18] for a very readable overview.

Pointwise Ergodic Theorems for Operators

Early in the history of ergodic theorems there were attempts to generalize the ergodic theorem to more general

linear operators on L_p spaces, that is, operators which do not arise by composition with a mapping of X . In the case $p = 1$ the main motivation for this comes from the theory of Markov processes.

If (X, \mathcal{B}) is a measurable space a *sub-stochastic kernel* on X is a non-negative function P on $X \times \mathcal{B}$ such that

- (a) for each $x \in X$ $P(x, \cdot) = P_x$ is a measure on \mathcal{B} such that $P_x(X) \leq 1$ and
- (b) $P(\cdot, A)$ is a measurable function for each $A \in \mathcal{B}$.

It is most intuitive to think about the *stochastic* case, namely when each P_x is a probability measure. One then views $P(x, A)$ as the probability that the point x moves into the set A in one unit of time, so one has stochastic dynamics as opposed to deterministic dynamics, namely the case when $P_x = \delta_{Tx}$ for a map T . In this case the measures P_x are called *transition probabilities*.

If μ is a σ -finite measure on X one may define the measure $P\mu = \int P_x d\mu(x)$. $P\nu$ is also meaningful if ν is a finite signed measure. The case when $P\mu = \mu$ is the stochastic analogue of measure-preserving dynamics and the case when $P\mu \ll \mu$ is the analogue of non-singular dynamics. It is easy to see that given any σ -finite measure λ there is always a μ such that $\lambda \ll \mu$ and $P\mu \ll \mu$. Let \tilde{L}_1 denote the space of finite signed measures ν such that $\nu \ll \mu$, which is identified with $L_1 = L_1(\mu, \mathbb{R})$ via the Radon-Nikodym theorem. If $P\mu \ll \mu$ then P maps $\tilde{L}_1(\mu)$ into itself so the restriction of P is an operator T on $L_1(\mu)$. T is a positive contraction, that is $\|T\| \leq 1$ and T maps non-negative functions to non-negative functions. As proved in, for example, [153], every positive contraction arises in this way from a substochastic kernel under the assumption that (X, \mathcal{B}) is standard. This simply means that there is some complete metric on X for which \mathcal{B} is the σ -algebra of Borel sets. Virtually all measurable spaces encountered in analysis are standard so this should be viewed as a technicality only. See [153], [80] and [135] for more about the relation between kernels and positive contractions.

The case when X is finite, P is stochastic and μ is a probability measure is classical in probability theory. P and μ determine a probability measure ν on $X^{\mathbb{N}}$ characterized by its values on cylinder sets, namely for all $x_1, \dots, x_n \in X$

$$\begin{aligned} \nu\{x \in X^{\mathbb{N}} : x(i) = x_i, 1 \leq i \leq n-1\} \\ = \mu(x_1) \prod_{i=1}^{n-1} P_{x_i}(x_{i+1}). \end{aligned} \quad (21)$$

The co-ordinate functions $X_i(x) = x(i)$ on the space $X^{\mathbb{N}}$ endowed with the probability ν form a *Markov process*,

which will be stationary if and only if μ is P -invariant. For a general X the analogous construction is possible provided X is standard.

Hopf [101] initiated the systematic study of positive L_1 contractions and proved the following ergodic theorem.

Theorem 19 *Suppose (X, \mathcal{B}, μ) is a probability space and T is a positive contraction on $L^1(\mu)$ satisfying $T1 = 1$ and $T^*1 = 1$. Then $\lim_{n \rightarrow \infty} n^{-1} \sum_{k=0}^{n-1} T^k f$ exists a.e.*

The importance of Hopf's article lies less in this convergence result than in the methods he developed. He proved that the maximal inequality (5) generalizes to all positive L_1 contractions T and used this to obtain the decomposition of X into its conservative and dissipative parts C and D , characterized by the fact that for any $p \in L_1$ such that $p > 0$ a.e. $\sum_{k=0}^{\infty} T^k p$ is infinite a.e. on C and finite a.e. on D . These results are the cornerstone of much of the subsequent work on L_1 contractions.

Theorem 19 contains Birkhoff's theorem for an automorphism τ of (X, \mathcal{B}, μ) , simply by defining $Tf = f \circ \tau$. In fact one can also deduce Theorem 19 from Birkhoff's theorem (if one assumes only that X is standard). Indeed the hypotheses of Hopf's theorem imply that the kernel P associated to T is stochastic ($T^*1 = 1$) and that μ is P -invariant ($T1 = 1$). Hopf's theorem then follows by applying Birkhoff's theorem to the shift on the stationary Markov process associated to P and μ . In fact Kakutani [123] (see also Doob [71]) had already made essentially the same observation, except that his result assumes the stationary Markov process to be already given.

In 1955 Dunford and Schwartz [73] made essential use of Hopf's work to prove the following result.

Theorem 20 *Suppose $\mu(X) = 1$ and T is a (not necessarily positive) contraction with respect to both the L_1 and L_{∞} norms. Then the conclusion of Hopf's theorem remains valid.*

Note that the assumption that T contracts the L_{∞} -norm is meaningful, as $L_{\infty} \subset L_1$. The proof of the result is reduced to the positive case by defining a positive contraction $|T|$ analogous to the total variation of a complex measure.

Then in 1960 Chacón and Ornstein [61] proved a definitive ratio ergodic theorem for all positive contractions of L_1 which generalizes both Hopf's theorem and the Hurewicz theorem.

Theorem 21 *Suppose T is a positive contraction of $L_1(\mu)$, where μ is σ -finite, $f, g \in L_1$ and $g \geq 0$. Then*

$$\frac{\sum_{i=0}^n T^i f}{\sum_{i=0}^n T^i g} \quad (22)$$

converges a.e. on the set $\{\sum_{i=0}^{\infty} T^i g > 0\}$.

In 1963 Chacón [58] proved a very general theorem for non-positive operators which includes the Chacón–Ornstein theorem as well as the Dunford–Schwartz theorem.

Theorem 22 *Suppose T is a contraction of L_1 and $p_n \geq 0$ is a sequence of measurable functions with the property that*

$$g \in L_1, |g| \leq p_n \Rightarrow |Tg| \leq p_{n+1}. \tag{23}$$

Then

$$\frac{\sum_{i=0}^n T^i f}{\sum_{i=0}^n p_i} \tag{24}$$

converges a.e. to a finite limit on the set $\{\sum_{i=0}^\infty p_i > 0\}$.

If T is an L_1, L_∞ -contraction and $p_n = 1$ for all n then the hypotheses of this theorem are satisfied, so Theorem 22 reduces to the result of Dunford and Schwartz. See [59] for a concise overview of all of the above theorems in this section and the relations between them.

The identification of the limit in the Chacón–Ornstein theorem on the conservative part C of X is a difficult problem. It was solved by Neveu [152] in case $C = X$, and in general by Chacón [57]. Chacón [60] has shown that there is a non-singular automorphism τ of (X, \mathcal{B}, μ) such that for the associated invertible isometry T of $L_1(\mu)$ given by (11) there is an $f \in L_1(\mu)$ such that $\limsup A_n f = \infty$ and $\liminf A_n f = -\infty$.

In 1975 Akcoglu [3] solved a major open problem when he proved the following celebrated theorem.

Theorem 23 *Suppose $T: L_p \mapsto L_p$ is a positive contraction. Then $A_n f = \frac{1}{n} \sum_{i=0}^{n-1} T^i f$ converges a.e. Moreover one has the strong L_p inequality*

$$\left\| \sup_n |A_n f| \right\|_p \leq \frac{p}{p-1} \|f\|_p. \tag{25}$$

As usual, the maximal inequality (25) is the key to the convergence. Note that it is identical in form to (10) the classical strong L_p inequality for automorphisms. (25) was proved by A. Ionesco–Tulcea (now Bellow) [106] in the case of positive invertible isometries of L_p . It is a result of Banach [16], see also [140], that in this case T arises from a non-singular automorphism τ of (X, \mathcal{B}, μ) in the form $Tf = \rho^{1/p} f \circ \tau$. By a series of reductions Bellow was able to show that in this case (25) can be deduced from (10).

Akcoglu’s brilliant idea was to consider a *dilation* S of T which is a positive invertible isometry on a larger L_p space $\tilde{L}_p = L_p(Y, \mathcal{C}, \nu)$. What this means is that there is a positive isometric injection $D: L_p \rightarrow \tilde{L}_p$ and a positive projection P on \tilde{L}_p whose range is $D(L_p)$ such that

$DT^n = PS^n D$ for all $n \geq 0$. Given the existence of such an S it is not hard to deduce (25) for T from (25) for S . In fact Akcoglu constructs a dilation only in the case when L_p is finite dimensional and shows how to reduce the proof of (25) to this case. In the finite dimensional case the construction is very concrete and P is a conditional expectation operator. Later Akcoglu and Kopp [7] gave a construction in the general case. It is noteworthy that the proof of Akcoglu’s theorem consists ultimately of a long string of reductions to the classical strong L_p inequality (10), which in turn is a consequence of (5).

Subadditive and Multiplicative Ergodic Theorems

Consider a family $\{X_{n,m}\}$ of real-valued random variables on a probability space indexed by the set of pairs $(n, m) \in \mathbb{Z}^2$ such that $0 \leq n < m$. $\{X_{(n,m)}\}$ is called a (stationary) *subadditive process* if

- (a) the joint distribution of $\{X_{n,m}\}$ is the same as that of $\{X_{n+1,m+1}\}$
- (b) $X_{n,m} \leq X_{n,l} + X_{l,m}$ whenever $n < l < m$.

Denoting the index set by $\{n < m\} \subset \mathbb{Z}^2$ the distribution of the process is a measure μ on $\mathbb{R}^{\{n < m\}}$ which is invariant under the shift $Tx(n, m) = x(n + 1, m + 1)$. Thus there is no loss of generality in assuming that there is an underlying endomorphism T such that $X_{n,m} \circ T = X_{n+1,m+1}$. In 1968 Kingman [129] proved the following generalization of Birkhoff’s theorem. $\gamma = \inf \frac{1}{n} \int X_{0,n} d\mu$ is called the *time constant* of the process.

Theorem 24 *If the $X_{n,m}$ are integrable and $\gamma > -\infty$ then $\frac{1}{n} X_{0,n}$ converges a.e. and in L_1 -norm to a \mathbb{T} -invariant limit $\bar{X} \in L_1(\mu)$ satisfying $\int \bar{X} d\mu = \gamma$.*

It is easy to deduce from the above that if one assumes only that $X_{0,1}^+$ is integrable then $\frac{1}{n} X_{0,n}$ still converges a.e. to a T -invariant limit \bar{X} taking values in $[-\infty, \infty)$.

Subadditive processes first arose in the work of Hammersley and Welsh [99] on percolation theory. Here is an example. Let G be the graph with vertex set \mathbb{Z}^2 and with edges joining every pair of nearest neighbors. Let E denote the edge set and let $\{T_e : e \in E\}$ be non-negative integrable i.i.d. random variables. To each finite path P in G associate the “travel time” $T(P) = \sum_{e \in E} T_e$. For integers $m > n \geq 0$ let $X_{n,m}$ be the infimum of $T(P)$ over all paths P joining $(0, n)$ to $(0, m)$. This is a subadditive process with $0 \leq \gamma < \int T_e d\mu$ and it is not hard to see that the underlying endomorphism is ergodic. Thus Kingman’s theorem yields the result that $\frac{1}{n} X_{0,n} \rightarrow \gamma$ a.e.

Suppose now that T is an ergodic automorphism of a probability space (X, \mathcal{B}, μ) and P is a function on X

taking values in the space of $d \times d$ real matrices. Define $P_{n,m} = P(T^{m-1}x)P(T^{m-2}x) \dots P(T^n x)$ and let $P_{n,m}(i, j)$ denote the i, j entry of $P_{n,m}$. Then $X_{n,m} = \log(\|P_{n,m}\|)$ (use any matrix norm) is a subadditive process so one obtains the first part of the following result of Furstenberg and Kesten [87] (1960) originally proved by more elaborate methods. The second part can also be deduced from the subadditive theorem with a little more work. See Kingman [130] for details and for some other applications of subadditive processes.

Theorem 25

- (a) Suppose $\int \log^+(|P|)d\mu < \infty$. Then $\|P_{0,n}\|^{1/n}$ converges a.e. to a finite limit.
- (b) Suppose that for each i, j $P(i, j)$ is a strictly positive function such that $\log P(i, j)$ is integrable. Then the limit $p = \lim(P_{0,n}(i, j))^{\frac{1}{n}}$ exists a.e. and is independent of i and j .

Partial results generalizing Kingman's theorem to the multiparameter case were obtained by Smythe [189] and Nguyen [157]. In 1981 Akcoglu and Krengel [8] obtained a definitive multi-parameter subadditive theorem. They consider an action $\{T_m\}$ of the semigroup $G = \mathbb{Z}_{\geq 0}^d$ by endomorphisms of a measure space (X, \mathcal{B}, μ) . Using the standard total ordering $<$ of G an interval in G is any set of the form $\{k \in G : m < k < n\}$ for any $m < n \in G$. Let \mathcal{I} denote the set of non-empty intervals. Reversing the direction of the inequality, they define a superadditive process as a collection of integrable functions $F_I, I \in \mathcal{I}$, such that

- (a) $F_I \circ T_m = F_{I+m}$,
- (b) $F_I \geq F_{I_1} + \dots + F_{I_k}$ whenever I is the disjoint union of I_1, \dots, I_k and
- (c) $\gamma = \sup_{I \in \mathcal{I}} |I|^{-1} \int F_I d\mu < \infty$.

A sequence $\{I_n\}$ of sets in \mathcal{I} is called regular if there is an increasing sequence I'_n such that $I_n \subset I'_n$ and $|I'_n| \leq C|I_n|$ for some constant C .

Theorem 26 (Akcoglu–Krengel) Suppose F_I is a superadditive process and $\{I_n\}$ is regular. Then $\frac{1}{|I_n|} \int F_{I_n} d\mu$ converges a.e.

$\{F_I\}$ is additive if the inequality in (b) is replaced by equality. In this case $F_I = \sum_{n \in I} f \circ T_n$ where f is an integrable function. Thus in the additive case the Akcoglu–Krengel result is a theorem about ordinary multi-dimensional ergodic averages, which is in fact a special case of an earlier result of Tempelman [196] (see Sect. “Amenable Groups” below).

Kingman's proof of Theorem 24 hinged on the existence of a certain (typically non-unique) decomposition

for subadditive processes. Akcoglu and Krengel's proof of the multi-parameter result does not depend on a Kingman-type decomposition, in fact they show that there is no such decomposition in general. They prove a weak maximal inequality

$$\mu\{\sup |I_n|^{-1} F_{I_n} > \lambda\} < \frac{C}{\lambda} \gamma, \tag{26}$$

where C is a constant depending only on the dimension, and show that this is sufficient to prove their result. In the case $d = 1$ the Akcoglu–Krengel argument provides a new and more natural proof of Kingman's theorem, similar in spirit to Wiener's arguments.

Akcoglu and Sucheston [9] have proved a ratio ergodic theorem for subadditive processes with respect to a positive L_1 contraction, generalizing both the Chacón–Ornstein theorem and Kingman's theorem.

In 1968 Oseledec [164] proved his celebrated multiplicative ergodic theorem, which gives very precise information about the random matrix products studied by Furstenberg and Kesten. His theorem is an important tool for the study of Lyapunov exponents in differentiable dynamics, see notably Pesin [169]. If A is a $d \times d$ matrix let $\|A\| = \sup\{\|Ax\| : \|x\| = 1\}$ where $\|x\|$ is the Euclidean norm on \mathbb{R}^n .

Theorem 27 Suppose T is an endomorphism of the probability space (X, \mathcal{B}, μ) . Suppose P is a measurable function on X whose values are $d \times d$ real matrices such that $\int \log^+ \|P\| d\mu < \infty$ and let $P_n(x) = P(T^{n-1}x)P(T^{n-2}x) \dots P(x)$. Then there is a T -invariant subset X' of X with measure 1 such that for $x \in X'$ the following hold.

- (a) $\lim_{n \rightarrow \infty} (P_n^*(x)P_n(x))^{\frac{1}{2n}} = A(x)$ exists.
- (b) Let $0 \leq \exp \lambda_1(x) \leq \exp \lambda_2(x) \leq \dots \leq \exp \lambda_r(x)$ be the distinct eigenvalues of $A(x)$ ($r = r(x)$ may depend on x and λ_1 may be $-\infty$) with multiplicities $m_1(x), \dots, m_r(x)$. Let $E_i(x)$ be the eigenspace corresponding to $\exp(\lambda_i(x))$ and set

$$F_i(x) = E_1(x) + \dots + E_i(x).$$

Then for each $u \in F_i(x) \setminus F_{i-1}(x)$

$$\lim \frac{1}{n} \log \|P_n(x)u\| = \lambda_i(x).$$

- (c) The functions m_i and λ_i are T -invariant.
- (d) If T is ergodic, $\det P(x) = 1$ a.e. and

$$\limsup \frac{1}{n} \int \log \|P_n\| d\mu > 0$$

then the λ_i are constants, $\lambda_1 < 0$ and $\lambda_r > 0$.

Raghunathan [174] gave a much shorter proof of Osledec's theorem, valid for matrices with entries in a locally compact normed field. He showed that it could be reduced to the Furstenberg–Kesten theorem by considering the exterior powers of P . Ruelle [180] extended Osledec's theorem to the case where P takes values in the set of bounded operators on a Hilbert space. Walters [199] has given a proof (under slightly stronger hypotheses) which avoids the matrix calculations and tools from multilinear algebra used in other proofs.

Entropy and the Shannon–McMillan–Breiman Theorem

The notion of entropy was introduced by Shannon in his landmark work [185] which laid the foundations for a mathematical theory of information. Suppose (X, \mathcal{B}, μ) is a probability space, P is a finite measurable partition of X and T is an automorphism of (X, \mathcal{B}, μ) . $P(x)$ denotes the atom of P containing x . The *entropy* of P is

$$\begin{aligned} h(P) &= - \sum_{p \in P} \mu(p) \log(\mu(p)) \\ &= - \int \log(\mu(P(x))) d\mu(x) \geq 0. \end{aligned} \quad (27)$$

$-\log(\mu(A))$ may be viewed as a quantitative measure of the amount of information contained in the statement that a randomly chosen $x \in X$ happens to belong to A . So $h(P)$ is the expected information if one is about to observe which atom of P a randomly chosen point falls in. See Billingsley [34] for more motivation of this concept. See also the article in this collection on entropy by J. King or any introductory book on ergodic theory, e. g. Petersen [171].

If P and Q are partitions $P \vee Q$ denotes the common refinement which consists of all sets $p \cap q$, $p \in P$, $q \in Q$. It is intuitive and not hard to show that $h(P \vee Q) \leq h(P) + h(Q)$. Now let $P_0^n = \bigvee_{i=0}^{n-1} T^{-i} P$ and $h_n = h(P_0^n)$. The subadditivity of entropy implies that $h_{n+m} \leq h_n + h_m$, so by a well-known elementary lemma the limit

$$h(P, T) = \lim_n \frac{h_n}{n} = \inf_n \frac{h_n}{n} \geq 0 \quad (28)$$

exists.

If one thinks of $P(x)$ as a measurement performed on the space X and Tx as the state succeeding x after one second has elapsed then $h(P, T)$ is the expected information per second obtained by repeating the experiment every second for a very long time. See [177] for an alternative and very useful approach to $h(P, T)$ via *name-counting*.

The following result, which is known as the Shannon–McMillan–Breiman theorem, has proved to be of fundamental importance in ergodic theory, notably, for example, in the proof of Ornstein's celebrated isomorphism theorem for Bernoulli shifts [159].

Theorem 28 *If T is ergodic then*

$$\lim_{n \rightarrow \infty} -\frac{1}{n} \log(\mu(P_0^{n-1}(x))) = h(P, T) \quad (29)$$

a.e. and in L_1 -norm.

In other words, the actual information obtained per second by observing x over time converges to the constant $h(P, T)$, namely the limiting expected information per second. Shannon [185] formulated Theorem 28 and proved convergence in probability. McMillan [149] proved L_1 convergence and Breiman [49] obtained the a.e. convergence.

The original proofs of a.e. convergence used the martingale convergence theorem, were not very intuitive and did not generalize to \mathbb{Z}^n -actions, where the martingale theorem is not available. Ornstein and Weiss [161] (1983) found a beautiful and more natural argument which bypasses the martingale theorem and allows generalization to a class of groups which includes \mathbb{Z}^n .

Amenable Groups

Let G be any countable group and $T = \{T_g\}$ an action of G by automorphisms of a probability space. Suppose σ is a complex measure on G , that is, $\{\sigma(g)\}_{g \in G}$ is an absolutely summable sequence. Let T_g act on functions via $T_g f = f \circ T_g$, so T_g is an isometry of L_p for every $1 \leq p \leq \infty$. Let $\sigma_n(T) = \sum_{g \in G} \sigma(g) T_g$. A very general framework for formulating ergodic theorems is to consider a sequence $\{\sigma_n\}$ and ask whether $\sigma_n(T)f$ converges, a.e. or in mean, for f in some L_p space. When $\sigma_n(T)f$ converges for all actions T and all f in L_p in p -norm or a.e. then one says that σ_n is *mean* or *pointwise good* in L_p . When the σ_n are probability measures it is natural to call such results weighted ergodic theorems and this terminology is retained for complex σ as well.

Birkhoff's theorem says that if $G = \mathbb{Z}$ and σ_n is the normalized counting measure on $\{0, 1, \dots, n-1\}$ then $\{\sigma_n\}$ is pointwise good in L_1 . This section will be concerned only with sequences $\{\sigma_n\}$ such that σ_n is normalized counting measure on a finite subset $F_n \subset G$ so one speaks of mean or pointwise good sequences $\{F_n\}$. A natural condition to require of $\{F_n\}$, which will ensure that the limiting function is invariant, is that it be asymptoti-

cally (left) invariant in the sense that

$$\frac{|gF_n \Delta F_n|}{|F_n|} \rightarrow 0 \quad \forall g \in G. \quad (30)$$

Such a sequence is called a *Følner sequence* and a group G is *amenable* if it has a Følner sequence. As in most of this article G is restricted to be a discrete countable group for simplicity but most of the results to be seen actually hold for a general locally compact group.

Amenability of G is equivalent to the existence of a finitely additive left invariant probability measure on G . It is not hard to see that any Abelian, and more generally any solvable, group is amenable. On the other hand the free group F_2 on two generators is not amenable. See Patterson [167] for more information on amenable groups. The Følner property by itself is enough to give a mean ergodic theorem.

Theorem 29 *Any Følner sequence is mean good in L_p for $1 \leq p < \infty$.*

The proof of this result is rather similar to the proof of Theorem 3. In fact Theorem 29 is only a special case of quite general results concerning amenable semi-groups acting on abstract Banach spaces. See the book of Patterson [167] for more on this.

Turning to pointwise theorems, the Følner condition alone does not yield a pointwise theorem, even when $G = \mathbb{Z}$ and the F_n are intervals. For example Akcoglu and del Junco [6] have shown that when $G = \mathbb{Z}$ and $F_n = [n, n + \sqrt{n}] \cap \mathbb{Z}$ the pointwise ergodic theorem fails for any aperiodic T and for some characteristic function f . See also del Junco and Rosenblatt [119].

The following pointwise result of Tempelman [196] is often quoted. A Følner sequence $\{F_n\}$ is called *regular* if there is a constant C such that $|F_n^{-1}F_n| \leq C|F_n|$ and there is an increasing sequence F'_n such that $F_n \subset F'_n$ and $|F'_n| \leq C|F_n|$.

Theorem 30 *Any regular Følner sequence is pointwise good in L_1 .*

In case the F_n are intervals in \mathbb{Z}^n this result can be proved by a variant of Wiener's covering argument and in the general case by an abstraction thereof. The condition $|F_n^{-1}F_n| \leq C|F_n|$ captures the property of rectangles which is needed for the covering argument. Emerson [78] independently proved a very similar result.

The work on ergodic theorems for abstract locally compact groups was pioneered by Calderón [53] who built on Wiener's methods. The main result in this paper is somewhat technical but it already contains the germ of Tempelman's theorem. Other ergodic theorems

for amenable groups, whose main interest lies in the case of continuous groups, include Tempelman [195], Renaud [175], Greenleaf [93] and Greenleaf and Emerson [94]. The discrete versions of these results are all rather close to Tempelman's theorem.

Among pointwise theorems for discrete groups Tempelman's result was essentially the best available for a long time. It was not known whether every amenable group had a Følner sequence which is pointwise good for some L_p . In 1988 Shulman [187] introduced the notion of a *tempered Følner sequence* $\{F_n\}$, namely one for which

$$\left| \bigcup_{i < n} F_i^{-1} F_n \right| < C|F_n|, \quad (31)$$

for some constant C . The advantage of the tempered condition is that any Følner sequence has a tempered subsequence, and in particular any amenable group has a tempered Følner sequence.

Shulman proved a maximal inequality in L_2 for such F_n which implies that $\{F_n\}$ is pointwise good in L_2 . An account of this work may be found in Section 5.6 of Tempelman's book [194].

Lindenstrauss [145] was able to extend the result to L_1 .

Theorem 31 *Any tempered Følner sequence is pointwise good in L_1 .*

The key new idea in his proof is to use a probabilistic argument to establish a covering lemma. In the discrete case Ornstein and Weiss [201] have given a non-probabilistic proof of Lindenstrauss's covering lemma. Lindenstrauss also generalizes the a.e. convergence in the Shannon–McMillan–Breiman theorem to this setting. L_1 convergence was already established by Kieffer [128] in 1975.

Subsequence and Weighted Theorems

In this section G and T are as in the previous section and σ_n is a sequence of complex measures on G .

This section will be concerned with conditions on σ_n that ensure that it is mean or pointwise good. For the most part G will be \mathbb{Z} .

Hopf's ergodic theorem gives a class of examples for free. Choose any probability measure λ on G , define the operator $T_\lambda = \lambda(T)$ and observe that $(T_\lambda)^n = T_{\lambda^{*n}}$, where λ^{*n} denotes the convolution power. Since T_λ satisfies the hypotheses of Hopf's theorem it follows that the sequence $\sigma_n = \frac{1}{n} \sum_{i=0}^{n-1} \lambda^{*i}$ is pointwise good in L_1 .

Another sort of example is given by choosing a sequence g_n in G and letting $\sigma_n = \frac{1}{n} \sum_{i=0}^{n-1} \delta_{g_n}$. If one has convergence for such a sequence one speaks of a *subsequence ergodic theorem*. This section will mainly focus on

the case $G = \mathbb{Z}$ and sequences which are the increasing enumeration of a subset $S \subset \mathbb{N}$. Given $S \subset \mathbb{N}$ write $\sigma_{S,n}$ for the corresponding probabilities σ_n and say S is good if $\sigma_{S,n}$ is good.

Perhaps the first subsequence ergodic theorem is due to Blum and Hanson [38] who proved that an automorphism T of a probability space is *strongly mixing* if and only if $\frac{1}{n} \sum_{i=0}^{n-1} T^{mi} f$ converges in L_2 norm for every $f \in L_2$ and every increasing $\{m_i\}$. Strong mixing means that $\mu(T^{-n}A \cap B) \rightarrow \mu(A)\mu(B)$. In 1969 Brunel and Keane [51] proved the first pointwise subsequence ergodic theorem

Theorem 32 *Suppose that T is a translation on a compact Abelian group G with Haar measure λ , $g \in G$, and $E \subset G$ is any Borel set with $\lambda(E) > 0$ and $\lambda(\partial E) = 0$. Let $S = \{i > 0 : T^i g \in E\}$. Then S is pointwise good in L_1 .*

Krengel [133] constructed the first example of a sequence $S \subset \mathbb{N}$ which is pointwise universally bad, in the strong sense that for any aperiodic T the a.e. convergence of $\sigma_{S,n}(T)f$ fails for some characteristic function f . Bellow [17] proved that any lacunary sequence (meaning $a_{n+1} > ca_n$ for some $c > 1$) is pointwise universally bad in L_1 .

Later Akcoglu et al. [1] were able to show that for lacunary sequences $\{\sigma_{S,n}\}$ is even *strongly sweeping out*. A sequence $\{\sigma_n\}$ of probability measures on \mathbb{Z} is said to be strongly sweeping out if for any ergodic T and for all $\delta > 0$ there is a characteristic function f with $\int f d\mu < \delta$ such that $\limsup \sigma_n(T)f = 1$ a.e. It is not difficult to show that if $\{\sigma_n\}$ is strongly sweeping out then there are characteristic functions f such that $\liminf \sigma_n(T)f = 0$ and $\limsup \sigma_n(T)f = 1$. Thus for lacunary sequences the ergodic theorem fails in the worst possible way.

Bellow and Losert [21] gave the first example of a sequence $S \subset \mathbb{Z}$ of density 0 which is universally good for pointwise convergence, answering a question posed by Furstenberg. They construct an S which is pointwise good in L_1 . This paper also contains a good overview of the progress on weighted and subsequence ergodic theorems at that time.

Weyl's theorem on uniform distribution (Theorem 9) suggests the possibility of an ergodic theorem for the sequence $\{n^2\}$. It is not hard to see that $\{n^2\}$ is mean good in L_2 . In fact the spectral theorem and the dominated convergence theorem show that it is enough to prove that the L_∞ -bounded sequence of functions $\frac{1}{n} \sum_{i=0}^{n-1} z^{n^2}$ on the unit circle converges at each point z of the unit circle. When z is not a root of unity the sequence converges to 0 by Weyl's result and when z is a root of unity the convergence is trivial because $\{z^{n^2}\}$ is periodic. In 1987 Bourgain [39,43]

proved his celebrated pointwise ergodic theorem for polynomial subsequences.

Theorem 33 *If p is any polynomial with rational coefficients taking integer values on the integers then $S = \{p(n)\}$ is pointwise good in L_2 .*

The first step in Bourgain's argument is to reduce the problem of proving a maximal inequality to the case of the shift map on the integers, via Calderón's transfer principle. Then the problem is transferred to the circle by using Fourier transforms. At this point the problem becomes a very delicate question about exponential sums and a whole arsenal of tools is brought to bear. See Rosenblatt and Wierdl [176] and Quas and Wierdl [28](Appendix B) for nice expositions of Bourgain's methods.

Bourgain subsequently improved this to all L_p , $p > 1$ and also extended it to sequences $\{[q(n)]\}$ where now q is an arbitrary real polynomial and $[\cdot]$ denotes the greatest integer function. He also announced that his methods can be used to show that the sequence of primes is pointwise good in L_p for any $p > \frac{1+\sqrt{3}}{2}$. Wierdl [205] (1988) soon extended the result for primes to all $p > 1$.

Theorem 34 *The primes are pointwise good in L_p for $p > 1$.*

It has remained a major open question for quite some time whether any of these results hold for $p = 1$. In 2005 there appeared a preprint of Mauldin and Buczolicz [148], which remains unpublished, showing that polynomial sequences are L_1 -universally bad.

Another major result of Bourgain's is the so-called return times theorem [44]. A simplification of Bourgain's original proof was published jointly with Furstenberg, Katznelson and Ornstein as an appendix to an article [47] of Bourgain. To state it let us agree to say that a sequence of complex numbers $\{a(n)\}_{n \geq 0}$ has property P if the sequence of complex measures $\sigma_n = \frac{1}{n} \sum_{i=0}^{n-1} a(i)\delta_i$ has property P , where δ_i denotes the point mass at i .

Theorem 35 (Bourgain) *Suppose T is an automorphism of a probability space (X, \mathcal{B}, μ) , $1 \leq p, q \leq \infty$ are conjugate exponents and $f \in L_p(\mu)$. Then for almost all x the sequence $\{f(T^n x)\}$ is pointwise good in L_q .*

Applying this to characteristic functions $f = 1_E$ one sees that the return time sequence $\{i > 0 : S^i x \in E\}$ is good for pointwise convergence in L_1 . Theorem 32 is a very special case. It is also easy to see that Theorem 35 contains the Wiener-Wintner theorem.

In 1998 Rudolph [179] proved a far-reaching generalization of the return times theorem using the technique of *joinings*. For an introduction to joinings see the article

by de la Rue in this collection and also Thouvenot [198], Glasner [90] (2003) and Rudolph's book [177]. Rudolph's result concerns the convergence of multiple averages

$$\frac{1}{N} \sum_{n=0}^{N-1} \prod_{j=1}^k f_j(T_j^n x) \quad (32)$$

where each T_j is an automorphism of a probability space $(X_j, \mathcal{B}_j, \mu_j)$ and the f_j are L_∞ functions. The point is that the convergence occurs whenever each $x_j \in X_j'$, sets of measure one which may be chosen sequentially for $j = 1, \dots, k$ without knowing what T_i or f_i are for any $i > j$. He actually proves something stronger, namely he identifies an intrinsic property of a sequence $\{a_i\}$, which he calls *fully generic*, such that the following hold.

- (a) The constant sequence $\{1\}$ is fully generic.
- (b) If $\{a_i\}$ is fully generic then for any T and $f \in L_\infty$ the sequence $a_i f(T^i x)$ is fully generic for almost all x .
- (c) Fully generic implies pointwise good in L_∞ .

The definition of fully generic will not be quoted here as it is somewhat technical.

For a proof of the basic return times theorem using joinings see Rudolph [178]. Assani, Lesigne and Rudolph [13] took a first step towards the multiple theorem, a Wiener–Wintner version of the return times theorem. Also Assani [11] independently gave a proof of Rudolph's result in the case when all the T_j are weakly mixing.

Ornstein and Weiss [162] have proved the following version of the return times theorem for abstract discrete groups. As with \mathbb{Z} , let us say that a sequence $\{a_g\}_{g \in G}$ of complex numbers has property P for $\{F_n\}$ if the sequence $\sigma_n = \frac{1}{|F_n|} \sum_{g \in F_n} a(g) \delta_g$ of complex measures has property P .

Theorem 36 *Suppose that the increasing Følner sequence $\{F_n\}$ satisfies the Tempelman condition $\sup_n |F_n^{-1} F_n| / |F_n| < \infty$ and $\bigcup F_n = G$. If $b \in L_\infty$ then for a.a. x the sequence $\{b(T_g x)\}$ is pointwise good in L_1 for $\{F_n\}$.*

Recently Demeter, Lacey, Tao and Thiele [67] have proved that the return times theorem remains valid for any $1 < p \leq \infty$ and $q \geq 2$. On the other hand Assani, Buczolic and Mauldin [14] (2005) showed that it fails for $p = q = 1$.

Bellow, Jones and Rosenblatt have a series of papers [22,23,24,25] studying general weighted averages associated to a sequence σ_n of probability measures on \mathbb{Z} , and, in some cases, more general groups. The following are a few of their results. [23] is concerned with \mathbb{Z} -actions and *moving block averages* given by $\sigma_n = m_{I_n}$, where the

I_n are finite intervals and m_I denotes normalized counting measure on I . They resolve the problem completely, obtaining a checkable necessary and sufficient condition for such a sequence to be pointwise good in L_1 .

[24] gives sufficient conditions on a sequence σ_n for it to be pointwise good in L_p , $p > 1$, via properties of the Fourier transforms $\hat{\sigma}_n$. A particular consequence is that if $\lim_{n \rightarrow \infty} \sum_{k \in \mathbb{Z}} |\sigma_n(k) - \sigma_n(k-1)| = 0$ then $\{\sigma_n\}$ has a subsequence which is pointwise good in L_p , $p > 1$. In [25] they obtain convergence results for sequences $\sigma_n = \sigma^n$, the convolution powers of a probability measure σ . A consequence of one of their main results is that if the expectation $\sum_{k \in \mathbb{Z}} k \sigma(k)$ is zero, the second moment $\sum_{k \in \mathbb{Z}} k^2 \sigma(k)$ is finite and σ is *aperiodic* (its support is not contained in any proper coset in \mathbb{Z}) then σ^n is pointwise good in L_p for $p > 1$.

Bellow and Calderón [19] later showed that this last result is valid also for $p = 1$. This is a consequence of the following sufficient condition for a sequence T to satisfy a weak L_1 inequality. Given an automorphism of a probability space (X, \mathcal{B}, μ) let $Mf = \sup |\sigma_n(T)f(x)|$ be the maximal operator associated to $\{\sigma_n\}$.

Theorem 37 (Bellow and Calderón) *Suppose there is an $\alpha \in (0, 1]$ and $C > 0$ such that for each $n > 1$ one has*

$$|\sigma_n(x+y) - \sigma_n(x)| \leq C \frac{|y|^\alpha}{|x|^{1+\alpha}} \quad \text{for all } x, y \in \mathbb{Z}$$

such that $0 < 2|y| \leq |x|$

Then there is a constant D such that

$$\mu\{Mf > \lambda\} \leq \frac{D}{\lambda} \|f\|_1 \quad \text{for all } T, \quad f \in L_1(\mu)$$

and $\lambda > 0$.

Ergodic Theorems and Multiple Recurrence

Suppose $S \subset \mathbb{N}$. The *upper density* of S is

$$\bar{d}(S) = \limsup_n \frac{|S \cap [1, n]|}{n}. \quad (33)$$

and the *density* $d(S)$ is the limit of the same quantity, if it exists. In 1975 Szemerédi [190] proved the following celebrated theorem, answering an old question of Erdős and Turán.

Theorem 38 *Any subset of \mathbb{N} with positive upper density contains an arithmetic progression of length k for each $k \geq 1$.*

This result has a distinctly ergodic-theoretic flavor. Letting T denote the shift map on \mathbb{Z} , it says that for each k there

is an n such that $S' = \bigcap_{i=1}^k T^{-in} S$ is non-empty. In fact the result gives more: there is an n for which $\bar{d}(S') > 0$. In this light Szemerédi's theorem becomes a multiple recurrence theorem for the shift map on \mathbb{N} , equipped with the invariant “measure-like” quantity \bar{d} . Of course \bar{d} is not even finitely additive so it is *not* a measure. d , however, is at least finitely additive, when defined, and $d(\mathbb{N}) = 1$.

This point of view suggests the following multiple recurrence theorem.

Theorem 39 *Suppose T is an automorphism of a probability space (X, \mathcal{B}, μ) , $\mu(B) > 0$ and $k \geq 1$. Then there is an $n > 0$ such that $\mu(\bigcap_{i=1}^k T^{in} B) > 0$.*

In 1977, Furstenberg [85] proved the following ergodic theorem which implies the multiple recurrence theorem. He also established a general *correspondence principle* which puts the shaky analogy between the multiple recurrence theorem and Szemerédi's theorem on a firm footing and allows each to be deduced from the other. Thus he obtained an ergodic theoretic proof of Szemerédi's combinatorial result.

Theorem 40 *Suppose T is an automorphism of a probability space (X, \mathcal{B}, μ) , $f \in L_\infty$, $f \geq 0$, $\int f d\mu > 0$ and $k \geq 1$. Then*

$$\liminf_N \frac{1}{N} \sum_{n=0}^{N-1} \int \prod_{i=1}^k T^{in} f d\mu > 0. \tag{34}$$

Furstenberg's result opened the door to the study of so-called ergodic Ramsey theory which has yielded a vast array of deep results in combinatorics, many of which have no non-ergodic proof as yet. The focus of this article is not on this direction but the reader is referred to Furstenberg's book [86] for an excellent introduction and to Bergelson [27,28] for surveys of later developments. There is also the article by Frantzikinakis and McCutcheon in this collection.

Furstenberg's proof relies on a deep structure theorem for a general automorphism which was also developed independently by Zimmer [213], [212] in a more general context. A *factor* of T is any sub- σ -algebra $\mathcal{F} \subset \mathcal{B}$ such that $T(\mathcal{F}) = \mathcal{F}$. (It is more accurate to think of the factor as the action of T on the measure space $(X, \mathcal{F}, \mu|_{\mathcal{F}})$.) The structure theorem asserts that there is a transfinite increasing sequence of factors $\{\mathcal{F}_\alpha\}$ of T such that the following conditions hold.

- (a) $\mathcal{F}_{\alpha+1}$ is compact relative to \mathcal{F}_α .
- (b) $\mathcal{F}_\alpha = \bigvee_{\beta < \alpha} \mathcal{F}_\beta$ whenever α is a limit ordinal.
- (c) \mathcal{B} is weakly mixing relative to $\bigvee \mathcal{F}_\alpha$.

(\bigvee denotes the σ -algebra generated by a collection of σ -algebras.) $\bigvee_\alpha \mathcal{F}_\alpha$ is called the *maximal distal factor* of T and if $\bigvee \mathcal{F}_\alpha = \mathcal{B}$ then T is called *distal*. The definitions of the relative properties in (a) and (c) above are somewhat technical so only their absolute versions (i. e. relative to the trivial σ -algebra $\{\emptyset, X\}$) will be described here.

T is said to be compact if for each $f \in L_2$ the orbit $\{T^i f : i \in \mathbb{Z}\}$ is pre-compact in the norm topology of L_2 . This turns out to be equivalent to the statement that T is a translation on a compact Abelian group endowed with its Haar measure. The property of weak mixing is a fundamental notion in ergodic theory which has many equivalent definitions. The most appropriate for our purposes is that T is weakly mixing if it has no compact factors. This turns out to be equivalent to the ergodicity of $T \times T$ acting on the product measure space $(X, \mathcal{B}, \mu) \times (X, \mathcal{B}, \mu)$.

The verification of 37 in the case of compact T is rather easy. In this case it is not hard to prove that for any $f \in L_\infty$ and $\epsilon > 0$ the set $\{n \in \mathbb{Z} : \|T^n f - f\|_2 < \epsilon\}$ has bounded gaps and (34) follows easily. In the case when T is weakly mixing (34) is a consequence of the following theorem which Furstenberg proves in [85] (as a warm-up for its much harder relative version).

Theorem 41 *If T is weakly mixing and f_1, f_2, \dots, f_k are L_∞ functions then*

$$\lim_N \frac{1}{N} \sum_{n=0}^{N-1} \int \prod_{i=1}^k T^{in} f_i d\mu = \prod_{i=1}^k \int f_i \tag{35}$$

Later Bergelson [26] showed that the result can be obtained easily by an induction argument using the following Hilbert space generalization of van der Corput's lemma.

Theorem 42 (Bergelson) *Suppose $\{x_n\}$ is a bounded sequence of vectors in Hilbert space such that for each $h > 0$ one has $\frac{1}{N} \sum_{n=0}^{N-1} \langle x_{n+h}, x_n \rangle \rightarrow 0$ as $N \rightarrow \infty$. Then $\|\frac{1}{N} \sum_{n=0}^{N-1} x_n\| \rightarrow 0$.*

Ryzhikov has also given a beautiful short proof of Theorem 41 using joinings ([182]). Bergelson's van der Corput lemma and variants of it have been a key tool in subsequent developments in ergodic Ramsey theory and in the convergence results to be discussed in this section. Bergelson [26] used it to prove the following mean ergodic theorem for weakly mixing automorphisms.

Theorem 43 *Suppose T is weakly mixing, f_1, \dots, f_k are L_∞ functions and p_1, \dots, p_k are polynomials with rational coefficients taking integer values on the integers such that no*

$p_i - p_j$ is constant for $i \neq j$. Then

$$\lim_{N \rightarrow \infty} \left\| \frac{1}{N} \sum_{n=0}^{N-1} \prod_{i=1}^k T^{p_i(n)} f_i - \prod_{i=1}^k \int f_i d\mu \right\| = 0. \quad (36)$$

Theorems 40 and 41 immediately raise the question of convergence of the multiple averages $\frac{1}{N} \sum_{n=0}^{N-1} \prod_{i=1}^k T^{in} f_i$ for a general T . Several authors obtained partial results on the question of mean convergence. It was finally resolved only recently by Host and Kra [104], who proved the following landmark theorem.

Theorem 44 *Suppose $f_1, f_2, \dots, f_k \in L_\infty$. Then there is a $g \in L_\infty$ such that*

$$\lim \left\| \frac{1}{N} \sum_{n=0}^{N-1} \prod_{i=1}^k T^{in} f_i - g \right\|_2 = 0. \quad (37)$$

Independently and somewhat later Ziegler [211] obtained the same result by somewhat different methods. Furstenberg had already established Theorem 44 for $k = 2$ in [85]. It was proved for $k = 3$ in the case of a totally ergodic T by Conze and Lesigne [63] and in general by Host and Kra [102]. It can also be obtained using the methods developed by Furstenberg and Weiss [88]. In this paper Furstenberg and Weiss proved a result for polynomial powers of T in the case $k = 2$. They also formalized the key notion of a *characteristic factor*. A factor C of T is said to be characteristic for the averages (37) if, roughly speaking, the L_2 limiting behavior of the averages is unchanged when any one of the f_i 's is replaced by its conditional expectation on C . This means that the question of convergence of these averages may be reduced to the case when f_i are all C -measurable. So the problem is to find the right (smallest) characteristic factor and prove convergence for that factor.

The importance of characteristic factors was already apparent in Furstenberg's original paper [85], where he showed that the maximal distal factor is characteristic for the averages (37). In fact he showed that for a given k a k -step distal factor is characteristic. (An automorphism is k -step distal if it is the top rung in a k -step ladder of factors as in the Furstenberg–Zimmer structure-theorem.) It turns out, though, that the right characteristic factor for (37) is considerably smaller. In their seminal paper [63] Conze and Lesigne identified the characteristic factor for $k = 3$, now called the Conze–Lesigne factor. As shown in [104], and [211], the characteristic factor for a general k is (isomorphic to) an inverse limit of k -step nilflows. A k -step nilflow is a compact homogeneous space N/Γ of a k -step nilpotent Lie group N , endowed with its

unique left-invariant probability measure, on which T acts via left translation by an element of N . Ergodic properties of nilflows have been studied for some time in ergodic theory, for example in Parry [166]. In this way the problem of L_2 -convergence of (37) is reduced to the case when T is a nilflow. In this case one has more: the averages converge pointwise by a result of Leibman [141] (See also Ziegler [210]).

There have already been a good many generalizations of (37). Host and Kra [103], Frantzikinakis and Kra [82, 83], and Leibman [141] have proved results which replace linear powers of T by polynomial powers. In increasing degrees of generality Conze and Lesigne [63], Frantzikinakis and Kra [81] and Tao [192] have obtained results which replace the maps T, T^2, \dots, T^k in (37) by commuting maps T_1, \dots, T_k . Bergelson and Leibman [30,31] have obtained results, both positive and negative, in the case of two non-commuting maps.

In the direction of pointwise convergence the only general result is the following theorem of Bourgain [48] which asserts pointwise convergence in the case $k = 2$.

Theorem 45 *Suppose S and T are powers of a single automorphism R and $f, g \in L_\infty$. Then $\frac{1}{N} \sum_{n=1}^N f(T^n x)g(S^n x)$ converges a.e.*

When T is a K -automorphism Derrien and Lesigne [68] have proved that the averages (35) converge pointwise to the product of the integrals, even with polynomial powers of T replacing the linear powers.

Gowers [91] has given a new proof of Szemerédi's theorem by purely finite methods using only harmonic analysis on \mathbb{Z}_n . His results give better quantitative estimates in the statement of finite versions of Szemerédi's theorem. Although his proof contains no ergodic theory it is to some extent guided by Furstenberg's approach.

This section would be incomplete without mentioning the spectacular recent result of Green and Tao [92] on primes in arithmetic progression and the subsequent extensions of the Green–Tao theorem due to Tao [191] and Tao and Ziegler [193].

Rates of Convergence

There are many results which say in various ways that, in general, there are no estimates for the rate of convergence of the averages $A_n f$ in Birkhoff's theorem. For example there is the following result of Krengel [134].

Theorem 46 *Suppose $\lim_{n \rightarrow \infty} c_n = \infty$ and T is any ergodic automorphism of a probability space. Then there is a bounded measurable f with $\int f d\mu = 0$ such that $\limsup c_n A_n f = \infty$ a.e.*

See Part I of Derriennic [69] for a selection of other results in this direction. In spite of these negative results one can obtain quantitative estimates by reformulating the ergodic theorem in various ways. Bishop [37] proved the following result which is purely finite and constructive in nature and evidently implies the a.e. convergence in Birkhoff's theorem. If $y = (y_1, \dots, y_n)$ is a finite sequence of real numbers and $a < b$, an *upcrossing* of y over $[a, b]$ is a minimal integer interval $[k, l] \subset [1, n]$ satisfying $y_k < a$ and $y_l > b$.

Theorem 47 *Suppose T is an automorphism of the probability space (X, \mathcal{B}, μ) . Let $U(n, a, b, f, x)$ be the number of upcrossings of the sequence $A_0 f(x), \dots, A_n f(x)$ over $[a, b]$. Then for every n*

$$\mu\{x : U(n, a, b, f, x) > k\} \leq \frac{\|f\|_1}{(b - a)k}. \tag{38}$$

Ivanov [107] has obtained the following stronger upcrossing inequality for an arbitrary *positive* measurable f , which also implies Birkhoff's theorem.

Theorem 48 *For any positive measurable f and $0 < a < b$*

$$\mu\{x : U(n, a, b, f, x) > k\} \leq \left(\frac{a}{b}\right)^k. \tag{39}$$

Note the exponential decay and the remarkable fact that the estimate does not depend on f . Ivanov has also obtained the following result (Theorem 23 in [121]) about *fluctuations* of $A_n f$. An ϵ -*fluctuation* of a real sequence $y = (y_1 \dots y_n)$ is a minimal integer interval $[k, l]$ satisfying $|y_k - y_l| \geq \epsilon$. If $f \in L_1(\mathbb{R})$ let $F(\epsilon, f, x)$ be the number of ϵ -fluctuations of the sequence $\{A_n f(x)\}_{n=0}^\infty$.

Theorem 49

$$\mu\{x : F(\epsilon, f, x) \geq k\} \leq C \frac{(\log k)^{\frac{1}{2}}}{k} \tag{40}$$

where C is a constant depending only on $\|f\|_1/\epsilon$. If $f \in L_\infty$ then

$$\mu\{x : F(\epsilon, f, x) \geq k\} \leq Ae^{-Bk}, \tag{41}$$

where A and B are constants depending only on $\|f\|_\infty/\epsilon$.

See Kachurovskii's survey [121] of results on rates of convergence in the ergodic theorem and also the article of Jones et al. [115] for more results on oscillation type inequalities.

Under special assumptions on f and T it is possible to give more precise results on speed of convergence. If the

sequence $T^i f$ is independent then there is a vast literature in probability theory giving very precise results, for example the central limit theorem and the law of the iterated logarithm (see, for example, [50]). See the surveys of Derriennic [69] (2006) and of Merlevède, Peligrad and Utev [150] for results on the central limit theorem for dynamical systems.

Ergodic Theorems for Non-amenable Groups

Guivarch [95] was the first to prove an ergodic theorem for a general pair of non-commuting unitary operators. Much work has been done in the last 15 years on mean and pointwise theorems for non-amenable groups. See the extensive survey by Nevo [155]. Here is just one result of Nevo [154] as a sample. Suppose G is a discrete group and $\{\sigma_n\}$ is a sequence of probability measures on G . Say that $\{\sigma_n\}$ is *mean ergodic* if for any unitary representation π of G on a Hilbert space \mathcal{H} and any $x \in \mathcal{H}$ one has $\sum_{g \in G} \sigma_n(g) \pi(g)x$ converges in norm to the projection of x on the subspace of π -invariant vectors. Say that $\{\sigma_n\}$ is *pointwise ergodic* if for any measure preserving action T of G on a probability space and $f \in L_2$ one has $\sum_{g \in G} \sigma_n(g) T_g f$ converges a.e. to the projection of f on the subspace of T -invariant functions.

Theorem 50 *Let G be the free group on k generators, $k \geq 1$. Let τ_n be the normalized counting measure on the set of elements whose word length (in terms of the generators and their inverses) is n . Let $\sigma_n = (\tau_n + \tau_{n+1})/2$ and $\sigma'_n = \frac{1}{n} \sum_{i=1}^n \sigma_i$. Then σ_n and σ'_n are mean and pointwise ergodic but τ_n is not mean ergodic.*

Future Directions

This section will be devoted to a few open problems and some questions. Many of these have been suggested by my colleagues acknowledged in the introduction.

The topic of convergence of Furstenberg's multiple averages has seen some remarkable achievements in the last few years and will likely continue to be vital for some time to come. The question of pointwise convergence of multiple averages is completely open, beyond Bourgain's result (Theorem 45). Even extending Bourgain's result to three different powers of R or to any two commuting automorphisms S and T would be a very significant achievement. Another natural question is whether one has pointwise convergence of the averages of the sequence $f(T^n(x))g(T^{n^2}(x))$, which are mean convergent by the result of Furstenberg and Weiss [88] (which is now subsumed in much more general results).

A long-standing open problem relating to Akcoglu's ergodic theorem (Theorem 23) for positive contractions of L_p is whether it can be extended to power-bounded operators T (this means that $\|T\|^n$ is bounded). It is also an open question whether it extends to non-positive contractions, excepting the case $p = 2$ where Burkholder [52] has shown that it fails.

There are many natural questions in the area of subsequence and weighted ergodic theorems. For example, which of Bourgain's several pointwise theorems can be extended to L_1 ? Are there other natural subsequences of an arithmetic character which have density 0 and for which an ergodic theorem is valid, either mean or pointwise, and in what L_p spaces might such theorems be valid? Are there higher dimensional analogues?

Since lacunary sequences are bad, to have any sort of pointwise theorem $l_n = \log \frac{a_n}{a_{n+1}}$ must get close to 0 and for simplicity let us assume that $\lim l_n = 0$. How fast must the convergence be in order to get an ergodic theorem? Jones and Wierdl [113] have shown that if $l_n > (\log n)^{-\frac{1}{2} + \epsilon}$ then the pointwise ergodic theorem fails in L_2 while Jones, Lacey and Wierdl [116] have shown that an only slightly faster rate permits a sequence which is pointwise good in L_2 . How well or badly does the ergodic theorem succeed or fail depending on the rate of convergence of l_n ? In particular is there a (slow) rate which still guarantees strong sweeping out? [116] contains some interesting conjectures in this direction.

There are also interesting questions concerning the mean and pointwise ergodic theorems for subsequences which are chosen randomly in some sense. See Bourgain [42] and [116] for some results in this direction. Again [116] contains some interesting conjectures along these lines.

In a recent paper [32] Bergelson and Leibman prove some very interesting and surprising results about the distribution of *generalized polynomials*. A generalized polynomial is any function which can be built starting with polynomials in $\mathbb{R}[x]$ using the operations of addition, multiplication and taking the greatest integer. As a consequence they derive a generalization of von Neumann's mean ergodic theorem to averages along generalized polynomial sequences. The following is a special case.

Theorem 51 *Suppose p is a generalized polynomial taking integer values on the integers and U is a unitary operator on \mathcal{H} . Then $\frac{1}{n} \sum_{i=0}^{n-1} U^{p(i)} x$ is norm convergent for all $x \in \mathcal{H}$.*

This begs the question: does one have pointwise convergence? If so, this would be a far-reaching generalization of Bourgain's polynomial ergodic theorem.

There are also lots of questions concerning the nature of Følner sequences $\{F_n\}$ in an amenable group which give a pointwise theorem. For example Lindenstrauss [145] has shown that in the *lamplighter* group, a semi-direct product of \mathbb{Z} with $\bigoplus_{i \in \mathbb{Z}} \mathbb{Z}/2\mathbb{Z}$ on which Z acts by the shift, there is no sequence satisfying Tempelman's condition and that any $\{F_n\}$ satisfying the Shulman condition must grow super-exponentially. So, it is natural to ask for slower rates of growth. In particular, in any amenable group is there always a sequence $\{F_n\}$ which is pointwise good and grows at most exponentially? Can one do better either in general or in particular groups?

Lindenstrauss's theorem at least guarantees the existence of Følner sequences which are pointwise good in L_1 but in particular groups there are often natural sequences which one hopes might be good. For example in $\bigoplus_{i=1}^{\infty} \mathbb{Z}$ one may take F_n to be a cube based at 0 of sidelength l_n and dimension d_n (that is, all but the first d_n co-ordinates are zero), where both sequences increase to ∞ . What conditions on l_n and d_n will give a good sequence? Note that no such sequence is regular in Tempelman's sense. If $d_n = n$ then $\{l_n\}$ must be superexponential to ensure Shulman's condition. Can one do better? What about $l_n = d_n = n$?

- A transformation T of a measure space (X, \mathcal{B}, μ) is *measure-preserving* if $\mu(T^{-1}A) = \mu(A)$ for all measurable $A \in \mathcal{B}$.
- A measure-preserving transformation (X, \mathcal{B}, μ, T) is *ergodic* if $T^{-1}(A) = A \pmod{\mu}$ implies $\mu(A) = 0$ or $\mu(A^c) = 0$ for each measurable set $A \in \mathcal{B}$.
- A measure-preserving transformation (X, \mathcal{B}, μ, T) of a probability space is *weak-mixing* if $\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{i=0}^{n-1} |\mu(T^{-i}A \cap B) - \mu(A)\mu(B)| = 0$ for all measurable sets $A, B \in \mathcal{B}$.
A measure-preserving transformation (X, \mathcal{B}, μ, T) of a probability space is *strong-mixing* if $\lim_{n \rightarrow \infty} \mu(T^{-n}A \cap B) = \mu(A)\mu(B)$ for all measurable sets $A, B \in \mathcal{B}$.
- A continuous transformation T of a compact metric space X is *uniquely ergodic* if there is only one T -invariant Borel probability measure on X . A continuous transformation of a topological space X is *topologically mixing* for any two open sets $U, V \subset X$ there exists $N > 0$ such that $T^{-n}(U) \cap V \neq \emptyset$, for each $n \geq N$.
- Suppose (X, \mathcal{B}, μ) is a probability space. A *finite partition* \mathcal{P} of X is a finite collection of disjoint $(\text{mod } \mu, \text{ i. e., up to sets of measure } 0)$ measurable sets $\{P_1, \dots, P_n\}$ such that $X = \cup P_i \pmod{\mu}$. The *entropy* of \mathcal{P} with respect to μ is $H(\mathcal{P}) = -\sum_i \mu(P_i) \ln \mu(P_i)$ (other bases are sometimes used for the logarithm).
- The *metric (or measure-theoretic) entropy* of T with respect to \mathcal{P} is $h_\mu(T, \mathcal{P}) = \lim_{n \rightarrow \infty} \frac{1}{n} H(\mathcal{P} \vee \dots \vee T^{-n+1}(\mathcal{P}))$, where $\mathcal{P} \vee \dots \vee T^{-n+1}(\mathcal{P})$ is the partition of X into sets of points with the same coding with respect to \mathcal{P} under T^i , $i = 0, \dots, n-1$. That is x, y are in the same set of the partition $\mathcal{P} \vee \dots \vee T^{-n+1}(\mathcal{P})$ if and only if $T^i(x)$ and $T^i(y)$ lie in the same set of the partition \mathcal{P} for $i = 0, \dots, n-1$.
- The *metric entropy* $h_\mu(T)$ of (X, \mathcal{B}, μ, T) is the supremum of $h_\mu(T, \mathcal{P})$ over all finite measurable partitions \mathcal{P} .
- If T is a continuous transformation of a compact metric space X , then the *topological entropy* of T is the supremum of the metric entropies $h_\mu(T)$, where the supremum is taken over all T -invariant Borel probability measures.
- A system (X, \mathcal{B}, μ, T) is *loosely Bernoulli* if it is isomorphic to the first-return system to a subset of positive measure of an irrational rotation or a (positive or infinite entropy) Bernoulli system.

- Two systems are *spectrally isomorphic* if the unitary operators that they induce on their L^2 spaces are unitarily equivalent.
- A *smooth dynamical system* consists of a differentiable manifold M and a differentiable map $f: M \rightarrow M$. The degree of differentiability may be specified.
- Two submanifolds S_1, S_2 of a manifold M *intersect transversely* at $p \in M$ if $T_p(S_1) + T_p(S_2) = T_p(M)$.
- An $(\epsilon-)$ small C^r *perturbation* of a C^r map f of a manifold M is a map g such that $d_{C^r}(f, g) < \epsilon$ i.e. the distance between f and g is less than ϵ in the C^r topology.
- A map T of an interval $I = [a, b]$ is *piecewise smooth* (C^k for $k \geq 1$) if there is a finite set of points $a = x_1 < x_2 < \dots < x_n = b$ such that $T|_{(x_i, x_{i+1})}$ is C^k for each i . The degree of differentiability may be specified.
- A measure μ on a measure space (X, \mathcal{B}) is *absolutely continuous* with respect to a measure ν on (X, \mathcal{B}) if $\nu(A) = 0$ implies $\mu(A) = 0$ for all measurable $A \in \mathcal{B}$.
- A Borel measure μ on a Riemannian manifold M is *absolutely continuous* if it is absolutely continuous with respect to the Riemannian volume on M .
- A measure μ on a measure space (X, \mathcal{B}) is *equivalent* to a measure ν on (X, \mathcal{B}) if μ is absolutely continuous with respect to ν and ν is absolutely continuous with respect to μ .

Definition of the Subject

Measure-preserving systems are a common model of processes which evolve in time and for which the rules governing the time evolution don't change. For example, in Newtonian mechanics the planets in a solar system undergo motion according to Newton's laws of motion: the planets move but the underlying rule governing the planets' motion remains constant. The model adopted here is to consider the time-evolution as a transformation (either a map in discrete time or a flow in continuous time) on a probability space or more generally a measure space. This is the setting of the subject called ergodic theory. Applications of this point of view include the areas of statistical physics, classical mechanics, number theory, population dynamics, statistics, information theory and economics. The purpose of this chapter is to present a flavor of the diverse range of examples of measure-preserving transformations which have played a role in the development and application of ergodic theory and smooth dynamical systems theory. We also present common constructions involving measure-preserving systems. Such constructions may be considered a way of putting 'building-block' dynamical systems to-

gether to construct examples or decomposing a complicated system into simple 'building-blocks' to understand it better.

Introduction

In this chapter we collect a brief list of some important examples of measure-preserving dynamical systems, which we denote typically by (X, \mathcal{B}, μ, T) or (T, X, \mathcal{B}, μ) or slight variations. These examples have played a formative role in the development of dynamical systems theory, either because they occur often in applications in one guise or another or because they have been useful simple models to understand certain features of dynamical systems. There is a fundamental difference in the dynamical properties of those systems which display hyperbolicity: roughly speaking there is some exponential divergence of nearby orbits under iteration of the transformation. In differentiable systems this is associated with the derivative of the transformation possessing eigenvalues of modulus greater than one on a 'dynamically significant' subset of phase space. Hyperbolicity leads to complex dynamical behavior such as positive topological entropy, exponential divergence of nearby orbits ("sensitivity to initial conditions") often coexisting with a dense set of periodic orbits. If ϕ, ψ are sufficiently regular functions on the phase space X of a hyperbolic measure-preserving transformation (T, X, μ) , then typically we have fast decay of correlations in the sense that

$$\left| \int_X \phi(T^n x) \psi(x) d\mu - \int \phi d\mu \int \psi d\mu \right| \leq Ca(n)$$

where $a(n) \rightarrow 0$. If $a(n) \rightarrow 0$ at an exponential rate we say that the system has exponential decay of correlations. A theme in dynamical systems is that the time series formed by sufficiently regular observations on systems with some degree of hyperbolicity often behave statistically like independent identically distributed random variables.

At this point it is appropriate to point out two pervasive differences between the usual probabilistic setting of a stationary stochastic process $\{X_n\}$ and the (smooth) dynamical systems setting of a time series of observations on a measure-preserving system $\{\phi \circ T^n\}$. The most crucial is that for deterministic dynamical systems the time series is usually not an independent process, which is a common assumption in the strictly probabilistic setting. Even if some weak-mixing is assumed in the probabilistic setting it is usually a mixing condition on the σ -algebras $\mathcal{F}_n = \sigma(X_1, \dots, X_n)$ generated by successive random variables, a condition which is not natural (and usually very difficult to check) for dynamical systems. Mix-

ing conditions on dynamical systems are given more naturally in terms of the mixing of the sets of the σ -algebra \mathcal{B} of the probability space (X, \mathcal{B}, μ) under the action of T and not by mixing properties of the σ -algebras generated by the random variables $\{\phi \circ T^n\}$. The other difference is that in the probabilistic setting, although $\{X_n\}$ satisfy moment conditions, usually no regularity properties, such as the Hölder property or smoothness, are assumed. In contrast in dynamical systems theory the transformation T is often a smooth or piecewise smooth transformation of a Riemannian manifold X and the observation $\phi: X \rightarrow \mathbb{R}$ is often assumed continuous or Hölder. The regularity of the observation ϕ turns out to play a crucial role in proving properties such as rates of decay of correlation, central limit theorems and so on.

An example of a hyperbolic transformation is an expanding map of the unit interval $T(x) = (2x)$ (where (x) is x modulo the integers). Here the derivative has modulus 2 at all points in phase space. This map preserves Lebesgue measure, has positive topological entropy, Lebesgue almost every point x has a dense orbit and periodic points for the map are dense in $[0, 1)$.

Non-hyperbolic systems are of course also an important class of examples, and in contrast to hyperbolic systems they tend to model systems of ‘low complexity’, for example systems displaying quasiperiodic behavior. The simplest non-trivial example is perhaps an irrational rotation of the unit interval $[0, 1)$ given by a map $T(x) = (x + \alpha)$, $\alpha \in \mathbb{R} \setminus \mathbb{Q}$. T preserves Lebesgue measure, every point has a dense orbit (there are no periodic orbits), yet the topological entropy is zero and nearby points stay the same distance from each other under iteration under T .

There is a natural notion of equivalence for measure-preserving systems. We say that measure-preserving systems (T, X, \mathcal{B}, μ) and (S, Y, \mathcal{C}, ν) are *isomorphic* if (possibly after deleting sets of measure 0 from X and Y) there is a one-to-one onto measurable map $\phi: X \rightarrow Y$ with measurable inverse ϕ^{-1} such that $\phi \circ T = S \circ \phi$ μ a.e. and $\mu(\phi^{-1}(A)) = \nu(A)$ for all $A \in \mathcal{C}$. If X, Y are compact topological spaces we say that T is *topologically conjugate* to S if there exists a homeomorphism $\phi: X \rightarrow Y$ such that $\phi \circ T = S \circ \phi$. In this case we call ϕ a *conjugacy*. If ϕ is C^r for some $r \geq 1$ we will call ϕ a *C^r -conjugacy* and similarly for other degrees of regularity.

We will consider $X = [0, 1)(\text{mod } 1)$ as a representation of the unit circle $S^1 = \{z \in \mathbb{C} : |z| = 1\}$ (under the map $x \rightarrow e^{2\pi ix}$) and similarly represent the k -dimensional torus $T^k = S^1 \times \dots \times S^1$ (k -times). If the σ -algebra is clear from the context we will write (T, X, μ) instead of (T, X, \mathcal{B}, μ) when denoting a measure-preserving system.

Examples

Rigid Rotation of a Compact Group

If G is a compact group equipped with Haar measure and $a \in G$, then the transformation $T(x) = ax$ preserves Haar measure and is called a *rigid rotation* of G . If G is abelian and the transformation is ergodic (in this setting transitivity implies ergodicity), then the transformation is uniquely ergodic. Such systems always have zero topological entropy.

The simplest example of such a system is a circle rotation. Take $X = [0, 1)(\text{mod } 1)$, with

$$T(x) = (x + \alpha) \quad \text{where } \alpha \in \mathbb{R}.$$

Then T preserves Lebesgue (Haar) measure and is ergodic (in fact uniquely ergodic) if and only if α is irrational. Similarly, the map

$$T(x_1, \dots, x_k) = (x_1 + \alpha_1, \dots, x_k + \alpha_k),$$

where $\alpha_1, \dots, \alpha_k \in \mathbb{R}$,

preserves k -dimensional Lebesgue (Haar) measure and is ergodic (uniquely ergodic) if and only if there are no integers m_1, \dots, m_k , not all 0, which satisfy $m_1\alpha_1 + \dots + m_k\alpha_k \in \mathbb{Z}$.

Adding Machines

Let $\{k_i\}_{i \in \mathbb{N}}$ be a sequence of integers with $k_i \geq 2$. Equip each cyclic group \mathbb{Z}_{k_i} with the discrete topology and form the product space $\Sigma = \prod_{i=1}^{\infty} \mathbb{Z}_{k_i}$ equipped with the product topology. An *adding machine* corresponding to the sequence $\{k_i\}_{i \in \mathbb{N}}$ is the topological space $\Sigma = \prod_{i=1}^{\infty} \mathbb{Z}_{k_i}$ together with the map

$$\sigma: \Sigma \rightarrow \Sigma$$

defined by

$$\sigma(k_1 - 1, k_2 - 1, \dots) = (0, 0, \dots)$$

if each entry in the \mathbb{Z}_{k_i} component is $k_i - 1$,

while

$$\sigma(k_1 - 1, k_2 - 1, \dots, k_n - 1, x_1, x_2, \dots) = (0, 0, \dots, 0, \underbrace{x_1 + 1, x_2, x_3, \dots}_{n \text{ times}})$$

when $x_1 \neq k_{n+1} - 1$.

The map σ may be thought of as ‘add one and carry’ and also as mapping each point to its successor in a certain order. See Sect. ‘[Adic Transformations](#)’ for generalizations. If each $k_i = 2$ then the system is called the *dyadic*

(or von Neumann-Kakutani) adding machine or 2-odometer. Adding machines give examples of naturally occurring minimal systems of low orbit complexity in the sense that the topological entropy of an adding machine is zero. In fact if f is a continuous map of an interval with zero topological entropy and S is a closed, topologically transitive invariant set without periodic orbits, then the restriction of f to S is topologically conjugate to the dyadic adding machine (Theorem 11.3.13 in [46]).

We say a non-empty set Λ is an attractor for a map T if there is an open set U containing Λ such that $\Lambda = \bigcap_{n \geq 0} T^n(U)$ (other definitions are found in the literature). The dyadic adding machine is topologically conjugate to the Feigenbaum attractor at the limit point of period doubling bifurcations (see Sect. “Unimodal Maps”). Furthermore, attractors for continuous unimodal maps of the interval are either periodic orbits, transitive cycles of intervals, or Cantor sets on which the dynamics is topologically conjugate to an adding machine [32].

Interval Exchange Maps

A map $T: [0, 1] \rightarrow [0, 1]$ is an interval exchange transformation if it is defined in the following way. Suppose that π is a permutation of $\{1, \dots, n\}$ and $l_i > 0, i = 1, \dots, n$, is a sequence of subintervals of I (open or closed) with $\sum_i l_i = 1$. Define t_i by $l_i = t_i - t_{i-1}$ with $t_0 = 0$. Suppose also that σ is an n -vector with entries ± 1 . T is defined by sending the interval $t_{i-1} \leq x < t_i$ of length l_i to the interval

$$\sum_{\pi(j) < \pi(i)} l_{\pi(j)} \leq x < \sum_{\pi(j) > \pi(i)} l_{\pi(j)}$$

with orientation preserved if the i th entry of σ is $+1$ and orientation reversed if the i th entry of σ is -1 . Thus on each interval l_i , T has the form $T(x) = \sigma_i x + a_i$, where σ_i is ± 1 . If $\sigma_i = 1$ for each i , the transformation is called orientation preserving.

The transformation T has finitely many discontinuities (at the endpoints of each l_i), and modulo this set of discontinuities is smooth. T is also invertible (neglecting the finite set of discontinuities) and preserves Lebesgue measure. These maps have zero topological entropy and arise naturally in studies of polygonal billiards and more generally area-preserving flows. There are examples of minimal but non-ergodic interval exchange maps [56,69].

Full Shifts and Shifts of Finite Type

Given a finite set (or alphabet) $A = \{0, \dots, d - 1\}$, take $X = \Omega^+(A) = A^{\mathbb{N}}$ (or $X = A^{\mathbb{Z}}$) the sets of one-sided

(two-sided) sequences, respectively, with entries from A . For example sequences in $A^{\mathbb{N}}$ have the form $x = \cdot x_0 x_1 \dots x_n \dots$. A cylinder set $C(y_{n_1}, \dots, y_{n_k}), y_{n_i} \in A$, of length k is a subset of X defined by fixing k entries; for example,

$$C(y_{n_1}, \dots, y_{n_k}) = \{x: x_{n_1} = y_{n_1}, \dots, x_{n_k} = y_{n_k}\}.$$

We define the set A^k to consist of all cylinders $C(y_1, \dots, y_k)$ determined by fixing the first k entries, i. e. an element of A^k is specified by fixing the first k entries of a sequence $\cdot x_0 \dots x_k$ by requiring $x_i = y_i, i = 0, \dots, k$.

Let $p = (p_0, \dots, p_{d-1})$ be a probability vector: all $p_i \geq 0$ and $\sum_{i=0}^{d-1} p_i = 1$. For any cylinder $B = C(b_1, \dots, b_k) \in A^k$, define

$$g_k(B) = p_{b_1} \dots p_{b_k}. \tag{1}$$

It can be shown that these functions on A^k extend to a shift-invariant measure μ_p on $A^{\mathbb{N}}$ (or $A^{\mathbb{Z}}$) called product measure. (See the article on [Measure Preserving Systems](#).) The space $A^{\mathbb{N}}$ or $A^{\mathbb{Z}}$ may be given a metric by defining

$$d(x, y) = \begin{cases} 1 & \text{if } x_0 \neq y_0; \\ \frac{1}{2^{|n|}} & \text{if } x_n \neq y_n \text{ and } x_i = y_i \text{ for } |i| < n. \end{cases}$$

The shift $\sigma(\cdot x_0 x_1 \dots x_n \dots) = \cdot x_1 x_2 \dots x_n \dots$ is ergodic with respect to μ_p . The measure-preserving system $(\Omega, \mathcal{B}, \mu, \sigma)$ (with \mathcal{B} the σ -algebra of Borel subsets of $\Omega(A)$, or its completion), is denoted by $\mathcal{B}(p)$ and is called the Bernoulli shift determined by p . This system models an infinite number of independent repetitions of an experiment with finitely many outcomes, the i th of which has probability p_i on each trial.

These systems are mixing of all orders (i. e. σ^n is mixing for all $n \geq 1$) and have countable Lebesgue spectrum (hence are all spectrally isomorphic). Kolmogorov and Sinai showed that two of them cannot be isomorphic unless they have the same entropy; Ornstein [81] showed the converse. $\mathcal{B}(1/2, 1/2)$ is isomorphic to the Lebesgue-measure-preserving transformation $x \rightarrow 2x \pmod 1$ on $[0, 1]$; similarly, $\mathcal{B}(1/3, 1/3, 1/3)$ is isomorphic to $x \rightarrow 3x \pmod 1$. Furstenberg asked whether the only nonatomic measure invariant for both $x \rightarrow 2x \pmod 1$ and $x \rightarrow 3x \pmod 1$ on $[0, 1]$ is Lebesgue measure. Lyons [68] showed that if one of the actions is K , then the measure must be Lebesgue, and Rudolph [100] showed the same thing under the weaker hypothesis that one of the actions has positive entropy. For further work on this question, see [50,87].

This construction can be generalized to model one-step finite-state Markov stochastic processes as dynamical systems. Again let $A = \{0, \dots, d-1\}$, and let $p = (p_0, \dots,$

p_{d-1}) be a probability vector. Let P be a $d \times d$ stochastic matrix with rows and columns indexed by A . This means that all entries of P are nonnegative, and the sum of the entries in each row is 1. We regard P as giving the transition probabilities between pairs of elements of A . Now we define for any cylinder $B = C(b_1, \dots, b_k) \in A^k$

$$\mu_{p,P}(B) = p_{b_1} P_{b_1 b_2} P_{b_2 b_3} \dots P_{b_{k-1} b_k} . \tag{2}$$

It can be shown that $\mu_{p,P}$ extends to a measure on the Borel σ -algebra of $\Omega^+(A)$, and its completion. (See the article on [► Measure Preserving Systems](#).) The resulting stochastic process is a (one-step, finite-state) Markov process. If p and P also satisfy

$$pP = p , \tag{3}$$

then the Markov process is stationary. In this case we call the (one or two-sided) measure-preserving system the Markov shift determined by p and P .

Aperiodic and irreducible Markov chains (those for which a power of the transition matrix P has all entries positive) are strongly mixing, in fact are isomorphic to Bernoulli shifts (usually by means of a complicated measure-preserving recoding).

More generally we say a set $\Lambda \subset A^{\mathbb{Z}}$ is a *subshift* if it is compact and invariant under σ . A subshift Λ is said to be of *finite type* (SFT) if there exists an $d \times d$ matrix $M = (a_{ij})$ such that all entries are 0 or 1 and $x \in \Lambda$ if and only if $a_{x_i x_{i+1}} = 1$ for all $i \in \mathbb{Z}$. Shifts of finite type are also called *topological Markov chains*. There are many invariant measures for a non-trivial shift of finite type. For example the orbit of each periodic point is the support of an invariant measure. An important role in the theory, derived from motivations of statistical mechanics, is played by *equilibrium measures* (or *equilibrium states*) for continuous functions $\phi: \Lambda \rightarrow \mathbb{R}$, i.e. those measures μ which maximize $\{h_\sigma(\mu) + \int_\Lambda \phi d\mu\}$ over all shift-invariant probability measures, where $h_\sigma(\mu)$ is the measure-theoretic entropy of σ with respect to μ . The study of full shifts or shifts of finite type has played a prominent role in the development of the hyperbolic theory of dynamical systems as physical systems with ‘chaotic’ dynamics ‘typically’ possess an invariant set with induced dynamics topologically conjugate to a shift of finite type (see the discussion by Smale in p. 147 in [108]). Dynamical systems in which there are transverse homoclinic connections are a common example (Theorem 5.3.5 in [45]). Furthermore in certain settings positive metric entropy implies the existence of shifts of finite type. One result along these lines is a theorem of Katok [53]. Let $h_{top}(f)$ denote the topological entropy of a map f and $h_\mu(f)$ denote metric entropy with respect to an invariant measure μ .

Theorem 1 (Katok) *Suppose $T: M \rightarrow M$ is a $C^{1+\epsilon}$ diffeomorphism of a closed manifold and μ is an invariant measure with positive metric entropy (i.e. $h_\mu(T) > 0$). Then for any $0 < \epsilon < h_\mu(T)$ there exists an invariant set Λ topologically conjugate to a transitive shift of finite type with $h_{top}(T|_\Lambda) > h_\mu(T) - \epsilon$.*

More Examples of Subshifts

We consider some further examples of systems that are given by the shift transformation on a subset of the set of (usually doubly-infinite) sequences on a finite alphabet, usually $\{0, 1\}$. Associated with each subshift is its *language*, the set of all finite blocks seen in all sequences in the subshift. These languages are *extractive* (or *factorial*) (every subword of a word in the language is also in the language) and *insertive* (or *extendable*) (every word in the language extends on both sides to longer words in the language). In fact these two properties characterize the languages (subsets of the set of finite-length words on an alphabet) associated with subshifts.

Prouhet–Thue–Morse An interesting (and often rediscovered) element of $\{0, 1\}^{\mathbb{Z}^+}$ is produced as follows. Start with 0 and at each stage write down the opposite ($0' = 1, 1' = 0$) or mirror image of what is available so far. Or, repeatedly apply the *substitution* $0 \rightarrow 01, 1 \rightarrow 10$.

The n th entry is the sum, mod 2, of the digits in the dyadic expansion of n . Using Keane’s *block multiplication* [55] according to which if B is a block, $B \times 0 = B, B \times 1 = B'$, and $B \times (\omega_1 \dots \omega_n) = (B \times \omega_1) \dots (B \times \omega_n)$, we may also obtain this sequence as

$$0 \times 01 \times 01 \times 01 \times \dots .$$

The orbit closure of this sequence is uniquely ergodic (there is a unique shift-invariant Borel probability measure, which is then necessarily ergodic). It is isomorphic to a skew product (see Sect. “[Skew Products](#)”) over the von Neumann-Kakutani adding machine, or odometer (see Sect. “[Adding Machines](#)”). *Generalized Morse systems*, that is, orbit closures of sequences like $0 \times 001 \times 001 \times 001 \times \dots$, are also isomorphic to skew products over compact group rotations.

Chacon System This is the orbit closure of the sequence generated by the substitution $0 \rightarrow 0010, 1 \rightarrow 1$. It is uniquely ergodic and is one of the first systems shown to be weakly mixing but not strongly mixing. It is *prime* (has no nontrivial factors) [30], and in fact has *minimal self joinings* [31]. It also has a nice description by means of cutting up the unit interval and stacking the pieces, using spacers (see Sect. “Cutting and Stacking”). This system has singular spectrum. It is not known whether or not its Cartesian square is loosely Bernoulli.

Sturmian Systems Take the orbit closure of the sequence $\omega_n = \chi_{[1-\alpha,1)}(n\alpha)$, where α is irrational. This is a uniquely ergodic system that is isomorphic to rotation by α on the unit interval. These systems have *minimal complexity* in the sense that the number of n -blocks grows as slowly as possible $(n + 1)$ [29].

Toeplitz Systems A bi-infinite sequence (x_i) is a Toeplitz sequence if the set of integers can be decomposed into arithmetic progressions such that each x_i is constant on each arithmetic progression. A shift space X is a Toeplitz shift if it is the closure of the orbit of a Toeplitz sequence. It is possible to construct Toeplitz shifts which are uniquely ergodic and isomorphic to a rotation on a compact abelian group [34].

Sofic Systems These are images of SFT’s under continuous factor maps (finite codes, or block maps). They correspond to *regular languages*—languages whose words are recognizable by finite automata. These are the same as the languages defined by *regular expressions*—finite expressions built up from \emptyset (empty set), ϵ (empty word), $+$ (union of two languages), \cdot (all concatenations of words from two languages), and $*$ (all finite concatenations of elements). They also have the characteristic property that the family of all *follower sets* of all blocks seen in the system is a finite family; similarly for *predecessor sets*. These are also generated by *phase-structure grammars* which are *linear*, in the sense that every production is either of the form $A \rightarrow Bw$ or $A \rightarrow w$, where A and B are variables and w is a string of terminals (symbols in the alphabet of the language).

(A *phase-structure grammar* consists of alphabets V of *variables* and A of *terminals*, a set of *productions*, which is finite set of pairs of words (α, w) , usually written $\alpha \rightarrow w$, of words on $V \cup A$, and a *start symbol* S . The associated language consists of all words on the alphabet A of terminals which can be made by starting with S and applying a finite sequence of productions.)

Sofic systems typically support many invariant measures (for example they have many periodic points) but topologically transitive ones (those with a dense orbit) have a unique measures of maximal entropy (see [65]).

Context-free Systems These are generated by phase-structure grammars in which all productions are of the form $A \rightarrow w$, where A is a variable and w is a string of variables and terminals.

Coded Systems These are systems all of whose blocks are concatenations of some (finite or infinite) list of blocks. These are the same as the closures of increasing sequences of SFT’s [60]. Alternatively, they are the closures of the images under finite edge-labelings of irreducible countable-state topological Markov chains. They need not be context-free. Squarefree languages are not coded, in fact do not contain any coded systems of positive entropy. See [13,14,15].

Smooth Expanding Interval Maps

Take $X = [0, 1)(\text{mod } 1)$, $m \in \mathbb{N}$, $m > 1$ and define

$$T(x) = (mx).$$

Then T preserves Lebesgue measure μ (recall that T preserves μ if $\mu(T^{-1}A) = \mu(A)$ for all $A \in \mathcal{B}$). Furthermore it can be shown that T is ergodic.

This simple map exemplifies many of the characteristics of systems with some degree of hyperbolicity. It is isomorphic to a Bernoulli shift. The map has positive topological entropy and exponential divergence of nearby orbits, and Hölder functions have exponential decay of correlations and satisfy the central limit theorem and other strong statistical properties [20].

If $m = 2$ the system is isomorphic to a model of tossing a fair coin, which is a common example of randomness. To see this let $\mathcal{P} = \{P_0 = [0, 1/2), P_1 = [1/2, 1]\}$ be a partition of $[0, 1]$ into two subintervals. We code the orbit under T of any point $x \in [0, 1)$ by 0’s and 1’s by letting $x_k = i$ if $T^k x \in P_i$, $k = 0, 1, 2, \dots$. The map $\phi: X \rightarrow \{0, 1\}^{\mathbb{N}}$ which associates a point x to its *itinerary* in this way is a measure-preserving map from (X, μ) to $\{0, 1\}^{\mathbb{N}}$ equipped with the Bernoulli measure from $p_0 = p_1 = \frac{1}{2}$. The map ϕ satisfies $\phi \circ T = \sigma \circ \phi$, μ a.e. and is invertible a.e., hence is an isomorphism. Furthermore, reading the binary expansion of x is equivalent to following the orbit of x under T and noting which element of the partition \mathcal{P} is entered at each time. Borel’s theorem on normal numbers (base m) may be seen as a special case of the Birkhoff Ergodic Theorem in this setting.

Piecewise C^2 Expanding Maps The main statistical features of the examples in Sect. “Smooth Expanding Interval Maps” generalize to a broader class of expanding maps of the interval. For example:

Let $X = [0, 1]$ and let $\mathcal{P} = \{I_1, \dots, I_n\}$ ($n \geq 2$) be a partition of X into intervals (closed, half-open or open) such that $I_i \cap I_j = \emptyset$ if $i \neq j$. Let I_i° denote the interior of I_i . Suppose $T: X \rightarrow X$ satisfies:

- (a) For each $i = 1, \dots, n$, $T|_{I_i}$ has a C^2 extension to the closure \bar{I}_i of I_i and $|T'(x)| \geq \alpha > 1$ for all $x \in I_i^\circ$.
- (b) $T(I_j) = \cup_{i \in P_j} I_i$ Lebesgue a.e. for some non-empty subset $P_j \subset \{1, \dots, n\}$.
- (c) For each I_j there exists n_j such that $T^{n_j}(I_j) = [0, 1]$ Lebesgue a.e.

Then T has an invariant measure μ which is absolutely continuous with respect to Lebesgue measure m , and there exists $C > 0$ such that $\frac{1}{C} \leq \frac{d\mu}{dm} \leq C$. Furthermore T is ergodic with respect to μ and displays the same statistical properties listed above for the C^2 expanding maps [20]. (See the “Folklore Theorem” in the article on [Measure Preserving Systems](#).)

More Interval Maps

Continued Fraction Map This is the map $T: [0, 1] \rightarrow [0, 1]$ given by $Tx = 1/x \bmod 1$, and it corresponds to the shift $[0; a_1, a_2, \dots] \rightarrow [0; a_2, a_3, \dots]$ on the continued fraction expansions of points in the unit interval (a map on $\mathbb{N}^{\mathbb{N}}$). It preserves a unique finite measure equivalent to Lebesgue measure, the Gauss measure $dx/(\log 2)(1+x)$. It is Bernoulli with entropy $\pi^2/6 \log 2$ (in fact the natural partition into intervals is a weak Bernoulli generator, for the definition and details see [91]). By using the Ergodic Theorem, Khintchine and Lévy showed that

$$(a_1 \cdots a_n)^{1/n} \rightarrow \prod_{k=1}^{\infty} \left[1 + \frac{1}{k^2 + 2k} \right]^{\frac{\log k}{\log 2}} \text{ a.e. as } n \rightarrow \infty;$$

if $[0; a_1, \dots, a_n] = \frac{p_n}{q_n}$, then $\frac{1}{n} \log q_n \rightarrow \frac{\pi^2}{12 \log 2}$ a.e.;

$$\frac{1}{n} \log \left| x - \frac{p_n(x)}{q_n(x)} \right| \rightarrow \frac{\pi^2}{6 \log 2} \text{ a.e.};$$

and if m is Lebesgue measure (or any equivalent measure) and μ is Gauss measure, then for each interval I , $m(T^{-n}I) \rightarrow \mu(I)$, in fact exponentially fast, with a best constant 0.30366... see [10,75].

The Farey Map This is the map $U: [0, 1] \rightarrow [0, 1]$ given by $Ux = x/(1-x)$ if $0 \leq x \leq 1/2$, $Ux = (1-x)/x$

if $1/2 \leq x \leq 1$. It is ergodic for the σ -finite infinite measure dx/x (Rényi and Parry). It is also ergodic for the Minkowski measure d , which is a measure of maximal entropy. This map corresponds to the shift on the Farey tree of rational numbers which provide the intermediate convergence (best one-sided) as well as the continued fraction (best two-sided) rational approximations to irrational numbers. See [61,62].

f -Expansions Generalizing the continued fraction map, let $f: [0, 1] \rightarrow [0, 1]$ and let $\{I_n\}$ be a finite or infinite partition of $[0, 1]$ into subintervals. We study the map f by coding itineraries with respect to the partition $\{I_n\}$. For many examples, absolutely continuous (with respect to Lebesgue measure) invariant measures can be found and their dynamical properties determined. See [104].

β -Shifts This is the special case of f -expansions when $f(x) = \beta x \bmod 1$ for some fixed $\beta > 1$. This map of the interval is called the β -transformation. With a proper choice of partition, it is represented by the shift on a certain subshift of the set of all sequences on the alphabet $D = \{0, 1, \dots, \lfloor \beta \rfloor\}$, called the β -shift. A point x is expanded as an infinite series in negative powers of β with coefficients from this set; $d_\beta(x)_n = \lfloor \beta f^n(x) \rfloor$. (By convention terminating expansions are replaced by eventually periodic ones.) A one-sided sequence on the alphabet D is in the β -shift if and only if all of its shifts are lexicographically less than or equal to the expansion $d_\beta(1)$ of 1 base β . A one-sided sequence on the alphabet D is the valid expansion of 1 for some β if and only if it lexicographically dominates all its shifts. These were first studied by Bissinger [11], Everett [35], Rényi [93] and Parry [84,85]; there are good summaries by Bertrand-Mathis [9] and Blanchard [12].

For $\beta = \frac{1+\sqrt{5}}{2}$, $d_\beta(1) = 10101010\dots$.
 For $\beta = \frac{3}{2}$, $d_\beta(1) = 10100001\dots$ (not eventually periodic).

Every β -shift is coded. The topological entropy of a β -shift is $\log \beta$. There is a unique measure of maximal entropy $\log \beta$. A β -shift is a shift of finite type if and only if the β -expansion of 1 is finite. It is sofic if and only if the expansion of 1 is eventually periodic. If β is a Pisot–Vijayaragavhan number (algebraic integer all of whose conjugates have modulus less than 1), then the β -shift is sofic. If the β -shift is sofic, then β is a Perron number (algebraic integer of maximum modulus among its conjugates).

Theorem 2 (Parry [86]) Every strongly transitive (for every nonempty open set U , $\cup_{n>0} T^n U = X$) piecewise mono-

tonic map on $[0, 1]$ is topologically conjugate to a β -transformation.

Gaussian Systems

Consider a real-valued stationary process $\{f_k: -\infty < k < \infty\}$ on a probability space (Ω, \mathcal{F}, P) . The process (and the associated measure-preserving system consisting of the shift and a shift-invariant measure on $\mathbb{R}^{\mathbb{Z}}$) is called *Gaussian* if for each $d \geq 1$, any d of the f_k form an \mathbb{R}^d -valued Gaussian random variable on Ω : this means that with $E(f_k) = m$ for all k and

$$A_{ij} = \int_{\Omega} (f_{k_i} - m)(f_{k_j} - m) dP = C(k_i - k_j) \quad \text{for } i, j = 1, \dots, d,$$

where $C(\cdot)$ is a function, for each Borel set $B \subset \mathbb{R}$,

$$P\{\omega: (f_{k_1}(\omega), \dots, f_{k_d}(\omega)) \in B\} = \frac{1}{2\pi^{d/2} \sqrt{\det A}} \int_B \exp\left[-\frac{1}{2}(x - (m, \dots, m))^{tr} \cdot A^{-1}(x - (m, \dots, m))\right] dx_1 \cdots dx_d.$$

where A is a matrix with entries (A_{ij}) . The function $C(k)$ is positive semidefinite and hence has an associated measure σ on $[0, 2\pi)$ such that

$$C(k) = \int_0^{2\pi} e^{ikt} d\sigma(t).$$

Theorem 3 (de la Rue [33]) *The Gaussian system is ergodic if and only if the “spectral measure” σ is continuous (i. e., nonatomic), in which case it is also weakly mixing. It is mixing if and only if $C(k) \rightarrow 0$ as $|k| \rightarrow \infty$. If σ is singular with respect to Lebesgue measure, then the entropy is 0; otherwise the entropy is infinite.*

For more details see [28].

Hamiltonian Systems

(This paragraph is from the article on [► Measure Preserving Systems](#).) Many systems that model physical situations can be studied by means of Hamilton’s equations. The state of the entire system at any time is specified by a vector $(q, p) \in \mathbb{R}^{2n}$, the *phase space*, with q listing the coordinates of the positions of all of the particles, and p listing the coordinates of their momenta. We assume there is a time-independent *Hamiltonian function* $H(q, p)$ such that the time development of the system satisfies *Hamilton’s equations*:

$$\frac{dq_i}{dt} = \frac{\partial H}{\partial p_i}, \quad \frac{dp_i}{dt} = -\frac{\partial H}{\partial q_i}, \quad i = 1, \dots, n. \quad (4)$$

Often in applications the Hamiltonian function is the sum of kinetic and potential energy:

$$H(q, p) = K(p) + U(q). \quad (5)$$

Solving these equations with initial state (q, p) for the system produces a flow $(q, p) \rightarrow T_t(q, p)$ in phase space which moves (q, p) to its position $T_t(q, p)$ t units of time later. According to *Liouville’s formula* Theorem 3.2 in [69], this flow preserves Lebesgue measure on \mathbb{R}^{2n} . Calculating dH/dt by means of the Chain Rule

$$\frac{dH}{dt} = \sum_i \left(\frac{\partial H}{\partial p_i} \frac{dp_i}{dt} + \frac{\partial H}{\partial q_i} \frac{dq_i}{dt} \right)$$

and using Hamilton’s equations shows that H is constant on orbits of the flow, and thus each set of constant energy $X(H_0) = \{(q, p): H(q, p) = H_0\}$ is an invariant set. There is a natural invariant measure on a constant energy set $X(H_0)$ for the restricted flow, namely the measure given by rescaling the volume element dS on $X(H_0)$ by the factor $1/|\nabla H|$.

Billiard Systems These form an important class of examples in ergodic theory and dynamical systems, motivated by natural questions in physics, particularly the behavior of gas models. Consider the motion of a particle inside a bounded region D in \mathbb{R}^d with piecewise smooth (C^1 at least) boundaries. In the case of planar billiards we have $d = 2$. The particle moves in a straight line with constant speed until it hits the boundary, at which point it undergoes a perfectly elastic collision with the angle of incidence equal to the angle of reflection and continues in a straight line until it next hits the boundary. It is usual to normalize and consider unit speed, as we do in this discussion for convenience. We take coordinates (x, v) given by the Euclidean coordinates in $x \in D$ together with a direction vector $v \in S^{d-1}$. A flow ϕ_t is defined with respect to Lebesgue almost every (x, v) by translating x a distance t defined by the direction vector v , taking account of reflections at boundaries. ϕ_t preserves a measure absolutely continuous with respect to Riemannian volume on (x, v) coordinates. The flow we have described is called a *billiard flow*. The corresponding *billiard map* is formed by taking the Poincaré map corresponding to the cross-section given by the boundary ∂D . We will describe the planar billiard map; the higher dimensional generalization is clear. The billiard map is a map $T: \partial D \rightarrow \partial D$, where ∂D is coordinatized by (s, θ) , $s \in [0, L)$, where L is the length of ∂D and $\theta \in (0, \pi)$ measures the angle that inward pointing vec-

tors make with the tangent line to ∂D at s . Given a point (s, θ) , the angle θ defines an oriented line $l(s, \theta)$ which intersects ∂D in two points s and s' . Reflecting l in the tangent line to ∂D at the point s' gives another oriented line passing through s' with angle θ' (measured with respect to the angular coordinate system based at s'). The billiard map is the map $T(s, \theta) = (s', \theta')$. T preserves a measure $\mu = \sin \theta ds \times d\theta$. The billiard flow may be modeled as a suspension flow over the billiard map (see Sect. “Suspension Flows”).

If the region D is a polygon in the plane (or polyhedron in \mathbb{R}^d), then ∂D consists of the faces of the polyhedron. The dynamical behavior of the billiard map or flow in regions with only flat (non-curved) boundaries is quite different to that of billiard flows or maps in regions D with strictly convex or strictly concave boundaries. The topological entropy of a flat polygonal billiard is zero. Research interest focuses on the existence and density of periodic or transitive orbits. It is known that if all the angles between sides are rational multiples of π then there are periodic orbits [17,74,112] and they are dense in the phase space [16]. It is also known that a residual set of polygonal billiards are topologically transitive and ergodic [58,117].

On the other hand, billiard maps in which ∂D has strictly convex components are physical examples of non-uniformly hyperbolic systems (with singularities). The meaning of concave or convex varies in the literature. We will consider a billiard flow inside a circle to be a system with a strictly concave boundary, while a billiard flow on the torus from which a circle has been excised to be a billiard flow with strictly convex boundary.

The class of billiards with some strictly convex boundary components, sometimes called *dispersing billiards* or *Sinai billiards*, was introduced by Sinai [106] who proved many of their fundamental properties. Lazutkin [63] proved that planar billiards with generic strictly concave boundary are not ergodic. Nevertheless Bunimovich [22,23] produced a large of billiard systems, *Bunimovich billiards*, with strictly concave boundary segments (perhaps with some flat boundaries as well) which were ergodic and non-uniformly hyperbolic. For more details see [26,54,66,109]. We will discuss possibly the simplest example of a dispersing billiard, namely a toral billiard with a single convex obstacle. Take the torus T^2 and consider a single strictly convex subdomain S with C^∞ boundary. The domain of the billiard map is $[0, L) \times (0, \pi)$, where L is the length of ∂S . The measure $\sin(\theta) ds \times d\theta$ is preserved. If the curvature of ∂S is everywhere non-zero, then the billiard map T has positive topological entropy, periodic points are dense, and in fact the system is isomorphic to a Bernoulli shift [41].

KAM-Systems and Stably Non-Ergodic Behavior

A celebrated theorem of Kolmogorov, Arnold and Moser (the KAM theorem) implies that the set of ergodic area-preserving diffeomorphisms of a compact surface without boundary is not dense in the C^r topology for $r \geq 4$. This has important implications, in that there are natural systems in which ergodicity is not generic. The constraint of perturbing in the class of area-preserving diffeomorphisms is an appropriate imposition in many physical models. We will take the version of the KAM theorem as given in Theorem 5.1 in [69] (original references include [3,59,79]). An elliptic fixed point for an area-preserving diffeomorphism T of a surface M is called a *non-degenerate elliptic fixed point* if there is a local C^r , $r \geq 4$, change of coordinates h so that in polar coordinates

$$hTh^{-1}(r, \theta) = (r, \theta + \alpha_0 + \alpha_1 r) + F(r, \theta),$$

where all derivatives of F up to order 3 vanish, $\alpha_1 \neq 0$ and $\alpha_0 \neq 0, \frac{\pm\pi}{2}, \pi, \frac{\pm 2\pi}{3}$. A map of the form

$$\tau(r, \theta) = (r, \theta + \alpha_0 + \alpha_1 r),$$

where $\alpha_1 \neq 0$, is called a *twist map*. Note that a twist map leaves invariant the circle $r = k$, for any constant k , and rotates each invariant curve by a rigid rotation $\alpha_1 r$, the magnitude of the rotation depending upon r . With respect to two-dimensional Lebesgue measure a twist map is certainly not ergodic.

Theorem 4 *Suppose T is a volume-preserving diffeomorphism of class C^r , $r \geq 4$, of a surface M . If x is a non-degenerate elliptic fixed point, then for every $\epsilon > 0$ there exists a neighborhood U_ϵ of x and a set $U_{0,\epsilon} \subset U_\epsilon$ with the properties:*

- (a) $U_{0,\epsilon}$ is a union of T -invariant simple closed curves of class C^{r-1} containing x in their interior.
- (b) The restriction of T to each such invariant curve is topologically conjugate to an irrational rotation.
- (c) $m(U_\epsilon - U_{0,\epsilon}) \leq \epsilon m(U_\epsilon)$, where m is Lebesgue measure on M .

It is possible to prove the existence of a C^r volume preserving diffeomorphism ($r \geq 4$) with a non-degenerate elliptic fixed point and also show that if T possesses a non-degenerate elliptic fixed point then there is a neighborhood V of T in the C^r topology on volume-preserving diffeomorphisms such that each $T' \in V$ possesses a non-degenerate elliptic fixed point Chapter II, Sect. 6 in [69]. As a corollary we have

Corollary 1 *Let M be a compact surface without boundary and $\text{Diff}^r(M)$ the space of C^r area-preserving diffeomorphisms with the C^r topology. Then the set of $T \in \text{Diff}^r(M)$ which are ergodic with respect to the probability measure determined by normalized area is not dense in $\text{Diff}^r(M)$ for $r \geq 4$.*

Smooth Uniformly Hyperbolic Diffeomorphisms and Flows

Time series of measurements on deterministic dynamical systems sometimes display limit laws exhibited by independent identically distributed random variables, such as the central limit theorem, and also various mixing properties. The models of hyperbolicity we discuss in this section have played a key role in showing how this phenomenon of ‘chaotic behavior’ arises in deterministic dynamical systems. Hyperbolic sets and their associated dynamics have also been pivotal in studies of structural stability. A smooth system is C^r *structurally stable* if a small perturbation in the C^r topology gives rise to a system which is topologically conjugate to the original. When modeling a physical system it is desirable that slight changes in the modeling parameters do not greatly affect the qualitative or quantitative behavior of the ensemble of orbits considered as a whole. The orbit of a point may change drastically under perturbation (especially if the system has sensitive dependence on initial conditions) but the collection of all orbits should ideally be ‘similar’ to the original unperturbed system. In the latter case one would hope that statistical properties also vary only slightly under perturbation. Structural stability is one, quite strong, notion of stability. The conclusion of a body of work on structural stability is that a system is C^1 structurally stable if and only if it is uniformly hyperbolic and satisfies a technical assumption called strong transversality (see below for details).

Suppose M is a C^1 compact Riemannian manifold equipped with metric d and tangent space TM with norm $\|\cdot\|$. Suppose also that $U \subset M$ is a non-empty open subset and $T: U \rightarrow T(U)$ is a C^1 diffeomorphism. A compact T invariant set $\Lambda \subset U$ is called a *hyperbolic set* if there is a splitting of the tangent space $T_p M$ at each point $p \in \Lambda$ into two invariant subspaces, $T_p M = E^u(p) \oplus E^s(p)$, and a number $0 < \lambda < 1$ such that for $n \geq 0$

$$\|D_p T^n v\| \leq C \lambda^n \|v\| \text{ for } v \in E^s(p),$$

$$\|D_p T^{-n} v\| < C \lambda^n \|v\| \text{ for } v \in E^u(p).$$

The subspace E^u is called the *unstable* or *expanding subspace* and the subspace E^s the *stable* or *contracting subspace*. The stable and unstable subspaces may be integrated

to produce *stable* and *unstable manifolds*

$$W^s(p) = \{y: d(T^n p, T^n y) \rightarrow 0\} \text{ as } n \rightarrow \infty,$$

$$W^u(p) = \{y: d(T^{-n} p, T^{-n} y) \rightarrow 0\} \text{ as } n \rightarrow \infty.$$

The stable and unstable manifolds are immersions of Euclidean spaces of the same dimension as $E^s(p)$ and $E^u(p)$, respectively, and are of the same differentiability as T . Moreover, $T_p(W^s(p)) = E^s(p)$ and $T_p(W^u(p)) = E^u(p)$. It is also useful to define *local stable manifolds* and *local unstable manifolds* by

$$W_\epsilon^s(p) = \{y \in W^s(p): d(T^n p, T^n y) < \epsilon\} \text{ for all } n \geq 0,$$

$$W_\epsilon^u(p) = \{y \in W^u(p): d(T^{-n} p, T^{-n} y) < \epsilon\} \text{ for all } n \geq 0.$$

Finally we discuss the notion of strong transversality. We say a point x is *non-wandering* if for each open neighborhood U of x there exists an $n > 0$ such that $T^n(U) \cap U \neq \emptyset$. The NW set of non-wandering points is called the *non-wandering set*. We say a dynamical system has the *strong transversal property* if $W^s(x)$ intersects $W^u(y)$ transversely for each pair of points $x, y \in NW$. In the $C^r, r \geq 1$ topology Robbin [94], de Melo [78] and Robinson [95,96] proved that dynamical systems with the strong transversal property are structurally stable, and Robinson [97] in addition showed that strong transversality was also necessary. Mañé [70] showed that a C^1 structurally stable diffeomorphism must be uniformly hyperbolic and Hayashi [47] extended this to flows. Thus a C^1 diffeomorphism or flow on a compact manifold is structurally stable if and only if it is uniformly hyperbolic and satisfies the strong transversality condition.

Geodesic Flow on Manifold of Negative Curvature The study of the geodesic flow on manifolds of negative sectional curvature by Hedlund and Hopf was pivotal to the development of the ergodic theory of hyperbolic systems. Suppose that M is a geodesically complete Riemannian manifold. Let $\gamma_{p,v}(t)$ be the geodesic with $\gamma_{p,v}(0) = p$ and $\dot{\gamma}_{p,v}(0) = v$, where $\dot{\gamma}_{p,v}$ denotes the derivative with respect to time t . The geodesic flow is a flow ϕ_t on the tangent bundle TM of $M, \phi_t: \mathbb{R} \times TM \rightarrow TM$, defined by

$$\phi_t(p, v) = (\gamma_{p,v}(t), \dot{\gamma}_{p,v}(t)).$$

where $(p, v) \in TM$. Since geodesics have constant speed, if $\|v\| = 1$ then $\|\dot{\gamma}_{p,v}(t)\| = 1$ for all t , and thus the unit tangent bundle $T^1 M = \{(p, v) \in TM: \|v\| = 1\}$ is preserved

under the geodesic flow. The geodesic flow and its restriction to the unit tangent bundle both preserve a volume form, Liouville measure. In 1934 Hedlund [48] proved that the geodesic flow on the unit tangent bundle of a surface of strictly negative constant sectional curvature is ergodic, and in 1939 Hopf [49] extended this result to manifolds of arbitrary dimension and strictly negative (not necessarily constant) curvature. Hopf’s technique of proof of ergodicity (Hopf argument) was extremely influential and used the foliation of the tangent space into stable and unstable manifolds. For a clear exposition of this technique, and the property of absolute continuity of the foliations into stable and unstable manifolds, see [66]. The geodesic flow on manifolds of constant negative sectional curvature is an Anosov flow (see Sect. “Anosov Systems”). We remark that for surfaces sectional curvature is the same as Gaussian curvature. Recently the time-one map of the geodesic flow on the unit tangent bundle of a surface with constant negative curvature, which is a partially hyperbolic system (see Sect. “Partially Hyperbolic Dynamical Systems”), was shown to be stably ergodic [44], so the geodesic flow is still playing a major role in the development of ergodic theory.

Horocycle Flow All surfaces endowed with a Riemannian metric of constant negative curvature are quotients of the upper half-plane $\mathcal{H}^+ := \{x + iy \in \mathbb{C} : y > 0\}$ with the metric $ds^2 = \frac{dx^2 + dy^2}{y^2}$, whose sectional curvature is -1 . The orientation-preserving isometries of this metric are exactly the linear fractional (also known as Möbius) transformations:

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SL(2, \mathbb{R}), \quad [z \in \mathcal{H}^+ \mapsto \frac{az + b}{cz + d} \in \mathcal{H}^+].$$

Since each matrix $\pm I$ corresponds to the identity transformation, we consider matrices in $PSL(2, \mathbb{R}) := SL(2, \mathbb{R})/\{\pm I\}$.

The unit tangent bundle, $S\mathcal{H}^+$, of the upper half-plane can be identified with $PSL(2, \mathbb{R})$. Then the geodesic flow corresponds to the transformations

$$t \in \mathbb{R} \mapsto \begin{pmatrix} e^t & 0 \\ 0 & e^{-t} \end{pmatrix}$$

seen as acting on $PSL(2, \mathbb{R})$. The unstable foliation of an element $A \in PSL(2, \mathbb{R}) \cong S\mathcal{H}^+$ is given by

$$\begin{pmatrix} 1 & t \\ 0 & 1 \end{pmatrix} A, \quad t \in \mathbb{R},$$

and the flow along this foliation, given by

$$t \in \mathbb{R} \mapsto \begin{pmatrix} 1 & t \\ 0 & 1 \end{pmatrix},$$

is called the *horocycle flow*. Similarly for the flow induced on the unit tangent bundle of each quotient of the upper half-plane by a discrete group of linear fractional transformations.

The geodesic and horocycle flows acting on a (finite-volume) surface of constant negative curvature form the fundamental example of a transverse pair of actions. The geodesic flow often has many periodic orbits and many invariant measures, has positive entropy, and is in fact Bernoulli with respect to the natural measure [82], while the horocycle flow is often uniquely ergodic [39,72] and of entropy zero, although mixing of all orders [73]. See [46] for more details.

Markov Partitions and Coding If (X, T, \mathcal{B}, μ) is a dynamical system then a finite partition of X induces a coding of the orbits and a semi-conjugacy with a subshift on a symbol space (it may not of course be a full conjugacy). For hyperbolic systems a special class of partitions, *Markov partitions*, induce a conjugacy for the invariant dynamics to a subshift of finite type. A Markov partition \mathcal{P} for an invariant subset Λ of a diffeomorphism T of a compact manifold M is a finite collection of sets $R_i, 1 \leq i \leq n$ called *rectangles*. The rectangles have the property, for some $\epsilon > 0$, if $x, y \in R_i$ then $W_\epsilon^s(x) \cap W_\epsilon^u(y) \in R_i$. This is sometimes described as being closed under *local product structure*. We let $W^u(x, R_i)$ denote $W_\epsilon^u(x) \cap R_i$ and $W^s(x, R_i)$ denote $W_\epsilon^s(x) \cap R_i$. Furthermore we require for all i, j :

- (1) Each R_i is the closure of its interior.
- (2) $\Lambda \subset \cup_i R_i$
- (3) $R_i \cap R_j = \partial R_i \cap \partial R_j$ if $i \neq j$
- (4) if $x \in R_i^o$ and $T(x) \in R_j^o$ then $W^u(T(x), R_j) \subset T(W^u(x, R_i))$ and $W^s(x, R_i) \subset T^{-1}(W^s(T(x), R_j))$

Anosov Systems An *Anosov diffeomorphism* [2] is a uniformly hyperbolic system in which the entire manifold is a hyperbolic set. Thus an Anosov diffeomorphism is a C^1 diffeomorphism T of M with a DT -invariant splitting (which is a continuous splitting) of the tangent space $TM(x)$ at each point p into a disjoint sum

$$T_p M = E^u(p) \oplus E^s(p)$$

and there exist constants $0 < \lambda < 1$, constant $C > 0$ such that $\|DT^n v\| < C\lambda^n \|v\|$ for all $v \in E^s(p)$ and $\|DT^{-n} w\| \leq C\lambda^n \|w\|$ for all $w \in E^u(p)$.

A similar definition holds for Anosov flows $\phi: \mathbb{R} \times M \rightarrow M$. A flow is *Anosov* if there is a splitting of the tangent bundle into flow-invariant subspaces E^u, E^s, E^c so

$D_p\phi_t E_p^s = E_{\phi_t(p)}^s$, $D_p\phi_t E_p^u = E_{\phi_t(p)}^u$ and $D_p\phi_t E_p^c = E_{\phi_t(p)}^c$, and at each point $p \in M$

$$\begin{aligned} T_p M &= E_p^s \oplus E_p^u \oplus E_p^c \\ \|(D_p\phi_t)v\| &< C\lambda^t \|v\| \text{ for } v \in E^s(p) \\ \|(D_p\phi_{-t})v\| &< C\lambda^t \|v\| \text{ for } v \in E^u(p) \end{aligned}$$

for some $0 < \lambda < 1$. The tangent to the flow direction $E^c(p)$ is a neutral direction:

$$\|(D_p\phi_t)v\| = \|v\| \text{ for } v \in E^c(p).$$

Anosov proved that Anosov flows and diffeomorphisms which preserve a volume form are ergodic [2] and are also structurally stable. Sinai [105] constructed Markov partitions for Anosov diffeomorphisms and hence coded trajectories via a subshift of finite type. Using ideas from statistical physics in [107] Sinai constructed Gibbs measures for Anosov systems. An SRB measure (see Sect. “Physically Relevant Measures and Strange Attractors”) is a type of Gibbs measure corresponding to the potential $-\log|\det(DT|_{E^u})|$ and is characterized by the property of absolutely continuous conditional measures on unstable manifolds.

The simplest examples of Anosov diffeomorphisms are perhaps the two-dimensional hyperbolic toral automorphisms (the $n > 2$ generalization is clear). Suppose A is a 2×2 matrix with integer entries

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix}$$

such that $\det(A) = 1$ and A has no eigenvalues of modulus 1. Then A defines a transformation of the two-dimensional torus $T^2 = S^1 \times S^1$ such that if $v \in T^2$,

$$v = \begin{pmatrix} v_1 \\ v_2 \end{pmatrix},$$

then

$$Av = \begin{pmatrix} (av_1 + bv_2) \\ (cv_1 + dv_2) \end{pmatrix}.$$

A preserves Lebesgue (or Haar) measure and is ergodic. A prominent example of such a matrix is

$$\begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix},$$

which is sometimes called the Arnold Cat Map. Each point with rational coordinates $(p_1/q_1, p_2/q_2)$ is periodic. There are two eigenvalues $1/\lambda < 1 < \lambda = (3 + \sqrt{5})/2$ with orthogonal eigenvectors, and the projections of the eigenspaces from \mathbb{R}^2 to T^2 are the stable and unstable subspaces.

Axiom A Systems In the case of Anosov diffeomorphisms the splitting into contracting and expanding bundles holds on the entire phase space M . A system $T: M \rightarrow M$ is an *Axiom A system* if the non-wandering set NW is a hyperbolic set and periodic points are dense in the non-wandering set. $NW \subset M$ may have Lebesgue measure zero. A set $A \subset M$ is *locally maximal* if there exists an open set U such that $A = \bigcap_{n \in \mathbb{Z}} T^n(U)$. The solenoid and horseshoe discussed below are examples of locally maximal sets. Bowen [18] constructed Markov partitions for Axiom A diffeomorphisms. Ruelle imported ideas from statistical physics, in particular the idea of an equilibrium state and the variational principle, to the study of Axiom A systems (see [101,102]) This work extended the notion of Gibbs measure and other ideas from statistical mechanics, introduced by Sinai for Anosov systems [107], into Axiom A systems.

One achievement of the Axiom A program was the Smale Decomposition Theorem, which breaks the dynamics of Axiom A systems into locally maximal sets and describes the dynamics on each [18,19,108].

Theorem 5 (Spectral Decomposition Theorem) *If T is Axiom A then there is a unique decomposition of the non-wandering set NW of T*

$$NW = \Lambda_1 \cup \dots \cup \Lambda_k$$

as a disjoint union of closed, invariant, locally maximal hyperbolic sets Λ_i such that T is transitive on each Λ_i . Furthermore each Λ_i may be further decomposed into a disjoint union of closed sets Λ_i^j , $j = 1, \dots, n_i$ such that T^{n_i} is topologically mixing on each Λ_i^j and T cyclically permutes the Λ_i^j .

Horseshoe Maps This type of map was introduced by Steven Smale in the 1960’s and has played a pivotal role in the development of dynamical systems theory. It is perhaps the canonical example of an Axiom A system [108] and is conjugate to a full shift on 2 symbols. Let S be a unit square in \mathbb{R}^2 and let T be a diffeomorphism of S onto its image such that $S \cap T(S)$ consists of two disjoint horizontal strips S_0 and S_1 . Think of stretching S uniformly in the horizontal direction and contracting uniformly in the vertical direction to form a long thin rectangle, and then bending the rectangle into the shape of a horseshoe and laying the straight legs of the horseshoe back on the unit square S . This transformation may be realized by a diffeomorphism and we may also require that T restricted to $T^{-1}S_i$, $i = 0, 1$, acts as a linear map. The restriction of T to the maximal invariant set $H = \bigcap_{i=-\infty}^{\infty} T^i S$ is a Smale horseshoe map. H is a Cantor set, the product of a Cantor

set in the horizontal direction and a Cantor set in the vertical direction. The conjugacy with the shift on two symbols is realized by mapping $x \in H$ to its itinerary with respect to the sets S_0 and S_1 under powers of T (positive and negative powers).

Solenoids The solenoid is defined on the solid torus X in \mathbb{R}^3 which we coordinatize as a circle of two-dimensional solid disks, so that

$$X = \{(\theta, z): \theta \in [0, 1) \text{ and } |z| \leq 1, z \in \mathbb{C}\}$$

The transformation $T: X \rightarrow X$ is given by

$$T(\theta, z) = \left(2\theta \pmod{1}, \frac{1}{4}z + \frac{1}{2}e^{2\pi i\theta}\right)$$

Geometrically the transformation stretches the torus to twice its length, shrinks its diameter by a factor of 4, then twists it and doubles it over, placing the resultant object without self-intersection back inside the original solid torus. $T(X)$ intersects each disk $D_c = \{(\theta, z): \theta = c\}$ in two smaller disks of $\frac{1}{4}$ the diameter. The transformation T contracts volume by a factor of 2 upon each application, yet there is expansion in the θ direction ($\theta \rightarrow 2\theta$). The solenoid $A = \bigcap_{n \geq 0} T^n(X)$ has zero Lebesgue measure, is T -invariant and is (locally) topologically a line segment cross a two-dimensional Cantor set (A intersects each disk D_c in a Cantor set). The set A is an *attractor*, in that all points inside X limit under iteration by T upon A . $T: A \rightarrow A$ is an Axiom A system.

Partially Hyperbolic Dynamical Systems

Partially hyperbolic dynamical systems are a generalization of uniformly hyperbolic systems in that an invariant central direction is allowed but the contraction in the central direction is strictly weaker than the contraction in the contracting direction and the expansion in the central direction is weaker than the expansion in the expanding direction. More precisely, suppose M is a C^1 compact (adapted) Riemannian manifold equipped with metric d and tangent space TM with norm $\|\cdot\|$. A C^1 diffeomorphism T of M is a partially hyperbolic diffeomorphism if there is a nontrivial continuous DT invariant splitting of the tangent space T_pM at each point p into a disjoint sum

$$T_pM = E^u(p) \oplus E^c(p) \oplus E^s(p)$$

and continuous positive functions $m, M, \tilde{\gamma}, \gamma$ such that

- E^s is contracted:
if $v^s \in E^s(x) \setminus \{0\}$ then $\frac{\|D_p T^n v^s\|}{\|v^s\|} \leq m(p) < 1$;
- E^u is expanded:
if $v^u \in E^u(x) \setminus \{0\}$ then $\frac{\|D_p T^n v^u\|}{\|v^u\|} \geq M(p) > 1$;

- E^c is uniformly dominated by E^u and E^s :
if $v^c \in E^c(x) \setminus \{0\}$ then there are numbers $\tilde{\gamma}(p), \gamma(p)$ such that $m(p) < \tilde{\gamma}(p) \leq \frac{\|D_p T^n v^c\|}{\|v^c\|} \leq \gamma(p) < M(p)$.

The notion of partial hyperbolicity was introduced by Brin and Pesin [21] who proved existence and properties, including absolute continuity, of invariant foliations in this setting. There has been intense recent interest in partially hyperbolic systems primarily because significant progress has been made in establishing that certain volume-preserving partially hyperbolic systems are ‘stably ergodic’—that is, they are ergodic and under small (C^r topology) volume-preserving perturbations remain ergodic. This phenomenon had hitherto been restricted to uniformly hyperbolic systems. For recent developments, and precise statements, on stable ergodicity of partially hyperbolic systems see [24,92].

Compact Group Extensions of Uniformly Hyperbolic Systems

A natural example of a partially hyperbolic system is given by a compact group extension of an Anosov diffeomorphism. If the following terms are not familiar see Sect. “Constructions” on standard constructions. Suppose that (T, M, μ) is an Anosov diffeomorphism, G is a compact connected Lie group and $h: M \rightarrow G$ is a differentiable map. The skew product $F: M \times G \rightarrow M \times G$ given by

$$F(x, g) = (Tx, h(x)g)$$

has a central direction in its tangent space corresponding to the Lie algebra LG of G (as a group element h acts isometrically on G so there is no expansion or contraction) and uniformly expanding and contracting bundles corresponding to those of the tangent space of $T: M \rightarrow M$. Thus $T(M \times G) = E^u \oplus LG \oplus E^s$.

Time-One Maps of Anosov Flows

Another natural context in which partial hyperbolicity arises is in time-one maps of uniformly hyperbolic flows. Suppose $\phi_t: \mathbb{R} \times M \rightarrow M$ is an Anosov flow. The diffeomorphism $\phi_1: M \rightarrow M$ is a partially hyperbolic diffeomorphism with central direction given by the flow direction. There is no expansion or contraction in the central direction.

Non-Uniformly Hyperbolic Systems

The assumption of uniform hyperbolicity is quite restrictive and few ‘chaotic systems’ found in applications are likely to exhibit uniform hyperbolicity. A natural weakening of this assumption, and one that is non-trivial and

greatly extends the applicability of the theory, is to require the hyperbolic splitting (no longer uniform) to hold only at almost every point of phase space. A systematic theory was built by Pesin [89,90] on the assumption that the system has non-zero Lyapunov exponents μ almost everywhere where μ is a Lebesgue equivalent invariant probability measure. Recall that a number λ is a *Lyapunov exponent* for $p \in M$ if $\|D_p T^n v\| \sim e^{\lambda n}$ for some unit vector $v \in T_p M$. Oseledec's theorem [83] (see also p. 232 in [113]), which is also called the Multiplicative Ergodic Theorem, implies that if T is a C^1 diffeomorphism of M then for any T -invariant ergodic measure μ almost every point has well-defined Lyapunov exponents. One of the highlights of Pesin theory is the following structure theorem: If $T: M \rightarrow M$ is a $C^{1+\epsilon}$ diffeomorphism with a T -invariant Lebesgue equivalent Borel measure μ such that T has non-zero Lyapunov exponents with respect to μ then T has at most a countable number of ergodic components $\{C_i\}$ on each of which the restriction of T is either Bernoulli or Bernoulli times a rotation (by which we mean the support of $\mu_i = \mu|_{C_i}$ consists of a finite number n_i of sets $\{S_1^i, \dots, S_{n_i}^i\}$ cyclically permuted and T^{n_i} is Bernoulli when restricted to each S_j^i) [90,114]. This structure theorem has been generalized to SRB measures with non-zero Lyapunov exponents [64,90].

Physically Relevant Measures and Strange Attractors

(This paragraph is from the article on [► Measure Preserving Systems](#).) For Hamiltonian systems and other volume-preserving systems it is natural to consider ergodicity (and other statistical properties) of the system with respect to Lebesgue measure. In dissipative systems a measure equivalent to Lebesgue may not be invariant (for example the solenoid). Nevertheless Lebesgue measure has a distinguished role since sampling by experimenters is done with respect to Lebesgue measure. The idea of a physically relevant measure μ is that it determines the statistical behavior of a positive Lebesgue measure set of orbits, even though the support of μ may have zero Lebesgue measure. An example of such a situation in the uniformly hyperbolic setting is the solenoid Λ , where the attracting set Λ has Lebesgue measure zero and is (locally) topologically the product of a two-dimensional Cantor set and a line segment. Nevertheless Λ determines the behavior of all points in a solid torus in \mathbb{R}^3 . More generally, suppose that $T: M \rightarrow M$ is a diffeomorphism on a compact Riemannian manifold and that m is a version of Lebesgue measure on M , given by a smooth volume form. Although Lebesgue measure m is a distinguished physically relevant measure, m may not be invariant under T , and the system may even

be volume contracting in the sense that $m(T^n A) \rightarrow 0$ for all measurable sets A . Nevertheless an experimenter might observe long-term “chaotic” behavior whenever the state of the system gets close to some compact invariant set X which attracts a positive m -measure of orbits in the sense that these orbits limit on X . Possibly $m(X) = 0$, so that X is effectively invisible to the observer except through its effects on orbits not contained in X . The dynamics of T restricted to X can in fact be quite complicated—maybe a full shift, or a shift of finite type, or some other complicated topological dynamical system. Suppose there is a T -invariant measure μ supported on X such that for all continuous functions $\phi: M \rightarrow \mathbb{R}$

$$\frac{1}{n} \sum_{k=0}^{n-1} \phi \circ T^k(x) \rightarrow \int_X \phi \, d\mu, \quad (6)$$

for a positive m -measure of points $x \in M$. Then the long-term equilibrium dynamics of an observable set of points $x \in M$ (i. e. a set of points of positive m measure) is described by (X, T, μ) . In this situation μ is described as a *physical measure*. There has been a great deal of research on the properties of systems with attractors supporting physical measures.

In the dissipative non-uniformly hyperbolic setting the theory of ‘physically relevant’ measures is best developed in the theory of SRB (for Sinai, Ruelle and Bowen) measures. These dynamically invariant measures may be supported on a set of Lebesgue measure zero yet determine the asymptotic behavior of points in a set of positive Lebesgue measure.

If T is a diffeomorphism of M and μ is a T -invariant Borel probability measure with positive Lyapunov exponents which may be integrated to unstable manifolds, then we call μ an *SRB measure* if the conditional measure μ induces on the unstable manifolds is absolutely continuous with respect to the Riemannian volume element on these manifolds. The reason for this definition is technical but is motivated by the following observations. Suppose that the diffeomorphism has no zero Lyapunov exponents with respect to μ . Since T is a diffeomorphism, this implies T has negative Lyapunov exponents as well as positive Lyapunov exponents and corresponding local stable manifolds as well as local unstable manifolds. Suppose that a T -invariant set A consists of a union of unstable manifolds and is the support of an ergodic SRB measure μ and that $\phi: M \rightarrow \mathbb{R}$ is a continuous function. Since μ has absolutely continuous conditional measures on unstable manifolds with respect to conditional Lebesgue measure on the unstable manifolds, almost every point x in the

union of unstable manifolds U satisfies

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{j=0}^{n-1} \phi \circ T^j(x) = \int \phi \, d\mu . \tag{7}$$

If $y \in W_e^s(x)$ for such an $x \in U$ then $d(T^n x, T^n y) \rightarrow \infty$ and hence (7) implies

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{j=0}^{n-1} \phi \circ T^j(y) = \int \phi \, d\mu .$$

Furthermore, if the holonomy between unstable manifolds defined by sliding along stable manifolds is absolutely continuous (takes sets of zero Lebesgue measure on W^u to sets of zero Lebesgue measure on W^u), there is a positive Lebesgue measure of points (namely an unstable manifold and the union of stable manifolds through it) satisfying (7). Thus an SRB measure with absolutely continuous holonomy maps along stable manifolds is a physically relevant measure. If the stable foliation possesses this property it is called *absolutely continuous*. An Axiom A attractor for a C^2 diffeomorphism is an example of an SRB attractor [19,101,102,107]. The examples we have given of SRB measures and attractors and measures have been uniformly hyperbolic.

Recently much progress has been made in understanding the statistical properties of non-uniformly hyperbolic systems by using a tower (see Sect. “[Induced Transformations](#)”) to construct SRB measures. We refer to Young’s original papers [115,116], the book by Baladi [5] and to [114] for a recent survey on SRB measures in the non-uniformly hyperbolic setting.

Unimodal Maps Unimodal Maps of an interval are simple examples of non-uniformly hyperbolic dynamical systems that have played an important role in the development of dynamical systems theory. Suppose $I \subset \mathbb{R}$ is an interval; for simplicity we take $I = [0, 1]$. A *unimodal map* is a map $T: [0, 1] \rightarrow [0, 1]$ such that there exists a point $0 < c < 1$ and

- T is C^2 ;
- $T'(x) > 0$ for $x < c$, $T'(x) < 0$ for $x > c$;
- $T'(c) = 0$.

Such a map is clearly not uniformly expanding, as $|T'(x)| < 1$ for points in a neighborhood of c . The family of maps $T_\mu(x) = \mu x(1 - x)$, $0 < \mu \leq 4$, is a family of unimodal maps with $c = 1/2$ and $T_2(1/2) = 1/2$, $T_4(1/2) = 1$.

We could have taken the interval I to be $[-1, 1]$ or indeed any interval with an obvious modification of the definition above. A well-studied family of unimodal maps

in this setting is the *logistic family* $f_a: [-1, 1] \rightarrow [-1, 1]$, $f_a(x) = 1 - ax^2$, $a \in (0, 2]$. The families f_a and T_μ are equivalent under a smooth coordinate change, so statements about one family may be translated into statements about the other.

Unimodal maps are studied because of the insights they offer into transitions from regular or periodic to chaotic behavior as a parameter (e. g. μ or a) is varied, the existence of absolutely continuous measures, and rates of decay of correlations of regular observations for non-uniformly hyperbolic systems.

Results of Jakobson [52] and Benedicks and Carleson [6] implies that in the case of the logistic family there is a positive Lebesgue measure set of a such that f_a has an absolutely continuous ergodic invariant measure μ_a . It has been shown by Keller and Nowicki [57] (see also Young [116]) that if f_a is mixing with respect to μ_a then the decay of correlations for Lipschitz observations on I is exponential. It is also known that the set of a such that f_a is mixing with respect to μ_a has positive Lebesgue measure. There is a well-developed theory concerning bifurcations the maps T_μ undergo as μ varies [27]. We briefly describe the period-doubling route to chaos in the family $T_\lambda(x) = \lambda x(1 - x)$. For a nice account see [46]. We let c_λ denote the fixed point $\frac{\lambda-1}{\lambda}$. For $3 < \lambda \leq 1 + \sqrt{6}$, all points in $[0, 1]$ except for $0, c_\lambda$ and their preimages are attracted to a unique periodic orbit $O(p_\lambda)$ of period 2. There is a monotone sequence of parameter values λ_n ($\lambda_1 = 3$) such that for $\lambda_n < \lambda \leq \lambda_{n+1}$, T_λ has a unique attracting periodic orbit $O(\lambda_n)$ of period 2^n and for each $k = 1, 2, \dots, n - 1$ a unique repelling orbit of period 2^k . All points in the interval $[0, 1]$ except for the repelling periodic orbits and their preimages are attracted to the attracting periodic orbit of period 2^n . At $\lambda = \lambda_n$ the periodic orbit $O(\lambda_n)$ undergoes a period-doubling bifurcation. Feigenbaum [36] found that the limit $\delta = \frac{\lambda_n - \lambda_{n-1}}{\lambda_{n+1} - \lambda_n} \sim 4.699 \dots$ exists and that in a wide class of unimodal maps this period-doubling cascade occurs and the differences between successive bifurcation parameters give the same limiting ratio, an example of *universality*. At the end of the period-doubling cascade at a parameter $\lambda_\infty \sim 3.569 \dots$, T_{λ_∞} has an invariant Cantor set C (the Feigenbaum attractor) which is topologically conjugate to the dyadic adding machine coexisting with isolated repelling orbits of period 2^n , $n = 0, 1, 2, \dots$. There is a unique repelling orbit of period 2^n for $n \geq 1$ along with two fixed points. The Cantor set C is the ω -limit set for all points that are not periodic or preimages of periodic orbits. C is the set of accumulation points of periodic orbits. Despite this picture of incredible complexity the topological entropy is zero for $\lambda \leq \lambda_\infty$. For $\lambda > \lambda_\infty$ the map T_λ

has positive topological entropy and infinitely many periodic orbits whose periods are not powers of 2. For each $\lambda \geq \lambda_\infty$, T_λ possesses an invariant Cantor set which is repelling for $\lambda > \lambda_\infty$. We say that T_λ is *hyperbolic* if there is only one attracting periodic orbit and the only recurrent sets are the attracting periodic orbit, repelling periodic orbits and possibly a repelling invariant Cantor set. It is known that the set of $\lambda \in [0, 4]$ for which T_λ is hyperbolic is open and dense [43]. Remarkably, by Jakobson's result [52] there is also a positive Lebesgue measure set of parameters λ for which T_λ has an absolutely continuous invariant measure μ_λ with a positive Lyapunov exponent.

Intermittent Maps Maps of the unit interval $T: [0, 1] \rightarrow [0, 1]$ which are expanding except at the point $x = 0$, where they are locally of form $T(x) \sim x + x^{1+\alpha}$, $\alpha > 0$, have been extensively studied both for the insights they give into rates of decay of correlations for non-uniformly hyperbolic systems (hyperbolicity is lost at the point $x = 0$, where the derivative is 1) and for their use as models of intermittent behavior in turbulence [71]. A fixed point where the derivative is 1 is sometimes called an *indifferent fixed point*. It is a model of *intermittency* in the sense that orbits close to 1 will stay close for many iterates (since the expansion is very weak there) and hence a time series of observations will be quite uniform for long periods of time before displaying chaotic type behavior after moving away from the indifferent fixed into that part of the domain where the map is uniformly expanding.

A particularly simple model [67] is provided by

$$T(x) = \begin{cases} x(1 + 2^\alpha x^\alpha) & \text{if } x \in [0, 1/2); \\ 2x - 1 & \text{if } x \in [1/2, 1]. \end{cases}$$

For $\alpha = 0$ the map is uniformly expanding and Lebesgue measure is invariant. In this case the rate of decay of correlations for Hölder observations is exponential. For $0 < \alpha < 1$ the map has an SRB measure μ_α with support the unit interval. For $\alpha \geq 1$ there are no absolutely continuous invariant probability measures though there are σ -finite absolutely continuous measures. Upper and lower polynomial bounds on the rate of decay of observations on such maps have been given as a function of $0 < \alpha < 1$ and the regularity of the observable. For details see [51,67,103].

Hénon Diffeomorphisms The Hénon family of diffeomorphisms was introduced and studied as Poincaré maps for the Lorenz system of equations. It is a two-parameter two-dimensional family which shares many characteristics with the logistic family and for small $b > 0$ may be considered a two-dimensional 'perturbation' of the logistic fam-

ily. The parametrized mapping is defined as

$$T_{a,b}(x, y) = (1 - ax^2 + y, bx),$$

so $T_{a,b}: \mathbb{R}^2 \rightarrow \mathbb{R}^2$ with $0 < a < 2$ and $b > 0$. Benedicks and Carleson [7] showed that for a positive-measure set of parameters (a, b) , $T_{a,b}$ has a topologically transitive attractor $\Lambda_{a,b}$. Benedicks and Young [8] later proved that for a positive-measure set of parameters (a, b) , $T_{a,b}$ has a topologically transitive SRB attractor $\Lambda_{a,b}$ with SRB measure $\mu_{a,b}$ and that $(T_{a,b}, \Lambda_{a,b}, \mu_{a,b})$ is isomorphic to a Bernoulli shift.

Complex Dynamics

Complex dynamics is concerned with the behavior of rational maps

$$\frac{\alpha_1 z^d + \alpha_2 z^{d-1} + \cdots + \alpha_{d+1}}{\beta_1 z^d + \beta_2 z^{d-1} + \cdots + \beta_{d+1}}$$

of the extended complex plane $\hat{\mathbb{C}}$ to itself, in which the domain is \mathbb{C} completed with the point at infinity (called the Riemann sphere). Recall that a family F of meromorphic functions is called *normal* on a domain D if every sequence possesses a subsequence that converges uniformly (in the spherical metric $\hat{\mathbb{C}} \sim S^2$) on compact subsets of D . A family is *normal at a point* $z \in \hat{\mathbb{C}}$ if it is normal on a neighborhood of z . The *Fatou set* $F(R) \subset \hat{\mathbb{C}}$ of a rational map $R: \hat{\mathbb{C}} \rightarrow \hat{\mathbb{C}}$ is the set of points $z \in \hat{\mathbb{C}}$ such that the family of forward iterates $\{R^n\}_{n \geq 0}$ is normal at z . The *Julia set* $J(R)$ is the complement of the Fatou set $F(R)$. The Fatou set is open and hence the Julia set is a closed set. Another characterization in the case $d > 1$ is that $J(R)$ is the closure of the set of all repelling periodic orbits of $R: \hat{\mathbb{C}} \rightarrow \hat{\mathbb{C}}$. Both $F(R)$ and $J(R)$ are invariant under R . The dynamics of greatest interest is the restriction $R: J(R) \rightarrow J(R)$. The Julia set often has a complicated fractal structure. In the case that $R_a(z) = z^2 - a$, $a \in \mathbb{C}$, the *Mandelbrot set* is defined as the set of a for which the orbit of the origin 0 is bounded. The topology of the Mandelbrot set has been the subject of intense research. The study of complex dynamics is important because of the fascinating and complicated dynamics displayed and also because techniques and results in complex dynamics have direct implications for the behavior of one-dimensional maps. For more details see [25].

Infinite Ergodic Theory

We may also consider a measure-preserving transformation (T, X, μ) of a measure space such that $\mu(X) = \infty$. For example X could be the real line equipped with Lebesgue measure. This setting also arises with compact X

in applications. For example, suppose $T: [0, 1] \rightarrow [0, 1]$ is the simple model of intermittency given in Sect. “Intermittent Maps” and $\gamma \in (1, 2)$. Then T possesses an absolutely continuous invariant measure μ with support $[0, 1]$, but $\mu([0, 1]) = \infty$. The Radon–Nikodym derivative of μ with respect to Lebesgue measure m exists but is not in $L^1(m)$.

In this setting we say a measurable set A is a *wandering set* for T if $\{T^{-n}A\}_{n=0}^\infty$ are disjoint. Let $D(T)$ be the measurable union of the collection of wandering sets for T . The transformation T is *conservative* with respect to μ if $(X \setminus D(T)) = X \pmod{\mu}$ (see the article on [Measure Preserving Systems](#)). It is usually necessary to assume T conservative with respect to μ to say anything interesting about its behavior. For example if $T(x) = x + \alpha$, $\alpha > 0$, is a translation of the real line then $D(T) = X$. The definition of ergodicity in this setting remains the same: T is *ergodic* if $A \in \mathcal{B}$ and $T^{-1}A = A \pmod{\mu}$ implies that $\mu(A) = 0$ or $\mu(A^c) = 0$. However the equivalence of ergodicity of T with respect to μ and the equality of time and space averages for $L^1(\mu)$ functions no longer holds. Thus in general μ ergodic does not imply that

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{i=0}^{n-1} \phi \circ T^i(x) = \int_X \phi \, d\mu \quad \mu \text{ a.e. } x \in X$$

for all $\phi \in L^1(\mu)$. In the example of the intermittent map with $\gamma \in (1, 2)$ the orbit of Lebesgue almost every $x \in X$ is dense in X , yet the fraction of time spent near the indifferent fixed point $x = 0$ tends to one for Lebesgue almost every $x \in X$. In fact it may be shown Sect. 2.4 in [1] that when $\mu(x) = \infty$ there are no constants $a_n > 0$ such that

$$\lim_{n \rightarrow \infty} \frac{1}{a_n} \sum_{i=0}^{n-1} \phi \circ T^i(x) = \int_X \phi \, d\mu \quad \mu \text{ a.e. } x \in X$$

Nevertheless it is sometimes possible to obtain distributional limits, rather than almost sure limits, of Birkhoff sums under suitable normalization. We refer the reader to Aaronson’s book [1] for more details.

Constructions

We give examples of some of the standard constructions in dynamical systems. Often these constructions appear in modeling situations (for example skew products are often used to model systems which react to inputs from other systems, continuous time systems are often modeled as suspension flows over discrete-time dynamics) or to reduce systems to simpler components (often a factor system or induced system is simpler to study). Unless stated otherwise, in the sequel we will be discussing measure-preserving

transformations on Lebesgue spaces (see the article on [Measure Preserving Systems](#)).

Products

Given measure-preserving systems (X, \mathcal{B}, μ, T) and (Y, \mathcal{C}, ν, S) , their *product* consists of their completed product measure space with the transformation $T \times S: X \times Y \rightarrow X \times Y$ defined by $(T \times S)(x, y) = (Tx, Sy)$ for all $(x, y) \in X \times Y$. Neither ergodicity nor transitivity is in general preserved by taking products; for example the product of an irrational rotation on the unit circle with itself is not ergodic. For a list of which mixing properties are preserved in various settings by forming a product see [113]. Given any countable family of measure-preserving transformations on probability spaces, their direct product is defined similarly.

Factors

We say that a measure-preserving system (Y, \mathcal{C}, ν, S) is a *factor* of a measure-preserving system (X, \mathcal{B}, μ, T) if (possibly after deleting a set of measure 0 from X) there is a measurable onto map $\phi: X \rightarrow Y$ such that

$$\begin{aligned} \phi^{-1}C &\subset \mathcal{B}, \\ \phi T &= S\phi, \quad \text{and} \\ \mu T^{-1} &= \nu. \end{aligned} \tag{8}$$

For Lebesgue spaces, there is a correspondence of factors of (X, \mathcal{B}, μ, T) and T -invariant complete sub- σ -algebras of \mathcal{B} . According to Rokhlin’s theory of Lebesgue spaces [98] factors also correspond to certain partitions of X (see the article on [Measure Preserving Systems](#)). A factor map $\phi: X \rightarrow Y$ between Lebesgue spaces is an *isomorphism* if and only if it has a measurable inverse, or equivalently $\phi^{-1}C = \mathcal{B}$ up to sets of measure 0.

Skew Products

If (X, \mathcal{B}, μ, T) is a measure-preserving system, (Y, \mathcal{C}, ν) is a measure-space, and $\{S_x: x \in X\}$ is a family of measure-preserving maps $Y \rightarrow Y$ such that the map that takes (x, y) to $S_x y$ is jointly measurable in the two variables x and y , then we may define a *skew product system* consisting of the product measure space of X and Y equipped with product measure $\mu \times \nu$ together with the measure-preserving map $T \times S: X \times Y \rightarrow X \times Y$ defined by

$$(T \times S)(x, y) = (Tx, S_x y). \tag{9}$$

The space Y is called the *fiber* of the skew product and the space X the *base*. Sometimes in the literature the word

skew product has a more general meaning and refers to the structure $(T \times S)(x, y) = (Tx, S_x y)$ (without any assumption of measure-preservation), where the action of the map on the fiber Y is determined or ‘driven’ by the map $T: X \rightarrow X$.

Some common examples of skew products include:

Random Dynamical Systems Suppose that X indexes a collection of mappings $S_x: Y \rightarrow Y$. We may have a transformation $T: X \rightarrow X$ which is a full shift. Then the sequence of mappings $\{S_{T^n x}\}$ may be considered a (random) choice of a mapping $Y \rightarrow Y$ from the set $\{S_x: x \in X\}$. The projection onto Y of the orbits of $(Tx, S_x y)$ give the orbits of a point $y \in Y$ under a random composition of maps $S_{T^n x} \circ \dots \circ S_{Tx} \circ S_x$. More generally we could consider the choice of maps S_x that are composed to come from any ergodic dynamical system, (T, X, μ) to model the effect of perturbations by a stationary ergodic ‘noise’ process.

Group Extensions of Dynamical Systems Suppose Y is a group, ν is a measure on Y invariant under a left group action, and $S_x y := g(x)y$ is given by a group-valued function $g: X \rightarrow Y$. In this setting g is often called a *cocycle*, since upon defining $g^{(n)}(x)$ by $(T \times S)^{(n)}(x, y) = (T^n x, g^{(n)}(x)y)$ we have a cocycle relation, namely $g^{(m+n)}(x) = g^{(m)}(T^n x)g^{(n)}(x)$. Group extensions arise often in modeling systems with symmetry [37]. Common examples are provided by a random composition of matrices from a group of matrices (or more generally from a set of matrices which may form a group or not).

Induced Transformations

Since by the Poincaré Recurrence Theorem (see [113]) a measure-preserving transformation (T, X, μ, \mathcal{B}) on a probability space is recurrent, given any set B of positive measure, the return-time function

$$n_B(x) = \inf\{n \geq 1: T^n x \in B\} \tag{10}$$

is finite μ a.e. We may define the *first-return map* by

$$T_B x = T^{n_B(x)} x. \tag{11}$$

Then (after perhaps discarding as usual a set of measure 0) $T_B: B \rightarrow B$ is a measurable transformation which preserves the probability measure $\mu_B = \mu/\mu(B)$. The system $(B, \mathcal{B} \cap B, \mu_B, T_B)$ is called an *induced, first-return or derived transformation*. If (T, X, μ, \mathcal{B}) is ergodic then $(B, \mathcal{B} \cap B, \mu_B, T_B)$ is ergodic, but the converse is not in general true.

The construction of the transformation T_B allows us to represent the forward orbit of points in B via a *tower or skyscraper* over B . For each $n = 1, 2, \dots$, let

$$B_n = \{x \in B: n_B(x) = n\}. \tag{12}$$

Then $\{B_1, B_2, \dots\}$ form a partition of B , which we think of as the bottom floor or base of the tower. The next floor is made up of TB_2, TB_3, \dots , which form a partition of $TB \setminus B$, and so on. All these sets are disjoint. A *column* is a part of the tower of the form $B_n \cup TB_n \cup \dots \cup T^{n-1}B_n$ for some $n = 1, 2, \dots$. The action of T on the entire tower is pictured as mapping each x not at the top of its column straight up to the point Tx above it on the next level, and mapping each point on the top level to $T^{n_B} x \in B$. An equivalent way to describe the transformation on the tower is to write for each n and $j < n$, $T^j B_n$ as $\{(x, j): x \in B_n\}$, and then the transformation F on the tower is

$$F(x, l) = \begin{cases} (x, l + 1) & \text{if } l < n_B(x) - 1; \\ (T^{n_B(x)} x, 0) & \text{if } l = n_B(x) - 1. \end{cases}$$

If T preserves a measure μ , then F preserves $\mu \times dl$, where l is counting measure.

Sometimes the process of inducing yields an induced map which is easier to analyze (perhaps it has stronger hyperbolicity properties) than the original system. Sometimes it is possible to ‘lift’ ergodic or statistical properties from an induced system to the original system, so the process of inducing plays an important role in the study of statistical properties of dynamical systems [77].

It is possible to generalize the tower construction and relax the condition that $n_B(x)$ is the first-return time function. We may take a measurable set $B \subset X$ of positive μ measure and define for almost every point $x \in B$ a *height or ceiling* function $R: B \rightarrow \mathbb{N}$ and take a countable partition $\{X_n\}$ of B into the sets on which R is constant. We define the *tower* as the set $\Delta := \{(x, l): x \in B, 0 \leq l < R(x)\}$ and the *tower map* $F: \Delta \rightarrow \Delta$ by

$$F(x, l) = \begin{cases} (x, l + 1) & \text{if } l < R(x) - 1; \\ (T^{R(x)} x, 0) & \text{if } l = R(x) - 1. \end{cases}$$

In this setting, if $\int_B R(x) d\mu < \infty$, we may define an F -invariant probability measure on Δ as $\frac{\mu}{C(R, B)} \times dl$, where dl is counting measure and $C(R, B)$ is the normalizing constant $C(R, B) = \mu(B) \int_B R(x) d\mu$. This viewpoint is connected with the construction of systems by cutting and stacking—see Sect. ‘Cutting and Stacking’.

Suspension Flows

The tower construction has an analogue in which the height function R takes values in \mathbb{R} rather than \mathbb{N} . Such towers are commonly used to model dynamical systems with continuous time parameter. Let (T, X, μ) be a measure-preserving system and $R: X \rightarrow (0, \infty)$ a measurable “ceiling” function on X . The set

$$X^R = \{(x, t): 0 \leq R(x) < t\}, \tag{13}$$

with measure ν given locally by the product of μ on X with Lebesgue measure m on \mathbb{R} , is a measure space in a natural way. If μ is a finite measure and R is integrable with respect to μ then ν is a finite measure. We define an action of \mathbb{R} on X^R by letting each point x flow at unit speed up the vertical lines $\{(x, t): 0 \leq t < R(x)\}$ under the graph of R until it hits the ceiling, then jump to Tx , and so on. More precisely, defining $R_n(x) = R(x) + \dots + R(T^n x)$,

$$T_s(x, t) = \begin{cases} (x, s + t) & \text{if } 0 \leq s + t < R(x), \\ (Tx, s + t - R(x)) & \text{if } R(x) \leq s + t < R(x) + R(Tx) \\ \dots & \dots \\ (T^n x, s + t - [R(x) + \dots + R(T^{n-1} x)]) & \text{if } R_{n-1}(x) \leq s + t < R_n(x). \end{cases} \tag{14}$$

Ergodicity of (T, X, μ) implies the ergodicity of (T_s, X^R, ν) .

Cutting and Stacking

Several of the most interesting examples in ergodic theory have been constructed by this method; in fact, because of Rokhlin’s Lemma (see Sect. “Rokhlin’s Lemma”) every ergodic measure-preserving transformation on a Lebesgue space is isomorphic to one constructed by cutting and stacking. For example, the von Neumann-Kakutani adding machine (or 2-odometer) (Sect. “Adding Machines”), the Chacon weakly mixing but not strongly mixing system (Sect. “Chacon System”), Ornstein’s mixing rank one examples (see e.g. p. 160 ff. in [80]), and many more.

We construct a Lebesgue measure-preserving transformation T on an interval X (bounded or maybe unbounded) by defining it as a translation on each of a pairwise disjoint countable collection of subintervals. The construction proceeds by stages, at each stage defining T on an additional part of X , until eventually T is defined a.e.

At each stage X is represented as a *tower*, which is defined to be a disjoint union of *columns*. A *column* is defined

to be a finite disjoint union of intervals of equal length, which are numbered from 0, for the “floor”, to the last one, for the “roof”, and which we picture as lying each above the preceding-numbered interval. T is defined on each *level* of a column (i. e. each interval in the column) except the roof by mapping it by translation to the next higher interval in the column.

At stage 0, we have just one column, consisting of all of X as the floor, and T is not defined anywhere. To pass from one stage to the next, the columns are *cut* and *stacked*. This means that each column is divided, by vertical cuts, into a disjoint union of subcolumns of equal height (but maybe not equal width), and then some of these subcolumns are stacked above others (of the same width) so as to form a new tower. This allows the definition of T to be extended to some parts of X that were previously tops of towers, since they now may have levels above them. (Sometimes columns of height 1 are thought of as forming a reservoir for “spacers” to be inserted between subcolumns that are being stacked.) If the measure of the union of the tops of the columns tends to 0, eventually T becomes defined a.e. This description in words can be made precise with cumbersome notation, but the process can also be given a neater graphical description, which we sketch in the next section.

Adic Transformations

A.M. Vershik has introduced a family of models, called *adic* or *Bratteli–Vershik* transformations, into ergodic theory and dynamical systems. One begins with a graph which is arranged in levels, finitely many vertices on each level, with connections only from each level to the adjacent ones. The space X consists of the set of all infinite paths in this graph; it is a compact metric space in a natural way. We are given an order on the set of edges into each vertex, and then X is partially ordered as follows: x and y are comparable if they agree from some point on, in which case we say that $x < y$ if at the last level n where they traverse different edges, the edge x_n of x is smaller than the edge y_n of y . A map T is defined by letting Tx be the smallest y that is larger than x , if there is one. In nice situations, T is a homeomorphism after defining it and its inverse on perhaps countably many maximal and minimal elements. Invariant measures can sometimes be defined by assigning weights to edges, which are then multiplied to define the measure of each cylinder set. This is a nice combinatorial way to present the cutting and stacking method of constructing m.p.t.’s, allows for more convenient analysis of questions such as orbit equivalence, and leads to the construction of many interesting examples, such as those

based on the Pascal or Euler graphs [4,38,76]. Odometers and generalizations are natural examples of adic systems. Vershik showed that in fact every ergodic measure-preserving transformation on a Lebesgue space is isomorphic to a uniquely ergodic adic transformation. See [111].

Rokhlin's Lemma

The following result is the fundamental starting point for many constructions in ergodic theory, from representing arbitrary systems in terms of cutting and stacking or adic systems, to constructing useful partitions and symbolic codings of abstract systems, to connecting convergence theorems in abstract ergodic theory with those in harmonic analysis. It allows us to picture arbitrarily long stretches of the action of a measure-preserving transformation as a translation within the set of integers. In the ergodic nonatomic case the statement follows readily from the construction of induced transformations.

Lemma 1 (Rokhlin's Lemma) *Let $T: X \rightarrow X$ be a measure-preserving transformation on a probability space (X, \mathcal{B}, μ) . Suppose that (X, \mathcal{B}, μ) is nonatomic and $T: X \rightarrow X$ is ergodic, or, more generally, (T, X, \mathcal{B}, μ) is aperiodic: that is to say, the set $\{x \in X: \text{there is } n \in \mathbb{N} \text{ such that } T^n x = x\}$ of periodic points has measure 0. Then given $n \in \mathbb{N}$ and $\epsilon > 0$, there is a measurable set $B \subset X$ such that the sets $B, TB, \dots, T^{n-1}B$ are pairwise disjoint and $\mu(\bigcup_{k=0}^{n-1} T^k B) > 1 - \epsilon$.*

Inverse Limits

Suppose that for each $i = 1, 2, \dots$ we have a Lebesgue probability space $(X_i, \mathcal{B}_i, \mu_i)$ and a measure-preserving transformation $T_i: X_i \rightarrow X_i$. Suppose also that for each $i \leq j$ there is a factor map $\phi_{ji}: (T_j, X_j, \mathcal{B}_j, \mu_j) \rightarrow (T_i, X_i, \mathcal{B}_i, \mu_i)$, such that each ϕ_{jj} is the identity on X_j and $\phi_{ji}\phi_{kj} = \phi_{ki}$ whenever $k \geq j \geq i$. Let

$$X = \{x \in \prod_{i=1}^{\infty} X_i: \phi_{ji}x_j = x_i \text{ for all } j \geq i\}. \quad (15)$$

For each j , let $\pi_j: X \rightarrow X_j$ be the projection defined by $\pi_j x = x_j$.

Let \mathcal{B} be the smallest σ -algebra of subsets of X which contains all the $\pi_j^{-1}\mathcal{B}_j$. Define μ on each $\pi_j^{-1}\mathcal{B}_j$ by

$$\mu(\pi_j^{-1}B) = \mu_j(B) \quad \text{for all } B \in \mathcal{B}_j. \quad (16)$$

Because $\phi_{ji}\pi_j = \pi_i$ for all $j \geq i$, the $\pi_j^{-1}\mathcal{B}_j$ are increasing, and so their union is an algebra. The set function μ can, with some difficulty, be shown to be countably additive on this algebra: since we are dealing with Lebesgue spaces, by means of measure-theoretic isomorphisms it is possible to replace the entire situation by compact metric spaces and

continuous maps, then use regularity of the measures involved—see p. 137 ff. in [88]. Thus by Carathéodory's Theorem (see the article on [▶ Measure Preserving Systems](#)) μ extends to all of \mathcal{B} .

Define $T: X \rightarrow X$ by $T(x_j) = (T_j x_j)$. Then (T, X, \mathcal{B}, μ) is a measure-preserving system such that any system which has all the $(T_j, X_j, \mathcal{B}_j, \mu_j)$ as factors, also has (T, X, \mathcal{B}, μ) a factor.

Natural Extension

The natural extension is a way to produce an invertible system from a non-invertible system. The original system is a factor of its natural extension and its orbit structure and ergodic properties are captured by the natural extension, as will be seen from its construction. Let (T, X, \mathcal{B}, μ) be a measure-preserving transformation of a Lebesgue probability space. Define

$$\begin{aligned} \Omega &:= \{(x_0, x_1, x_2, \dots): x_n \\ &= T(x_{n+1}), x_n \in X, n = 0, 1, 2, \dots\} \end{aligned}$$

with $\sigma: \Omega \rightarrow \Omega$ defined by $\sigma((x_0, x_1, x_2, \dots)) = (T(x_0), x_0, x_1, \dots)$. The map σ is invertible on Ω . Given the invariant measure μ we define the invariant measure for the natural extension $\tilde{\mu}$ on Ω by defining it first on cylinder sets $C(A_0, A_1, \dots, A_k)$ by

$$\begin{aligned} \tilde{\mu}(C(A_0, A_1, \dots, A_k)) \\ = \mu(T^{-k}(A_0) \cap T^{-k+1}(A_1) \cdots \cap T^{-k+i}(A_i) \cap \cdots \cap A_k) \end{aligned}$$

and then extending it to Ω using Kolmogorov's extension theorem. We think of (x_0, x_1, x_2, \dots) as being an inverse branch of $x_0 \in X$ under the mapping $T: X \rightarrow X$. The maps $\sigma, \sigma^{-1}: \Omega \rightarrow \Omega$ are ergodic with respect to $\tilde{\mu}$ if (T, X, \mathcal{B}, μ) is ergodic [113]. If $\pi: \Omega \rightarrow X$ is projection onto the first component i. e. $\pi(x_0, \dots, x_n, \dots) = x_0$ then $\pi \circ \sigma^n(x_0, \dots, x_n, \dots) = T^n(x_0)$ for all x_0 and thus the natural extension yields information about the orbits of X under T .

The natural extension is an inverse limit. Let (X, \mathcal{B}, μ) be a Lebesgue probability space and $T: X \rightarrow X$ a map such that $T^{-1}\mathcal{B} \subset \mathcal{B}$ and $\mu T^{-1} = \mu$. For each $i = 1, 2, \dots$ let $(T_i, X_i, \mathcal{B}_i, \mu_i) = (T, X, \mathcal{B}, \mu)$, and $\phi_{ji} = T^{j-i}$ for each $j > i$. Then the inverse limit $(\hat{T}, \hat{X}, \hat{\mathcal{B}}, \hat{\mu})$ of this system is an invertible measure-preserving system which is the natural extension of (T, X, \mathcal{B}, μ) . We have

$$\hat{T}^{-1}(x_1, x_2, \dots) = (x_2, x_3, \dots). \quad (17)$$

The original system (T, X, \mathcal{B}, μ) is a factor of $(\hat{T}, \hat{X}, \hat{\mathcal{B}}, \hat{\mu})$ (using any π_i as the factor map), and any factor mapping from an invertible system onto (T, X, \mathcal{B}, μ) consists

of a factor mapping onto $(\hat{T}, \hat{X}, \hat{B}, \hat{\mu})$ followed by projection onto the first coordinate.

Joinings

Given measure-preserving systems (T, X, \mathcal{B}, μ) and (S, Y, \mathcal{C}, ν) , a *joining* of the two systems is a $T \times S$ -invariant measure P on their product measurable space that projects to μ and ν , respectively, under the projections of $X \times Y$ to X and Y , respectively. That is, if $\pi_1: X \times Y \rightarrow X$ is the projection onto the first component i.e. $\pi_1(x, y) = x$ then $P(\pi_1^{-1}(A)) = \mu(A)$ for all $A \in \mathcal{B}$ and similarly for $\pi_2: X \times Y \rightarrow Y$.

This concept is the ergodic-theoretic version of the notion in probability theory of a *coupling*. The product measure $\mu \times \nu$ is always a joining of the two systems. If product measure is the only joining of the two systems, then we say that they are disjoint and write $X \perp Y$ [40]. If \mathcal{D} is any family of systems, we write \mathcal{D}^\perp for the family of all measure-preserving systems which are disjoint from every system in \mathcal{D} . Extensive recent accounts of the use of joinings in ergodic theory are in [42,99,110].

Future Directions

The basic examples and constructions presented here are idealized, and many of the underlying assumptions (such as uniform hyperbolicity) are seldom satisfied in applications, yet they have given important insights into the behavior of real-world physical systems. Recent developments have improved our understanding of the ergodic properties of non-uniformly and partially hyperbolic systems. The ergodic properties of deterministic systems will continue to be an active research area for the foreseeable future. The directions will include, among others: establishing statistical and ergodic properties under weakened dependence assumptions; the study of systems which display ‘anomalous statistics’; the study of the stability and typicality of ergodic behavior and mixing in dynamical systems; the ergodic theory of infinite-dimensional systems; advances in number theory (see the sections on Szemerédi and Ramsey theory); research into models with non-singular rather than invariant measures; and infinite-measure systems. Other chapters in this Encyclopedia discuss in more detail these and other topics.

Glossary

Configuration space and the shift Let \mathbb{M} be a finitely generated group or monoid (usually abelian). Typically, $\mathbb{M} = \mathbb{N} := \{0, 1, 2, \dots\}$ or $\mathbb{M} = \mathbb{Z} := \{\dots, -1, 0, 1, 2, \dots\}$, or $\mathbb{M} = \mathbb{N}^E$, \mathbb{Z}^D , or $\mathbb{Z}^D \times \mathbb{N}^E$ for some $D, E \in \mathbb{N}$. In some applications, \mathbb{M} could be nonabelian (although usually amenable), but to avoid notational complexity we will generally assume \mathbb{M} is abelian and additive, with operation ‘+’.

Let \mathcal{A} be a finite set of symbols (called an *alphabet*). Let $\mathcal{A}^{\mathbb{M}}$ denote the set of all functions $\mathbf{a}: \mathbb{M} \rightarrow \mathcal{A}$, which we regard as \mathbb{M} -indexed *configurations* of elements in \mathcal{A} . We write such a configuration as $\mathbf{a} = [a_m]_{m \in \mathbb{M}}$, where $a_m \in \mathcal{A}$ for all $m \in \mathbb{M}$, and refer to $\mathcal{A}^{\mathbb{M}}$ as *configuration space*.

Treat \mathcal{A} as a discrete topological space; then \mathcal{A} is compact (because it is finite), so $\mathcal{A}^{\mathbb{M}}$ is compact in the Tychonoff product topology. In fact, $\mathcal{A}^{\mathbb{M}}$ is a *Cantor space*: it is compact, perfect, totally disconnected, and metrizable. For example, if $\mathbb{M} = \mathbb{Z}^D$, then the standard metric on $\mathcal{A}^{\mathbb{Z}^D}$ is defined $d(\mathbf{a}, \mathbf{b}) = 2^{-\Delta(\mathbf{a}, \mathbf{b})}$, where $\Delta(\mathbf{a}, \mathbf{b}) := \min\{|z|; a_z \neq b_z\}$.

Any $\mathbf{v} \in \mathbb{M}$, determines a continuous *shift map* $\sigma^{\mathbf{v}}: \mathcal{A}^{\mathbb{M}} \rightarrow \mathcal{A}^{\mathbb{M}}$ defined by $\sigma^{\mathbf{v}}(\mathbf{a})_m = a_{m+\mathbf{v}}$ for all $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$ and $m \in \mathbb{M}$. The set $\{\sigma^{\mathbf{v}}\}_{\mathbf{v} \in \mathbb{M}}$ is then a continuous \mathbb{M} -action on $\mathcal{A}^{\mathbb{M}}$, which we denote simply by “ σ ”.

If $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$ and $\mathbb{U} \subset \mathbb{M}$, then we define $\mathbf{a}_{\mathbb{U}} \in \mathcal{A}^{\mathbb{U}}$ by $\mathbf{a}_{\mathbb{U}} := [a_u]_{u \in \mathbb{U}}$. If $m \in \mathbb{M}$, then strictly speaking, $\mathbf{a}_{m+\mathbb{U}} \in \mathcal{A}^{m+\mathbb{U}}$; however, it will often be convenient to ‘abuse notation’ and treat $\mathbf{a}_{m+\mathbb{U}}$ as an element of $\mathcal{A}^{\mathbb{U}}$ in the obvious way.

Cellular automata Let $\mathbb{H} \subset \mathbb{M}$ be some finite subset, and let $\phi: \mathcal{A}^{\mathbb{H}} \rightarrow \mathcal{A}$ be a function (called a *local rule*). The *cellular automaton* (CA) determined by ϕ is the function $\Phi: \mathcal{A}^{\mathbb{M}} \rightarrow \mathcal{A}^{\mathbb{M}}$ defined by $\Phi(\mathbf{a})_m = \phi(\mathbf{a}_{m+\mathbb{H}})$ for all $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$ and $m \in \mathbb{M}$. Curtis, Hedlund and Lyndon showed that cellular automata are exactly the continuous transformations of $\mathcal{A}^{\mathbb{M}}$ which commute with all shifts (see Theorem 3.4 in [58]). We refer to \mathbb{H} as the *neighborhood* of Φ . For example, if $\mathbb{M} = \mathbb{Z}$, then typically $\mathbb{H} := [-l \dots r] := \{-l, 1-l, \dots, r-1, r\}$ for some *left radius* $l \geq 0$ and *right radius* $r \geq 0$. If $-l \geq 0$, then ϕ can either define CA on $\mathcal{A}^{\mathbb{N}}$ or define a *one-sided* CA on $\mathcal{A}^{\mathbb{Z}}$. If $\mathbb{M} = \mathbb{Z}^D$, then typically

$\mathbb{H} \subseteq [-R \dots R]^D$, for some *radius* $R \geq 0$. Normally we assume that ℓ , r , and R are chosen to be minimal. Several specific classes of CA will be important to us:

Linear CA Let $(\mathcal{A}, +)$ be a finite abelian group (e. g. $\mathcal{A} = \mathbb{Z}/p$, where $p \in \mathbb{N}$; usually p is prime). Then Φ is a *linear CA* (LCA) if the local rule ϕ has the form

$$\phi(\mathbf{a}_{\mathbb{H}}) := \sum_{h \in \mathbb{H}} \varphi_h(a_h), \quad \forall \mathbf{a}_{\mathbb{H}} \in \mathcal{A}^{\mathbb{H}}, \quad (1)$$

where $\varphi_h: \mathcal{A} \rightarrow \mathcal{A}$ is an endomorphism of $(\mathcal{A}, +)$, for each $h \in \mathbb{H}$. We say that Φ has *scalar coefficients* if, for each $h \in \mathbb{H}$, there is some scalar $c_h \in \mathbb{Z}$, so that $\varphi_h(a_h) := c_h \cdot a_h$; then $\phi(\mathbf{a}_{\mathbb{H}}) := \sum_{h \in \mathbb{H}} c_h a_h$. For example, if $\mathcal{A} = (\mathbb{Z}/p, +)$, then *all* endomorphisms are scalar multiplications, so *all* LCA have scalar coefficients.

If $c_h = 1$ for all $h \in \mathbb{H}$, then Φ has local rule $\phi(\mathbf{a}_{\mathbb{H}}) := \sum_{h \in \mathbb{H}} a_h$; in this case, Φ is called an *additive cellular automaton*; see [► Additive Cellular Automata](#).

Affine CA If $(\mathcal{A}, +)$ is a finite abelian group, then an *affine CA* is one with a local rule $\phi(\mathbf{a}_{\mathbb{H}}) := c + \sum_{h \in \mathbb{H}} \varphi_h(a_h)$, where c is some constant and where $\varphi_h: \mathcal{A} \rightarrow \mathcal{A}$ are endomorphisms of $(\mathcal{A}, +)$. Thus, Φ is an LCA if $c = 0$.

Permutative CA Suppose $\Phi: \mathcal{A}^{\mathbb{Z}} \rightarrow \mathcal{A}^{\mathbb{Z}}$ has local rule $\phi: \mathcal{A}^{[-\ell \dots r]} \rightarrow \mathcal{A}$. Fix $\mathbf{b} = [b_{1-\ell}, \dots, b_{r-1}, b_r] \in \mathcal{A}^{(-\ell \dots r]}$. For any $a \in \mathcal{A}$, define $[a \ \mathbf{b}] := [a, b_{1-\ell}, \dots, b_{r-1}, b_r] \in \mathcal{A}^{[-\ell \dots r]}$. We then define the function $\phi_{\mathbf{b}}: \mathcal{A} \rightarrow \mathcal{A}$ by $\phi_{\mathbf{b}}(a) := \phi([a \ \mathbf{b}])$. We say that Φ is *left-permutative* if $\phi_{\mathbf{b}}: \mathcal{A} \rightarrow \mathcal{A}$ is a permutation (i. e. a bijection) for all $\mathbf{b} \in \mathcal{A}^{(-\ell \dots r]}$. Likewise, given $\mathbf{b} = [b_{-\ell}, \dots, b_{r-1}] \in \mathcal{A}^{[-\ell \dots r)}$ and $c \in \mathcal{A}$, define $[\mathbf{b} \ c] := [b_{-\ell}, b_{1-\ell}, \dots, b_{r-1}, c] \in \mathcal{A}^{[-\ell \dots r]}$, and define ${}_{\mathbf{b}}\phi: \mathcal{A} \rightarrow \mathcal{A}$ by ${}_{\mathbf{b}}\phi(c) := \phi([\mathbf{b} \ c])$; then Φ is *right-permutative* if ${}_{\mathbf{b}}\phi: \mathcal{A} \rightarrow \mathcal{A}$ is a permutation for all $\mathbf{b} \in \mathcal{A}^{[-\ell \dots r)}$. We say Φ is *bipermutative* if it is both left- and right-permutative. More generally, if \mathbb{M} is any monoid, $\mathbb{H} \subset \mathbb{M}$ is any neighborhood, and $h \in \mathbb{H}$ is any fixed coordinate, then we define *h-permutativity* for a CA on $\mathcal{A}^{\mathbb{M}}$ in the obvious fashion.

For example, suppose $(\mathcal{A}, +)$ is an abelian group and Φ is an affine CA on $\mathcal{A}^{\mathbb{Z}}$ with local rule $\phi(\mathbf{a}_{\mathbb{H}}) = c + \sum_{h=-\ell}^r \varphi_h(a_h)$. Then Φ is left-permutative iff $\varphi_{-\ell}$ is an automorphism, and right-permutative iff φ_r is an automorphism. If $\mathcal{A} = \mathbb{Z}/p$, and p is prime, then *every* nontrivial endomorphism is an automorphism (because it is

multiplication by a nonzero element of \mathbb{Z}/p , which is a field), so in this case, *every* affine CA is permutative in every coordinate of its neighborhood (and in particular, bipermutative). If $\mathcal{A} \neq \mathbb{Z}/p$, however, then not all affine CA are permutative.

Permutative CA were introduced by Hedlund [58], §6, and are sometimes called *permutive CA*. Right permutative CA on $\mathcal{A}^{\mathbb{N}}$ are also called *toggle automata*. For more information, see Sect. 7 of

[► Topological Dynamics of Cellular Automata](#).

Subshifts A *subshift* is a closed, σ -invariant subset $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$. For any $\mathbb{U} \subset \mathbb{M}$, let $\mathbf{X}_{\mathbb{U}} := \{\mathbf{x}_{\mathbb{U}}; \mathbf{x} \in \mathbf{X}\} \subset \mathcal{A}^{\mathbb{U}}$. We say \mathbf{X} is a *subshift of finite type* (SFT) if there is some finite $\mathbb{U} \subset \mathbb{M}$ such that \mathbf{X} is entirely described by $\mathbf{X}_{\mathbb{U}}$, in the sense that $\mathbf{X} = \{\mathbf{x} \in \mathcal{A}^{\mathbb{M}}; \mathbf{x}_{\mathbb{U}+m} \in \mathbf{X}_{\mathbb{U}}, \forall m \in \mathbb{M}\}$.

In particular, if $\mathbb{M} = \mathbb{Z}$, then a (two-sided) *Markov subshift* is an SFT $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}}$ determined by a set $\mathbf{X}_{\{0,1\}} \subset \mathcal{A}^{\{0,1\}}$ of *admissible transitions*; equivalently, \mathbf{X} is the set of all bi-infinite directed paths in a digraph whose vertices are the elements of \mathcal{A} , with an edge $a \rightsquigarrow b$ iff $(a, b) \in \mathbf{X}_{\{0,1\}}$. If $\mathbb{M} = \mathbb{N}$, then a *one-sided Markov subshift* is a subshift of $\mathcal{A}^{\mathbb{N}}$ defined in the same way.

If $D \geq 2$, then an SFT in $\mathcal{A}^{\mathbb{Z}^D}$ can be thought of as the set of admissible ‘tilings’ of \mathbb{R}^D by Wang tiles corresponding to the elements of $\mathbf{X}_{\mathbb{U}}$. (Wang tiles are unit squares (or (hyper)cubes) with various ‘notches’ cut into their edges (or (hyper)faces) so that they can only be juxtaposed in certain ways.)

A subshift $\mathbf{X} \subseteq \mathcal{A}^{\mathbb{Z}^D}$ is *strongly irreducible* (or *topologically mixing*) if there is some $R \in \mathbb{N}$ such that, for any disjoint finite subsets $\mathbb{V}, \mathbb{U} \subset \mathbb{Z}^D$ separated by a distance of at least R , and for any $\mathbf{u} \in \mathbf{X}_{\mathbb{U}}$ and $\mathbf{v} \in \mathbf{X}_{\mathbb{V}}$, there is some $\mathbf{x} \in \mathbf{X}$ such that $\mathbf{x}_{\mathbb{U}} = \mathbf{u}$ and $\mathbf{x}_{\mathbb{V}} = \mathbf{v}$. Please see [► Symbolic Dynamics](#) for more about subshifts.

Measures For any finite subset $\mathbb{U} \subset \mathbb{M}$, and any $\mathbf{b} \in \mathcal{A}^{\mathbb{U}}$, let $\langle \mathbf{b} \rangle := \{\mathbf{a} \in \mathcal{A}^{\mathbb{M}}; \mathbf{a}_{\mathbb{U}} := \mathbf{b}\}$ be the *cylinder set* determined by \mathbf{b} . Let \mathfrak{B} be the sigma-algebra on $\mathcal{A}^{\mathbb{M}}$ generated by all cylinder sets. A (probability) measure μ on $\mathcal{A}^{\mathbb{M}}$ is a countably additive function $\mu: \mathfrak{B} \rightarrow [0, 1]$ such that $\mu[\mathcal{A}^{\mathbb{M}}] = 1$. A measure on $\mathcal{A}^{\mathbb{M}}$ is entirely determined by its values on cylinder sets. We will be mainly concerned with the following classes of measures:

Bernoulli measure Let β_0 be a probability measure on \mathcal{A} . The *Bernoulli measure* induced by β_0 is the measure β on $\mathcal{A}^{\mathbb{M}}$ such that, for any finite subset $\mathbb{U} \subset \mathbb{M}$, and any $\mathbf{a} \in \mathcal{A}^{\mathbb{U}}$, if $U := |\mathbb{U}|$, then $\beta[\langle \mathbf{a} \rangle] = \prod_{h \in \mathbb{H}} \beta_0(a_h)$.

Invariant measure Let μ be a measure on $\mathcal{A}^{\mathbb{M}}$, and let $\Phi: \mathcal{A}^{\mathbb{M}} \rightarrow \mathcal{A}^{\mathbb{M}}$ be a cellular automaton. The measure $\Phi\mu$ is defined by $\Phi\mu(\mathbf{B}) = \mu(\Phi^{-1}(\mathbf{B}))$, for any $\mathbf{B} \in \mathfrak{B}$. We say that μ is Φ -invariant (or that Φ is μ -preserving) if $\Phi\mu = \mu$. For more information, see [► Ergodic Theory: Basic Examples and Constructions](#).

Uniform measure Let $A := |\mathcal{A}|$. The uniform measure η on $\mathcal{A}^{\mathbb{M}}$ is the Bernoulli measure such that, for any finite subset $U \subset \mathbb{M}$, and any $\mathbf{b} \in \mathcal{A}^U$, if $U := |U|$, then $\mu[\{\mathbf{b}\}] = 1/A^U$.

The *support* of a measure μ is the smallest closed subset $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$ such that $\mu[\mathbf{X}] = 1$; we denote this by $\text{supp}(\mu)$. We say μ has *full support* if $\text{supp}(\mu) = \mathcal{A}^{\mathbb{M}}$ – equivalently, $\mu[\mathbf{C}] > 0$ for every cylinder subset $\mathbf{C} \subset \mathcal{A}^{\mathbb{M}}$.

Notation Let $\mathcal{CA}(\mathcal{A}^{\mathbb{M}})$ denote the set of all cellular automata on $\mathcal{A}^{\mathbb{M}}$. If $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$, then let $\mathcal{CA}(\mathbf{X})$ be the subset of all $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$ such that $\Phi(\mathbf{X}) \subseteq \mathbf{X}$. Let $\mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{M}})$ be the set of all probability measures on $\mathcal{A}^{\mathbb{M}}$, and let $\mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{M}}; \Phi)$ be the subset of Φ -invariant measures. If $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$, then let $\mathfrak{M}_{\text{ens}}(\mathbf{X})$ be the set of probability measures μ with $\text{supp}(\mu) \subseteq \mathbf{X}$, and define $\mathfrak{M}_{\text{ens}}(\mathbf{X}; \Phi)$ in the obvious way.

Font conventions Upper case calligraphic letters ($\mathcal{A}, \mathcal{B}, \mathcal{C}, \dots$) denote finite alphabets or groups. Upper-case bold letters ($\mathbf{A}, \mathbf{B}, \mathbf{C}, \dots$) denote subsets of $\mathcal{A}^{\mathbb{M}}$ (e.g. subshifts), lowercase bold-faced letters ($\mathbf{a}, \mathbf{b}, \mathbf{c}, \dots$) denote elements of $\mathcal{A}^{\mathbb{M}}$, and Roman letters (a, b, c, \dots) are elements of \mathcal{A} or ordinary numbers. Lower-case sans-serif (\dots, m, n, p) are elements of \mathbb{M} , upper-case hollow font ($\mathbb{U}, \mathbb{V}, \mathbb{W}, \dots$) are subsets of \mathbb{M} . Upper-case Greek letters (Φ, Ψ, \dots) are functions on $\mathcal{A}^{\mathbb{M}}$ (e.g. CA, block maps), and lower-case Greek letters (ϕ, ψ, \dots) are other functions (e.g. local rules, measures.)

Acronyms in square brackets (e.g. [► Topological Dynamics of Cellular Automata](#)) indicate cross-references to related entries in the Encyclopedia; these are listed at the end of this article.

Definition of the Subject

Loosely speaking, a *cellular automaton* (CA) is the ‘discrete’ analogue of a partial differential evolution equation: it is a spatially distributed, discrete-time, symbolic dynamical system governed by a local interaction rule which is invariant in space and time. In a CA, ‘space’ is discrete (usually the D -dimensional lattice, \mathbb{Z}^D) and the local statespace at each point in space is also discrete (a finite ‘alphabet’, usually denoted by \mathcal{A}).

A *measure-preserving dynamical system* (MPDS) is a dynamical system equipped with an invariant probability measure. Any MPDS can be represented as a stationary stochastic process (SSP) and vice versa; ‘chaos’ in the MPDS can be quantified via the information-theoretic ‘entropy’ of the corresponding SSP. An MPDS Φ on a statespace \mathbf{X} also defines a unitary linear operator Φ_* on the Hilbert space $L^2(\mathbf{X})$; the spectral properties of Φ_* encode information about the global periodic structure and long-term informational asymptotics of Φ . *Ergodic theory* is the study of MPDSs and SSPs, and lies at the interface between dynamics, probability theory, information theory, and unitary operator theory.

Please refer to the Glossary for precise definitions of ‘CA’, ‘MPDS’, etc. Also, see [► Ergodic Theory: Basic Examples and Constructions](#) for an introduction to ergodic theory.

Introduction

The study of CA as symbolic dynamical systems began with Hedlund [58], and the study of CA as MPDSs began with Coven and Paul [24] and Willson [144]. (Further historical details will unfold below, where appropriate.) The ergodic theory of CA is important for several reasons:

- CA are topological dynamical systems ([► Topological Dynamics of Cellular Automata](#), [► Chaotic Behavior of Cellular Automata](#)). We can gain insight into the topological dynamics of a CA by identifying its invariant measures, and then studying the corresponding measurable dynamics.
- CA are often proposed as stylized models of spatially distributed systems in statistical physics – for example, as microscale models of hydrodynamics, or of atomic lattices ([► Cellular Automata Modeling of Physical Systems](#)). In this context, the distinct invariant measures of a CA correspond to distinct ‘phases’ of the physical system ([► Phase Transitions in Cellular Automata](#)).
- CA can also act as information-processing systems ([► Cellular Automata, Universality of](#), [► Cellular Automata as Models of Parallel Computation](#)). Ergodic theory studies the ‘informational’ aspect of dynamical systems, so it is particularly suited to explicitly ‘informational’ dynamical systems like CA.

Article Roadmap

In Sect. “[Invariant Measures for CA](#)”, we characterize the invariant measures for various classes of CA. Then, in

Sect. “[Limit Measures and Other Asymptotics](#)”, we investigate which measures are ‘generic’ in the sense that they arise as the attractors for some large class of initial conditions. In Sect. “[Measurable Dynamics](#)” we study the mixing and spectral properties of CA as measure-preserving dynamical systems. Finally, in Sect. “[Entropy](#)”, we look at entropy. These sections are logically independent, and can be read in any order.

Invariant Measures for CA

The Uniform Measure vs. Surjective Cellular Automata

The uniform measure η plays a central role in the ergodic theory of cellular automata, because of the following result.

Theorem 1 *Let $\mathbb{M} = \mathbb{Z}^D \times \mathbb{N}^E$, let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$ and let η be the uniform measure on $\mathcal{A}^{\mathbb{M}}$. Then $(\Phi$ preserves $\eta) \iff (\Phi$ is surjective).*

Proof sketch “ \implies ” If Φ preserves η , then Φ must map $\text{supp}(\eta)$ onto itself. But $\text{supp}(\eta) = \mathcal{A}^{\mathbb{M}}$; hence Φ is surjective.

“ \impliedby ” The case $D = 1$ follows from a result of W.A. Blankenship and Oscar S. Rothaus, which first appeared in Theorem 5.4 in [58]. The Blankenship–Rothaus Theorem states that, if $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ is surjective and has neighborhood $[-\ell \dots r]$, then for any $k \in \mathbb{N}$ and any $\mathbf{a} \in \mathcal{A}^k$, the Φ -preimage of the cylinder set $\langle \mathbf{a} \rangle$ is a disjoint union of exactly $A^{r+\ell}$ cylinder sets of length $k + r + \ell$; it follows that $\mu[\Phi^{-1}(\mathbf{a})] = A^{r+\ell}/A^{k+r+\ell} = A^{-k} = \mu(\mathbf{a})$. This result was later reproved by Kleveland (see Theorem 5.1 in [74]). The special case $\mathcal{A} = \{0, 1\}$ also appeared in Theorem 2.4 in [131].

The case $D \geq 2$ follows from the multidimensional version of the Blankenship–Rothaus Theorem, which was proved by Maruoka and Kimura (see Theorem 2 in [93]) (their proof assumes that $D = 2$ and that Φ has a ‘quiescent’ state, but neither hypothesis is essential). Alternately, “ \impliedby ” follows from recent, more general results of Meester, Burton, and Steif; see Example 9 below. \square

Example 2 Let $\mathbb{M} = \mathbb{Z}$ or \mathbb{N} and consider CA on $\mathcal{A}^{\mathbb{M}}$.

- (a) Say that Φ is *bounded-to-one* if there is some $B \in \mathbb{N}$ such that every $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$ has at most B preimages. Then $(\Phi$ is bounded-to-one) $\iff (\Phi$ is surjective).
- (b) Any *posexpansive* CA on $\mathcal{A}^{\mathbb{M}}$ is surjective (see Subsect. “[Posexpansive and Permutative CA](#)” below).
- (c) Any left- or right-permutative CA on $\mathcal{A}^{\mathbb{Z}}$ (or right-permutative CA on $\mathcal{A}^{\mathbb{N}}$) is surjective. This includes, for example, most linear CA.

Hence, in any of these cases, Φ preserves the uniform measure.

Proof For (a), see Theorem 5.9 in [58], or Corollary 8.1.20, p. 271 in [81]. For (b), see Proposition 2.2 in [9], in the case $\mathcal{A}^{\mathbb{N}}$; their argument also works for $\mathcal{A}^{\mathbb{Z}}$.

Part (c) follows from (b) because any permutative CA is *posexpansive* (Proposition 11 below). There is also a simple direct proof for a right-permutative CA on $\mathcal{A}^{\mathbb{N}}$: using right-permutativity, you can systematically construct a preimage of any desired image sequence, one entry at a time. See Theorem 6.6 in [58] for the proof in $\mathcal{A}^{\mathbb{Z}}$. \square

The surjectivity of a one-dimensional CA can be determined in finite time using certain combinatorial tests (\blacktriangleright [Topological Dynamics of Cellular Automata](#)). However, for $D \geq 2$, it is formally undecidable whether an arbitrary CA on $\mathcal{A}^{\mathbb{Z}^D}$ is surjective (\blacktriangleright [Tiling Problem and Undecidability in Cellular Automata](#)). This problem is sometimes referred to as the *Garden of Eden problem*, because an element of $\mathcal{A}^{\mathbb{Z}^D}$ with no Φ -preimage is called a *Garden of Eden* (GOE) configuration for Φ (because it could only ever occur at the ‘beginning of time’). However, it is known that a CA is surjective if it is ‘almost injective’ in a certain sense, which we now specify.

Let $(\mathbb{M}, +)$ be any monoid, and let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$ have neighborhood $\mathbb{H} \subset \mathbb{M}$. If $\mathbb{B} \subset \mathbb{M}$ is any subset, then we define

$$\begin{aligned} \overline{\mathbb{B}} &:= \mathbb{B} + \mathbb{H} = \{\mathbf{b} + \mathbf{h}; \mathbf{b} \in \mathbb{B}, \mathbf{h} \in \mathbb{H}\}; \\ \text{and } \partial\mathbb{B} &:= \overline{\mathbb{B}} \cap \overline{\mathbb{B}^c}. \end{aligned}$$

If \mathbb{B} is finite, then so is $\overline{\mathbb{B}}$ (because \mathbb{H} is finite). If Φ has local rule $\phi: \mathcal{A}^{\mathbb{H}} \rightarrow \mathcal{A}$, then ϕ induces a function $\Phi_{\mathbb{B}}: \mathcal{A}^{\mathbb{B}} \rightarrow \mathcal{A}^{\mathbb{B}}$ in the obvious fashion. A *\mathbb{B} -bubble* (or *\mathbb{B} -diamond*) is a pair $\mathbf{b}, \mathbf{b}' \in \mathcal{A}^{\mathbb{B}}$ such that:

$$\mathbf{b} \neq \mathbf{b}'; \quad \mathbf{b}_{\partial\mathbb{B}} = \mathbf{b}'_{\partial\mathbb{B}}; \quad \text{and} \quad \Phi_{\mathbb{B}}(\mathbf{b}) = \Phi_{\mathbb{B}}(\mathbf{b}').$$

Suppose $\mathbf{a}, \mathbf{a}' \in \mathcal{A}^{\mathbb{M}}$ are two configurations such that

$$\mathbf{a}_{\overline{\mathbb{B}}} = \mathbf{b}, \quad \mathbf{a}'_{\overline{\mathbb{B}}} = \mathbf{b}', \quad \text{and} \quad \mathbf{a}_{\mathbb{B}^c} = \mathbf{a}'_{\mathbb{B}^c}.$$

Then it is easy to verify that $\Phi(\mathbf{a}) = \Phi(\mathbf{a}')$. We say that \mathbf{a} and \mathbf{a}' form a *mutually erasable pair* (because Φ ‘erases’ the difference between \mathbf{a} and \mathbf{a}'). Figure 1 is a schematic representation of this structure in the case $D = 1$ (hence

Ergodic Theory of Cellular Automata, Figure 1
A ‘diamond’ in $\mathcal{A}^{\mathbb{Z}}$

the term ‘diamond’). If $D = 2$, then \mathbf{a} and \mathbf{a}' are like two membranes which are glued together everywhere except for a \mathbb{B} -shaped ‘bubble’. We say that Φ is *pre-injective* if any (and thus, all) of the following three conditions hold:

- Φ admits no bubbles.
- Φ admits no mutually erasable pairs.
- For any $\mathbf{c} \in \mathcal{A}^{\mathbb{M}}$, if $\mathbf{a}, \mathbf{a}' \in \Phi^{-1}\{\mathbf{c}\}$ are distinct, then \mathbf{a} and \mathbf{a}' must differ in infinitely many locations.

For example, any injective CA is preinjective (because a mutually erasable pair for Φ gives two distinct Φ -preimages for some point). More to the point, however, if \mathbb{B} is finite, and Φ admits a \mathbb{B} -bubble $(\mathbf{b}, \mathbf{b}')$, then we can embed N disjoint copies of \mathbb{B} into \mathbb{M} , and thus, by making various choices between \mathbf{b} and \mathbf{b}' on different translates, we obtain a configuration with 2^N distinct Φ -preimages (where N is arbitrarily large). But if some configurations in $\mathcal{A}^{\mathbb{M}}$ have such a large number of preimages, then other configurations in $\mathcal{A}^{\mathbb{M}}$ must have very few preimages, or even none. This leads to the following result:

Theorem 3 (Garden of Eden) *Let \mathbb{M} be a finitely generated amenable group (e. g. $\mathbb{M} = \mathbb{Z}^D$). Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$.*

- (a) *Φ is surjective if and only if Φ is pre-injective.*
- (b) *Let $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$ be a strongly irreducible SFT such that $\Phi(\mathbf{X}) \subseteq \mathbf{X}$. Then $\Phi(\mathbf{X}) = \mathbf{X}$ if and only if $\Phi|_{\mathbf{X}}$ is pre-injective.*

Proof (a) The case $\mathbb{M} = \mathbb{Z}^2$ was originally proved by Moore [103] and Myhill [104]; see [▶ Cellular Automata and Groups](#). The case $\mathbb{M} = \mathbb{Z}$ was implicit Hedlund (Lemma 5.11, and Theorems 5.9 and 5.12 in [58]). The case when \mathbb{M} is a finite-dimensional group was proved by Machi and Mignosi [92]. Finally, the general case was proved by Ceccherini-Silberstein, Machi, and Scarabotti (see Theorem 3 in [20]), see [▶ Cellular Automata and Groups](#).

(b) The case $\mathbb{M} = \mathbb{Z}$ is Corollary 8.1.20 in [81] (actually this holds for any sofic subshift); see also Fiorenzi [38]. The general case is Corollary 4.8 in [39]. □

Corollary 4 (Incompressibility) *Suppose \mathbb{M} is a finitely generated amenable group and $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$. If Φ is injective, then Φ is surjective.*

Remark 5 (a) A *cellular network* is a CA-like system defined on an infinite, locally finite digraph, with different local rules at different nodes. By assuming a kind of ‘amenability’ for this digraph, and then imposing some weak global statistical symmetry conditions on the local rules, Gromov (see Theorem 8.F’ in [51]) has generalized the GOE Theorem 3 to a large class of such cellular net-

works (which he calls ‘endomorphisms of symbolic algebraic varieties’). See also [19].

(b) In the terminology suggested by Gottschalk [46], Incompressibility Corollary 4 says that the group \mathbb{M} is *surjunctive*; Gottschalk claims that ‘surjunctivity’ was first proved for all residually finite groups by Lawton (unpublished); see [▶ Cellular Automata and Groups](#). For a recent direct proof (not using the GOE theorem), see Weiss (see Theorem 1.6 in [143]). Weiss also defines *sofic* groups (a class containing both residually finite groups and amenable groups) and shows that Corollary 4 holds whenever \mathbb{M} is a sofic group (see Theorem 3.2 in [143]); see also [▶ Cellular Automata and Groups](#).

(c) If $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$ is an SFT such that $\Phi(\mathbf{X}) \subseteq \mathbf{X}$, then Corollary 4 holds as long as \mathbf{X} is ‘semi-strongly irreducible’; see Fiorenzi (see Corollary 4.10 in [40]).

Invariance of Maxentropy Measures

If $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^D}$ is any subshift with topological entropy $h_{\text{top}}(\mathbf{X}, \sigma)$, and $\mu \in \mathfrak{M}_{\text{inv}}(\mathbf{X}, \sigma)$ has measurable entropy $h(\mu, \sigma)$, then in general, $h(\mu, \sigma) \leq h_{\text{top}}(\mathbf{X}, \sigma)$; we say μ is a *measure of maximal entropy* (or *maxentropy measure*) if $h(\mu, \sigma) = h_{\text{top}}(\mathbf{X}, \sigma)$. (See Example 75(a) for definitions.)

Every subshift admits one or more maxentropy measures. If $D = 1$ and $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}}$ is an irreducible subshift of finite type (SFT), then Parry (see Theorem 10 in [110]) showed that \mathbf{X} admits a *unique* maxentropy measure $\eta_{\mathbf{X}}$ (now called the *Parry measure*); see Theorem 8.10, p. 194 in [142] or Sect. 13.3, pp. 443–444 in [81]. Theorem 1 is then a special case of the following result:

Theorem 6 (Coven, Paul, Meester and Steif) *Let $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^D}$ be an SFT having a unique maxentropy measure $\eta_{\mathbf{X}}$, and let $\Phi \in \mathcal{CA}(\mathbf{X})$. Then Φ preserves $\eta_{\mathbf{X}}$ if and only if $\Phi(\mathbf{X}) = \mathbf{X}$.*

Proof The case $D = 1$ is Corollary 2.3 in [24]. The case $D \geq 2$ follows from Theorem 2.5(iii) in [95], which states: if \mathbf{X} and \mathbf{Y} are SFTs, and $\Phi: \mathbf{X} \rightarrow \mathbf{Y}$ is a factor mapping, and μ is a maxentropy measure on \mathbf{X} , then $\Phi(\mu)$ is a maxentropy measure on \mathbf{Y} . □

For example, if $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}}$ is an irreducible SFT and $\eta_{\mathbf{X}}$ is its Parry measure, and $\Phi(\mathbf{X}) = \mathbf{X}$, then Theorem 6 says $\Phi(\eta_{\mathbf{X}}) = \eta_{\mathbf{X}}$, as observed by Coven and Paul (see Theorem 5.1 in [24]). Unfortunately, higher-dimensional SFTs do *not*, in general, have unique maxentropy measures. Burton and Steif [14] provided a plethora of examples of such nonuniqueness, but they also gave a sufficient condition for uniqueness of the maxentropy measure, which we now explain.

Let $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^D}$ be an SFT and let $\mathbb{U} \subset \mathbb{Z}^D$. For any $\mathbf{x} \in \mathbf{X}$, let $\mathbf{x}_{\mathbb{U}} := [x_u]_{u \in \mathbb{U}}$ be its ‘projection’ to $\mathcal{A}^{\mathbb{U}}$, and let $\mathbf{X}_{\mathbb{U}} := \{\mathbf{x}_{\mathbb{U}}; \mathbf{x} \in \mathbf{X}\} \subseteq \mathcal{A}^{\mathbb{U}}$. Let $\mathbb{V} := \mathbb{U}^c \subset \mathbb{Z}^D$. For any $\mathbf{u} \in \mathcal{A}^{\mathbb{U}}$ and $\mathbf{v} \in \mathcal{A}^{\mathbb{V}}$, let $[\mathbf{uv}]$ denote the element of $\mathcal{A}^{\mathbb{Z}^D}$ such that $[\mathbf{uv}]_{\mathbb{U}} = \mathbf{u}$ and $[\mathbf{uv}]_{\mathbb{V}} = \mathbf{v}$. Let

$$\mathbf{X}^{(\mathbf{u})} := \{\mathbf{v} \in \mathcal{A}^{\mathbb{V}}; [\mathbf{uv}] \in \mathbf{X}\}$$

be the set of all ‘ \mathbf{X} -admissible completions’ of \mathbf{u} (thus, $\mathbf{X}^{(\mathbf{u})} \neq \emptyset \Leftrightarrow \mathbf{u} \in \mathbf{X}_{\mathbb{U}}$). If $\mu \in \mathcal{M}_{\text{inv}}(\mathcal{A}^{\mathbb{Z}^D})$, and $\mathbf{u} \in \mathcal{A}^{\mathbb{U}}$, then let $\mu^{(\mathbf{u})}$ denote the conditional measure on $\mathcal{A}^{\mathbb{V}}$ induced by \mathbf{u} . If \mathbb{U} is finite, then $\mu^{(\mathbf{u})}$ is just the restriction of μ to the cylinder set $\langle \mathbf{u} \rangle$. If \mathbb{U} is infinite, then the precise definition of $\mu^{(\mathbf{u})}$ involves a ‘disintegration’ of μ into ‘fibre measures’ (we will suppress the details).

Let $\mu_{\mathbb{U}}$ be the projection of μ onto $\mathcal{A}^{\mathbb{U}}$. If $\text{supp}(\mu) \subseteq \mathbf{X}$, then $\text{supp}(\mu_{\mathbb{U}}) \subseteq \mathbf{X}_{\mathbb{U}}$, and for any $\mathbf{u} \in \mathcal{A}^{\mathbb{U}}$, $\text{supp}(\mu^{(\mathbf{u})}) \subseteq \mathbf{X}^{(\mathbf{u})}$. We say that μ is a *Burton–Steif measure* on \mathbf{X} if:

- (1) $\text{supp}(\mu) = \mathbf{X}$; and
- (2) For any $\mathbb{U} \subset \mathbb{Z}^D$ whose complement \mathbb{U}^c is finite, and for $\mu_{\mathbb{U}}$ -almost any $\mathbf{u} \in \mathbf{X}_{\mathbb{U}}$, the measure $\mu^{(\mathbf{u})}$ is uniformly distributed on the (finite) set $\mathbf{X}^{(\mathbf{u})}$.

For example, if $\mathbf{X} = \mathcal{A}^{\mathbb{Z}^D}$, then the only Burton–Steif measure is the uniform Bernoulli measure. If $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}}$ is an irreducible SFT, then the only Burton–Steif measure is the Parry measure. If $r > 0$ and $\mathbb{B} := [-r \dots r]^D \subset \mathbb{Z}^D$, and \mathbf{X} is an SFT determined by a set of admissible words $\mathbf{X}_{\mathbb{B}} \subset \mathcal{A}^{\mathbb{B}}$, then it is easy to check that any Burton–Steif measure μ on \mathbf{X} must be a Markov random field with interaction range r .

Theorem 7 (Burton and Steif) *Let $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^D}$ be a subshift of finite type.*

- (a) *Any maxentropy measure on \mathbf{X} is a Burton–Steif measure.*
- (b) *If \mathbf{X} is strongly irreducible, then any Burton–Steif measure on \mathbf{X} is a maxentropy measure for \mathbf{X} .*

Proof (a) and (b) are Propositions 1.20 and 1.21 of [15], respectively. For a proof in the case when \mathbf{X} is a symmetric nearest-neighbor subshift of finite type, see Propositions 1.19 and 4.1 of [14], respectively. \square

Any subshift admits at least one maxentropy measure, so any SFT admits at least one Burton–Steif measure. Theorems 6 and 7 together imply:

Corollary 8 *If $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^D}$ is an SFT which admits a unique Burton–Steif measure $\eta_{\mathbf{X}}$, then $\eta_{\mathbf{X}}$ is the unique maxentropy measure for \mathbf{X} . Thus, if $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$ and $\Phi(\mathbf{X}) = \mathbf{X}$, then $\Phi(\eta_{\mathbf{X}}) = \eta_{\mathbf{X}}$.*

Example 9 If $\mathbf{X} = \mathcal{A}^{\mathbb{Z}^D}$, then we get Theorem 1, because the unique Burton–Steif measure on $\mathcal{A}^{\mathbb{Z}^D}$ is the uniform Bernoulli measure.

Remark If $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$ is a subshift admitting a unique maxentropy measure μ , and $\text{supp}(\mu) = \mathbf{X}$, then Wiess (see Theorem 4.2 in [143]) has observed that \mathbf{X} automatically satisfies Incompressibility Corollary 4. In particular, this applies to any SFT having a unique Burton–Steif measure.

Periodic Invariant Measures

If $P \in \mathbb{N}$, then a sequence $\mathbf{a} \in \mathcal{A}^{\mathbb{Z}}$ is *P-periodic* if $\sigma^P(\mathbf{a}) = \mathbf{a}$. If $A := |\mathcal{A}|$, then there are exactly A^P such sequences, and a measure μ on $\mathcal{A}^{\mathbb{Z}}$ is called *P-periodic* if μ is supported entirely on these *P-periodic* sequences. More generally, if \mathbb{M} is any monoid and $\mathbb{P} \subset \mathbb{M}$ is any submonoid, then a configuration $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$ is *P-periodic* if $\sigma^{\mathbf{p}}(\mathbf{a}) = \mathbf{a}$ for all $\mathbf{p} \in \mathbb{P}$. (For example, if $\mathbb{M} = \mathbb{Z}$ and $\mathbb{P} := P\mathbb{Z}$, then the \mathbb{P} -periodic configurations are the *P-periodic* sequences). Let $\mathcal{A}^{\mathbb{M}/\mathbb{P}}$ denote the set of \mathbb{P} -periodic configurations. If $P := |\mathbb{M}/\mathbb{P}|$, then $|\mathcal{A}^{\mathbb{M}/\mathbb{P}}| = A^P$. A measure μ is called *P-periodic* if $\text{supp}(\mu) \subseteq \mathcal{A}^{\mathbb{M}/\mathbb{P}}$.

Proposition 10 *Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$. If $\mathbb{P} \subset \mathbb{M}$ is any submonoid and $|\mathbb{M}/\mathbb{P}|$ is finite, then there exists a \mathbb{P} -periodic, Φ -invariant measure.*

Proof sketch If $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$, then $\Phi(\mathcal{A}^{\mathbb{M}/\mathbb{P}}) \subseteq \mathcal{A}^{\mathbb{M}/\mathbb{P}}$. Thus, if μ is \mathbb{P} -periodic, then $\Phi^t(\mu)$ is \mathbb{P} -periodic for all $t \in \mathbb{N}$. Thus, the Cesàro limit of the sequence $\{\Phi^t(\mu)\}_{t=1}^{\infty}$ is \mathbb{P} -periodic and Φ -invariant. This Cesàro limit exists because $\mathcal{A}^{\mathbb{M}/\mathbb{P}}$ is finite. \square

These periodic measures have finite (hence discrete) support, but by convex-combining them, it is easy to obtain (nonergodic) Φ -invariant measures with countable, dense support. When studying the invariant measures of CA, we usually regard these periodic measures (and their convex combinations) as somewhat trivial, and concentrate instead on invariant measures supported on aperiodic configurations.

Posexpansive and Permutative CA

Let $\mathbb{B} \subset \mathbb{M}$ be a finite subset, and let $\mathcal{B} := \mathcal{A}^{\mathbb{B}}$. If $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$, then we define a continuous function $\Phi_{\mathbb{B}}^{\mathbb{N}}: \mathcal{A}^{\mathbb{M}} \rightarrow \mathcal{B}^{\mathbb{N}}$ by

$$\Phi_{\mathbb{B}}^{\mathbb{N}}(\mathbf{a}) := [\mathbf{a}_{\mathbb{B}}; \Phi(\mathbf{a})_{\mathbb{B}}; \Phi^2(\mathbf{a})_{\mathbb{B}}; \Phi^3(\mathbf{a})_{\mathbb{B}}; \dots] \in \mathcal{B}^{\mathbb{N}}. \quad (2)$$

Clearly, $\Phi_{\mathbb{B}}^{\mathbb{N}} \circ \Phi = \sigma \circ \Phi_{\mathbb{B}}^{\mathbb{N}}$. We say that Φ is *B-posexpansive* if $\Phi_{\mathbb{B}}^{\mathbb{N}}$ is injective. Equivalently, for any $\mathbf{a}, \mathbf{a}' \in$

$\mathcal{A}^{\mathbb{M}}$, if $\mathbf{a} \neq \mathbf{a}'$, then there is some $t \in \mathbb{N}$ such that $\Phi^t(\mathbf{a})_{\mathbb{B}} \neq \Phi^t(\mathbf{a}')_{\mathbb{B}}$. We say Φ is *positively expansive* (or *posexpansive*) if Φ is \mathbb{B} -posexpansive for some finite \mathbb{B} (it is easy to see that this is equivalent to the usual definition of positive expansiveness a topological dynamical system). For more information see Sect. 8 [► Topological Dynamics of Cellular Automata](#).

Thus, if $\mathbf{X} := \Phi_{\mathbb{B}}^{\mathbb{N}}(\mathcal{A}^{\mathbb{M}}) \subset \mathcal{B}^{\mathbb{N}}$, then \mathbf{X} is a compact, shift-invariant subset of $\mathcal{B}^{\mathbb{N}}$, and $\Phi_{\mathbb{B}}^{\mathbb{N}}: \mathcal{A}^{\mathbb{M}} \rightarrow \mathbf{X}$ is an isomorphism from the system $(\mathcal{A}^{\mathbb{M}}, \Phi)$ to the one-sided subshift (\mathbf{X}, σ) , which is sometimes called the *canonical factor* or *column shift* of Φ . The easiest examples of posexpansive CA are one-dimensional, permutative automata.

Proposition 11 (a) *Suppose $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{N}})$ has neighborhood $[r \dots R]$, where $0 \leq r < R$. Let $\mathbb{B} := [0 \dots R]$ and let $\mathcal{B} := \mathcal{A}^{\mathbb{B}}$. Then*

$$(\Phi \text{ is right permutative}) \iff (\Phi \text{ is } \mathbb{B}\text{-posexpansive, and } \Phi_{\mathbb{B}}^{\mathbb{N}}(\mathcal{A}^{\mathbb{N}}) = \mathcal{B}^{\mathbb{N}}).$$

(b) *Suppose $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ has neighborhood $[-L \dots R]$, where $-L < 0 < R$. Let $\mathbb{B} := [-L \dots R]$, and let $\mathcal{B} := \mathcal{A}^{\mathbb{B}}$. Then*

$$(\Phi \text{ is bipermutative}) \iff (\Phi \text{ is } \mathbb{B}\text{-posexpansive, and } \Phi_{\mathbb{B}}^{\mathbb{N}}(\mathcal{A}^{\mathbb{Z}}) = \mathcal{B}^{\mathbb{N}}).$$

Thus, one-sided, right-permutative CA and two-sided, bipermutative CA are both topologically conjugate the one-sided full shift $(\mathcal{B}^{\mathbb{N}}, \sigma)$, where \mathcal{B} is an alphabet with $|\mathcal{A}|^{R+L}$ symbols (setting $L = 0$ in the one-sided case).

Proof Suppose $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$ (where $\mathbb{M} = \mathbb{N}$ or \mathbb{Z}). Draw a picture of the spacetime diagram for Φ . For any $t \in \mathbb{N}$, and any $\mathbf{b} \in \mathcal{B}^{(0 \dots t)}$, observe how (bi)permutativity allows you to reconstruct a unique $\mathbf{a}_{[-tL \dots tR]} \in \mathcal{A}^{[-tL \dots tR]}$ such that $\mathbf{b} = (\mathbf{a}_{\mathbb{B}}, \Phi(\mathbf{a})_{\mathbb{B}}, \Phi^2(\mathbf{a})_{\mathbb{B}}, \dots, \Phi^{t-1}(\mathbf{a})_{\mathbb{B}})$. By letting $t \rightarrow \infty$, we see that the function $\Phi_{\mathbb{B}}^{\mathbb{N}}$ is a bijection between $\mathcal{A}^{\mathbb{M}}$ and $\mathcal{B}^{\mathbb{N}}$. \square

Remark 12 (a) The idea of Proposition 11 is implicit in Theorem 6.7 in [58], but it was apparently first stated explicitly by Shereshevsky and Afraïmovich (see Theorem 1 in [130]). It was later rediscovered by Kleveland (see Corollary 7.3 in [74]) and Fagnani and Margara (see Theorem 3.2 in [35]).

(b) Proposition 11(b) has been generalized to higher dimensions by Allouche and Skordev (see Proposition 1 in [3]), who showed that, if $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}^D})$ is permutative in the ‘corner’ entries of its neighborhood, then Φ is conjugate to a full shift $(\mathcal{K}^{\mathbb{N}}, \sigma)$, where \mathcal{K} is an uncountable, compact space.

Proposition 11 is quite indicative of the general case. Po-expansiveness occurs only in one-dimensional CA, in which it takes a very specific form. To explain this, suppose (\mathbb{M}, \cdot) is a group with finite generating set $\mathbb{G} \subset \mathbb{M}$. For any $r > 0$, let $\mathbb{B}(r) := \{\mathbf{g}_1 \cdot \mathbf{g}_2 \cdots \mathbf{g}_r; \mathbf{g}_1, \dots, \mathbf{g}_r \in \mathbb{G}\}$. The *dimension* (or *growth degree*) of (\mathbb{M}, \cdot) is defined $\dim(\mathbb{M}, \cdot) := \limsup_{r \rightarrow \infty} \log |\mathbb{B}(r)| / \log(r)$; see [50] or [49]. It can be shown that this number is independent of the choice of generating set \mathbb{G} , and is always an integer. For example, $\dim(\mathbb{Z}^D, +) = D$. If $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$ is a subshift, then we define its topological entropy $h_{\text{top}}(\mathbf{X})$ with respect to $\dim(\mathbb{M})$ in the obvious fashion (see Example 75(a)).

Theorem 13 *Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$.*

- (a) *If $\mathbb{M} = \mathbb{Z}^D \times \mathbb{N}^E$ with $D + E \geq 2$, then Φ cannot be posexpansive.*
- (b) *If \mathbb{M} is any group with $\dim(\mathbb{M}) \geq 2$, and $\mathbf{X} \subseteq \mathcal{A}^{\mathbb{M}}$ is any subshift with $h_{\text{top}}(\mathbf{X}) > 0$, and $\Phi(\mathbf{X}) \subseteq \mathbf{X}$, then the system (\mathbf{X}, Φ) cannot be posexpansive.*
- (c) *Suppose $\mathbb{M} = \mathbb{Z}$ or \mathbb{N} , and Φ has neighborhood $[-L \dots R] \subset \mathbb{M}$. Let $\bar{L} := \max\{0, L\}$, $\bar{R} := \max\{0, R\}$ and $\mathbb{B} := [-\bar{L} \dots \bar{R}]$. If Φ is posexpansive, then Φ is \mathbb{B} -posexpansive.*

Proof (a) is Corollary 2 in [127]; see also Theorem 4.4 in [37]. Part (b) follows by applying Theorem 1.1 in [128] to the natural extension of (\mathbf{X}, Φ) .

(c) The case $\mathbb{M} = \mathbb{Z}$ is Proposition 7 in [75]. The case $\mathbb{M} = \mathbb{N}$ is Proposition 2.3 in [9]. \square

Proposition 11 says bipermutative CA on $\mathcal{A}^{\mathbb{Z}}$ are conjugate to full shifts. Using his formidable theory of *textile systems*, Nasu extended this to *all* posexpansive CA on $\mathcal{A}^{\mathbb{Z}}$.

Theorem 14 (Nasu’s) *Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ and let $\mathbb{B} \subset \mathbb{Z}$. If Φ is \mathbb{B} -posexpansive, then $\Phi_{\mathbb{B}}^{\mathbb{N}}(\mathcal{A}^{\mathbb{Z}}) \subseteq \mathcal{B}^{\mathbb{N}}$ is a one-sided SFT which is conjugate to a one-sided full shift $C^{\mathbb{N}}$ for some alphabet C with $|C| \geq 3$.*

Proof sketch The fact that $\mathbf{X} := \Phi_{\mathbb{B}}^{\mathbb{N}}(\mathcal{A}^{\mathbb{Z}})$ is an SFT follows from Theorem 10 in [75] or Theorem 10.1 in [76]. Next, Theorem 3.12(1) on p. 49 of [105] asserts that, if Φ is any surjective endomorphism of an irreducible, aperiodic, SFT $\mathbf{Y} \subseteq \mathcal{A}^{\mathbb{Z}}$, and (\mathbf{Y}, Φ) is itself conjugate to an SFT, then (\mathbf{Y}, Φ) is actually conjugate to a full shift $(C^{\mathbb{N}}, \sigma)$ for some alphabet C with $|C| \geq 3$. Let $\mathbf{Y} := \mathcal{A}^{\mathbb{Z}}$ and invoke Kůrka’s result.

For a direct proof not involving textile systems, see Theorem 4.9 in [86]. \square

Remark 15 (a) See Theorem 60(d) for an ‘ergodic’ version of Theorem 14.

(b) In contrast to Proposition 11, Nasu’s Theorem 14 does *not* say that $\Phi_{\mathbb{B}}^{\mathbb{N}}(\mathcal{A}^{\mathbb{Z}})$ itself is a full shift – only that it is conjugate to one.

If $(\mathbf{X}, \mu; \Psi)$ is a measure-preserving dynamical system (MPDS) with sigma-algebra \mathfrak{B} , then a *one-sided generator* is a finite partition $\mathfrak{P} \subset \mathfrak{B}$ such that $\bigvee_{t=0}^{\infty} \Psi^{-t}\mathfrak{P} \stackrel{\mu}{=} \mathfrak{B}$. If \mathfrak{P} has C elements, and C is a finite set with $|C| = C$, then \mathfrak{P} induces an essentially injective function $p: \mathbf{X} \rightarrow C^{\mathbb{N}}$ such that $p \circ \Psi = \sigma \circ p$. Thus, if $\lambda := p(\mu)$, then $(\mathbf{X}, \mu; \Psi)$ is measurably isomorphic to the (one-sided) stationary stochastic process $(C^{\mathbb{N}}, \lambda; \sigma)$. If Ψ is invertible, then a (two-sided) *generator* is a finite partition $\mathfrak{P} \subset \mathfrak{B}$ such that $\bigvee_{t=-\infty}^{\infty} \Psi^t\mathfrak{P} \stackrel{\mu}{=} \mathfrak{B}$. The Krieger Generator Theorem says every finite-entropy, invertible MPDS has a generator; indeed, if $h(\Psi, \mu) \leq \log_2(C)$, then $(\mathbf{X}, \mu; \Psi)$ has a generator with C or less elements (► [Ergodic Theory: Basic Examples and Constructions](#)). If $|C| = C$, then once again, \mathfrak{P} induces a measurable isomorphism from $(\mathbf{X}, \mu; \Psi)$ to a two-sided stationary stochastic process $(C^{\mathbb{Z}}, \lambda; \sigma)$, for some stationary measure λ on $\mathcal{A}^{\mathbb{Z}}$.

Corollary 16 (Universal Representation) *Let $\mathbb{M} = \mathbb{N}$ or \mathbb{Z} , and let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{M}})$ have neighborhood $\mathbb{H} \subset \mathbb{M}$. Suppose that*

- either $\mathbb{M} = \mathbb{N}$, Φ is right-permutative, and $\mathbb{H} = [r \dots R]$ for some $0 \leq r < R$, and then let $C := R \log_2 |\mathcal{A}|$;*
- or $\mathbb{M} = \mathbb{Z}$, Φ is bipermutative, and $\mathbb{H} = [-L \dots R]$, and then let $C := (\bar{L} + \bar{R}) \log_2 |\mathcal{A}|$ where $\bar{L} := \max\{0, L\}$ and $\bar{R} := \max\{0, R\}$;*
- or $\mathbb{M} = \mathbb{Z}$ and Φ is positively expansive, and $h_{\text{top}}(\mathcal{A}^{\mathbb{M}}, \Phi) = \log_2(C)$ for some $C \in \mathbb{N}$.*

- (a) *Let $(\mathbf{X}, \mu; \Psi)$ be any MPDS with a one-sided generator having at most C elements. Then there exists $\nu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{M}}, \Phi)$ such that the system $(\mathcal{A}^{\mathbb{M}}, \nu; \Phi)$ is measurably isomorphic to $(\mathbf{X}, \mu; \Psi)$.*
- (b) *Let $(\mathbf{X}, \mu; \Psi)$ be an invertible MPDS, with measurable entropy $h(\mu, \phi) \leq \log_2(C)$. Then there exists $\nu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{M}}, \Phi)$ such that the natural extension of the system $(\mathcal{A}^{\mathbb{M}}, \nu; \Phi)$ is measurably isomorphic to (\mathbf{X}, μ, Ψ) .*

Proof Under each of the three hypotheses, Proposition 11 or Theorem 14 yields a topological conjugacy $\Gamma: (C^{\mathbb{N}}, \sigma) \rightarrow (\mathcal{A}^{\mathbb{M}}, \Phi)$, where C is a set of cardinality C .

- (a) As discussed above, there is a measure λ on $C^{\mathbb{N}}$ such that $(C^{\mathbb{N}}, \lambda; \sigma)$ is measurably isomorphic to (\mathbf{X}, μ, Ψ) . Thus, $\nu := \Gamma[\lambda]$ is a Φ -invariant measure on $\mathcal{A}^{\mathbb{M}}$, and $(\mathcal{A}^{\mathbb{M}}, \nu; \Phi)$ is isomorphic to $(C^{\mathbb{N}}, \mu, \Psi)$ via Γ .
- (b) As discussed above, there is a measure λ on $C^{\mathbb{Z}}$ such that $(C^{\mathbb{Z}}, \lambda; \sigma)$ is measurably isomorphic to (\mathbf{X}, μ, Ψ) .

Let $\lambda_{\mathbb{N}}$ be the projection of λ to $C^{\mathbb{N}}$; then $(C^{\mathbb{N}}, \lambda_{\mathbb{N}}; \sigma)$ is a one-sided stationary process. Thus, $\nu := \Gamma[\lambda_{\mathbb{N}}]$ is a Φ -invariant measure on $\mathcal{A}^{\mathbb{M}}$, and $(\mathcal{A}^{\mathbb{M}}, \nu; \Phi)$ is isomorphic to $(C^{\mathbb{N}}, \lambda_{\mathbb{N}}; \sigma)$ via Γ . Thus, the natural extension of $(\mathcal{A}^{\mathbb{M}}, \nu; \Phi)$ is isomorphic to the natural extension of $(C^{\mathbb{N}}, \lambda_{\mathbb{N}}; \sigma)$, which is $(C^{\mathbb{Z}}, \lambda; \sigma)$, which is in turn isomorphic to $(\mathbf{X}, \mu; \Psi)$. □

Remark 17 The Universal Representation Corollary implies that studying the measurable dynamics of the CA Φ with respect to some arbitrary Φ -invariant measure ν will generally tell us nothing whatsoever about Φ . For these measurable dynamics to be meaningful, we must pick a measure on $\mathcal{A}^{\mathbb{M}}$ which is somehow ‘natural’ for Φ . First, this measure should be shift-invariant (because one of the defining properties of CA is that they commute with the shift). Second, we should seek a measure which has maximal Φ -entropy or is distinguished in some other way. (In general, the measures ν given by the Universal Representation Corollary will neither be σ -invariant, nor have maximal entropy for Φ .)

If $\Phi_{\mathbb{N}} \in \text{CA}(\mathcal{A}^{\mathbb{N}})$, and $\Phi_{\mathbb{Z}} \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ is the CA obtained by applying the same local rule to all coordinates in \mathbb{Z} , then $\Phi_{\mathbb{Z}}$ can *never* be posexpansive: if $\mathbb{B} = [-B \dots B]$, and $\mathbf{a}, \mathbf{a}' \in \mathcal{A}^{\mathbb{Z}}$ are any two sequences such that $\mathbf{a}_{(-\infty \dots -B)} \neq \mathbf{a}'_{(-\infty \dots -B)}$, then $\Phi^t(\mathbf{a})_{\mathbb{B}} = \Phi^t(\mathbf{a}')_{\mathbb{B}}$ for all $t \in \mathbb{N}$, because the local rule of Φ only propagates information to the left. Thus, in particular, the posexpansive CA on $\mathcal{A}^{\mathbb{Z}}$ are completely unrelated to the posexpansive CA on $\mathcal{A}^{\mathbb{N}}$. Nevertheless, posexpansive CA on $\mathcal{A}^{\mathbb{N}}$ behave quite similarly to those on $\mathcal{A}^{\mathbb{Z}}$.

Theorem 18 *Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{N}})$ have neighborhood $[r \dots R]$, where $0 \leq r < R$, and let $\mathbb{B} := [0 \dots R)$. Suppose Φ is posexpansive. Then:*

- (a) $\mathbf{X} := \Phi_{\mathbb{B}}^{\mathbb{N}}(\mathcal{A}^{\mathbb{N}}) \subseteq \mathcal{B}^{\mathbb{N}}$ is a topologically mixing SFT.
- (b) The topological entropy of Φ is $\log_2(k)$ for some $k \in \mathbb{N}$.
- (c) If η is the uniform measure on $\mathcal{A}^{\mathbb{N}}$, then $\Phi_{\mathbb{B}}^{\mathbb{N}}(\eta)$ is the Parry measure on \mathbf{X} . Thus, η is the maxentropy measure for Φ .

Proof See Corollary 3.7 and Theorems 3.8 and 3.9 in [9] or Theorem 4.8(1,2,4) in [86]. □

Remark (a) See Theorem 58 for an ‘ergodic’ version of Theorem 18.

(b) The analog of Nasu’s Theorem 14 (i. e. conjugacy to a full shift) is *not* true for posexpansive CA on $\mathcal{A}^{\mathbb{N}}$. See [13] for a counterexample.

(c) If $\Phi: \mathcal{A}^{\mathbb{N}} \rightarrow \mathcal{A}^{\mathbb{N}}$ is invertible, then we define the function $\Phi_{\mathbb{B}}^{\mathbb{Z}}: \mathcal{A}^{\mathbb{N}} \rightarrow \mathcal{B}^{\mathbb{Z}}$ by extending the defini-

tion of $\Phi_{\mathbb{B}}^{\mathbb{N}}$ to negative times. We say that Φ is *expansive* if $\Phi_{\mathbb{B}}^{\mathbb{Z}}$ is bijective for some finite $\mathbb{B} \subset \mathbb{N}$. Expansiveness is a much weaker condition than *positive* expansiveness. Nevertheless, the analog of Theorem 18(a) is true: if $\Phi: \mathcal{A}^{\mathbb{N}} \rightarrow \mathcal{A}^{\mathbb{N}}$ is invertible and expansive, then $\mathcal{B}^{\mathbb{Z}}$ is conjugate to a (two-sided) subshift of finite type; see Theorem 1.3 in [106].

Measure Rigidity in Algebraic CA

Theorem 1 makes the uniform measure η a ‘natural’ invariant measure for a surjective CA Φ . However, Proposition 10 and Corollary 16 indicate that there are many other (unnatural) Φ -invariant measures as well. Thus, it is natural to seek conditions under which the uniform measure η is the unique (or almost unique) measure which is Φ -invariant, shift-invariant, and perhaps ‘nondegenerate’ in some other sense – a phenomenon which is sometimes called *measure rigidity*. Measure rigidity has been best understood when Φ is compatible with an underlying algebraic structure on $\mathcal{A}^{\mathbb{M}}$.

Let $\star: \mathcal{A}^{\mathbb{M}} \times \mathcal{A}^{\mathbb{M}} \rightarrow \mathcal{A}^{\mathbb{M}}$ be a binary operation (‘multiplication’) and let $\bullet^{-1}: \mathcal{A}^{\mathbb{M}} \rightarrow \mathcal{A}^{\mathbb{M}}$ be an unary operation (‘inversion’) such that $(\mathcal{A}^{\mathbb{M}}, \star)$ is a group, and suppose both operations are continuous and commute with all \mathbb{M} -shifts; then $(\mathcal{A}^{\mathbb{M}}, \star)$ is called a *group shift*. For example, if (\mathcal{A}, \cdot) is itself a finite group, and $\mathcal{A}^{\mathbb{M}}$ is treated as a Cartesian product and endowed with componentwise multiplication, then $(\mathcal{A}^{\mathbb{M}}, \cdot)$ is a group shift. However, not all group shifts arise in this manner; see [70,71,72,73,124]. If $(\mathcal{A}^{\mathbb{M}}, \star)$ is a group shift, then a *subgroup shift* is a closed, shift-invariant subgroup $\mathbf{G} \subset \mathcal{A}^{\mathbb{M}}$ (i. e. \mathbf{G} is both a subshift and a subgroup).

If (\mathbf{G}, \star) is a subgroup shift, then the *Haar measure* on \mathbf{G} is the unique probability measure $\eta_{\mathbf{G}}$ on \mathbf{G} which is invariant under translation by all elements of \mathbf{G} . That is, if $\mathbf{g} \in \mathbf{G}$, and $\mathbf{U} \subset \mathbf{G}$ is any measurable subset, and $\mathbf{U} \star \mathbf{g} := \{\mathbf{u} \star \mathbf{g}; \mathbf{u} \in \mathbf{U}\}$, then $\eta_{\mathbf{G}}[\mathbf{U} \star \mathbf{g}] = \eta_{\mathbf{G}}[\mathbf{U}]$. In particular, if $\mathbf{G} = \mathcal{A}^{\mathbb{M}}$, then $\eta_{\mathbf{G}}$ is just the uniform Bernoulli measure on $\mathcal{A}^{\mathbb{M}}$. The Haar measure is a maxentropy measure on \mathbf{G} (see Subsect. “[Invariance of Maxentropy Measures](#)”).

If $(\mathcal{A}^{\mathbb{M}}, \star)$ is a group shift, and $\mathbf{G} \subseteq \mathcal{A}^{\mathbb{M}}$ is a subgroup shift, and $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$, then Φ is called an *endomorph*ic (or *algebraic*) CA on \mathbf{G} if $\Phi(\mathbf{G}) \subseteq \mathbf{G}$ and $\Phi: \mathbf{G} \rightarrow \mathbf{G}$ is an endomorphism of (\mathbf{G}, \star) as a topological group. Let $\mathcal{ECA}(\mathbf{G}, \star)$ denote the set of endomorphic CA on \mathbf{G} . For example, suppose $(\mathcal{A}, +)$ is abelian, and let $(\mathbf{G}, \star) := (\mathcal{A}^{\mathbb{M}}, +)$ with the product group structure; then the endomorphic CA on $\mathcal{A}^{\mathbb{M}}$ are exactly the linear CA. However, if (\mathcal{A}, \cdot) is a *nonabelian* group, then

endomorphic CA on $(\mathcal{A}^{\mathbb{M}}, \cdot)$ are *not* the same as multiplicative CA.

Even in this context, CA admit many nontrivial invariant measures. For example, it is easy to check the following:

Proposition 19 *Let $\mathcal{A}^{\mathbb{M}}$ be a group shift and let $\Phi \in \mathcal{ECA}(\mathcal{A}^{\mathbb{M}}, \star)$. Let $\mathbf{G} \subseteq \mathcal{A}^{\mathbb{M}}$ be any Φ -invariant subgroup shift; then the Haar measure on \mathbf{G} is Φ -invariant.*

For example, if $(\mathcal{A}, +)$ is any nonsimple abelian group, and $(\mathcal{A}^{\mathbb{M}}, +)$ has the product group structure, then $\mathcal{A}^{\mathbb{M}}$ admits many nontrivial subgroup shifts; see [73]. If Φ is any linear CA on $\mathcal{A}^{\mathbb{M}}$ with scalar coefficients, then every subgroup shift of $\mathcal{A}^{\mathbb{M}}$ is Φ -invariant, so Proposition 19 yields many nontrivial Φ -invariant measures. To isolate η as a unique measure, we must impose further restrictions. The first nontrivial results in this direction were by Host, Maass, and Martínez [61]. Let $h(\Phi, \mu)$ be the entropy of Φ relative to the measure μ (see Sect. “[Entropy](#)” for definition).

Proposition 20 *Let $\mathcal{A} := \mathbb{Z}/p$, where p is prime. Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ be a linear CA with neighborhood $\{0, 1\}$, and let $\mu \in \mathfrak{M}_{\text{mes}}(\mathcal{A}^{\mathbb{Z}}; \Phi, \sigma)$. If μ is σ -ergodic, and $h(\Phi, \mu) > 0$, then μ is the Haar measure η on $\mathcal{A}^{\mathbb{Z}}$.*

Proof See Theorem 12 in [61]. □

A similar idea is behind the next result, only with the roles of Φ and σ reversed. If μ is a measure on $\mathcal{A}^{\mathbb{N}}$, and $\mathbf{b} \in \mathcal{A}^{[1 \dots \infty]}$, then we define the conditional measure $\mu^{(\mathbf{b})}$ on \mathcal{A} by $\mu^{(\mathbf{b})}(a) := \mu[x_0 = a | \mathbf{x}_{[1 \dots \infty]} = \mathbf{b}]$, where \mathbf{x} is a μ -random sequence. For example, if μ is a Bernoulli measure, then $\mu^{(\mathbf{b})}(a) = \mu[x_0 = a]$, independent of \mathbf{b} ; if μ is a Markov measure, then $\mu^{(\mathbf{b})}(a) = \mu[x_0 = a | x_1 = b_1]$.

Proposition 21 *Let (\mathcal{A}, \cdot) be any finite (possibly nonabelian) group, and let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{N}})$ have multiplicative local rule $\phi: \mathcal{A}^{\{0,1\}} \rightarrow \mathcal{A}$ defined by $\phi(a_0, a_1) := a_0 \cdot a_1$. Let $\mu \in \mathfrak{M}_{\text{mes}}(\mathcal{A}^{\mathbb{Z}}; \Phi, \sigma)$. If μ is Φ -ergodic, then there is some subgroup $C \subset \mathcal{A}$ such that, for every $\mathbf{b} \in \mathcal{A}^{[1 \dots \infty]}$, $\text{supp}(\mu^{(\mathbf{b})})$ is a right coset of C , and $\mu^{(\mathbf{b})}$ is uniformly distributed on this coset.*

Proof See Theorem 3.1 in [113]. □

Example 22 Let Φ and μ be as in Proposition 21. Let η be the Haar measure on $\mathcal{A}^{\mathbb{N}}$

(a) μ has *complete connections* if $\text{supp}(\mu^{(\mathbf{b})}) = \mathcal{A}$ for μ -almost all $\mathbf{b} \in \mathcal{A}^{[1 \dots \infty]}$. Thus, if μ has complete connections in Proposition 21, then $\mu = \eta$.

(b1) Suppose $h(\mu, \sigma) > h_0 := \max\{\log_2 |C|; C \text{ a proper subgroup of } \mathcal{A}\}$. Then $\mu = \eta$.

(b2) In particular, suppose $\mathcal{A} = (\mathbb{Z}/p, +)$, where p is prime; then $h_0 = 0$. Thus, if Φ has local rule $\phi(a_0, a_1) := a_0 + a_1$, and μ is any σ -invariant, Φ -ergodic measure with $h(\mu, \sigma) > 0$, then $\mu = \eta$. This is closely analogous to Proposition 20, but ‘dual’ to it, because the roles of Φ and σ are reversed in the ergodicity and entropy hypotheses.

(c) If $C \subset \mathcal{A}$ is a subgroup, and μ is the Haar measure on the subgroup shift $C^{\mathbb{N}} \subset \mathcal{A}^{\mathbb{N}}$, then μ satisfies the conditions of Proposition 21. Other, less trivial possibilities also exist (see Examples 3.2(b,c) in [113]).

If μ is a measure on $\mathcal{A}^{\mathbb{Z}}$, and $\mathbf{X}, \mathbf{Y} \subset \mathcal{A}^{\mathbb{Z}}$, then we say \mathbf{X} essentially equals \mathbf{Y} and write $\mathbf{X} \overline{\mu} \mathbf{Y}$ if $\mu[\mathbf{X} \Delta \mathbf{Y}] = 0$. If $n \in \mathbb{N}$, then let

$$\mathfrak{S}_n(\mu) := \left\{ \mathbf{X} \subset \mathcal{A}^{\mathbb{Z}}; \sigma^n(\mathbf{X}) \overline{\mu} \mathbf{X} \right\}$$

be the sigma-algebra of subsets of $\mathcal{A}^{\mathbb{Z}}$ which are ‘essentially’ σ^n -invariant. Thus, μ is σ -ergodic if and only if $\mathfrak{S}_1(\mu)$ is trivial (i. e. contains only sets of measure zero or one). We say μ is totally σ -ergodic if $\mathfrak{S}_n(\mu)$ is trivial for all $n \in \mathbb{N}$ (► Ergodicity and Mixing Properties).

Let $(\mathcal{A}^{\mathbb{Z}}, *)$ be any group shift. The identity element \mathbf{e} of $(\mathcal{A}^{\mathbb{Z}}, *)$ is a constant sequence. Thus, if $\Phi \in \text{ECA}(\mathcal{A}^{\mathbb{Z}}, *)$ is surjective, then $\ker(\Phi) := \{\mathbf{a} \in \mathcal{A}^{\mathbb{Z}}; \Phi(\mathbf{a}) = \mathbf{e}\}$ is a finite, shift-invariant subgroup of $\mathcal{A}^{\mathbb{Z}}$ (i. e. a finite collection of σ -periodic sequences).

Proposition 23 *Let $(\mathcal{A}^{\mathbb{Z}}, *)$ be a (possibly nonabelian) group shift, and let $\Phi \in \text{ECA}(\mathcal{A}^{\mathbb{Z}}, *)$ be bipermutative, with neighborhood $\{0, 1\}$. Let $\mu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{Z}}; \Phi, \sigma)$. Suppose that:*

- (IE) μ is totally ergodic for σ ;
 - (H) $h(\Phi, \mu) > 0$; and
 - (K) $\ker(\Phi)$ contains no nontrivial σ -invariant subgroups.
- Then μ is the Haar measure on $\mathcal{A}^{\mathbb{Z}}$.

Proof See Theorem 5.2 in [113]. □

Example 24 If $\mathcal{A} = \mathbb{Z}/p$ and $(\mathcal{A}^{\mathbb{Z}}, +)$ is the product group, then Φ is a linear CA and condition (c) is automatically satisfied, so Proposition 23 becomes a special case of Proposition 20.

If $\Phi \in \text{ECA}(\mathcal{A}^{\mathbb{Z}}, *)$, then we have an increasing sequence of finite, shift-invariant subgroups $\ker(\Phi) \subseteq \ker(\Phi^2) \subseteq \ker(\Phi^3) \subseteq \dots$. If $\mathbf{K}(\Phi) := \bigcup_{n=1}^{\infty} \ker(\Phi^n)$, then $\mathbf{K}(\Phi)$ is a countable, shift-invariant subgroup of $(\mathcal{A}^{\mathbb{Z}}, *)$.

Theorem 25 *Let $(\mathcal{A}^{\mathbb{Z}}, +)$ be an abelian group shift, and let $\mathbf{G} \subseteq \mathcal{A}^{\mathbb{Z}}$ be a subgroup shift. Let $\Phi \in \text{ECA}(\mathbf{G}, +)$ be bipermutative, and let $\mu \in \mathfrak{M}_{\text{ens}}(\mathbf{G}; \Phi, \sigma)$. Suppose:*

- (I) $\mathfrak{S}_{kP}(\mu) = \mathfrak{S}_1(\mu)$, where P is the lowest common multiple of the σ -periods of all elements in $\ker(\Phi)$, and

$k \in \mathbb{N}$ is any common multiple of all prime factors of $|\mathcal{A}|$.

- (H) $h(\Phi, \mu) > 0$.

Furthermore, suppose that either:

- (E1) μ is ergodic for the $\mathbb{N} \times \mathbb{Z}$ action (Φ, σ) ;
 - (K1) Every infinite, σ -invariant subgroup of $\mathbf{K}(\Phi) \cap \mathbf{G}$ is dense in \mathbf{G} ;
- or:
- (E2) μ is σ -ergodic;
 - (K2) Every infinite, (Φ, σ) -invariant subgroup of $\mathbf{K}(\Phi) \cap \mathbf{G}$ is dense in \mathbf{G} .

Then μ is the Haar measure on \mathbf{G} .

Proof See Theorems 3.3 and 3.4 of [122], or Théorèmes V.4 and V.5 on p. 115 of [120]. In the special case when \mathbf{G} is irreducible and has topological entropy $\log_2(p)$ (where p is prime), Sobottka has given a different and simpler proof, by using his theory of ‘quasigroup shifts’ to establish an isomorphism between Φ and a linear CA on \mathbb{Z}/p , and then invoking Theorem 7. See Theorems 7.1 and 7.2 of [136], or Teoremas IV.3.1 and IV.3.2 on pp. 100–101 of [134]. □

Example 26 (a) Let $\mathcal{A} := \mathbb{Z}/p$, where p is prime. Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ be linear, and suppose that $\mu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{Z}}; \Phi, \sigma)$ is (Φ, σ) -ergodic, $h(\Phi, \mu) > 0$, and $\mathfrak{S}_{p(p-1)}(\mu) = \mathfrak{S}_1(\mu)$. Setting $k = p$ and $P = p - 1$ in Theorem 25, we conclude that μ is the Haar measure on $\mathcal{A}^{\mathbb{Z}}$. For Φ with neighborhood $\{0, 1\}$, this result first appeared as Theorem 13 in [61].

(b) If $(\mathcal{A}^{\mathbb{Z}}, *)$ is abelian, then Proposition 23 is a special case of Theorem 25 [hypothesis (IE) of the former implies hypotheses (I) and (E2) of the latter, while (K) implies (K2)]. Note, however, that Proposition 23 also applies to nonabelian groups.

An algebraic \mathbb{Z}^D -action is an action of \mathbb{Z}^D by automorphisms on a compact abelian group \mathbf{G} . For example, if $\mathbf{G} \subseteq \mathcal{A}^{\mathbb{Z}^D}$ is an abelian subgroup shift, then σ is an algebraic \mathbb{Z}^D -action. The invariant measures of algebraic \mathbb{Z}^D -actions have been studied in Schmidt (see Sect. 29 in [124]), Silberger (see Sect. 7 in [132]), and Einsiedler [28,29].

If $\Phi \in \text{CA}(\mathbf{G})$, then a complete history for Φ is a sequence $(\mathbf{g}_t)_{t \in \mathbb{Z}} \in \mathbf{G}^{\mathbb{Z}}$ such that $\Phi(\mathbf{g}_t) = \mathbf{g}_{t+1}$ for all $t \in \mathbb{Z}$. Let $\Phi^{\mathbb{Z}}(\mathbf{G}) \subset \mathbf{G}^{\mathbb{Z}} \subseteq (\mathcal{A}^{\mathbb{Z}^D})^{\mathbb{Z}} \cong \mathcal{A}^{\mathbb{Z}^{D+1}}$ be the set of all complete histories for Φ ; then $\Phi^{\mathbb{Z}}(\mathbf{G})$ is a subshift of $\mathcal{A}^{\mathbb{Z}^{D+1}}$. If $\Phi \in \text{ECA}[\mathbf{G}]$, then $\Phi^{\mathbb{Z}}(\mathbf{G})$ is itself an abelian subgroup shift, and the shift action of \mathbb{Z}^{D+1} on $\Phi^{\mathbb{Z}}(\mathbf{G})$ is thus an algebraic \mathbb{Z}^{D+1} -action. Any (Φ, σ) -invariant measure on \mathbf{G} extends in the obvious way to a σ -invariant measure on $\Phi^{\mathbb{Z}}(\mathbf{G})$. Thus, any result about the invariant measures (or rigidity) of algebraic \mathbb{Z}^{D+1} -actions can

be translated immediately into a result about the invariant measures (or rigidity) of endomorphic cellular automata.

Proposition 27 *Let $G \subseteq \mathcal{A}^{\mathbb{Z}^D}$ be an abelian subgroup shift and let $\Phi \in ECA(G)$. Suppose $\mu \in \mathfrak{M}_{\text{ens}}(G; \Phi, \sigma)$ is (Φ, σ) -totally ergodic, and has entropy dimension $d \in [1 \dots D]$ (see Subsect. “Entropy Geometry and Expansive Subdynamics”). If the system $(G, \mu; \Phi, \sigma)$ admits no factors whose d -dimensional measurable entropy is zero, then there is a Φ -invariant subgroup shift $G' \subseteq G$ and some element $\mathbf{x} \in G$ such that μ is the translated Haar measure on the ‘affine’ subset $G' + \mathbf{x}$.*

Proof This follows from Corollary 2.3 in [29]. □

If we remove the requirement of ‘no zero-entropy factors’, and instead require G and Φ to satisfy certain technical algebraic conditions, then μ must be the Haar measure on G (see Theorem 1.2 in [29]). These strong hypotheses are probably necessary, because in general, the system (G, σ, Φ) admits uncountably many distinct nontrivial invariant measures, even if (G, σ, Φ) is *irreducible*, meaning that G contains no proper, infinite, Φ -invariant subgroup shifts:

Proposition 28 *Let $G \subseteq \mathcal{A}^{\mathbb{Z}^D}$ be an abelian subgroup shift, let $\Phi \in ECA(G)$, and suppose (G, σ, Φ) is irreducible. For any $s \in [0, 1)$, there exists a (Φ, σ) -ergodic measure $\mu \in \mathfrak{M}_{\text{ens}}(G; \Phi, \sigma)$ such that $h(\mu, \Phi^n \circ \sigma^z) = s \cdot h_{\text{top}}(G, \Phi^n \circ \sigma^z)$ for every $n \in \mathbb{N}$ and $z \in \mathbb{Z}^D$.*

Proof This follows from Corollary 1.4 in [28]. □

Let $\mu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{M}}; \sigma)$ and let $\mathbb{H} \subset \mathbb{M}$ be a finite subset. We say that μ is \mathbb{H} -mixing if, for any \mathbb{H} -indexed collection $\{\mathbf{U}_h\}_{h \in \mathbb{H}}$ of measurable subsets of $\mathcal{A}^{\mathbb{M}}$,

$$\lim_{n \rightarrow \infty} \mu \left[\bigcap_{h \in \mathbb{H}} \sigma^{nh}(\mathbf{U}_h) \right] = \prod_{h \in \mathbb{H}} \mu[\mathbf{U}_h].$$

For example, if $|\mathbb{H}| = H$, then any H -multiply σ -mixing measure (see Subsect. “Mixing and Ergodicity”) is \mathbb{H} -mixing.

Proposition 29 *Let $G \subseteq \mathcal{A}^{\mathbb{Z}^D}$ be an abelian subgroup shift and let $\Phi \in ECA(G)$ have neighborhood \mathbb{H} (with $|\mathbb{H}| \geq 2$). Suppose (G, σ, Φ) is irreducible, and let $\mu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{Z}^D}; \Phi, \sigma)$. Then μ is \mathbb{H} -mixing if and only if μ is the Haar measure of G .*

Proof This follows from [124], Corollary 29.5, p. 289 (note that Schmidt uses ‘almost minimal’ to mean ‘irreducible’). A significant generalization of Proposition 29 appears in [115] □

The Furstenberg Conjecture

Let $\mathbb{T}^1 = \mathbb{R}/\mathbb{Z}$ be the circle group, which we identify with the interval $[0, 1)$. Define the functions $\times_2, \times_3: \mathbb{T}^1 \rightarrow \mathbb{T}^1$ by $\times_2(t) = 2t \pmod{1}$ and $\times_3(t) = 3t \pmod{1}$. Clearly, these maps commute, and preserve the Lebesgue measure on \mathbb{T}^1 . Furstenberg [44] speculated that the *only* nonatomic \times_2 - and \times_3 -invariant measure on \mathbb{T}^1 was the Lebesgue measure. Rudolph [119] showed that, if ρ is (\times_2, \times_3) -invariant measure and *not* Lebesgue, then the systems $(\mathbb{T}^1, \rho, \times_2)$ and $(\mathbb{T}^1, \rho, \times_3)$ have zero entropy; this was later generalized in [60,69]. It is not known whether any nonatomic measures exist on \mathbb{T}^1 which satisfy Rudolph’s conditions; this is considered an outstanding problem in abstract ergodic theory.

To see the connection between Furstenberg’s Conjecture and cellular automata, let $\mathcal{A} = \{0, 1, 2, 3, 4, 5\}$, and define the surjection $\Psi: \mathcal{A}^{\mathbb{N}} \rightarrow \mathbb{T}^1$ by mapping each $\mathbf{a} \in \mathcal{A}^{\mathbb{N}}$ to the element of $[0, 1)$ having \mathbf{a} as its base-6 expansion. That is:

$$\Psi(a_0, a_1, a_2, \dots) := \sum_{n=0}^{\infty} \frac{a_n}{6^{n+1}}.$$

The map Ψ is injective everywhere except on the countable set of sequences ending in $[000 \dots]$ or $[555 \dots]$ (on this set, Ψ is 2-to-1). Furthermore, Ψ defines a semiconjugacy from \times_2 and \times_3 into two CA on $\mathcal{A}^{\mathbb{N}}$. Let $\mathbb{H} := \{0, 1\}$, and define local maps $\xi_2, \xi_3: \mathcal{A}^{\mathbb{H}} \rightarrow \mathcal{A}$ as follows:

$$\begin{aligned} \xi_2(a_0, a_1) &= \left[2a_0 \right]_6 + \left[\frac{a_1}{3} \right] \text{ and} \\ \xi_3(a_0, a_1) &= \left[3a_0 \right]_6 + \left[\frac{a_1}{2} \right], \end{aligned}$$

where, $[a]_6$ is the least residue of a , mod 6. If $\mathcal{E}_p \in CA(\mathcal{A}^{\mathbb{N}})$ has local map ξ_p (for $p = 2, 3$), then it is easy to check that \mathcal{E}_p corresponds to multiplication by p in base-6 notation. In other words, $\Psi \circ \times_p = \mathcal{E}_p \circ \Psi$ for $p = 2, 3$.

If λ is the Lebesgue measure on \mathbb{T}^1 , then $\Psi(\lambda) = \eta$, where η is the uniform Bernoulli measure on $\mathcal{A}^{\mathbb{N}}$. Thus, η is \mathcal{E}_2 - and \mathcal{E}_3 -invariant, and Furstenberg’s Conjecture asserts that η is the *only* nonatomic measure on $\mathcal{A}^{\mathbb{N}}$ which is both \mathcal{E}_2 - and \mathcal{E}_3 -invariant. The shift map $\sigma: \mathcal{A}^{\mathbb{N}} \rightarrow \mathcal{A}^{\mathbb{N}}$ corresponds to multiplication by 6 in base-6 notation. Hence, $\mathcal{E}_2 \circ \mathcal{E}_3 = \sigma$. From this it follows that a measure μ is $(\mathcal{E}_2, \mathcal{E}_3)$ -invariant if and only if μ is (\mathcal{E}_2, σ) -invariant if and only if μ is (σ, \mathcal{E}_3) -invariant. Thus, Furstenberg’s Conjecture equivalently asserts that η is the only stationary, \mathcal{E}_3 -invariant nonatomic measure on $\mathcal{A}^{\mathbb{N}}$, and Rudolph’s result asserts that η is the only such nonatomic measure with nonzero entropy; this is analogous to the

‘measure rigidity’ results of Subsect. “[Measure Rigidity in Algebraic CA](#)”. The existence of zero-entropy, (σ, \mathcal{E}_3) -invariant, nonatomic measures remains an open question.

Remark 30 (a) There is nothing special about 2 and 3; the same results hold for any pair of prime numbers.

(b) Lyons [85] and Rudolph and Johnson [68] have also established that a wide variety of \times_2 -invariant probability measures on \mathbb{T}^1 will weak* converge, under the iteration of \times_3 , to the Lebesgue measure (and vice versa). In the terminology of Subsect. “[Asymptotic Randomization by Linear Cellular Automata](#)”, these results immediately translate into equivalent statements about the ‘asymptotic randomization’ of initial probability measures on $\mathcal{A}^{\mathbb{N}}$ under the iteration of \mathcal{E}_2 or \mathcal{E}_3 .

Domains, Defects, and Particles

Suppose $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$, and there is a collection of Φ -invariant subshifts $\mathbf{P}_1, \mathbf{P}_2, \dots, \mathbf{P}_N \subset \mathcal{A}^{\mathbb{Z}}$ (called *phases*). Any sequence \mathbf{a} can be expressed a finite or infinite concatenation

$$\mathbf{a} = [\dots \mathbf{a}_{-2} \mathbf{d}_{-2} \mathbf{a}_{-1} \mathbf{d}_{-1} \mathbf{a}_0 \mathbf{d}_0 \mathbf{a}_1 \mathbf{d}_1 \mathbf{a}_2 \dots],$$

where each *domain* \mathbf{a}_k is a finite word (or half-infinite sequence) which is admissible to phase \mathbf{P}_n for some $n \in [1 \dots N]$, and where each *defect* \mathbf{d}_k is a (possibly empty) finite word (note that this decomposition may not be unique). Thus, $\Phi(\mathbf{a}) = \mathbf{a}'$, where

$$\mathbf{a}' = [\dots \mathbf{a}'_{-2} \mathbf{d}'_{-2} \mathbf{a}'_{-1} \mathbf{d}'_{-1} \mathbf{a}'_0 \mathbf{d}'_0 \mathbf{a}'_1 \mathbf{d}'_1 \mathbf{a}'_2 \dots],$$

and, for every $k \in \mathbb{Z}$, \mathbf{a}'_k belongs to the same phase as \mathbf{a}_k . We say that Φ has *stable phases* if, for any such \mathbf{a} and \mathbf{a}' in $\mathcal{A}^{\mathbb{Z}}$, it is the case that, for all $k \in \mathbb{Z}$, $|\mathbf{d}'_k| \leq |\mathbf{d}_k|$. In other words, the defects do not grow over time. However, they may propagate sideways; for example, \mathbf{d}'_k may be slightly to the right of \mathbf{d}_k , if the domain \mathbf{a}'_k is larger than \mathbf{a}_k , while the domain \mathbf{a}'_{k+1} is slightly smaller than \mathbf{a}_{k+1} . If \mathbf{a}_k and \mathbf{a}_{k+1} belong to different phases, then the defect \mathbf{d}_k is sometimes called a *domain boundary* (or ‘wall’, or ‘edge particle’). If \mathbf{a}_k and \mathbf{a}_{k+1} belong to the same phase, then the defect \mathbf{d}_k is sometimes called a *dislocation* (or ‘kink’).

Often $\mathbf{P}_n = \{\mathbf{p}\}$ where $\mathbf{p} = [\dots ppp \dots]$ is a constant sequence, or each \mathbf{P}_n consists of the σ -orbit of a single periodic sequence. More generally, the phases $\mathbf{P}_1, \dots, \mathbf{P}_N$ may be subshifts of finite type. In this case, most sequences in $\mathcal{A}^{\mathbb{Z}}$ can be fairly easily and unambiguously decomposed into domains separated by defects. However, if the phases are more complex (e.g. sofic shifts), then the exact definition of a ‘defect’ is actually fairly complicated – see [114] for a rigorous discussion.

Example 31 Let $\mathcal{A} = \{0, 1\}$ and let $\mathbb{H} = \{-1, 0, 1\}$. *Elementary cellular automaton* (ECA) #184 is the CA $\Phi: \mathcal{A}^{\mathbb{Z}} \rightarrow \mathcal{A}^{\mathbb{Z}}$ with local rule $\phi: \mathcal{A}^{\mathbb{H}} \rightarrow \mathcal{A}$ given as follows: $\phi(a_{-1}, a_0, a_1) = 1$ if $a_0 = a_1 = 1$, or if $a_{-1} = 1$ and $a_0 = 0$. On the other hand, $\phi(a_{-1}, a_0, a_1) = 0$ if $a_{-1} = a_0 = 0$, or if $a_1 = 0$ and $a_0 = 1$. Heuristically, each ‘1’ represents a ‘car’ moving cautiously to the right on a single-lane road. During each iteration, each car will advance to the site in front of it, unless that site is already occupied, in which case the car will remain stationary. ECA#184 exhibits one stable phase \mathbf{P} , given by the 2-periodic sequence $[\dots 0101.0101 \dots]$ and its translate $[\dots 1010.1010 \dots]$ (here the decimal point indicates the zeroth coordinate), and Φ acts on \mathbf{P} like the shift. The phase \mathbf{P} admits two dislocations of width 2. The dislocation $\mathbf{d}_0 = [00]$ moves uniformly to the right, while the dislocation $\mathbf{d}_1 = [11]$ moves uniformly to the left. In the traffic interpretation, \mathbf{P} represents freely flowing traffic, \mathbf{d}_0 represents a stretch of empty road, and \mathbf{d}_1 represents a traffic jam.

Example 32 Let $\mathcal{A} := \mathbb{Z}/N$, and let $\mathbb{H} := [-1 \dots 1]$. The one-dimensional, N -color *cyclic cellular automaton* (CCA $_N$) $\Phi: \mathcal{A}^{\mathbb{Z}} \rightarrow \mathcal{A}^{\mathbb{Z}}$ has local rule $\phi: \mathcal{A}^{\mathbb{H}} \rightarrow \mathcal{A}$ defined:

$$\phi(\mathbf{a}) := \begin{cases} a_0 + 1 & \text{if there is some } h \in \mathbb{H} \\ & \text{with } a_h = a_0 + 1; \\ a_0 & \text{otherwise.} \end{cases}$$

(here, addition is mod N). The CCA has phases $\mathbf{P}_0, \mathbf{P}_1, \dots, \mathbf{P}_{N-1}$, where $\mathbf{P}_a = \{[\dots aaa \dots]\}$ for each $a \in \mathcal{A}$. A domain boundary between \mathbf{P}_a and \mathbf{P}_{a-1} moves with constant velocity towards the \mathbf{P}_{a-1} side. All other domain boundaries are stationary.

In a *particle cellular automaton* (PCA), $\mathcal{A} = \{\emptyset\} \sqcup \mathcal{P}$, where \mathcal{P} is a set of ‘particle types’ and \emptyset represents a vacant site. Each particle $p \in \mathcal{P}$ is assigned some (constant) velocity vector $v(p) \in (-\mathbb{H})$ (where \mathbb{H} is the neighborhood of the automaton). Particles propagate with constant velocity through \mathbb{M} until two particles try to simultaneously enter the same site in the lattice, at which point the outcome is determined by a *collision rule*: a stylized ‘chemical reaction equation’. For example, an equation “ $p_1 + p_2 \rightsquigarrow p_3$ ” means that, if particle types p_1 and p_2 collide, they coalesce to produce a particle of type p_3 . On the other hand, “ $p_1 + p_2 \rightsquigarrow \emptyset$ ” means that the two particles annihilate on contact. Formally, given a set of velocities and collision

rules, the local rule $\phi: \mathcal{A}^{\mathbb{H}} \rightarrow \mathcal{A}$ is defined

$$\phi(\mathbf{a}) := \begin{cases} p & \text{if there is a unique } \mathbf{h} \in \mathbb{H} \text{ and } p \in \mathcal{P} \text{ with} \\ & a_{\mathbf{h}} = p \text{ and } v(p) = -\mathbf{h} ; \\ q & \text{if } \{p \in \mathcal{P}; a_{-v(p)} = p\} = \{p_1, p_2, \dots, p_n\}, \\ & \text{and } p_1 + \dots + p_n \rightsquigarrow q . \end{cases}$$

Example 33 The one-dimensional *ballistic annihilation model* (BAM) contains two particle types: $\mathcal{P} = \{\pm 1\}$, with the following rules:

$$v(1) = 1, \quad v(-1) = -1, \quad \text{and} \quad -1 + 1 \rightsquigarrow \emptyset .$$

(This CA is sometimes also called *Just Gliders*.) Thus, $a_z = 1$ if the cell z contains a particle moving to the right with velocity 1, whereas $a_z = -1$ if the cell z contains a particle moving left with velocity -1, and $a_z = \emptyset$ if cell z is vacant. Particles move with constant velocity until they collide with oncoming particles, at which point both particles are annihilated. If $\mathcal{B} := \{\pm 1, \emptyset\}$ and $\mathbb{H} = [-1 \dots 1] \subset \mathbb{Z}$, then we can represent the BAM using $\Psi \in \mathcal{CA}(\mathcal{B}^{\mathbb{Z}})$ with local rule $\psi: \mathcal{B}^{\mathbb{H}} \rightarrow \mathcal{B}$ defined:

$$\psi(b_{-1}, b_0, b_1) := \begin{cases} -1 & \text{if } b_1 = -1 \text{ and} \\ & b_{-1}, b_0 \in \{-1, \emptyset\}; \\ 1 & \text{if } b_{-1} = 1 \text{ and } b_0, b_1 \in \{1, \emptyset\}; \\ \emptyset & \text{otherwise .} \end{cases}$$

Particle CA can be seen as ‘toy models’ of particle physics or microscale chemistry. More interestingly, however, one-dimensional PCA often arise as factors of coalescent-domain CA, with the ‘particles’ tracking the motion of the defects.

Example 34 (a) Let $\mathcal{A} := \{0, 1\}$ and let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ be ECA#184. Let $\mathcal{B} := \{\pm 1, 0\}$, and let $\Psi \in \mathcal{CA}(\mathcal{B}^{\mathbb{Z}})$ be the BAM. Let $\mathbb{G} := \{0, 1\}$, and let $\Gamma: \mathcal{A}^{\mathbb{Z}} \rightarrow \mathcal{B}^{\mathbb{Z}}$ be the block map with local rule $\gamma: \mathcal{A}^{\mathbb{G}} \rightarrow \mathcal{B}$ defined

$$\gamma(a_0, a_1) := 1 - a_0 - a_1 = \begin{cases} 1 & \text{if } [a_0, a_1] = [0, 0] = \mathbf{d}_0; \\ -1 & \text{if } [a_0, a_1] = [1, 1] = \mathbf{d}_1; \\ 0 & \text{otherwise .} \end{cases}$$

Then $\Gamma \circ \Phi = \Psi \circ \Gamma$; in other words, the BAM is a factor of ECA#184, and tracks the motion of the dislocations.

(b) Again, let $\Psi \in \mathcal{CA}(\mathcal{B}^{\mathbb{Z}})$ be the BAM. Let $\mathcal{A} = \mathbb{Z}/3$, and let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ be the 3-color CCA. Let $\mathbb{G} := \{0, 1\}$, and let $\Gamma: \mathcal{A}^{\mathbb{Z}} \rightarrow \mathcal{B}^{\mathbb{Z}}$ be the block map with local rule $\gamma: \mathcal{A}^{\mathbb{G}} \rightarrow \mathcal{B}$ defined

$$\gamma(a_0, a_1) := (a_0 - a_1) \bmod 3 .$$

Then $\Gamma \circ \Phi = \Psi \circ \Gamma$; in other words, the BAM is a factor of CCA₃, and tracks the motion of the domain boundaries.

Thus, it is often possible to translate questions about coalescent domain CA into questions about particle CA, which are generally easier to study. For example, the invariant measures of the BAM have been completely characterized.

Proposition 35 Let $\mathcal{B} = \{\pm 1, 0\}$, and let $\Psi: \mathcal{B}^{\mathbb{Z}} \rightarrow \mathcal{B}^{\mathbb{Z}}$ be the BAM.

(a) The sets $\mathbf{R} := \{0, 1\}^{\mathbb{Z}}$ and $\mathbf{L} := \{0, -1\}^{\mathbb{Z}}$ are Ψ -invariant, and Ψ acts as a right-shift on \mathbf{R} and as a left-shift on \mathbf{L} .

(b) Let $\mathbf{L}^+ := \{0, -1\}^{\mathbb{N}}$ and $\mathbf{R}^- := \{0, 1\}^{-\mathbb{N}}$, and let

$$\mathbf{X} := \{ \mathbf{a} \in \mathcal{A}^{\mathbb{Z}}; \exists z \in \mathbb{Z} \text{ such that } \mathbf{a}_{(-\infty \dots z]} \in \mathbf{R}^- \text{ and } \mathbf{a}_{[z \dots \infty)} \in \mathbf{L}^+ \} .$$

Then \mathbf{X} is Ψ -invariant. For any $\mathbf{x} \in \mathbf{X}$, Ψ acts as a right shift on $\mathbf{a}_{(-\infty \dots z]}$, and as a left-shift on $\mathbf{x}_{(z \dots \infty)}$. (The boundary point z executes some kind of random walk.)

(c) Any Ψ -invariant measure on $\mathcal{A}^{\mathbb{Z}}$ can be written in a unique way as a convex combination of four measures δ_0, ρ, λ , and μ , where: δ_0 is the point mass on the ‘vacuum’ configuration $[\dots 0 0 0 \dots]$, ρ is any shift-invariant measure on \mathbf{R} , λ is any shift-invariant measure on \mathbf{L} , and μ is a measure on \mathbf{X} .

Furthermore, there exist shift-invariant measures μ_- and μ_+ on \mathbf{R}^- and \mathbf{L}^+ , respectively, such that, for μ -almost all $\mathbf{x} \in \mathbf{X}$, $\mathbf{x}_{(-\infty \dots z]}$ is μ_- -distributed and $\mathbf{x}_{[z \dots \infty)}$ is μ_+ -distributed.

Proof (a) and (b) are obvious; (c) is Theorem 1 in [8]. \square

Remark 36 (a) Proposition 35(c) can be immediately translated into a complete characterization of the invariant measures of ECA#184, via the factor map Γ in Example 34(a); see [8], Theorem 3. Likewise, using the factor map in Example 34(b) we get a complete characterization of the invariant measures for CCA₃.

(b) Proposition 48 and Corollaries 49 and 50 describe the limit measures of the BAM, CCA₃, and ECA#184. Also, Blank [10] has characterized invariant measures for a broad class of multilane, multi-speed traffic models (including ECA#184); see Remark 51(b).

(c) Kůrka [78] has defined, for any $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$, a construction similar to the set \mathbf{X} in Proposition 35(b). For any $n \in \mathbb{N}$ and $z \in \mathbb{Z}$, let $\mathbf{S}_{z,n}$ be the set of fixed points of $\Phi^n \circ \sigma^z$; then $\mathbf{S}_{z,n}$ is a subshift of finite type, which Kůrka calls a *signal subshift with velocity* $v = z/n$. (For example, if Φ is the BAM, then $\mathbf{R} = \mathbf{S}_{1,1}$ and $\mathbf{L} = \mathbf{S}_{-1,1}$.)

Now, suppose that $z_1/n_1 > z_2/n_2 > \dots > z_j/n_j$. The *join* of the signal subshifts $\mathbf{S}_{z_1, n_1}, \mathbf{S}_{z_2, n_2}, \dots, \mathbf{S}_{z_j, n_j}$ is the set \mathbf{S} of all infinite sequences $[\mathbf{a}_1 \mathbf{a}_2 \dots \mathbf{a}_j]$, where for all $j \in [1..J]$, \mathbf{a}_j is a (possibly empty) finite word or (half-)infinite sequence admissible to the subshift \mathbf{S}_{z_j, n_j} . (For example, if \mathbf{S} is the join of $\mathbf{S}_{1,1} = \mathbf{R}$ and $\mathbf{S}_{-1,1} = \mathbf{L}$ from Proposition 35(a), then $\mathbf{S} = \mathbf{L} \cup \mathbf{X} \cup \mathbf{R}$.) It follows that $\mathbf{S} \subseteq \Phi(\mathbf{S}) \subseteq \Phi^2(\mathbf{S}) \subseteq \dots$. If we define $\Phi^\infty(\mathbf{S}) := \bigcup_{t=0}^\infty \Phi^t(\mathbf{S})$, then $\Phi^\infty(\mathbf{S}) \subseteq \Phi^\infty(\mathcal{A}^{\mathbb{Z}})$, where $\Phi^\infty(\mathcal{A}^{\mathbb{Z}}) := \bigcap_{t=0}^\infty \Phi^t(\mathcal{A}^{\mathbb{Z}})$ is the omega limit set of Φ (see Proposition 5 in [78]). The support of any Φ -invariant measure must be contained in $\Phi^\infty(\mathcal{A}^{\mathbb{Z}})$, so invariant measures may be closely related to the joins of signal subshifts. See **► Topological Dynamics of Cellular Automata** for more information.

In the case of the BAM, it is not hard to check that $\Phi^\infty(\mathbf{S}) = \mathbf{S} = \Phi^\infty(\mathcal{A}^{\mathbb{Z}})$; this suggests an alternate proof of Proposition 35(c). It would be interesting to know whether a conclusion analogous to Proposition 35(c) holds for other $\Phi \in \mathbf{CA}(\mathcal{A}^{\mathbb{Z}})$ such that $\Phi^\infty(\mathcal{A}^{\mathbb{Z}})$ is a join of signal subshifts.

Limit Measures and Other Asymptotics

Asymptotic Randomization by Linear Cellular Automata

The results of Subsect. “**Measure Rigidity in Algebraic CA**” suggest that the uniform Bernoulli measure η is the ‘natural’ measure for algebraic CA, because η is the unique invariant measure satisfying any one of several collections of reasonable criteria. In this section, we will see that η is ‘natural’ in quite another way: it is the unique limit measure for linear CA from a large set of initial conditions.

If $\{\mu_n\}_{n=1}^\infty$ is a sequence of measures on $\mathcal{A}^{\mathbb{M}}$, then this sequence *weak* converges* to the measure μ_∞ (“ $wk * \lim \mu_n = \mu_\infty$ ”) if, for all cylinder sets $\mathbf{B} \subset \mathcal{A}^{\mathbb{M}}$, $\lim_{n \rightarrow \infty} \mu_n[\mathbf{B}] = \mu_\infty[\mathbf{B}]$. Equivalently, for all continuous functions $f: \mathcal{A}^{\mathbb{M}} \rightarrow \mathbb{C}$, we have

$$\lim_{n \rightarrow \infty} \int_{\mathcal{A}^{\mathbb{M}}} f d\mu_n = \int_{\mathcal{A}^{\mathbb{M}}} f d\mu_\infty .$$

The *Cesàro average* (or *Cesàro limit*) of $\{\mu_n\}_{n=1}^\infty$ is $wk * \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \mu_n$, if this limit exists.

Let $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{M}})$ and let $\Phi \in \mathbf{CA}(\mathcal{A}^{\mathbb{M}})$. For any $t \in \mathbb{N}$, the measure $\Phi^t \mu$ is defined by $\Phi^t \mu(\mathbf{B}) = \mu(\Phi^{-t}(\mathbf{B}))$, for any measurable subset $\mathbf{B} \subset \mathcal{A}^{\mathbb{M}}$. We say that Φ *asymptotically randomizes* μ if the Cesàro average of the sequence $\{\Phi^n \mu\}_{n=1}^\infty$ is η . Equivalently, there is a sub-

set $\mathbb{J} \subset \mathbb{N}$ of density 1, such that

$$wk * \lim_{\substack{j \rightarrow \infty \\ j \in \mathbb{J}}} \Phi^j \mu = \eta .$$

The uniform measure η is the measure of maximal entropy on $\mathcal{A}^{\mathbb{M}}$. Thus, asymptotic randomization is kind of ‘Second Law of Thermodynamics’ for CA.

Let $(\mathcal{A}, +)$ be a finite abelian group, and let Φ be a linear cellular automaton (LCA) on $\mathcal{A}^{\mathbb{M}}$. Recall that Φ has *scalar coefficients* if there is some finite $\mathbb{H} \subset \mathbb{M}$, and integer coefficients $\{c_h\}_{h \in \mathbb{H}}$ so that Φ has a local rule of the form

$$\phi(\mathbf{a}_{\mathbb{H}}) := \sum_{h \in \mathbb{H}} c_h a_h , \tag{3}$$

An LCA Φ is *proper* if Φ has scalar coefficients as in Eq. (3), and if, furthermore, for any prime divisor p of $|\mathcal{A}|$, there are at least two $h, h' \in \mathbb{H}$ such that $c_h \not\equiv 0 \not\equiv c_{h'} \pmod p$. For example, if $\mathcal{A} = \mathbb{Z}/n$ for some $n \in \mathbb{N}$, then every LCA on $\mathcal{A}^{\mathbb{M}}$ has scalar coefficients; in this case, Φ is proper if, for every prime p dividing n , at least two of these coefficients are coprime to p . In particular, if $\mathcal{A} = \mathbb{Z}/p$ for some prime p , then Φ is proper as long as $|\mathbb{H}| \geq 2$.

Let $\text{PLCA}(\mathcal{A}^{\mathbb{M}})$ be the set of proper linear CA on $\mathcal{A}^{\mathbb{M}}$. If $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{M}})$, recall that μ has *full support* if $\mu[\mathbf{B}] > 0$ for every cylinder set $\mathbf{B} \subset \mathcal{A}^{\mathbb{M}}$.

Theorem 37 *Let $(\mathcal{A}, +)$ be a finite abelian group, let $\mathbb{M} := \mathbb{Z}^D \times \mathbb{N}^E$ for some $D, E \geq 0$, and let $\Phi \in \text{PLCA}(\mathcal{A}^{\mathbb{M}})$. Let μ be any Bernoulli measure or Markov random field on $\mathcal{A}^{\mathbb{M}}$ having full support. Then Φ asymptotically randomizes μ .*

History Theorem 37 was first proved for simple one-dimensional LCA randomizing Bernoulli measures on $\mathcal{A}^{\mathbb{Z}}$, where \mathcal{A} was a cyclic group. In the case $\mathcal{A} = \mathbb{Z}/2$, Theorem 37 was independently proved for the *nearest-neighbor XOR CA* (having local rule $\phi(a_{-1}, a_0, a_1) = a_{-1} + a_1 \pmod 2$) by Miyamoto [100] and Lind [82]. This result was then generalized to $\mathcal{A} = \mathbb{Z}/p$ for any prime p by Cai and Luo [16]. Next, Maass and Martínez [87] extended the Miyamoto/Lind result to the *binary Ledrappier CA* (local rule $\phi(a_0, a_1) = a_0 + a_1 \pmod 2$). Soon after, Ferrari et al. [36] considered the case when \mathcal{A} was an abelian group of order p^k (p prime), and proved Theorem 37 for any *Ledrappier CA* (local rule $\phi(a_0, a_1) = c_0 a_0 + c_1 a_1$, where $c_0, c_1 \not\equiv 0 \pmod p$) acting on any measure on $\mathcal{A}^{\mathbb{Z}}$ having full support and ‘rapidly decaying correlations’ (see Part II(a) below). For example, this includes any Markov measure on $\mathcal{A}^{\mathbb{Z}}$ with full support. Next, Pivato and Yas-sawi [116] generalized Theorem 37 to any PLCA acting on any fully supported N -step Markov chain on $\mathcal{A}^{\mathbb{Z}}$

or any nontrivial Bernoulli measure on $\mathcal{A}^{\mathbb{Z}^D \times \mathbb{N}^E}$, where $\mathcal{A} = \mathbb{Z}/p^k$ (p prime). Finally, Pivato and Yassawi [117] proved Theorem 37 in full generality, as stated above.

The proofs of Theorem 37 and its variations all involve two parts:

Part I. A careful analysis of the local rule of Φ^t (for all $t \in \mathbb{N}$), showing that the neighborhood of Φ^t grows large as $t \rightarrow \infty$ (and in some cases, contains large ‘gaps’).

Part II. A demonstration that the measure μ exhibits ‘rapidly decaying correlations’ between widely separated elements of \mathbb{M} ; hence, when these elements are combined using Φ^t , it is as if we are summing independent random variables.

Part I Any linear CA with scalar coefficients can be written as a ‘Laurent polynomial of shifts’. That is, if Φ has local rule (3), then for any $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$,

$$\Phi(\mathbf{a}) := \sum_{\mathbf{h} \in \mathbb{H}} c_{\mathbf{h}} \sigma^{\mathbf{h}}(\mathbf{a}) \quad (\text{where we add configurations componentwise}).$$

We indicate this by writing “ $\Phi = F(\sigma)$ ”, where $F \in \mathbb{Z}[x_1^{\pm 1}, x_2^{\pm 1}, \dots, x_D^{\pm 1}]$ is the D -variable Laurent polynomial defined:

$$F(x_1, \dots, x_D) := \sum_{(h_1, \dots, h_D) \in \mathbb{H}} c_{\mathbf{h}} x_1^{h_1} x_2^{h_2} \dots x_D^{h_D}.$$

For example, if Φ is the *nearest-neighbor XOR CA*, then $\Phi = \sigma^{-1} + \sigma^1 = F(\sigma)$, where $F(x) = x^{-1} + x$. If Φ is a *Ledrappier CA*, then $\Phi = c_0 \mathbf{Id} + c_1 \sigma^1 = F(\sigma)$, where $F(x) = c_0 + c_1 x$.

It is easy to verify that, if F and G are two such polynomials, and $\Phi = F(\sigma)$ while $\Gamma = G(\sigma)$, then $\Phi \circ \Gamma = (F \cdot G)(\sigma)$, where $F \cdot G$ is the product of F and G in the polynomial ring $\mathbb{Z}[x_1^{\pm 1}, x_2^{\pm 1}, \dots, x_D^{\pm 1}]$. In particular, this means that $\Phi^t = F^t(\sigma)$ for all $t \in \mathbb{N}$. Thus, iterating an LCA is equivalent to computing the powers of a polynomial.

If $\mathcal{A} = \mathbb{Z}/p$, then we can compute the coefficients of F^t modulo p . If p is prime, then this can be done using a result of Lucas [84], which provides a formula for the binomial coefficient $\binom{a}{b}$ in terms of the base- p expansions of a and b . For example, if $p = 2$, then Lucas’ theorem says that Pascal’s triangle, modulo 2, looks like a ‘discrete Sierpinski triangle’, made out of 0’s and 1’s. (This is why fragments of the Sierpinski triangle appear frequently in the spacetime diagrams of linear CA on $\mathcal{A} = \mathbb{Z}/2$, a phenomenon which has inspired much literature on ‘fractals and automatic sequences in cellular

automata’; see [2,4,5,6,7,52,53,54,55,56,57,94,138,139,140,145,146,147,148,149].) Thus, Lucas’ Theorem, along with some combinatorial lemmas about the structure of base- p expansions, provides the machinery for Part I.

Part II There are two approaches to analyzing probability measures on $\mathcal{A}^{\mathbb{M}}$; one using renewal theory, and the other using harmonic analysis.

II(a) Renewal theory This approach was developed by Maass, Martínez and their collaborators. Loosely speaking, if $\mu \in \mathfrak{M}_{\text{res}}(\mathcal{A}^{\mathbb{Z}}, \sigma)$ has sufficiently large support and sufficiently rapid decay of correlations (e. g. a Markov chain), and $\mathbf{a} \in \mathcal{A}^{\mathbb{Z}}$ is a μ -random sequence, then we can treat \mathbf{a} as if there is a sparse, randomly distributed set of ‘renewal times’ when the normal stochastic evolution of \mathbf{a} is interrupted by independent, random ‘errors’. By judicious use of Part I described above, one can use this ‘renewal process’ to make it seem as though Φ^t is summing independent random variables.

For example, if $(\mathcal{A}, +)$ be an abelian group of order p^k where p is prime, and $\mu \in \mathfrak{M}_{\text{res}}(\mathcal{A}^{\mathbb{Z}}, \sigma)$ has *complete connections* (see Example 22(a)) and *summable decay* (which means that a certain sequence of coefficients (measuring long-range correlation) decays fast enough that its sum is finite), and $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ is a Ledrappier CA, then Ferrari et al. (see Theorem 1.3 in [36]) showed that Φ asymptotically randomizes μ . (For example, this applies to any N -step Markov chain with full support on $\mathcal{A}^{\mathbb{Z}}$.) Furthermore, if $\mathcal{A} = \mathbb{Z}/p \times \mathbb{Z}/p$, and $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ has linear local rule $\phi \left(\begin{bmatrix} x_0 \\ y_0 \end{bmatrix}, \begin{bmatrix} x_1 \\ y_1 \end{bmatrix} \right) = (y_0, x_0 + y_1)$, then Maass and Martínez [88] showed that Φ randomizes any Markov measure with full support on $\mathcal{A}^{\mathbb{Z}}$. Maass and Martínez again handled Part II using renewal theory. However, in this case, Part I involves some delicate analysis of the (noncommutative) algebra of the matrix-valued coefficients; unfortunately, their argument does not generalize to other LCA with noncommuting, matrix-valued coefficients. (However, Proposition 8 of [117] suggests a general strategy for dealing with such LCA.)

II(b) Harmonic analysis This approach to Part II was implicit in the early work of Lind [82] and Cai and Luo [16], but was developed in full generality by Pivato and Yassawi [116,117,118]. We regard $\mathcal{A}^{\mathbb{M}}$ as a direct product of copies of the group $(\mathcal{A}, +)$, and endow it with the product group structure; then $(\mathcal{A}^{\mathbb{M}}, +)$ is a compact abelian topological group. A *character* on $(\mathcal{A}^{\mathbb{M}}, +)$ is a continuous group homomorphism $\chi : \mathcal{A}^{\mathbb{M}} \rightarrow \mathbb{T}$, where $\mathbb{T} := \{c \in \mathbb{C}; |c| = 1\}$ is the unit circle group. If μ is

a measure on $\mathcal{A}^{\mathbb{M}}$, then the *Fourier coefficients* of μ are defined: $\hat{\mu}[\chi] = \int_{\mathcal{A}^{\mathbb{M}}} \chi \, d\mu$, for every character χ .

If $\chi: \mathcal{A}^{\mathbb{M}} \rightarrow \mathbb{T}$ is any character, then there is a unique finite subset $\mathbb{K} \subset \mathbb{M}$ (called the *support* of χ) and a unique collection of nontrivial characters $\chi_k: \mathcal{A} \rightarrow \mathbb{T}$ for all $k \in \mathbb{K}$, such that,

$$\chi(\mathbf{a}) = \prod_{k \in \mathbb{K}} \chi_k(a_k), \quad \forall \mathbf{a} \in \mathcal{A}^{\mathbb{M}}. \tag{4}$$

We define $\text{rank}[\chi] := |\mathbb{K}|$. The measure μ is called *harmonically mixing* if, for all $\epsilon > 0$, there is some R such that for all characters χ , $(\text{rank}[\chi] \geq R) \implies (|\hat{\mu}[\chi]| < \epsilon)$.

The set $\mathfrak{Sm}(\mathcal{A}^{\mathbb{M}})$ of harmonically mixing measures on $\mathcal{A}^{\mathbb{M}}$ is quite inclusive. For example, if μ is any (N -step) Markov chain with full support on $\mathcal{A}^{\mathbb{Z}}$, then $\mu \in \mathfrak{Sm}(\mathcal{A}^{\mathbb{Z}})$ (see Propositions 8 and 10 in [116]), and if $\nu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{Z}})$ is absolutely continuous with respect to this μ , then $\nu \in \mathfrak{Sm}(\mathcal{A}^{\mathbb{Z}})$ also (see Corollary 9 in [116]). If $\mathcal{A} = \mathbb{Z}_{/p}$ (p prime) then any nontrivial Bernoulli measure on $\mathcal{A}^{\mathbb{M}}$ is harmonically mixing (see Proposition 6 in [116]). Furthermore, if $\mu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{Z}}; \sigma)$ has complete connections and summable decay, then $\mu \in \mathfrak{Sm}(\mathcal{A}^{\mathbb{Z}})$ (see Theorem 23 in [61]). If $\mathfrak{M} := \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{M}}; \mathbb{C})$ is the set of all complex-valued measures on $\mathcal{A}^{\mathbb{M}}$, then \mathfrak{M} is *Banach algebra* (i. e. it is a vector space under the obvious definition of addition and scalar multiplication for measures, and a Banach space under the total variation norm, and finally, since $\mathcal{A}^{\mathbb{M}}$ is a topological group, \mathfrak{M} is a ring under convolution). Then $\mathfrak{Sm}(\mathcal{A}^{\mathbb{M}})$ is an ideal in \mathfrak{M} , is closed under the total variation norm, and is dense in the weak* topology on \mathfrak{M} (see Propositions 4 and 7 in [116]).

Finally, if μ is any Markov random field on $\mathcal{A}^{\mathbb{M}}$ which is *locally free* (which roughly means that the boundary of any finite region does not totally determine the interior of that region), then $\mu \in \mathfrak{Sm}(\mathcal{A}^{\mathbb{M}})$ (see Theorem 1.3 in [118]). In particular, this implies:

Proposition 38 *If $(\mathcal{A}, +)$ is any finite group, and $\mu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{M}})$ is any Markov random field with full support, then μ is harmonically mixing.*

Proof This follows from Theorem 1.3 in [118]. It is also a special case of Theorem 15 in [117]. \square

If χ is a character, and Φ is a LCA, then $\chi \circ \Phi^t$ is also a character, for any $t \in \mathbb{N}$ (because it is a composition of two continuous group homomorphisms). We say Φ is *diffusive* if there is a subset $\mathbb{J} \subset \mathbb{N}$ of density 1, such that, for every character χ of $\mathcal{A}^{\mathbb{M}}$,

$$\lim_{\mathbb{J} \ni j \rightarrow \infty} \text{rank}[\chi \circ \Phi^j] = \infty.$$

Proposition 39 *Let $(\mathcal{A}, +)$ be any finite abelian group and let \mathbb{M} be any monoid. If μ is harmonically mixing and Φ is diffusive, then Φ asymptotically randomizes μ .*

Proof See Theorem 12 in [117]. \square

Proposition 40 *Let $(\mathcal{A}, +)$ be any abelian group and let $\mathbb{M} := \mathbb{Z}^D \times \mathbb{N}^E$ for some $D, E \geq 0$. If $\Phi \in \text{PLCA}(\mathcal{A}^{\mathbb{M}})$, then Φ is diffusive.*

Proof The proof uses Lucas' theorem, as described in Part I above. See Theorem 15 in [116] for the case $\mathcal{A} = \mathbb{Z}_{/p}$ when p prime. See Theorem 6 in [117] for the case when \mathcal{A} is any cyclic group. That proof easily extends to any finite abelian group \mathcal{A} : write \mathcal{A} as a product of cyclic groups and decompose Φ into separate automata over these cyclic factors. \square

Proof of Theorem 37 Combine Propositions 38, 39, and 40. \square

Remark (a) Proposition 40 can be generalized: we do not need the coefficients of Φ to be integers, but merely to be a collection of automorphisms of \mathcal{A} which commute with one another (so that Lucas' theorem from Part I is still applicable). See Theorem 9 in [117].

(b) For simplicity, we stated Theorem 37 for measures with full support; however, Proposition 39 actually applies to many Markov random fields *without* full support, because harmonic mixing only requires 'local freedom' (see Theorem 1.3 in [118]). For example, the support of a Markov chain on $\mathcal{A}^{\mathbb{Z}}$ is Markov subshift. If $\mathcal{A} = \mathbb{Z}_{/p}$ (p prime), then Proposition 39 yields asymptotic randomization of the Markov chain as long as the transition digraph of the underlying Markov subshift admits at least *two* distinct paths of length 2 between any pair of vertices in \mathcal{A} . More generally, if $\mathbb{M} = \mathbb{Z}^D$, then the support of any Markov random field on $\mathcal{A}^{\mathbb{Z}^D}$ is an SFT, which we can regard as the set of all tilings of \mathbb{R}^D by a certain collection of Wang tiles. If $\mathcal{A} = \mathbb{Z}_{/p}$ (p prime), then Proposition 39 yields asymptotic randomization of the Markov random field as long as the underlying Wang tiling is flexible enough that any hole can always be filled in at least two ways; see Sect. 1 in [118].

Remark 41 (Generalizations and Extensions) (a) Pivato and Yassawi (see Thm 3.1 in [118]) proved a variation of Theorem 60 where diffusion (of Φ) is replaced with a slightly stronger condition called *dispersion*, so that harmonic mixing (of μ) can be replaced with a slightly weaker condition called *dispersion mixing* (DM). It is unknown whether all proper linear CA are dispersive, but a very large class are (including, for example, $\Phi = \text{Id} + \sigma$).

Any uniformly mixing measure with positive entropy is DM (see Theorem 5.2 in [118]); this includes, for example, any mixing *quasimarkov measure* (i.e. the image of a Markov measure under a block map; these are the natural measures supported on sofic shifts). Quasimarkov measures are not, in general, harmonically mixing (see Sect. 2 in [118]), but this result shows they are still asymptotically randomized by most linear CA.

(b) Suppose $\mathbf{G} \subset \mathcal{A}^{\mathbb{Z}^D}$ is a σ -transitive *subgroup shift* (see Subsect. “[Measure Rigidity in Algebraic CA](#)” for definition), and let $\Phi \in \text{PLCA}(\mathbf{G})$. If \mathbf{G} satisfies an algebraic condition called the *follower lifting property* (FLP) and μ is any Markov random field with $\text{supp}(\mu) = \mathbf{G}$, then Maass, Martínez, Pivato, and Yassawi [89] have shown that Φ asymptotically randomizes μ to a maxentropy measure on \mathbf{G} . Furthermore, if $D = 1$, then this maxentropy measure is the Haar measure on \mathbf{G} . In particular, if \mathcal{A} is an abelian group of prime-power order, then *any* transitive Markov subgroup $\mathbf{G} \subset \mathcal{A}^{\mathbb{Z}}$ satisfies the FLP, so this result holds for any multistep Markov measure on \mathbf{G} . See also [90] for the special case when $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ has local rule $\phi(x_0, x_1) = x_0 + x_1$. In the special case when Φ has local rule $\phi(x_0, x_1) = c_0x_0 + c_1x_1 + a$, the result has been extended to measures with complete connections and summable decay; see Teorema III.2.1, p. 71 in [134] or see Theorem 1 in [91].

(c) All the aforementioned results concern asymptotic randomization of initial measures with nonzero entropy. Is nonzero entropy either necessary or sufficient for asymptotic randomization? First let $\mathbf{X}_N \subset \mathcal{A}^{\mathbb{Z}}$ be the set of N -periodic points (see Subsect. “[Periodic Invariant Measures](#)”) and suppose $\text{supp}(\mu) \subseteq \mathbf{X}_N$. Then the Cesàro limit of $\{\Phi^t(\mu)\}_{t \in \mathbb{N}}$ will also be a measure supported on \mathbf{X}_N , so μ_∞ cannot be the uniform measure on $\mathcal{A}^{\mathbb{Z}}$. Nor, in general, will μ_∞ be the uniform measure on \mathbf{X}_N ; this follows from Jen’s (1988) exact characterization of the limit cycles of linear CA acting on \mathbf{X}_N .

What if μ is a *quasiperiodic* measure, such as the unique σ -invariant measure on a Sturmian shift? There exist quasiperiodic measures on $(\mathbb{Z}/l_2)^{\mathbb{Z}}$ which are *not* asymptotically randomized by the Ledrappier CA (see Sect. 15 in [112]). But it is unknown whether this extends to all quasiperiodic measures or all linear CA.

There is also a measure μ on $\mathcal{A}^{\mathbb{Z}}$ which has zero σ -entropy, yet is still asymptotically randomized by Φ (see Sect. 8 in [118]). Loosely speaking, μ is a Toeplitz measure with a very low density of ‘bit errors’. Thus, μ is ‘almost’ deterministic (so it has zero entropy), but by sufficiently increasing the density of ‘bit errors’, we can introduce just enough randomness to allow asymptotic randomization to occur.

(d) Suppose (G, \cdot) is a *nonabelian* group and $\Phi: G^{\mathbb{Z}} \rightarrow G^{\mathbb{Z}}$ has *multiplicative* local rule $\phi(\mathbf{g}) := g_{h_1}^{n_1} g_{h_2}^{n_2} \cdots g_{h_j}^{n_j}$, for some $\{h_1, \dots, h_j\} \subset \mathbb{Z}$ (possibly not distinct) and $n_1, \dots, n_j \in \mathbb{N}$. If G is nilpotent, then G can be decomposed into a tower of abelian group extensions; this induces a structural decomposition of Φ into a tower of skew products of ‘relative’ linear CA. This strategy was first suggested by Moore [102], and was developed by Pivato (see Theorem 21 in [111]), who proved a version of Theorem 37 in this setting.

(e) Suppose (Q, \star) is a *quasigroup* – that is, \star is a binary operation such that for any $q, r, s \in Q$, $(q \star r = q \star s) \iff (r = s) \iff (r \star q = s \star q)$. Any finite *associative* quasigroup has an identity, and any associative quasigroup with an identity is a group. However there are also many nonassociative finite quasigroups. If we define a ‘multiplicative’ CA $\Phi: Q^{\mathbb{Z}} \rightarrow Q^{\mathbb{Z}}$ with local rule $\phi: Q^{\{0,1\}} \rightarrow Q$ given by $\phi(q_0, q_1) = q_0 \star q_1$, then it is easy to see that Φ is bipermutative if and only if (Q, \star) is a quasigroup. Thus, quasigroups seem to provide the natural algebraic framework for studying bipermutative CA; this was first proposed by Moore [101], and later explored by Host, Maass, and Martínez (see Sect. 3 in [61]), Pivato (see Sect. 2 in [113]), and Sobottka [134,135,136].

Note that $Q^{\mathbb{Z}}$ is a quasigroup under componentwise \star -multiplication. A *quasigroup shift* is a subshift $\mathbf{X} \subset Q^{\mathbb{Z}}$ which is also a subquasigroup; it follows that $\Phi(\mathbf{X}) \subseteq \mathbf{X}$. If \mathbf{X} and Φ satisfy certain strong algebraic conditions, and $\mu \in \mathfrak{M}_{\text{loc}}(\mathbf{X}; \sigma)$ has complete connections and summable decay, then the sequence $\{\Phi^t \mu\}_{t=1}^\infty$ Cesàro-converges to a maxentropy measure μ_∞ on \mathbf{X} (thus, if \mathbf{X} is irreducible, then μ_∞ is the Parry measure; see Subsect. “[Invariance of Maxentropy Measures](#)”). See Theorem 6.3(i) in [136], or Teorema IV.5.3, p. 107 in [134].

Hybrid Modes of Self-Organization

Most cellular automata do not asymptotically randomize; instead they seem to weak* converge to limit measures concentrated on small (i.e. low-entropy) subsets of the statespace $\mathcal{A}^{\mathbb{M}}$ – a phenomenon which can be interpreted as a form of ‘self-organization’. Exact limit measures have been computed for a few CA. For example, let $\mathcal{A} = \{0, 1, 2\}$ and let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}^D})$ be the *Greenberg–Hastings* model (a simple model of an excitable medium). Durrett and Steif [26] showed that, if $D \geq 2$ and μ is any Bernoulli measure on $\mathcal{A}^{\mathbb{Z}^D}$, then $\mu_\infty := wk * \lim_{t \rightarrow \infty} \Phi^t \mu$ exists; μ_∞ -almost all points are 3-periodic for Φ , and although μ_∞ is not a Bernoulli measure, the system $(\mathcal{A}^{\mathbb{Z}^D}, \mu_\infty, \sigma)$ is measurably isomorphic to a Bernoulli system.

In other cases, the limit measure cannot be exactly computed, but can still be estimated. For example, let $\mathcal{A} = \{\pm 1\}$, $\theta \in (0, 1)$, and $R > 0$, and let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ be the (R, θ) -threshold voter CA (where each cell computes the fraction of its radius- R neighbors which disagree with its current sign, and negates its sign if this fraction is at least θ). Durrett and Steif [27] and Fisch and Gravner [43] have described the long-term behavior of Φ in the limit as $R \rightarrow \infty$. If $\theta < 1/2$, then every initial condition falls into a two-periodic orbit (and if $\theta < 1/4$, then every cell simply alternates its sign). Let η be the uniform Bernoulli measure on $\mathcal{A}^{\mathbb{Z}}$; if $1/2 < \theta$, then for any finite subset $\mathbb{B} \subset \mathbb{Z}$, if R is large enough, then ‘most’ initial conditions (relative to η) converge to orbits that are fixed inside \mathbb{B} . Indeed, there is a critical value $\theta_c \approx 0.6469076$ such that, if $\theta_c < \theta$, and R is large enough, then ‘most’ initial conditions (for η) are already fixed inside \mathbb{B} ; see also [137] for an analysis of behavior at the critical value.

In still other cases, the limit measure is known to exist, but is still mysterious; this is true for the Cesàro limit measures of Coven CA, for example see [87], Theorem 1. However, for most CA, it is difficult to even show that limit measures exist. Except for the linear CA of Subsect. “Asymptotic Randomization by Linear Cellular Automata”, there is no large class of CA whose limit measures have been exactly characterized. Often, it is much easier to study the dynamical asymptotics of CA at a purely topological level.

If $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{M}})$, then $\mathcal{A}^{\mathbb{M}} \supseteq \Phi(\mathcal{A}^{\mathbb{M}}) \supseteq \Phi^2(\mathcal{A}^{\mathbb{M}}) \supseteq \dots$. The limit set of Φ is the nonempty subshift $\Phi^\infty(\mathcal{A}^{\mathbb{M}}) := \bigcap_{t=1}^\infty \Phi^t(\mathcal{A}^{\mathbb{M}})$. For any $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$, the omega-limit set of \mathbf{a} is the set $\omega(\mathbf{a}, \Phi)$ of all cluster points of the Φ -orbit $\{\Phi^t(\mathbf{a})\}_{t=1}^\infty$. A closed subset $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$ is a (Conley) attractor if there exists a clopen subset $\mathbf{U} \supseteq \mathbf{X}$ such that $\Phi(\mathbf{U}) \subseteq \mathbf{U}$ and $\mathbf{X} = \bigcap_{t=1}^\infty \Phi^t(\mathbf{U})$. It follows that $\omega(\Phi, \mathbf{u}) \subseteq \mathbf{X}$ for all $\mathbf{u} \in \mathbf{U}$. For example, $\Phi^\infty(\mathcal{A}^{\mathbb{M}})$ is an attractor (let $\mathbf{U} := \mathcal{A}^{\mathbb{M}}$). The topological attractors of CA were analyzed by Hurley [63,65,66], who discovered severe constraints on the possible attractor structures a CA could exhibit; see Sect. 9 of ▶ Topological Dynamics of Cellular Automata and ▶ Cellular Automata, Classification of.

Within pure topological dynamics, attractors and (omega) limit sets are the natural formalizations of the heuristic notion of ‘self-organization’. The corresponding formalization in pure ergodic theory is the weak* limit measure. However, both weak* limit measures and topological attractors fail to adequately describe the sort of self-organization exhibited by many CA. Thus, several ‘hybrid’ notions self-organization have been developed, which combine topological and measurable criteria. These hybrid notions are more flexible and inclusive than purely

topological notions. However, they do not require the explicit computation (or even the existence) of weak* limit measures, so in practice they are much easier to verify than purely ergodic notions.

Milnor–Hurley μ -attractors If $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$ is a closed subset, then for any $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$, we define $d(\mathbf{a}, \mathbf{X}) := \inf_{\mathbf{x} \in \mathbf{X}} d(\mathbf{a}, \mathbf{x})$. If $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{M}})$, then the basin (or realm) of \mathbf{X} is the set

$$\begin{aligned} \text{Basin}(\mathbf{X}) &:= \left\{ \mathbf{a} \in \mathcal{A}^{\mathbb{M}} ; \lim_{t \rightarrow \infty} d(\Phi^t(\mathbf{a}), \mathbf{X}) = 0 \right\} \\ &= \left\{ \mathbf{a} \in \mathcal{A}^{\mathbb{M}} ; \omega(\mathbf{a}, \Phi) \subseteq \mathbf{X} \right\}. \end{aligned}$$

Suppose $\Phi(\mathbf{X}) \subseteq \mathbf{X}$. If $\mu \in \mathfrak{M}_{\text{inv}}(\mathcal{A}^{\mathbb{M}})$, then \mathbf{X} is a μ -attractor if $\mu[\text{Basin}(\mathbf{X})] > 0$; we call \mathbf{X} a lean μ -attractor if in addition, $\mu[\text{Basin}(\mathbf{X})] > \mu[\text{Basin}(\mathbf{Y})]$ for any proper closed subset $\mathbf{Y} \subsetneq \mathbf{X}$. Finally, a μ -attractor \mathbf{X} is minimal if $\mu[\text{Basin}(\mathbf{Y})] = 0$ for any proper closed subset $\mathbf{Y} \subsetneq \mathbf{X}$. For example, if \mathbf{X} is a μ -attractor, and (\mathbf{X}, Φ) is minimal as a dynamical system, then \mathbf{X} is a minimal μ -attractor. This concept was introduced by Milnor [96,97] in the context of smooth dynamical systems; its ramifications for CA were first explored by Hurley [64,65].

If $\mu \in \mathfrak{M}_{\text{inv}}(\mathcal{A}^{\mathbb{Z}^D}, \sigma)$, then μ is weakly σ -mixing if, for any measurable sets $\mathbf{U}, \mathbf{V} \subset \mathcal{A}^{\mathbb{Z}^D}$, there is a subset $\mathbb{J} \subset \mathbb{Z}^D$ of density 1 such that $\lim_{\mathbb{J} \ni j \rightarrow \infty} \mu[\sigma^j(\mathbf{U}) \cap \mathbf{V}] = \mu[\mathbf{U}] \cdot \mu[\mathbf{V}]$ (see Subsect. “Mixing and Ergodicity”). For example, any Bernoulli measure is weakly mixing. A subshift $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^D}$ is σ -minimal if \mathbf{X} contains no proper non-empty subshifts. For example, if \mathbf{X} is just the σ -orbit of some σ -periodic point, then \mathbf{X} is σ -minimal.

Proposition 42 Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{M}})$, let $\mu \in \mathfrak{M}_{\text{inv}}(\mathcal{A}^{\mathbb{M}}, \sigma)$, and let \mathbf{X} be a μ -attractor.

- (a) If μ is σ -ergodic, and $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$ is a subshift, then $\mu[\text{Basin}(\mathbf{X})] = 1$.
- (b) If \mathbb{M} is countable, and \mathbf{X} is σ -minimal subshift with $\mu[\text{Basin}(\mathbf{X})] = 1$, then \mathbf{X} is lean.
- (c) Suppose $\mathbb{M} = \mathbb{Z}^D$ and μ is weakly σ -mixing.
 - (i) If \mathbf{X} is a minimal μ -attractor, then \mathbf{X} is a subshift, so $\mu[\text{Basin}(\mathbf{X})] = 1$, and thus \mathbf{X} is the only lean μ -attractor of Φ .
 - (ii) If \mathbf{X} is a Φ -periodic orbit which is also a lean μ -attractor, then \mathbf{X} is minimal, $\mu[\text{Basin}(\mathbf{X})] = 1$, and \mathbf{X} contains only constant configurations.

Proof (a) If \mathbf{X} is σ -invariant, then $\text{Basin}(\mathbf{X})$ is also σ -invariant; hence $\mu[\text{Basin}(\mathbf{X})] = 1$ because μ is σ -ergodic.

(b) Suppose $\mathbf{Y} \subsetneq \mathbf{X}$ was a proper closed subset with $\mu[\text{Basin}(\mathbf{Y})] = 1$. For any $\mathbf{m} \in \mathbb{M}$, it is easy

to check that $\text{Basin}(\sigma^m[\mathbf{Y}]) = \sigma^m[\text{Basin}(\mathbf{Y})]$. Thus, if $\tilde{\mathbf{Y}} := \bigcap_{m \in \mathbb{M}} \sigma^m(\mathbf{Y})$, then $\text{Basin}(\tilde{\mathbf{Y}}) = \bigcap_{m \in \mathbb{M}} \sigma^m[\text{Basin}(\mathbf{Y})]$, so $\mu[\text{Basin}(\tilde{\mathbf{Y}})] = 1$ (because \mathbb{M} is countable). Thus, $\tilde{\mathbf{Y}}$ is nonempty, and is a subshift of \mathbf{X} . But \mathbf{X} is σ -minimal, so $\tilde{\mathbf{Y}} = \mathbf{X}$, which means $\mathbf{Y} = \mathbf{X}$. Thus, \mathbf{X} is a lean μ -attractor.

(c) In the case when μ is a Bernoulli measure, (c)[i] is Theorem B in [64] or Proposition 2.7 in [65], while (c)[ii] is Theorem A in [65]. Hurley’s proofs easily extend to the case when μ is weakly σ -mixing. The only property we require of μ is this: for any nontrivial measurable sets $\mathbf{U}, \mathbf{V} \subset \mathcal{A}^{\mathbb{Z}^D}$, and any $\mathbf{z} \in \mathbb{Z}^D$, there is some $\mathbf{x}, \mathbf{y} \in \mathbb{Z}^D$ with $\mathbf{z} = \mathbf{x} - \mathbf{y}$, such that $\mu[\sigma^{\mathbf{y}}(\mathbf{U}) \cap \mathbf{V}] > 0$ and $\mu[\sigma^{\mathbf{x}}(\mathbf{U}) \cap \mathbf{V}] > 0$. This is clearly true if μ is weakly mixing (because if $\mathbb{J} \subset \mathbb{Z}^D$ has density 1, then $\mathbb{J} \cap (\mathbf{z} + \mathbb{J}) \neq \emptyset$ for any $\mathbf{z} \in \mathbb{Z}^D$).

Proofsketch for (c)[i] If \mathbf{X} is a (minimal) μ -attractor, then so is $\sigma^{\mathbf{y}}(\mathbf{X})$, and $\text{Basin}[\sigma^{\mathbf{y}}(\mathbf{X})] = \sigma^{\mathbf{y}}[\text{Basin}(\mathbf{X})]$. Thus, weak mixing yields $\mathbf{x}, \mathbf{y} \in \mathbb{Z}^D$ such that $\text{Basin}[\sigma^{\mathbf{x}}(\mathbf{X})] \cap \text{Basin}(\mathbf{X})$ and $\text{Basin}[\sigma^{\mathbf{y}}(\mathbf{X})] \cap \text{Basin}(\mathbf{X})$ are both nontrivial. But the basins of distinct minimal μ -attractors must be disjoint; thus $\sigma^{\mathbf{x}}(\mathbf{X}) = \mathbf{X} = \sigma^{\mathbf{y}}(\mathbf{X})$. But $\mathbf{x} - \mathbf{y} = \mathbf{z}$, so this means $\sigma^{\mathbf{z}}(\mathbf{X}) = \mathbf{X}$. This holds for all $\mathbf{z} \in \mathbb{Z}^D$, so \mathbf{X} is a subshift, so (a) implies $\mu[\text{Basin}(\mathbf{X})] = 1$. \square

Section 4 of [64] contains several examples showing that the minimal topological attractor of Φ can be different from its minimal μ -attractor. For example, a CA can have different minimal μ -attractors for different choices of μ . On the other hand, there is a CA possessing a minimal topological attractor but with no minimal μ -attractors for any Bernoulli measure μ .

Hilmy–Hurley Centers

Let $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$. For any closed subset $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$, we define

$$\mu_{\mathbf{a}}[\mathbf{X}] := \liminf_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \mathbf{1}_{\mathbf{X}}(\Phi^n(\mathbf{a})).$$

(Thus, if μ is a Φ -ergodic measure on $\mathcal{A}^{\mathbb{M}}$, then Birkhoff’s Ergodic Theorem asserts that $\mu_{\mathbf{a}}[\mathbf{X}] = \mu[\mathbf{X}]$ for μ -almost all $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$). The *center* of \mathbf{a} is the set:

$$\text{Cent} < (\mathbf{a}, \Phi) := \bigcap \left\{ \text{closed subsets } \mathbf{X} \subseteq \mathcal{A}^{\mathbb{M}}; \mu_{\mathbf{a}}[\mathbf{X}] = 1 \right\}$$

Thus, $\text{Cent}(\mathbf{a}, \Phi)$ is the smallest closed subset such that $\mu_{\mathbf{a}}[\text{Cent}(\mathbf{a}, \Phi)] = 1$. If $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$ is closed, then the *well* of \mathbf{X} is the set

$$\text{Well}(\mathbf{X}) := \left\{ \mathbf{a} \in \mathcal{A}^{\mathbb{M}}; \text{Cent}(\mathbf{a}, \Phi) \subseteq \mathbf{X} \right\}.$$

If $\mu \in \mathfrak{M}_{\text{dens}}(\mathcal{A}^{\mathbb{M}})$, then \mathbf{X} is a μ -center if $\mu[\text{Well}(\mathbf{X})] > 0$; we call \mathbf{X} a *lean μ -center* if in addition, $\mu[\text{Well}(\mathbf{X})] > \mu[\text{Well}(\mathbf{Y})]$ for any proper closed subset $\mathbf{Y} \subsetneq \mathbf{X}$. Finally, a μ -center \mathbf{X} is *minimal* if $\mu[\text{Well}(\mathbf{Y})] = 0$ for any proper closed subset $\mathbf{Y} \subsetneq \mathbf{X}$. This concept was introduced by Hilmy [59] in the context of smooth dynamical systems; its ramifications for CA were first explored by Hurley [65].

Proposition 43 *Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$, let $\mu \in \mathfrak{M}_{\text{dens}}(\mathcal{A}^{\mathbb{M}}, \sigma)$, and let \mathbf{X} be a μ -center.*

- (a) *If μ is σ -ergodic, and $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$ is a subshift, then $\mu[\text{Well}(\mathbf{X})] = 1$.*
- (b) *If \mathbb{M} is countable, and \mathbf{X} is σ -minimal subshift with $\mu[\text{Well}(\mathbf{X})] = 1$, then \mathbf{X} is lean.*
- (c) *Suppose $\mathbb{M} = \mathbb{Z}^D$ and μ is weakly σ -mixing. If \mathbf{X} is a minimal μ -center, then \mathbf{X} is a subshift, \mathbf{X} is the only lean μ -center, and $\mu[\text{Well}(\mathbf{X})] = 1$.*

Proof (a) and (b) are very similar to the proofs of Proposition 42(a,b).

(c) is proved for Bernoulli measures as Theorem B in [65]. The proof is quite similar to Proposition 42(c)[i], and again, we only need μ to be weakly mixing. \square

Section 4 of [65] contains several examples of minimal μ -centers which are not μ -attractors. In particular, the analogue of Proposition 42(c)[ii] is false for μ -centers.

Kürka–Maass μ -limit Sets If $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$ and $\mu \in \mathfrak{M}_{\text{dens}}(\mathcal{A}^{\mathbb{M}}, \sigma)$, then Kürka and Maass define the *μ -limit set* of Φ :

$$\Lambda(\Phi, \mu) := \bigcap \left\{ \text{closed subsets } \mathbf{X} \subset \mathcal{A}^{\mathbb{M}}; \lim_{t \rightarrow \infty} \Phi^t \mu(\mathbf{X}) = 1 \right\}.$$

It suffices to take this intersection only over all *cylinder sets* \mathbf{X} . By doing this, we see that $\Lambda(\Phi, \mu)$ is a subshift of $\mathcal{A}^{\mathbb{M}}$, and is defined by the following property: for any finite $\mathbb{B} \subset \mathbb{M}$ and any word $\mathbf{b} \in \mathcal{A}^{\mathbb{B}}$, \mathbf{b} is admissible to $\Lambda(\Phi, \mu)$ if and only if $\liminf_{t \rightarrow \infty} \Phi^t \mu[\mathbf{b}] > 0$.

Proposition 44 *Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$ and $\mu \in \mathfrak{M}_{\text{dens}}(\mathcal{A}^{\mathbb{M}}, \sigma)$.*

- (a) *If $wk * \lim_{t \rightarrow \infty} \Phi^t \mu = \nu$, then $\Lambda(\Phi, \mu) = \text{supp}(\nu)$. Suppose $\mathbb{M} = \mathbb{Z}$.*
- (b) *If Φ is surjective and has an equicontinuous point, and μ has full support on $\mathcal{A}^{\mathbb{Z}}$, then $\Lambda(\Phi, \mu) = \mathcal{A}^{\mathbb{Z}}$.*
- (c) *If Φ is left- or right-permutative and μ is connected (see below), then $\Lambda(\Phi, \mu) = \mathcal{A}^{\mathbb{Z}}$.*

Proof For (a), see Proposition 2 in [79]. For (b,c), see Theorems 2 and 3 in [77]; for earlier special cases of these results, see also Propositions 4 and 5 in [79]. \square

Remark 45 (a) In Proposition 44(c), the measure μ is *connected* if there is some constant $C > 0$ such that, for any finite word $\mathbf{b} \in \mathcal{A}^*$, and any $a \in \mathcal{A}$, we have $\mu[\mathbf{b} a] \geq C \cdot \mu[\mathbf{b}]$ and $\mu[a \mathbf{b}] \geq C \cdot \mu[\mathbf{b}]$.

For example, any Bernoulli, Markov, or N -step Markov measure with full support is connected. Also, any measure with ‘complete connections’ (see Example 22(a)) is connected.

(b) Proposition 44(a) shows that μ -limit sets are closely related to the weak* limits of measures. Recall from Subsect. “Asymptotic Randomization by Linear Cellular Automata” that the uniform Bernoulli measure η is the weak* limit of a large class of initial measures under the action of linear CA. Presumably the same result should hold for a much larger class of *permutative* CA, but so far this is unproven, except in some special cases [see Remarks 41(d,e)]. Proposition 44(a,c) implies that the limit measure of a permutative CA (if it exists) must have full support – hence it can’t be ‘too far’ from η .

K urka’s Measure Attractors Let $\mathfrak{M}_{\text{inv}}^{\sigma} := \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{M}}, \sigma)$ have the weak* topology, and define $\Phi_* : \mathfrak{M}_{\text{inv}}^{\sigma} \rightarrow \mathfrak{M}_{\text{inv}}^{\sigma}$ by $\Phi_*(\mu) = \mu \circ \Phi^{-1}$. Then Φ_* is continuous, so we can treat $(\mathfrak{M}_{\text{inv}}^{\sigma}, \Phi_*)$ itself as a compact topological dynamical system. The “weak* limit measures” of Φ are simply the attracting fixed points of $(\mathfrak{M}_{\text{inv}}^{\sigma}, \Phi_*)$. However, even if the Φ_* -orbit of a measure μ does not weak* converge to a fixed point, we can still consider the omega-limit set of μ . In particular, the limit set $\Phi_*^{\infty}(\mathfrak{M}_{\text{inv}}^{\sigma})$ is the union of the omega-limit sets of all σ -invariant initial measures under Φ_* . K urka defines the *measure attractor* of Φ :

$$\text{MeasAttr}(\Phi) := \overline{\bigcup \{ \text{supp}(\mu) ; \mu \in \Phi_*^{\infty}(\mathfrak{M}_{\text{inv}}^{\sigma}) \}} \subseteq \mathcal{A}^{\mathbb{M}}.$$

(The bar denotes topological closure.) A configuration $\mathbf{a} \in \mathcal{A}^{\mathbb{Z}^D}$ is *densely recurrent* if any word which occurs in \mathbf{a} does so with nonzero frequency. Formally, for any finite $\mathbb{B} \subset \mathbb{Z}^D$

$$\limsup_{N \rightarrow \infty} \frac{\#\{ \mathbf{z} \in [-N \dots N]^D ; \mathbf{a}_{\mathbb{B}+\mathbf{z}} = \mathbf{a}_{\mathbb{B}} \}}{(2N + 1)^D} > 0.$$

If $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^D}$ is a subshift, then the *densely recurrent subshift* of \mathbf{X} is the closure \mathbf{D} of the set of all densely recurrent points in \mathbf{X} . If $\mu \in \mathfrak{M}_{\text{inv}}^{\sigma}(\mathbf{X})$, then the Birkhoff Ergodic Theorem implies that $\text{supp}(\mu) \subseteq \mathbf{D}$; see Proposition 8.8 in [1], p. 164. From this it follows that $\mathfrak{M}_{\text{inv}}^{\sigma}(\mathbf{X}) = \mathfrak{M}_{\text{inv}}^{\sigma}(\mathbf{D})$. On the other hand, $\mathbf{D} = \bigcup \{ \text{supp}(\mu) ; \mu \in \mathfrak{M}_{\text{inv}}^{\sigma}(\mathbf{D}) \}$. In other words, densely recurrent subshifts are the only subshifts which are ‘covered’ by their own set of shift-invariant measures.

Proposition 46 Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})[\mathcal{A}^{\mathbb{Z}^D}]$. Let \mathbf{D} be the densely recurrent subshift of $\Phi^{\infty}(\mathcal{A}^{\mathbb{Z}^D})$. Then $\mathbf{D} = \text{MeasAttr}(\Phi)$, and $\Phi^{\infty}(\mathfrak{M}_{\text{inv}}^{\sigma}) = \mathfrak{M}_{\text{ens}}(\mathbf{D}, \sigma)$.

Proof Case $D = 1$ is Proposition 13 in [78]. The same proof works for $D \geq 2$. □

Synthesis

The various hybrid modes of self-organization are related as follows:

Proposition 47 Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$.

(a) Let $\mu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{M}}, \sigma)$ and let $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$ be any closed set.

- [i] If \mathbf{X} is a topological attractor and μ has full support, then \mathbf{X} is a μ -attractor.
- [ii] If \mathbf{X} is a μ -attractor, then \mathbf{X} is a μ -center.
- [iii] Suppose $\mathbb{M} = \mathbb{Z}^D$, and that μ is weakly σ -mixing. Let \mathbf{Y} be the intersection of all topological attractors of Φ . If Φ has a minimal μ -attractor \mathbf{X} , then $\mathbf{X} \subseteq \mathbf{Y}$.
- [iv] If μ is σ -ergodic, then $\Lambda(\Phi, \mu) \subseteq \bigcap \{ \mathbf{X} \subseteq \mathcal{A}^{\mathbb{M}} ; \mathbf{X} \text{ a subshift and } \mu\text{-attractor} \} \subseteq \Phi^{\infty}(\mathcal{A}^{\mathbb{Z}^D})$.
- [v] Thus, if μ is σ -ergodic and has full support, then

$$\Lambda(\Phi, \mu) \subseteq \bigcap \{ \mathbf{X} \subseteq \mathcal{A}^{\mathbb{M}} ; \mathbf{X} \text{ a subshift and a topological attractor} \}.$$

[vi] If \mathbf{X} is a subshift, then $(\Lambda(\Phi, \mu) \subseteq \mathbf{X}) \iff (\omega(\Phi_*, \mu) \subseteq \mathfrak{M}_{\text{inv}}^{\sigma}(\mathbf{X}))$.

(b) Let $\mathbb{M} = \mathbb{Z}^D$. Let \mathfrak{B} be the set of all Bernoulli measures on $\mathcal{A}^{\mathbb{Z}^D}$, and for any $\beta \in \mathfrak{B}$, let \mathbf{X}_{β} be the minimal β -attractor for Φ (if it exists).

There is a comeager subset $\mathbf{A} \subset \mathcal{A}^{\mathbb{Z}^D}$ such that $\bigcup_{\beta \in \mathfrak{B}} \mathbf{X}_{\beta} \subseteq \bigcap_{\mathbf{a} \in \mathbf{A}} \omega(\mathbf{a}, \Phi)$.

(c) $\text{MeasAttr}(\Phi) = \overline{\bigcup \{ \Lambda(\Phi, \mu) ; \mu \in \mathfrak{M}_{\text{inv}}^{\sigma}(\mathcal{A}^{\mathbb{M}}) \}}$.

(d) If $\mathbb{M} = \mathbb{Z}^D$, then $\text{MeasAttr}(\Phi) \subseteq \Phi^{\infty}(\mathcal{A}^{\mathbb{Z}^D})$.

Proof (a)[i]: If \mathbf{U} is a clopen subset and $\Phi^{\infty}(\mathbf{U}) = \mathbf{X}$, then $\mathbf{U} \subseteq \text{Basin}(\mathbf{X})$; thus, $0 < \mu[\mathbf{U}] \leq \mu[\text{Basin}(\mathbf{X})]$, where the “ $<$ ” is because μ has full support.

(a)[ii]: For any $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$, it is easy to see that $\text{Cent}(\mathbf{a}, \Phi) \subseteq \omega(\mathbf{a}, \Phi)$. Thus, $\text{Well}(\mathbf{X}) \supseteq \text{Basin}(\mathbf{X})$. Thus, $\mu[\text{Well}(\mathbf{X})] \geq \mu[\text{Basin}(\mathbf{X})] > 0$.

(a)[iii] is Proposition 3.3 in [64]. (Again, Hurley states and proves this in the case when μ is a Bernoulli measure, but his proof only requires weak mixing).

(a)[iv]: Let \mathbf{X} be a subshift and a μ -attractor; we claim that $\Lambda(\Phi, \mu) \subseteq \mathbf{X}$. Proposition 42(a) says $\mu[\text{Basin}(\mathbf{X})] = 1$.

Let $\mathbb{B} \subset \mathbb{M}$ be any finite set. If $\mathbf{b} \in \mathcal{A}^{\mathbb{B}} \setminus \mathbf{X}_{\mathbb{B}}$, then

$$\{\mathbf{a} \in \mathcal{A}^{\mathbb{M}}; \exists T \in \mathbb{N} \text{ such that } \forall t \geq T, \Phi^t(\mathbf{a})_{\mathbb{B}} \neq \mathbf{b}\} \supseteq \text{Basin}(\mathbf{X}).$$

It follows that the left-hand set has μ -measure 1, which implies that $\lim_{t \rightarrow \infty} \Phi^t \mu(\mathbf{b}) = 0$ – hence \mathbf{b} is a forbidden word in $\Lambda(\Phi, \mu)$.

Thus, all the words forbidden in \mathbf{X} are also forbidden in $\Lambda(\Phi, \mu)$. Thus $\Lambda(\Phi, \mu) \subseteq \mathbf{X}$. (The case $\mathbb{M} = \mathbb{Z}$ of (a)[iv] appears as Prop. 1 in [79] and as Prop. II.27, p. 67 in [120]; see also Cor. II.30 in [120] for a slightly stronger result.)

(a)[v] follows from (a)[iv] and (a)[i].

(a)[vi] is Proposition 1 in [77] or Proposition 10 in [78]; the argument is fairly similar to (a)[iv]. (Kůrka assumes $\mathbb{M} = \mathbb{Z}$, but this is not necessary.)

(b) is Proposition 5.2 in [64].

(c) Let $\mathbf{X} \subset \mathcal{A}^{\mathbb{M}}$ be a subshift and let $\mathfrak{M}_{\text{inv}}^{\sigma} = \mathfrak{M}_{\text{inv}}^{\sigma}(\mathcal{A}^{\mathbb{M}})$. Then

$$\begin{aligned} (\text{MeasA}_{\text{tr}}(\Phi) \subseteq \mathbf{X}) &\iff (\text{supp}(\nu) \subseteq \mathbf{X}, \forall \nu \in \Phi_*^{\infty}(\mathfrak{M}_{\text{inv}}^{\sigma})) \\ &\iff (\nu \in \mathfrak{M}_{\text{inv}}^{\sigma}(\mathbf{X}), \forall \nu \in \Phi_*^{\infty}(\mathfrak{M}_{\text{inv}}^{\sigma})) \\ &\iff (\Phi_*^{\infty}(\mathfrak{M}_{\text{inv}}^{\sigma}) \subseteq \mathfrak{M}_{\text{inv}}^{\sigma}(\mathbf{X})) \\ &\iff (\omega(\Phi_*, \mu) \subseteq \mathfrak{M}_{\text{inv}}^{\sigma}(\mathbf{X}), \forall \mu \in \mathfrak{M}_{\text{inv}}^{\sigma}) \\ &\iff (\Lambda(\Phi, \mu) \subseteq \mathbf{X}, \forall \mu \in \mathfrak{M}_{\text{inv}}^{\sigma}) \\ (*) & \\ &\iff (\bigcup \{\Lambda(\Phi, \mu) \mid \mu \in \mathfrak{M}_{\text{inv}}^{\sigma}\} \subseteq \mathbf{X}). \end{aligned}$$

where (*) is by (a)[vi]. It follows that $\text{MeasA}_{\text{tr}}(\Phi) = \bigcup \{\Lambda(\Phi, \mu); \mu \in \mathfrak{M}_{\text{inv}}^{\sigma}(\mathcal{A}^{\mathbb{M}})\}$.

(d) follows immediately from Proposition 46. \square

Examples and Applications The most natural examples of these hybrid modes of self-organization arise in the *particle cellular automata* (PCA) introduced in Subsect. “**Domains, Defects, and Particles**”. The long-term dynamics of a PCA involves a steady reduction in particle density, as particles coalesce or annihilate one another in collisions. Thus, presumably, for almost any initial configuration $\mathbf{a} \in \mathcal{A}^{\mathbb{Z}}$, the sequence $\{\Phi^t(\mathbf{a})\}_{t=1}^{\infty}$ should converge to the subshift \mathbf{Z} of configurations containing no particles (or at least, no particles of certain types), as $t \rightarrow \infty$. Unfortunately, this presumption is generally *false* if we interpret ‘convergence’ in the strict topological dynamical sense: the occasional particles will continue to wander near the origin at arbitrarily large times in the future orbit of \mathbf{a} (albeit with diminishing frequency), so $\omega(\mathbf{a}, \Phi)$ will *not* be contained in \mathbf{Z} . However, the presumption becomes true if we

instead employ one of the more flexible hybrid notions introduced above. For example, most initial probability measures μ should converge, under iteration of Φ to a measure concentrated on configurations with few or no particles; hence we expect that $\Lambda(\Phi, \mu) \subseteq \mathbf{Z}$. As discussed in Subsect. “**Domains, Defects, and Particles**”, a result about self-organization in a PCA can sometimes be translated into an analogous result about self-organization in associated coalescent-domain CA.

Proposition 48 *Let $\mathcal{A} = \{0, \pm 1\}$ and let $\Psi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ be the Ballistic Annihilation Model (BAM) from Example 33. Let $\mathbf{R} := \{0, 1\}^{\mathbb{Z}}$ and $\mathbf{L} := \{0, -1\}^{\mathbb{Z}}$.*

- (a) *If $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}}, \sigma)$, then $\nu = wk * \lim_{t \rightarrow \infty} \Psi^t(\mu)$ exists, and has one of three forms: either $\nu \in \mathfrak{M}_{\text{cons}}(\mathbf{R}, \sigma)$, or $\nu \in \mathfrak{M}_{\text{cons}}(\mathbf{L}, \sigma)$, or $\nu = \delta_0$, the point mass on the sequence $\mathbf{0} = [\dots 000 \dots]$.*
- (b) *Thus, the measure attractor of Φ is $\mathbf{R} \cup \mathbf{L}$ (note that $\mathbf{R} \cap \mathbf{L} = \{\mathbf{0}\}$).*
- (c) *In particular, if μ is a Bernoulli measure on $\mathcal{A}^{\mathbb{Z}}$ with $\mu[+1] = \mu[-1]$, then $\nu = \delta_0$.*
- (d) *Let μ be a Bernoulli measure on $\mathcal{A}^{\mathbb{Z}}$.*

- [i] *If $\mu[+1] > \mu[-1]$, then \mathbf{R} is a μ -attractor – i. e. $\mu[\text{Basin}(\mathbf{R})] > 0$.*
- [ii] *If $\mu[+1] < \mu[-1]$, then \mathbf{L} is a μ -attractor.*
- [iii] *If $\mu[+1] = \mu[-1]$, then $\{\mathbf{0}\}$ is not a μ -attractor, because $\mu[\text{Basin}\{\mathbf{0}\}] = 0$. However, $\Lambda(\Phi, \mu) = \{\mathbf{0}\}$.*

Proof (a) is Theorem 6 of [8], and (b) follows from (a). (c) follows from Theorem 2 of [42]. (d)[i,ii] were first observed by Gilman (see Sect. 3, pp. 111–112 in [45], and later by Kůrka and Maass (see Example 4 in [80]). (d)[iii] follows immediately from (c): the statement $\Lambda(\Phi, \mu) = \{\mathbf{0}\}$ is equivalent to asserting that $\lim_{t \rightarrow \infty} \Phi^t \mu[\pm 1] = 0$, which a consequence of (c). Another proof of (d)[iii] is Proposition 11 in [80]; see also Example 3 in [79] or Prop. II.32, p. 70 in [120]. \square

Corollary 49 *Let $\mathcal{A} = \mathbb{Z}/3$, let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ be the CCA_3 (see Example 32), and let η be the uniform Bernoulli measure on $\mathcal{A}^{\mathbb{Z}}$. Then $wk * \lim_{t \rightarrow \infty} \Phi^t(\eta) = \frac{1}{3}(\delta_0 + \delta_1 + \delta_2)$, where δ_a is the point mass on the sequence $[\dots aaa \dots]$ for each $a \in \mathcal{A}$.*

Proof Combine Proposition 48(c) with the factor map Γ in Example 34(b). See Theorem 1 of [42] for details. \square

Corollary 50 *Let $\mathcal{A} = \{0, 1\}$, let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ be $\text{ECA}\#184$ (see Example 31).*

- (a) $\text{MeasAttr}(\Phi) = \mathbf{R} \cup \mathbf{L}$, where $\mathbf{R} \subset \mathcal{A}^{\mathbb{Z}}$ is the set of sequences not containing [11], and $\mathbf{L} \subset \mathcal{A}^{\mathbb{Z}}$ is the set of sequences not containing [00].
- (b) If η is the uniform Bernoulli measure on $\mathcal{A}^{\mathbb{Z}}$, then $wk * \lim_{t \rightarrow \infty} \Phi^t(\eta) = \frac{1}{2}(\delta_0 + \delta_1)$, where δ_0 and δ_1 are the point masses on $[\dots 010.101 \dots]$ and $[\dots 101.010 \dots]$.
- (c) Let μ be a Bernoulli measure on $\mathcal{A}^{\mathbb{Z}}$.
 - [i] If $\mu[0] > \mu[1]$, then \mathbf{R} is a μ -attractor – i. e. $\mu[\text{Basin}(\mathbf{R})] > 0$.
 - [ii] If $\mu[0] < \mu[1]$, then \mathbf{L} is a μ -attractor.

Proof sketch Let Γ be the factor map from Example 34(a). To prove (a), apply Γ to Proposition 48(b); see Example 26, Sect. 9 in [78] for details. To prove (b), apply Γ to Proposition 48(c); see Proposition 12 in [80] for details. To prove (c), apply Γ to Proposition 48(d)[i,ii]; \square

Remark 51 (a) The other parts of Proposition 48 can likewise be translated into equivalent statements about the measure attractors and μ -attractors of CCA_3 and $\text{ECA}\#184$.

(b) Recall that $\text{ECA}\#184$ is a model of single-lane, traffic, where each car is either stopped or moving rightwards at unit speed. Blank [10] has extended Corollary 50(c) to a much broader class of CA models of multi-lane, multi-speed traffic. For any such model, let $\mathbf{R} \subset \mathcal{A}^{\mathbb{Z}}$ be the set of ‘free flowing’ configurations where each car has enough space to move rightwards at its maximum possible speed. Let $\mathbf{L} \subset \mathcal{A}^{\mathbb{Z}}$ be the set of ‘jammed’ configurations where the cars are so tightly packed that the jammed clusters can propagate (leftwards) through the cars at maximum speed. If μ is any Bernoulli measure, then $\mu[\text{Basin}(\mathbf{R})] = 1$ if the μ -average density of cars is greater than $1/2$, whereas $\mu[\text{Basin}(\mathbf{L})] = 1$ if the density is less than $1/2$ Theorems 1.2 and 1.3 in [10]. Thus, $\mathbf{L} \sqcup \mathbf{R}$ is a (non-lean) μ -attractor, although not a topological attractor Lemma 2.13 in [10].

Example 52 A cyclic addition and ballistic annihilation model (CABAM) contains the same ‘moving’ particles ± 1 as the BAM (Example 33), but also has one or more ‘stationary’ particle types. Let $3 \leq N \in \mathbb{N}$, and let $\mathcal{P} = \{1, 2, \dots, N - 1\} \subset \mathbb{Z}/N$, where we identify $N - 1$ with -1 , modulo N . It will be convenient to represent the ‘vacant’ state \emptyset as 0 ; thus, $\mathcal{A} = \mathbb{Z}/N$. The particles 1 and -1 have velocities and collisions as in the BAM, namely:

$$v(1) = 1, \quad v(-1) = -1, \quad \text{and} \quad -1 + 1 \rightsquigarrow \emptyset.$$

We set $v(p) = 0$, for all $p \in [2 \dots N - 2]$, and employ the following collision rule:

$$\text{If } p_{-1} + p_0 + p_1 \equiv q, \pmod{N}, \text{ then } p_{-1} + p_0 + p_1 \rightsquigarrow q. \tag{5}$$

(here, any one of p_{-1} , p_0 , p_1 , or q could be 0 , signifying vacancy). For example, if $N = 5$ and a (rightward moving) type $+1$ particle strikes a (stationary) type 3 particle, then the $+1$ particle is annihilated and the 3 particle turns into a (stationary) 4 particle. If another $+1$ particle hits the 4 particle, then both are annihilated, leaving a vacancy (0).

Let $\mathcal{B} = \mathbb{Z}/N$, and let $\Psi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ be the CABAM. Then the set of fixed points of Ψ is $\mathbf{F} = \{\mathbf{f} \in \mathcal{B}^{\mathbb{Z}}; f_z \neq \pm 1, \forall z \in \mathbb{Z}\}$. Note that, if $\mathbf{b} \in \text{Basin}[\mathbf{F}]$ – that is, if $\omega(\mathbf{b}, \Psi) \subseteq \mathbf{F}$ – then in fact $\lim_{t \rightarrow \infty} \Psi^t(\mathbf{b})$ exists and is a Ψ -fixed point.

Proposition 53 Let $\mathcal{B} = \mathbb{Z}/N$, let $\Psi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ be the CABAM, and let η be the uniform Bernoulli measure on $\mathcal{B}^{\mathbb{Z}}$. If $N \geq 5$, then \mathbf{F} is a ‘global’ η -attractor – that is, $\eta[\text{Basin}(\mathbf{F})] = 1$. However, if $N \leq 4$, then $\eta[\text{Basin}(\mathbf{F})] = 0$.

Proof See Theorem 1 of [41]. \square

Let $\mathcal{A} = \mathbb{Z}/N$ and let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ be the N -color CCA from Example 32. Then the set of fixed points of Φ is $\mathbf{F} = \{\mathbf{f} \in \mathcal{A}^{\mathbb{Z}}; f_z - f_{z+1} \neq \pm 1, \forall z \in \mathbb{Z}\}$. Note that, if $\mathbf{a} \in \text{Basin}[\mathbf{F}]$, then in fact $\lim_{t \rightarrow \infty} \Phi^t(\mathbf{a})$ exists and is a Φ -fixed point.

Corollary 54 Let $\mathcal{A} = \mathbb{Z}/N$, let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ be the N -color CCA, and let η be the uniform Bernoulli measure on $\mathcal{A}^{\mathbb{Z}}$. If $N \geq 5$, then \mathbf{F} is a ‘global’ η -attractor – that is, $\eta[\text{Basin}(\mathbf{F})] = 1$. However, if $N \leq 4$, then $\eta[\text{Basin}(\mathbf{F})] = 0$.

Proof sketch Let $\mathcal{B} = \mathbb{Z}/N$ and let $\Psi \in \text{CA}(\mathcal{B}^{\mathbb{Z}})$ be the N -particle CABAM. Construct a factor map $\Gamma: \mathcal{A}^{\mathbb{Z}} \rightarrow \mathcal{B}^{\mathbb{Z}}$ with local rule $\gamma(a_0, a_1) := (a_0 - a_1) \pmod{N}$, similar to Example 34(b). Then $\Gamma \circ \Phi = \Psi \circ \Gamma$, and the Ψ -particles track the Φ -domain boundaries. Now apply Γ to Proposition 53. \square

Example 55 Let $\mathcal{A} = \{0, 1\}$ and let $\mathbb{H} = \{-1, 0, 1\}$. Elementary Cellular Automaton #18 is the one-dimensional CA with local rule $\phi: \mathcal{A}^{\mathbb{H}} \rightarrow \mathcal{A}$ given: $\phi[100] = 1 = \phi[001]$, and $\phi(\mathbf{a}) = 0$ for all other $\mathbf{a} \in \mathcal{A}^{\mathbb{H}}$.

Empirically, $\text{ECA}\#18$ has one stable phase: the *odd sofic shift* \mathbf{S} , defined by the \mathcal{A} -labeled digraph $\textcircled{1} \rightleftharpoons \textcircled{0} \rightleftharpoons \textcircled{0}$. In other words, a sequence is admissible to \mathbf{S} as long as an pair of consecutive ones are separated by an *odd* number of zeroes. Thus, a *defect* is any word of the form $10^{2m}1$ (where 0^{2m} represents $2m$ zeroes) for any $m \in \mathbb{N}$. Thus, defects can be arbitrarily large, they can grow and move arbitrarily quickly, and they can coalesce across arbitrarily large distances. Thus, it is impossible to construct a particle CA which tracks the motion of these defects. Nevertheless, in computer simulations, one can visually follow the moving defects through time, and they appear to per-

form random walks. Over time, the density of defects decreases as they randomly collide and annihilate. This was empirically observed by Grassberger [47,48] and Boccaro et al. [11]. Lind (see Sect. 5 in [82]) conjectured that this gradual elimination of defects caused almost all initial conditions to converge, in some sense, to \mathbf{S} under application of Φ .

Eloranta and Numelin [34] proved that the defects of Φ individually perform random walks. However, the motions of neighboring defects are highly correlated. They are not *independent* random walks, so one cannot use standard results about stochastic interacting particle systems to conclude that the defect density converges to zero. To solve problems like this, Kůrka [77] developed a theory of ‘particle weight functions’ for CA.

Let \mathcal{A}^* be the set of all finite words in the alphabet \mathcal{A} . A *particle weight function* is a bounded function $p: \mathcal{A}^* \rightarrow \mathbb{N}$, so that, for any $\mathbf{a} \in \mathcal{A}^{\mathbb{Z}}$, we interpret

$$\begin{aligned} \#_p(\mathbf{a}) &:= \sum_{r=0}^{\infty} \sum_{z \in \mathbb{Z}} p(\mathbf{a}_{[z, \dots, z+r]}) \quad \text{and} \\ \delta_p(\mathbf{a}) &:= \sum_{r=0}^{\infty} \lim_{N \rightarrow \infty} \frac{1}{2N} \sum_{z=-N}^N p(\mathbf{a}_{[z, \dots, z+r]}) \end{aligned}$$

to be, respectively the ‘number of particles’ and ‘density of particles’ in configuration \mathbf{a} (clearly $\#_p(\mathbf{a})$ is finite if and only if $\delta_p(\mathbf{a}) = 0$). The function p can count the single-letter ‘particles’ of a PCA, or the short-length ‘domain boundaries’ found in ECA#184 and the CCA of Examples 31 and 32. However, p can also track the arbitrarily large defects of ECA#18. For example, define $p_{18}(10^{2m}1) = 1$ (for any $m \in \mathbb{N}$), and define $p_{18}(\mathbf{a}) = 0$ for all other $\mathbf{a} \in \mathcal{A}^*$.

Let $\mathbf{Z}_p := \{\mathbf{a} \in \mathcal{A}^{\mathbb{Z}}; \#_p(\mathbf{a}) = 0\}$ be the set of *vacuum configurations*. (For example, if $p = p_{18}$ as above, then \mathbf{Z}_p is just the odd sofic shift \mathbf{S} .) If the iteration of a CA Φ decreases the number (or density) of particles, then one expects \mathbf{Z}_p to be a limit set for Φ in some sense. Indeed, if $\mu \in \mathfrak{M}_{\text{ltiv}}^{\sigma} := \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}}, \sigma)$, then we define $\Delta_p(\mu) := \int_{\mathcal{A}^{\mathbb{Z}}} \delta_p d\mu$. If Φ is ‘ p -decreasing’ in a certain sense, then Δ_p acts as a Lyapunov function for the dynamical system $(\mathfrak{M}_{\text{ltiv}}^{\sigma}, \Phi_*)$. Thus, with certain technical assumptions, we can show that, if $\mu \in \mathfrak{M}_{\text{ltiv}}^{\sigma}$ is connected, then $\Lambda(\Phi, \mu) \subseteq \mathbf{Z}_p$ (see Theorem 8 in [77]). Furthermore, under certain conditions, $\text{M}_{\text{easAttv}}(\Phi) \subseteq \mathbf{Z}_p$ (see Theorem 7 in [77]). Using this machinery, Kůrka proved:

Proposition 56 *Let $\Phi: \mathcal{A}^{\mathbb{Z}} \rightarrow \mathcal{A}^{\mathbb{Z}}$ be ECA#18, and let $\mathbf{S} \subset \mathcal{A}^{\mathbb{Z}}$ be the odd sofic shift. If $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}}, \sigma)$ is connected, then $\Lambda(\Phi, \mu) \subseteq \mathbf{S}$.*

Proof See Example 6.3 of [77]. □

Measurable Dynamics

If $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{M}})$ and $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{M}}, \Phi)$, then the triple $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is a *measure-preserving dynamical system* (MPDS), and thus, amenable to the methods of classical ergodic theory.

Mixing and Ergodicity

If $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{M}})$, then the topological dynamical system $(\mathcal{A}^{\mathbb{M}}, \Phi)$ is *topologically transitive* (or *topologically ergodic*) if, for any open subsets $\mathbf{U}, \mathbf{V} \subseteq \mathcal{A}^{\mathbb{M}}$, there exists $t \in \mathbb{N}$ such that $\mathbf{U} \cap \Phi^{-t}(\mathbf{V}) \neq \emptyset$. Equivalently, there exists some $\mathbf{a} \in \mathcal{A}^{\mathbb{M}}$ whose orbit $\mathcal{O}(\mathbf{a}) := \{\Phi^t(\mathbf{a})\}_{t=0}^{\infty}$ is dense in $\mathcal{A}^{\mathbb{M}}$. If $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{M}}, \Phi)$, then the system $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is *ergodic* if, for any nontrivial measurable $\mathbf{U}, \mathbf{V} \subseteq \mathcal{A}^{\mathbb{M}}$, there exists some $t \in \mathbb{N}$ such that $\mu[\mathbf{U} \cap \Phi^{-t}(\mathbf{V})] > 0$. The system $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is *totally ergodic* if $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi^n)$ is ergodic for every $n \in \mathbb{N}$. The system $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is *(strongly) mixing* if, for any nontrivial measurable $\mathbf{U}, \mathbf{V} \subseteq \mathcal{A}^{\mathbb{M}}$.

$$\lim_{t \rightarrow \infty} \mu[\mathbf{U} \cap \Phi^{-t}(\mathbf{V})] = \mu[\mathbf{U}] \cdot \mu[\mathbf{V}]. \tag{6}$$

The system $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is *weakly mixing* if the limit (6) holds as $n \rightarrow \infty$ along an increasing subsequence $\{t_n\}_{n=1}^{\infty}$ of *density one* – i. e. such that $\lim_{n \rightarrow \infty} t_n/n = 1$. For any $M \in \mathbb{N}$, we say $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is *M-mixing* if, for any measurable $\mathbf{U}_0, \mathbf{U}_1, \dots, \mathbf{U}_M \subseteq \mathcal{A}^{\mathbb{M}}$.

$$\lim_{\substack{|t_n - t_m| \rightarrow \infty \\ \forall n \neq m \in \{0, \dots, M\}}} \mu \left[\bigcap_{m=0}^M \Phi^{-t_m}(\mathbf{U}_m) \right] = \prod_{m=0}^M \mu[\mathbf{U}_m] \tag{7}$$

(thus, ‘strong’ mixing is 1-mixing). We say $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is *multimixing* (or *mixing of all orders*) if $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is M -mixing for all $M \in \mathbb{N}$.

We say $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is a *Bernoulli endomorphism* if its natural extension (► [Ergodic Theory: Basic Examples and Constructions](#)) is measurably isomorphic to a system $(\mathcal{B}^{\mathbb{Z}}, \beta; \sigma)$, where $\beta \in \mathfrak{M}_{\text{cons}}(\mathcal{B}^{\mathbb{Z}}; \sigma)$ is a Bernoulli measure. We say $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is a *Kolmogorov endomorphism* if its natural extension is a Kolmogorov (or ‘K’) automorphism; see ► [Ergodicity and Mixing Properties](#). The following chain of implications is well-known; see ► [Ergodicity and Mixing Properties](#).

Theorem 57 *Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{M}})$, let $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{M}}, \Phi)$, and let $\mathbf{X} = \text{supp}(\mu)$. Then \mathbf{X} is a compact, Φ -invariant set. Furthermore:*

$$(\mu, \Phi) \text{ is Bernoulli} \implies (\mu, \Phi) \text{ is Kolmogorov} \implies (\mu, \Phi) \text{ is multimixing} \implies (\mu, \Phi) \text{ is mixing}$$

$\implies (\mu, \Phi)$ is weakly mixing $\implies (\mu, \Phi)$ is totally ergodic $\implies (\mu, \Phi)$ is ergodic \implies The system (\mathbf{X}, Φ) is topologically transitive $\implies \Phi: \mathbf{X} \rightarrow \mathbf{X}$ is surjective.

Theorem 58 Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{N}})$ be posexpansive (see Subsect. “Posexpansive and Permutative CA”). Then $(\mathcal{A}^{\mathbb{N}}, \Phi)$ has topological entropy $\log_2(k)$ for some $k \in \mathbb{N}$, Φ preserves the uniform measure η , and $(\mathcal{A}^{\mathbb{N}}, \eta; \Phi)$ is a uniformly distributed Bernoulli endomorphism on an alphabet of cardinality k .

Proof Extend the argument of Theorem 18. See Corollary 3.10 in [9] or Theorem 4.8(5) in [86]. \square

Example 59 Suppose $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{N}})$ is right-permutative, with neighborhood $[r \dots R]$, where $0 \leq r < R$. Then $h_{\text{top}}(\Phi) = \log_2(|\mathcal{A}|^R)$, so Theorem 58 says that $(\mathcal{A}^{\mathbb{N}}, \eta; \Phi)$ is a uniformly distributed Bernoulli endomorphism on the alphabet $\mathcal{B} := \mathcal{A}^R$.

In this case, it is easy to see this directly. If $\Phi_{\mathbb{B}}^{\mathbb{N}}: \mathcal{A}^{\mathbb{N}} \rightarrow \mathcal{B}^{\mathbb{N}}$ is as in Eq. (2), then $\beta := \Phi_{\mathbb{B}}^{\mathbb{N}}(\eta)$ is the uniform Bernoulli measure on $\mathcal{B}^{\mathbb{N}}$, and $\Phi_{\mathbb{B}}^{\mathbb{N}}$ is an isomorphism from $(\mathcal{A}^{\mathbb{N}}, \mu; \Phi)$ to $(\mathcal{B}^{\mathbb{N}}, \beta; \sigma)$.

Theorem 60 Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ have neighborhood $[L \dots R]$. Suppose that

- either** (a) $0 \leq L < R$ and Φ is right-permutative;
- or** (b) $L < R \leq 0$ and Φ is left-permutative;
- or** (c) $L < R$ and Φ is bipermutative;
- or** (d) Φ is posexpansive.

Then Φ preserves the uniform measure η , and $(\mathcal{A}^{\mathbb{Z}}, \eta; \Phi)$ is a Bernoulli endomorphism.

Proof For cases (a) and (b), see Theorem 2.2 in [125]. For case (c), see Theorem 2.7 in [125] or Corollary 7.3 in [74]. For (d), extend the argument of Theorem 14; see Theorem 4.9 in [86]. \square

Remark Theorem 60(c) can be extended to some higher-dimensional permutative CA using Proposition 1 in [3]; see Remark 12(b).

Theorem 61 Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ have neighborhood $[L \dots R]$. Suppose that

- either** (a) Φ is surjective and $0 < L \leq R$;
- or** (b) Φ is surjective and $L \leq R < 0$;
- or** (c) Φ is right-permutative and $R \neq 0$;
- or** (d) Φ is left-permutative and $L \neq 0$.

Then Φ preserves η , and $(\mathcal{A}^{\mathbb{Z}}, \eta; \Phi)$ is a Kolmogorov endomorphism.

Proof Cases (a) and (b) are Theorem 2.4 in [125]. Cases (c) and (d) are from [129]. \square

Corollary 62 Any CA satisfying the hypotheses of Theorem 61 is multimixing.

Proof This follows from Theorems 57 and 61. See also Theorem 3.2 in [131] for a direct proof that any CA satisfying hypotheses (a) or (b) is 1-mixing. See Theorem 6.6 in [74] for a proof that any CA satisfying hypotheses (c) or (d) is multimixing. \square

Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}^D})$ have neighborhood \mathbb{H} . An element $x \in \mathbb{H}$ is *extremal* if $\langle x, x \rangle > \langle x, h \rangle$ for all $h \in \mathbb{H} \setminus \{x\}$. We say Φ is *extremally permutative* if Φ is permutative in some extremal coordinate.

Theorem 63 Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}^D})$ and let η be the uniform measure. If Φ is extremally permutative, then $(\mathcal{A}^{\mathbb{Z}^D}, \eta; \Phi)$ is mixing.

Proof See Theorem A in [144] for the case $D = 2$ and $\mathcal{A} = \mathbb{Z}/2$. Willson described Φ as ‘linear’ in an extremal coordinate (which is equivalent to permutative when $\mathcal{A} = \mathbb{Z}/2$), and then concluded that Φ was ‘ergodic’ – however, he did this by explicitly showing that Φ was mixing. His proof technique easily generalizes to any extremally permutative CA on any alphabet, and any $D \geq 1$. \square

Theorem 64 Let $\mathcal{A} = \mathbb{Z}/m$. Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}^D})$ have linear local rule $\phi: \mathcal{A}^{\mathbb{H}} \rightarrow \mathcal{A}$ given by $\phi(\mathbf{a}_{\mathbb{H}}) = \sum_{h \in \mathbb{H}} c_h \cdot a_h$, where $c_h \in \mathbb{Z}$ for all $h \in \mathbb{H}$. Let η be the uniform measure on $\mathcal{A}^{\mathbb{Z}^D}$. The following are equivalent:

- (a) Φ preserves η and $(\mathcal{A}^{\mathbb{Z}^D}, \eta, \Phi)$ is ergodic.
- (b) $(\mathcal{A}^{\mathbb{Z}^D}, \Phi)$ is topologically transitive.
- (c) $\text{gcd}\{c_h\}_{0 \neq h \in \mathbb{H}}$ is coprime to m .
- (d) For all prime divisors p of m , there is some nonzero $h \in \mathbb{H}$ such that c_h is not divisible by p .

Proof Theorem 3.2 in [18]; see also [17]. For a different proof in the case $D = 2$, see Theorem 6 in [123]. \square

Spectral Properties

If $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{M}})$, then let $\mathbf{L}_{\mu}^2 = \mathbf{L}^2(\mathcal{A}^{\mathbb{M}}, \mu)$ be the set of measurable functions $f: \mathcal{A}^{\mathbb{M}} \rightarrow \mathbb{C}$ such that $\|f\|_2 := (\int_{\mathcal{A}^{\mathbb{M}}} |f|^2 d\mu)^{1/2}$ is finite. If $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{M}})$ and $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{M}}, \Phi)$, then Φ defines a unitary linear operator $\Phi_*: \mathbf{L}_{\mu}^2 \rightarrow \mathbf{L}_{\mu}^2$ by $\Phi_*(f) = f \circ \Phi$ for all $f \in \mathbf{L}_{\mu}^2$. If $f \in \mathbf{L}_{\mu}^2$, then f is an *eigenfunction* of Φ , with *eigenvalue* $c \in \mathbb{C}$, if $\Phi_*(f) = c \cdot f$. By definition of Φ_* , any eigenvalue must be an element of the unit circle $\mathbb{T} := \{c \in \mathbb{C}; |c| = 1\}$. Let $\mathbb{S}_{\Phi} \subset \mathbb{T}$ be the set of all eigenvalues of Φ , and for any $s \in \mathbb{S}_{\Phi}$, let $\mathbf{E}_s(\Phi) := \{f \in \mathbf{L}_{\mu}^2; \Phi_* f = sf\}$ be the corresponding eigenspace. For example, if f is constant μ -almost everywhere, then $f \in \mathbf{E}_1(\Phi)$. Let $\mathbf{E}(\Phi) := \bigsqcup_{s \in \mathbb{S}_{\Phi}} \mathbf{E}_s(\Phi)$. Note that \mathbb{S}_{Φ} is a group. Indeed, if $s_1, s_2 \in \mathbb{S}_{\Phi}$, and $f_1 \in \mathbf{E}_{s_1}$ and $f_2 \in \mathbf{E}_{s_2}$,

then $(f_1 f_2) \in E_{s_1 s_2}$ and $(1/f_1) \in E_{1/s_1}$. Thus, S_Φ is called the *spectral group* of Φ .

If $s \in S_\Phi$, then heuristically, an s -eigenfunction is an ‘observable’ of the dynamical system $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ which exhibits quasiperiodically recurrent behavior. Thus, the spectral properties of Φ characterize the ‘recurrent aspect’ of its dynamics (or the lack thereof). For example:

- $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is ergodic $\iff E_1(\Phi)$ contains only constant functions $\iff \dim[E_s(\Phi)] = 1$ for all $s \in S_\Phi$.
- $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is weakly mixing (see Subsect. “Mixing and Ergodicity”) $\iff E(\Phi)$ contains only constant functions $\iff (\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is ergodic and $S_\Phi = \{1\}$.

We say $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ has *discrete spectrum* if L^2_μ is spanned by $E(\Phi)$. In this case, $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is measurably isomorphic to an MPDS defined by translation on a compact abelian group (e.g. an irrational rotation of a torus, an odometer, etc.).

If $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{M}}, \sigma)$, then there is a natural unitary \mathbb{M} -action on L^2_μ , where $\sigma_*^m(f) = f \circ \sigma_*^m$. A *character* of \mathbb{M} is a monoid homomorphism $\chi: \mathbb{M} \rightarrow \mathbb{T}$. The set $\widehat{\mathbb{M}}$ of all characters is a group under pointwise multiplication, called the *dual group* of \mathbb{M} . If $f \in L^2_\mu$ and $\chi \in \widehat{\mathbb{M}}$, then f is a χ -eigenfunction of $(\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ if $\sigma_*^m(f) = \chi(m) \cdot f$ for all $m \in \mathbb{M}$; then χ is called a *eigencharacter*. The *spectral group* of $(\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ is then the subgroup $S_\sigma \subset \widehat{\mathbb{M}}$ of all eigencharacters. For any $\chi \in S_\sigma$, let $E_\chi(\sigma)$ be the corresponding eigenspace, and let $E(\sigma) := \bigsqcup_{\chi \in S_\sigma} E_\chi(\sigma)$.

- $(\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ is ergodic $\iff E_1(\sigma)$ contains only constant functions $\iff \dim[E_\chi(\sigma)] = 1$ for all $\chi \in S_\sigma$.
- $(\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ is weakly mixing $\iff E(\sigma)$ contains only constant functions $\iff (\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ is ergodic and $S_\sigma = \{1\}$.

$(\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ has *discrete spectrum* if L^2_μ is spanned by $E(\sigma)$. In this case, the system $(\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ is measurably isomorphic to an action of \mathbb{M} by translations on a compact abelian group.

Example 65 Let $\mathbb{M} = \mathbb{Z}$; then any character $\chi: \mathbb{Z} \rightarrow \mathbb{T}$ has the form $\chi(n) = c^n$ for some $c \in \mathbb{T}$, so a χ -eigenfunction is just a eigenfunction with eigenvalue c . In this case, the aforementioned spectral properties for the \mathbb{Z} -action by shifts are equivalent to the corresponding spectral properties of the CA $\Phi = \sigma^1$. Bernoulli measures and irreducible Markov chains are weakly mixing. On other hand, several important classes of symbolic dynamical systems have dis-

crete spectrum, including Sturmian shifts, constant-length substitution shifts, and regular Toeplitz shifts; see ► [Symbolic Dynamics](#) and ► [Dynamics of Cellular Automata in Non-compact Spaces](#).

Proposition 66 Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$, and let $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{M}}; \Phi, \sigma)$ be σ -ergodic.

- (a) $E(\sigma) \subseteq E(\Phi)$.
- (b) If $(\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ has discrete spectrum, then so does $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$.
- (c) Suppose μ is Φ -ergodic. If $(\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ is weakly mixing, then so is $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$.

Proof (a) Suppose $\chi \in \widehat{\mathbb{M}}$ and $f \in E_\chi$. Then $f \circ \Phi \in E_\chi$ also, because for all $m \in \mathbb{M}$, $f \circ \Phi \circ \sigma^m = f \circ \sigma^m \circ \Phi = \chi(m) \cdot f \circ \Phi$. But if $(\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ is ergodic, then $\dim[E_\chi(\sigma)] = 1$; hence $f \circ \Phi$ must be a scalar multiple of f . Thus, f is also an eigenfunction for Φ . (b) follows from (a).

(c) By reversing the roles of Φ and σ in (a), we see that $E(\Phi) \subseteq E(\sigma)$. But if $(\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ is weakly mixing, then $E(\sigma) = \{\text{constant functions}\}$. Thus, $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is also weakly mixing. \square

Example 67 (a) Let μ be any Bernoulli measure on $\mathcal{A}^{\mathbb{M}}$. If μ is Φ -invariant and Φ -ergodic, then $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$ is weakly mixing (because $(\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ is weakly mixing).

(b) Let $P \in \mathbb{N}$ and suppose μ is a Φ -invariant measure supported on the set X_P of P -periodic sequences (see Proposition 10). Then $(\mathcal{A}^{\mathbb{Z}}, \mu; \sigma)$ has discrete spectrum (with rational eigenvalues). But X_P is finite, so the system (X_P, Φ) is also periodic; hence $(\mathcal{A}^{\mathbb{Z}}, \mu; \Phi)$ also has discrete spectrum (with rational eigenvalues).

(c) Downarowicz [25] has constructed an example of a regular Toeplitz shift $X \subset \mathcal{A}^{\mathbb{Z}}$ and $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ (not the shift) such that $\Phi(X) \subseteq X$. Any regular Toeplitz shift is uniquely ergodic, and the unique shift-invariant measure μ has discrete spectrum; thus, $(\mathcal{A}^{\mathbb{Z}}, \mu; \Phi)$ also has discrete spectrum.

Aside from Examples 67(b,c), the literature contains no examples of discrete-spectrum, invariant measures for CA; this is an interesting area for future research.

Entropy

Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{M}})$. For any finite $\mathbb{B} \subset \mathbb{M}$, let $\mathcal{B} := \mathcal{A}^{\mathbb{B}}$, let $\Phi_{\mathbb{B}}^{\mathbb{N}}: \mathcal{A}^{\mathbb{N}} \rightarrow \mathcal{B}^{\mathbb{N}}$ be as in Eq. (2), and let $\mathbf{X} := \Phi_{\mathbb{B}}^{\mathbb{N}}(\mathcal{A}^{\mathbb{M}}) \subseteq \mathcal{A}^{\mathbb{N}}$; then define

$$H_{\text{top}}(\mathbb{B}; \Phi) := h_{\text{top}}(\mathbf{X}) = \lim_{T \rightarrow \infty} \frac{1}{T} \log_2(\#\mathbf{X}_{[0..T]}).$$

If $\mu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{M}}, \Phi)$, let $\nu := \Phi_{\mathbb{B}}^{\mathbb{N}}(\mu)$; then ν is a σ -invariant measure on $\mathcal{B}^{\mathbb{N}}$. Define

$$H_{\mu}(\mathbb{B}; \Phi) := h_{\nu}(\sigma) = - \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{\mathbf{b} \in \mathcal{B}^{\{0 \dots T\}}} \nu[\mathbf{b}] \log_2(\nu[\mathbf{b}]).$$

The *topological entropy* of $(\mathcal{A}^{\mathbb{M}}, \Phi)$ and the *measurable entropy* of $(\mathcal{A}^{\mathbb{M}}, \Phi, \mu)$ are then defined

$$h_{\text{top}}(\Phi) := \sup_{\substack{\mathbb{B} \subset \mathbb{M} \\ \text{finite}}} H_{\text{top}}(\mathbb{B}; \Phi) \quad \text{and} \\ h_{\mu}(\Phi) := \sup_{\substack{\mathbb{B} \subset \mathbb{M} \\ \text{finite}}} H_{\mu}(\mathbb{B}; \Phi).$$

The famous *Variational Principle* states that $h_{\text{top}}(\Phi) = \sup \{h_{\mu}(\Phi); \mu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{M}}, \Phi)\}$; see [► Entropy in Ergodic Theory](#) or Sect. 10 [► Topological Dynamics of Cellular Automata](#).

If \mathbb{M} has more than one dimension (e.g. $\mathbb{M} = \mathbb{Z}^D$ or \mathbb{N}^D for $D \geq 2$) then most CA on $\mathcal{A}^{\mathbb{M}}$ have infinite entropy. Thus, entropy is mainly of interest in the case $\mathbb{M} = \mathbb{Z}$ or \mathbb{N} . Coven [23] was the first to compute the topological entropy of a CA; he showed that $h_{\text{top}}(\Phi) = 1$ for a large class of left-permutative, one-sided CA on $\{0, 1\}^{\mathbb{N}}$ (which have since been called *Coven CA*). Later, Lind [83] showed how to construct CA whose topological entropy was any element of a countable dense subset of \mathbb{R}_+ , consisting of logarithms of certain algebraic numbers. Theorems 14 and 18(b) above characterize the topological entropy of posexpansive CA. However, Hurd et al. [62] showed that there is no algorithm which can compute the topological entropy of an arbitrary CA; see [► Tiling Problem and Undecidability in Cellular Automata](#).

Measurable entropy has also been computed for a few special classes of CA. For example, if $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ is bipermutative with neighborhood $\{0, 1\}$ and $\mu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{Z}}, \Phi; \sigma)$ is σ -ergodic, then $h_{\mu}(\Phi) = \log_2(K)$ for some integer $K \leq |\mathcal{A}|$ (see Thm 4.1 in [113]). If η is the uniform measure, and Φ is posexpansive, then Theorems 58 and 60 above characterize $h_{\eta}(\Phi)$. Also, if Φ satisfies the conditions of Theorem 61, then $h_{\eta}(\Phi) > 0$, and furthermore, all factors of the MPDS $(\mathcal{A}^{\mathbb{Z}}, \mu; \Phi)$ also have positive entropy.

However, unlike abstract dynamical systems, CA come with an explicit spatial ‘geometry’. The most fruitful investigations of CA entropy are those which have interpreted entropy in terms of how information propagates through this geometry.

Lyapunov Exponents

Wolfram [150] suggested that the propagation speed of ‘perturbations’ in a one-dimensional CA Φ could trans-

form ‘spatial’ entropy [i.e. $h(\sigma)$] into ‘temporal’ entropy [i.e. $h(\Phi)$]. He compared this propagation speed to the ‘Lyapunov exponent’ of a smooth dynamical system: it determines the exponential rate of divergence between two initially close Φ -orbits (see pp. 172, 261 and 514 in [151]). Shereshevsky [126] formalized Wolfram’s intuition and proved the conjectured entropy relationship; his results were later improved by Tisseur [141]. Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$, let $\mathbf{a} \in \mathcal{A}^{\mathbb{Z}}$, and let $z \in \mathbb{Z}$. Define

$$\mathbf{W}_z^+(\mathbf{a}) := \left\{ \mathbf{w} \in \mathcal{A}^{\mathbb{Z}} ; \mathbf{w}_{[z \dots \infty]} = \mathbf{a}_{[z \dots \infty]} \right\}, \quad \text{and} \\ \mathbf{W}_z^-(\mathbf{a}) := \left\{ \mathbf{w} \in \mathcal{A}^{\mathbb{Z}} ; \mathbf{w}_{(-\infty \dots z]} = \mathbf{a}_{(-\infty \dots z]} \right\}.$$

Thus, we obtain each $\mathbf{w} \in \mathbf{W}_z^+(\mathbf{a})$ (respectively $\mathbf{W}_z^-(\mathbf{a})$) by ‘perturbing’ \mathbf{a} somewhere to the left (resp. right) of coordinate z . Next, for any $t \in \mathbb{N}$, define

$$\tilde{\Lambda}_t^+(\mathbf{a}) := \min \{z \in \mathbb{N} ; \Phi^t[\mathbf{W}_0^+(\mathbf{a})] \subseteq \mathbf{W}_z^+(\Phi^t[\mathbf{a}])\}, \\ \text{and} \\ \tilde{\Lambda}_t^-(\mathbf{a}) := \min \{z \in \mathbb{N} ; \Phi^t[\mathbf{W}_0^-(\mathbf{a})] \subseteq \mathbf{W}_{-z}^-(\Phi^t[\mathbf{a}])\}.$$

Thus, $\tilde{\Lambda}_t^{\pm}$ measures the farthest distance which any perturbation of \mathbf{a} at coordinate 0 could have propagated by time t . Next, define $\Lambda_t^{\pm}(\mathbf{a}) := \max_{z \in \mathbb{Z}} \tilde{\Lambda}_t^{\pm}[\sigma^z(\mathbf{a})]$. Then Shereshevsky [126] defined the (*maximum*) *Lyapunov exponents*

$$\lambda^+(\Phi, \mathbf{a}) := \lim_{t \rightarrow \infty} \frac{1}{t} \Lambda_t^+(\mathbf{a}), \quad \text{and} \\ \lambda^-(\Phi, \mathbf{a}) := \lim_{t \rightarrow \infty} \frac{1}{t} \Lambda_t^-(\mathbf{a}),$$

whenever these limits exist. Let $\mathbf{G}(\Phi) := \{\mathbf{g} \in \mathcal{A}^{\mathbb{Z}}; \lambda^{\pm}(\Phi, \mathbf{g}) \text{ both exist}\}$. The subset $\mathbf{G}(\Phi)$ is ‘generic’ within $\mathcal{A}^{\mathbb{Z}}$ in a very strong sense, and the Lyapunov exponents detect ‘chaotic’ topological dynamics.

Proposition 68 *Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$.*

- (a) *Let $\mu \in \mathfrak{M}_{\text{ens}}(\mathcal{A}^{\mathbb{Z}}; \sigma)$. Suppose that either: [i] μ is also Φ -invariant; or: [ii] μ is σ -ergodic and $\text{supp}(\mu)$ is a Φ -invariant subset. Then $\mu(\mathbf{G}) = 1$.*
- (b) *The set \mathbf{G} and the functions $\lambda^{\pm}(\Phi, \bullet)$ are (Φ, σ) -invariant. Thus, if μ is either Φ -ergodic or σ -ergodic, then there exist constants $\lambda_{\mu}^{\pm}(\Phi) \geq 0$ such that $\lambda^{\pm}(\Phi, \mathbf{g}) = \lambda_{\mu}^{\pm}(\Phi)$ for μ -all $\mathbf{g} \in \mathbf{G}$.*
- (c) *If Φ is posexpansive, then there is a constant $c > 0$ such that $\lambda^{\pm}(\Phi, \mathbf{g}) \geq c$ for all $\mathbf{g} \in \mathbf{G}$.*
- (d) *Let η be the uniform Bernoulli measure. If Φ is surjective, then $h_{\text{top}}(\Phi) \leq (\lambda_{\eta}^+(\Phi) + \lambda_{\eta}^-(\Phi)) \cdot \log |\mathcal{A}|$.*

Proof (a) follows from the fact that, for any $\mathbf{a} \in \mathcal{A}^{\mathbb{Z}}$, the sequence $[\Lambda_t^{\pm}(\mathbf{a})]_{t \in \mathbb{N}}$ is subadditive in t . Condition [i]

is Theorem 1 in [126], and follows from Kingman’s sub-additive ergodic theorem. Condition [ii] is Proposition 3.1 in [141].

(b) is clear by definition of λ^\pm . (c) is Theorem 5.2 in [37]. (d) is Proposition 5.3 in [141]. \square

For any Φ -ergodic $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}}; \Phi, \sigma)$, Shereshevsky (see Theorem 2 in [126]) showed that $h_\mu(\Phi) \leq (\lambda_\mu^+(\Phi) + \lambda_\mu^-(\Phi)) \cdot h_\mu(\sigma)$. Tisseur later improved this estimate. For any $T \in \mathbb{N}$, let

$$\begin{aligned} \tilde{I}_T^+(\mathbf{a}) &:= \min \{z \in \mathbb{N}; \forall t \in [1 \dots T], \\ &\quad \Phi^t[\mathbf{W}_{-z}^+(\mathbf{a})] \subseteq \mathbf{W}_0^+(\Phi^t[\mathbf{a}])\} \quad \text{and} \\ \tilde{I}_T^-(\mathbf{a}) &:= \min \{z \in \mathbb{N}; \forall t \in [1 \dots T], \\ &\quad \Phi^t[\mathbf{W}_z^-(\mathbf{a})] \subseteq \mathbf{W}_0^-(\Phi^t[\mathbf{a}])\}. \end{aligned}$$

Next, for any $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}}, \sigma)$, define $\hat{I}_T^\pm(\mu) := \int_{\mathcal{A}^{\mathbb{Z}}} \tilde{I}_T^\pm(\mathbf{a}) d\mu[\mathbf{a}]$.

Tisseur then defined the *average Lyapunov exponents*: $I_\mu^\pm(\Phi) := \liminf_{T \rightarrow \infty} \hat{I}_T^\pm(\mu)/T$.

Theorem 69 *Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ and let $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}}; \sigma)$.*

- (a) *If $\text{supp}(\mu)$ is Φ -invariant, then $I_\mu^+(\Phi) \leq \lambda_\mu^+(\Phi)$ and $I_\mu^-(\Phi) \leq \lambda_\mu^-(\Phi)$, and one or both inequalities are sometimes strict.*
- (b) *If μ is σ -ergodic and Φ -invariant, then $h_\mu(\Phi) \leq (I_\mu^+(\Phi) + I_\mu^-(\Phi)) \cdot h_\mu(\sigma)$, and this inequality is sometimes strict.*
- (c) *If $\text{supp}(\mu)$ contains Φ -equicontinuous points, then $I_\mu^+(\Phi) = I_\mu^-(\Phi) = h_\mu(\Phi) = 0$.*

Proof See [141]: (a) is Proposition 3.2 and Example 6.1; (b) is Theorem 5.1 and Example 6.2; and (c) is Proposition 5.2. \square

Directional Entropy

Milnor [98,99] introduced directional entropy to capture the intuition that information in a CA propagates in particular directions with particular ‘velocities’, and that different CA ‘mix’ information in different ways. Classical entropy is unable to detect this informational anisotropy. For example, if $\mathcal{A} = \{0, 1\}$ and $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$ has local rule $\phi(a_0, a_1) = a_0 + a_1 \pmod{2}$, then $h_{\text{top}}(\Phi) = 1 = h_{\text{top}}(\sigma)$, despite the fact that Φ vigorously ‘mixes’ information together and propagates any ‘perturbation’ outwards in an expanding cone, whereas σ merely shifts information to the left in a rigid and essentially trivial fashion.

If $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}^D})$, then a *complete history* for Φ is a sequence $(\mathbf{a}_t)_{t \in \mathbb{Z}} \in (\mathcal{A}^{\mathbb{Z}^D})^{\mathbb{Z}} \cong \mathcal{A}^{\mathbb{Z}^{D+1}}$ such that $\Phi(\mathbf{a}_t) =$

\mathbf{a}_{t+1} for all $t \in \mathbb{Z}$. Let $\mathbf{X}^{\text{Hist}} := \mathbf{X}^{\text{Hist}}(\Phi) \subset \mathcal{A}^{\mathbb{Z}^{D+1}}$ be the subshift of all complete histories for Φ , and let σ be the \mathbb{Z}^{D+1} shift action on \mathbf{X}^{Hist} ; then $(\mathbf{X}^{\text{Hist}}; \sigma)$ is conjugate to the natural extension of the system $(\mathbf{Y}; \Phi, \sigma)$, where $\mathbf{Y} := \Phi^\infty(\mathcal{A}^{\mathbb{M}}) := \bigcap_{t=1}^\infty \Phi^t(\mathcal{A}^{\mathbb{Z}^D})$ is the omega-limit set of Φ . If $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}^D}; \Phi, \sigma)$, then $\text{supp}(\mu) \subseteq \mathbf{Y}$, and μ extends to a σ -invariant measure $\tilde{\mu}$ on \mathbf{X}^{Hist} in the obvious way.

Let $\vec{v} = (v_0; v_1, \dots, v_D) \in \mathbb{R} \times \mathbb{R}^D \cong \mathbb{R}^{D+1}$. For any bounded open subset $B \subset \mathbb{R}^{D+1}$ and $T > 0$, let $B(T\vec{v}) := \{\mathbf{b} + t\vec{v}; \mathbf{b} \in B \text{ and } t \in [0, T]\}$ be the ‘sheared cylinder’ in \mathbb{R}^{D+1} with cross-section B and length $T|\vec{v}|$ in the direction \vec{v} , and let $\mathbb{B}(T\vec{v}) := B(T\vec{v}) \cap \mathbb{Z}^{D+1}$. Let $\mathbf{X}^{\text{Hist}}_{\mathbb{B}(T\vec{v})} := \{\mathbf{x}_{\mathbb{B}(T\vec{v})}; \mathbf{x} \in \mathbf{X}^{\text{Hist}}(\Phi)\}$. We define

$$\begin{aligned} H_{\text{top}}(\Phi; B, \vec{v}) &:= \limsup_{T \rightarrow \infty} \frac{1}{T} \log_2[\#\mathbf{X}^{\text{Hist}}_{\mathbb{B}(T\vec{v})}]; \quad \text{and} \\ H_\mu(\Phi; B, \vec{v}) &:= -\limsup_{T \rightarrow \infty} \frac{1}{T} \sum_{\mathbf{x} \in \mathbf{X}^{\text{Hist}}_{\mathbb{B}(T\vec{v})}} \tilde{\mu}[\mathbf{x}] \log_2(\tilde{\mu}[\mathbf{x}]). \end{aligned}$$

We then define the \vec{v} -directional topological entropy and \vec{v} -directional μ -entropy of Φ by

$$h_{\text{top}}(\Phi; \vec{v}) := \sup_{\substack{B \subset \mathbb{R}^{D+1} \\ \text{open \& bounded}}} h_{\text{top}}(\Phi; B, \vec{v}); \quad \text{and} \quad (8)$$

$$h_\mu(\Phi; \vec{v}) := \sup_{\substack{B \subset \mathbb{R}^{D+1} \\ \text{open \& bounded}}} h_\mu(\Phi; B, \vec{v}). \quad (9)$$

Proposition 70 *Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}^D})$ and let $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}^D}; \Phi, \sigma)$.*

- (a) *Directional entropy is homogeneous. That is, for any $\vec{v} \in \mathbb{R}^{D+1}$ and $r > 0$, $h_{\text{top}}(\Phi, r\vec{v}) = r \cdot h_{\text{top}}(\Phi, \vec{v})$ and $h_\mu(\Phi, r\vec{v}) = r \cdot h_\mu(\Phi, \vec{v})$.*
- (b) *If $\vec{v} = (t; \mathbf{z}) \in \mathbb{Z} \times \mathbb{Z}^D$, then $h_{\text{top}}(\Phi, \vec{v}) = h_{\text{top}}(\Phi^t \circ \sigma^{\mathbf{z}})$ and $h_\mu(\Phi, \vec{v}) = h_\mu(\Phi^t \circ \sigma^{\mathbf{z}})$.*
- (c) *There is an extension of the $\mathbb{Z} \times \mathbb{Z}^D$ -system $(\mathbf{X}^{\text{Hist}}, \Phi; \sigma)$ to an $\mathbb{R} \times \mathbb{R}^D$ -system $(\tilde{\mathbf{X}}, \tilde{\Phi}, \tilde{\sigma})$ such that, for any $\vec{v} = (t; \vec{u}) \in \mathbb{R} \times \mathbb{R}^D$ we have $h_{\text{top}}(\Phi, \vec{v}) = h_{\text{top}}(\tilde{\Phi}^t \circ \tilde{\sigma}^{\vec{u}})$.*

For any $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}^D}; \Phi, \sigma)$, there is an extension $\tilde{\mu} \in \mathfrak{M}_{\text{cons}}(\tilde{\mathbf{X}}; \tilde{\Phi}, \tilde{\sigma})$ such that for any $\vec{v} = (t; \vec{u}) \in \mathbb{R} \times \mathbb{R}^D$ we have $h_\mu(\Phi, \vec{v}) = h_{\tilde{\mu}}(\tilde{\Phi}^t \circ \tilde{\sigma}^{\vec{u}})$.

Proof (a),(b) follow from the definition. (c) is Proposition 2.1 in [109]. \square

Remark 71 Directional entropy can actually be defined for any continuous \mathbb{Z}^{D+1} -action on a compact metric space, and in particular, for any subshift of $\mathcal{A}^{\mathbb{Z}^{D+1}}$. The directional entropy of a CA Φ is then just the directional

entropy of the subshift $\mathbf{X}^{\text{Hist}}(\Phi)$. Proposition 70 holds for any subshift.

Directional entropy is usually infinite for multidimensional CA (for the same reason that classical entropy is usually infinite). Thus, most of the analysis has been for one-dimensional CA. For example, Kitchens and Schmidt (see Sect. 1 in [72]) studied the directional topological entropy of one-dimensional linear CA, while Smilie (see Proposition 1.1 in [133]) computed the directional topological entropy for ECA#184. If Φ is linear, then the function $\vec{v} \mapsto h_{\text{top}}(\Phi, \vec{v})$ is piecewise linear and convex, but if Φ is ECA#184, it is neither.

If \vec{v} has rational entries, then Proposition 70(a,b) shows that $h(\Phi, \vec{v})$ is a rational multiple of the classical entropy of some composite CA, which can be computed through classical methods. However, if \vec{v} is irrational, then $h(\Phi, \vec{v})$ is quite difficult to compute using the formulae (8) and (9), and Proposition 70(c), while theoretically interesting, is not very computationally useful. Can we compute $h(\Phi, \vec{v})$ as the limit of $h(\Phi, \vec{v}_k)$ where $\{\vec{v}_k\}_{k=1}^{\infty}$ is a sequence of rational vectors tending to \vec{v} ? In other words, is directional entropy continuous as a function of \vec{v} ? What other properties has $h(\Phi, \vec{v})$ as a function of \vec{v} ?

Theorem 72 Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ and let $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}}; \Phi)$.

- (a) The function $\mathbb{R}^2 \ni \vec{v} \mapsto h_{\mu}(\Phi, \vec{v}) \in \mathbb{R}$ is continuous.
- (b) Suppose there is some $(t, z) \in \mathbb{N} \times \mathbb{Z}$ with $t \geq 1$, such that $\Phi^t \circ \sigma^z$ is posexpansive. Then the function $\mathbb{R}^2 \ni \vec{v} \mapsto h_{\text{top}}(\Phi, \vec{v}) \in \mathbb{R}$ is convex, and thus, Lipschitz-continuous.
- (c) However, there exist other $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$ for which the function $\mathbb{R}^2 \ni \vec{v} \mapsto h_{\text{top}}(\Phi, \vec{v}) \in \mathbb{R}$ is not continuous.
- (d) Suppose Φ has neighborhood $[-\ell \dots r] \subset \mathbb{Z}$. If $\vec{v} = (t; z) \in \mathbb{R}^2$, then let $z_{\ell} := x - \ell t$ and $z_r := x + rt$. Let $L := \log |\mathcal{A}|$.

- [i] Suppose $z_{\ell} \cdot z_r \geq 0$. Then $h_{\mu}(\Phi; \vec{v}) \leq \max\{|z_{\ell}|, |z_r|\} \cdot L$. Furthermore:
 - If Φ is right-permutative, and $|z_{\ell}| \leq |z_r|$, then $h_{\mu}(\Phi; \vec{v}) = |z_r| \cdot L$.
 - If Φ is left-permutative, and $|z_r| \leq |z_{\ell}|$, then $h_{\mu}(\Phi; \vec{v}) = |z_{\ell}| \cdot L$.
- [ii] Suppose $z_{\ell} \cdot z_r \leq 0$. Then $h_{\mu}(\Phi; \vec{v}) \leq |z_r - z_{\ell}| \cdot L$. Furthermore, if Φ is bipermutative in this case, then $h_{\mu}(\Phi; \vec{v}) = |z_r - z_{\ell}| \cdot L$.

Proof (a) is Corollary 3.3 in [109], while (b) is Théorème III.11 and Corollaire III.12, pp. 79–80 in [120]. (c) is Proposition 1.2 in [133].

(d) summarizes the main results of [21]. See also Example 6.2 in [99] for an earlier analysis of permutative

CA in the case $r = \ell = 1$; see also Example 6.4 in [12] and Sect. 1 in Sect. 1 in [72] for the special case when Φ is linear. \square

Remark 73 (a) In fact, the conclusion of Theorem 72(b) holds as long as Φ has any posexpansive directions (even irrational ones). A posexpansive direction is analogous to an expansive subspace (see Subsect. “Entropy Geometry and Expansive Subdynamics”), and is part of Sablik’s theory of ‘directional dynamics’ for one-dimensional CA; see Remark 84(b) below. Using this theory, Sablik has also shown that $h_{\mu}(\Phi; \vec{v}) = 0 = h_{\text{top}}(\Phi, \vec{v})$ whenever \vec{v} is an equicontinuous direction for Φ , whereas $h_{\mu}(\Phi; \vec{v}) \neq 0 \neq h_{\text{top}}(\Phi, \vec{v})$ whenever \vec{v} is a right- or left posexpansive direction for Φ . See Sect. §III.4.5–Sect. §III.4.6, pp. 86–88 in [120].

(b) Courbage and Kamiński have defined a ‘directional’ version of the Lyapunov exponents introduced in Subsect. “Lyapunov Exponents”. If $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$, $\mathbf{a} \in \mathcal{A}^{\mathbb{Z}}$ and $\vec{v} = (t; z) \in \mathbb{N} \times \mathbb{Z}$, then $\lambda_{\vec{v}}^{\pm}(\Phi, \mathbf{a}) := \lambda^{\pm}(\Phi^t \circ \sigma^z, \mathbf{a})$, where λ^{\pm} are defined as in Subsect. “Lyapunov Exponents”. If $\vec{v} \in \mathbb{R}^2$ is irrational, then the definition of $\lambda_{\vec{v}}^{\pm}(\Phi, \mathbf{a})$ is somewhat more subtle. For any Φ and \mathbf{a} , the function $\mathbb{R}^2 \ni \vec{v} \mapsto \lambda_{\vec{v}}^{\pm}(\Phi, \mathbf{a}) \in \mathbb{R}$ is homogeneous and continuous (see Lemma 2 and Proposition 3 in [22]). If $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}}; \Phi, \sigma)$ is σ -ergodic, then $\lambda_{\vec{v}}^{\pm}(\Phi, \bullet)$ is constant μ -almost everywhere, and is related to $h_{\mu}(\Phi; \vec{v})$ through an inequality exactly analogous to Theorem 69(b); see Theorem 1 in [22].

Cone Entropy For any $\vec{v} \in \mathbb{R}^{D+1}$, any angle $\theta > 0$, and any $N > 0$, we define

$$\mathbb{K}(N\vec{v}, \theta) := \left\{ \mathbf{z} \in \mathbb{Z}^{D+1}; |\mathbf{z}| \leq N|\vec{v}| \text{ and } \mathbf{z} \bullet \vec{v} / |\mathbf{z}||\vec{v}| \geq \cos(\theta) \right\}.$$

Geometrically, this is the set of all \mathbb{Z}^{D+1} -lattice points in a cone of length $N|\vec{v}|$ which subtends an angle of 2θ around an axis parallel to \vec{v} , and which has its apex at the origin. If $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}^D})$, then let $\mathbf{X}^{\text{Hist}}(N\vec{v}, \theta) := \{\mathbf{x}_{\mathbb{K}(N\vec{v}, \theta)}; \mathbf{x} \in \mathbf{X}^{\text{Hist}}(\Phi)\}$. If $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}^D}; \Phi)$, and $\tilde{\mu}$ is the extension of μ to \mathbf{X}^{Hist} , then the cone entropy of (Φ, μ) in direction \vec{v} is defined

$$h_{\mu}^{\text{cone}}(\Phi, \vec{v}) := - \lim_{\theta \searrow 0} \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{\mathbf{x} \in \mathbf{X}^{\text{Hist}}(N\vec{v}, \theta)} \tilde{\mu}[\mathbf{x}] \log_2(\tilde{\mu}[\mathbf{x}]).$$

Park [107,108] attributes this concept to Doug Lind. Like directional entropy, cone entropy can be defined for any

continuous \mathbb{Z}^{D+1} -action, and is generally infinite for multidimensional CA. However, for one-dimensional CA, Park has proved:

Theorem 74 *If $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}})$, $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}}; \Phi)$ and $\tilde{\nu} \in \mathbb{R}^2$, then $h_{\mu}^{\text{cone}}(\Phi, \tilde{\nu}) = h_{\mu}(\Phi, \tilde{\nu})$.*

Proof See Theorem 1 in [108]. □

Entropy Geometry and Expansive Subdynamics

Directional entropy is the one-dimensional version of a multidimensional ‘entropy density’ function, which was introduced by Milnor [99] to address the fact that classical and directional entropy are generally infinite for multidimensional CA. Milnor’s ideas were then extended by Boyle and Lind [12], using their theory of *expansive subdynamics*.

Let $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^{D+1}}$ be a subshift, and let $\mu \in \mathfrak{M}_{\text{cons}}(\mathbf{X}; \sigma)$. For any bounded $B \subset \mathbb{R}^{D+1}$, let $\mathbb{B} := B \cap \mathbb{Z}^{D+1}$, let $\mathbf{X}_{\mathbb{B}} := \mathbf{X}_{\mathbb{B}}$, and then define

$$H_{\mathbf{X}}(B) := \log_2 |\mathbf{X}_{\mathbb{B}}| \quad \text{and}$$

$$H_{\mu}(B) := - \sum_{\mathbf{x} \in \mathbf{X}_{\mathbb{B}}} \mu[\mathbf{x}] \log_2(\mu[\mathbf{x}]).$$

The *topological entropy dimension* $\dim(\mathbf{X})$ is the smallest $d \in [0 \dots D+1]$ having some constant $c > 0$ such that, for any finite $B \subset \mathbb{R}^{D+1}$, $H_{\mathbf{X}}(B) \leq c \cdot \text{diam}[B]^d$. The *measurable entropy dimension* $\dim(\mu)$ is defined similarly, only with H_{μ} in place of $H_{\mathbf{X}}$. Note that $\dim(\mu) \leq \dim(\mathbf{X})$, because $H_{\mu}(B) \leq H_{\mathbf{X}}(B)$ for all $B \subset \mathbb{R}^{D+1}$.

For any bounded $B \subset \mathbb{R}^{D+1}$ and ‘scale factor’ $s > 0$, let $sB := \{sb; b \in B\}$. For any radius $r > 0$, let $(sB)^r := \{\mathbf{x} \in \mathbb{R}^{D+1}; d(\mathbf{x}, sB) \leq r\}$. Define the *d-dimensional topological entropy density* of B by

$$h_{\mathbf{X}}^d(B) := \sup_{r>0} \limsup_{s \rightarrow \infty} H_{\mathbf{X}}[(sB)^r] / s^d. \tag{10}$$

Define *d-dimensional measurable entropy density* $h_{\mu}^d(B)$ similarly, only using H_{μ} instead of $H_{\mathbf{X}}$. Note that, for any $d < \dim(\mathbf{X})$ [respectively, $d < \dim(\mu)$], $h_{\mathbf{X}}^d(B)$ [resp. $h_{\mu}^d(B)$] will be infinite, whereas for for any $d > \dim(\mathbf{X})$ [resp. $d > \dim(\mu)$], $h_{\mathbf{X}}^d(B)$ [resp. $h_{\mu}^d(B)$] will be zero; hence $\dim(\mathbf{X})$ [resp. $\dim(\mu)$] is the unique value of d for which the function $h_{\mathbf{X}}^d$ [resp. h_{μ}^d] defined in Eq. (10) could be nontrivial.

Example 75 (a) If $d = D + 1$, and B is a unit cube centered at the origin, then $h_{\mathbf{X}}^{D+1}(B)$ (resp. $h_{\mu}^{D+1}(B)$) is just the classical $(D+1)$ -dimensional topological (resp. measurable) entropy of \mathbf{X} (resp. μ) as a $(D+1)$ -dimensional

subshift (resp. random field); see ▶ [Entropy in Ergodic Theory](#).

(b) However, the most important case for Milnor [99] (and us) is when $\mathbf{X} = \mathbf{X}^{\text{Hist}}(\Phi)$ for some $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}^D})$. In this case, $\dim(\mu) \leq \dim(\mathbf{X}) \leq D < D+1$. In particular, if $d = 1$, then for any $\tilde{\nu} \in \mathbb{R}^{D+1}$, if $B := \{r\tilde{\nu}; r \in [0, 1]\}$, then $h_{\mathbf{X}}^1(B) = h_{\text{top}}(\Phi; \tilde{\nu})$ and $h_{\mu}^1(B) = h_{\mu}(\Phi; \tilde{\nu})$ are *directional entropies* of Subsect. “[Directional Entropy](#)”.

For any $d \in [0 \dots D+1]$, let λ^d be the d -dimensional Hausdorff measure on \mathbb{R}^{D+1} such that, if $P \subset \mathbb{R}^{D+1}$ is any *d-plane* (i.e. a d -dimensional linear subspace of \mathbb{R}^{D+1}), then λ^d restricts to the d -dimensional Lebesgue measure on P .

Theorem 76 *Let $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^{D+1}}$ be a subshift, and let $\mu \in \mathfrak{M}_{\text{cons}}(\mathbf{X}; \sigma)$. Let $d = \dim(\mathbf{X})$ (or $\dim(\mu)$) and let h^d be $h_{\mathbf{X}}^d$ (or h_{μ}^d). Let $B, C \subset \mathbb{R}^{D+1}$ be compact sets. Then*

- (a) $h^d(B)$ is well-defined and finite.
- (b) If $B \subseteq C$ then $h^d(B) \leq h^d(C)$.
- (c) $h^d(B \cup C) \leq h^d(B) + h^d(C)$.
- (d) $h^d(B + \tilde{\nu}) = h^d(B)$ for any $\tilde{\nu} \in \mathbb{R}^{D+1}$.
- (e) $h^d(sB) = s^d \cdot h^d(B)$ for any $s > 0$.
- (f) There is some constant c such that $h_d(B) \leq c\lambda^d(B)$ for all compact $B \subset \mathbb{R}^{D+1}$.
- (g) If $d \in \mathbb{N}$, then for any d -plane $P \subset \mathbb{R}^{D+1}$, there is some $\mathfrak{S}^d(P) \geq 0$ such that $h^d(B) = \mathfrak{S}^d(P) \cdot \lambda^d(B)$ for any compact subset $B \subset P$ with $\lambda^d(\partial B) = 0$.
- (h) There is a constant $\overline{H}_{\mathbf{X}}^d < \infty$ such that $\mathfrak{S}_{\mathbf{X}}^d(P) \leq \overline{H}_{\mathbf{X}}^d$ for all d -planes P .

Proof See Theorems 1 and 2 and Corollary 1 in [99], or see Theorems 6.2, 6.3, and 6.13 in [12]. □

Example 77 Let $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}^D})$ and let $\mathbf{X} := \mathbf{X}^{\text{Hist}}(\Phi)$. If $P := \{0\} \times \mathbb{R}^D$, then $\mathfrak{S}^D(P)$ is the classical D -dimensional entropy of the omega limit set $\mathbf{Y} := \Phi^{\infty}(\mathcal{A}^{\mathbb{Z}^D})$; heuristically, this measures the asymptotic level of ‘spatial disorder’ in \mathbf{Y} . If $P \subset \mathbb{R}^{D+1}$ is some other D -plane, then $\mathfrak{S}^D(P)$ measures some combination of the ‘spatial disorder’ of \mathbf{Y} with the dynamical entropy of Φ .

Let $d \in [1 \dots D+1]$, and let $P \subset \mathbb{R}^{D+1}$ be a d -plane. For any $r > 0$, let $P(r) := \{z \in \mathbb{Z}^{D+1}; d(z, P) < r\}$. We say P is *expansive* for \mathbf{X} if there is some $r > 0$ such that, for any $\mathbf{x}, \mathbf{y} \in \mathbf{X}$, $(\mathbf{x}_{P(r)} = \mathbf{y}_{P(r)}) \iff (\mathbf{x} = \mathbf{y})$. If P is spanned by d rational vectors, then $P \cap \mathbb{Z}^{D+1}$ is a rank- d sublattice $\mathbb{L} \subset \mathbb{Z}^{D+1}$, and P is expansive if and only if the induced \mathbb{L} -action on \mathbf{X} is expansive. However, if P is ‘irrational’, then expansiveness is a more subtle concept; see Sect. 2 in [12] for more information.

If $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}^D})$ and $\mathbf{X} = \mathbf{X}^{\text{Hist}}(\Phi)$, then Φ is *quasi-invertible* if \mathbf{X} admits an expansive D -plane P (this is a natural extension of Milnor’s (1988; §7) definition in terms of

‘causal cones’). Heuristically, if we regard \mathbb{Z}^{D+1} as ‘space-time’ (in the spirit of special relativity), then \mathbb{P} can be seen as ‘space’, and any direction transversal to \mathbb{P} can be interpreted as the flow of ‘time’.

Example 78 (a) If Φ is invertible, then it is quasi-invertible, because $\{0\} \times \mathbb{R}^D$ is an expansive D -plane (recall that the zeroth coordinate is time).

(b) Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}})$, so that $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^2}$. Let Φ have neighborhood $[-\ell \dots r]$, with $-\ell \leq 0 \leq r$, and let $\mathbb{L} \subset \mathbb{R}^2$ be a line with slope S through the origin (Fig. 2).

- [i] If Φ is right-permutative, and $0 < S \leq \frac{1}{\ell+1}$, then \mathbb{L} is expansive for \mathbf{X} .
- [ii] If Φ is left-permutative, and $\frac{-1}{r+1} \leq S < 0$, then \mathbb{L} is expansive for \mathbf{X} .
- [iii] If Φ is bipermutative, and $\frac{-1}{r+1} \leq S < 0$ or $0 < S \leq \frac{1}{\ell+1}$, then \mathbb{L} is expansive for \mathbf{X} .
- [iv] If Φ is posexpansive (see Subsect. “[Posexpansive and Permutative CA](#)”) then the ‘time’ axis $\mathbb{L} = \mathbb{R} \times \{0\}$ is expansive for \mathbf{X} .

Hence, in any of these cases, Φ is quasi-invertible. (Presumably, something similar is true for multidimensional permutative CA.)

Proposition 79 Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}^D})$, let $\mathbf{X} = \mathbf{X}^{\text{Hist}}(\Phi)$, let $\mu \in \mathfrak{M}_{\text{cons}}(\mathbf{X}; \sigma)$, and let \mathfrak{S}^d and $\overline{H}_{\mathbf{X}}^d$ be as in Theorem 76(g,h).

- (a) If $\mathfrak{S}_{\mathbf{X}}^D(\{0\} \times \mathbb{R}^D) = 0$, then $\overline{H}_{\mathbf{X}}^D = 0$.
- (b) Let $d \in [1 \dots D]$, and suppose that \mathbf{X} admits an expansive d -plane. Then:

- [i] $\dim(\mathbf{X}) \leq d$;
- [ii] There is a constant $\overline{H}_{\mu}^d < \infty$ such that $\mathfrak{S}_{\mu}^d(P) \leq \overline{H}_{\mu}^d$ for all d -planes P ;
- [iii] If $\mathfrak{S}^d(P) = 0$ for some expansive d -plane P , then $\overline{H}^d = 0$.

Proof (a) is Corollary 3 in [99], (b)[i] is Corollary 1.4 in [128], and (b)[ii] is Theorem 6.19(2) in [12].

(b)[iii]: See Theorem 6.3(4) in [12] for “ $\overline{H}_{\mathbf{X}}^d = 0$ ”. See Theorem 6.19(1) in [12] for “ $\overline{H}_{\mu}^d = 0$ ”. \square

If $d \in [1 \dots D+1]$, then a d -frame in \mathbb{R}^{D+1} is a d -tuple $F := (\vec{v}_1, \dots, \vec{v}_d)$, where $\vec{v}_1, \dots, \vec{v}_d \in \mathbb{R}^{D+1}$ are linearly independent. Let $\mathfrak{F}_{\text{time}}(D+1, d)$ be the set of all d -frames in \mathbb{R}^{D+1} ; then $\mathfrak{F}_{\text{time}}(D+1, d)$ is an open subset of $\mathbb{R}^{D+1} \times \dots \times \mathbb{R}^{D+1} := \mathbb{R}^{(D+1) \times d}$. Let

$$\mathfrak{E}_{\text{expansive}}(\mathbf{X}, d) := \{F \in \mathfrak{F}_{\text{time}}(D+1, d) ; \text{span}(F) \text{ is expansive for } \mathbf{X}\} .$$

Then $\mathfrak{E}_{\text{expansive}}(\mathbf{X}, d)$ is an open subset of $\mathfrak{F}_{\text{time}}(D+1, d)$, by Lemma 3.4 in [12]. A connected component of $\mathfrak{E}_{\text{expansive}}(\mathbf{X}, d)$ is called an *expansive component* for \mathbf{X} . For any $F \in \mathfrak{F}_{\text{time}}(D+1, d)$, let $[F]$ be the d -dimensional parallelepiped spanned by F , and let $\mathfrak{h}_{\mathbf{X}}^d(F) := h_{\mathbf{X}}^d([F]) = \mathfrak{S}_{\mathbf{X}}^d(\text{span}(F)) \cdot \lambda^d([F])$, where the last equality is by Theorem 76(g). The next result is a partial extension of Theorem 72(b).

Proposition 80 Let $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^{D+1}}$ be a subshift, suppose $d := \dim(\mathbf{X}) \in \mathbb{N}$, and let $\mathfrak{C} \subset \mathfrak{E}_{\text{expansive}}(\mathbf{X}, d)$ be an expan-

Ergodic Theory of Cellular Automata, Figure 2

Example 78(b)[iii]: A left permutative CA Φ is quasi-invertible. In this picture, $[-\ell \dots r] = [-1 \dots 2]$, and \mathbb{L} is a line of slope $-1/3$. If $x \in \mathbf{X}$ and we know the entries of x in a neighborhood of \mathbb{L} , then we can reconstruct the rest of x as shown. Entries above \mathbb{L} are directly computed using the local rule of Φ . Entries below \mathbb{L} are interpolated via left-permutativity. In both cases, the reconstruction occurs in consecutive diagonal lines, whose order is indicated by shading from darkest to lightest in the figure

sive component. Then the function $h_{\mathbf{X}}^d: \mathcal{C} \rightarrow \mathbb{R}$ is convex in each of its d distinct \mathbb{R}^{D+1} -valued arguments. Thus, $h_{\mathbf{X}}^d$ is Lipschitz-continuous on \mathcal{C} .

Proof See Theorem 6.9(1,4) in [12]. □

For measurable entropy, we can say much more. Recall that a d -linear form is a function $\omega: \mathbb{R}^{(D+1) \times d} \rightarrow \mathbb{R}$ which is linear in each of its d distinct \mathbb{R}^{D+1} -valued arguments and antisymmetric.

Theorem 81 *Let $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^{D+1}}$ be a subshift and let $\mu \in \mathfrak{M}_{\text{cons}}(\mathbf{X}; \sigma)$. Suppose $d := \dim(\mu) \in \mathbb{N}$, and let $\mathcal{C} \subset \mathcal{E}_{\text{expansive}}(\mathbf{X}, d)$ be an expansive component for \mathbf{X} . Then there is a d -linear form $\omega: \mathbb{R}^{(D+1) \times d} \rightarrow \mathbb{R}$ such that h_{μ}^d agrees with ω on \mathcal{C} .*

Proof Theorem 6.16 in [12]. □

If $\bar{H}_{\mu}^d \neq 0$, then Theorem 81 means that there is an orthogonal $(D + 1 - d)$ -frame $\bar{w} := (\bar{w}_{d+1}, \dots, \bar{w}_{D+1})$ (transversal to all frames in \mathcal{C}) such that, for any d -frame $\bar{v} := (\bar{v}_1, \dots, \bar{v}_d) \in \mathcal{C}$,

$$h_{\mu}^d(\bar{v}) = \det(\bar{v}_1, \dots, \bar{v}_d; \bar{w}_{d+1}, \dots, \bar{w}_{D+1}). \tag{11}$$

Thus, the d -plane orthogonal to $\{\bar{w}_{d+1}, \dots, \bar{w}_{D+1}\}$ is the d -plane which maximizes \mathfrak{S}_{μ}^d – this is the d -plane manifesting the most rapid decay of correlation with distance. On the other hand, $\text{span}(\bar{w})$ is the $(D + 1 - d)$ -plane along which correlations decay the most slowly. Also, if $\bar{v} \in \mathcal{C}$, then Eq. (11) implies that \mathcal{C} cannot contain any frame spanning $\text{span}(\bar{v})$ with reversed orientation (e.g. an odd permutation of \bar{v}), because entropy is nonnegative.

Example 82 Let $\Phi \in \text{CA}(\mathcal{A}^{\mathbb{Z}^D})$ be quasi-invertible, and let \mathbb{P} be an expansive D -plane for $\mathbf{X} := \mathbf{X}^{\text{hist}}(\Phi)$ (see Example 78). The D -frames spanning \mathbb{P} fall into two expansive components (related by orientation-reversal); let \mathcal{C} be union of these two components. Let $\mu \in \mathfrak{M}_{\text{cons}}(\mathcal{A}^{\mathbb{Z}^D}; \Phi)$, and extend μ to a σ -invariant measure on \mathbf{X} . In this case, Theorem 81 is equivalent to Theorem 4 in [99], which says there a vector $\bar{w} \in \mathbb{R}^{D+1}$ such that, for any D -frame $(\bar{v}_1, \dots, \bar{v}_D) \in \mathcal{C}$, $h_{\mu}^d(F) = |\det(\bar{v}_1, \dots, \bar{v}_D; \bar{w})|$. Thus, $\mathfrak{S}_{\mu}^d(\mathbb{P})$ is maximized when \mathbb{P} is the hyperplane orthogonal to \bar{w} . Heuristically, \bar{w} points in the direction of minimum correlation decay (or maximum ‘causality’) – the direction which could most properly be called ‘time’ for the MPDS (Φ, μ) .

Theorem 81 yields the following generalization the Variational Principle:

Theorem 83 *Let $\mathbf{X} \subset \mathcal{A}^{\mathbb{Z}^{D+1}}$ be a subshift and suppose $d := \dim(\mathbf{X}) \in \mathbb{N}$.*

- (a) *If $F \in \mathcal{E}_{\text{expansive}}(\mathbf{X}, d)$, then there exists $\mu \in \mathfrak{M}_{\text{cons}}(\mathbf{X}; \sigma)$ such that $h_{\mathbf{X}}^d(F) = h_{\mu}^d(F)$.*
- (b) *Let $\mathcal{C} \subset \mathcal{E}_{\text{expansive}}(\mathbf{X}, d)$ be an expansive component for \mathbf{X} . There exists some $\mu \in \mathfrak{M}_{\text{cons}}(\mathbf{X}; \sigma)$ such that $h_{\mathbf{X}}^d = h_{\mu}^d$ on \mathcal{C} if and only if $h_{\mathbf{X}}^d$ is a d -linear form on \mathcal{C} .*

Proof Proposition 6.24 and Theorem 6.25 in [12]. □

Remark 84 (a) If $\mathbf{G} \subset \mathcal{A}^{\mathbb{Z}^D}$ is an abelian subgroup shift and $\Phi \in \text{ECA}(\mathbf{G})$, then $\mathbf{X}^{\text{hist}}(\Phi)$ is a subgroup shift of $\mathcal{A}^{\mathbb{Z}^{D+1}}$, which can be viewed as an algebraic \mathbb{Z}^{D+1} -action (see discussion prior to Proposition 27). In this context, the expansive subspaces of $\mathbf{X}^{\text{hist}}(\Phi)$ have been completely characterized by Einsiedler et al. (see Theorem 8.4 in [33]). Furthermore, certain dynamical properties (such as positive entropy, completely positive entropy, or Bernoullicity) are common amongst all elements of each expansive component of $\mathbf{X}^{\text{hist}}(\Phi)$ (see Theorem 9.8 in [33]) (this sort of ‘commonality’ within expansive components was earlier emphasized by Boyle and Lind (see [12])). If $\mathbf{X}^{\text{hist}}(\Phi)$ has entropy dimension 1 (e.g. Φ is a one-dimensional linear CA), the structure of $\mathbf{X}^{\text{hist}}(\Phi)$ has been thoroughly analyzed by Einsiedler and Lind [30]. Finally, if \mathbf{G}_1 and \mathbf{G}_2 are subgroup shifts, and $\Phi_k \in \text{ECA}(\mathbf{G}_k)$ and $\mu_k \in \mathfrak{M}_{\text{cons}}(\mathbf{G}_k; \Phi, \sigma)$ for $k = 1, 2$, with $\dim(\mu_1) = \dim(\mu_2) = 1$, then Einsiedler and Ward [32] have given conditions for the measure-preserving systems $(\mathbf{G}_1, \mu_1; \Phi_1, \sigma)$ and $(\mathbf{G}_2, \mu_2; \Phi_2, \sigma)$ to be disjoint.

(b) Boyle and Lind’s ‘expansive subdynamics’ concerns expansiveness along certain directions in the space-time diagram of a CA. Recently, M. Sablik has developed a theory of *directional dynamics*, which explores other topological dynamical properties (such as equicontinuity and sensitivity to initial conditions) along spatiotemporal directions in a CA; see [120], Chapitre II or [121].

Future Directions and Open Problems

1. We now have a fairly good understanding of the ergodic theory of linear and/or ‘abelian’ CA. The next step is to extend these results to CA with nonlinear and/or nonabelian algebraic structures. In particular:
 - (a) Almost all the measure rigidity results of Subsect. “[Measure Rigidity in Algebraic CA](#)” are for endomorphic CA on abelian group shifts, except for Propositions 21 and 23. Can we extend these results to CA on nonabelian group shifts or other permutative CA?
 - (b) Likewise, the asymptotic randomization results of Subsect. “[Asymptotic Randomization by Linear Cellular Automata](#)” are almost exclusively

for linear CA with scalar coefficients, and for $\mathbb{M} = \mathbb{Z}^D \times \mathbb{N}^E$. Can we extend these results to LCA with noncommuting, matrix-valued coefficients? (The problem is: if the coefficients do not commute, then the ‘polynomial representation’ and Lucas’ theorem become inapplicable.) Also, can we obtain similar results for multiplicative CA on *nonabelian* groups? (See Remark 41(d).) What about other permutative CA? (See Remark 41(e).) Finally, what if \mathbb{M} is a nonabelian group? (For example, Lind and Schmidt (unpublished) [31] have recently investigated algebraic actions of the discrete Heisenberg group.)

2. Cellular automata are often seen as models of spatially distributed computation. Meaningful ‘computation’ could possibly occur when a CA interacts with a highly structured initial configuration (e. g. a substitution sequence), whereas such computation is probably impossible in the roiling cauldron of noise arising from a mixing, positive entropy measure (e. g. a Bernoulli measure or Markov random field). Yet almost all the results in this article concern the interaction of CA with such mixing, positive-entropy measures. We are starting to understand the topological dynamics of CA acting on non-mixing and/or zero-entropy symbolic dynamical systems, (e. g. substitution shifts, automatic shifts, regular Toeplitz shifts, and quasisturmian shifts); see ► [Dynamics of Cellular Automata in Non-compact Spaces](#). However, almost nothing is known about the interaction of CA with the natural invariant measures on these systems. In particular:
 - (a) The invariant measures discussed in Sect. “[Invariant Measures for CA](#)” all have nonzero entropy (see, however, Example 67(c)). Are there any nontrivial zero-entropy measures for interesting CA?
 - (b) The results of Subsect. “[Asymptotic Randomization by Linear Cellular Automata](#)” all concern the asymptotic randomization of initial measures with nonzero entropy, except for Remark 41(c). Are there similar results for zero-entropy measures?
 - (c) Zero-entropy systems often have an appealing combinatorial description via cutting-and-stacking constructions, Bratteli diagrams, or finite state machines. Likewise, CA admit a combinatorial description (via local rules). How do these combinatorial descriptions interact?
3. As we saw in Subsect. “[Domains, Defects, and Particles](#)”, and also in Propositions 48–56, emergent defect dynamics can be a powerful tool for analyzing the measurable dynamics of CA. Defects in one-dimensional CA generally act like ‘particles’, and their ‘kinematics’

is fairly well-understood. However, in higher dimensions, defects can be much more topologically complicated (e. g. they can look like curves or surfaces), and their evolution in time is totally mysterious. Can we develop a theory of multidimensional defect dynamics?

4. Almost all the results about mixing and ergodicity in Subsect. “[Mixing and Ergodicity](#)” are for one-dimensional (mostly permutative) CA and for the uniform measure on $\mathcal{A}^{\mathbb{Z}}$. Can similar results be obtained for other CA and/or measures on $\mathcal{A}^{\mathbb{Z}}$? What about CA in $\mathcal{A}^{\mathbb{Z}^D}$ for $D \geq 2$?
5. Let μ be a (Φ, σ) -invariant measure on $\mathcal{A}^{\mathbb{M}}$. Proposition 66 suggests an intriguing correspondence between certain spectral properties (namely, weak mixing and discrete spectrum) for the system $(\mathcal{A}^{\mathbb{M}}, \mu; \sigma)$ and those for the system $(\mathcal{A}^{\mathbb{M}}, \mu; \Phi)$. Does a similar correspondence hold for other spectral properties, such as continuous spectrum, Lebesgue spectral type, spectral multiplicity, rigidity, or mild mixing?
6. Let $\mathbf{X} \in \mathcal{A}^{\mathbb{Z}^{D+1}}$ be a subshift admitting an expansive D -plane $\mathbb{P} \subset \mathbb{R}^{D+1}$. As discussed in Subsect. “[Entropy Geometry and Expansive Subdynamics](#)”, if we regard \mathbb{Z}^{D+1} as ‘spacetime’, then we can treat \mathbb{P} as a ‘space’, and a transversal direction as ‘time’. Indeed, if \mathbb{P} is spanned by rational vectors, then the Curtis–Hedlund–Lyndon theorem implies that \mathbf{X} is isomorphic to the history shift of some invertible $\Phi \in \mathcal{CA}(\mathcal{A}^{\mathbb{Z}^D})$ acting on some Φ -invariant subshift $\mathbf{Y} \subseteq \mathcal{A}^{\mathbb{Z}^D}$ (where we embed \mathbb{Z}^D in \mathbb{P}). If \mathbb{P} is irrational, then this is not the case; however, \mathbf{X} still seems very much like the history shift of a spatially distributed symbolic dynamical system, closely analogous to a CA, except with a continually fluctuating ‘spatial distribution’ of state information, and perhaps with occasional nonlocal interactions. For example, Proposition 79(b)[i] implies that $\dim(\mathbf{X}) \leq D$, just as for a CA. How much of the theory of invertible CA can be generalized to such systems?

I will finish with the hardest problem of all. Cellular automata are tractable mainly because of their *homogeneity*: CA are embedded in a highly regular spatial geometry (i. e. a lattice or other Cayley digraph) with the same local rule everywhere. However, many of the most interesting spatially distributed symbolic dynamical systems are not nearly this homogeneous. For example:

- CA are often proposed as models of spatially distributed physical systems. Yet in many such systems (e. g. living tissues, quantum ‘foams’), the underlying geometry is not a flat Euclidean space, but a curved manifold. A good discrete model of such a manifold

can be obtained through a Voronoi tessellation of sufficient density; a realistic symbolic dynamical model would be a CA-like system defined on the dual graph of this Voronoi tessellation.

- As mentioned in question #3, defects in multidimensional CA may have the geometry of curves, surfaces, or other embedded submanifolds (possibly with varying nonzero thickness). To model the evolution of such a defect, we could treat it as a CA-like object whose underlying geometry is an (evolving) manifold, and whose local rules (although partly determined by the local rule of the original CA) are spatially heterogeneous (because they are also influenced by incoming information from the ambient ‘nondefective’ space).
- The CA-like system arising in question #6 has a D -dimensional planar geometry, but the distribution of ‘cells’ within this plane (and, presumably, the local rules between them) are constantly fluctuating.

More generally, any topological dynamical system on a Cantor space can be represented as a *cellular network*: a CA-like system defined on an infinite digraph, with different local rules at different nodes. Gromov [51] has generalized the Garden of Eden Theorem 3 to this setting (see Remark 5(a)). However, other than Gromov’s work, basically nothing is known about such systems. Can we generalize any of the theory of cellular automata to cellular networks? Is it possible to develop a nontrivial ergodic theory for such systems?

Acknowledgments

I would like to thank François Blanchard, Mike Boyle, Maurice Courbage, Doug Lind, Petr Kůrka, Servet Martínez, Kyewon Koh Park, Mathieu Sablik, Jeffrey Steif, and Marcelo Sobottka, who read draft versions of this article and made many invaluable suggestions, corrections, and comments. (Any errors which remain are mine.) To Reem.

Glossary

Dynamical system A (discrete time) dynamical system describes the time evolution of a point in phase space. More precisely a space X is given and the time evolution is given by a map $T: X \rightarrow X$. The main interest is to describe the asymptotic behavior of the trajectories (orbits) $T^n(x)$, i. e. the evolution of an initial point $x \in X$ under the iterates of the map T . More generally one is interested in obtaining information on the geometrically complicated invariant sets or measures which describe the asymptotic behavior.

Fractal geometry Many objects of interest (invariant sets, invariant measures etc.) exhibit a complicated structure that is far from being smooth or regular. The aim of fractal geometry is to study those objects. One of the main tools is the fractal dimension theory that helps to extract important properties of geometrically “irregular” sets.

Definition of the Subject

The connection between fractal geometry and dynamical system theory is very diverse. There is no unified approach and many of the ideas arose from significant examples. Also the dynamical system theory has been shown to have a strong impact on classical fractal geometry. In this article there are first presented some examples showing nontrivial results coming from the application of dimension theory. Some of these examples require a deeper knowledge of the theory of smooth dynamical systems then can be provided here. Nevertheless, the flavor of these examples can be understood. Then there is a brief overview of some of the most developed parts of the application of fractal geometry to dynamical system theory. Of course a rigorous and complete treatment of the theory cannot be given. The cautious reader may wish to check the original papers. Finally, there is an outlook over the most recent developments. This article is by no means meant to be complete. It is intended to give some of the ideas and results from this field.

Introduction

In this section some of the aspects of fractal geometry in dynamical systems are pointed out. Some notions that are used will be defined later on and I intend only to give a flavor of the applications. The nonfamiliar reader will find the definitions in the corresponding sections and can return to this section later. The *geometry* of many invariant sets or invariant measures of dynamical systems (including attractors, measures defining the statistical properties)

look very complicated at *all scales*, and their geometry is impossible to describe using standard geometric tools. For some important classes of dynamical systems, these complicated structures are intensively studied using notions of dimension. In many cases it becomes possible to relate these notions of dimension to other fundamental dynamical characteristics, such as Lyapunov exponents, entropies, pressure, etc.

On the other hand tools from dynamical systems, especially from ergodic theory and thermodynamic formalism, are extremely useful to explore the fractal properties of the objects in question. This includes dimensions of limit sets of geometric constructions (the standard Cantor set being the most famous example), which a priori, are not related to dynamical systems [46,100]. Many dimension formulas for asymptotic sets of dynamical systems are obtained by means of Bowen-type formulas, i. e. as roots of some functionals arising from thermodynamic formalism.

The dimension of a set is a subtle characteristic which measures the *geometric complexity* of the set at arbitrarily fine scales. There are many notions of dimension, and most definitions involve a measurement of geometric complexity at scale ε (which ignores the irregularities of the set at size less than ε) and then considers the limiting measurement as $\varepsilon \rightarrow 0$. A priori (and in general) these different notions can be different. An important result is the affirmative solution of the Eckmann–Ruelle conjecture by Barreira, Pesin and Schmeling [17], which says that for smooth nonuniformly hyperbolic systems, the pointwise dimension is almost everywhere constant with respect to a hyperbolic measure. This result implies that many dimension characteristics for the measure coincide.

The deep connection between dynamical systems and dimension theory seems to have been first discovered by Billingsley [21] through several problems in number theory.

Another link between dynamical systems and dimension theory is through Pesin’s theory of dimension-like characteristics. This general theory is a unification of many notions of dimension along with many fundamental quantities in dynamical system such as entropies, pressure, etc.

However, there are numerous examples of dynamical systems exhibiting pathological behavior with respect to fractal geometrical characteristics. In particular higher-dimensional systems seem to be as complicated as general objects considered in geometric measure theory. Therefore, a clean and unified theory is still not available.

The study of characteristic notions like entropy, exponents or dimensions is an essential issue in the theory of dynamical systems. In many cases it helps to classify or to understand the dynamics. Most of these charac-

teristics were introduced for different questions and concepts. For example, entropy was introduced to distinguish nonisomorphic systems and appeared to be a complete invariant for Bernoulli systems (Ornstein). Later, the thermodynamic formalism (see [107]) introduced new quantities like the pressure. Bowen [27] and also Ruelle discovered a remarkable connection between the thermodynamic formalism and the dimension theory for invariant sets. Since then many efforts were taken to find the relations between all these different quantities. It occurred that the dimension of invariant sets or measures carries lots of information about the system, combining its combinatorial complexity with its geometric complexity. Unfortunately it is extremely difficult to compute the dimension in general. The general flavor is that local divergence of orbits and global recurrence cause complicated global behavior (chaos). It is impossible to study the exact (infinite) trajectory of all orbits. One way out is to study the statistical properties of “typical” orbits by means of an invariant measure. Although the underlying system might be smooth the invariant measures may often be singular.

Preliminaries

Throughout the article the following situation is considered. Let M be a compact Riemannian manifold without boundary. On M is acting a dynamical system generated by a $C^{1+\alpha}$ diffeomorphism $T: M \rightarrow M$. The presence of a dynamical system provides several important additional tools and methods for the theory of fractal dimensions. Also the theory of fractal dimensions allows one to draw deep conclusions about the dynamical system. The importance and relevance of the study of fractal dimension will be explained in later sections.

In the next sections some of the most important tools in the fractal theory of dynamical systems are considered. The definitions given here are not necessarily the original definitions but rather the ones which are closer to contemporary use. More details can be found in [95].

Some Ergodic Theory

Ergodic theory is a powerful method to analyze statistical properties of dynamical systems. All the following facts can be found in standard books on ergodic theory like [103,124].

The main idea in ergodic theory is to relate global quantities to observations along single orbits. Let us consider an **invariant measure**: $\mu(f^{-1}A) = \mu(A)$ for all measurable sets A . Such a measure “selects” typical trajectories. It is important to note that the properties vary with the in-

variant measures. Any such invariant measure can be decomposed into elementary parts (ergodic components).

An invariant measure is called **ergodic** if for any invariant set $A = T^{-1}A$ one has $\mu(A)\mu(M \setminus A) = 0$ (with the agreement $0 \cdot \infty = 0$), i. e. from the measure-theoretic point of view there are no nontrivial invariant subsets.

The importance of ergodic **probability** measures (i. e. $\mu(M) = 1$) lies in the following theorem of Birkhoff

Theorem 1 (Birkhoff) *Let μ be an ergodic probability measure and $\varphi \in L^1(\mu)$. Then*

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^{n-1} \varphi(T^k x) = \int_M \varphi d\mu \quad \mu - a.e.$$

Hausdorff Dimension

With $Z \subset \mathbb{R}^N$ and $s \geq 0$ one defines

$$m_H(s, Z) = \lim_{\delta \rightarrow 0} \inf_{\{B_i\}} \left\{ \sum_i \text{diam}(B_i)^s : \sup_i \text{diam}(B_i) < \varepsilon \text{ and } \bigcup_i B_i \supset Z \right\}.$$

Note that this limit exists. $m_H(s, Z)$ is called the **s-dimensional outer Hausdorff measure of Z**. It is immediate that there exists a unique value s^* , called the **Hausdorff dimension of Z**, at which $m_H(s, Z)$ jumps from ∞ to 0.

In general it is very hard to find optimal coverings and hence it is often impossible to compute the Hausdorff dimension of a set. Therefore a simpler notion – the lower and upper **Box dimension** – was introduced. The difference to the Hausdorff dimension is that the covering balls are assumed to have the same radius ε . Since then the limit as $\varepsilon \rightarrow 0$ does not have to exist one arrives at the notion of the upper and lower dimension.

Dimension of a Measure

Definition 1 Let $Z \subset \mathbb{R}^N$ and let μ be a probability measure supported on Z . Define the **Hausdorff dimension of the measure μ** by

$$\dim_H(\mu) \equiv \inf_{K \subset Z: \mu(K)=1} \dim_H(K).$$

Pointwise Dimension

Most invariant sets or measures are not strongly self-similar, i. e. the local geometry at arbitrarily fine scales might look different from point to point. Therefore, the notion

of pointwise dimension with respect to a Borel probability measure is defined.

Let μ be a Borel probability measure. By $B(x, \varepsilon)$ the ball with center x and radius ε is denoted. The **pointwise dimension** of the measure μ at the point x is defined as

$$d_\mu(x) := \lim_{\varepsilon \rightarrow 0} \frac{\log \mu(B(x, \varepsilon))}{\log \varepsilon}$$

if the above limit exists. If $d_\mu(x) = d$, then for small ε the measure of small balls scales as $\mu(B(x, \varepsilon)) \asymp \varepsilon^d$.

Proposition 1 *Suppose μ is a probability measure supported on $Z \subset \mathbb{R}^N$. Then $d_\mu(x) = d$ for μ - almost all $x \in Z$ implies $\dim_H(\mu) = d$.*

One should not take the existence of a local dimension (even for good measures) for granted. Later on it will be seen that the spectrum of the pointwise dimension (dimension spectrum) is a main object of study in classical multifractal analysis.

The dimension of a measure or a set of measures is its geometric complexity. However, under the presence of a dynamical system one also wants to measure the dynamical (combinatorial) complexity of the system. This leads to the notion of entropy.

Dimension-Like Characteristics and Topological Entropy

Pesin’s theory of dimension-like characteristics provides a unified treatment of dimensions and important dynamical quantities like entropies and pressure. The topological entropy of a continuous map f with respect to a subset Z in a metric space (X, ρ) (in particular $X = M$ – a Riemannian manifold) can be defined as a dimension-like characteristic. For each $n \in \mathbb{N}$ and $\varepsilon > 0$, define the **Bowen ball** $B_n(x, \varepsilon) = \{y \in X : \rho(T^i(x), T^i(y)) \leq \varepsilon \text{ for } 0 \leq i \leq n\}$. Then let

$$m_h(Z, \alpha, \varepsilon, n) := \lim_{n \rightarrow \infty} \inf \left\{ \sum_i e^{\alpha n_i} : n_i > n, \bigcup_i B_{n_i}(x, \varepsilon) \supset Z \right\}.$$

This gives rise to an outer measure that jumps from ∞ to 0 at some value α^* . This threshold value α^* is called the **topological entropy of Z** (at scale ε). However, in many situations this value does not depend on ε . The topological entropy is denoted by $h_{\text{top}}(T|Z)$.

If Z is f - invariant and compact, this definition of topological entropy coincides with the usual definition of topological entropy [124].

The **entropy h_μ of a measure μ** is defined as $h_\mu = \inf \{h_{\text{top}}(T|Z) : \mu(Z) = 1\}$. For ergodic measures this definition coincides with the Kolmogorov–Sinai entropy (see [95]).

One has to note that in the definition of entropy metric (“round”) balls are substituted by Bowen balls and the metric diameter by the “depth” of the Bowen ball. Therefore, the relation between entropy and dimension is determined by the relation of “round” balls to “oval” dynamical Bowen balls. If one understands how metric balls can be efficiently used to cover dynamical balls one can use the dynamical and relatively easy relation to compute notion of entropy to determine the dimension. However, in higher dimensions this relation is by far nontrivial. A heuristic argument for comparing “round” balls with dynamical balls is given in Subsect. “The Kaplan–Yorke Conjecture”.

The Pressure Functional

A useful tool in the dimension analysis of dynamical systems is the pressure functional. It was originally defined by means of statistical physics (thermodynamic formalism) as the free energy (or pressure) of a potential φ (see for example [107]). However, in this article a dimension-like definition (see [95]) is more suitable. Again an outer measure using Bowen balls will be used. Let $\varphi : M \rightarrow \mathbb{R}$ be a continuous function and

$$m_p(Z, \alpha, \varepsilon, n, \varphi) = \lim_{n \rightarrow \infty} \inf \left\{ \sum_i \exp(-\alpha n_i) + \sup_{x \in B_{n_i}(x, \varepsilon)} \sum_{k=0}^{n_i} \varphi(T^k x) \right\}.$$

This defines an outer measure that jumps from ∞ to 0 as α increases. The threshold value α^* is called the **topological pressure** of the potential φ denoted by $P(\varphi)$. In many situations it does not depend on ε .

There is also a third way of defining the pressure in terms of a variational principle (see [124]):

$$P(\varphi) = \sup_{\mu \text{-invariant}} \left(h_\mu + \int_M \varphi d\mu \right)$$

Brief Tour Through Some Examples

Before describing the fractal theory of dynamical systems in more detail some ideas about its role are presented. The application of dimension theory has many different aspects. At this point some (but by far not all) important examples are considered that should give the reader some

feeling about the importance and wide use of dimension theory in dynamical system theory.

Dimension of Conformal Repellers: Ruelle's Pressure Formula

Computing or estimating a dimension via a *pressure formula* is a fundamental technique. Explicit properties of pressure help to analyze subtle characteristics. For example, the smooth dependence of the Hausdorff dimension of basic sets for Axiom-A surface diffeomorphisms on the derivative of the map follows from smoothness of pressure.

Ruelle proved the following pressure formula for the Hausdorff dimension of a conformal repeller. A conformal repeller J is an invariant set $T(J) = J = \{x \in M: f^n x \in V \forall n \in \mathbb{N} \text{ and some neighborhood } V \text{ of } J\}$ such that for any $x \in J$ the differential $D_x T = a(x) \text{Iso}_x$ where $a(x)$ is a scalar with $|a(x)| > 1$ and Iso_x an isometry of the tangent space $T_x M$.

Theorem 2 ([108]) *Let $T: J \rightarrow J$ be a conformal repeller, and consider the function $t \rightarrow P(-t \log |D_x T|)$, where P denotes pressure. Then*

$$P(-s \log |D_x T|) = 0 \iff s = \dim_H(J)$$

Iterated Function Systems

In fractal geometry one of the most-studied objects are iterated function systems, where there are given n contractions F_1, \dots, F_n of \mathbb{R}^d . The unique compact set J fulfilling $J = \bigcup_i F_i(J)$ is called the attractor of the iterated function system (see [42]). One question is to evaluate its Hausdorff dimension. Often (for example under the open set condition) the attractor J can be represented as the repeller of a piecewise expanding map $T: \mathbb{R}^d \rightarrow \mathbb{R}^d$ where the F_i are the inverse branches of the map T . In general it is by far not trivial to determine the dimension of J or even the dimension of a measure sitting on J . The following example explains some of those difficulties.

Let $1/2 < \lambda < 1$ and consider the maps $F_i: [0, 1] \rightarrow [0, 1]$ given by $F_1(x) = \lambda x$ and $F_2(x) = \lambda x + (1 - \lambda)$. Then the images of F_1, F_2 have an essential overlap and $J = [0, 1]$. If one randomizes this construction in the way that one applies both maps each with probability $1/2$ a probability measure is induced on J . This measure might be absolute continuous with respect to Lebesgue measure or not. Already Erdős realized that for some special values of λ (for example for the inverse of the golden mean) the induced measure is singular. In a breakthrough paper B. Solomyak ([119]) proved that for a.e. λ the in-

duced measure is absolutely continuous. A main ingredient in the proof is a transversality condition in the parameter space: the images of arbitrary two random samples of the (infinite) applications of the maps F_i have to cross with nonzero speed when the parameter λ changes. This is a general mechanism which allows one to handle more general situations.

Homoclinic Bifurcations for Dissipative Surface Diffeomorphisms

Homoclinic tangencies and their bifurcations play a fundamental role in the theory of dynamical systems [87,88,89]. Systems with homoclinic tangencies have a complicated and subtle quasi-local behavior. Newhouse showed that homoclinic tangencies can persist under small perturbations, and that horseshoes may co-exist with infinitely many sinks in a neighborhood of the homoclinic orbit and hence the system is not hyperbolic (**Newhouse phenomenon**).

Let $T_\mu: M^2 \rightarrow M^2$ be a smooth parameter family of surface diffeomorphisms that exhibits for $\mu = 0$ an invariant hyperbolic set Λ_0 (horseshoe) and undergoes a homoclinic bifurcation. The Hausdorff dimension of the hyperbolic set Λ_0 for T_0 determines whether hyperbolicity is the *typical* dynamical phenomenon near T_0 or not. If $\dim_H \Lambda_0 < 1$, then hyperbolicity is the prevalent dynamical phenomenon near f_0 . This is not the case if $\dim_H \Lambda_0 > 1$.

More precisely, let \mathcal{NW}_μ denote the set of nonwandering points of T_μ in an open neighborhood of Λ_0 after the homoclinic bifurcation. Let ℓ denote Lebesgue measure.

Theorem 3 ([87,88]) *If $\dim_H \Lambda_0 < 1$, then*

$$\lim_{\mu_0 \rightarrow 0} \frac{\ell\{\mu \in [0, \mu_0]: \mathcal{NW}_\mu \text{ is hyperbolic}\}}{\mu_0} = 1.$$

The hyperbolicity co-exists with the Newhouse phenomena for a residual set of parameter values.

Theorem 4 (Palis–Yoccoz) *If $\dim_H \Lambda_0 > 1$, then*

$$\lim_{\mu_0 \rightarrow 0} \frac{\ell\{\mu \in [0, \mu_0]: \mathcal{NW}_\mu \text{ is hyperbolic}\}}{\mu_0} < 1.$$

Some Applications to Number Theory

Sometimes dimension problems in number theory can be transferred to dynamical systems and attacked using tools from dynamics.

Example Diadic expansion of numbers:

Consider a real number expanded in base 2, i.e. $x = \sum_{n=1}^{\infty} x_n/2^n$. Let

$$X_p = \left\{ x: \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^{n-1} x_k = p \right\}.$$

Borel showed that $\ell(X_{1/2}) = 1$, where ℓ denotes Lebesgue measure. This result is an easy consequence of the Birkhoff ergodic theorem applied to the characteristic function of the digit 1 (which in this simple case is the Strong Law of Large Numbers for i.i.d. processes).

One can ask how large is the set X_p in general. Eggleston [39] discovered the following wonderful dimension formula, which Billingsley [21] interpreted in terms of dynamics and proved using tools from ergodic theory.

Theorem 5 ([39]) *The Hausdorff dimension of X_p is given by*

$$\dim_H(X_p) = (1/\log 2)[-p \log p - (1-p) \log(1-p)].$$

The underlying dynamical system is $E_2(x) = 2x \bmod 1$ and the dimension is the dimension of the Bernoulli p measure. Other cases included that by Rényi who proposed generalization of the base d expansion from integer base d to noninteger base β . In this case the underlying dynamical system is the (in general non-Markovian) beta shift $\beta(x) = \beta x \bmod 1$ studied in [110].

There are many investigations concerning the approximation of real numbers by rationals by using dynamical methods. The underlying dynamical system in this case is the Gauss map $T(x) = (1/x) \bmod 1$. This map is uniformly expanding, but has infinitely many branches.

Example Continued fraction approximation of numbers

Consider the continued fraction expansion of $x \in [0, 1]$, i.e.,

$$x = \frac{1}{a_1 + \frac{1}{a_2 + \frac{1}{a_3 + \frac{1}{a_4 + \ddots}}}} = [a_1, a_2, a_3, a_4, \dots],$$

and the approximants $p_n(x)/q_n(x) = [a_1, a_2, \dots, a_n]$ (i.e. the approximation given by the finite continued fraction after step n).

The set of numbers which admit a *faster approximation* by rational numbers is defined as follows. For $\tau \geq 2$, let \mathcal{F}_τ

$$\mathcal{F}_\tau = \left\{ x \in [0, 1]: \left| x - \frac{p}{q} \right| \leq \frac{1}{q^\tau} \text{ for infinitely many } p/q \right\}.$$

It is well known that this set has zero measure for each $\tau \geq 2$. Jarnik [58] computed the Hausdorff dimension of \mathcal{F}_τ and showed that $\dim_H(\mathcal{F}_\tau) = 2/\tau$. However, nowadays there are methods from dynamical systems which not only allow unified proofs but also can handle more subtle subsets of the reals defined by some properties of their continued fraction expansion (see for example [3,105]).

Infinite Iterated Function Systems and Parabolic Systems

In the previous section a system with infinitely many branches appeared. This can be regarded as an iterated function system with infinitely many maps F_i . This situation is quite general. If one considers a (one-dimensional) system with a parabolic (indifferent) fixed point, i.e. there is a fixed point where the derivative has absolute value equal to 1, one often uses an induced system. For this one chooses nearby the parabolic point a higher iterate of the map in order to achieve uniform expansion away from the parabolic point. This leads to infinitely many branches since the number of iterates has to be increased the closer the parabolic point is. The main difference to the finite iterated function system is that the setting is no longer compact and many properties of the pressure functional are lost.

Mauldin and Urbański and others (see for example [3,75,76,78]) developed a thermodynamic formalism adapted to the pressure functional for infinite iterated function systems. Besides noncompactness one of the main problems is the loss of analyticity (phase transitions) and convexity of the pressure functional for infinite iterated function systems.

Complex Dynamics

Let $T: \mathbb{C} \rightarrow \mathbb{C}$ be a polynomial and J its Julia set (repeller of this system). If this set is hyperbolic, i.e. the derivative at each point has absolute value larger than 1 the study of the dimension can be related to the study of a finite iterated function system. However, in the presence of a parabolic fixed point this leads to an infinite iterated function system.

If one considers the coefficients of the polynomial as parameters one often sees a qualitative change in the

asymptotic behavior. For example, the classical Mandelbrot set for polynomials $z^2 + c$ is the locus of values $c \in \mathbb{C}$ for which the orbit of the origin stays bounded. This set is well known to be fractal. However, its complete description is still not available.

Embedology and Computational Aspects of Dimension

Tools from dynamical systems are becoming increasingly important to study the time evolution of deterministic systems in engineering and the physical and biological sciences. One of the main ideas is to model a “real world” system by a smooth dynamical system which possesses a strange attractor with a natural ergodic invariant measure. When studying a complicated real world system, one can measure only a very small number of variables. The challenge is to reconstruct the underlying attractor from the time measurement of a scalar quantity. An idealized measurement is considered as a function $h: M^n \rightarrow \mathbb{R}$.

The main tool researchers currently use to *reconstruct* the model system is called attractor reconstruction (see papers and references in [86]). This method is based on embedding with time delays (see the influential paper [33], where the authors attribute the idea of delay coordinates to Ruelle), where one attempts to reconstruct the attractor for the model using a single long trajectory. Then one considers the points in \mathbb{R}^{p+1} defined by $(x_k, x_{k+\tau}, x_{k+2\tau}, \dots, x_{k+p\tau})$.

Takens [122] showed that for a smooth $T: M^n \rightarrow M^n$ and for typical smooth h , the mapping $\varphi: M^n \rightarrow \mathbb{R}^{2n+1}$ defined by $x \rightarrow (h(x), h(f^\tau(x)), \dots, h(f^{2n\tau}(x)))$ is an embedding. Since the box dimension of the attractor Λ may be much less than the dimension of the ambient manifold n , an interesting mathematical question is whether there exists $p < 2n + 1$ such that the mapping on the attractor $\varphi: \Lambda \rightarrow \mathbb{R}^p$ defined by $x \rightarrow (h(x), h(f(x)), \dots, h(f^p(x)))$ is 1 – 1? It is known that for a typical smooth h the mapping φ is 1 – 1 for $p > 2 \dim_B(\Lambda)$ [29].

Denjoy Systems

This section will give some ideas indicating the principle difficulties that arise in systems with low complexity. Contrary to hyperbolic systems (each vector in the tangent space is either contracted or expanded) finer mechanisms determine the local behavior of the scaling of balls. While in hyperbolic systems the dynamical scaling of small balls is exponential in a low-complexity system this scaling is subexponential and hence the linearization error is of the same magnitude. Up to now there is no general dimension theory for low complexity systems.

A specific example presented here is considered in [67]. Poincaré showed that to each orientation preserving homeomorphism of the circle $S^1 = \mathbb{R}/\mathbb{Z}$ is associated a unique real parameter $\alpha \in [0, 1)$, called the rotation number, so that the ordered orbit structure of T is the same as that of the rigid rotation R_α , where $R_\alpha(t) = (t + \alpha) \bmod 1$, provided that α is irrational. Half a century later, Denjoy [35] constructed examples of C^1 diffeomorphisms that are not conjugate (via a homeomorphism) to rotations. This was improved later on by Herman [55]. In these examples, the minimal set of T is necessarily a Cantor set Ω .

The arithmetic properties of the rotation number have a strong effect on the properties of T . One area that has been well understood is the relation between the differentiability of T , the differentiability of the conjugation and the arithmetic properties of the rotation number. (See, for example, Herman [55]) Without stating any precise theorem, the results differ sharply for Diophantine and for Liouville rotation numbers (definition follows). Roughly speaking the conjugating map is always regular for Diophantine rotation numbers while it might be not smooth at all for Liouville rotation numbers.

Definition 2 An irrational number α is of Diophantine class $\nu = \nu(\alpha) \in \mathbb{R}^+$ if

$$\|q\alpha\| < \frac{1}{q^\mu}$$

has infinitely many solutions in integers q for $\mu < \nu$ and at most finitely many for $\mu > \nu$ where $\|\cdot\|$ denotes the distance to the nearest integer.

In [67] the effect of the rotation number on the dimension of Ω is studied. There the main result is

Theorem 6 Assume that $0 < \delta < 1$ and that $\alpha \in (0, 1)$ is of Diophantine class $\nu \in (0, \infty)$. Then an orientation preserving $C^{1+\delta}$ diffeomorphism of the circle with rotation number α and minimal set Ω_α^δ satisfies

$$\dim_H \Omega_\alpha^\delta \geq \frac{\delta}{\nu}.$$

Furthermore, these results are sharp, i. e. the standard Denjoy examples attain the minimum.

Return Times and Dimension

Recently an interesting connection between the pointwise dimensions, multifractal analysis, and recurrence behavior of trajectories was discovered [1,11,23]. Roughly speaking,

given an ergodic probability measure μ the return time asymptotics (as the neighborhood of the point shrinks) of μ -a.e point is determined by the pointwise dimension of μ at this point. The deeper understanding of this relation would help to get a unified approach to dimensions, exponents, entropies, recurrence times and correlation decay.

Dimension Theory of Low-Dimensional Dynamical Systems – Young’s Dimension Formula

In this section a remarkable extension of Ruelle’s dimension formula by Young [128] for the dimension of a measure is discussed.

Theorem 7 *Let $T: M^2 \rightarrow M^2$ be a C^2 surface diffeomorphism and let μ be an ergodic measure. Then*

$$\dim_H(\mu) = h_\mu(f) \left(\frac{1}{\lambda^1} - \frac{1}{\lambda^2} \right),$$

where $\lambda^1 \leq \lambda^2$ are the two Lyapunov exponents for μ .

In [79], Manning and McCluskey prove the following dimension formula for a basic set (horseshoe) of an Axiom-A surface diffeomorphism which is a set-version of Young’s formula.

Theorem 8 *Let Λ be a basic set for a C^2 Axiom-A surface diffeomorphism $T: M^2 \rightarrow M^2$. Then $\dim_H(\Lambda) = s_1 + s_2$, where s_1 and s_2 satisfy*

$$\begin{aligned} P(-s \log \|DT_x|E_x^u\|) &= 0 \\ P(s \log \|DT_x|E_x^s\|) &= 0. \end{aligned}$$

where E^s and E^u are the stable and unstable directions, respectively.

Some Remarks on Dimension Theory for Low-Dimensional versus High-Dimensional Dynamical Systems

Unlike lower dimensions (one, two, or conformal repellers), for higher-dimensional dynamical systems there are no general dimension formulas (besides the Ledrappier–Young formula), and in general dimension theory is much more difficult. This is due to several problems:

- 1) The geometry of the Bowen balls differs in a substantial way from round balls.
- 2) Number theoretic properties of some scaling rates [104, 106] enter into dimension calculations in ways they do

not in low dimensions (see Subsect. “Iterated Function Systems”).

- 3) The dimension theory of sets is often reduced to the theory of invariant measures. However, there is no invariant measure of full dimension in general and measure-theoretic considerations do not apply [79].
- 4) The stable and unstable foliations for higher dimensional systems are typically not C^1 [51,109]. Hence, to split the system into an expanding and a contracting part is far more subtle.

Dimension Theory of Higher-Dimensional Dynamical Systems

Here an example of a hyperbolic attractor in dimension 3 is considered to highlight some of the difficulties. Let Δ denote the unit disc in \mathbb{R}^2 . Let $f: S^1 \times \Delta \rightarrow S^1 \times \Delta$ be of the form

$$T(t, x, y) = (\varphi(t), \psi^1(t, x), \psi^2(t, y)),$$

with

$$0 < \max_{S^1 \times \Delta} \frac{\partial}{\partial x} \psi^1(t, x) < \min_{S^1 \times \Delta} \frac{\partial}{\partial y} \psi^2(t, y) < \lambda < 1.$$

The limit set

$$\Lambda := \bigcap_{n \in \mathbb{N}} T^n(S^1 \times \Delta)$$

is called the attractor or the *solenoid*. It is an example of a structurally stable basic set and is one of the fundamental examples of a uniformly hyperbolic attractor.

The following result can be proved.

Theorem 9 ([24,52]) *For all t , the thermodynamic pressure*

$$P \left(\dim_H \Lambda_t^s \log \left| \frac{\partial}{\partial y} \psi^2(t, y) \right| \right) = 0.$$

In particular, the stable dimension is independent of the stable section.

In this particular case the invariant axes for strong and weak contraction split the system smoothly and the difficulty is to show that the strong contraction is dominated by the weaker. In particular one has to ensure that effects as described in Subsect. “Iterated Function Systems” do not appear. In the general situation this is not the case and one lacks a similar theorem in the general situation. In particular, the unstable foliation is not better than Hölder and does not provide a “nice” coordinate.

Hyperbolic Measures

Given $x \in M$ and a vector $v \in T_x M$ the **Lyapunov exponent** is defined as

$$\chi(x, v) = \lim_{n \rightarrow \infty} \frac{1}{n} \log \|D_x T^n v\|.$$

provided this limit exists. For fixed x , the numbers $\chi(x, \cdot)$ attain only finitely many values. By ergodicity they are μ -a.e. constant, and the corresponding values are denoted by

$$\chi_1 \leq \dots \leq \chi_p,$$

where $p = \dim M$. Denote by s (s stands for stable) the largest index such that $\chi_s < 0$.

Definition 3 The invariant ergodic measure μ is said to be **hyperbolic** if $\chi_i \neq 0$ for every $i = 1, \dots, p$.

The Kaplan–Yorke Conjecture

In this section a heuristic argument for the dimension of an invariant ergodic measure will be given. This argument uses a specific cover of a dynamical ball by “round” balls. These ideas are essentially developed by Kaplan and Yorke [61] for the estimation of the dimension of an invariant set. Their estimates always provide an upper bound for the dimension. Kaplan and Yorke conjectured that in typical situations these estimates also provide a lower bound for the dimension of an attractor. Ledrappier and Young [72,73] showed that in case this holds for an invariant measure, then this measure has to be very special: an SBR-measure (after Sinai, Ruelle, and Bowen) (an SRB-measure is a measure that describes the asymptotic behavior for a set of initial points of positive Lebesgue measure and has absolutely continuous conditional measures on unstable manifolds).

Consider a small ball B in the phase space. The image $T^n B$ is almost an ellipsoid with axes of length

$$e^{\chi_1 n}, \dots, e^{\chi_p n}.$$

For $1 \leq i \leq s$, cover $T^n B$ by balls of radius $e^{\chi_i n}$. Then approximately

$$\frac{\exp[\chi_{i+1} n]}{\exp[\chi_i n]} \cdots \frac{\exp[\chi_p n]}{\exp[\chi_i n]}.$$

balls are needed for covering. The dimension can be estimated from above by

$$\dim_B \Lambda \leq \frac{\sum_{j>i} \chi_j}{|\chi_i|} + (p - i) := \dim_L^i \Lambda. \quad (1)$$

This is the Kaplan–Yorke formula.

General Theory

In this section the dimension theory of higher-dimensional dynamical systems is investigated. Most developed is this theory for invariant measures. There is an important connection between Lyapunov exponents and the measure theoretic entropy and dimensions of measures that will be presented here.

Let μ be an ergodic invariant measure. The Oseledec and Pesin Theory guarantee that local stable manifolds exist at μ -a.e. point. As for the Kaplan–Yorke formula the idea is to consider the contributions to the entropy and to the dimension in the directions of χ_i .

Historically the first connections between exponents and entropy were discovered by Margulis and Ruelle. They proved that

$$h_\mu(f) \leq - \sum_{i=1}^s \chi_i$$

for a C^1 diffeomorphism T . Pesin [91] showed that this inequality is actually an equality if the measure μ is essentially the Riemannian volume on unstable manifolds. Ledrappier and Young [72] showed that this is indeed a necessary condition. They also provided an exact formula:

Theorem 10 (Ledrappier–Young [72,73]) With $d^0 = 0$ for a C^2 diffeomorphism holds

$$h_\mu(f) = - \sum_{i=1}^s \chi_i (d^i - d^{i-1})$$

where d^i are the dimensions of the (conditional) measure on the i th unstable leaves.

The proof of this theorem is difficult and uses the theory of *nonuniform hyperbolic systems* (Pesin theory).

In dimension 1 and 2 the above theorem resembles Ruelle’s and Young’s theorems.

The reader should note that the above theorem includes also the existence of the pointwise dimension along the stable and unstable direction. Here the question arises whether this implies the existence of the pointwise dimension itself.

The Existence of the Pointwise Dimension for Hyperbolic Measure – the Eckmann–Ruelle Conjecture

In [17], Barreira, Pesin, and Schmeling prove that every hyperbolic measure has an *almost* local product structure, i.e., the measure of a small ball can be approximated by the product of the stable conditional measure of the sta-

ble component and the unstable conditional measure of the unstable component, up to small exponential error. This was used to prove the existence of the pointwise dimension of every hyperbolic measure almost everywhere. Moreover, the pointwise dimension is the sum of the contributions from its stable and unstable part. This implies that most dimension-type characteristics of the measure (including the Hausdorff dimension, box dimension, and information dimension) coincide, and provides a rigorous mathematical justification of the concept of fractal dimension for hyperbolic measures. The existence of the pointwise dimension for hyperbolic measures had been conjectured long before by Eckmann and Ruelle.

The hypotheses of this theorem are sharp. Ledrappier and Misiurewicz [70] constructed an example of a non-hyperbolic measure for which the pointwise dimension is not constant a.e. In [101], Pesin and Weiss present an example of a Hölder homeomorphism with Hölder constant arbitrarily close to one, where the pointwise dimension for the unique measure of maximal entropy does not exist a.e. There is also a one-dimensional example by Cutler [34].

Endomorphisms

The previous section indicates that the dimensional properties of hyperbolic measures under invariant conditions for a diffeomorphism are understood. However, partial differential equations often generate only semi-flows and the corresponding dynamical system is noninvertible. Also, Poincaré sections sometimes introduce singularities. For such dynamical systems the theory of diffeomorphisms does not apply. However, the next theorem allows under some conditions application of this theory. It essentially rules out similar situations as considered in Subsect. “Iterated Function Systems”.

Definition 4 A system (possibly with singularities) is *almost surely invertible* if it is invertible on a set of full measure. This implies that a full measure set of points has unique forward and backward trajectories.

Theorem 11 (Schmeling–Troubetzkoy [114]) *A two-dimensional system with singularities is almost surely invertible (w.r.t. an SRB-measure) if and only if Young’s formula holds.*

Multifractal Analysis

A group of physicists [50] suggested the idea of a multifractal analysis.

The Dynamical Characteristic View of Multifractal Analysis

The aim of multifractal analysis is an attempt to understand the fine structure of the level sets of the fundamental asymptotic quantities in ergodic theory (e. g., Birkhoff averages, local entropy, Lyapunov exponents). For ergodic measures these quantities are a.e. constant, however may depend on the underlying ergodic measure. Important elements of multifractal analysis entail determining the range of values these characteristics attain, an analysis of the dimension of the level sets, and an understanding of the sets where the limits do not exist. A general concept of multifractal analysis was proposed by Barreira, Schmeling and Pesin [16]. An important field of applications of multifractal analysis is to describe sets of real numbers that have constraints on their digits or continued fraction expansion.

General Multifractal Formalism

In this section the abstract theory of multifractal analysis is described. Let X, Y be two measurable spaces and $g: X \setminus \mathcal{B} \rightarrow Y$ be any measurable function where \mathcal{B} is a measurable (possibly empty) subset of X (in the standard applications $Y = \mathbb{R}$ or $Y = \mathbb{C}$). The associated **multifractal decomposition** of X is defined as

$$X = \mathcal{B} \cup \bigcup_{\alpha \in Y} K_{\alpha}^g$$

where

$$K_{\alpha}^g := \{x \in X : g(x) = \alpha\}$$

For a given set function $G: 2^X \rightarrow \mathbb{R}$ the **multifractal spectrum** is defined by

$$\mathcal{F}(\alpha) := G(K_{\alpha}^g).$$

At this point some classical and concrete examples of this general framework are considered.

The Entropy Spectrum

Let μ be an ergodic invariant measure for $T: X \rightarrow X$. If one sets

$$g^E(x) := h_{\mu}(x) \in Y = \mathbb{R}$$

and

$$G^E(Z) = h_{\text{top}}(T|Z)$$

the associated multifractal spectrum $f_{\mu}^E(\alpha)$ is called the **entropy spectrum**.

The Dimension Spectrum

This is the **classical multifractal spectrum**.

Let μ be an invariant ergodic measure on a complete separable metric space X .

Set

$$g^D(x) := d_\mu(x) \in Y = \mathbb{R}$$

and

$$G^D(Z) = \dim_H Z.$$

The associated multifractal spectrum $f_\mu^D(\alpha)$ is called the **dimension spectrum**.

The Lyapunov Spectrum

Let

$$g^L(x) := \chi(x) = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^{n-1} \psi(\mathbb{T}^k x) \in Y = \mathbb{R}$$

where $\psi(x) = \log |D_x T|$ and

$$G^D(Z) = \dim_H Z \quad \text{or} \quad G^E(Z) = h_{\text{top}}(\sigma|Z).$$

The associated multifractal spectra $f_L^D(\alpha)$ and $f_L^E(\alpha)$ are called **Lyapunov spectra**.

It was observed by H. Weiss [126] and Barreira, Pesin and Schmeling [16] that for conformal repellers

$$f_L^D(\alpha) = f_{\mu_h}^D\left(\frac{\log 2}{\alpha}\right) \quad (2)$$

where the dimension spectrum on the right-hand side is with respect to the measure of maximal entropy, and

$$f_L^E(\alpha) = f_{\mu_D}^E(\dim_H \Lambda \cdot \alpha) \quad (3)$$

where the entropy spectrum on the right-hand side is with respect to the measure of maximal dimension.

The following list summarizes the state of the art for the dynamical characteristic multifractal analysis of dynamical systems. The precise statements can be found in the original papers.

- [102,126] For conformal repellers and Axiom-A surface diffeomorphisms, a complete multifractal analysis exists for the Lyapunov exponent.
- [16,102,126] For mixing a subshift of finite type, a complete multifractal analysis exists for the Birkhoff average for a Hölder continuous potential and for the local entropy for a Gibbs measure with Hölder continuous potential.

- [12,97] There is a complete multifractal analysis for hyperbolic flows.
- [123] There is a generalization of the multifractal analysis on subshifts with specification and continuous potentials.
- [13,19] There is an analysis of “mixed” spectra like the dimension spectrum of local entropies and also an analysis of joint level sets determined by more than one (measurable) function.
- [105] For the Gauss map (and a class of nonuniformly hyperbolic maps) a complete multifractal analysis exists for the Lyapunov exponent.
- [57] A general approach to multifractal analysis for repellers with countably many branches is developed. It shows in contrary to finitely many branches features of nonanalytic behavior.

In the first three statements the multifractal spectra are analytic concave functions that can be computed by means of the Legendre transform of the pressure functional with respect to a suitable chosen family of potentials. In the remaining items this is no longer the case. Analyticity and convexity properties of the pressure functional are lost. However, the authors succeeded to provide a satisfactory theory in these cases.

Multifractal Analysis and Large Deviation Theory

There are deep connections between large deviation theory and multifractal analysis. The variational formula for pressure is an important tool in the analysis, and can be viewed (and proven) as a large deviation result [41]. Some authors use large deviation theory as a tool to effect multifractal analysis.

Future Directions

The dimension theory is fast developing and of great importance in the theory of dynamical systems. In the most ideal situations (low dimensions and hyperbolicity) a generally far reaching and powerful theory has been developed. It uses ideas from statistical physics, fractal geometry, probability theory and other fields.

Unfortunately, the richness of this theory does not carry over to higher-dimensional systems. However, recent developments have shown that it is possible to obtain a general theory for the dimension of measures. Part of this theory is the development of the analytic tools of nonuniformly hyperbolic systems.

Therefore, the dimension theory of dynamical systems is far from complete. In particular, it is usually difficult to apply the general theory to concrete examples, for instance

if one really wants to *compute* the dimension. The general theory does not provide a way to compute the dimension but gives rather connections to other characteristics. Moreover, in the presence of neutral directions (zero Lyapunov exponents) one encounters all the difficulties arising in low-complexity systems.

Another important open problem is to understand the dimension theory of invariant sets in higher-dimensional spaces. One way would be to relate the dimension of sets to the dimension of measures. Such a connection is not clear. The reason is that most systems do not exhibit a measure whose dimension coincides with the dimension of its support (invariant set). But there are some reasons to conjecture that any compact invariant set of an expanding map in any dimension carries a measure of maximal dimension (see [48,63]). If this conjecture is true one obtains an invariant measure whose unstable dimension coincides with the unstable dimension of the invariant set. There is also a measure of maximal stable dimension. Combining these two measures one could establish an analogous theory for invariant sets as for invariant measures.

Last but not least one has to mention the impact of the dimension theory of dynamical systems on other fields. This new point of view makes in many cases the posed problems more tractable. This is illustrated in examples from number theory, geometric limit constructions and others. The applications of the dimension theory of dynamical systems to other questions seem to be unlimited.

Glossary

Diophantine approximation Diophantine approximation refers to approximation of real numbers by rational numbers, or more generally, finding integer points at which some (possibly vector-valued) functions attain values close to integers.

Metric number theory Metric number theory (or, specifically, metric Diophantine approximation) refers to the study of sets of real numbers or vectors with prescribed Diophantine approximation properties.

Homogeneous spaces A homogeneous space G/Γ of a group G by its subgroup Γ is the space of cosets $\{g\Gamma\}$. When G is a Lie group and Γ is a discrete subgroup, the space G/Γ is a smooth manifold and locally looks like G itself.

Lattice; unimodular lattice A lattice in a Lie group is a discrete subgroup of finite covolume; unimodular stands for covolume equal to 1.

Ergodic theory The study of statistical properties of orbits in abstract models of dynamical systems.

Hausdorff dimension A nonnegative number attached to a metric space and extending the notion of topological dimension of “sufficiently regular” sets, such as smooth submanifolds of real Euclidean spaces.

Definition of the Subject

The theory of Diophantine approximation, named after Diophantus of Alexandria, in its simplest set-up deals with the approximation of real numbers by rational numbers. Various higher-dimensional generalizations involve studying values of linear or polynomial maps at integer points. Often a certain “approximation property” is fixed, and one wants to characterize the set of numbers (vectors, matrices) which share this property, by means of certain measures (Lebesgue, or Hausdorff, or some other interesting measures). This is usually referred to as *metric* Diophantine approximation.

The starting point for the theory is an elementary fact that \mathbb{Q} , the set of rational numbers, is dense in \mathbb{R} , the reals. In other words, every real number can be approximated by rationals: for any $y \in \mathbb{R}$ and any $\varepsilon > 0$ there ex-

ists $p/q \in \mathbb{Q}$ with

$$|y - p/q| < \varepsilon. \quad (1)$$

To answer questions like “how well can various real numbers be approximated by rational numbers? i. e., how small can ε in (1) be chosen for varying $p/q \in \mathbb{Q}$?”, a natural approach has been to compare the accuracy of the approximation of y by p/q to the “complexity” of the latter, which can be measured by the size of its denominator q in its reduced form. This seemingly simple set-up has led to introducing many important Diophantine approximation properties of numbers/vectors/matrices, which show up in various fields of mathematics and physics, such as differential equations, KAM theory, transcendental number theory.

Introduction

As the first example of refining the statement about the density of \mathbb{Q} in \mathbb{R} , consider a theorem by Kronecker stating that for any $y \in \mathbb{R}$ and any $c > 0$, there exist infinitely many $q \in \mathbb{Z}$ such that

$$|y - p/q| < c/|q| \quad \text{i. e. } |qy - p| < c \quad (2)$$

for some $p \in \mathbb{Z}$. A comparison of (1) and (2) shows that it makes sense to multiply both sides of (1) by q , since in the right hand side of (2) one would still be able to get very small numbers. In other words, approximation of y by p/q translates into approximating integers by integer multiples of y .

Also, if y is irrational, (p, q) can be chosen to be relatively prime, i. e. one gets infinitely many different rational numbers p/q satisfying (2). However if $y \in \mathbb{Q}$ the latter is no longer true for small enough c . Thus it seems to be more convenient to talk about pairs (p, q) rather than $p/q \in \mathbb{Q}$, avoiding a necessity to consider the two cases separately.

At this point it is convenient to introduce the following central definition: if ψ is a function $\mathbb{N} \rightarrow \mathbb{R}_+$ and $y \in \mathbb{R}$, say that y is ψ -approximable (notation: $y \in \mathcal{W}(\psi)$) if there exist infinitely many $q \in \mathbb{N}$ such that

$$|qy - p| < \psi(q) \quad (3)$$

for some $p \in \mathbb{Z}$. Because of Kronecker’s Theorem, it is natural to assume that $\psi(x) \rightarrow 0$ as $x \rightarrow \infty$. Often ψ will be assumed non-increasing, although many results do not require monotonicity of ψ .

One can similarly consider a higher-dimensional version of the above set-up. Note that $y \in \mathbb{R}$ in the above formulas plays the role of a linear map from \mathbb{R} to another copy of \mathbb{R} , and one asks how close values of this map

at integers are from integers. It is natural to generalize it by taking a linear operator Y from \mathbb{R}^n to \mathbb{R}^m for fixed $m, n \in \mathbb{N}$, that is, an $m \times n$ -matrix (interpreted as a system of m linear forms Y_i on \mathbb{R}^n). We will denote by $M_{m,n}$ the space of $m \times n$ matrices with real coefficients. For ψ as above, one says that $Y \in M_{m,n}$ is ψ -approximable (notation: $Y \in \mathcal{W}_{m,n}(\psi)$) if there are infinitely many $\mathbf{q} \in \mathbb{Z}^n$ such that

$$\|Y\mathbf{q} + \mathbf{p}\| \leq \psi(\|\mathbf{q}\|) \quad (4)$$

for some $\mathbf{p} \in \mathbb{Z}^m$. Here $\|\cdot\|$ is the supremum norm on \mathbb{R}^k given by $\|y\| = \max_{1 \leq i \leq k} |y_i|$. (This definition is slightly different from the one used in [58], where powers of norms were considered).

Traditionally, one of the main goals of metric Diophantine approximation has been to understand how big the sets $\mathcal{W}_{m,n}(\psi)$ are for fixed m, n and various functions ψ . Of course, (4) is not the only interesting condition that can be studied; various modifications of the approximation properties can also be considered. For example the Oppenheim Conjecture, now a theorem of Margulis [69] and a basis for many important recent developments [22,34,35], states that indefinite irrational quadratic forms can take arbitrary small values at integer points; Littlewood’s conjecture, see (18) below, deals with a similar statement about products of linear forms. See the article [▶ Ergodic Theory: Rigidity](#) by Nitica and surveys [32,70] for details.

We remark that the standard tool for studying Diophantine approximation properties of real numbers ($m = n = 1$) is the continued fraction expansion, or, equivalently, the Gauss map $x \mapsto 1/x \pmod{1}$ of the unit interval, see [49]. However the emphasis of this survey lies in higher-dimensional theory, and the dynamical system described below can be thought of as a replacement for the continued fraction technique applicable in the one-dimensional case. Additional details about interactions between ergodic theory and number theory can be found in the article by Nitica mentioned above, in [▶ Ergodic Theory: Recurrence](#) by Frantzikinakis and McCutcheon and [▶ Ergodic Theory: Interactions with Combinatorics and Number Theory](#) by Ward, as well as in the survey papers [32,33,50,58,66,70,71].

Here is a brief outline of the rest of the article. In the next section we survey basic results, some classical, some obtained relatively recently, in metric Diophantine approximation. Sect. “[Connection with Dynamics on the Space of Lattices](#)” is devoted to a description of the connection between Diophantine approximation and dynamics, specifically flows on the space of

lattices. In Sect. “[Diophantine Approximation with Dependent Quantities: The Set-Up](#)” and Sect. “[Further Results](#)”, we specialize to the set-up of Diophantine approximation on manifolds, or, more generally, approximation properties of vectors with respect to measures satisfying some natural conditions, and show how applications of homogeneous dynamics contributed to important recent developments in the field. Sect. “[Future Directions](#)” mentions several open questions and directions for further investigation.

Basic Facts

General references for this section: [17,80].

The simplest choice for functions ψ happens to be the following: let us denote $\psi_{c,v}(x) = cx^{-v}$. It was shown by Dirichlet in 1842 that with the choice $c = 1$ and $v = n/m$, all $Y \in M_{m,n}$ are ψ -approximable. Moreover, Dirichlet’s Theorem states that for any $Y \in M_{m,n}$ and for any $t > 0$ there exist $\mathbf{q} = (q_1, \dots, q_n) \in \mathbb{Z}^n \setminus \{0\}$ and $\mathbf{p} = (p_1, \dots, p_m) \in \mathbb{Z}^m$ satisfying the following system of inequalities:

$$\|Y\mathbf{q} - \mathbf{p}\| < e^{-t/m} \quad \text{and} \quad \|\mathbf{q}\| \leq e^{t/n}. \tag{5}$$

From this it easily follows that $\mathcal{W}_{m,n}(\psi_{1,n/m}) = M_{m,n}$. In fact, it is this paper of Dirichlet which gave rise to his box principle. Later another proof of the same result was given by Minkowski. The constant $c = 1$ is not optimal: the smallest value of c for which $\mathcal{W}_{1,1}(\psi_{c,1}) = \mathbb{R}$ is $1/\sqrt{5}$, and the optimal constants are not known in higher dimensions, although some estimates can be given [80].

Systems of linear forms which do not belong to $\mathcal{W}_{m,n}(\psi_{c,n/m})$ for some positive c are called *badly approximable*; that is, we set

$$\text{BA}_{m,n} \stackrel{\text{def}}{=} M_{m,n} \setminus \bigcup_{c>0} \mathcal{W}_{m,n}(\psi_{c,n/m}).$$

Their existence in arbitrary dimensions was shown by Perron. Note that a real number y ($m = n = 1$) is badly approximable if and only if its continued fraction coefficients are uniformly bounded. It was proved by Jarnik [46] in the case $m = n = 1$ and by Schmidt in the general case [78] that badly approximable matrices form a set of full Hausdorff dimension: that is, $\dim(\text{BA}_{m,n}) = mn$.

On the other hand, it can be shown that each of the sets $\mathcal{W}_{m,n}(\psi_{c,n/m})$ for any $c > 0$ has full Lebesgue measure, and hence the complement $\text{BA}_{m,n}$ to their intersection has measure zero. This is a special case of a theorem due to Khintchine [48] in the case $n = 1$ and to Groshev [42] in full generality, which gives the precise condition on the function ψ under which the set of ψ -approximable matrices has full measure. Namely, if ψ is non-increasing (this

assumption can be removed in higher dimensions but not for $n = 1$, see [29]), then λ -almost no (resp. λ -almost every) $Y \in M_{m,n}$ is ψ -approximable, provided the sum

$$\sum_{k=1}^{\infty} k^{n-1} \psi(k)^m \tag{6}$$

converges (resp. diverges). (Here and hereafter λ stands for Lebesgue measure). This statement is usually referred to as the Khintchine–Groshev Theorem. The convergence case of this theorem follows in a straightforward manner from the Borel–Cantelli Lemma, but the divergence case is harder. It was reproved and sharpened in 1960 by Schmidt [76], who showed that if the sum (6) diverges, then for almost all Y the number of solutions to (4) with $\|\mathbf{q}\| \leq N$ is asymptotic to the partial sum of the series (6) (up to a constant), and also gave an estimate for the error term.

A special case of the convergence part of the theorem shows that $\mathcal{W}_{m,n}(\psi_{1,v})$ has measure zero whenever $v > n/m$. Y is said to be *very well approximable* if it belongs to $\mathcal{W}_{m,n}(\psi_{1,v})$ for some $v > n/m$. That is,

$$\text{VWA}_{m,n} \stackrel{\text{def}}{=} \bigcup_{v>n/m} \mathcal{W}_{m,n}(\psi_{1,v}).$$

More specifically, let us define the *Diophantine exponent* $\omega(Y)$ of Y (sometimes called “the exact order” of Y) to be the supremum of $v > 0$ for which $Y \in \mathcal{W}_{m,n}(\psi_{1,v})$. Then $\omega(Y)$ is always not less than n/m , and is equal to n/m for Lebesgue-a.e. Y ; in fact, $\text{VWA}_{m,n} = \{Y \in M_{m,n} : \omega(Y) > n/m\}$.

The Hausdorff dimension of the null sets $\mathcal{W}_{m,n}(\psi_{1,v})$ was computed independently by Besicovitch [14] and Jarnik [45] in the one-dimensional case and by Dodson [26] in general: when $v > n/m$, one has

$$\dim(\mathcal{W}_{m,n}(\psi_{1,v})) = (n - 1)m + \frac{m + n}{v + 1}. \tag{7}$$

See [27] for a nice exposition of ideas involved in the proof of both the aforementioned formula and the Khintchine–Groshev Theorem.

Note that it follows from (7) that the null set $\text{VWA}_{m,n}$ has full Hausdorff dimension. Matrices contained in the intersection

$$\bigcap_v \mathcal{W}_{m,n}(\psi_{1,v}) = \{Y \in M_{m,n} : \omega(Y) = \infty\}$$

are called *Liouville* and form a set of Hausdorff dimension $(n - 1)m$, that is, to the dimension of Y for which $Y\mathbf{q} \in \mathbb{Z}$ for some $\mathbf{q} \in \mathbb{Z}^n \setminus \{0\}$ (the latter belong to $\mathcal{W}_{m,n}(\psi)$ for any positive ψ).

Note also that the aforementioned properties behave nicely with respect to transposition; this is described by the so-called Khintchine’s Transference Principle (Chap. V in [17]). For example, $Y \in \text{BA}_{m,n}$ if and only if $Y^T \in \text{BA}_{n,m}$, and $Y \in \text{VWA}_{m,n}$ if and only if $Y^T \in \text{VWA}_{n,m}$. In particular, many problems related to approximation properties of vectors ($n = 1$) and linear forms ($m = 1$) reduce to one another.

We refer the readers to [43] and [8] for very detailed and comprehensive recent accounts of various further aspects of the theory.

Connection with Dynamics on the Space of Lattices

General references for this section: [4,86].

Interactions between Diophantine approximation and the theory of dynamical systems has a long history. Already in Kronecker’s Theorem one can see a connection. Indeed, the statement of the theorem can be rephrased as follows: the points on the orbit of 0 under the rotation of the circle \mathbb{R}/\mathbb{Z} by y approach the initial point 0 arbitrarily closely. This is a special case of the Poincare Recurrence Theorem in measurable dynamics. And, likewise, all the aforementioned properties of $Y \in M_{m,n}$ can be restated in terms of recurrence properties of the \mathbb{Z}^n -action on the m -dimensional torus $\mathbb{R}^m/\mathbb{Z}^m$ given by $x \mapsto Yx \pmod{\mathbb{Z}^m}$. In other words, fixing Y gives rise to a dynamical system in which approximation properties of Y show up.

However the theme of this section is a different dynamical system, whose phase space is (essentially) the space of parameters Y , and which can be used to read the properties of Y from the behavior of the associated trajectory.

It has been known for a long time (see [81] for a historical account) that Diophantine properties of real numbers can be coded by the behavior of geodesics on the quotient of the hyperbolic plane by $\text{SL}_2(\mathbb{Z})$. In fact, the latter flow can be viewed as the suspension flow of the Gauss map mentioned at the end of Sect. “Introduction”. There have been many attempts to construct a higher-dimensional analogue of the Gauss map so that it captures all the features of simultaneous approximation, see [47,63,65] and references therein. On the other hand, it seems to be more natural and efficient to generalize the suspension flow itself, and this is where one needs higher rank homogeneous dynamics.

As was mentioned above, in the basic set-up of simultaneous Diophantine approximation one takes a system of m linear forms Y_1, \dots, Y_m on \mathbb{R}^n and looks at the values of $|Y_i(\mathbf{q}) + p_i|, p_i \in \mathbb{Z}$, when $\mathbf{q} = (q_1, \dots, q_n) \in \mathbb{Z}^n$

is far from 0. The trick is to put together

$$Y_1(\mathbf{q}) + p_1, \dots, Y_m(\mathbf{q}) + p_m \quad \text{and} \quad q_1, \dots, q_n,$$

and consider the collection of vectors

$$\left\{ \begin{pmatrix} Y\mathbf{q} + \mathbf{p} \\ \mathbf{q} \end{pmatrix} \mid \mathbf{p} \in \mathbb{Z}^m, \mathbf{q} \in \mathbb{Z}^n \right\} = L_Y \mathbb{Z}^k$$

where $k = m + n$ and

$$L_Y \stackrel{\text{def}}{=} \begin{pmatrix} I_m & Y \\ 0 & I_n \end{pmatrix}, \quad Y \in M_{m,n}. \tag{8}$$

This collection is a unimodular lattice in \mathbb{R}^k , that is, a discrete subgroup of \mathbb{R}^k with covolume 1. Our goal is to keep track of vectors in such a lattice having small projections onto the first m components of \mathbb{R}^k and big projections onto the last n components. This is where dynamics comes into the picture. Denote by g_t the one-parameter subgroup of $\text{SL}_k(\mathbb{R})$ given by

$$g_t = \text{diag}(\underbrace{e^{t/m}, \dots, e^{t/m}}_{m \text{ times}}, \underbrace{e^{-t/n}, \dots, e^{-t/n}}_{n \text{ times}}). \tag{9}$$

The vectors in the lattice $L_Y \mathbb{Z}^k$ are moved by the action of $g_t, t > 0$, and a special role is played by the moment t when the “small” and “big” projections equalize.

That is, one is led to consider a new dynamical system. Its phase space is the space of unimodular lattices in \mathbb{R}^k , which can be naturally identified with the homogeneous space

$$\Omega_k \stackrel{\text{def}}{=} G/\Gamma, \quad \text{where } G = \text{SL}_k(\mathbb{R}) \text{ and } \Gamma = \text{SL}_k(\mathbb{Z}), \tag{10}$$

and the action is given by left multiplication by elements of the subgroup (9) of G , or perhaps other subgroups $H \subset G$. Study of such systems has a rich history; for example, they are known to be ergodic and mixing whenever H is unbounded [74]. What is important in this particular case is that the space Ω_k happens to be noncompact, and its structure at infinity is described via Mahler’s Compactness Criterion, see Chap. V in [4]: a sequence of lattices $g_i \mathbb{Z}^k$ goes to infinity in $\Omega_k \iff$ there exists a sequence $\{\mathbf{v}_i \in \mathbb{Z}^k \setminus \{0\}\}$ such that $g_i(\mathbf{v}_i) \rightarrow 0$ as $i \rightarrow \infty$. Equivalently, for $\varepsilon > 0$ consider a subset K_ε of Ω_k consisting of lattices with no nonzero vectors of norm less than ε ; then all the sets K_ε are compact, and every compact subset of Ω_k is contained in one of them. Moreover, one can choose a metric on Ω_k such that $\text{dist}(A, \mathbb{Z}^k)$ is, up to a uniform multiplicative constant,

equal to $-\log \min_{v \in \Lambda \setminus \{0\}} \|v\|$ (see [25]); then the length of the smallest nonzero vector in a lattice Λ will determine how far away is this lattice in the “cusp” of Ω_k .

Using Mahler’s Criterion, it is not hard to show that $Y \in \text{BA}_{m,n}$ if and only if the trajectory

$$\{g_t L_Y \mathbb{Z}^k : t \in \mathbb{R}_+\} \tag{11}$$

is bounded in Ω_k . This was proved by Dani [20] in 1985, and later generalized in [57] to produce a criterion for Y to be ψ -approximable for any non-increasing function ψ . An important special case is a criterion for a system of linear forms to be very well approximable: $Y \in \text{VWA}_{m,n}$ if and only if the trajectory (11) has linear growth, that is, there exists a positive γ such that $\text{dist}(g_t L_Y \mathbb{Z}^k, \mathbb{Z}^k) > \gamma t$ for an unbounded set of $t > 0$.

This correspondence allows one to link various Diophantine and dynamical phenomena. For example, from the results of [55] on abundance of bounded orbits on homogeneous spaces one can deduce the aforementioned theorem of Schmidt [78]: the set $\text{BA}_{m,n}$ has full Hausdorff dimension. And a dynamical Borel–Cantelli Lemma established in [57] can be used for an alternative proof of the Khintchine–Groshev Theorem; see also [87] for an earlier geometric approach. Note that both proofs are based on the following two properties of the g_t -action: mixing, which forces points to return to compact subsets and makes preimages of cusp neighborhoods quasi-independent, and hyperbolicity, which implies that the behavior of points on unstable leaves is generic. The latter is important since the orbits of the group $\{L_Y \mathbb{Z}^k : Y \in M_{m,n}\}$ are precisely the unstable leaves with respect to the g_t -action.

We note that other types of Diophantine problems, such as conjectures of Oppenheim and Littlewood mentioned in the previous section, can be reduced to statements involving Ω_k by means of the same principle: Mahler’s Criterion is used to relate small values of some function at integer points to excursions to infinity in Ω_k of orbit of the stabilizer of this function.

Other important and useful recent applications of homogeneous dynamics to metric Diophantine approximation are related to the circle of ideas roughly called “Diophantine approximation with dependent quantities” (terminology borrowed from [84]), to be surveyed in the next two sections.

Diophantine Approximation with Dependent Quantities: The Set-Up

General references for this section: [12,84].

Here we restrict ourselves to Diophantine properties of vectors in \mathbb{R}^n . In particular, we will look more closely

at the set of very well approximable vectors, which we will simply denote by VWA, dropping the subscripts. In many cases it does not matter whether one works with row or column vectors, in view of the duality remark made at the end of Sect. “Basic Facts”.

We begin with a non-example of an application of dynamics to Diophantine approximation: a celebrated and difficult theorem which currently, to the best of the author’s knowledge, has no dynamical proof. Suppose that $\mathbf{y} = (y_1, \dots, y_n) \in \mathbb{R}^n$ is such that each y_i is algebraic and $1, y_1, \dots, y_n$ are linearly independent over \mathbb{Q} . It was established by Roth for $n = 1$ [75] and then generalized to arbitrary n by Schmidt [79], that \mathbf{y} as above necessarily belongs to the complement of VWA. In other words, vectors with very special algebraic properties happen to follow the behavior of a generic vector in \mathbb{R}^n .

We would like to view the above example as a special case of a general class of problems. Namely, suppose we are given a Radon measure μ on \mathbb{R}^n . Let us say that μ is *extremal* [85] if μ -a.e. $\mathbf{y} \in \mathbb{R}^n$ is not very well approximable. Further, define the *Diophantine exponent* $\omega(\mu)$ of μ to be the μ -essential supremum of the function $\omega(\cdot)$; in other words,

$$\omega(\mu) \stackrel{\text{def}}{=} \sup \{v | \mu(\mathcal{W}(\psi_{1,v})) > 0\}.$$

Clearly it only depends on the measure class of μ . If μ is naturally associated with a subset \mathcal{M} of \mathbb{R}^n supporting μ (for example, if \mathcal{M} is a smooth submanifold of \mathbb{R}^n and μ is the measure class of the Riemannian volume on \mathcal{M} , or, equivalently, the pushforward $\mathbf{f}_* \lambda$ of λ by a smooth map \mathbf{f} parametrizing \mathcal{M}), one defines the Diophantine exponent $\omega(\mathcal{M})$ of \mathcal{M} to be equal to that of μ , and says that \mathcal{M} is extremal if $\mathbf{f}(\mathbf{x})$ is not very well approximable for λ -a.e. \mathbf{x} .

Then $\omega(\mu) \geq n$ for any μ , and $\omega(\lambda) = \omega(\mathbb{R}^n)$ is equal to n . The latter justifies the use of the word “extremal”: μ is *extremal* if $\omega(\mu)$ is equal to n , i.e. attains the smallest possible value. The aforementioned results of Roth and Schmidt then can be interpreted as the extremality of atomic measures supported on algebraic vectors without rational dependence relations.

Historically, the first measure (other than λ) to be considered in the set-up described above was the pushforward of λ by the map

$$\mathbf{f}(x) = (x, x^2, \dots, x^n). \tag{12}$$

The extremality of $\mathbf{f}_* \lambda$ for \mathbf{f} as above was conjectured in 1932 by K. Mahler [67] and proved in 1964 by Sprindžuk [82,83]. It was important for Mahler’s study of transcendental numbers: this result, roughly speaking, says

that almost all transcendental numbers are “not very algebraic”. At about the same time Schmidt [77] proved the extremality of $\mathbf{f}_*\lambda$ when $\mathbf{f}: I \rightarrow \mathbb{R}^2, I \subset \mathbb{R}$, is C^3 and satisfies

$$\begin{vmatrix} f'_1(x) & f'_2(x) \\ f''_1(x) & f''_2(x) \end{vmatrix} \neq 0 \text{ for } \lambda\text{-a.e. } x \in I;$$

in other words, the curve parametrized by \mathbf{f} has nonzero curvature at almost all points. Since then, a lot of attention has been devoted to showing that measures $\mathbf{f}_*\lambda$ are extremal for other smooth maps \mathbf{f} .

To describe a broader class of examples, recall the following definition. Let $\mathbf{x} \in \mathbb{R}^d$ and let $\mathbf{f} = (f_1, \dots, f_n)$ be a C^k map from a neighborhood of \mathbf{x} to \mathbb{R}^n . Say that \mathbf{f} is *nondegenerate at \mathbf{x}* if \mathbb{R}^n is spanned by partial derivatives of \mathbf{f} at \mathbf{x} up to some order. Say that \mathbf{f} is *nondegenerate* if it is nondegenerate at λ -a.e. \mathbf{x} . It was conjectured by Sprindžuk [84] in 1980 that $\mathbf{f}_*\lambda$ for real analytic nondegenerate \mathbf{f} are extremal. Many special cases were established since then (see [12] for a detailed exposition of the theory and many related results), but the general case stood open until the mid-1990s [56], when Sprindžuk’s conjecture was proved using the dynamical approach (later Beresnevich [6] succeeded in establishing and extending this result without use of dynamics). The proof in [56] uses the correspondence outlined in the previous section plus a measure estimate for flows on the space of lattices which is described below.

In the subsequent work the method of [56] was adapted to a much broader class of measures. To define it we need to introduce some more notation and definitions. If $\mathbf{x} \in \mathbb{R}^d$ and $r > 0$, denote by $B(\mathbf{x}, r)$ the open ball of radius r centered at \mathbf{x} . If $B = B(\mathbf{x}, r)$ and $c > 0$, cB will denote the ball $B(\mathbf{x}, cr)$. For $B \subset \mathbb{R}^d$ and a real-valued function f on B , let

$$\|f\|_B \stackrel{\text{def}}{=} \sup_{\mathbf{x} \in B} |f(\mathbf{x})|.$$

If ν is a measure on \mathbb{R}^d such that $\nu(B) > 0$, define $\|f\|_{\nu, B} \stackrel{\text{def}}{=} \|f\|_{B \cap \text{supp } \nu}$; this is the same as the $L^\infty(\nu)$ -norm of $f|_B$ if f is continuous and B is open. If $D > 0$ and $U \subset \mathbb{R}^d$ is an open subset, let us say that ν is *D-Federer on U* if for any ball $B \subset U$ centered at $\text{supp } \nu$ one has $\frac{\nu(3B)}{\nu(B)} < D$ whenever $3B \subset U$. This condition is often called “doubling” in the literature. See [54,72] for examples and references. ν is called *Federer* if for ν -a.e. $\mathbf{x} \in \mathbb{R}^d$ there exist a neighborhood U of \mathbf{x} and $D > 0$ such that ν is *D-Federer on U* .

Given $C, \alpha > 0$, open $U \subset \mathbb{R}^d$ and a measure ν on U , a function $f: U \rightarrow \mathbb{R}$ is called *(C, α)-good on U with respect to ν* if for any ball $B \subset U$ centered in $\text{supp } \nu$ and any

$\varepsilon > 0$ one has

$$\nu(\{\mathbf{x} \in B : |f(\mathbf{x})| < \varepsilon\}) \leq C \left(\frac{\varepsilon}{\|f\|_{\nu, B}} \right)^\alpha \nu(B). \quad (13)$$

This condition was formally introduced in [56] for ν being Lebesgue measure, and in [54] for arbitrary ν . A basic example is given by polynomials, and the upshot of the above definition is the formalization of a property needed for the proof of several basic facts [19,21,68] about polynomial maps into the space of lattices.

In [54] a strengthening of this property was considered: f was called *absolutely (C, α)-good on U with respect to ν* if for B and ε as above one has

$$\nu(\{\mathbf{x} \in B : |f(\mathbf{x})| < \varepsilon\}) \leq C \left(\frac{\varepsilon}{\|f\|_B} \right)^\alpha \nu(B). \quad (14)$$

There is no difference between (13) and (14) when ν has full support, but it turns out to be useful for describing measures supported on proper (e.g. fractal) subsets of \mathbb{R}^d .

Now suppose that we are given a measure ν on \mathbb{R}^d , an open $U \subset \mathbb{R}^d$ with $\nu(U) > 0$ and a map $\mathbf{f} = (f_1, \dots, f_n): \mathbb{R}^d \rightarrow \mathbb{R}^n$. Following [62], say that a pair (\mathbf{f}, ν) is *(absolutely) good on U* if any linear combination of $1, f_1, \dots, f_n$ is (absolutely) (C, α) -good on U with respect to ν . If for ν -a.e. \mathbf{X} there exists a neighborhood U of \mathbf{X} and $C, \alpha > 0$ such that ν is (absolutely) (C, α) -good on U , we will say that the pair (\mathbf{f}, ν) is *(absolutely) good*.

Another relevant notion is the nonplanarity of (\mathbf{f}, ν) . Namely, (\mathbf{f}, ν) is said to be *nonplanar* if whenever B is a ball with $\nu(B) > 0$, the restrictions of $1, f_1, \dots, f_n$ to $B \cap \text{supp } \nu$ are linearly independent over \mathbb{R} ; in other words, $\mathbf{f}(B \cap \text{supp } \nu)$ is not contained in any proper affine subspace of \mathbb{R}^n . Note that absolutely good implies both good and nonplanar, but the converse is in general not true.

Many examples of (absolutely) good and nonplanar pairs (\mathbf{f}, ν) can be found in the literature. Already the case $n = d$ and $\mathbf{f} = \text{Id}$ is very interesting. A measure μ on \mathbb{R}^n is said to be *friendly* (resp., *absolutely friendly*) if and only if it is Federer and the pair (Id, μ) is good and nonplanar (resp., absolutely good). See [54,88,89] for many examples. An important class of measures is given by limit measures of irreducible system of self-similar or self-conformal contractions satisfying the Open Set Condition [44]; those are shown to be absolutely friendly in [54]. The prime example is the middle-third Cantor set on the real line. The term “friendly” was cooked up as a loose abbreviation for “Federer, nonplanar and decaying”, and later proved to be particularly friendly in dealing with problems arising in metric number theory, see e.g. [36].

Also let us say that a pair (\mathbf{f}, ν) is *nondegenerate* if \mathbf{f} is nondegenerate at ν -a.e. \mathbf{X} . When ν is Lebesgue measure on \mathbb{R}^d , it is proved in Proposition 3.4 in [56], that a nondegenerate (\mathbf{f}, ν) is good and nonplanar. The same conclusion is derived in Proposition 7.3 in [54], assuming that ν is absolutely friendly. Thus volume measures on smooth nondegenerate manifolds are friendly, but not absolutely friendly.

It turns out that all the aforementioned examples of measures can be proved to be extremal by a generalization of the argument from [56]. Specifically, let ν be a Federer measure on \mathbb{R}^d , U an open subset of \mathbb{R}^d , and $\mathbf{f}: U \rightarrow \mathbb{R}^n$ a continuous map such that the pair (\mathbf{f}, ν) is good and nonplanar; then $\mathbf{f}_* \nu$ is extremal. This can be derived from the Borel–Cantelli Lemma, the correspondence described in the previous section, and the following measure estimate: if ν, U and \mathbf{f} are as above, then for ν -a.e. $\mathbf{x}_0 \in U$ there exists a ball $B \subset U$ centered at \mathbf{x}_0 and $\tilde{C}, \alpha > 0$ such that for any $t \in \mathbb{R}_+$ and any $\varepsilon > 0$,

$$\nu(\{\mathbf{x} \in B : g_t L_{\mathbf{f}(\mathbf{x})} \mathbb{Z}^{n+1} \notin K_\varepsilon\}) < \tilde{C} \varepsilon^\alpha. \tag{15}$$

Here g_t is as in (9) with $m = 1$ (assuming that the row vector viewpoint is adopted). This is a quantitative way of saying that for fixed t , the “flow” $\mathbf{x} \mapsto g_t L_{\mathbf{f}(\mathbf{x})} \mathbb{Z}^{n+1}$, $B \rightarrow \Omega_{n+1}$, cannot diverge, and in fact must spend a big (uniformly in t) proportion of time inside compact sets K_ε .

The inequality (15) is derived from a general “quantitative non-divergence” estimate, which can be thought of a substantial generalization of theorems of Margulis and Dani [19,21,68] on non-divergence of unipotent flows on homogeneous spaces. One of its most general versions [54] deals with a measure ν on \mathbb{R}^d , a continuous map $h: \tilde{B} \rightarrow G$, where \tilde{B} is a ball in \mathbb{R}^d centered at $\text{supp } \nu$ and G is as in (10). To describe the assumptions on h , one needs to employ the combinatorial structure of lattices in \mathbb{R}^k , and it will be convenient to use the following notation: if V is a nonzero rational subspace of \mathbb{R}^k and $g \in G$, define $\ell_V(g)$ to be the covolume of $g(V \cap \mathbb{Z}^k)$ in gV . Then, given positive constants C, D, α , there exists $C_1 = C_1(d, k, C, \alpha, D) > 0$ with the following property. Suppose ν is D -Federer on \tilde{B} , $0 < \rho \leq 1$, and h is such that for each rational $V \subset \mathbb{R}^k$

- (i) $\ell_V \circ h$ is (C, α) -good on \tilde{B} with respect to ν , and
- (ii) $\|\ell_V \circ h\|_{\nu, B} \geq \rho$, where $B = 3^{-(k-1)} \tilde{B}$. Then
- (iii) for any positive $\varepsilon \leq \rho$, one has

$$\nu(\{\mathbf{x} \in B : h(\mathbf{x}) \mathbb{Z}^k \notin K_\varepsilon\}) \leq C_1 (\varepsilon \rho)^\alpha \nu(B). \tag{16}$$

Taking $h(\mathbf{x}) = g_t L_{\mathbf{f}(\mathbf{x})}$ and unwinding the definitions of good and nonplanar pairs, one can show that (i) and (ii)

can be verified for some balls B centered at ν -almost every point, and derive (15) from (16).

Further Results

The approach to metric Diophantine approximation using quantitative non-divergence, that is, the implication (i) + (ii) \Rightarrow (iii), is not omnipotent. In particular, it is difficult to use when more precise results are needed, such as for example computing/estimating the Hausdorff dimension of the set of $\psi_{1,\nu}$ -approximable vectors on a manifold. See [9,10] for such results. On the other hand, the dynamical approach can often treat much more general objects than its classical counterpart, and also can be perturbed in a lot of directions, producing many generalizations and modifications of the main theorems from the preceding section.

One of the most important of them is the so-called *multiplicative* version of the set-up of Sect. “Diophantine Approximation with Dependent Quantities: The Set-Up”. Namely, define functions $\Pi(\mathbf{x}) \stackrel{\text{def}}{=} \prod_i |x_i|$ and $\Pi_+(\mathbf{x}) \stackrel{\text{def}}{=} \prod_i \max(|x_i|, 1)$. Then, given a function $\psi: \mathbb{N} \rightarrow \mathbb{R}_+$, one says that $Y \in M_{m,n}$ is *multiplicatively ψ -approximable* (notation: $Y \in \mathcal{W}_{m,n}^\times(\psi)$) if there are infinitely many $\mathbf{q} \in \mathbb{Z}^n$ such that

$$\Pi(Y\mathbf{q} + \mathbf{p})^{1/m} \leq \psi(\Pi_+(\mathbf{q})^{1/n}) \tag{17}$$

for some $\mathbf{p} \in \mathbb{Z}^m$. Since $\Pi(\mathbf{x}) \leq \Pi_+(\mathbf{x}) \leq \|\mathbf{x}\|^k$ for $\mathbf{x} \in \mathbb{R}^k$, any ψ -approximable Y is multiplicatively ψ -approximable; but the converse is in general not true, see e.g. [37]. However if one, as before, considers the family $\{\psi_{1,\nu}\}$, the critical parameter for which the drop from full measure to measure zero occurs is again n/m . That is, if one defines the *multiplicative Diophantine exponent* $\omega^\times(Y)$ of Y by $\omega^\times(Y) \stackrel{\text{def}}{=} \sup\{v: Y \in \mathcal{W}_{m,n}^\times(\psi_{1,\nu})\}$, then clearly $\omega^\times(Y) \geq \omega(Y)$ for all Y , and yet $\omega^\times(Y) = n/m$ for λ -a.e. $Y \in M_{m,n}$.

Now specialize to \mathbb{R}^n (by the same duality principle as before, it does not matter whether to think in terms of row or column vectors, but we will adopt the row vector set-up), and define the *multiplicative exponent* $\omega^\times(\mu)$ of a measure μ on \mathbb{R}^n by $\omega^\times(\mu) \stackrel{\text{def}}{=} \sup\{v | \mu(\mathcal{W}^\times(\psi_{1,\nu})) > 0\}$; then $\omega^\times(\lambda) = n$. Following Sprindžuk [85], say that μ is *strongly extremal* if $\omega^\times(\mu) = n$. It turns out that all the results mentioned in the previous section have their multiplicative analogues; that is, the measures described there happen to be strongly extremal. This was conjectured by A. Baker [1] for the curve (12), and then by Sprindžuk in 1980 [85] for analytic nondegenerate manifolds. (We remark that only very few results in this set-up can be obtained by the standard methods, see e.g. [10]). The proof

of this stronger statement is based on using the multi-parameter action of

$$g_{\mathbf{t}} = \text{diag}(e^{t_1+\dots+t_n}, e^{-t_1}, \dots, e^{-t_n}),$$

where $\mathbf{t} = (t_1, \dots, t_n)$

instead of g_t considered in the previous section. One can show that the choice $h(\mathbf{x}) = g_{\mathbf{t}}L_{\mathbf{f}(\mathbf{x})}$ allows one to verify (i) and (ii) uniformly in $\mathbf{t} \in \mathbb{R}_+^n$, and the proof is finished by applying a multi-parameter version of the correspondence described in Sect. “[Connection with Dynamics on the Space of Lattices](#)”. Namely, one can show that $\mathbf{y} \in \text{VWA}_{1,n}^\times$ if and only if the trajectory $\{g_{\mathbf{t}}L_{\mathbf{y}}\mathbb{Z}^k : \mathbf{t} \in \mathbb{R}_+^n\}$ grows linearly, that is, for some $\gamma > 0$ one has $\text{dist}(g_{\mathbf{t}}L_{\mathbf{y}}\mathbb{Z}^{n+1}, \mathbb{Z}^{n+1}) > \gamma\|\mathbf{t}\|$ for an unbounded set of $\mathbf{t} \in \mathbb{R}_+^n$. A similar correspondence was recently used in [30] to prove that the set of exceptions to Littlewood’s Conjecture, which, using the terminology introduced above, can be called *badly multiplicatively approximable* vectors:

$$\text{BA}_{n,1}^\times \stackrel{\text{def}}{=} \mathbb{R}^n \setminus \bigcup_{c>0} \mathcal{W}_{n,1}^\times(\psi_{c,1/n})$$

$$= \left\{ \mathbf{y} : \inf_{q \in \mathbb{Z} \setminus \{0\}, \mathbf{p} \in \mathbb{Z}^n} |q| \cdot \Pi(q\mathbf{y} - \mathbf{p}) > 0 \right\}, \quad (18)$$

has Hausdorff dimension zero. This was done using a measure rigidity result for the action of the group of diagonal matrices on the space of lattices. See [18] for an implicit description of this correspondence and [32,66,70] for more detail.

The dynamical approach also turned out to be fruitful in studying Diophantine properties of pairs (\mathbf{f}, ν) for which the nonplanarity condition fails. Note that obvious examples of non-extremal measures are provided by proper affine subspaces of \mathbb{R}^n whose coefficients are rational or are well enough approximable by rational numbers. On the other hand, it is clear from a Fubini argument that almost all translates of any given subspace are extremal. In [51] the method of [56] was pushed further to produce criteria for the extremality, as well as the strong extremality, of arbitrary affine subspaces \mathcal{L} of \mathbb{R}^n . Further, it was shown that if \mathcal{L} is extremal (resp. strongly extremal), then so is any smooth submanifold of \mathcal{L} which is nondegenerate in \mathcal{L} at a.e. point. (The latter property is a straightforward generalization of the definition of nondegeneracy in \mathbb{R}^n : a map \mathbf{f} is *nondegenerate in \mathcal{L} at \mathbf{x}* if the linear part of \mathcal{L} is spanned by partial derivatives of \mathbf{f} at \mathbf{x}). In other words, extremality and strong extremality pass from affine subspaces to their nondegenerate submanifolds.

A more precise analysis makes it possible to study Diophantine exponents of measures with supports contained

in arbitrary proper affine subspaces of \mathbb{R}^n . Namely, in [53] it is shown how to compute $\omega(\mathcal{L})$ for any \mathcal{L} , and furthermore proved that if ν is a Federer measure on \mathbb{R}^d , U an open subset of \mathbb{R}^d , and $\mathbf{f}: U \rightarrow \mathbb{R}^n$ a continuous map such that the pair (\mathbf{f}, ν) is good and nonplanar in \mathcal{L} , then $\omega(\mathbf{f}_* \nu) = \omega(\mathcal{L})$. Here we say, generalizing the definition from Sect. “[Diophantine Approximation with Dependent Quantities: The Set-Up](#)”, that (\mathbf{f}, ν) is *nonplanar in \mathcal{L}* if for any ball B with $\nu(B) > 0$, the \mathbf{f} -image of $B \cap \text{supp } \nu$ is not contained in any proper affine subspace of \mathcal{L} . (It is easy to see that for a smooth map $\mathbf{f}: U \rightarrow \mathcal{L}$, (\mathbf{f}, λ) is good and nonplanar in \mathcal{L} whenever \mathbf{f} is nondegenerate in \mathcal{L} at a.e. point). It is worthwhile to point out that these new applications require a strengthening of the measure estimate described at the end of Sect. “[Diophantine Approximation with Dependent Quantities: The Set-Up](#)”: it was shown in [53] that (i) and (ii) would still imply (iii) if ρ in (ii) is replaced by $\rho^{\dim V}$.

Another application concerns badly approximable vectors. Using the dynamical description of the set $\text{BA} \subset \mathbb{R}^n$ due to Dani [20], it turns out to be possible to find badly approximable vectors inside supports of certain measures on \mathbb{R}^n . Namely, if a subset K of \mathbb{R}^n supports an absolutely friendly measure, then $\text{BA} \cap K$ has Hausdorff dimension not less than the Hausdorff dimension of this measure. In particular, it proves that limit measures of irreducible system of self-similar/self-conformal contractions satisfying the Open Set Condition, such as e.g. the middle-third Cantor set on the real line, contain subsets of full Hausdorff dimension consisting of badly approximable vectors. This was established in [60] and later independently in [64] using a different approach. See also [36] for a stronger result.

The proof in [60] uses quantitative nondivergence estimates and an iterative procedure, which requires the measure in question to be absolutely friendly and not just friendly. A similar question for even the simplest not-absolutely friendly measures is completely open. For example, it is not known whether there exist uncountably many badly approximable pairs of the form (x, x^2) . An analogous problem for atomic measures supported on algebraic numbers, that is, a “badly approximable” version of Roth’s Theorem, is currently beyond reach as well — there are no known badly approximable (or, for that matter, well approximable) algebraic numbers of degree bigger than two.

It has been recently understood that the quantitative nondivergence method can be applied to the question of improvement to Dirichlet’s Theorem (see the beginning of Sect. “[Basic Facts](#)”). Given a positive $\varepsilon < 1$, let us say that Dirichlet’s Theorem *can be ε -improved* for $Y \in M_{m,n}$, writing $Y \in \text{DI}_{m,n}(\varepsilon)$, if for every sufficiently large t the

system

$$\|Y\mathbf{q} - \mathbf{p}\| < \varepsilon e^{-t/m} \quad \text{and} \quad \|\mathbf{q}\| < \varepsilon e^{t/n} \quad (19)$$

(that is, (5) with the right hand side terms multiplied by ε) has a nontrivial integer solution (\mathbf{p}, \mathbf{q}) . It is a theorem of Davenport and Schmidt [24] that $\lambda(\text{DI}_{m,n}(\varepsilon)) = 0$ for any $\varepsilon < 1$; in other words, Dirichlet’s Theorem cannot be improved for Lebesgue-generic systems of linear forms. By a modification of the correspondence between dynamics and approximation, (19) is easily seen to be equivalent to $g_t L_Y \mathbb{Z}^k \in K_\varepsilon$, and since the complement to K_ε has nonempty interior for any $\varepsilon < 1$, the result of Davenport and Schmidt follows from the ergodicity of the g_t -action on Ω_k .

Similar questions with λ replaced by $\mathbf{f}_* \lambda$ for some specific smooth maps \mathbf{f} were considered in [2,3,15,23]. For example, [15], Theorem 7, provides an explicitly computable constant $\varepsilon_0 = \varepsilon_0(n)$ such that for \mathbf{f} as in (12),

$$\mathbf{f}_* \lambda(\text{DI}_{1,n}(\varepsilon)) = 0 \quad \text{for } \varepsilon < \varepsilon_0 .$$

This had been previously done in [23] for $n = 2$ and in [2] for $n = 3$. In [62] this is extended to a much broader class of measures using estimates described in Sect. “Diophantine Approximation with Dependent Quantities: The Set-Up”. In particular, almost every point of any nondegenerate smooth manifold is proved not to lie in $\text{DI}(\varepsilon)$ for small enough ε depending only on the manifold. Earlier this was done in [61] for the set of *singular* vectors, defined as the intersection of $\text{DI}(\varepsilon)$ over all positive ε ; those correspond to divergent g_t -trajectories. As before, the advantage of the method is allowing a multiplicative generalization of the Dirichlet-improvement set-up; see [62] for more detail.

It is also worthwhile to mention that a generalization of the measure estimate discussed in Sect. “Diophantine Approximation with Dependent Quantities: The Set-Up” was used in [13] to estimate the measure of the set of points \mathbf{x} in a ball $B \subset \mathbb{R}^d$ for which the system

$$\begin{cases} |\mathbf{f}(\mathbf{x}) \cdot \mathbf{q} + p| < \varepsilon \\ |\mathbf{f}'(\mathbf{x}) \cdot \mathbf{q}| < \delta \\ |q_i| < Q_i, \quad i = 1, \dots, n, \end{cases}$$

where \mathbf{f} is a smooth nondegenerate map $B \rightarrow \mathbb{R}^n$, has a nonzero integer solution. For that, $L_{\mathbf{f}(\mathbf{x})}$ as in (15) has to be replaced by the matrix

$$\begin{pmatrix} 1 & 0 & \mathbf{f}(\mathbf{x}) \\ 0 & 1 & \mathbf{f}'(\mathbf{x}) \\ 0 & 0 & I_n \end{pmatrix},$$

and therefore (i) and (ii) turn into more complicated conditions, which nevertheless can be checked when \mathbf{f} is smooth and nondegenerate and ν is Lebesgue measure. This has resulted in proving the convergence case of Khintchine–Groshev Theorem for nondegenerate manifolds [13], in both standard and multiplicative versions. The aforementioned estimate was also used in [7] for the proof of the divergence case, and in [38,40] for establishing the convergence case of Khintchine–Groshev theorem for affine hyperplanes and their nondegenerate submanifolds. This generalized results obtained by standard methods for the curve (12) by Bernik and Beresnevich [6,11].

Finally, let us note that in many of the problems mentioned above, the ground field \mathbb{R} can be replaced by \mathbb{Q}_p , and in fact several fields can be taken simultaneously, thus giving rise to the S -arithmetic setting where $S = \{p_1, \dots, p_s\}$ is a finite set of normalized valuations of \mathbb{Q} , which may or may not include the infinite valuation (cf. [83,90]). The space of lattices in \mathbb{R}^{n+1} is replaced there by the space of lattices in \mathbb{Q}_S^{n+1} , where \mathbb{Q}_S is the product of the fields \mathbb{R} and $\mathbb{Q}_{p_1}, \dots, \mathbb{Q}_{p_s}$. This is the subject of the paper [59], where S -arithmetic analogues of many results reviewed in Sect. “Diophantine Approximation with Dependent Quantities: The Set-Up” have been established. Similarly one can consider versions of the above theorems over local fields of positive characteristic [39]. See also [52] where Sprindžuk’s solution [83] of the complex case of Mahler’s Conjecture has been generalized (the latter involves studying small values of linear forms with coefficients in \mathbb{C} at real integer points), and [31] which establishes a p -adic analogue of the result of [30] on the set of exceptions to Littlewood’s Conjecture.

Future Directions

Interactions between ergodic theory and number theory have been rapidly expanding during the last two decades, and the author has no doubts that new applications of dynamics to Diophantine approximation will emerge in the near future. Specializing to the topics discussed in the present paper, it is fair to say that the list of “further results” contained in the previous section is by no means complete, and many even further results are currently in preparation. This includes: extending proofs of extremality and strong extremality of certain measures to the set-up of systems of linear forms (namely, with $\min(m, n) > 1$; this was mentioned as work in progress in [56]); proving Khintchine-type theorems (both convergence and divergence parts) for p -adic and S -arithmetic nondegenerate manifolds, see [73] for results in this direction; extending [38,40] to establish Khintchine-type theo-

rems for submanifolds of arbitrary affine subspaces. The work of Druțu [28], who used ergodic theory on homogeneous spaces to compute the Hausdorff dimension of the intersection of $\mathcal{W}_{n,1}(\psi_{1,\nu})$, $\nu > 1$, with some rational quadratic hypersurfaces in \mathbb{R}^n deserves a special mention; it is plausible that using this method one can treat more general situations. Several other interesting open directions are listed in [41], Section 9, in the final sections of papers [7,54], in the book [15], and in surveys by Frantzikinakis–McCutcheon, Nitica and Ward in this volume.

Glossary

Almost everywhere (abbreviated a. e.) A property that makes sense for each point x in a measure space (X, \mathcal{B}, μ) is said to hold almost everywhere (or a. e.) if the set $N \subset X$ on which it does not hold satisfies $N \in \mathcal{B}$ and $\mu(N) = 0$.

Čech–Stone compactification of \mathbb{N} , $\beta\mathbb{N}$

A compact Hausdorff space that contains \mathbb{N} as a dense subset with the property that any map from \mathbb{N} to a compact Hausdorff space K extends uniquely to a continuous map $\beta\mathbb{N} \rightarrow K$. This property and the fact that $\beta\mathbb{N}$ is a compact Hausdorff space containing \mathbb{N} characterizes $\beta\mathbb{N}$ up to homeomorphism.

Curvature An intrinsic measure of the curvature of a Riemannian manifold depending only on the Riemannian metric; in the case of a surface it determines whether the surface is locally convex (positive curvature), locally saddle-shaped (negative) or locally flat (zero).

Diophantine approximation Theory of the approximation of real numbers by rational numbers: how small

can the distance from a given irrational real number to a rational number be made in terms of the denominator of the rational?

Equidistributed A sequence is equidistributed if the asymptotic proportion of time it spends in an interval is proportional to the length of the interval.

Ergodic A measure-preserving transformation is ergodic if the only invariant functions are equal to a constant a. e.; equivalently if the transformation exhibits the convergence in the quasi-ergodic hypothesis.

Ergodic theory The study of statistical properties of orbits in abstract models of dynamical systems; more generally properties of measure-preserving (semi-) group actions on measure spaces.

Geodesic (flow) The shortest path between two points on a Riemannian manifold; such a geodesic path is uniquely determined by a starting point and the initial tangent vector to the path (that is, a point in the unit tangent bundle). The transformation on the unit tangent bundle defined by flowing along the geodesic defines the geodesic flow.

Haar measure (on a compact group) If G is a compact topological group, the unique measure μ defined on the Borel sets of G with the property that $\mu(A + g) = \mu(A)$ for all $g \in G$ and $\mu(G) = 1$.

Measure-theoretic entropy A numerical invariant of measure-preserving systems that reflects the asymptotic growth in complexity of measurable partitions refined under iteration of the map.

Mixing A measure-preserving system is mixing if measurable sets (events) become asymptotically independent as they are moved apart in time (under iteration).

(Quasi) Ergodic hypothesis The assumption that, in a dynamical system evolving in time and preserving a natural measure, there are some reasonable conditions under which the ‘time average’ along orbits of an observable (that is, the average value of a function defined on the phase space) will converge to the ‘space average’ (that is, the integral of the function with respect to the preserved measure).

Recurrence Return of an orbit in a dynamical system close to its starting point infinitely often.

S-Unit theorems A circle of results stating that linear equations in fields of zero characteristic have only finitely many solutions taken from finitely-generated multiplicative subgroups of the multiplicative group of the field (apart from infinite families of solutions arising from vanishing sub-sums).

Topological entropy A numerical invariant of topological dynamical systems that measures the asymptotic

growth in the complexity of orbits under iteration. The *variational principle* states that the topological entropy of a topological dynamical system is the supremum over all invariant measures of the measure-theoretic entropies of the dynamical systems viewed as measurable dynamical systems.

Definition of the Subject

Number theory is a branch of pure mathematics concerned with the properties of numbers in general, and integers in particular. The areas of most relevance to this article are *Diophantine analysis* (the study of how real numbers may be approximated by rational numbers, and the consequences for solutions of equations in integers); *analytic number theory*, and in particular asymptotic estimates for the number of primes smaller than X as a function of X ; *equidistribution*, and questions about how the digits of real numbers are distributed. Combinatorics is concerned with identifying structures in discrete objects; of most interest here is that part of combinatorics connected with Ramsey theory, asserting that large subsets of highly structured objects must automatically contain large replicas of that structure. Ergodic theory is the study of asymptotic behavior of group actions preserving a probability measure; it has proved to be a powerful part of dynamical systems with wide applications.

Introduction

Ergodic theory, part of the mathematical study of dynamical systems, has pervasive connections with number theory and combinatorics. This article briefly surveys how these arise through a small sample of results. Unsurprisingly, many details are suppressed, and of course the selection of topics reflects the author's interests far more than it does the full extent of the flow of ideas between ergodic theory and number theory. In addition the selection of topics has been chosen in part to be complementary to those in related articles in the Encyclopedia. A particularly enormous lacuna is the theory of arithmetic dynamical systems itself – the recent monograph by Silverman [94] gives a comprehensive overview.

More sophisticated aspects of this connection – in particular the connections between ergodic theory on homogeneous spaces and Diophantine analysis – are covered in the articles ► [Ergodic Theory on Homogeneous Spaces and Metric Number Theory](#) and ► [Ergodic Theory: Rigidity](#); more sophisticated overviews of the connections with combinatorics may be found in the article ► [Ergodic Theory: Recurrence](#).

Ergodic Theory

While the early origins of ergodic theory lie in the quasi-ergodic hypothesis of classical Hamiltonian dynamics, the mathematical study of ergodic theory concerns various properties of group actions on measure spaces, including but not limited to several special branches:

1. The classical study of single measure-preserving transformations.
2. Measure-preserving actions of \mathbb{Z}^d ; more generally of countable amenable groups.
3. Measure-preserving actions of \mathbb{R}^d and more general amenable groups, called flows.
4. Measure-preserving actions of lattices in Lie groups.
5. Measure-preserving actions of Lie groups.

The ideas and conditions surrounding the quasi-ergodic hypothesis were eventually placed on a firm mathematical footing by developments starting in 1890. For a single measure-preserving transformation $T: X \rightarrow X$ of a probability space (X, \mathcal{B}, μ) , Poincaré [74] showed a *recurrence theorem*: if $E \in \mathcal{B}$ is any measurable set, then for a. e. $x \in E$ there is an infinite set of return times, $0 < n_1 < n_2 < \dots$ with $T^{n_i}(x) \in E$ (of course Poincaré noted this in a specific setting, concerned with a natural invariant measure for the “three-body” problem in planetary motion).

Poincaré's qualitative result was made quantitative in the 1930s, when von Neumann [105] used the approach of Koopman [52] to show the *mean ergodic theorem*: if $f \in L^2(\mu)$ then there is some $\bar{f} \in L^2(\mu)$ for which

$$\left\| \frac{1}{N} \sum_{n=0}^{N-1} f \circ T^n - \bar{f} \right\|_2 \rightarrow 0 \quad \text{as } N \rightarrow \infty;$$

clearly \bar{f} then has the property that $\|\bar{f} - \bar{f} \circ T\|_2 = 0$ and $\int \bar{f} d\mu = \int f d\mu$. Around the same time, Birkhoff [13] showed the more delicate *pointwise ergodic theorem*: for any $g \in L^1(\mu)$ there is some $\bar{g} \in L^1(\mu)$ for which

$$\frac{1}{N} \sum_{n=0}^{N-1} g(T^n x) \rightarrow \bar{g}(x) \quad \text{a. e.};$$

again it is then clear that $\bar{g}(Tx) = \bar{g}(x)$ a. e. and $\int \bar{g} d\mu = \int g d\mu$.

The map T is called *ergodic* if the invariance condition forces the function (f or g) to be equal to a constant a. e. Thus an ergodic map has the property that the *time* or *ergodic average* $(1/N) \sum_{n=0}^{N-1} f \circ T^n$ converges to the *space average* $\int f d\mu$. An overview of ergodic theorems and their

many extensions may be found in the article ► [Ergodic Theorems](#).

Thus ergodic theory at its most basic level makes strong statements about the asymptotic behavior of orbits of a dynamical system as seen by *observables* (measurable functions on the space X). Applying the ergodic theorem to the indicator function of a measurable set A shows that ergodicity guarantees that a. e. orbit spends an asymptotic proportion of time in A equal to the volume $\mu(A)$ of that set (as measured by the invariant measure). This points to the start of the pervasive connections between ergodic theory and number theory – but as this and other articles relate, the connections extend far beyond this.

Frequency of Returns

In this section we illustrate the way in which a dynamical point of view may unify, explain and extend quite disparate results from number theory.

Normal Numbers

Borel [15] showed (as a consequence of what became the Borel–Cantelli Lemma in probability) that a. e. real number (with respect to Lebesgue measure) is *normal* to every base: that is, has the property that any block of k digits in the base- r expansion appears with asymptotic frequency r^{-k} .

Continued Fraction Digits

Analogs of normality results for the continued fraction expansion of real numbers were found by Khinchin, Kuz'min, Lévy and others. Any irrational $x \in [0, 1]$ has a unique expansion as a continued fraction

$$x = \frac{1}{a_1(x) + \frac{1}{a_2(x) + \frac{1}{a_3(x) + \dots}}}$$

and, just as in the case of the familiar base- r expansion, it turns out that the digits $(a_n(x))$ obey precise statistical rules for a. e. x . Gauss conjectured that the appearance of individual digits would obey the law

$$\frac{1}{N} |\{k: 1 \leq k \leq N, a_k(x) = j\}| \rightarrow \frac{2 \log(1+j) - \log j - \log(2+j)}{\log 2}. \quad (1)$$

This was eventually proved by Kuz'min [54] and Lévy [59], and the probability distribution of the digits is the *Gauss–*

Kuz'min law. Khinchin [50] developed this further, showing for example that

$$\begin{aligned} \lim_{n \rightarrow \infty} (a_1(x)a_2(x) \dots a_n(x))^{1/n} \\ &= \prod_{n=1}^{\infty} \left(\frac{(n+1)^2}{n(n+2)} \right)^{\log n / \log 2} \\ &= 2.68545 \dots \quad \text{for a. e. } x. \end{aligned}$$

Lévy [60] showed that the denominator $q_n(x)$ of the n th convergent $(p_n(x))/q_n(x)$ (the rational obtained by truncating the continued fraction expansion of x at the n th term) grows at a specific exponential rate,

$$\lim_{n \rightarrow \infty} \frac{1}{n} \log q_n(x) = \frac{\pi^2}{12 \log 2} \quad \text{for a. e. } x.$$

First Digits

The astronomer Newcomb [67] noted that the first digits of large collections of numerical data that are not dimensionless have a specific and non-uniform distribution:

“The law of probability of the occurrence of numbers is such that all mantissæ of their logarithms are equally probable.”

This is now known as Benford's Law, following his popularization and possible rediscovery of the phenomenon [6]. In both cases, this was an empirical observation eventually made rigorous by Hill [42]. Arnold (App. 12 in [3]), pointed out the dynamics behind this phenomena in certain cases, best illustrated by the statistical behavior of the sequence 1, 2, 4, 8, 1, 3, 6, 1, ... of first digits of powers of 2. Empirically, the digit 1 appears about 30% of the time, while the digit 9 appears about 5% of the time.

Equidistribution

Weyl [109] (and, separately, Bohl [14] and Sierpiński [91]) found an important instance of *equidistribution*. Writing $\{\cdot\}$ for the fractional part, a sequence (a_n) of real numbers is said to be equidistributed modulo 1 if, for any interval $[a, b] \subset [0, 1)$,

$$\frac{1}{N} |\{k: 1 \leq k \leq N, \{a_k\} \in [a, b]\}| \rightarrow (b-a) \quad \text{as } N \rightarrow \infty;$$

equivalently if

$$\frac{1}{N} \sum_{k=1}^N f(a_k) \rightarrow \int_0^1 f(t) dt \quad \text{as } N \rightarrow \infty$$

for all continuous functions f . Weyl showed that the sequence $\{n\alpha\}$ is equidistributed if and only if α is irrational. This result was refined and extended in many directions; for example, Hlawka [44] and others found rates for the convergence in terms of the discrepancy of the sequence, Weyl [110] proved equidistribution for $\{n^2\alpha\}$, and Vinogradov for $\{p_n\alpha\}$ where p_n is the n th prime.

The Ergodic Context

All the results of this section are manifestations of various kinds of convergence of ergodic averages. Borel’s theorem on normal numbers is an immediate consequence of the fact that Lebesgue measure on $[0, 1)$ is invariant and ergodic for the map $x \mapsto bx$ modulo 1 with $b \geq 2$. The asymptotic properties of continued fraction digits are all a consequence of the fact that the *Gauss measure* defined by

$$\mu(A) = \frac{1}{\log 2} \int_A \frac{dx}{1+x} \quad \text{for } A \subset [0, 1)$$

is invariant and ergodic for the Gauss map $x \mapsto \{\frac{1}{x}\}$, and the orbit of an irrational number under the Gauss map determine the digits appearing in the continued fraction expansion much as the orbit under the map $x \mapsto bx \pmod{1}$ determines the digits in the base b expansion.

The results on equidistribution and the frequency of first digits are related to ergodic averaging of a different sort. For example, writing $R_\alpha(t) = t + \alpha$ modulo 1 for the circle rotation by α , the first digit of 2^n is the digit j if and only if

$$\log_{10} j \leq R_{\log_{10}(2)}(0) < \log_{10}(j + 1).$$

Thus the asymptotic frequency of appearance concerns the orbit of a *specific point*. In order to see what this means, consider a continuous map $T: X \rightarrow X$ of a compact metric space (X, d) . The space $\mathcal{M}(T)$ of Borel probability measures on the Borel σ -algebra of (X, d) is a non-empty compact convex set in the weak*-topology, each extreme point is an ergodic measure for T , and these ergodic measures are mutually singular. If $\mathcal{M}(T)$ is not a singleton and $\mu_1, \mu_2 \in \mathcal{M}(T)$ are distinct ergodic measures, then for a continuous function f with $\int_X f d\mu_1 \neq \int_X f d\mu_2$ it is clear that the ergodic averages $\frac{1}{N} \sum_{n=0}^{N-1} f(T^n x)$ must converge to $\int_X f d\mu_1$ a. e. with respect to μ_1 and to $\int_X f d\mu_2$ a. e. with respect to μ_2 . Thus the presence of many invariant measures for a continuous map means that ergodic averages along the orbits of specific points need not converge to the space average with respect to a chosen invariant measure.

In the extreme situation of *unique ergodicity* (a single invariant measure, which is necessarily an extreme point of $\mathcal{M}(T)$ and hence ergodic) the convergence of ergodic averages is much more uniform. Indeed, if T is uniquely ergodic with $\mathcal{M}(T) = \{\mu\}$ then, for any continuous function $f: X \rightarrow \mathbb{R}$,

$$\frac{1}{N} \sum_{n=0}^{N-1} f(T^n x) \rightarrow \int_X f d\mu \text{ uniformly in } x$$

(see Oxtoby [69]). The circle rotation R_α is uniquely ergodic for irrational α , leading to the equidistribution results.

The ergodic viewpoint on equidistribution also places equidistribution results in a wider context. Weyl’s result that $\{n^2\alpha\}$ (indeed, the fractional part of any polynomial with at least one irrational coefficient) is equidistributed for irrational α was given another proof by Furstenberg [29] using the notion of unique ergodicity. These methods were then used in the study of nilsystems (translations on quotients of nilpotent Lie groups) by Auslander, Green and Hahn [4] and Parry [70], and these nilsystems play an essential role for polynomial (and other non-conventional) ergodic averaging (see Host and Kra [45] and Leibman [58] in the polynomial case; Host and Kra [46] in the multiple linear case). Remarkably, nilsystems are starting to play a role within combinatorics – an example is the work on the asymptotic number of 4-step arithmetic progressions in the primes by Green and Tao [40]. Pointwise ergodic theorems have also been found along sequences other than \mathbb{N} ; notably for integer-valued polynomials and along the primes for L^2 functions by Bourgain [16,17]. For more details, see the survey paper of del Junco on ergodic theorems.

Ergodic Ramsey Theory and Recurrence

In 1927 van der Waerden proved a conjecture attributed to Baudet: if the natural numbers are written as a disjoint union of finitely many sets,

$$\mathbb{N} = C_1 \sqcup C_2 \sqcup \dots \sqcup C_r, \tag{2}$$

then there must be one set C_j that contains arbitrarily long arithmetic progressions. That is, there is some $j \in \{1, \dots, r\}$ such that for any $k \geq 1$ there are $a \geq 1$ and $n \geq 1$ with

$$a, a + n, a + 2n, \dots, a + (k - 1)n \in C_j.$$

The original proof appears in van der Waerden’s paper [103], and there is a discussion of how he found the proof in [104].

Work of Furstenberg and Weiss [34] and others placed the theorem of van der Waerden in the context of topological dynamics, giving alternative proofs. Specifically, van der Waerden’s theorem is a consequence of *topological multiple recurrence*: the return of points under iteration in a topological dynamical system close to their starting point along finite sequences of times. The same approach readily gives dynamical proofs of Rado’s extension [76] of van der Waerden’s theorem, and of Hindman’s theorem [43]. The theorems of Rado and Hindman introduce a new theme: given a set $A = \{n_1, n_2, \dots\}$ of natural numbers, write $FS(A)$ for the set of numbers obtained as finite sums $n_{i_1} + \dots + n_{i_j}$ with $i_1 < i_2 < \dots < i_j$. Rado showed that for any large n there is some C_s containing some $FS(A)$ for a set A of cardinality n . Hindman showed that there is some C_s containing some $FS(A)$ for an *infinite* set A .

In the theorem of van der Waerden, it is clear that for any reasonable notion of “proportion” or “density” one of the sets C_j must occupy a positive proportion of \mathbb{N} . A set $A \subset \mathbb{N}$ is said to have *positive upper density* if there are sequences (M_i) and (N_i) with $N_i - M_i \rightarrow \infty$ as $i \rightarrow \infty$ such that

$$\lim_{i \rightarrow \infty} \frac{1}{N_i - M_i} |\{a \in A : M_i < a < N_i\}| > 0.$$

Erdős and Turán [26] conjectured the stronger statement that any subset of \mathbb{N} with positive upper density must contain arbitrary long arithmetic progressions. This statement was shown for arithmetic progressions of length 3 by Roth [79] in 1952, then for length 4 by Szemerédi [96] in 1969. The general result was eventually proved by Szemerédi [97] in 1975 in a lengthy and extremely difficult argument.

Furstenberg saw that Szemerédi’s Theorem would follow from a deep extension of the Poincaré recurrence phenomena described in Sect. “Ergodic Theory” and proved that extension [30] (see also the survey article by Furstenberg, Katznelson and Ornstein [33]). The *multiple recurrence* result of Furstenberg says that for any measure-preserving system (X, \mathcal{B}, μ, T) and set $A \in \mathcal{B}$ with $\mu(A) > 0$, and for any $k \in \mathbb{N}$,

$$\liminf_{N-M \rightarrow \infty} \frac{1}{N-M+1} \cdot \sum_{n=M}^N \mu(A \cap T^{-n}A \cap T^{-2n}A \cap \dots \cap T^{-kn}A) > 0.$$

An immediate consequence is that in the same setting there must be some $n \geq 1$ for which

$$\mu(A \cap T^{-n}A \cap T^{-2n}A \cap \dots \cap T^{-kn}A) > 0. \quad (3)$$

A general *correspondence principle*, due to Furstenberg, shows that statements in combinatorics like Szemerédi’s Theorem are equivalent to statements in ergodic theory like (3).

This opened up a significant new field of *ergodic Ramsey theory*, in which methods from dynamical systems and ergodic theory are used to produce new results in infinite combinatorics. For an overview, see the articles ► [Ergodic Theory on Homogeneous Spaces and Metric Number Theory](#), ► [Ergodic Theory: Rigidity](#), ► [Ergodic Theory: Recurrence](#) and the survey articles of Bergelson [7,8,10]. The field is too large to give an overview here, but a few examples will give a flavor of some of the themes.

Call a set $R \subset \mathbb{Z}$ a *set of recurrence* if, for any finite measure-preserving invertible transformation T of a finite measure space (X, \mathcal{B}, μ) and any set $A \in \mathcal{B}$ with $\mu(A) > 0$, there are infinitely many $n \in R$ for which $\mu(A \cap T^{-n}A) > 0$. Thus Poincaré recurrence is the statement that \mathbb{N} is a set of recurrence. Furstenberg and Katznelson [31] showed that if T_1, \dots, T_k form a family of commuting measure-preserving transformations and A is a set of positive measure, then

$$\liminf_{N \rightarrow \infty} \frac{1}{N} \sum_{n=0}^{N-1} \mu(T_1^{-n}A \cap \dots \cap T_k^{-n}A) > 0.$$

This remarkable multiple recurrence implies a multi-dimensional form of Szemerédi’s theorem. Recently, Gowers has found a non-ergodic proof of this [38].

Furstenberg also gave an ergodic proof of Sárközy’s theorem [80]: if $p \in \mathbb{Q}[t]$ is a polynomial with $p(\mathbb{Z}) \subset \mathbb{Z}$ and $p(0) = 0$, then $\{p(n)\}_{n>0}$ is a set of recurrence. This was extended to multiple polynomial recurrence by Bergelson and Leibman [11].

Topology and Coloring Theorems

The existence of idempotent ultrafilters in the Čech–Stone compactification $\beta\mathbb{N}$ gives rise to an algebraic approach to many questions in topological dynamics (this notion has its origins in the work of Ellis [24]). Using these methods, results like Hindman’s finite sums theorem find elegant proofs, and many new results in combinatorics have been found. For example, in the partition (2) there must be one set C_j containing a triple x, y, z solving $x - y = z^2$.

A deeper application is to improve a strengthening of Kronecker’s theorem. To explain this, recall that a set S is called *IP* if there is a sequence (n_i) of natural numbers (which do not need to be distinct) with the property that S contains all the terms of the sequence and all finite sums of terms of the sequence with distinct indices.

A set S is called IP^* if it has non-empty intersection with every IP set, and a set S is called IP_+^* if there is some $t \in \mathbb{Z}$ for which $S - t$ is IP^* . Thus being IP^* (or IP_+^*) is an extreme form of ‘fatness’ for a set. Now let $1, \alpha_1, \dots, \alpha_k$ be numbers that are linearly independent over the rationals, and for any $d \in \mathbb{N}$ and kd non-empty intervals $I_{ij} \subset [0, 1]$ ($1 \leq i \leq d, 1 \leq j \leq k$), let

$$D = \{n \in \mathbb{N} : \{n^i \alpha_j\} \in I_{ij} \text{ for all } i, j\}.$$

Kronecker showed that if $d = 1$ then D is non-empty; Hardy and Littlewood showed that D is infinite, and Weyl showed that D has positive density. Bergelson [9] uses these algebraic methods to improve the result by showing that D is an IP_+^* set.

Polynomialization and IP -sets

As mentioned above, Bergelson and Leibman [11] extended multiple recurrence to a polynomial setting. For example, let

$$\{p_{i,j} : 1 \leq i \leq k, 1 \leq j \leq t\}$$

be a collection of polynomials with rational coefficients and $p_{i,j}(\mathbb{Z}) \subset \mathbb{Z}, p_{i,j}(0) = 0$. Then if $\mu(A) > 0$, we have

$$\liminf_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \mu \left(\bigcap_{i=1}^k \left(\prod_{j=1}^t T_j^{p_{i,j}(n)} \right)^{-1} A \right) > 0.$$

Using the Furstenberg correspondence principle, this gives a multi-dimensional polynomial Szemerédi theorem: If $P: \mathbb{Z}^r \rightarrow \mathbb{Z}^\ell$ is a polynomial mapping with the property that $P(0) = 0$, and $F \subset \mathbb{Z}^r$ is a finite configuration, then any set $S \subset \mathbb{Z}^\ell$ of positive upper Banach density contains a set of the form $u + P(nF)$ for some $u \in \mathbb{Z}^\ell$ and $n \in \mathbb{N}$.

In a different direction, motivated in part by Hindman’s theorem, the multiple recurrence results generalize to IP -sets. Furstenberg and Katznelson [32] proved a linear IP -multiple recurrence theorem in which the recurrence is guaranteed to occur along an IP -set. A combinatorial proof of this result has been found by Nagle, Rödl and Schacht [66]. Bergelson and McCutcheon [12] extended these results by proving a polynomial IP -multiple recurrence theorem. To formulate this, make the following definitions. Write \mathcal{F} for the family of non-empty finite subsets of \mathbb{N} , so that a sequence indexed by \mathcal{F} is an IP -set. More generally, an \mathcal{F} -sequence $(n_\alpha)_{\alpha \in \mathcal{F}}$ taking values in an abelian group is called an IP -sequence if $n_{\alpha \cup \beta} = n_\alpha + n_\beta$ whenever $\alpha \cap \beta = \emptyset$. An IP -ring is a set of the form $\mathcal{F}^{(1)} = \{\bigcup_{i \in \beta} \alpha_i : \beta \in \mathcal{F}\}$ where $\alpha_1 < \alpha_2 < \dots$ is a sequence in \mathcal{F} , and $\alpha < \beta$ means $a < b$ for all $a \in \alpha, b \in \beta$;

write $\mathcal{F}_<^m$ for the set of m -tuples $(\alpha_1, \dots, \alpha_m)$ from \mathcal{F}^m with $\alpha_i < \alpha_j$ for $i < j$. Write $PE(m, d)$ for the collection of all expressions of the form $T(\alpha_1, \dots, \alpha_m) = \prod_{i=1}^r T_i^{p_i((n_{\alpha_j}^{(b)}))_{1 \leq b \leq k, 1 \leq j \leq m}}$, $(\alpha_1, \dots, \alpha_m) \in (\mathcal{F} \cup \emptyset)_{<}^m$, where each p_i is a polynomial in a $k \times m$ matrix of variables with integer coefficients and zero constant term with degree $\leq d$. Then for every $m, t \in \mathbb{N}$, there is an IP -ring $\mathcal{F}^{(1)}$, and an $a = a(A, m, t, d) > 0$, such that, for every set of polynomial expressions $\{S_0, \dots, S_t\} \subset PE(m, d)$,

$$IP - \lim_{(\alpha_1, \dots, \alpha_m) \in (\mathcal{F}^{(1)})_{<}^m} \mu \left(\bigcap_{i=0}^t S_i(\alpha_1, \dots, \alpha_m)^{-1} A \right) > 0.$$

There are a large number of deep combinatorial consequences of this result, not all of which seem accessible by other means.

Sets of Primes

In a remarkable development, Szemerédi’s theorem and some of the ideas behind ergodic Ramsey theory joined results of Goldston and Yıldırım [37] in playing a part in Green and Tao’s proof [39] that the set of primes contains arbitrarily long arithmetic progressions. This profound result is surveyed from an ergodic point of view in the article of Kra [53]. As with Szemerédi’s theorem itself, this result has been extended to a polynomial setting by Tao and Ziegler [101]. Given integer-valued polynomials $f_1, \dots, f_k \in \mathbb{Z}[t]$ with

$$f_1(0) = \dots = f_k(0) = 0$$

and any $\varepsilon > 0$, Tao and Ziegler proved that there are infinitely many integers x, m with $1 \leq m \leq x^\varepsilon$ for which $x + f_1(m), \dots, x + f_k(m)$ are primes.

Orbit-Counting as an Analogous Development

Some of the connections between number theory and ergodic theory arise through developments that are analogous but not directly related. A remarkable instance of this concerns the long history of attempts to count prime numbers laid alongside the problem of counting closed orbits in dynamical systems.

Counting Orbits and Geodesics

Consider first the fundamental arithmetic function $\pi(X) = |\{p \leq X : p \text{ is prime}\}|$. Tables of primes prepared by Felkel and Vega in the 18th century led Legendre to suggest that $\pi(X)$ is approximately $x/(\log(X) - 1.08)$. Gauss,

using both computational evidence and a heuristic argument, suggested that $\pi(X)$ is approximated by

$$\text{li}(X) = \int_2^X \frac{dt}{\log t}.$$

Both of these suggestions imply the well-known asymptotic formula

$$\pi(X) \sim \frac{X}{\log X}. \tag{4}$$

Riemann brought the analytic ideas of Dirichlet and Chebyshev (who used the zeta function to find a weaker version of (4) with upper and lower bounds for the quantity $\frac{\pi(X)\log(X)}{X}$) to bear by proposing that the zeta function

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s} = \prod_p (1 - p^{-s})^{-1}, \tag{5}$$

already studied by Euler, would connect properties of the primes to analytic methods. An essential step in these developments, due to Riemann, is the meromorphic extension of ζ from the region $\Re(s) > 1$ in (5) to the whole complex plane and a functional equation relating the value of the extension at s to the value at $1 - s$. Moreover, Riemann showed that the extension has readily understood real zeros, and that all the other zeros he could find were symmetric about $\Re(s) = \frac{1}{2}$. The *Riemann hypothesis* asserts that zeros in the region $0 < \Re(s) < 1$ all lie on the line $\Re(s) = \frac{1}{2}$, and this remains open.

Analytic properties of the Riemann zeta function were used by Hadamard and de la Vallée Poussin to prove (4), the *Prime Number Theorem*, in 1896. Tauberian methods developed by Wiener and Ikehara [111] later gave different approaches to the Prime Number Theorem.

These ideas initiated the widespread use of zeta functions in several parts of mathematics, but it was not until the middle of the 20th century that Selberg [88] introduced a zeta function dealing directly with quantities arising in dynamical systems: the lengths of closed geodesics on surfaces of constant curvature -1 . The geodesic flow acts on the unit tangent bundle to the surface by moving a point and unit tangent vector at that point along the unique geodesic they define at unit speed. Closed geodesics are then in one-to-one correspondence with periodic orbits of the associated geodesic flow on the unit tangent bundle, and it is in this sense that the quantities are dynamical. The function defined by Selberg takes the form

$$Z(s) = \prod_{\tau} \prod_{k=0}^{\infty} \left(1 - e^{-(s+k)|\tau|}\right),$$

in which τ runs over all the closed geodesics, and $|\tau|$ denotes the length of the geodesic. In a direct echo of the Riemann zeta function, Selberg found an analytic continuation to the complex plane, and showed that the zeros of Z lie on the real axis or on the line $\Re(s) = \frac{1}{2}$ (the analogue of the Riemann hypothesis for Z ; see also the paper of Hejhal [41]). The zeros of Z are closely connected to the eigenvalues for the Laplace–Beltrami operator, and thus give information about the lengths of closed geodesics via Selberg’s trace formula in the same paper. Huber [47] and others used this approach to give an analogue of the prime number theorem for closed geodesics – a *prime orbit theorem*.

Sinai [92] considered closed geodesics on a manifold M with negative curvature bounded between $-R^2$ and $-r^2$, and found the bounds

$$(\dim(M) - 1)r \leq \liminf_{T \rightarrow \infty} \frac{\log \pi(T)}{T} \leq \limsup_{T \rightarrow \infty} \frac{\log \pi(T)}{T} \leq (\dim(M) - 1)R$$

for the number $\pi(T)$ of closed geodesics of multiplicity one with length less than T , analogous to Chebyshev’s result.

The essential dynamical feature behind the geodesic flow on a manifold of negative curvature is that it is an example of an *Anosov flow* [2]. These are smooth dynamical \mathbb{R} -actions (equivalently, first-order differential equations on Riemannian manifolds) with the property that the tangent bundle has a continuously varying splitting into a direct sum $E^u \oplus E^s \oplus E^o$ and the action of the differential of the flow acts on E^u as an exponential expansion, on E^s as an exponential contraction, E^o is the one-dimensional bundle of vectors that are tangent to orbits, and the expansion and contraction factors are bounded. In the setting of Anosov flows, the natural orbit counting function is $\pi(X) = |\{\tau : \tau \text{ a closed orbit of length } |\tau| \leq X\}|$. Margulis [62,63] generalized the picture to weak-mixing Anosov flows by showing a prime orbit theorem of the form

$$\pi(X) \sim \frac{e^{h_{\text{top}}X}}{h_{\text{top}}X} \tag{6}$$

for the counting function $\pi(X) = |\{\tau : \tau \text{ a closed orbit of length } |\tau| \leq X\}|$ where as before h_{top} denotes the topological entropy of the flow. Integral to Margulis’ work is a result on the spatial distribution of the closed geodesics reflected in a flow-invariant probability measure, now called the Margulis measure.

Anosov also studied discrete dynamical systems with similar properties: diffeomorphisms of compact manifolds

with a similar splitting of the tangent space (though in this setting E^o disappears). The archetypal Anosov diffeomorphism is a hyperbolic toral automorphism of the sort considered in Subsect. “[Orbit Growth and Convergence](#)”; for such automorphisms of the 2-torus Adler and Weiss [1] constructed Markov partitions, allowing the dynamics of the toral automorphism to be modeled by a topological Markov shift, and used this to determine when two such automorphisms are measurably isomorphic. Sinai [93], Ratner [77], Bowen [18,20] and others developed the construction of Markov partitions in general for Anosov diffeomorphisms and flows.

Around the same time, Smale [95] introduced a more permissive hyperbolicity axiom for diffeomorphisms, Axiom A. Maps satisfying Axiom A are diffeomorphisms satisfying the same hypothesis as that of Anosov diffeomorphisms, but only on the set of points that return arbitrarily close under the action of the flow (or iteration of the map).

Thus Markov partitions, and with them associated transfer operators became a substitute for the geometrical Laplace–Beltrami operators of the setting considered by Selberg. Bowen [19] extended the uniform distribution result of Margulis to this setting and found an analogue of Chebychev’s theorem for closed orbits. Parry [71] (in a restricted case) and Parry and Pollicott [73] went on to prove the prime orbit theorem in this more general setting. The methods are an adaptation of the Ikehara–Wiener–Tauberian approach to the prime number theorem.

Thus many facets of the prime number theorem story find their echoes in the study of closed orbits for hyperbolic flows: the role played by meromorphic extensions of suitable zeta functions, Tauberian methods, and so on. Moreover, related results from number theory have analogues in dynamics, for example Mertens’ theorem [65] in the work of Sharp [89] and Noorani [68] and Dirichlet’s theorem in work of Parry [72].

The “elementary” proof (not using analytic methods) of the prime number theorem by Erdős [25] and Selberg [87] (see the survey by Goldfeld [36] for the background to the results and the unfortunate priority dispute) has an echo in some approaches to orbit-counting problems from an elementary (non-Tauberian) perspective, including work of Lalley [56] on special flows and Everest, Miles, Stevens and the author [27] in the algebraic setting.

In a different direction Lalley [55] found orbit asymptotics for closed orbits satisfying constraints in the Axiom A setting without using Tauberian theorems. His more direct approach is still analytic, using complex transfer operators (the same objects used to by Parry and Pol-

licott to study the dynamical zeta function at complex values) and indeed somewhat parallels a Tauberian argument.

Further resonances with number theory arise here. For example, there are results on the distribution of closed orbits for group extensions (analogous to Chebotarev’s theorem) and for orbits with homological constraints (see Sharp [90], Katsuda and Sunada [49]).

Of course the great diversity of dynamical systems subsumed in the phrase “prime orbit theorem” creates new problems and challenges, and in particular if there is not much geometry to work with then the reliance on Markov partitions and transfer operators makes it difficult to find higher-order asymptotics.

Dolgopyat [22] has nonetheless managed to push the Markov methods to obtain uniform bounds on iterates of the associated transfer operators to the region $\Re(s) > \sigma_0$ with $\sigma_0 < 1$. This result has wide implications; an example most relevant to the analogy with number theory is the work of Pollicott and Sharp [75] in which Dolgopyat’s result is used to show that for certain geodesic flows there is a two-term prime orbit theorem of the form

$$\pi(X) = \text{li}\left(e^{h_{\text{top}}X}\right) + O\left(e^{cX}\right)$$

for some $c < h_{\text{top}}$.

For non-positive curvature manifolds less is known: Knieper [51] finds upper and lower bounds for the function counting closed geodesics on rank-1 manifolds of non-positive curvature of the form

$$A \frac{e^{hX}}{X} \leq \pi(X) \leq B e^{hX}$$

for constants $A, B > 0$.

Counting Orbits for Group Endomorphisms

A prism through which to view some of the deeper issues that arise in Subsect. “[Counting Orbits and Geodesics](#)” is provided by group endomorphisms. The price paid for having simple closed formulas for all the quantities involved is of course a severe loss of generality, but the diversity of examples illustrates many of the phenomena that may be expected in more general settings when hyperbolicity is lost.

Consider an endomorphism $T: X \rightarrow X$ of a compact group with the property that $F_n(T) < \infty$ for all $n \geq 1$. The number of closed orbits of length n under T is then

$$O_n(T) = \frac{1}{n} \sum_{d|n} \mu(n/d) F_d(T). \quad (7)$$

In simple situations (hyperbolic toral automorphisms for example) it is straightforward to show that

$$\pi_T(X) = |\{\tau : \tau \text{ a closed orbit under } T \text{ of length } \leq X\}| \sim \frac{e^{(X+1)h_{\text{top}}(T)}}{X} . \tag{8}$$

Waddington [106] considered quasihyperbolic toral automorphisms, showing that the asymptotic (8) in this case is multiplied by an explicit almost-periodic function bounded away from zero and infinity.

This result has been extended further into non-hyperbolic territory, which is most easily seen via the so-called connected S -integer dynamical systems introduced by Chothi, Everest and the author [21]. Fix an algebraic number field \mathbb{K} with set of places $P(\mathbb{K})$ and set of infinite places $P_\infty(\mathbb{K})$, an element of infinite multiplicative order $\xi \in \mathbb{K}^*$, and a finite set $S \subset P(\mathbb{K}) \setminus P_\infty(\mathbb{K})$ with the property that $|\xi|_w \leq 1$ for all $w \notin S \cup P_\infty(\mathbb{K})$. The associated ring of S -integers is

$$R_S = \{x \in \mathbb{K} : |x|_w \leq 1 \text{ for all } w \notin S \cup P_\infty(\mathbb{K})\} .$$

Let X be the compact character group of R_S , and define the endomorphism $T: X \rightarrow X$ to be the dual of the map $x \mapsto \xi x$ on R_S . Following Weil [108], write \mathbb{K}_w for the completion at w , and for w finite, write r_w for the maximal compact subring of \mathbb{K}_w . Notice that if $S = P$ then $R_S = \mathbb{K}$ and $F_n(T) = 1$ for all $n \geq 1$ by the product formula for \mathbb{A} -fields. As the set S shrinks, more and more periodic orbits come into being, and if S is as small as possible (given ξ) then the resulting system is (more or less) hyperbolic or quasi-hyperbolic.

For S finite, it turns out that there are still sufficiently many periodic orbits to have the growth rate result (10), but the asymptotic (8) is modified in much the same way as Waddington observed for quasi-hyperbolic toral automorphisms:

$$\liminf_{X \rightarrow \infty} \frac{X \pi_T(X)}{e^{(X+1)h_{\text{top}}(T)}} > 0 \tag{9}$$

and there is an associated pair (X^*, a_T) , where X^* is a compact group and $a_T \in X^*$, with the property that if $a_T^{N_j}$ converges in X^* as $j \rightarrow \infty$, then there is convergence in (9).

A simple special case will illustrate this. Taking $\mathbb{K} = \mathbb{Q}$, $\xi = 2$ and $S = \{3\}$ gives a compact group endomorphism T with

$$F_n(T) = (2^n - 1)|2^n - 1|_3 .$$

For this example the results of [21] are sharper: The expression in (9) converges along (X_j) if and only if 2^{X_j} converges in the ring of 3-adic integers \mathbb{Z}_3 , the expression has uncountably many limit points, and the upper and lower limits are transcendental.

Similarly, the dynamical analogue of Mertens' theorem found by Sharp may be found for S -integer systems with S finite. Writing

$$\mathcal{M}_T(N) = \sum_{|\tau| \leq N} \frac{1}{e^{h(T)|\tau|}} ,$$

it is shown in [21] that for an ergodic S -integer map T with $\mathbb{K} = \mathbb{Q}$ and S finite, there are constants $k_T \in \mathbb{Q}$ and C_T such that

$$\mathcal{M}_T(N) = k_T \log N + C_T + O(1/N) .$$

Without the restriction that $\mathbb{K} = \mathbb{Q}$, it is shown that there are constants $k_T \in \mathbb{Q}$, C_T and $\delta > 0$ with

$$\mathcal{M}_T(N) = k_T \log N + C_T + O(N^{-\delta}) .$$

Diophantine Analysis as a Toolbox

Many problems in ergodic theory and dynamical system exploit ideas and results from number theory in a direct way; we illustrate this by describing a selection of dynamical problems that call on particular parts of number theory in an essential way. The example of mixing in Subsect. "Mixing and Additive Relations in Fields" is particularly striking for two reasons: the results needed from number theory are relatively recent, and the ergodic application directly motivated a further development in number theory.

Orbit Growth and Convergence

The analysis of periodic orbits – how their number grows as the length grows and how they spread out through space – is of central importance in dynamics (see Katok [48] for example). An instance of this is that for many simple kinds of dynamical systems $T: X \rightarrow X$ (where T is a continuous map of a compact metric space (X, d)) the logarithmic growth rate of the number of periodic points exists and coincides with the topological entropy $h(T)$ (an invariant giving a quantitative measure of the average rate of growth in orbit complexity under T). That is, writing

$$F_n(T) = |\{x \in X : T^n x = x\}| ,$$

we find

$$\frac{1}{n} \log F_n(T) \longrightarrow h_{\text{top}}(T) \tag{10}$$

for many of the simplest dynamical systems. For example, if $X = \mathbb{T}^r$ is the r -torus and $T = T_A$ is the automorphism of the torus corresponding to a matrix A in $GL_r(\mathbb{Z})$, then T_A is ergodic with respect to Lebesgue measure if and only if no eigenvalue of A is a root of unity. Under this assumption, we have

$$F_n(T_A) = \prod_{i=1}^r |\lambda_i^n - 1|$$

and

$$h_{\text{top}}(T_A) = \sum_{i=1}^r \log \max\{1, |\lambda_i|\} \tag{11}$$

where $\lambda_1, \dots, \lambda_r$ are the eigenvalues of A . It follows that the convergence in (10) is clear under the assumption that T_A is *hyperbolic* (that is, no eigenvalue has modulus one). Without this assumption the convergence is less clear: for $r \geq 4$ the automorphism T_A may be ergodic without being hyperbolic. That is, while no eigenvalues are unit roots some may have unit modulus. As pointed out by Lind [61] in his study of these *quasihyperbolic* automorphisms, the convergence (10) does still hold for these systems, but this requires a significant Diophantine result (the theorem of Gel'fond [35] suffices; one may also use Baker's theorem [5]). Even further from hyperbolicity lie the family of S -integer systems [21,107]; their orbit-growth properties are intimately tied up with Artin's conjecture on primitive roots and prime divisors of linear recurrence sequences.

Mixing and Additive Relations in Fields

The problem of higher-order mixing for commuting group automorphisms provides a striking example of the dialogue between ergodic theory and number theory, in which deep results from number theory have been used to solve problems in ergodic theory, and questions arising in ergodic theory have motivated further developments in number theory.

An action T of a countable group Γ on a probability space (X, \mathcal{B}, μ) is called k -fold mixing or mixing on $(k + 1)$ sets if

$$\mu(A_0 \cap T^{-g_1} A_1 \cap \dots \cap T^{-g_k} A_k) \longrightarrow \mu(A_0) \dots \mu(A_k) \tag{12}$$

as

$$g_i g_j^{-1} \longrightarrow \infty \text{ for } i \neq j$$

with the convention that $g_0 = 1_\Gamma$, for any sets $A_0, \dots, A_k \in \mathcal{B}$; $g_n \rightarrow \infty$ in Γ means that for any finite set $F \subset \Gamma$ there is an N with $n > N \implies g_n \notin F$. For $k = 1$

the property is called simply *mixing*. This notion for single transformations goes back to the foundational work of Rohlin [78], where he showed that ergodic group endomorphisms are mixing of all orders (and so the notion is not useful for distinguishing between group endomorphisms as measurable dynamical systems). He raised the (still open) question of whether any measure-preserving transformation can be mixing without being mixing of all orders.

A class of group actions that are particularly easy to understand are the *algebraic dynamical systems* studied systematically by Schmidt [83]: here X is a compact abelian group, each T^g is a continuous automorphism of X , and μ is the Haar measure on X . Schmidt [82] related mixing properties of algebraic dynamical systems with $\Gamma = \mathbb{Z}^d$ to statements in arithmetic, and showed that a mixing action on a connected group could only fail to mix in a certain way. Later Schmidt and the author [85] showed that for X connected, mixing implies mixing of all orders. The proof proceeds by showing that the result is exactly equivalent to the following statement: if \mathbb{K} is a field of characteristic zero, and G is a finitely generated subgroup of the multiplicative group \mathbb{K}^\times , then the equation

$$a_1 x_1 + \dots + a_n x_n = 1 \tag{13}$$

for fixed $a_1, \dots, a_n \in \mathbb{K}^\times$ has a finite number of solutions $x_1, \dots, x_n \in G$ for which no subsum $\sum_{i \in I} a_i x_i$ with $I \subsetneq \{1, \dots, n\}$ vanishes. The bound on the number of solutions to (13) follows from the profound extensions to W. Schmidt's subspace theorem in Diophantine geometry [86] by Evertse and Schlickewei (see [28,81,102] for the details).

The argument in [85] may be cast as follows: failure of k -fold mixing in a connected algebraic dynamical system implies (via duality) an infinite set of solutions to an equation of the shape (13) in some field of characteristic zero. The S -unit theorem means that this can only happen if there is some proper subsum that vanishes infinitely often. This infinite family of solutions to a homogeneous form of (13) with fewer terms can then be translated back via duality to show that the system fails to mix for some strictly lower order, proving that mixing implies mixing of all orders by induction.

Mixing properties for algebraic dynamical systems without the assumption of connectedness are quite different, and in particular it is possible to have mixing actions that are not mixing of all orders. This is a simple consequence of the fact that the constituents of a disconnected algebraic dynamical system are associated with fields of positive characteristic, where the presence of the

Frobenius automorphism can prevent higher-order mixing. Ledrappier [57] pointed this out via examples of the following shape. Let

$$X = \left\{ x \in \mathbb{F}_2^{\mathbb{Z}^2} : x_{(a+1,b)} + x_{(a,b)} + x_{(a,b+1)} = 0 \pmod{2} \right\}$$

and define the \mathbb{Z}^2 -action T to be the natural shift action,

$$(T^{(n,m)}x)_{(a,b)} = x_{(a+n,b+m)}.$$

It is readily seen that this action is mixing with respect to the Haar measure. The condition $x_{(a+1,b)} + x_{(a,b)} + x_{(a,b+1)} = 0 \pmod{2}$ implies that, for any $k \geq 1$,

$$x_{(0,2^k)} = \sum_{j=0}^{2^k} \binom{2^k}{j} x_{(j,0)} = x_{(0,0)} + x_{(2^k,0)} \pmod{2} \quad (14)$$

since every entry in the 2^k th row of Pascal’s triangle is even apart from the first and the last. Now let $A = \{x \in X : x_{(0,0)} = 0\}$ and let $x_* \in X$ be any element with $x_{(0,0)} = 1$. Then X is the disjoint union of A and $A + x_*$, so

$$\mu(A) = \mu(A + x_*) = \frac{1}{2}.$$

However, (14) shows that

$$x \in A \cap T_{-(2^k,0)}A \implies x \in T_{-(0,2^k)}A,$$

so

$$A \cap T_{-(2^k,0)}A \cap T_{-(0,2^k)}(A + x_*) = \emptyset$$

for all $k \geq 1$, which shows that T cannot be mixing on three sets.

The full picture of higher-order mixing properties on disconnected groups is rather involved; see Schmidt’s monograph [83]. A simple illustration is the construction by Einsiedler and the author [23] of systems with any prescribed order of mixing. When such systems fail to be mixing of all orders, they fail in a very specific way – along dilates of a specific *shape* (a finite subset of \mathbb{Z}^d). In the example above, the shape that fails to mix is $\{(0,0), (1,0), (0,1)\}$. This gives an order of mixing as detected by shapes; computing this is in principle an algebraic problem. On the other hand, there is a more natural definition of the order of mixing, namely the largest k for which (12) holds; computing this is in principle a Diophantine problem. A conjecture emerged (formulated explicitly by Schmidt [84]) that for any algebraic dynamical system, if every set of cardinality $r \geq 2$ is a mixing shape, then the system is mixing on r sets.

This question motivated Masser [64] to prove an appropriate analogue of the S -unit theorem on the number of solutions to (13) in positive characteristic as follows. Let H be a multiplicative group and fix $n \in \mathbb{N}$. An infinite subset $A \subset H^n$ is called *broad* if it has both of the following properties:

- if $h \in H$ and $1 \leq j \leq n$, then there are at most finitely many (a_1, \dots, a_n) in A with $a_j = h$;
- if $n \geq 2$, $h \in H$ and $1 \leq i < j \leq n$ then there are at most finitely many $(a_1, \dots, a_n) \in H$ with $a_i a_j^{-1} = h$.

Then Masser’s theorem says the following. Let \mathbb{K} be a field of characteristic $p > 0$, let G be a finitely-generated subgroup of \mathbb{K}^\times and suppose that the equation

$$a_1 x_1 + \dots + a_n x_n = 1$$

has a broad set of solutions $(x_1, \dots, x_n) \in G^n$ for some constants $a_1, \dots, a_n \in \mathbb{K}^\times$. Then there is an $m \leq n$, constants $b_1, \dots, b_m \in \mathbb{K}^\times$ and some $(g_1, \dots, g_m) \in G^m$ with the following properties:

- $g_j \neq 1$ for $1 \leq j \leq m$;
- $g_i g_j^{-1} \neq 1$ for $1 \leq i < j \leq m$;
- there are infinitely many k for which

$$b_1 g_1^k + b_2 g_2^k + \dots + b_m g_m^k = 1.$$

The proof that shapes detect the order of mixing in algebraic dynamics then proceeds much as in the connected case.

Future Directions

The interaction between ergodic theory, number theory and combinatorics continues to expand rapidly, and many future directions of research are discussed in the articles [► Ergodic Theory on Homogeneous Spaces and Metric Number Theory](#), [► Ergodic Theory: Rigidity](#) and [► Ergodic Theory: Recurrence](#). Some of the directions most relevant to the examples discussed in this article include the following.

The recent developments mentioned in Subsect. “[Sets of Primes](#)” clearly open many exciting prospects involving finding new structures in arithmetically significant sets (like the primes). The original conjecture of Erdős and Turán [26] asked if $\sum_{a \in A \subset \mathbb{N}} \frac{1}{a} = \infty$ is sufficient to force the set A to contain arbitrary long arithmetic progressions, and remains open. This would of course imply both Szemerédi’s theorem [97] and the result of Green and Tao [39] on arithmetic progressions in the primes. More generally, it is clear that there is still much to come from the dialogue subsuming the four parallel proofs of

Szemerédi's: one by purely combinatorial methods, one by ergodic theory, one by hypergraph theory, and one by Fourier analysis and additive combinatorics. For an overview, see the survey papers of Tao [98,99,100].

In the context of the orbit-counting results in Sect. "Orbit-Counting as an Analogous Development", a natural problem is to on the one hand obtain finer asymptotics with better control of the error terms, and on the other to extend the situations that can be handled. In particular, relaxing the hypotheses related to hyperbolicity (or negative curvature) is a constant challenge.

Ergodic Theory, Introduction to

BRYNA KRA

Northwestern University, Evanston, USA

Ergodic theory lies at the intersection of many areas of mathematics, including smooth dynamics, statistical mechanics, probability, harmonic analysis, and group actions. Problems, techniques, and results are related to many other areas of mathematics, and ergodic theory has had applications both within mathematics and to numerous other branches of science. Ergodic theory has particularly strong overlap with other branches of dynamical systems; to clarify what distinguishes it from other areas of dynamics, we start with a quick overview of dynamical systems.

Dynamical systems is the study of systems that evolve with time. The evolution of a dynamical system is given by some fixed rule that determines the states of the system a short time into the future, given only the present states. Reflecting the origins of the subject in celestial mechanics, the set of states through which the system evolves with time is called an orbit. Many important concepts in dynamical systems are related to understanding the orbits in the system: Do the orbits fill out the entire space? Do orbits collapse? Do orbits return to themselves? What are statistical properties of the orbits? Are orbits stable under perturbation? For simple dynamical systems, knowing the individual orbits is often sufficient to answer such questions. However, in most dynamical systems it is impossible to write down explicit formulae for orbits, and even when one can, many systems are too complicated to be understood just in terms of individual orbits. The orbits may only be known approximately, some orbits may appear to be random while others exhibit regular behavior, and vary-

ing the parameters defining the system may give rise to qualitatively different behaviors. The various branches of dynamical systems have been developed for understanding long term properties of the orbits.

To make the notion of a dynamical system more precise, let X denote the collection of all states of the system. The evolution of these states is given by some fixed rule $T: X \rightarrow X$, dictating where each state $x \in X$ is mapped. An application of the transformation $T: X \rightarrow X$ corresponds to the passage of a unit of time and for a positive integer n , the map $T^n = T \circ T \circ \dots \circ T$ denotes the composition of T with itself taken n times. Given a state $x \in X$, the orbit of the point x under the transformation T is the collection of iterates x, Tx, T^2x, \dots of the state x . Thus the single transformation T generates a semigroup of transformations acting on X , by considering the powers T^n . More generally, one can consider a family of transformations $\{T_t: t \in \mathbb{R}\}$ with each $T_t: X \rightarrow X$. Assuming that $T_0(x) = x$ and that $T_{t+s}(x) = T_t(T_s(x))$ for all states $x \in X$ and all real t and s , this models the evolution of continuous time in a system. Autonomous differential equations are examples of such continuous time systems.

In almost all cases of interest, the space X has some underlying structure which is preserved by the transformation T . Different underlying structures X and different properties of the transformation T give rise to different branches of dynamical systems. When X is a smooth manifold and $T: X \rightarrow X$ is a differentiable mapping, one is in the framework of differentiable dynamics. When X is a topological space and $T: X \rightarrow X$ is a continuous map, one is in the framework of topological dynamics. When X is a measure space and $T: X \rightarrow X$ is a measure preserving map, one is in the framework of ergodic theory. These categories are not mutually exclusive, and the relations among them are deep and interesting. Some of these relations are explored in the articles [► Topological Dynamics](#), [► Symbolic Dynamics](#), and [► Smooth Ergodic Theory](#).

To further explain the role of ergodic theory, a few definitions are needed. The state space X is assumed to be a measure space, endowed with a σ -algebra \mathcal{B} of measurable sets and a measure μ . The measure μ assigns each set $B \in \mathcal{B}$ a non-negative number (its measure), and usually one assumes that $\mu(X) = 1$ (thus μ is a probability measure). The transformation $T: X \rightarrow X$ is assumed to be a measurable and measure preserving map: For all $B \in \mathcal{B}$, $\mu(T^{-1}B) = \mu(B)$. The quadruple (X, \mathcal{B}, μ, T) is called a measure preserving system. For the precise definitions and background on measure preserving transformations, see the article [► Measure Preserving Systems](#). An extensive discussion of examples of measure preserving systems and basic constructions used in ergodic theory is

given in [► Ergodic Theory: Basic Examples and Constructions](#).

The origins of ergodic theory are in the nineteenth century work of Boltzmann on the foundations of statistical mechanics. Boltzmann hypothesized that for large systems of interacting particles in equilibrium, the “time average” is equal to the “space average”. This question can be reformulated in the context of modern terminology. Assume that (X, \mathcal{B}, μ, T) is a measure preserving system and that $f: X \rightarrow \mathbb{R}$ is some measurement taken on the system. Thus if $x \in X$ is a state, evaluating the sequence

$$f(x), f(Tx), f(T^2x), \dots$$

can be viewed as successive values of this measurement. Boltzmann’s question can be phrased as: Under what conditions is the time mean equal to the space mean? In short, when does

$$\lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=0}^{N-1} f(T^n x) = \int_X f \, d\mu ?$$

Boltzmann hypothesized that if orbits went “everywhere” in the space, then such a conclusion would hold.

The study of the equality of space and time averages has been a major direction of research in ergodic theory. The long term behavior of the average

$$\lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=0}^{N-1} f(T^n x),$$

and especially the existence of this limit, is a basic question. Roughly speaking, the ergodic theorem states that starting at almost any initial point, the distribution of its iterates obeys some asymptotic law. This, and more general convergence questions, are addressed in the article [► Ergodic Theorems](#).

Perhaps the earliest result in ergodic theory is the Poincaré Recurrence Theorem: In a finite measure space, some iterate of any set with positive measure intersects the set itself in a set of positive measure. More generally, the qualitative behavior of orbits is used to understand conditions under which the time average is equal to the space average of the system (see the article [► Ergodic Theory: Recurrence](#)). If the time average is equal almost everywhere to the space average, then the system is said to be ergodic. Ergodicity is a key notion, giving a simple expression for the time average of an arbitrary function. Moreover, using the Ergodic Decomposition Theorem, the study of arbitrary measure preserving systems can be reduced to ergodic ones. Ergodicity and related properties of a system

are discussed in the article ► [Ergodicity and Mixing Properties](#).

Another central problem in ergodic theory is the classification of measure preserving systems. There are various notions of equivalence, and a classical approach to checking if systems are equivalent is finding invariants that are preserved under the equivalence. This subject, including an introduction to Ornstein Theory, is covered in the article ► [Isomorphism Theory in Ergodic Theory](#). A map $T: X \rightarrow X$ determines an associated unitary operator $U = U_T$ defined on $L^2(X)$ by

$$U_T f(x) = f(Tx).$$

There are also numerical invariants that can be assigned to a system, for example entropy, and this is discussed in the article ► [Entropy in Ergodic Theory](#).

When two systems are not equivalent, one would like to understand what properties they do have in common. An essential tool in such a classification is the notion of joinings (see the article ► [Joinings in Ergodic Theory](#)). Roughly speaking, a joining is a way of embedding two systems in the same space. When this can be done in a nontrivial manner, one obtains information on properties shared by the systems.

Some systems have predictable behavior and can be classified according to the behavior of individual points and their iterates. Others have behavior that is too complex or unpredictable to be understood on the level of orbits. Ergodic theory provides a statistical understanding of such systems and this is discussed in the article ► [Chaos and Ergodic Theory](#). A prominent role in chaotic dynamical systems is played by one dimensional Gibbs measure and by equilibrium states and (see the article ► [Pressure and Equilibrium States in Ergodic Theory](#)). Rigidity theory addresses the opposite case, studying what kinds of properties in a system are obstructions to general chaotic behavior. The role of ergodic theory in this area is discussed in the article ► [Ergodic Theory: Rigidity](#).

Another important class of systems arises when one relaxes the condition that the transformation T preserves the measure of sets on X , only requiring that the transformation preserve the negligible sets. Such systems are discussed in ► [Joinings in Ergodic Theory](#).

Ergodic theory has seen a burst of recent activity, and most of this activity comes from interaction with other fields. Historically, ergodic theory has interacted with numerous fields, including other areas of dynamics, probability, statistical mechanics, and harmonic analysis. More recently, ergodic theory and its techniques have been imported into number theory and combinatorics, proving new results that have yet to be proved by other methods,

and in turn, combinatorial problems have given rise to new areas of research within ergodic theory itself. Problems related to Diophantine approximation are discussed in ► [Ergodic Theory on Homogeneous Spaces and Metric Number Theory](#) and ► [Ergodic Theory: Rigidity](#) and ones related to combinatorial problems are addressed in ► [Ergodic Theory: Interactions with Combinatorics and Number Theory](#) and in ► [Ergodic Theory: Recurrence](#). Interaction with problems that are geometric in nature, in particular dimension theory, is discussed in ► [Ergodic Theory: Fractal Geometry](#).

Nonsingular dynamical system Let (X, \mathcal{B}, μ) be a standard Borel space equipped with a σ -finite measure. A Borel map $T: X \rightarrow X$ is a *nonsingular transformation* of X if for any $N \in \mathcal{B}$, $\mu(T^{-1}N) = 0$ if and only if $\mu(N) = 0$. In this case the measure μ is called *quasi-invariant* for T ; and the quadruple (X, \mathcal{B}, μ, T) is called a *nonsingular dynamical system*. If $\mu(A) = \mu(T^{-1}A)$ for all $A \in \mathcal{B}$ then μ is said to be

invariant under T or, equivalently, T is *measure-preserving*.

Conservativeness T is *conservative* if for all sets A of positive measure there exists an integer $n > 0$ such that $\mu(A \cap T^{-n}A) > 0$.

Ergodicity T is *ergodic* if every measurable subset A of X that is invariant under T (i. e., $T^{-1}A = A$) is either μ -null or μ -conull. Equivalently, every Borel function $f: X \rightarrow \mathbb{R}$ such that $f \circ T = f$ is constant a. e.

Types II, II₁, II_∞ and III Suppose that μ is non-atomic and T ergodic (and hence conservative). If there exists a σ -finite measure ν on \mathcal{B} which is equivalent to μ and invariant under T then T is said to be of *type II*. It is easy to see that ν is unique up to scaling. If ν is finite then T is of *type II₁*. If ν is infinite then T is of *type II_∞*. If T is not of type II then T is said to be of *type III*.

Definition of the Subject

An abstract measurable dynamical system consists of a set X (phase space) with a transformation $T: X \rightarrow X$ (evolution law or time) and a finite or σ -finite measure μ on X that specifies a class of negligible subsets. Nonsingular ergodic theory studies systems where T respects μ in a weak sense: the transformation preserves only the class of negligible subsets but it may not preserve μ . This survey is about dynamics and invariants of nonsingular systems. Such systems model ‘non-equilibrium’ situations in which events that are impossible at some time remain impossible at any other time. Of course, the first question that arises is whether it is possible to find an equivalent invariant measure, i. e. pass to a hidden equilibrium without changing the negligible subsets? It turns out that there exist systems which do not admit an equivalent invariant finite or even σ -finite measure. They are of our primary interest here. In a way (Baire category) most of systems are like that.

Nonsingular dynamical systems arise naturally in various fields of mathematics: topological and smooth dynamics, probability theory, random walks, theory of numbers, von Neumann algebras, unitary representations of groups, mathematical physics and so on. They also can appear in the study of probability preserving systems: some criteria of mild mixing and distality, a problem of Furstenberg on disjointness, etc. We briefly discuss this in Sect. “Applications. Connections with Other Fields”. Nonsingular ergodic theory studies all of them from a general point of view:

- What is the qualitative nature of the dynamics?
- What are the orbits?
- Which properties are typical withing a class of systems?

- How do we find computable invariants to compare or distinguish various systems?

Typically there are two kinds of results: some are extensions to nonsingular systems of theorems for finite measure-preserving transformations (for instance, the entire Sect. “Basic Results”) and the other are about new properly ‘nonsingular’ phenomena (see Sect. “Mixing Notions and Multiple Recurrence” or Sect. “Orbit Theory”). Philosophically speaking, the dynamics of nonsingular systems is more diverse comparatively with their finite measure-preserving counterparts. That is why it is usually easier to construct counterexamples than to develop a general theory. Because of shortage of space we concentrate only on invertible transformations, and we have not included as many references as we had wished. Nonsingular endomorphisms and general group or semigroup actions are practically not considered here (with some exceptions in Sect. “Applications. Connections with Other Fields” devoted to applications). A number of open problems are scattered through the entire text.

We thank J. Aaronson, J.R. Choksi, V.Ya. Golodets, M. Lemańczyk, F. Parreau, E. Roy for useful remarks.

Basic Results

This section includes the basic results involving conservativeness and ergodicity as well as some direct nonsingular counterparts of the basic machinery from classic ergodic theory: mean and pointwise ergodic theorems, Rokhlin lemma, ergodic decomposition, generators, Glimm–Effros theorem and special representation of nonsingular flows. The historically first example of a transformation of type III (due to Ornstein) is also given here with full proof.

Nonsingular Transformations

In this paper we will consider only *invertible* nonsingular transformations, i. e. those which are bijections when restricted to an invariant Borel subset of full measure. Thus when we refer to a nonsingular dynamical system (X, \mathcal{B}, μ, T) we shall assume that T is an invertible nonsingular transformation. Of course, each measure ν on \mathcal{B} which is *equivalent* to μ , i. e. μ and ν have the same null sets, is also quasi-invariant under T . In particular, since μ is σ -finite, T admits an equivalent quasi-invariant probability measure. For each $i \in \mathbb{Z}$, we denote by ω_i^μ or ω_i the Radon–Nikodym derivative $d(\mu \circ T^i)/d\mu \in L^1(X, \mu)$. The derivatives satisfy the cocycle equation $\omega_{i+j}(x) = \omega_i(x) \omega_j(T^i x)$ for a. e. x and all $i, j \in \mathbb{Z}$.

Basic Properties of Conservativeness and Ergodicity

A measurable set W is said to be *wandering* if for all $i, j \geq 0$ with $i \neq j$, $T^{-i}W \cap T^{-j}W = \emptyset$. Clearly, if T has a wandering set of positive measure then it cannot be conservative. A nonsingular transformation T is *incompressible* if whenever $T^{-1}C \subset C$, then $\mu(C \setminus T^{-1}C) = 0$. A set W of positive measure is said to be *weakly wandering* if there is a sequence $n_i \rightarrow \infty$ such that $T^{n_i}W \cap T^{n_j}W = \emptyset$ for all $i \neq j$. Clearly, a finite measure-preserving transformation cannot have a weakly wandering set. Hajian and Kakutani [83] showed that a nonsingular transformation T admits an equivalent finite invariant measure if and only if T does not have a weakly wandering set.

Proposition 1 (see e. g. [123]) *Let (X, \mathcal{B}, μ, T) be a nonsingular dynamical system. The following are equivalent:*

- (i) T is conservative.
- (ii) For every measurable set A , $\mu(A \setminus \bigcup_{n=1}^{\infty} T^{-n}A) = 0$.
- (iii) T is incompressible.
- (iv) Every wandering set for T is null.

Since any finite measure-preserving transformation is incompressible, we deduce that it is conservative. This is the statement of the classical Poincaré recurrence lemma. If T is a conservative nonsingular transformation of (X, \mathcal{B}, μ) and $A \in \mathcal{B}$ a subset of positive measure, we can define an *induced transformation* T_A of the space $(A, \mathcal{B} \cap A, \mu \upharpoonright A)$ by setting $T_A x := T^n x$ if $n = n(x)$ is the smallest natural number such that $T^n x \in A$. T_A is also conservative. As shown in [179], if $\mu(X) = 1$ and T is conservative and ergodic, $\int_A \sum_{i=0}^{n(x)-1} \omega(x) d\mu(x) = 1$, which is a nonsingular version of the well-known Kac’s formula.

Theorem 2 (Hopf Decomposition, see e. g. [3]) *Let T be a nonsingular transformation. Then there exist disjoint invariant sets $C, D \in \mathcal{B}$ such that $X = C \sqcup D$, T restricted to C is conservative, and $D = \bigsqcup_{n=-\infty}^{\infty} T^n W$, where W is a wandering set. If $f \in L^1(X, \mu)$, $f > 0$, then $C = \{x: \sum_{i=0}^{n(x)-1} f(T^i x) \omega_i(x) = \infty \text{ a. e.}\}$ and $D = \{x: \sum_{i=0}^{n(x)-1} f(T^i x) \omega_i(x) < \infty \text{ a. e.}\}$.*

The set C is called the *conservative part* of T and D is called the *dissipative part* of T .

If T is ergodic and μ is non-atomic then T is automatically conservative. The translation by 1 on the group \mathbb{Z} furnished with the counting measure is an example of an ergodic non-conservative (infinite measure-preserving) transformation.

Proposition 4 *Let (X, \mathcal{B}, μ, T) be a nonsingular dynamical system. The following are equivalent:*

- (i) T is conservative and ergodic.

- (ii) For every set A of positive measure, $\mu(X \setminus \bigcup_{n=1}^{\infty} T^{-n}A) = 0$. (In this case we will say A sweeps out.)
- (iii) For every measurable set A of positive measure and for a. e. $x \in X$ there exists an integer $n > 0$ such that $T^n x \in A$.
- (iv) For all sets A and B of positive measure there exists an integer $n > 0$ such that $\mu(T^{-n}A \cap B) > 0$.
- (v) If A is such that $T^{-1}A \subset A$, then $\mu(A) = 0$ or $\mu(A^c) = 0$.

This survey is mainly about systems of type III. For some time it was not quite obvious whether such systems exist at all. The historically first example was constructed by Ornstein in 1960.

Example 5 (Ornstein [149]) Let $A_n = \{0, 1, \dots, n\}$, $\nu_n(0) = 0.5$ and $\nu_n(i) = 1/(2n)$ for $0 < i \leq n$ and all $n \in \mathbb{N}$. Denote by (X, μ) the infinite product probability space $\bigotimes_{n=1}^{\infty} (A_n, \nu_n)$. Of course, μ is non-atomic. A point of X is an infinite sequence $x = (x_n)_{n=1}^{\infty}$ with $x_n \in A_n$ for all n . Given $a_1 \in A_1, \dots, a_n \in A_n$, we denote the cylinder $\{x = (x_i)_{i=1}^{\infty} \in X: x_1 = a_1, \dots, x_n = a_n\}$ by $[a_1, \dots, a_n]$. Define a Borel map $T: X \rightarrow X$ by setting

$$(Tx)_i = \begin{cases} 0, & \text{if } i < l(x) \\ x_i + 1, & \text{if } i = l(x) \\ x_i, & \text{if } i > l(x), \end{cases} \tag{1}$$

where $l(x)$ is the smallest number l such that $x_l \neq l$. It is easy to verify that T is a nonsingular transformation of (X, μ) and

$$\begin{aligned} \frac{d\mu \circ T}{d\mu}(x) &= \prod_{n=1}^{\infty} \frac{\nu_n((Tx)_n)}{\nu_n(x_n)} \\ &= \begin{cases} (l(x) - 1)! & \text{if } x_{l(x)} = 0 \\ l(x) & \text{if } x_{l(x)} \neq 0. \end{cases} \end{aligned}$$

We prove that T is of type III by contradiction. Suppose that there exists a T -invariant σ -finite measure ν equivalent to μ . Let $\varphi := d\mu/d\nu$. Then

$$\omega_i^\mu(x) = \varphi(x) \varphi(T^i x)^{-1} \text{ for a. a. } x \in X \text{ and all } i \in \mathbb{Z}. \tag{2}$$

Fix a real $C > 1$ such that the set $E_C := \varphi^{-1}([C^{-1}, C]) \subset X$ is of positive measure. By a standard approximation argument, for each sufficiently large n , there is a cylinder $[a_1, \dots, a_n]$ such that $\mu(E_C \cap [a_1, \dots, a_n]) > 0.9\mu([a_1, \dots, a_n])$. Since $\nu_{n+1}(0) = 0.5$, it follows that $\mu(E_C \cap [a_1, \dots, a_n, 0]) > 0.8\mu([a_1, \dots, a_n, 0])$. Moreover, by the pigeon hole principle there is $0 < i \leq n+1$ with $\mu(E_C \cap$

$[a_1, \dots, a_n, i] > 0.8\mu([a_1, \dots, a_n, i])$. Find $N_n > 0$ such that $T^{N_n}[a_1, \dots, a_n, 0] = [a_1, \dots, a_n, i]$. Since $\omega_{N_n}^\mu$ is constant on $[a_1, \dots, a_n, 0]$, there is a subset $E_0 \subset E_C \cap [a_1, \dots, a_n, 0]$ of positive measure such that $T^{N_n}E_0 \subset E_C \cap [a_1, \dots, a_n, i]$. Moreover, $\omega_{N_n}^\mu(x) = \nu_{n+1}(i)/\nu_{n+1}(0) = (n+1)^{-1}$ for a.a. $x \in [a_1, \dots, a_n, 0]$. On the other hand, we deduce from (2) that $\omega_{N_n}^\mu(x) \geq C^{-2}$ for all $x \in E_0$, a contradiction.

Mean and Pointwise Ergodic Theorems.

Rokhlin Lemma

Let (X, \mathcal{B}, μ, T) be a nonsingular dynamical system. Define a unitary operator U_T of $L^2(X, \mu)$ by setting

$$U_T f := \sqrt{\frac{d(\mu \circ T)}{d\mu}} \cdot f \circ T. \tag{3}$$

We note that U_T preserves the cone of positive functions $L^2_+(X, \mu)$. Conversely, every positive unitary operator in $L^2(X, \mu)$ that preserves $L^2_+(X, \mu)$ equals U_T for a μ -nonsingular transformation T .

Theorem 6 (von Neumann mean Ergodic Theorem, see e. g. [3]) *If T has no μ -absolutely continuous T -invariant probability, then $n^{-1} \sum_{i=0}^{n-1} U_T^i \rightarrow 0$ in the strong operator topology.*

Denote by \mathcal{I} the sub- σ -algebra of T -invariant sets. Let $\mathbb{E}_\mu[\cdot|\mathcal{I}]$ stand for the conditional expectation with respect to \mathcal{I} . Note that if T is ergodic, then $\mathbb{E}_\mu[f|\mathcal{I}] = \int f d\mu$. Now we state a nonsingular analogue of Birkhoff's pointwise ergodic theorem, due to Hurewicz [105] and in the form stated by Halmos [84].

Theorem 7 (Hurewicz pointwise Ergodic Theorem) *If T is conservative, $\mu(X) = 1$, $f, g \in L^1(X, \mu)$ and $g > 0$, then*

$$\frac{\sum_{i=0}^{n-1} f(T^i x) \omega_i(x)}{\sum_{i=0}^{n-1} g(T^i x) \omega_i(x)} \rightarrow \frac{\mathbb{E}_\mu[f|\mathcal{I}]}{\mathbb{E}_\mu[g|\mathcal{I}]} \text{ as } n \rightarrow \infty \text{ for a. e. } x.$$

A transformation T is *aperiodic* if the T -orbit of a. e. point from X is infinite. The following classical statement can be deduced easily from Proposition 1.

Lemma 8 (Rokhlin's lemma [161]) *Let T be an aperiodic nonsingular transformation. For each $\varepsilon > 0$ and integer $N > 1$ there exists a measurable set A such that the sets $A, TA, \dots, T^{N-1}A$ are disjoint and $\mu(A \cup TA \cup \dots \cup T^{N-1}A) > 1 - \varepsilon$.*

This lemma was refined later (for ergodic transformations) by Lehrer and Weiss as follows.

Theorem 9 (ε -free Rokhlin lemma [132]) *Let T be ergodic and μ non-atomic. Then for a subset $B \subset X$ and any N for which $\bigcup_{k=0}^\infty T^{-kN}(X \setminus B) = X$, there is a set A such that the sets $A, TA, \dots, T^{N-1}A$ are disjoint and $A \cup TA \cup \dots \cup T^{N-1}A \supset B$.*

The condition $\bigcup_{k=0}^\infty T^{-kN}(X \setminus B) = X$ holds of course for each $B \neq X$ if T is *totally ergodic*, i. e. T^p is ergodic for any p , or if N is prime.

Ergodic Decomposition

A proof of the following theorem may be found in [3].

Theorem 10 (Ergodic Decomposition Theorem) *Let T be a conservative nonsingular transformation on a standard probability space (X, \mathcal{B}, μ) . There there exists a standard probability space (Y, ν, \mathcal{A}) and a family of probability measures μ_y on (X, \mathcal{B}) , for $y \in Y$, such that*

- (i) *For each $A \in \mathcal{B}$ the map $y \mapsto \mu_y(A)$ is Borel and for each $A \in \mathcal{B}$*

$$\mu(A) = \int \mu_y(A) d\nu(y).$$

- (ii) *For $y, y' \in Y$ the measures μ_y and $\mu_{y'}$ are mutually singular.*
- (iii) *For each $y \in Y$ the transformation T is nonsingular and conservative, ergodic on (X, \mathcal{B}, μ_y) .*
- (iv) *For each $y \in Y$*

$$\frac{d\mu \circ T}{d\mu} = \frac{d\mu_y \circ T}{d\mu_y} \mu_{y \circ a. e.}$$

- (v) *(Uniqueness) If there exists another probability space (Y', ν', \mathcal{A}') and a family of probability measures $\mu'_{y'}$ on (X, \mathcal{B}) , for $y' \in Y'$, satisfying (i)–(iv), then there exists a measure-preserving isomorphism $\theta: Y \rightarrow Y'$ such that $\mu_y = \mu'_{\theta y}$ for ν -a. e. y .*

It follows that if T preserves an equivalent σ -finite measure then the system $(X, \mathcal{B}, \mu_y, T)$ is of type II for a. a. y . The space (Y, ν, \mathcal{A}) is called *the space of T -ergodic components*.

Generators

It was shown in [157,162] that a nonsingular transformation T on a standard probability space (X, \mathcal{B}, μ) has a *countable generator*, i. e. a countable partition \mathcal{P} so that $\bigvee_{n=-\infty}^\infty T^n \mathcal{P}$ generates the measurable sets. It was refined by Krengel [126]: if T is of

type II_∞ or III then there exists a generator P consisting of two sets only. Moreover, given a sub- σ -algebra $\mathcal{F} \subset \mathcal{B}$ such that $\mathcal{F} \subset T\mathcal{F}$ and $\bigcup_{k>0} T^k\mathcal{F} = \mathcal{B}$, the set $\{A \in \mathcal{F} \mid (A, X \setminus A) \text{ is a generator of } T\}$ is dense in \mathcal{F} . It follows, in particular, that T is isomorphic to the shift on $\{0, 1\}^{\mathbb{Z}}$ equipped with a quasi-invariant probability measure.

The Glimm–Effros Theorem

The classical Bogoliouboff–Krylov theorem states that each homeomorphism of a compact space admits an ergodic invariant probability measure [33]. The following statement by Glimm [76] and Effros [61] is a “nonsingular” analogue of that theorem. (We consider here only a particular case of \mathbb{Z} -actions.)

Theorem 11 *Let X be a Polish space and $T: X \rightarrow X$ an aperiodic homeomorphism. Then the following are equivalent:*

- (i) T has a recurrent point x , i. e. $x = \lim_{n \rightarrow \infty} T^{n_i} x$ for a sequence $n_1 < n_2 < \dots$.
- (ii) There is an orbit of T which is not locally closed.
- (iii) There is no a Borel set which intersects each orbit of T exactly once.
- (iv) There is a continuous probability Borel measure μ on X such that (X, μ, T) is an ergodic nonsingular system.

A natural question arises: under the conditions of the theorem how many such μ can exist? It turns out that there is a wealth of such measures. To state a corresponding result we first write an important definition.

Definition 12 Two nonsingular systems (X, \mathcal{B}, μ, T) and $(X, \mathcal{B}', \mu', T')$ are called *orbit equivalent* if there is a one-to-one bi-measurable map $\varphi: X \rightarrow X$ with $\mu' \circ \varphi \sim \mu$ and such that φ maps the T -orbit of x onto the T' -orbit of $\varphi(x)$ for a. a. $x \in X$.

The following theorem was proved in [116,128] and [174].

Theorem 13 *Let (X, T) be as in Theorem 11. Then for each ergodic dynamical system (Y, C, ν, S) of type II_∞ or III, there exist uncountably many mutually disjoint Borel measures μ on X such that (X, T, \mathcal{B}, μ) is orbit equivalent to (Y, C, ν, S) .*

On the other hand, T may not have any finite invariant measure. Indeed, let T be an irrational rotation on the circle \mathbb{T} and X a non-empty T -invariant G_δ subset of \mathbb{T} of full Lebesgue measure. Let (X, T) contain a recurrent point. Then the unique ergodicity of (\mathbb{T}, T) implies that (X, T) has no finite invariant measures.

Let T be an aperiodic Borel transformation of a standard Borel space X . Denote by $\mathcal{M}(T)$ the set of all ergodic T -nonsingular continuous measures on X . Given $\mu \in \mathcal{M}(T)$, let $N(\mu)$ denote the family of all Borel μ -null subsets. Shelah and Weiss showed [178] that $\bigcap_{\mu \in \mathcal{M}(T)} N(\mu)$ coincides with the collection of all Borel T -wandering sets.

Special Representations of Ergodic Flows

Nonsingular flows (= \mathbb{R} -actions) appear naturally in the study of orbit equivalence for systems of type III (see Sect. “Orbit Theory”). Here we record some basic notions related to nonsingular flows. Let (X, \mathcal{B}, μ) be a standard Borel space with a σ -finite measure μ on \mathcal{B} . A nonsingular flow on (X, μ) is a Borel map $S: X \times \mathbb{R} \ni (x, t) \mapsto S_t x \in X$ such that $S_t S_s = S_{t+s}$ for all $s, t \in \mathbb{R}$ and each S_t is a nonsingular transformation of (X, μ) . Conservativeness and ergodicity for flows are defined in a similar way as for transformations.

A very useful example of a flow is a flow built under a function. Let (X, \mathcal{B}, μ, T) be a nonsingular dynamical system and f a positive Borel function on X such that $\sum_{i=0}^\infty f(T^i x) = \sum_{i=0}^\infty f(T^{-i} x) = \infty$ for all $x \in X$. Set $X^f := \{(x, s): x \in X, 0 \leq s < f(x)\}$. Define μ^f to be the restriction of the product measure $\mu \times \text{Leb}$ on $X \times \mathbb{R}$ to X^f and define, for $t \geq 0$,

$$S_t^f(x, s) := \left(T^n x, s + t - \sum_{i=0}^{n-1} f(T^i x) \right),$$

where n is the unique integer that satisfies

$$\sum_{i=0}^{n-1} f(T^i x) < s + t \leq \sum_{i=0}^n f(T^i x).$$

A similar definition applies when $t < 0$. In particular, when $0 < s + t < \varphi(x)$, $S_t^f(x, s) = (x, s + t)$, so that the flow moves the point (x, s) up t units, and when it reaches $(x, \varphi(x))$ it is sent to $(Tx, 0)$. It can be shown that $S^f = (S_t^f)_{t \in \mathbb{R}}$ is a free μ^f -nonsingular flow and that it preserves μ^f if and only if T preserves μ [148]. It is called the *flow built under the function φ with the base transformation T* . Of course, S^f is conservative or ergodic if and only if so is T .

Two flows $S = (S_t)_{t \in \mathbb{R}}$ on (X, \mathcal{B}, μ) and $V = (V_t)_{t \in \mathbb{R}}$ on (Y, C, ν) are said to be *isomorphic* if there exist invariant co-null sets $X' \subset X$ and $Y' \subset Y$ and an invertible nonsingular map $\rho: X' \rightarrow Y'$ that intertwines the actions of the flows: $\rho \circ S_t = V_t \circ \rho$ on X' for all t . The following nonsingular version of Ambrose–Kakutani representation theorem was proved by Krengel [120] and Kubo [130].

Theorem 14 *Let S be a free nonsingular flow. Then it is isomorphic to a flow built under a function.*

Rudolph showed that in the Ambrose–Kakutani theorem one can choose the function φ to take two values. Krenge[122] showed that this can also be assumed in the non-singular case.

Panorama of Examples

This section is devoted entirely to examples of nonsingular systems. We describe here the most popular (and simple) constructions of nonsingular systems: odometers, nonsingular Markov odometers, tower transformations, rank-one and finite rank systems and nonsingular Bernoulli shifts.

Nonsingular Odometers

Given a sequence m_n of natural numbers, we let $A_n := \{0, 1, \dots, m_n - 1\}$. Let ν_n be a probability on A_n and $\nu_n(a) > 0$ for all $a \in A_n$. Consider now the infinite product probability space $(X, \mu) := \prod_{n=1}^{\infty} (A_n, \nu_n)$. Assume that $\prod_{n=1}^{\infty} \max\{\nu_n(a) \mid a \in A_n\} = 0$. Then μ is non-atomic. Given $a_1 \in A_1, \dots, a_n \in A_n$, we denote by $[a_1, \dots, a_n]$ the cylinder $x = (x_i)_{i>0} \mid x_1 = a_1, \dots, x_n = a_n$. If $x \neq (0, 0, \dots)$, we let $l(x)$ be the smallest number l such that the l th coordinate of x is not $m_l - 1$. We define a Borel map $T: X \rightarrow X$ by (1) if $x \neq (m_1, m_2, \dots)$ and put $Tx := (0, 0, \dots)$ if $x = (m_1, m_2, \dots)$. Of course, T is isomorphic to a rotation on a compact monothetic totally disconnected Abelian group. It is easy to check that T is μ -nonsingular and

$$\begin{aligned} \frac{d\mu \circ T}{d\mu}(x) &= \prod_{n=1}^{\infty} \frac{\nu_n((Tx)_n)}{\nu_n(x_n)} \\ &= \frac{\nu_{l(x)}(x_{l(x)} + 1)}{\nu_{l(x)}(x_{l(x)})} \prod_{n=1}^{l(x)-1} \frac{\nu_n(0)}{\nu_n(m_n - 1)} \end{aligned}$$

for a. a. $x = (x_n)_{n>0} \in X$. It is also easy to verify that T is ergodic. It is called the *nonsingular odometer* associated to $(m_n, \nu_n)_{n=1}^{\infty}$. We note that Ornstein’s transformation (Example 5) is a nonsingular odometer.

Markov Odometers

We define Markov odometers as in [54]. An ordered Bratteli diagram B [102] consists of

- (i) a vertex set V which is a disjoint union of finite sets $V^{(n)}, n \geq 0, V_0$ is a singleton;
- (ii) an edge set E which is a disjoint union of finite sets $E^{(n)}, n > 0$;

- (iii) source mappings $s_n: E^{(n)} \rightarrow V^{(n-1)}$ and range mappings $r_n: E^{(n)} \rightarrow V^{(n)}$ such that $s_n^{-1}(v) \neq \emptyset$ for all $v \in V^{(n-1)}$ and $r_n^{-1}(v) \neq \emptyset$ for all $v \in V^{(n)}, n > 0$;
- (iv) a partial order on E so that $e, e' \in E$ are comparable if and only if $e, e' \in E^{(n)}$ for some n and $r_n(e) = r_n(e')$.

A *Bratteli compactum* X_B of the diagram B is the space of infinite paths

$$\{x = (x_n)_{n>0} \mid x_n \in E^{(n)} \text{ and } r(x_n) = s(x_{n+1})\}$$

on B . X_B is equipped with the natural topology induced by the product topology on $\prod_{n>0} E^{(n)}$. We will assume always that the diagram is *essentially simple*, i. e. there is only one infinite path $x_{\max} = (x_n)_{n>0}$ with x_n maximal for all n and only one $x_{\min} = (x_n)_{n>0}$ with x_n minimal for all n . The *Bratteli–Vershik* map $T_B: X_B \rightarrow X_B$ is defined as follows: $Tx_{\max} = x_{\min}$. If $x = (x_n)_{n>0} \neq x_{\max}$ then let k be the smallest number such that x_k is not maximal. Let y_k be a successor of x_k . Let (y_1, \dots, y_k) be the unique path such that y_1, \dots, y_{k-1} are all minimal. Then we let $T_Bx := (y_1, \dots, y_k, x_{k+1}, x_{k+2}, \dots)$. It is easy to see that T_B is a homeomorphism of X_B . Suppose that we are given a sequence $P^{(n)} = (P_{(v,e) \in V^{n-1} \times E^{(n)}}^{(n)})$ of stochastic matrices, i. e.

- (i) $P_{v,e}^{(n)} > 0$ if and only if $v = s_n(e)$ and
- (ii) $\sum_{\{e \in E^{(n)} \mid s_n(e)=v\}} P_{v,e}^{(n)} = 1$ for each $v \in V^{(n-1)}$.

For $e_1 \in E^{(1)}, \dots, e_n \in E^{(n)}$, let $[e_1, \dots, e_n]$ denote the cylinder $\{x = (x_j)_{j>0} \mid x_1 = e_1, \dots, x_n = e_n\}$. Then we define a *Markov measure* on X_B by setting

$$\mu_P([e_1, \dots, e_n]) = P_{s_1(e_1), e_1}^1 P_{s_2(e_2), e_2}^2 \cdots P_{s_n(e_n), e_n}^n$$

for each cylinder $[e_1, \dots, e_n]$. The dynamical system (X_B, μ_P, T_B) is called a *Markov odometer*. It is easy to see that every nonsingular odometer is a Markov odometer where the corresponding $V^{(n)}$ are all singletons.

Tower Transformations

This construction is a discrete analogue of flow under a function. Given a nonsingular dynamical system (X, μ, T) and a measurable map $f: X \rightarrow \mathbb{N}$, we define a new dynamical system (X^f, μ^f, T^f) by setting

$$\begin{aligned} X^f &:= \{(x, i) \in X \times \mathbb{Z}_+ \mid 0 \leq i < f(x)\}, \\ d\mu^f(x, i) &:= d\mu(x) \quad \text{and} \\ T^f(x, i) &:= \begin{cases} (x, i + 1), & \text{if } i + 1 < f(x) \\ (Tx, 0), & \text{otherwise.} \end{cases} \end{aligned}$$

Then T^f is μ^f -nonsingular and $(d\mu^f \circ T^f/d\mu^f)(x, i) = (d\mu \circ T/d\mu)(x)$ for a. a. $(x, i) \in X^f$. This transformation is called the (Kakutani) *tower over T with height function f* . It is easy to check that T^f is conservative if and only if T is conservative; T^f is ergodic if and only if T is ergodic; T^f is of type III if and only if T is of type III. Moreover, the induced transformation $(T^f)_{X \times \{0\}}$ is isomorphic to T . Given a subset $A \subset X$ of positive measure, T is the tower over the induced transformation T_A with the first return time to A as the height function.

Rank-One Transformations. Chacón Maps. Finite Rank

The definition uses the process of “cutting and stacking”. We construct by induction a sequence of columns C_n . A column C_n consists of a finite sequence of bounded intervals (left-closed, right-open) $C_n = \{I_{n,0}, \dots, I_{n,h_n-1}\}$ of height h_n . A column C_n determines a column map T_{C_n} that sends each interval $I_{n,i}$ to the interval above it $I_{n,i+1}$ by the unique orientation-preserving affine map between the intervals. T_{C_n} remains undefined on the top interval I_{n,h_n-1} . Set $C_0 = \{[0, 1]\}$ and let $\{r_n > 2\}$ be a sequence of positive integers, let $\{s_n\}$ be a sequence of functions $s_n: \{0, \dots, r_n - 1\} \rightarrow \mathbb{N}_0$, and let $\{w_n\}$ be a sequence of probability vectors on $\{0, \dots, r_n - 1\}$. If C_n has been defined, column C_{n+1} is defined as follows. First “cut” (i. e., subdivide) each interval $I_{n,i}$ in C_n into r_n subintervals $I_{n,i}[j]$, $j = 0, \dots, r_n - 1$, whose lengths are in the proportions $w_n(0) : w_n(1) : \dots : w_n(r_n - 1)$. Next place, for each $j = 0, \dots, r_n - 1$, $s_n(j)$ new subintervals above $I_{n,h_n-1}[j]$, all of the same length as $I_{n,h_n-1}[j]$. Denote these intervals, called *spacers*, by $S_{n,0}[j], \dots, S_{n,s_n(j)-1}[j]$. This yields, for each $j \in \{0, \dots, r_n - 1\}$, r_n subcolumns each consisting of the subintervals

$$I_{n,0}[j], \dots, I_{n,h_n-1}[j]$$

followed by the spacers $S_{n,0}[j], \dots, S_{n,s_n(j)-1}[j]$.

Finally each subcolumn is stacked from left to right so that the top subinterval in subcolumn j is sent to the bottom subinterval in subcolumn $j + 1$, for $j = 0, \dots, r_n - 2$ (by the unique orientation-preserving affine map between the intervals). For example, $S_{n,s_n(0)-1}[0]$ is sent to $I_{n,0}[1]$. This defines a new column C_{n+1} and new column map $T_{C_{n+1}}$, which remains undefined on its top subinterval. Let X be the union of all intervals in all columns and let μ be Lebesgue measure restricted to X . We assume that as $n \rightarrow \infty$ the maximal length of the intervals in C_n converges to 0, so we may define a transformation T of (X, μ) by $Tx := \lim_{n \rightarrow \infty} T_{C_n}x$. One can verify that T is well-defined a. e. and that it is nonsingular and ergodic. T is

said to be the *rank-one* transformation associated with $(r_n, w_n, s_n)_{n=1}^\infty$. If all the probability vectors w_n are uniform the resulting transformation is measure-preserving. The measure is infinite (σ -finite) if and only if the total mass of the spacers is infinite. In the case $r_n = 3$ and $s_n(0) = s_n(2) = 0, s_n(1) = 1$ for all $n \geq 0$, the associated rank-one transformation is called a *nonsingular Chacón map*.

It is easy to see that every nonsingular odometer is of rank-one (the corresponding maps s_n are all trivial). Each rank-one map T is a tower over a nonsingular odometer (to obtain such an odometer reduce T to a column C_n).

A rank N transformation is defined in a similar way. A nonsingular transformation T is said to be of *rank N or less* if at each stage of its construction there exists N disjoint columns, the levels of the columns generate the σ -algebra and the Radon–Nikodym derivative of T is constant on each non-top level of every column. T is said to be of *rank N* if it is of rank N or less and not of rank $N - 1$ or less. A rank N transformation, $N \geq 2$, need not be ergodic.

Nonsingular Bernoulli Transformations – Hamachi’s Example

A *nonsingular Bernoulli* transformation is a transformation T such that there exists a countable generator \mathcal{P} (see Subsect. “Generators”) such that the partitions $T^n \mathcal{P}$, $n \in \mathbb{Z}$, are mutually independent and such that the Radon–Nikodym derivative ω_1 is measurable with respect to the sub- σ -algebra $\bigvee_{n=-\infty}^0 T^n \mathcal{P}$.

In [87], Hamachi constructed examples of conservative nonsingular Bernoulli transformations, hence ergodic (see Subsect. “Weak Mixing, Mixing, K -Property”), with a 2-set generating partition that are of type III. Krenge [121] asked if there are of type II_∞ examples of nonsingular Bernoulli automorphisms and the question remains open. Hamachi’s construction is the left-shift on the space $X = \prod_{n=-\infty}^\infty \{0, 1\}$. The measure is a product $\mu = \prod_{n=-\infty}^\infty \mu_n$ where $\mu_n = (1/2, 1/2)$ for $n \geq 0$ and for $n < 0$ μ_n is chosen carefully alternating on large blocks between the uniform measure and different non-uniform measures. Kakutani’s criterion for equivalence of infinite product measures is used to verify that μ is nonsingular.

Mixing Notions and multiple recurrence

The study of mixing and multiple recurrence are central topics in classical ergodic theory [33,70]. Unfortunately, these notions are considerably less ‘smooth’ in the world of nonsingular systems. The very concepts of any kind of mixing and multiple recurrence are not well understood in view of their ambiguity. Below we discuss nonsingular

systems possessing a surprising diversity of such properties that seem equivalent but are different indeed.

Weak Mixing, Mixing, K-Property

Let T be an ergodic conservative nonsingular transformation. A number $\lambda \in \mathbb{C}$ is an L^∞ -eigenvalue for T if there exists a nonzero $f \in L^\infty$ so that $f \circ T = \lambda f$ a. e. It follows that $|\lambda| = 1$ and f has constant modulus, which we assume to be 1. Denote by $e(T)$ the set of all L^∞ -eigenvalues of T . T is said to be *weakly mixing* if $e(T) = \{1\}$. We refer to Theorem 2.7.1 in [3] for proof of the following Keane’s ergodic multiplier theorem: given an ergodic probability preserving transformation S , the product transformation $T \times S$ is ergodic if and only if $\sigma_S(e(T)) = 0$, where σ_S denotes the measure of (reduced) maximal spectral type of the unitary U_S (see (3)). It follows that T is weakly mixing if and only $T \times S$ is ergodic for every ergodic probability preserving S . While in the finite measure-preserving case this implies that $T \times T$ is ergodic, it was shown in [5] that there exists a weakly mixing nonsingular T with $T \times T$ not conservative, hence not ergodic. In [11], a weakly mixing T was constructed with $T \times T$ conservative but not ergodic. A nonsingular transformation T is said to be *doubly ergodic* if for all sets of positive measure A and B there exists an integer $n > 0$ such that $\mu(A \cap T^{-n}A) > 0$ and $\mu(A \cap T^{-n}B) > 0$. Furstenberg [70] showed that for finite measure-preserving transformations double ergodicity is equivalent to weak mixing. In [20] it is shown that for nonsingular transformations weak mixing does not imply double ergodicity and double ergodicity does not imply that $T \times T$ is ergodic.

T is said to have *ergodic index* k if the Cartesian product of k copies of T is ergodic but the product of $k + 1$ copies of T is not ergodic. If all finite Cartesian products of T are ergodic then T is said to have *infinite ergodic index*. Parry and Kakutani [113] constructed for each $k \in \mathbb{N} \cup \{\infty\}$, an infinite Markov shift of ergodic index k . A stronger property is *power weak mixing*, which requires that for all nonzero integers k_1, \dots, k_r the product $T^{k_1} \times \dots \times T^{k_r}$ is ergodic [47]. The following examples were constructed in [12,36,38]:

- (i) power weakly mixing rank-one transformations,
- (ii) non-power weakly mixing rank-one transformations with infinite ergodic index,
- (iii) non-power weakly mixing rank-one transformations with infinite ergodic index and such that $T^{k_1} \times \dots \times T^{k_r}$ are all conservative, $k_1, \dots, k_r \in \mathbb{Z}$,

of types II_∞ and III (and various subtypes of III, see Sect. “Orbit Theory”). Thus we have the following scale

of properties (equivalent to weak mixing in the probability preserving case), where every next property is strictly stronger than the previous ones:

- T is weakly mixing $\iff T$ is doubly ergodic
- $\iff T \times T$ is ergodic
- $\iff T \times T \times T$ is ergodic
- $\iff \dots$
- $\iff T$ has infinite ergodic index
- $\iff T$ is power weakly mixing .

We also mention a recent example of a power weakly mixing transformation of type II_∞ which embeds into a flow [46].

We now consider several attempts to generalize the notion of (strong) mixing. Given a sequence of measurable sets $\{A_n\}$ let $\sigma_k(\{A_n\})$ denote the σ -algebra generated by A_k, A_{k+1}, \dots . A sequence $\{A_n\}$ is said to be *remotely trivial* if $\bigcap_{k=0}^\infty \sigma_k(\{A_n\}) = \{\emptyset, X\} \text{ mod } \mu$, and it is *semi-remotely trivial* if every subsequence contains a subsequence that is remotely trivial. Krengel and Sucheston [124] define a nonsingular transformation T of a σ -finite measure space to be *mixing* if for every set A of finite measure the sequence $\{T^{-n}A\}$ is semi-remotely trivial, and *completely mixing* if $\{T^{-n}A\}$ is semi-remotely trivial for all measurable sets A . They show that T is completely mixing if and only if it is type II_1 and mixing for the equivalent finite invariant measure. Thus there are no type III and II_∞ completely mixing nonsingular transformations on probability spaces. We note that this definition of mixing in infinite measure spaces depends on the choice of measure inside the equivalence class (but it is independent if we replace the measure by an equivalent measure with the same collection of sets of finite measure).

Hajian and Kakutani showed [83] that an ergodic infinite measure-preserving transformation T is either of *zero type*: $\lim_{n \rightarrow \infty} \mu(T^{-n}A \cap A) = 0$ for all sets A of finite measure, or of *positive type*: $\limsup_{n \rightarrow \infty} \mu(T^{-n}A \cap A) > 0$ for all sets A of finite positive measure. T is mixing if and only if it is of zero type [124]. For $0 \leq \alpha \leq 1$ Kakutani suggested a related definition of α -type: an infinite measure preserving transformation is of α -type if $\limsup_{n \rightarrow \infty} \mu(A \cap T^n A) = \alpha \mu(A)$ for every subset A of finite measure. In [153] examples of ergodic transformations of any α -type and a transformation of not any type were constructed.

It may seem that mixing is stronger than any kind of nonsingular weak mixing considered above. However, it is not the case: if T is a weakly mixing infinite measure preserving transformation of zero type and S is an ergodic probability preserving transformation then $T \times S$ is er-

godic and of zero type. On the other hand, the L^∞ -spectrum $e(T \times S)$ is nontrivial, i. e. $T \times S$ is not weakly mixing, whenever S is not weakly mixing. We also note that there exist rank-one infinite measure-preserving transformations T of zero type such that $T \times T$ is not conservative (hence not ergodic) [11]. In contrast to that, if T is of positive type all of its finite Cartesian products are conservative [7]. Another result that suggests that there is no good definition of mixing in the nonsingular case was proved recently in [110]. It is shown there that while the mixing finite measure-preserving transformations are measurably sensitive, there exists no infinite measure-preserving system that is measurably sensitive. (Measurable sensitivity is a measurable version of the strong sensitive dependence on initial conditions – a concept from topological theory of chaos.)

A nonsingular transformation T of (X, \mathcal{B}, μ) is called K -automorphism [180] if there exists a sub- σ -algebra $\mathcal{F} \subset \mathcal{B}$ such that $T^{-1}\mathcal{F} \subset \mathcal{F}$, $\bigcap_{k \geq 0} T^{-k}\mathcal{F} = \{\emptyset, X\}$, $\bigvee_{k=0}^{+\infty} T^k\mathcal{F} = \mathcal{B}$ and the Radon–Nikodym derivative $d\mu \circ T/d\mu$ is \mathcal{F} -measurable (see also [156] for the case when T is of type II_∞ ; the authors in [180] required T to be conservative). Evidently, a nonsingular Bernoulli transformation (see Subject. “Nonsingular Bernoulli Transformations – Hamachi’s Example”) is a K -automorphism. Parry [156] showed that a type II_∞ K -automorphism is either dissipative or ergodic. Krengel [121] proved the same for a class of Bernoulli nonsingular transformations, and finally Silva and Thieullen extended this result to nonsingular K -automorphisms [180]. It is also shown in [180] that if T is a nonsingular K -automorphism, for any ergodic nonsingular transformation S , if $S \times T$ is conservative, then it is ergodic. It follows that a conservative nonsingular K -automorphism is weakly mixing. However, it does not necessarily have infinite ergodic index [113]. Krengel and Sucheston [124] showed that an infinite measure-preserving conservative K -automorphism is mixing.

Multiple and Polynomial Recurrence

Let p be a positive integer. A nonsingular transformation T is called p -recurrent if for every subset B of positive measure there exists a positive integer k such that

$$\mu(B \cap T^{-k}B \cap \dots \cap T^{-kp}B) > 0.$$

If T is p -recurrent for any $p > 0$, then it is called *multiply recurrent*. It is easy to see that T is 1-recurrent if and only if it is conservative. T is called *rigid* if $T^{n_k} \rightarrow \text{Id}$ for a sequence $n_k \rightarrow \infty$. Clearly, if T is rigid then it is multiply recurrent. Furstenberg showed [70] that every finite measure-preserving transformation is multiply recurrent.

In contrast to that Eigen, Hajian and Halverson [64] constructed for any $p \in \mathbb{N} \cup \{\infty\}$, a nonsingular odometer of type II_∞ which is p -recurrent but not $(p+1)$ -recurrent. Aaronson and Nakada showed in [7] that an infinite measure preserving Markov shift T is p -recurrent if and only if the product $T \times \dots \times T$ (p times) is conservative. It follows from this and [5] that in the class of ergodic Markov shifts infinite ergodic index implies multiple recurrence. However, in general this is not true. It was shown in [12,45] and [82] that for each $p \in \mathbb{N} \cup \{\infty\}$ there exist

- (i) power weakly mixing rank-one transformations and
- (ii) non-power weakly mixing rank-one transformations with infinite ergodic index

which are p -recurrent but not $(p+1)$ -recurrent (the latter holds when $p \neq \infty$, of course).

A subset A is called p -wandering if $\mu(A \cap T^k A \cap \dots \cap T^{pk} A) = 0$ for each k . Aaronson and Nakada established in [7] a p -analogue of Hopf decomposition (see Theorem 2).

Proposition 15 *If (X, \mathcal{B}, μ, T) is conservative aperiodic nonsingular dynamical system and $p \in \mathbb{N}$ then $X = C_p \cup D_p$, where C_p and D_p are T -invariant disjoint subsets, D_p is a countable union of p -wandering sets, $T \upharpoonright C_p$ is p -recurrent and $\sum_{k=1}^{\infty} \mu(B \cap T^{-k}B \cap \dots \cap T^{-dk}B) = \infty$ for every $B \subset C_p$.*

Let T be an infinite measure-preserving transformation and let \mathcal{F} be a σ -finite factor (i. e., invariant subalgebra) of T . Inoue [106] showed that for each $p > 0$, if $T \upharpoonright \mathcal{F}$ is p -recurrent then so is T provided that the extension $T \rightarrow T \upharpoonright \mathcal{F}$ is isometric. It is unknown yet whether the latter assumption can be dropped. However, partial progress was recently achieved in [140]: if $T \upharpoonright \mathcal{F}$ is multiply recurrent then so is T .

Let $\mathcal{P} := \{q \in \mathbb{Q}[t] \mid q(\mathbb{Z}) \subset \mathbb{Z} \text{ and } q(0) = 0\}$. An ergodic conservative nonsingular transformation T is called p -polynomially recurrent if for every $q_1, \dots, q_p \in \mathcal{P}$ and every subset B of positive measure there exists $k \in \mathbb{N}$ with

$$\mu(B \cap T^{q_1(k)}B \cap \dots \cap T^{q_p(k)}B) > 0.$$

If T is p -polynomially recurrent for every $p \in \mathbb{N}$ then it is called *polynomially recurrent*. Furstenberg’s theorem on multiple recurrence was significantly strengthened in [17], where it was shown that every finite measure-preserving transformation is polynomially recurrent. However, Danilenko and Silva [45] constructed

- (i) nonsingular transformations T which are p -polynomially recurrent but not $(p+1)$ -polynomially recurrent (for each fixed $p \in \mathbb{N}$),

- (ii) polynomially recurrent transformations T of type Π_∞ ,
- (iii) rigid (and hence multiply recurrent) transformations T which are not polynomially recurrent.

Moreover, such T can be chosen inside the class of rank-one transformations with infinite ergodic index.

Topological Group $\text{Aut}(X, \mu)$

Let (X, \mathcal{B}, μ) be a standard probability space and let $\text{Aut}(X, \mu)$ denote the group of all nonsingular transformations of X . Let ν be a finite or σ -finite measure equivalent to μ ; the subgroup of the ν -preserving transformations is denoted by $\text{Aut}_0(X, \nu)$. Then $\text{Aut}(X, \mu)$ is a simple group [62] and it has no outer automorphisms [63]. Ryzhikov showed [169] that every element of this group is a product of three involutions (i. e. transformations of order 2). Moreover, a nonsingular transformation is a product of two involutions if and only if it is conjugate to its inverse by an involution.

Inspired by [85], Ionescu Tulcea [107] and Chacon and Friedman [21] introduced the *weak* and the *uniform* topologies respectively on $\text{Aut}(X, \mu)$. The weak one – we denote it by d_w – is induced from the weak operator topology on the group of unitary operators in $L^2(X, \mu)$ by the embedding $T \mapsto U_T$ (see Subject. “[Mean and Pointwise Ergodic Theorems. Rokhlin Lemma](#)”). Then $(\text{Aut}(X, \mu), d_w)$ is a Polish topological group and $\text{Aut}_0(X, \nu)$ is a closed subgroup of $\text{Aut}(X, \mu)$. This topology will not be affected if we replace μ with any equivalent measure. We note that T_n weakly converges to T if and only if $\mu(T_n^{-1}A \Delta T^{-1}A) \rightarrow 0$ for each $A \in \mathcal{B}$ and $d(\mu \circ T_n)/d\mu \rightarrow d(\mu \circ T)/d\mu$ in $L^1(X, \mu)$. Danilenko showed in [34] that $(\text{Aut}(X, \mu), d_w)$ is contractible. It follows easily from the Rokhlin lemma that periodic transformations are dense in $\text{Aut}(X, \mu)$.

For each $p \geq 1$, one can also embed $\text{Aut}(X, \mu)$ into the isometry group of $L^p(X, \mu)$ via a formula similar to (3) but with another power of the Radon–Nikodym derivative in it. The strong operator topology on the isometry group induces the very same weak topology on $\text{Aut}(X, \mu)$ for all $p \geq 1$ [24].

It is natural to ask which properties of nonsingular transformations are typical in the sense of Baire category. The following technical lemma (see see [24,68]) is an indispensable tool when considering such problems.

Lemma 16 *The conjugacy class of each aperiodic transformation T is dense in $\text{Aut}(X, \mu)$ endowed with the weak topology.*

Using this lemma and the Hurewicz ergodic theorem Choksi and Kakutani [24] proved that the ergodic transformations form a dense G_δ in $\text{Aut}(X, \mu)$. The same holds for the subgroup $\text{Aut}_0(X, \nu)$ [24,170]. Combined with [107] the above implies that the ergodic transformations of type III is a dense G_δ in $\text{Aut}(X, \mu)$. For further refinement of this statement we refer to Sect. “[Orbit Theory](#)”.

Since the map $T \mapsto T \times \cdots \times T$ (p times) from $\text{Aut}(X, \mu)$ to $\text{Aut}(X^p, \mu^{\otimes p})$ is continuous for each $p > 0$, we deduce that the set \mathcal{E}_∞ of transformations with infinite ergodic index is a G_δ in $\text{Aut}(X, \mu)$. It is non-empty by [113]. Since this \mathcal{E}_∞ is invariant under conjugacy, it is dense in $\text{Aut}(X, \mu)$ by Lemma 16. Thus we obtain that \mathcal{E}_∞ is a dense G_δ . In a similar way one can show that $\mathcal{E}_\infty \cap \text{Aut}_0(X, \nu)$ is a dense G_δ in $\text{Aut}_0(X, \nu)$ (see also [24,26,170] for original proofs of these claims).

The rigid transformations form a dense G_δ in $\text{Aut}(X, \mu)$. It follows that the set of multiply recurrent nonsingular transformations is residual [13]. A finer result was established in [45]: the set of polynomially recurrent transformations is also residual.

Given $T \in \text{Aut}(X, \mu)$, we denote the *centralizer* $\{S \in \text{Aut}(X, \mu) \mid ST = TS\}$ of T by $C(T)$. Of course, $C(T)$ is a closed subgroup of $\text{Aut}(X, \mu)$ and $C(T) \supset \{T^n \mid n \in \mathbb{Z}\}$. The following problems solved recently (by the efforts of many authors) for probability preserving systems are still open for the nonsingular case. Are the properties:

- (i) T has square root;
- (ii) T embeds into a flow;
- (iii) T has non-trivial invariant sub- σ -algebra;
- (iv) $C(T)$ contains a torus of arbitrary dimension

typical (residual) in $\text{Aut}(X, \mu)$?

The *uniform* topology on $\text{Aut}(X, \mu)$, finer than d_w , is defined by the metric

$$d_u(T, S) = \mu(\{x: Tx \neq Sx\}) + \mu(\{x: T^{-1}x \neq S^{-1}x\}).$$

This topology is also complete metric. It depends only on the measure class of μ . However the uniform topology is not separable and that is why it is of less importance in ergodic theory. We refer to [21,24,27] and [68] for the properties of d_u .

Orbit Theory

Orbit theory is, in a sense, the most complete part of nonsingular ergodic theory. We present here the seminal Krieger’s theorem on orbit classification of ergodic nonsingular transformations in terms of ratio sets and associated flows. Examples of transformations of various types

$III_\lambda, 0 \leq \lambda \leq 1$ are also given here. Next, we consider the outer conjugacy problem for automorphisms of the orbit equivalence relations. This problem is solved in terms of a simple complete system of invariants. We discuss also a general theory of cocycles (of nonsingular systems) taking values in locally compact Polish groups and present an important orbit classification theorem for cocycles. This theorem is an analogue of the aforementioned result of Krieger. We complete the section by considering ITPFI-systems and their relation to AT-flows.

Full Groups. Ratio Set and Types $III_\lambda, 0 \leq \lambda \leq 1$

Let T be a nonsingular transformation of a standard probability space (X, \mathcal{B}, μ) . Denote by $Orb_T(x)$ the T -orbit of x , i. e. $Orb_T(x) = \{T^n x \mid n \in \mathbb{Z}\}$. The *full group* $[T]$ of T consists of all transformations $S \in Aut(X, \mu)$ such that $Sx \in Orb_T(x)$ for a. a. x . If T is ergodic then $[T]$ is topologically simple (or even algebraically simple if T is not of type II_∞) [62]. It is easy to see that $[T]$ endowed with the uniform topology d_u is a Polish group. If T is ergodic then $([T], d_u)$ is contractible [34].

The *ratio set* $r(T)$ of T was defined by Krieger [126] and as we shall see below it is the key concept in the orbit classification (see Definition 1). The ratio set is a subset of $[0, +\infty)$ defined as follows: $t \in r(T)$ if and only if for every $A \in \mathcal{B}$ of positive measure and each $\epsilon > 0$ there is a subset $B \subset A$ of positive measure and an integer $k \neq 0$ such that $T^k B \subset A$ and $|\omega_k^\mu(x) - t| < \epsilon$ for all $x \in B$. It is easy to verify that $r(T)$ depends only on the equivalence class of μ and not on μ itself. A basic fact is that $1 \in r(T)$ if and only if T is conservative. Assume now T to be conservative and ergodic. Then $r(T) \cap (0, +\infty)$ is a closed subgroup of the multiplicative group $(0, +\infty)$. Hence $r(T)$ is one of the following sets:

- (i) $\{1\}$;
- (ii) $\{0, 1\}$; in this case we say that T is of type III_0 ,
- (iii) $\{\lambda^n \mid n \in \mathbb{Z}\} \cup \{0\}$ for $0 < \lambda < 1$; then we say that T is of type III_λ ,
- (iv) $[0, +\infty)$; then we say that T is of type III_1 .

Krieger showed that $r(T) = \{1\}$ if and only if T is of type II. Hence we obtain a further subdivision of type III into subtypes $III_0, III_\lambda,$ or III_1 .

Example 17 (i) Fix $\lambda \in (0, 1)$. Let $v_n(0) := 1/(1 + \lambda)$ and $v_n(1) := \lambda/(1 + \lambda)$ for all $n = 1, 2, \dots$. Let T be the nonsingular odometer associated with the sequence $(2, v_n)_{n=1}^\infty$ (see Subsect. “Nonsingular Odometers”). We claim that T is of type III_λ . Indeed, the group Σ of finite permutations of \mathbb{N} acts on X by $(\sigma x)_n = x_{\sigma^{-1}(n)}$, for all $n \in \mathbb{N}, \sigma \in \Sigma$ and $x = (x_n)_{n=1}^\infty \in X$. This action preserves μ . Moreover,

it is ergodic by the Hewitt–Savage 0–1 law. It remains to notice that $(d\mu \circ T/d\mu)(x) = \lambda$ on the cylinder $[0]$ which is of positive measure.

(ii) Fix positive reals ρ_1 and ρ_2 such that $\log \rho_1$ and $\log \rho_2$ are rationally independent. Let $v_n(0) := 1/(1 + \rho_1 + \rho_2), v_n(1) := \rho_1/(1 + \rho_1 + \rho_2)$ and $v_n(2) := \rho_2/(1 + \rho_1 + \rho_2)$ for all $n = 1, 2, \dots$. Then the nonsingular odometer associated with the sequence $(3, v_n)_{n=1}^\infty$ is of type III_1 . This can be shown in a similar way as (i).

Non-singular odometer of type III_0 will be constructed in Example 19 below.

Maharam Extension, Associated Flow and Orbit Classification of Type III Systems

On $X \times \mathbb{R}$ with the σ -finite measure $\mu \times \kappa$, where $d\kappa(y) = \exp(y)dy$, consider the transformation

$$\tilde{T}(x, y) := \left(Tx, y - \log \frac{d\mu \circ T}{d\mu}(x) \right).$$

We call it the *Maharam extension* of T (see [136], where these transformations were introduced). It is measure-preserving and it commutes with the flow $S_t(x, y) := (x, y + t), t \in \mathbb{R}$. It is conservative if and only if T is conservative [136]. However \tilde{T} is not necessarily ergodic. Let (Z, ν) denote the space of \tilde{T} -ergodic components. Then $(S_t)_{t \in \mathbb{R}}$ acts nonsingularly on this space. The restriction of $(S_t)_{t \in \mathbb{R}}$ to (Z, ν) is called the *associated flow* of T . The associated flow is ergodic whenever T is ergodic. It is easy to verify that the isomorphism class of the associated flow is an invariant of the orbit equivalence of the underlying system.

Proposition 18 ([90])

- (i) T is of type II if and only if its associated flow is the translation on \mathbb{R} , i. e. $x \mapsto x + t, x, t \in \mathbb{R}$,
- (ii) T is of type $III_\lambda, 0 \leq \lambda < 1$ if and only if its associated flow is the periodic flow on the interval $[0, -\log \lambda)$, i. e. $x \mapsto x + t \pmod{-\log \lambda}$,
- (iii) T is of type III_1 if and only if its associated flow is the trivial flow on a singleton or, equivalently, \tilde{T} is ergodic,
- (iv) T is of type III_0 if and only if its associated flow is non-transitive.

Example 19 Let $A_n = \{0, 1, \dots, 2^{2^n}\}$ and $v_n(0) = 0.5$ and $v_n(i) = 0.5 \cdot 2^{-2^n}$ for all $0 < i \leq 2^n$. Let T be the nonsingular odometer associated with $(2^{2^n} + 1, v_n)_{n=0}^\infty$. It is straightforward that the associated flow of T is the flow built under the constant function 1 with the probability preserving 2-adic odometer (associated with $(2, \kappa_n)_{n=1}^\infty$,

$\kappa_n(0) = \kappa_n(1) = 0.5$) as the base transformation. In particular, T is of type III_0 .

A natural problem arises: to compute Krieger’s type (or the ratio set) for the nonsingular odometers – the simplest class of nonsingular systems. Some partial progress was achieved in [56,141,152], etc. However in the general setting this problem remains open.

The map $\Psi: \text{Aut}(X, \mu) \ni T \mapsto \tilde{T} \in \text{Aut}(X \times \mathbb{R}, \mu \times \kappa)$ is a continuous group homomorphism. Since the set \mathcal{E} of ergodic transformations on $X \times \mathbb{R}$ is a G_δ in $\text{Aut}(X \times \mathbb{R}, \mu \times \kappa)$ (see Sect. “Topological Group $\text{Aut}(X, \mu)$ ”), the subset $\Psi^{-1}(\mathcal{E})$ of type III_1 ergodic transformations on X is also G_δ . The latter subset is non-empty in view of Example 17(ii). Since it is invariant under conjugacy, we deduce from Lemma 16 that the set of ergodic transformations of type III_1 is a dense G_δ in $(\text{Aut}(X, \mu), d_w)$ [23,159].

Now we state the main result of this section – Krieger’s theorem on orbit classification for ergodic transformations of type III . It is a far reaching generalization of the basic result by H. Dye: any two ergodic probability preserving transformations are orbit equivalent [60].

Theorem 20 (Orbit equivalence for type III systems [125]–[129]) *Two ergodic transformations of type III are orbit equivalent if and only if their associated flows are isomorphic. In particular, for a fixed $0 < \lambda \leq 1$, any two ergodic transformations of type III_λ are orbit equivalent.*

The original proof of this theorem is rather complicated. Simpler treatment of it can be found in [90] and [117].

We also note that every nontransitive ergodic flow can be realized as the associated flow of a type III_0 transformation. However it is somewhat easier to construct a \mathbb{Z}^2 -action of type III_0 whose associated flow is the given one. For this, we take an ergodic nonsingular transformation Q on a probability space $(Z, \mathcal{B}, \lambda)$ and a measure-preserving transformation R of an infinite σ -finite measure space (Y, \mathcal{F}, ν) such that there is a continuous homomorphism $\pi: \mathbb{R} \rightarrow C(R)$ with $(d\nu \circ \pi(t)/d\nu)(y) = \exp(t)$ for a. a. y (for instance, take a type III_1 transformation T and put $R := \tilde{T}$ and $\pi(t) := S_t$). Let $\varphi: Z \rightarrow \mathbb{R}$ be a Borel map with $\inf_Z \varphi > 0$. Define two transformations R_0 and Q_0 of $(Z \times Y, \lambda \times \nu)$ by setting:

$$R_0(x, y) := (x, Ry), \quad Q_0(x, y) = (Qx, U_x y),$$

where $U_x = \pi(\varphi(x) - \log(d\mu \circ Q/d\mu)(x))$. Notice that R_0 and Q_0 commute. The corresponding \mathbb{Z}^2 -action generated by these transformations is ergodic. Take any transformation $V \in \text{Aut}(Z \times Y, \lambda \times \nu)$ whose orbits coincide

with the orbits of the \mathbb{Z}^2 -action. (According to [29], any ergodic nonsingular action of any countable amenable group is orbit equivalent to a single transformation.) Then V is of type III_0 . It is now easy to verify that the associated flow of V is the special flow built under $\varphi \circ Q^{-1}$ with the base transformation Q^{-1} . Since Q and φ are arbitrary, we deduce the following from Theorem 14.

Theorem 21 *Every nontransitive ergodic flow is an associated flow of an ergodic transformation of type III_0 .*

In [129] Krieger introduced a map Φ as follows. Let T be an ergodic transformation of type III_0 . Then the associated flow of T is a flow built under function with a base transformation $\Phi(T)$. We note that the orbit equivalence class of $\Phi(T)$ is well defined by the orbit equivalent class of T . If $\Phi^n(T)$ fails to be of type III_0 for some $1 \leq n < \infty$ then T is said to *belong to Krieger’s hierarchy*. For instance, the transformation constructed in Example 19 belongs to Krieger’s hierarchy. Connes gave in [28] an example of T such that $\Phi(T)$ is orbit equivalent to T (see also [73] and [90]). Hence T is not in Krieger’s hierarchy.

Normalizer of the Full Group. Outer Conjugacy Problem

Let

$$N[T] = \{R \in \text{Aut}(X, \mu) \mid R[T]R^{-1} = [T]\},$$

i. e. $N[T]$ is the *normalizer* of the full group $[T]$ in $\text{Aut}(X, \mu)$. We note that a transformation R belongs to $N[T]$ if and only if $R(\text{Orb}_T(x)) = \text{Orb}_T(Rx)$ for a. a. x . To define a topology on $N[T]$ consider the T -orbit equivalence relation $\mathcal{R}_T \subset X \times X$ and a σ -finite measure $\mu_{\mathcal{R}_T}$ on \mathcal{R}_T given by $\mu_{\mathcal{R}_T} = \int_X \sum_{y \in \text{Orb}_T(x)} \delta_{(x,y)} d\mu(x)$. For $R \in N[T]$, we define a transformation $i(R) \in \text{Aut}(\mathcal{R}_T, \mu_{\mathcal{R}_T})$ by setting $i(R)(x, y) := (Rx, Ry)$. Then the map $R \mapsto i(R)$ is an embedding of $N[T]$ into $\text{Aut}(\mathcal{R}_T, \mu_{\mathcal{R}_T})$. Denote by τ the topology on $N[T]$ induced by the weak topology on $\text{Aut}(\mathcal{R}_T, \mu_{\mathcal{R}_T})$ via i [34]. Then $(N[T], \tau)$ is a Polish group. A sequence R_n converges to R in $N[T]$ if $R_n \rightarrow R$ weakly (in $\text{Aut}(X, \mu)$) and $R_n T R_n^{-1} \rightarrow R T R^{-1}$ uniformly (in $[T]$).

Given $R \in N[T]$, denote by \tilde{R} the Maharam extension of R . Then $\tilde{R} \in N[\tilde{T}]$ and it commutes with $(S_t)_{t \in \mathbb{R}}$. Hence it defines a nonsingular transformation mod R on the space (Z, ν) of the associated flow $W = (W_t)_{t \in \mathbb{R}}$ of T . Moreover, mod R belongs to the centralizer $C(W)$ of W in $\text{Aut}(Z, \nu)$. Note that $C(W)$ is a closed subgroup of $(\text{Aut}(Z, \nu), d_w)$.

Let T be of type II_∞ and let μ' be the invariant σ -finite measure equivalent to μ . If $R \in N[T]$ then it is easy

to see that the Radon–Nikodym derivative $d\mu' \circ R/d\mu'$ is invariant under T . Hence it is constant, say c . Then $\text{mod } R = \log c$.

Theorem 22 ([86,90]) *If T is of type III then the map $\text{mod}: N[T] \rightarrow C(W)$ is a continuous onto homomorphism. The kernel of this homomorphism is the τ -closure of $[T]$. Hence the quotient group $N[T]/\overline{[T]}^\tau$ is (topologically) isomorphic to $C(W)$. In particular, $\overline{[T]}^\tau$ is co-compact in $N[T]$ if and only if W is a finite measure-preserving flow with a pure point spectrum.*

The following theorem describes the homotopical structure of normalizers.

Theorem 23 ([34]) *Let T be of type II or III_λ , $0 \leq \lambda < 1$. The group $\overline{[T]}^\tau$ is contractible. $N[T]$ is homotopically equivalent to $C(W)$. In particular, $N[T]$ is contractible if T is of type II. If T is of type III_λ with $0 < \lambda < 1$ then $\pi_1(N[T]) = \mathbb{Z}$.*

The outer period $p(R)$ of $R \in N[T]$ is the smallest positive integer n such that $R^n \in [T]$. We write $p(R) = 0$ if no such n exists.

Two transformations R and R' in $N[T]$ are called *outer conjugate* if there are transformations $V \in N[T]$ and $S \in [T]$ such that $VRV^{-1} = R'S$. The following theorem provides convenient (for verification) necessary and sufficient conditions for the outer conjugacy.

Theorem 24 ([30] for type II and [18] for type III) *Transformations $R, R' \in N[T]$ are outer conjugate if and only if $p(R) = p(R')$ and $\text{mod } R$ is conjugate to $\text{mod } R'$ in the centralizer of the associated flow for T .*

We note that in the case T is of type II, the second condition in the theorem is just $\text{mod } R = \text{mod } R'$. It is always satisfied when T is of type II_1 .

Cocycles of Dynamical Systems. Weak Equivalence of Cocycles

Let G be a locally compact Polish group and λ_G a left Haar measure on G . A Borel map $\varphi: X \rightarrow G$ is called a *cocycle* of T . Two cocycles φ and φ' are *cohomologous* if there is a Borel map $b: X \rightarrow G$ such that

$$\varphi'(x) = b(Tx)^{-1}\varphi(x)b(x)$$

for a.a. $x \in X$. A cocycle cohomologous to the trivial one is called a *coboundary*. Given a dense subgroup $G' \subset G$, then every cocycle is cohomologous to a cocycle with values in G' [81]. Each cocycle φ extends to a (unique) map $\alpha_\varphi: \mathcal{R}_T \rightarrow G$ such that $\alpha_\varphi(Tx, x) = \varphi(x)$ for a.a. x and $\alpha_\varphi(x, y)\alpha_\varphi(y, z) = \alpha_\varphi(x, z)$ for a.a. $(x, y), (y, z) \in \mathcal{R}_T$. α_φ is called the *cocycle of \mathcal{R}_T generated by φ* .

Moreover, φ and φ' are cohomologous via b as above if and only if α_φ and $\alpha_{\varphi'}$ are *cohomologous* via b , i.e. $\alpha_\varphi(x, y) = b(x)^{-1}\alpha_{\varphi'}(x, y)b(y)$ for $\mu_{\mathcal{R}_T}$ -a.a. $(x, y) \in \mathcal{R}_T$. The following notion was introduced by Golodets and Sinelshchikov [78,81]: two cocycles φ and φ' are *weakly equivalent* if there is a transformation $R \in N[T]$ such that the cocycles α_φ and $\alpha_{\varphi'} \circ (R \times R)$ of \mathcal{R}_T are cohomologous. Let $\mathcal{M}(X, G)$ denote the set of Borel maps from X to G . It is a Polish group when endowed with the topology of convergence in measure. Since T is ergodic, it is easy to deduce from Rokhlin’s lemma that the cohomology class of any cocycle is dense in $\mathcal{M}(X, G)$. Given $\varphi \in \mathcal{M}(X, G)$, we define the φ -skew product extension T_φ of T acting on $(X \times G, \mu \times \lambda_G)$ by setting $T_\varphi(x, g) := (Tx, \varphi(x)g)$. Thus Maharam extension is (isomorphic to) the Radon–Nikodym cocycle-skew product extension. We now specify some basic classes of cocycles [19,35,81,173]:

- (i) φ is called *transient* if T_φ is of type I.
- (ii) φ is called *recurrent* if T_φ is conservative (equivalently, T_φ is not transient).
- (iii) φ has *dense range in G* if T_φ is ergodic.
- (iv) φ is called *regular* if φ cobounds with dense range into a closed subgroup H of G (then H is defined up to conjugacy).

These properties are invariant under the cohomology and the weak equivalence. The Radon–Nikodym cocycle ω_1 is a coboundary if and only if T is of type II. It is regular if and only if T is of type II or III_λ , $0 < \lambda \leq 1$. It has dense range (in the multiplicative group \mathbb{R}_+^*) if and only if T is of type III_1 . Notice that ω_1 is never transient (since T is conservative).

Schmidt introduced in [176] an invariant $R(\varphi) := \{g \in G \mid \varphi - g \text{ is recurrent}\}$. He showed in particular that

- (i) $R(\varphi)$ is a cohomology invariant,
- (ii) $R(\varphi)$ is a Borel set in G ,
- (iii) $R(\log \omega_1) = \{0\}$ for each aperiodic conservative T ,
- (iv) there are cocycles φ such that $R(\varphi)$ and $G \setminus R(\varphi)$ are dense in G ,
- (v) if $\mu(X) = 1$, $\mu \circ T = \mu$ and $\varphi: X \rightarrow \mathbb{R}$ is integrable then $R(\varphi) = \{\int \varphi d\mu\}$.

We note that (v) follows from Atkinson theorem [15]. A nonsingular version of this theorem was established in [183]: if T is ergodic and μ -nonsingular and $f \in L^1(\mu)$ then

$$\liminf_{n \rightarrow \infty} \left| \sum_{j=0}^{n-1} f(T^j x)\omega_j(x) \right| = 0 \quad \text{for a.a. } x$$

if and only if $\int f d\mu = 0$.

Since T_φ commutes with the action of G on $X \times G$ by inverted right translations along the second coordinate, this action induces an ergodic G -action $W_\varphi = (W_\varphi(g))_{g \in G}$ on the space (Z, ν) of T_φ -ergodic components. It is called the *Mackey range (or Poincaré flow)* of φ [66,135,173,188]. We note that φ is regular (and cobounds with dense range into $H \subset G$) if and only if W_φ is transitive (and H is the stabilizer of a point $z \in Z$, i. e. $H = \{g \in G \mid W_\varphi(g)z = z\}$). Hence every cocycle taking values in a compact group is regular.

It is often useful to consider the *double cocycle* $\varphi_0 := \varphi \times \omega_1$ instead of φ . It takes values in the group $G \times \mathbb{R}_+^*$. Since T_{φ_0} is exactly the Maharam extension of T_φ , it follows from [136] that φ_0 is transient or recurrent if and only if φ is transient or recurrent respectively.

Theorem 25 (Orbit classification of cocycles [81]) *Let $\varphi, \varphi' : X \rightarrow G$ be two recurrent cocycles of an ergodic transformation T . They are weakly equivalent if and only if their Mackey ranges W_{φ_0} and $W_{\varphi'_0}$ are isomorphic.*

Another proof of this theorem was presented in [65].

Theorem 26 *Let T be an ergodic nonsingular transformation. Then there is a cocycle of T with dense range in G if and only if G is amenable.*

It follows that if G is amenable then the subset of cocycles of T with dense range in G is a dense G_δ in $\mathcal{M}(X, G)$ (just adapt the argument following Example 19). The ‘only if’ part of Theorem 26 was established in [187]. The ‘if’ part was considered by many authors in particular cases: G is compact [186], G is solvable or amenable almost connected [79], G is amenable unimodular [108], etc. The general case was proved in [78] and [100] (see also a recent treatment in [9]).

Theorem 21 is a particular case of the following result.

Theorem 27 ([10,65,80]) *Let G be amenable. Let V be an ergodic nonsingular action of $G \times \mathbb{R}_+^*$. Then there is an ergodic nonsingular transformation T and a recurrent cocycle φ of T with values in G such that V is isomorphic to the Mackey range of the double cocycle φ_0 .*

Given a cocycle $\varphi \in \mathcal{M}(X, G)$ of T , we say that a transformation $R \in N[T]$ is *compatible with φ* if the cocycles α_φ and $\alpha_\varphi \circ (R \times R)$ of \mathcal{R}_T are cohomologous. Denote by $D(T, \varphi)$ the group of all such R . It has a natural Polish topology which is stronger than τ [41]. Since $[T]$ is a normal subgroup in $D(T, \varphi)$, one can consider the outer conjugacy equivalence relation inside $D(T, \varphi)$. It is called *φ -outer conjugacy*. Suppose that G is Abelian. Then an analogue of Theorem 24 for the φ -outer conjugacy is established in [41]. Also, the cocycles φ with $D(T, \varphi) = N[T]$ are described there.

ITPFI Transformations and AT-Flows

A nonsingular transformation T is called *ITPFI*¹ if it is orbit equivalent to a nonsingular odometer (associated to a sequence $(m_n, \nu_n)_{n=1}^\infty$, see Subsect. “Nonsingular Odometers”). If the sequence m_n can be chosen bounded then T is called ITPFI of bounded type. If $m_n = 2$ for all n then T is called ITPFI₂. By [74], every ITPFI-transformation of bounded type is ITPFI₂. A remarkable characterization of ITPFI transformations in terms of their associated flows was obtained by Connes and Woods [31]. We first single out a class of ergodic flows. A nonsingular flow $V = (V_t)_{t \in \mathbb{R}}$ on a space (Ω, ν) is called *approximate transitive (AT)* if given $\epsilon > 0$ and $f_1, \dots, f_n \in L_+^1(X, \mu)$, there exists $f \in L_+^1(X, \mu)$ and $\lambda_1, \dots, \lambda_n \in L_+^1(\mathbb{R}, dt)$ such that

$$\left\| f_j - \int_{\mathbb{R}} f \circ V_t \frac{d\nu \circ V_t}{d\nu} \lambda_j(t) dt \right\|_1 < \epsilon$$

for all $1 \leq j \leq n$. A flow built under a constant ceiling function with a funny rank-one [67] probability preserving base transformation is AT [31]. In particular, each ergodic finite measure-preserving flow with a pure point spectrum is AT.

Theorem 28 ([31]) *An ergodic nonsingular transformation is ITPFI if and only if its associated flow is AT.*

The original proof of this theorem was given in the framework of von Neumann algebras theory. A simpler, purely measure theoretical proof was given later in [96] (the ‘only if’ part) and [88] (the ‘if’ part). It follows from Theorem 28 that every ergodic flow with pure point spectrum is the associated flow of an ITPFI transformation. If the point spectrum of V is $\theta\Gamma$, where Γ is a subgroup of \mathbb{Q} and $\theta \in \mathbb{R}$, then V is the associated flow of an ITPFI₂ transformation [91].

Theorem 29 ([54]) *Each ergodic nonsingular transformation is orbit equivalent to a Markov odometer (see Subsect. “Markov Odometers”).*

The existence of non-ITPFI transformations and ITPFI transformations of unbounded type was shown in [127]. In [55], an explicit example of a non-ITPFI Markov odometer was constructed.

Smooth Nonsingular Transformations

Diffeomorphisms of smooth manifolds equipped with smooth measures are commonly considered as physically natural examples of dynamical systems. Therefore

¹This abbreviates ‘infinite tensor product of factors of type I (came from the theory of von Neumann algebras).

the construction of smooth models for various dynamical properties is a well established problem of the modern (probability preserving) ergodic theory. Unfortunately, the corresponding ‘nonsingular’ counterpart of this problem is almost unexplored. We survey here several interesting facts related to the topic.

For $r \in \mathbb{N} \cup \{\infty\}$, denote by $\text{Diff}_+^r(\mathbb{T})$ the group of orientation preserving C^r -diffeomorphisms of the circle \mathbb{T} . Endow this set with the natural Polish topology. Fix $T \in \text{Diff}_+^r(\mathbb{T})$. Since $\mathbb{T} = \mathbb{R}/\mathbb{Z}$, there exists a C^1 -function $f: \mathbb{R} \rightarrow \mathbb{R}$ such that $T(x + \mathbb{Z}) = f(x) + \mathbb{Z}$ for all $x \in \mathbb{R}$. The *rotation number* $\rho(T)$ of T is the limit

$$\lim_{n \rightarrow \infty} \underbrace{(f \circ \dots \circ f)(x)}_{n \text{ times}} \pmod{1}.$$

The limit exists and does not depend on the choice of x and f . It is obvious that T is nonsingular with respect to Lebesgue measure $\lambda_{\mathbb{T}}$. Moreover, if $T \in \text{Diff}_+^r(\mathbb{T})$ and $\rho(T)$ is irrational then the dynamical system $(\mathbb{T}, \lambda_{\mathbb{T}}, T)$ is ergodic [33]. It is interesting to ask: which Krieger’s type can such systems have?

Katznelson showed in [114] that the subset of type III C^∞ -diffeomorphisms and the subset of type II $_\infty$ C^∞ -diffeomorphisms are dense in $\text{Diff}_+^\infty(\mathbb{T})$. Hawkins and Schmidt refined the idea of Katznelson from [114] to construct, for every irrational number $\alpha \in [0, 1)$ which is not of constant type (i. e. in whose continued fraction expansion the denominators are not bounded) a transformation $T \in \text{Diff}_+^2(\mathbb{T})$ which is of type III $_1$ and $\rho(T) = \alpha$ [97]. It should be mentioned that class C^2 in the construction is essential, since it follows from a remarkable result of Herman that if $T \in \text{Diff}_+^3(\mathbb{T})$ then under some condition on α (which determines a set of full Lebesgue measure), T is measure theoretically (and topologically) conjugate to a rotation by $\rho(T)$ [101]. Hence T is of type II $_1$.

In [94], Hawkins shows that every smooth paracompact manifold of dimension ≥ 3 admits a type III $_\lambda$ diffeomorphism for every $\lambda \in [0, 1]$. This extends a result of Herman [100] on the existence of type III $_1$ diffeomorphisms in the same circumstances.

It is also of interest to ask: which free ergodic flows are associated with smooth dynamical systems of type III $_0$? Hawkins proved that any free ergodic C^∞ -flow on a smooth, connected, paracompact manifold is the associated flow for a C^∞ -diffeomorphism on another manifold (of higher dimension) [95].

A nice result was obtained in [115]: if $T \in \text{Diff}_+^2(\mathbb{T})$ and the rotation number of T has unbounded continued fraction coefficients then $(\mathbb{T}, \lambda_{\mathbb{T}}, T)$ is ITPFI. Moreover, a converse also holds: given a nonsingular odometer R , the set of orientation-preserving C^∞ -diffeomorphisms of

the circle which are orbit equivalent to R is C^∞ -dense in the Polish set of all C^∞ -orientation-preserving diffeomorphisms with irrational rotation numbers. In contrast to that, Hawkins constructs in [93] a type III $_0$ C^∞ -diffeomorphism of the 4-dimensional torus which is not ITPFI.

Spectral Theory for Nonsingular Systems

While the spectral theory for probability preserving systems is developed in depth, the spectral theory of nonsingular systems is still in its infancy. We discuss below some problems related to L^∞ -spectrum which may be regarded as an analogue of the discrete spectrum. We also include results on computation of the maximal spectral type of the ‘nonsingular’ Koopman operator for rank-one nonsingular transformations.

L^∞ -Spectrum and Groups of Quasi-Invariance

Let T be an ergodic nonsingular transformation of (X, \mathcal{B}, μ) . A number $\lambda \in \mathbb{T}$ belongs to the L^∞ -spectrum $e(T)$ of T if there is a function $f \in L^\infty(X, \mu)$ with $f \circ T = \lambda f$. f is called an L^∞ -eigenfunction of T corresponding to λ . Denote by $\mathcal{E}(T)$ the group of all L^∞ -eigenfunctions of absolute value 1. It is a Polish group when endowed with the topology of converges in measure. If T is of type II $_1$ then the L^∞ -eigenfunctions are $L^2(\mu')$ -eigenfunctions of T , where μ' is an equivalent invariant probability measure. Hence $e(T)$ is countable. Osikawa constructed in [151] the first examples of ergodic nonsingular transformations with uncountable $e(T)$.

We state now a nonsingular version of the von Neumann–Halmos discrete spectrum theorem. Let $Q \subset \mathbb{T}$ be a countable infinite subgroup. Let K be a compact dual of Q_d , where Q_d denotes Q with the discrete topology. Let $k_0 \in K$ be the element defined by $k_0(q) = q$ for all $q \in Q$. Let $R: K \rightarrow K$ be defined by $Rk = k + k_0$. The system (K, R) is called a *compact group rotation*. The following theorem was proved in [6].

Theorem 30 *Assume that the L^∞ -eigenfunctions of T generate the entire σ -algebra \mathcal{B} . Then T is isomorphic to a compact group rotation equipped with an ergodic quasi-invariant measure.*

A natural question arises: which subgroups of \mathbb{T} can appear as $e(T)$ for an ergodic T ?

Theorem 31 ([1,143]) *$e(T)$ is a Borel subset of \mathbb{T} and carries a unique Polish topology which is stronger than the usual topology on \mathbb{T} . The Borel structure of $e(T)$ under this topology agrees with the Borel structure inherited from \mathbb{T} . There is a Borel map $\psi: e(T) \ni \lambda \mapsto \psi_\lambda \in \mathcal{E}(T)$ such that $\psi_\lambda \circ T = \lambda \psi_\lambda$ for each λ . Moreover, $e(T)$ is of Lebesgue*

measure 0 and it can have an arbitrary Hausdorff dimension.

A proper Borel subgroup E of \mathbb{T} is called

- (i) *weak Dirichlet* if $\limsup_{n \rightarrow \infty} \widehat{\lambda}(n) = 1$ for each finite complex measure λ supported on E ;
- (ii) *saturated* if $\limsup_{n \rightarrow \infty} |\widehat{\lambda}(n)| \geq |\lambda(E)|$ for each finite complex measure λ on \mathbb{T} , where $\widehat{\lambda}(n)$ denote the n th Fourier coefficient of λ .

Every countable subgroup of \mathbb{T} is saturated.

Theorem 32 $e(T)$ is σ -compact in the usual topology on \mathbb{T} [104] and saturated [104,139].

It follows that $e(T)$ is weak Dirichlet (this fact was established earlier in [175]).

It is not known if every Polish group continuously embedded in \mathbb{T} as a σ -compact saturated group is the eigenvalue group of some ergodic nonsingular transformation. This is the case for the so-called H_2 -groups and the groups of quasi-invariance of measures on \mathbb{T} (see below). Given a sequence n_j of positive integers and a sequence $a_j \geq 0$, the set of all $z \in \mathbb{T}$ such that $\sum_{j=1}^{\infty} a_j |1 - z^{n_j}|^2 < \infty$ is a group. It is called an H_2 -group. Every H_2 -group is Polish in an intrinsic topology stronger than the usual circle topology.

Theorem 33 ([104])

- (i) Every H_2 -group is a saturated (and hence weak Dirichlet) σ -compact subset of \mathbb{T} .
- (ii) If $\sum_{j=0}^{\infty} a_j = +\infty$ then the corresponding H_2 -group is a proper subgroup of \mathbb{T} .
- (iii) If $\sum_{j=0}^{\infty} a_j (n_j/n_{j+1})^2 < \infty$ then the corresponding H_2 -group is uncountable.
- (iv) Any H_2 -group is $e(T)$ for an ergodic nonsingular compact group rotation T .

It is an open problem whether every eigenvalue group $e(T)$ is an H_2 -group. It is known however that $e(T)$ is close ‘to be an H_2 -group’: if a compact subset $L \subset \mathbb{T}$ is disjoint from $e(T)$ then there is an H_2 -group containing $e(T)$ and disjoint from L .

Example 34 ([6], see also [151]) Let (X, μ, T) be the nonsingular odometer associated to a sequence $(2, \nu_j)_{j=1}^{\infty}$. Let n_j be a sequence of positive integers such that $n_j > \sum_{i < j} n_i$ for all j . For $x \in X$, we put $h(x) := n_{l(x)} - \sum_{j < l(x)} n_j$. Then h is a Borel map from X to the positive integers. Let S be the tower over T with height function h (see Subsect. “Tower Transformations”). Then $e(S)$ is the H_2 -group of all $z \in \mathbb{T}$ with $\sum_{j=1}^{\infty} \nu_j(0)\nu_j(1)|1 - z^{n_j}|^2 < \infty$.

It was later shown in [104] that if $\sum_{j=1}^{\infty} \nu_j(0)\nu_j(1)(n_j/n_{j+1})^2 < \infty$ then the L^∞ -eigenfunctions of S generate the entire σ -algebra, i. e. S is isomorphic (measure theoretically) to a nonsingular compact group rotation.

Let μ be a finite measure on \mathbb{T} . Let $H(\mu) := \{z \in \mathbb{Z} \mid \delta_z * \mu \sim \mu\}$, where $*$ means the convolution of measures. Then H_μ is a group called the *group of quasi-invariance of μ* . It has a Polish topology whose Borel sets agree with the Borel sets which $H(\mu)$ inherits from \mathbb{T} and the injection map of $H(\mu)$ into \mathbb{T} is continuous. This topology is induced by the weak operator topology on the unitary group in the Hilbert space $L^2(\mathbb{T}, \mu)$ via the map $H(\mu) \ni z \mapsto U_z$, $(U_z f)(x) = \sqrt{d(\delta_z * \mu)/d\mu}(x) f(xz)$ for $f \in L^2(\mathbb{T}, \mu)$. Moreover, $H(\mu)$ is saturated [104]. If $\mu(H(\mu)) > 0$ then either $H(\mu)$ is countable or μ is equivalent to $\lambda_{\mathbb{T}}$ [137].

Theorem 35 ([6]) Let μ be an ergodic with respect to the $H(\mu)$ -action by translations on \mathbb{T} . Then there is a compact group rotation (K, R) and a finite measure on K quasi-invariant and ergodic under R such that $e(R) = H(\mu)$. Moreover, there is a continuous one-to-one homomorphism $\psi: e(R) \rightarrow E(R)$ such that $\psi_\lambda \circ R = \lambda \psi_\lambda$ for all $\lambda \in e(R)$.

It was shown by Aaronson and Nadkarni [6] that if $n_1 = 1$ and $n_j = a_j a_{j-1} \cdots a_1$ for positive integers $a_j \geq 2$ with $\sum_{j=1}^{\infty} a_j^{-1} < \infty$ then the transformation S from Example 34 does not admit a continuous homomorphism $\psi: e(S) \rightarrow E(S)$ with $\psi_\lambda \circ T = \lambda \psi_\lambda$ for all $\lambda \in e(S)$. Hence $e(S) \neq H(\mu)$ for any measure μ satisfying the conditions of Theorem 35.

Assume that T is an ergodic nonsingular compact group rotation. Let \mathcal{B}_0 be the σ -algebra generated by a subcollection of eigenfunctions. Then \mathcal{B}_0 is invariant under T and hence a factor (see Sect. “Nonsingular Joinings and Factors”) of T . It is not known if every factor of T is of this form. It is not even known whether every factor of T must have non-trivial eigenvalues.

Unitary Operator Associated with a Nonsingular System

Let (X, \mathcal{B}, μ, T) be a nonsingular dynamical system. In this subsection we consider spectral properties of the unitary operator U_T defined by (3). First, we note that the spectrum of T is the entire circle \mathbb{T} [147]. Next, if U_T has an eigenvector then T is of type II_1 . Indeed, if there are $\lambda \in \mathbb{T}$ and $0 \neq f \in L^2(X, \mu)$ with $U_T f = \lambda f$ then the measure ν , $d\nu(x) := |f(x)|^2 d\mu(x)$, is finite, T -invariant and equivalent to μ . Hence if T is of type III or II_∞ then the maximal spectral type σ_T of U_T is continuous. Another ‘restriction’ on σ_T was recently found in [166]: no

Foiaş-Strătilă measure is absolutely continuous with respect to σ_T if T is of type Π_∞ . We recall that a symmetric measure on \mathbb{T} possesses *Foiaş-Strătilă property* if for each ergodic probability preserving system (Y, ν, S) and $f \in L^2(Y, \nu)$, if σ is the spectral measure of f then f is a Gaussian random variable [134]. For instance, measures supported on Kronecker sets possess this property.

Mixing is an L^2 -spectral property for type Π_∞ transformations: T is mixing if and only if σ_T is a Rajchman measure, i.e. $\widehat{\sigma}_T(n) := \int z^n d\sigma_T(z) \rightarrow 0$ as $|n| \rightarrow \infty$. Also, T is mixing if and only if $n^{-1} \sum_{i=0}^{n-1} U_T^{k_i} \rightarrow 0$ in the strong operator topology for each strictly increasing sequence $k_1 < k_2 < \dots$ [124]. This generalizes a well known theorem of Blum and Hanson for probability preserving maps. For comparison, we note that ergodicity is not an L^2 -spectral property of infinite measure preserving systems.

Now let T be a rank-one nonsingular transformation associated with a sequence $(r_n, w_n, s_n)_{n=1}^\infty$ as in Subsect. “Rank-One Transformations. Chacón Maps. Finite Rank”.

Theorem 36 ([25,104]) *The spectral multiplicity of U_T is 1 and the maximal spectral type σ_T of U_T (up to a discrete measure in the case T is of type Π_1) is the weak limit of the measures ρ_k defined as follows:*

$$d\rho_k(z) = \prod_{j=1}^k w_j(0) |P_j(z)|^2 dz,$$

where $P_j(z) := 1 + \sqrt{w_j(1)/w_j(0)} z^{-R_{1,j}} + \dots + \sqrt{w_j(m_j-1)/w_j(0)} z^{-R_{j-1,j}}$, $z \in \mathbb{T}$, $R_{i,j} := ih_{j-1} + s_j(0) + \dots + s_j(i)$, $1 \leq i \leq r_k - 1$ and h_j is the height of the j th column.

Thus the maximal spectral type of U_T is given by a so-called *generalized Riesz product*. We refer the reader to [25,103,104,148] for a detailed study of Riesz products: their convergence, mutual singularity, singularity to $\lambda_{\mathbb{T}}$, etc.

It was shown in [6] that $H(\sigma_T) \supset e(T)$ for any ergodic nonsingular transformation T . Moreover, σ_T is ergodic under the action of $e(T)$ by translations if T is isomorphic to an ergodic nonsingular compact group rotation. However it is not known:

- (i) Whether $H(\sigma_T) = e(T)$ for all ergodic T .
- (ii) Whether ergodicity of σ_T under $e(T)$ implies that T is an ergodic compact group rotation.

The first claim of Theorem 36 extends to the rank N nonsingular systems as follows: if T is an ergodic nonsingular transformation of rank N then the spectral multiplicity

of U_T is bounded by N (as in the finite measure-preserving case). It is not known whether this claim is true for a more general class of transformations which are defined as rank N but without the assumption that the Radon-Nikodym cocycle is constant on the tower levels.

Entropy and Other Invariants

Let T be an ergodic conservative nonsingular transformation of a standard probability space (X, \mathcal{B}, μ) . If \mathcal{P} is a finite partition of X , we define the entropy $H(\mathcal{P})$ of \mathcal{P} as $H(\mathcal{P}) = -\sum_{P \in \mathcal{P}} \mu(P) \log \mu(P)$. In the study of measure-preserving systems the classical (Kolmogorov–Sinai) entropy proved to be a very useful invariant for isomorphism [33]. The key fact of the theory is that if $\mu \circ T = \mu$ then the limit $\lim_{n \rightarrow \infty} n^{-1} H(\bigvee_{i=1}^n T^{-i} \mathcal{P})$ exists for every \mathcal{P} . However if T does not preserve μ , the limit may no longer exist. Some efforts have been made to extend the use of entropy and similar invariants to the nonsingular domain. These include Krengel’s entropy of conservative measure-preserving maps and its extension to nonsingular maps, Parry’s entropy and Parry’s nonsingular version of Shannon–McMillan–Breiman theorem, critical dimension by Mortiss and Dooley, etc. Unfortunately, these invariants are less informative than their classical counterparts and they are more difficult to compute.

Krengel’s and Parry’s Entropies

Let S be a conservative measure-preserving transformation of a σ -finite measure space (Y, \mathcal{E}, ν) . The *Krengel entropy* [119] of S is defined by

$$h_{Kr}(S) = \sup \{ \nu(E) h(S_E) \mid 0 < \nu(E) < +\infty \},$$

where $h(S_E)$ is the finite measure-preserving entropy of S_E . It follows from Abramov’s formula for the entropy of induced transformation that $h_{Kr}(S) = \mu(E) h(S_E)$ whenever E sweeps out, i.e. $\bigcup_{i \geq 0} S^{-i} E = X$. A generic transformation from $\text{Aut}_0(X, \mu)$ has entropy 0. Krengel raised a question in [119]: does there exist a zero entropy infinite measure-preserving S and a zero entropy finite measure-preserving R such that $h_{Kr}(S \times R) > 0$? This problem was recently solved in [44] (a special case was announced by Silva and Thieullen in an October 1995 AMS conference (unpublished)):

- (i) if $h_{Kr}(S) = 0$ and R is distal then $h_{Kr}(S \times R) = 0$;
- (ii) if R is not distal then there is a rank-one transformation S with $h_{Kr}(S \times R) = \infty$.

We also note that if a conservative $S \in \text{Aut}_0(X, \mu)$ commutes with another transformation R such that

$\nu \circ R = c\nu$ for a constant $c \neq 1$ then $h_{Kr}(S)$ is either 0 or ∞ [180].

Now let T be a type III ergodic transformation of (X, \mathcal{B}, μ) . Silva and Thieullen define an entropy $h^*(T)$ of T by setting $h^*(T) := h_{Kr}(\tilde{T})$, where \tilde{T} is the Maharam extension of T (see Subsect. “Maharam Extension, Associated Flow and Orbit Classification of Type III Systems”). Since \tilde{T} commutes with transformations which ‘multiply’ \tilde{T} -invariant measure, it follows that $h^*(T)$ is either 0 or ∞ .

Let T be the standard III_λ -odometer from Example 17(i). Then $h^*(T) = 0$. The same is true for a so-called ternary odometer associated with the sequence $(3, \nu_n)_{n=1}^\infty$, where $\nu_n(0) = \nu_n(2) = \lambda/(1 + 2\lambda)$ and $\nu_n(1) = \lambda/(1 + \lambda)$ [180]. It is not known however whether every ergodic nonsingular odometer has zero entropy. On the other hand, it was shown in [180] that $h^*(T) = \infty$ for every K -automorphism.

The Parry entropy [158] of S is defined by

$$h_{Pa}(S) := \left\{ H(S^{-1}\mathfrak{F}|\mathfrak{F}) \mid \mathfrak{F} \text{ is a } \sigma\text{-finite subalgebra of } \mathfrak{B} \text{ such that } \mathfrak{F} \subset S^{-1}\mathfrak{F} \right\}.$$

Parry showed [158] that $h_{Pa}(S) \leq h_{Kr}(S)$. It is still an open question whether the two entropies coincide. This is the case when S is of rank one (since $h_{Kr}(S) = 0$) and when S is quasi-finite [158]. The transformation S is called *quasi-finite* if there exists a subset of finite measure $A \subset Y$ such that the first return time partition $(A_n)_{n>0}$ of A has finite entropy. We recall that $x \in A_n \iff n$ is the smallest positive integer such that $T^n x \in A$. An example of non-quasi-finite ergodic infinite measure preserving transformation was constructed recently in [8].

Parry’s Generalization of Shannon–MacMillan–Breiman Theorem

Let T be an ergodic transformation of a standard nonatomic probability space (X, \mathcal{B}, μ) . Suppose that $f \circ T \in L^1(X, \mu)$ if and only if $f \in L^1(X, \mu)$. This means that there is $K > 0$ such that $K^{-1} < (d\mu \circ T)/(d\mu)(x) < K$ for a. a. x . Let \mathcal{P} be a finite partition of X . Denote by $C_n(x)$ the atom of $\bigvee_{i=0}^n T^{-i}\mathcal{P}$ which contains x . We put $\omega_{-1} = 0$. Parry shows in [155] that

$$\frac{\sum_{j=0}^n \log \mu(C_{n-j}(T^j x))(\omega_j(x) - \omega_{j-1}(x))}{\sum_{i=0}^n \omega_j(x)} \rightarrow$$

$$H\left(\mathcal{P} \mid \bigvee_{i=1}^\infty T^{-i}\mathcal{P}\right) - \int_X \log E\left(\frac{d\mu \circ T}{d\mu} \mid \bigvee_{i=0}^\infty T^{-i}\mathcal{P}\right) d\mu$$

for a. a. x . Parry also shows that under the aforementioned conditions on T ,

$$\frac{1}{n} \left(\sum_{j=0}^n H\left(\bigvee_{i=0}^j T^{-i}\mathcal{P}\right) - \sum_{j=0}^{n-1} H\left(\bigvee_{i=1}^{j+1} T^{-i}\mathcal{P}\right) \right) \rightarrow H\left(\mathcal{P} \mid \bigvee_{i=1}^\infty T^{-i}\mathcal{P}\right).$$

Critical Dimension

The critical dimension introduced by Mortiss [146] measures the order of growth for sums of Radon–Nikodym derivatives. Let (X, \mathcal{B}, μ, T) be an ergodic nonsingular dynamical system. Given $\delta > 0$, let

$$X_\delta := \left\{ x \in X \mid \liminf_{n \rightarrow \infty} \frac{\sum_{i=0}^{n-1} \omega_i(x)}{n^\delta} > 0 \right\} \text{ and} \quad (4)$$

$$X^\delta := \left\{ x \in X \mid \liminf_{n \rightarrow \infty} \frac{\sum_{i=0}^{n-1} \omega_i(x)}{n^\delta} = 0 \right\}. \quad (5)$$

Then X_δ and X^δ are T -invariant subsets.

Definition 37 ([57,146]) The lower critical dimension $\alpha(T)$ of T is $\sup \{ \delta \mid \mu(X_\delta) = 1 \}$. The upper critical dimension $\beta(T)$ of T is $\inf \{ \delta \mid \mu(X^\delta) = 1 \}$.

It was shown in [57] that the lower and upper critical dimensions are invariants for isomorphism of nonsingular systems. Notice also that

$$\alpha(T) = \liminf_{n \rightarrow \infty} \frac{\log \left(\sum_{i=1}^n \omega_i(x) \right)}{\log n} \text{ and}$$

$$\beta(T) = \limsup_{n \rightarrow \infty} \frac{\log \left(\sum_{i=1}^n \omega_i(x) \right)}{\log n}.$$

Moreover, $0 \leq \alpha(T) \leq \beta(T) \leq 1$. If T is of type II_1 then $\alpha(T) = \beta(T) = 1$. If T is the standard III_λ -odometer from Example 17 then $\alpha(T) = \beta(T) = \log(1 + \lambda) - \lambda/(1 + \lambda) \log \lambda$.

Theorem 38

(i) For every $\lambda \in [0, 1]$ and every $c \in [0, 1]$ there exists a nonsingular odometer of type III_λ with critical dimension equal to c [145].

(ii) For every $c \in [0, 1]$ there exists a nonsingular odometer of type Π_∞ with critical dimension equal to c [57].

Let T be the nonsingular odometer associated with a sequence $(m_n, \nu_n)_{n=1}^\infty$. Let $s(n) = m_1 \cdots m_n$ and let $H(\mathcal{P}_n)$ denote the entropy of the partition of the first n coordinates with respect to μ . We now state a nonsingular version of Shannon–MacMillan–Breiman theorem for T from [57].

Theorem 39 *Let m_i be bounded from above. Then*

(i)

$$\alpha(T) = \liminf_{n \rightarrow \infty} \inf \frac{-\sum_{i=1}^n \log m_i(x_i)}{\log s(n)} = \liminf_{n \rightarrow \infty} \frac{H(\mathcal{P}_n)}{\log s(n)}$$

and

(ii)

$$\beta(T) = \limsup_{n \rightarrow \infty} \inf \frac{-\sum_{i=1}^n \log m_i(x_i)}{\log s(n)} = \limsup_{n \rightarrow \infty} \frac{H(\mathcal{P}_n)}{\log s(n)}$$

for a. a. $x = (x_i)_{i \geq 1} \in X$.

It follows that in the case when $\alpha(T) = \beta(T)$, the critical dimension coincides with $\lim_{n \rightarrow \infty} H(\mathcal{P}_n)/(\log s(n))$. In [145] this expression (when it exists) was called *AC-entropy* (average coordinate). It also follows from Theorem 39 that if T is an odometer of bounded type then $\alpha(T^{-1}) = \alpha(T)$ and $\beta(T^{-1}) = \beta(T)$. In [58], Theorem 39 was extended to a subclass of Markov odometers. The critical dimensions for Hamachi shifts (see Subsect. “[Nonsingular Bernoulli Transformations – Hamachi’s Example](#)”) were investigated in [59]:

Theorem 40 *For any $\epsilon > 0$, there exists a Hamachi shift S with $\alpha(S) < \epsilon$ and $\beta(S) > 1 - \epsilon$.*

Nonsingular Restricted Orbit Equivalence

In [144] Mortiss initiated study of a nonsingular version of Rudolph’s restricted orbit equivalence [167]. This work is still in its early stages and does not yet deal with any form of entropy. However she introduced nonsingular orderings of orbits, defined sizes and showed that much of the basic machinery still works in the nonsingular setting.

Nonsingular Joinings and Factors

The theory of joinings is a powerful tool to study probabilistic preserving systems and to construct striking counterexamples. It is interesting to study what part of this machinery can be extended to the nonsingular case. However, the definition of nonsingular joining is far from being obvious. Some progress was achieved in understanding 2-fold joinings and constructing prime systems of any Krieger type. As far as we know the higher-fold nonsingular joinings have not been considered so far. It turned out however that an alternative coding technique, predating joinings in studying the centralizer and factors of the classical measure-preserving Chacón maps, can be used as well to classify factors of Cartesian products of some nonsingular Chacón maps.

Joinings, Nonsingular MSJ and Simplicity

In this section all measures are probability measures. A *nonsingular joining* of two nonsingular systems $(X_1, \mathcal{B}_1, \mu_1, T_1)$ and $(X_2, \mathcal{B}_2, \mu_2, T_2)$ is a measure $\hat{\mu}$ on the product $\mathcal{B}_1 \times \mathcal{B}_2$ that is nonsingular for $T_1 \times T_2$ and satisfies: $\hat{\mu}(A \times X_2) = \mu_1(A)$ and $\hat{\mu}(X_1 \times B) = \mu_2(B)$ for all $A \in \mathcal{B}_1$ and $B \in \mathcal{B}_2$. Clearly, the product $\mu_1 \times \mu_2$ is a nonsingular joining. Given a transformation $S \in C(T)$, the measure μ_S given by $\mu_S(A \times B) := \mu(A \cap S^{-1}B)$ is a nonsingular joining of (X, μ, T) and $(X, \mu \circ S^{-1}, T)$. It is called a *graph-joining* since it is supported on the graph of S . Another important kind of joinings that we are going to define now is related to factors of dynamical systems. Recall that given a nonsingular system (X, \mathcal{B}, μ, T) , a sub- σ -algebra \mathcal{A} of \mathcal{B} such that $T^{-1}(\mathcal{A}) = \mathcal{A} \text{ mod } \mu$ is called a *factor* of T . There is another, equivalent, definition. A nonsingular dynamical system (Y, \mathcal{C}, ν, S) is called a factor of T if there exists a measure-preserving map $\varphi: X \rightarrow Y$, called a *factor map*, with $\varphi T = S\varphi$ a. e. (If φ is only nonsingular, ν may be replaced with the equivalent measure $\mu \circ \varphi^{-1}$, for which φ is measure-preserving.) Indeed, the sub- σ -algebra $\varphi^{-1}(\mathcal{C}) \subset \mathcal{B}$ is T -invariant and, conversely, any T -invariant sub- σ -algebra of \mathcal{B} defines a factor map by immanent properties of standard probability spaces, see e.g. [3]. If φ is a factor map as above, then μ has a disintegration with respect to φ , i. e., $\mu = \int \mu_y d\nu(y)$ for a measurable map $y \mapsto \mu_y$ from Y to the probability measures on X so that $\mu_y(\varphi^{-1}(y)) = 1$, the measure $\mu_{S\varphi(x)} \circ T$ is equivalent to $\mu_{\varphi(x)}$ and

$$\frac{d\mu \circ T}{d\mu}(x) = \frac{d\nu \circ S}{d\nu}(\varphi(x)) \frac{d\mu_{S\varphi(x)} \circ T}{d\mu_{\varphi(x)}}(x) \tag{6}$$

for a. e. $x \in X$. Define now the *relative product* $\hat{\mu} = \mu \times_\varphi \mu$ on $X \times X$ by setting $\hat{\mu} = \int \mu_y \times \mu_y d\nu(y)$. Then

it is easy to deduce from (6) that $\hat{\mu}$ is a nonsingular self-joining of T .

We note however that the above definition of joining is not satisfactory since it does not reduce to the classical definition when we consider probability preserving systems. Indeed, the following result was proved in [168].

Theorem 41 *Let $(X_1, \mathcal{B}_1, \mu_1, T_1)$ and $(X_2, \mathcal{B}_2, \mu_2, T_2)$ be two finite measure-preserving systems such that $T_1 \times T_2$ is ergodic. Then for every $\lambda, 0 < \lambda < 1$, there exists a nonsingular joining $\hat{\mu}$ of μ_1 and μ_2 such that $(T_1 \times T_2, \hat{\mu})$ is ergodic and of type III_λ .*

It is not known however if the nonsingular joining $\hat{\mu}$ can be chosen in every orbit equivalence class. In view of the above, Rudolph and Silva [168] isolate an important subclass of joining. It is used in the definition of a nonsingular version of minimal self-joinings.

Definition 42

- (i) A nonsingular joining $\hat{\mu}$ of (X_1, μ_1, T_1) and (X_2, μ_2, T_2) is *rational* if there exist measurable functions $c^1: X_1 \rightarrow \mathbb{R}_+$ and $c^2: X_2 \rightarrow \mathbb{R}_+$ such that

$$\begin{aligned} \hat{\omega}_1^{\hat{\mu}}(x_1, x_2) &= \omega_1^{\mu_1}(x_1)\omega_1^{\mu_2}(x_2)c^1(x_1) \\ &= \omega_1^{\mu_1}(x_1)\omega_1^{\mu_2}(x_2)c^2(x_2) \quad \hat{\mu} \text{ a. e.} \end{aligned}$$

- (ii) A nonsingular dynamical system (X, \mathcal{B}, μ, T) has *minimal self-joinings (MSJ)* over a class \mathcal{M} of probability measures equivalent to μ , if for every $\mu_1, \mu_2 \in \mathcal{M}$, for every rational joining $\hat{\mu}$ of μ_1, μ_2 , a. e. ergodic component of $\hat{\mu}$ is either the product of its marginals or is the graph-joining supported on T^j for some $j \in \mathbb{Z}$.

Clearly, product measure, graph-joinings and the relative products are all rational joinings. Moreover, a rational joining of finite measure-preserving systems is measure-preserving and a rational joining of type II_1 's is of type II_1 [168]. Thus we obtain the finite measure-preserving theory as a special case. As for the definition of MSJ, it depends on a class \mathcal{M} of equivalent measures. In the finite measure-preserving case $\mathcal{M} = \{\mu\}$. However, in the nonsingular case no particular measure is distinguished. We note also that Definition 42(ii) involves some restrictions on all rational joinings and not only ergodic ones as in the finite measure-preserving case. The reason is that an ergodic component of a nonsingular joining needs not be a joining of measures equivalent to the original ones [2]. For finite measure-preserving transformations, MSJ over $\{\mu\}$ is the same as the usual 2-fold MSJ [49].

A nonsingular transformation T on (X, \mathcal{B}, μ) is called *prime* if its only factors are \mathcal{B} and $\{X, \emptyset\} \bmod \mu$. A (non-empty) class \mathcal{M} of probability measures equivalent to μ is said to be *centralizer stable* if for each $S \in C(T)$ and $\mu_1 \in \mathcal{M}$, the measure $\mu_1 \circ S$ is in \mathcal{M} .

Theorem 43 ([168]) *Let (X, \mathcal{B}, μ, T) be an ergodic nonatomic dynamical system such that T has MSJ over a class \mathcal{M} that is centralizer stable. Then T is prime and the centralizer of T consists of the powers of T .*

A question that arises is whether if such nonsingular dynamical systems (not of type II_1) exist. Expanding on Ornstein's original construction from [150], Rudolph and Silva construct in [168], for each $0 \leq \lambda \leq 1$, a nonsingular rank-one transformation T_λ that is of type III_λ and that has MSJ over a class \mathcal{M} that is centralizer stable. Type II_∞ examples with analogous properties were also constructed there. In this connection it is worth to mention the example by Aaronson and Nadkarni [6] of II_∞ ergodic transformations that have no factor algebras on which the invariant measure is σ -finite (except for the trivial and the entire ones); however these transformations are not prime.

A more general notion than MSJ called *graph self-joinings (GSJ)*, was introduced [181]: just replace the words "on T^j for some $j \in \mathbb{Z}$ " in Definition 3(ii) with "on S for some element $S \in C(T)$ ". For finite measure-preserving transformations, GSJ over $\{\mu\}$ is the same as the usual 2-fold simplicity [49]. The famous Veech theorem on factors of 2-fold simple maps (see [49]) was extended to nonsingular systems in [181] as follows: if a system (X, \mathcal{B}, μ, T) has GSJ then for every non-trivial factor \mathcal{A} of T there exists a locally compact subgroup H in $C(T)$ (equipped with the weak topology) which acts smoothly (i. e. the partition into H -orbits is measurable) and such that $\mathcal{A} = \{B \in \mathcal{B} \mid \mu(hB\Delta B) = 0 \text{ for all } h \in H\}$. It follows that there is a cocycle φ from $(X, \mathcal{A}, \mu \upharpoonright \mathcal{A})$ to H such that T is isomorphic to the φ -skew product extension $(T \upharpoonright \mathcal{A})_\varphi$ (see Subsect. "Cocycles of Dynamical Systems. Weak Equivalence of Cocycles"). Of course, the ergodic nonsingular odometers and, more generally, ergodic nonsingular compact group rotation (see Subsect. " L^∞ -Spectrum and Groups of Quasi-Invariance") have GSJ. However, except for this trivial case (the Cartesian square is non-ergodic) plus the systems with MSJ from [168], no examples of type III systems with GSJ are known. In particular, no smooth examples have been constructed so far. This is in sharp contrast with the finite measure preserving case where abundance of simple (or close to simple) systems are known (see [39,40,49,182]).

Nonsingular Coding and Factors of Cartesian Products of Nonsingular Maps

As we have already noticed above, the nonsingular MSJ theory was developed in [168] only for 2-fold self-joinings. The reasons for this were technical problems with extending the notion of rational joinings from 2-fold to n -fold self-joinings. However while the 2-fold nonsingular MSJ or GSJ properties of T are sufficient to control the centralizer and the factors of T , it is not clear whether it implies anything about the factors or centralizer of $T \times T$. Indeed, to control them one needs to know the 4-fold joinings of T . However even in the finite measure-preserving case it is a long standing open question whether 2-fold MSJ implies n -fold MSJ. That is why del Junco and Silva [51] apply an alternative – nonsingular coding – techniques to classify the factors of Cartesian products of nonsingular Chacón maps. The techniques were originally used in [48] to show that the classical Chacón map is prime and has trivial centralizer. They were extended to nonsingular systems in [50].

For each $0 < \lambda < 1$ we denote by T_λ the Chacón map (see Subsect. “Rank-One Transformations. Chacón Maps. Finite Rank”) corresponding the sequence of probability vectors $w_n = (\lambda/(1 + 2\lambda), 1/(1 + 2\lambda), \lambda/(1 + 2\lambda))$ for all $n > 0$. One can verify that the maps T_λ are of type III_λ . (The classical Chacón map corresponds to $\lambda = 1$.) All of these transformations are defined on the same standard Borel space (X, \mathcal{B}) . These transformations were shown to be power weakly mixing in [12]. The centralizer of any finite Cartesian product of nonsingular Chacón maps is computed in the following theorem.

Theorem 44 ([51]) *Let $0 < \lambda_1 < \dots < \lambda_k \leq 1$ and n_1, \dots, n_k be positive integers. Then the centralizer of the Cartesian product $T_{\lambda_1}^{\otimes n_1} \times \dots \times T_{\lambda_k}^{\otimes n_k}$ is generated by maps of the form $U_1 \times \dots \times U_k$, where each U_i , acting on the n_i -dimensional product space X^{n_i} , is a Cartesian product of powers of T_{λ_i} or a co-ordinate permutation on X^{n_i} .*

Let π denote the permutation on $X \times X$ defined by $\pi(x, y) = (y, x)$ and let $\mathcal{B}^{2\odot}$ denote the symmetric factor, i. e. $\mathcal{B}^{2\odot} = \{A \in \mathcal{B} \otimes \mathcal{B} \mid \pi(A) = A\}$. The following theorem classifies the factors of the Cartesian product of any two nonsingular type III_λ , $0 < \lambda < 1$, or type II_1 Chacón maps.

Theorem 45 ([51]) *Let T_{λ_1} and T_{λ_2} be two nonsingular Chacón systems. Let \mathcal{F} be a factor algebra of $T_{\lambda_1} \times T_{\lambda_2}$.*

- (i) *If $\lambda_1 \neq \lambda_2$ then \mathcal{F} is equal mod 0 to one of the four algebras $\mathcal{B} \otimes \mathcal{B}$, $\mathcal{B} \otimes \mathcal{N}$, $\mathcal{N} \otimes \mathcal{B}$, or $\mathcal{N} \otimes \mathcal{N}$, where $\mathcal{N} = \{\emptyset, X\}$.*

- (ii) *If $\lambda_1 = \lambda_2$ then \mathcal{F} is equal mod 0 to one of the following algebras $\mathcal{B} \otimes \mathcal{C}$, $\mathcal{B} \otimes \mathcal{N}$, $\mathcal{N} \otimes \mathcal{C}$, $\mathcal{N} \otimes \mathcal{N}$, or $(T^m \times \text{Id})\mathcal{B}^{2\odot}$ for some integer m .*

It is not hard to obtain type III_1 examples of Chacón maps for which the previous two theorems hold. However the construction of type II_∞ and type III_0 nonsingular Chacón transformations is more subtle as it needs the choice of ω_n to vary with n . In [92], Hamachi and Silva construct type III_0 and type II_∞ examples, however the only property proved for these maps is ergodicity of their Cartesian square. More recently, Danilenko [38] has shown that all of them (in fact, a wider class of nonsingular Chacón maps of all types) are power weakly mixing.

In [22], Choksi, Eigen and Prasad asked whether there exists a zero entropy, finite measure-preserving mixing automorphism S , and a nonsingular type III automorphism T , such that $T \times S$ has no Bernoulli factors. Theorem 45 provides a partial answer (with a mildly mixing only instead of mixing) to this question: if S is the finite measure-preserving Chacón map and T is a nonsingular Chacón map as above, the factors of $T \times S$ are only the trivial ones, so $T \times S$ has no Bernoulli factors.

Applications. Connections with Other Fields

In this – final – section we shed light on numerous mathematical sources of nonsingular systems. They come from the theory of stochastic processes, random walks, locally compact Cantor systems, horocycle flows on hyperbolic surfaces, von Neumann algebras, statistical mechanics, representation theory for groups and anticommutation relations, etc. We also note that such systems sometimes appear in the context of probability preserving dynamics (see also a criterium of distality in Subsect. “Krengel’s and Parry’s Entropies”).

Mild Mixing

An ergodic finite measure-preserving dynamical system (X, \mathcal{B}, μ, T) is called *mildly mixing* if for each non-trivial factor algebra $\mathcal{A} \subset \mathcal{B}$, the restriction $T \upharpoonright \mathcal{A}$ is not rigid. For equivalent definitions and extensions to actions of locally compact groups we refer to [3] and [177]. There is an interesting criterium of the mild mixing that involves nonsingular systems: T is mildly mixing if and only if for each ergodic nonsingular transformation S , the product $T \times S$ is ergodic [71]. Furthermore, $T \times S$ is then orbit equivalent to S [98]. Moreover, if R is a nonsingular transformation such that $R \times S$ is ergodic for any ergodic nonsingular S then R is of type II_1 (and mildly mixing) [177].

Disjointness and Furstenberg’s Class \mathcal{W}^\perp

Two probability preserving systems (X, μ, T) and (Y, ν, S) are called *disjoint* if $\mu \times \nu$ is the only $T \times S$ -invariant probability measure on $X \times Y$ whose coordinate projections are μ and ν respectively. Furstenberg in [69] initiated studying the class \mathcal{W}^\perp of transformations disjoint from all weakly mixing ones. Let \mathcal{D} denote the class of distal transformations and $\mathcal{M}(\mathcal{W}^\perp)$ the class of multipliers of \mathcal{W}^\perp (for the definitions see [75]). Then $\mathcal{D} \subset \mathcal{M}(\mathcal{W}^\perp) \subset \mathcal{W}^\perp$. In [43] and [133] it was shown by constructing explicit examples that these inclusions are strict. We record this fact here because nonsingular ergodic theory was the key ingredient of the arguments in the two papers pertaining to the theory of probability preserving systems. The examples are of the form $T_{\varphi,S}(x, y) = (Tx, S_{\varphi(x)}y)$, where T is an ergodic rotation on (X, μ) , $(S_g)_{g \in G}$ a mildly mixing action of a locally compact group G on Y and $\varphi: X \rightarrow G$ a measurable map. Let W_φ denote the Mackey action of G associated with φ and let (Z, κ) be the space of this action. The key observation is that there exists an affine isomorphism of the simplex of $T_{\varphi,S}$ -invariant probability measures whose pullback on X is μ and the simplex of $W_\varphi \times S$ quasi-invariant probability measures whose pullback on Z is κ and whose Radon–Nikodym cocycle is measurable with respect to Z . This is a far reaching generalization of Furstenberg theorem on relative unique ergodicity of ergodic compact group extensions.

Symmetric Stable and Infinitely Divisible Stationary Processes

Rosinsky in [163] established a remarkable connection between structural studies of stationary stochastic processes and ergodic theory of nonsingular transformations (and flows). For simplicity we consider only real processes in discrete time. Let $X = (X_n)_{n \in \mathbb{Z}}$ be a measurable stationary symmetric α -stable (S α S) process, $0 < \alpha < 2$. This means that any linear combination $\sum_{k=1}^n a_k X_{j_k}$, $j_k \in \mathbb{Z}$, $a_k \in \mathbb{R}$ has an S α S-distribution. (The case $\alpha = 2$ corresponds to Gaussian processes.) Then the process admits a spectral representation

$$X_n = \int_Y f_n(y) M(dy), \quad n \in \mathbb{Z}, \tag{7}$$

where $f_n \in L^\alpha(Y, \mu)$ for a standard σ -finite measure space (Y, \mathcal{B}, μ) and M is an independently scattered random measure on \mathcal{B} such that $E \exp(iuM(A)) = \exp(-|u|^\alpha \mu(A))$ for every $A \in \mathcal{B}$ of finite measure. By [163], one can choose the kernel $(f_n)_{n \in \mathbb{Z}}$ in a special way: there are a μ -nonsingular transformation T and measurable maps $\varphi: X \rightarrow \{-1, 1\}$ and $f \in L^\alpha(Y, \mu)$ such that

$f_n = U^n f$, $n \in \mathbb{Z}$, where U is the isometry of $L^\alpha(X, \mu)$ given by $Ug = \varphi \cdot (d\mu \circ T/d\mu)^{1/\alpha} \cdot g \circ T$. If, in addition, the smallest T -invariant σ -algebra containing $f^{-1}(\mathcal{B}_\mathbb{R})$ coincides with \mathcal{B} and $\text{Supp} \{f \circ T^n: n \in \mathbb{Z}\} = Y$ then the pair (T, φ) is called minimal. It turns out that minimal pairs always exist. Moreover, two minimal pairs (T, φ) and (T', φ') representing the same S α S process are equivalent in some natural sense [163]. Then one can relate ergodic-theoretical properties of (T, φ) to probabilistic properties of $(X_n)_{n \in \mathbb{Z}}$. For instance, let $Y = C \sqcup D$ be the Hopf decomposition of Y (see Theorem 2). We let $X_n^D := \int_D f_n(y) M(dy)$ and $X_n^C := \int_C f_n(y) M(dy)$. Then we obtain a unique (in distribution) decomposition of X into the sum $X^D + X^C$ of two independent stationary S α S-processes.

Another kind of decomposition was considered in [171]. Let P be the largest invariant subset of Y such that $T \upharpoonright P$ has a finite invariant measure. Partitioning Y into P and $N := Y \setminus P$ and restricting the integration in (7) to P and N we obtain a unique (in distribution) decomposition of X into the sum $X^P + X^N$ of two independent stationary S α S-processes. Notice that the process X is ergodic if and only if $\mu(P) = 0$.

Recently, Roy considered a more general class of *infinitely divisible (ID)* stationary processes [165]. Using Maruyama’s representation of the characteristic function of an ID process X without Gaussian part he singled out the Lévy measure Q of X . Then Q is a shift invariant σ -finite measure on $\mathbb{R}^\mathbb{Z}$. Decomposing the dynamical system $(\mathbb{R}^\mathbb{Z}, \tau, Q)$ in various natural ways (Hopf decomposition, 0-type and positive type, so-called ‘rigidity free’ part and its complement) he obtains corresponding decompositions for the process X . Here τ stands for the shift on $\mathbb{R}^\mathbb{Z}$.

Poisson Suspensions

Poisson suspensions are widely used in statistical mechanics to model ideal gas, Lorentz gas, etc (see [33]). Let (X, \mathcal{B}, μ) be a standard σ -finite non-atomic measure space and $\mu(X) = \infty$. Denote by \tilde{X} the space of unordered countable subsets of X . It is called the space of *configurations*. Fix $t > 0$. Let $A \in \mathcal{B}$ have positive finite measure and let $j \in \mathbb{Z}_+$. Denote by $[A, j]$ the subset of all configurations $\tilde{x} \in \tilde{X}$ such that $\#(\tilde{x} \cap A) = j$. Let $\tilde{\mathcal{B}}$ be the σ -algebra generated by all $[A, j]$. We define a probability measure $\tilde{\mu}_t$ on $\tilde{\mathcal{B}}$ by two conditions:

- (i) $\tilde{\mu}_t([A, j]) = \frac{(t\mu(A))^j}{j!} \exp(-t\mu(A))$;
- (ii) if A_1, \dots, A_p are pairwise disjoint then $\tilde{\mu}_t(\bigcap_{k=1}^p [A_k, j_k]) = \prod_{k=1}^p \tilde{\mu}_t([A_k, j_k])$.

If T is a μ -preserving transformation of X and $\tilde{x} = (x_1, x_2, \dots)$ is a configuration then we set $\tilde{T}\omega := (Tx_1, Tx_2, \dots)$. It is easy to verify that \tilde{T} is a $\tilde{\mu}$ -preserving transformation of \tilde{X} . The dynamical system $(\tilde{X}, \tilde{\mathcal{B}}, \tilde{\mu}, \tilde{T})$ is called the *Poisson suspension* above (X, \mathcal{B}, μ, T) . It is ergodic if and only if T has no invariant sets of finite positive measure. There is a canonical representation of $L^2(\tilde{X}, \tilde{\mu})$ as the Fock space over $L^2(X, \mu)$ such that the unitary operator $U_{\tilde{T}}$ is the ‘exponent’ of U_T . Thus, the maximal spectral type of $U_{\tilde{T}}$ is $\sum_{n \geq 0} (n!)^{-1} \sigma^{*n}$, where σ is a measure of the maximal spectral type of U_T . It is easy to see that a σ -finite factor of T corresponds to a factor (called Poissonian) of \tilde{T} . Moreover, a σ -finite measure-preserving joining (with σ -finite projections) of two infinite measure-preserving transformations T_1 and T_2 generates a joining (called Poissonian) of \tilde{T}_1 and \tilde{T}_2 [52,164]. Thus we see a similarity with the well studied theory of Gaussian dynamical systems [134]. However, the Poissonian case is less understood. There was a recent progress in this field. Parreau and Roy constructed Poisson suspensions whose ergodic self-joinings are all Poissonian [154]. In [111] partial solutions of the following (still open) problems are found:

- (i) whether the Pinsker factor of \tilde{T} is Poissonian,
- (ii) what is the relationship between Krengel’s entropy of T , Parry’s entropy of T and Kolmogorov–Sinai entropy of \tilde{T} .

Recurrence of Random Walks with Non-stationary Increments

Using nonsingular ergodic theory one can introduce the notion of recurrence for random walks obtained from certain non-stationary processes. Let T be an ergodic nonsingular transformation of a standard probability space (X, \mathcal{B}, μ) and let $f: X \rightarrow \mathbb{R}^n$ a measurable function. Define for $m \geq 1$, $Y_m: X \rightarrow \mathbb{R}^n$ by $Y_m := \sum_{n=0}^{m-1} f \circ T^n$. In other words, $(Y_m)_{m \geq 1}$ is the random walk associated with the (non-stationary) process $(f \circ T^n)_{n \geq 0}$. Let us call this random walk *recurrent* if the cocycle f of T is recurrent (see Subsect. “Cocycles of Dynamical Systems. Weak Equivalence of Cocycles”). It was shown in [176] that in the case $\mu \circ T = \mu$, i. e. the process is stationary, this definition is equivalent to the standard one.

Boundaries of Random Walks

Boundaries of random walks on groups retain valuable information on the underlying groups (amenability, entropy, etc.) and enable one to obtain integral representation for harmonic functions of the random

walk [112,186,187]. Let G be a locally compact group and ν a probability measure on G . Let T denote the (one-sided) shift on the probability space $(X, \mathcal{B}_X, \mu) := (G, \mathcal{B}_G, \nu)^{\mathbb{Z}^+}$ and $\varphi: X \rightarrow G$ a measurable map defined by $(y_0, y_1, \dots) \mapsto y_0$. Let T_φ be the φ -skew product extension of T acting on the space $(X \times G, \mu \times \lambda_G)$ (for non-invertible transformations the skew product extension is defined in the very same way as for invertible ones, see Subsect. “Cocycles of Dynamical Systems. Weak Equivalence of Cocycles”). Then T_φ is isomorphic to the *homogeneous random walk* on G with jump probability ν . Let $\mathcal{I}(T_\varphi)$ denote the sub- σ -algebra of T_φ -invariant sets and let $\mathcal{F}(T_\varphi) := \bigcap_{n > 0} T_\varphi^{-n}(\mathcal{B}_X \otimes \mathcal{B}_G)$. The former is called the *Poisson boundary* of T_φ and the latter one is called the *tail boundary* of T_φ . Notice that a nonsingular action of G by inverted right translations along the second coordinate is well defined on each of the two boundaries. The two boundaries (or, more precisely, the G -actions on them) are ergodic. The Poisson boundary is the Mackey range of φ (as a cocycle of T). Hence the Poisson boundary is amenable [187]. If the support of ν generates a dense subgroup of G then the corresponding Poisson boundary is weakly mixing [4]. As for the tail boundary, we first note that it can be defined for a wider family of *non-homogeneous* random walks. This means that the jump probability ν is no longer fixed and a sequence $(\nu_n)_{n > 0}$ of probability measures on G is considered instead. Now let $(X, \mathcal{B}_X, \mu) := \prod_{n > 0} (G, \mathcal{B}_G, \nu_n)$. The one-sided shift on X may not be nonsingular now. Instead of it, we consider the tail equivalence relation \mathcal{R} on X and a cocycle $\alpha: \mathcal{R} \rightarrow G$ given by $\alpha(x, y) = x_1 \cdots x_n y_n^{-1} \cdots y_1$, where $x = (x_i)_{i > 0}$ and $y = (y_i)_{i > 0}$ are \mathcal{R} -equivalent and n is the smallest integer such that $x_i = y_i$ for all $i > n$. The tail boundary of the random walk on G with time dependent jump probabilities $(\nu_n)_{n > 0}$ is the Mackey G -action associated with α . In the case of homogeneous random walks this definition is equivalent to the initial one. Connes and Woods showed [32] that the tail boundary is always amenable and AT. It is unknown whether the converse holds for general G . However it is true for $G = \mathbb{R}$ and $G = \mathbb{Z}$: the class of AT-flows coincides with the class of tail boundaries of the random walks on \mathbb{R} and a similar statement holds for \mathbb{Z} [32]. Jaworsky showed [109] that if G is countable and a random walk is homogeneous then the tail boundary of the random walk possesses a so-called SAT-property (which is stronger than AT).

Classifying σ -Finite Ergodic Invariant Measures

The description of ergodic finite invariant measures for topological (or, more generally, standard Borel) systems

is a well established problem in the classical ergodic theory [33]. On the other hand, it seems impossible to obtain any useful information about the system by analyzing the set of all ergodic quasi-invariant (or just σ -finite invariant) measures because this set is wildly huge (see Subsect. “The Glimm–Effros Theorem”). The situation changes if we impose some restrictions on the measures. For instance, if the system under question is a homeomorphism (or a topological flow) defined on a locally compact Polish space then it is natural to consider the class of (σ -finite) invariant Radon measures, i. e. measures taking finite values on the compact subsets. We give two examples.

First, the seminal results of Giordano, Putnam and Skau on the topological orbit equivalence of compact Cantor minimal systems were extended to locally compact Cantor minimal (l.c.c.m.) systems in [37] and [138]. Given a l.c.c.m. system X , we denote by $\mathcal{M}(X)$ and $\mathcal{M}_1(X)$ the set of invariant Radon measures and the set of invariant probability measures on X . Notice that $\mathcal{M}_1(X)$ may be empty [37]. It was shown in [138] that two systems X and X' are topologically orbit equivalent if and only if there is a homeomorphism of X onto X' which maps bijectively $\mathcal{M}(X)$ onto $\mathcal{M}(X')$ and $\mathcal{M}_1(X)$ onto $\mathcal{M}_1(X')$. Thus $\mathcal{M}(X)$ retains an important information on the system – it is ‘responsible’ for the topological orbit equivalence of the underlying systems. Uniquely ergodic l.c.c.m. systems (with unique up to scaling infinite invariant Radon measure) were constructed in [37].

The second example is related to study of the smooth horocycle flows on tangent bundles of hyperbolic surfaces. Let \mathbb{D} be the open disk equipped with the hyperbolic metric $|dz|/(1 - |z|^2)$ and let $\text{Möb}(\mathbb{D})$ denote the group of Möbius transformations of \mathbb{D} . A hyperbolic surface can be written in the form $M := \Gamma \backslash \text{Möb}(\mathbb{D})$, where Γ is a torsion free discrete subgroup of $\text{Möb}(\mathbb{D})$. Suppose that Γ is a nontrivial normal subgroup of a lattice Γ_0 in $\text{Möb}(\mathbb{D})$. Then M is a regular cover of the finite volume surface $M_0 := \Gamma_0 \backslash \text{Möb}(\mathbb{D})$. The group of deck transformations $G = \Gamma_0/\Gamma$ is finitely generated. The horocycle flow $(h_t)_{t \in \mathbb{R}}$ and the geodesic flow $(g_t)_{t \in \mathbb{R}}$ defined on the unit tangent bundle $T^1(\mathbb{D})$ descend naturally to flows, say h and g , on $T^1(M)$. We consider the problem of classification of the h -invariant Radon measures on M . According to Ratner, h has no finite invariant measures on M if G is infinite (except for measures supported on closed orbits). However there are infinite invariant Radon measures, for instance the volume measure. In the case when G is free Abelian and Γ_0 is co-compact, every homomorphism $\varphi: G \rightarrow \mathbb{R}$ determines a unique up to scaling ergodic invariant Radon measure (e.i.r.m.) m on $T^1(M)$ such that $m \circ dD = \exp(\varphi(D))m$ for all $D \in G$ [16] and ev-

ery e.i.r.m. arises this way [172]. Moreover all these measures are quasi-invariant under g . In the general case, an interesting bijection is established in [131] between the e.i.r.m. which are quasi-invariant under g and the ‘non-trivial minimal’ positive eigenfunctions of the hyperbolic Laplacian on M .

Von Neumann Algebras

There is a fascinating and productive interplay between nonsingular ergodic theory and von Neumann algebras. The two theories alternately influenced development of each other. Let (X, \mathcal{B}, μ, T) be a nonsingular dynamical system. Given $\varphi \in L^\infty(X, \mu)$ and $j \in \mathbb{Z}$, we define operators A_φ and U_j on the Hilbert space $L^2(Z \times \mathbb{Z}, \mu \times \nu)$ by setting

$$(A_\varphi f)(x, i) := \varphi(T^i x) f(x, i),$$

$$(U_j f)(x, i) := f(x, i - j).$$

Then $U_j A_\varphi U_j^* = A_{\varphi \circ T^j}$. Denote by \mathcal{M} the von Neumann algebra (i. e. the weak closure of the $*$ -algebra) generated by A_φ , $\varphi \in L^\infty(X, \mu)$ and U_j , $j \in \mathbb{Z}$. If T is ergodic and aperiodic then \mathcal{M} is a factor, i. e. $\mathcal{M} \cap \mathcal{M}' = \mathbb{C}1$, where \mathcal{M}' denotes the algebra of bounded operators commuting with \mathcal{M} . It is called a *Krieger’s factor*. Murray–von Neumann–Connes’ type of \mathcal{M} is exactly the Krieger’s type of T . The flow of weights of \mathcal{M} is isomorphic to the associated flow of T . Two Krieger’s factors are isomorphic if and only if the underlying dynamical systems are orbit equivalent [129]. Moreover, a number of important problems in the theory of von Neumann algebras such as classification of subfactors, computation of the flow of weights and Connes’ invariants, outer conjugacy for automorphisms, etc. are intimately related to the corresponding problems in nonsingular orbit theory. We refer to [42,66,73,74,89,142] for details.

Representations of CAR

Representations of canonical anticommutation relations (CAR) is one of the most elegant and useful chapters of mathematical physics, providing a natural language for many body quantum physics and quantum field theory. By a representation of CAR we mean a sequence of bounded linear operators a_1, a_2, \dots in a separable Hilbert space \mathcal{K} such that $a_j a_k + a_k a_j = 0$ and $a_j a_k^* + a_k^* a_j = \delta_{j,k}$.

Consider $\{0, 1\}$ as a group with addition mod 2. Then $X = \{0, 1\}^{\mathbb{N}}$ is a compact Abelian group. Let $\Gamma := \{x = (x_1, x_2, \dots) : \lim_{n \rightarrow \infty} x_n = 0\}$. Then Γ is a dense countable subgroup of X . It is generated by elements γ_k whose k -coordinate is 1 and the other ones

are 0. Γ acts on X by translations. Let μ be an ergodic Γ -quasi-invariant measure on X . Let $(C_k)_{k \geq 1}$ be Borel maps from X to the group of unitary operators in a Hilbert space \mathcal{H} satisfying $C_k^*(x) = C_k(x + \delta_k)$, $C_k(x)C_l(x + \delta_l) = C_l(x)C_k(x + \delta_k)$, $k \neq l$ for a. a. x . In other words, $(C_k)_{k \geq 1}$ defines a cocycle of the Γ -action. We now put $\widetilde{\mathcal{H}} := L^2(X, \mu) \otimes \mathcal{H}$ and define operators a_k in $\widetilde{\mathcal{H}}$ by setting

$$(a_k f)(x) = (-1)^{x_1 + \dots + x_{k-1}} (1 - x_k) \\ \times C_k(x) \sqrt{\frac{d\mu \circ \delta_k}{d\mu}}(x) f(x + \delta_k),$$

where $f: X \rightarrow \mathcal{H}$ is an element of $\widetilde{\mathcal{H}}$ and $x = (x_1, x_2, \dots) \in X$. It is easy to verify that a_1, a_2, \dots is a representation of CAR. The converse was established in [72] and [77]: every factor-representation (this means that the von Neumann algebra generated by all a_k is a factor) of CAR can be represented as above for some ergodic measure μ , Hilbert space \mathcal{H} and a Γ -cocycle $(C_k)_{k \geq 1}$. Moreover, using nonsingular ergodic theory Golodets [77] constructed for each $k = 2, 3, \dots, \infty$, an irreducible representation of CAR such that $\dim \mathcal{H} = k$. This answered a question of Gårding and Wightman [72] who considered only the case $k = 1$.

Unitary Representations of Locally Compact Groups

Nonsingular actions appear in a systematic way in the theory of unitary representations of groups. Let G be a locally compact second countable group and H a closed normal subgroup of G . Suppose that H is commutative (or, more generally, of type I, see [53]). Then the natural action of G by conjugation on H induces a Borel G -action, say α , on the dual space \widehat{H} – the set of unitarily equivalent classes of irreducible unitary representations of H . If now $U = (U_g)_{g \in G}$ is a unitary representation of G in a separable Hilbert space then by applying Stone decomposition theorem to $U \upharpoonright H$ one can deduce that α is nonsingular with respect to a measure μ of the ‘maximal spectral type’ for $U \upharpoonright H$ on \widehat{H} . Moreover, if U is irreducible then α is ergodic. Whenever μ is fixed, we obtain a one-to-one correspondence between the set of cohomology classes of irreducible cocycles for α with values in the unitary group on a Hilbert space \mathcal{H} and the subset of \widehat{G} consisting of classes of those unitary representations V for which the measure associated to $V \upharpoonright H$ is equivalent to μ . This correspondence is used in both directions. From information about cocycles we can deduce facts about representations and vice versa [53, 118].

Concluding Remarks

While some of the results that we have cited for nonsingular \mathbb{Z} -actions extend to actions of locally compact Polish groups (or subclasses of Abelian or amenable ones), many natural questions remain open in the general setting. For instance: what is Rokhlin lemma, or the pointwise ergodic theorem, or the definition of entropy for nonsingular actions of general countable amenable groups? The theory of abstract nonsingular equivalence relations [66] or, more generally, nonsingular groupoids [160] and polymorphisms [184] is also a beautiful part of nonsingular ergodic theory that has nice applications: description of semifinite traces of AF-algebras, classification of factor representations of the infinite symmetric group [185], path groups [14], etc. Nonsingular ergodic theory is getting even more sophisticated when we pass from \mathbb{Z} -actions to noninvertible endomorphisms or, more generally, semigroup actions (see [3] and references therein). However, due to restrictions of space we do not consider these issues in our survey.

Almost every, essentially Given a Lebesgue measure space (X, \mathcal{B}, μ) , a property $P(x)$ predicated of elements of X is said to hold for almost every $x \in X$, if the set $X \setminus \{x : P(x) \text{ holds}\}$ has zero measure. Two sets $A, B \in \mathcal{B}$ are essentially disjoint if $\mu(A \cap B) = 0$.

Conservative system Is an infinite measure preserving system such that for no set $A \in \mathcal{B}$ with positive measure are $A, T^{-1}A, T^{-2}A, \dots$ pairwise essentially disjoint.

(c_n) -Conservative system If $(c_n)_{n \in \mathbb{N}}$ is a decreasing sequence of positive real numbers, a conservative

ergodic measure preserving transformation T is (c_n) -conservative if for some non-negative function $f \in L^1(\mu)$, $\sum_{n=1}^{\infty} c_n f(T^n x) = \infty$ a.e.

Doubling map If \mathbb{T} is the interval $[0, 1]$ with its endpoints identified and addition performed modulo 1, the (non-invertible) transformation $T: \mathbb{T} \rightarrow \mathbb{T}$, defined by $Tx = 2x \bmod 1$, preserves Lebesgue measure, hence induces a measure preserving system on \mathbb{T} .

Ergodic system Is a measure preserving system (X, \mathcal{B}, μ, T) (finite or infinite) such that every $A \in \mathcal{B}$ that is T -invariant (i.e. $T^{-1}A = A$) satisfies either $\mu(A) = 0$ or $\mu(X \setminus A) = 0$. (One can check that the rotation R_α is ergodic if and only if α is irrational, and that the doubling map is ergodic).

Ergodic decomposition Every measure preserving system (X, \mathcal{X}, μ, T) can be expressed as an integral of ergodic systems; for example, one can write $\mu = \int \mu_t d\lambda(t)$, where λ is a probability measure on $[0, 1]$ and μ_t are T -invariant probability measures on (X, \mathcal{X}) such that the systems $(X, \mathcal{X}, \mu_t, T)$ are ergodic for $t \in [0, 1]$.

Ergodic theorem States that if (X, \mathcal{B}, μ, T) is a measure preserving system and $f \in L^2(\mu)$, then $\lim_{N \rightarrow \infty} \left\| \frac{1}{N} \sum_{n=1}^N T^n f - P_f \right\|_{L^2(\mu)} = 0$, where P_f denotes the orthogonal projection of the function f onto the subspace $\{f \in L^2(\mu): Tf = f\}$.

Hausdorff a -measure Let (X, \mathcal{B}, μ, T) be a measure preserving system endowed with a μ -compatible metric d . The Hausdorff a -measure $\mathcal{H}_a(X)$ of X is an outer measure defined for all subsets of X as follows: First, for $A \subset X$ and $\varepsilon > 0$ let $\mathcal{H}_{a,\varepsilon}(A) = \inf\{\sum_{i=1}^{\infty} r_i^a\}$, where the infimum is taken over all countable coverings of A by sets $U_i \subset X$ with diameter $r_i < \varepsilon$. Then define $\mathcal{H}_a(A) = \limsup_{\varepsilon \rightarrow 0} \mathcal{H}_{a,\varepsilon}(A)$.

Infinite measure preserving system Same as measure preserving system, but $\mu(X) = \infty$.

Invertible system Is a measure preserving system (X, \mathcal{B}, μ, T) (finite or infinite), with the property that there exists $X_0 \in \mathcal{B}$, with $\mu(X \setminus X_0) = 0$, and such that the transformation $T: X_0 \rightarrow X_0$ is bijective, with T^{-1} measurable.

Measure preserving system Is a quadruple (X, \mathcal{B}, μ, T) , where X is a set, \mathcal{B} is a σ -algebra of subsets of X (i.e. \mathcal{B} is closed under countable unions and complementation), μ is a probability measure (i.e. a countably additive function from \mathcal{B} to $[0, 1]$ with $\mu(X) = 1$), and $T: X \rightarrow X$ is measurable (i.e. $T^{-1}A = \{x \in X: Tx \in A\} \in \mathcal{B}$ for $A \in \mathcal{B}$), and μ -preserving (i.e. $\mu(T^{-1}A) = \mu(A)$). Moreover, throughout the discussion we assume that the measure space (X, \mathcal{B}, μ) is Lebesgue (see Sect. 1.0 in [2]).

μ -Compatible metric Is a separable metric on X , where (X, \mathcal{B}, μ) is a probability space, having the property that open sets are measurable.

Positive definite sequence Is a complex-valued sequence $(a_n)_{n \in \mathbb{Z}}$ such that for any $n_1, \dots, n_k \in \mathbb{Z}$ and $z_1, \dots, z_k \in \mathbb{C}$, $\sum_{i,j=1}^k a_{n_i-n_j} z_i \bar{z}_j \geq 0$.

Rotations on \mathbb{T} If \mathbb{T} is the interval $[0, 1]$ with its endpoints identified and addition performed modulo 1, then for every $\alpha \in \mathbb{R}$ the transformation $R_\alpha: \mathbb{T} \rightarrow \mathbb{T}$, defined by $R_\alpha x = x + \alpha \bmod 1$, preserves Lebesgue measure on \mathbb{T} and hence induces a measure preserving system on \mathbb{T} .

Syndetic set Is a subset $E \subset \mathbb{Z}$ having bounded gaps. If G is a general discrete group, a set $E \subset G$ is syndetic if $G = FE$ for some finite set $F \subset G$.

Upper density Is the number $\bar{d}(A) = \limsup_{N \rightarrow \infty} (|A \cap \{-N, \dots, N\}|) / (2N + 1)$, where $A \subset \mathbb{Z}$ (assuming the limit to exist). Alternatively for measurable $E \subset \mathbb{R}^m$, $\bar{D}(E) = \limsup_{l(S) \rightarrow \infty} (m(S \cap E)) / (m(S))$, where S ranges over all cubes in \mathbb{R}^m , and $l(S)$ denotes the length of the shortest edge of S .

Notation The following notation will be used throughout the article: $Tf = f \circ T$, $\{x\} = x - [x]$, $D\text{-}\lim_{n \rightarrow \infty} (a_n) = a \leftrightarrow \bar{d}(\{n: |a_n - a| > \varepsilon\}) = 0$ for every $\varepsilon > 0$.

Definition of the Subject

The basic principle that lies behind several recurrence phenomena is that the typical trajectory of a system with finite volume comes back infinitely often to any neighborhood of its initial point. This principle was first exploited by Poincaré in his 1890 King Oscar prize-winning memoir that studied planetary motion. Using the prototype of an ergodic-theoretic argument, he showed that in any system of point masses having fixed total energy that restricts its dynamics to bounded subsets of its phase space, the typical state of motion (characterized by configurations and velocities) must recur to an arbitrary degree of approximation.

Among the recurrence principle's more spectacularly counterintuitive ramifications is that isolated ideal gas systems that do not lose energy will return arbitrarily closely to their initial states, even when such a return entails a decrease in entropy from equilibrium, in apparent contradiction to the second law of thermodynamics. Such concerns, previously canvassed by Poincaré himself, were more infamously expounded by Zermelo [74] in 1896. Subsequent clarifications by Boltzmann, Maxwell and others led to an improved understanding of the second law's primarily statistical nature. (For an interesting historical/philosophical

discussion, see [68]; also [10]. For a probabilistic analysis of the likelihood of observing second law violations in small systems over short time intervals, see [28]).

These discoveries had a profound impact in dynamics, and the theory of measure preserving transformations (ergodic theory) evolved from these developments. Since then, the Poincaré recurrence principle has been applied to a variety of different fields in mathematics, physics, and information theory. In this article we survey the impact it has had in ergodic theory, especially as pertains to the field of *ergodic Ramsey theory*. (The heavy emphasis herein on the latter reflects authorial interest, and is not intended to transmit a proportionate image of the broader landscape of research relating to recurrence in ergodic theory.) Background information we assume in this article can be found in the books [35,63,71] (► [Measure Preserving Systems](#)).

Introduction

In this section we shall give several formulations of the Poincaré recurrence principle using the language of ergodic theory. Roughly speaking, the principle states that in a finite (or conservative) measure preserving system, every set of positive measure (or almost every point) comes back to itself infinitely many times under iteration. Despite the profound importance of these results, their proofs are extremely simple.

Theorem 1 (Poincaré Recurrence for Sets) *Let (X, \mathcal{B}, μ, T) be a measure preserving system and $A \in \mathcal{B}$ with $\mu(A) > 0$. Then $\mu(A \cap T^{-n}A) > 0$ for infinitely many $n \in \mathbb{N}$.*

Proof Since T is measure preserving, the sets $A, T^{-1}A, T^{-2}A, \dots$ have the same measure. These sets cannot be pairwise essentially disjoint, since then the union of finitely many of them would have measure greater than $\mu(X) = 1$. Therefore, there exist $m, n \in \mathbb{N}$, with $n > m$, such that $\mu(T^{-m}A \cap T^{-n}A) > 0$. Again since T is measure preserving, we conclude that $\mu(A \cap T^{-k}A) > 0$, where $k = n - m > 0$. Repeating this argument for the iterates $A, T^{-m}A, T^{-2m}A, \dots$, for all $m \in \mathbb{N}$, we easily deduce that $\mu(A \cap T^{-n}A) > 0$ for infinitely many $n \in \mathbb{N}$. ◻

We remark that the above argument actually shows that $\mu(A \cap T^{-n}A) > 0$ for some $n \leq \lceil \frac{1}{\mu(A)} \rceil + 1$.

Theorem 2 (Poincaré Recurrence for Points) *Let (X, \mathcal{B}, μ, T) be a measure preserving system and $A \in \mathcal{B}$. Then for almost every $x \in A$ we have that $T^n x \in A$ for infinitely many $n \in \mathbb{N}$.*

Proof Let B be the set of $x \in A$ such that $T^n x \notin A$ for all $n \in \mathbb{N}$. Notice that $B = A \setminus \bigcup_{n \in \mathbb{N}} T^{-n}A$; in particular, B is measurable. Since the iterates $B, T^{-1}B, T^{-2}B, \dots$ are

pairwise essentially disjoint, we conclude (as in the proof of Theorem 1) that $\mu(B) = 0$. This shows that for almost every $x \in A$ we have that $T^n x \in A$ for some $n \in \mathbb{N}$. Repeating this argument for the transformation T^m in place of T for all $m \in \mathbb{N}$, we easily deduce the advertised statement. ◻

Next we give a variation of Poincaré recurrence for measure preserving systems endowed with a compatible metric:

Theorem 3 (Poincaré Recurrence for Metric Systems)

Let (X, \mathcal{B}, μ, T) be a measure preserving system, and suppose that X is endowed with a μ -compatible metric. Then for almost every $x \in X$ we have

$$\liminf_{n \rightarrow \infty} d(x, T^n x) = 0.$$

The proof of this result is similar to the proof of Theorem 2 (see p. 61 in [35]). Applying this result to the doubling map $Tx = 2x$ on \mathbb{T} , we get that for almost every $x \in X$, every string of zeros and ones in the dyadic expansion of x occurs infinitely often.

We remark that all three formulations of the Poincaré Recurrence Theorem that we have given hold for conservative systems as well. See, e. g., [2] for details.

This article is structured as follows. In Sect. “[Quantitative Poincaré Recurrence](#)” we give a few quantitative versions of the previously mentioned qualitative results. In Sects. “[Subsequence Recurrence](#)” and “[Multiple Recurrence](#)” we give several refinements of the Poincaré recurrence theorem, by restricting the scope of the return time n , and by considering multiple intersections (for simplicity we focus on \mathbb{Z} -actions). In Sect. “[Connections with Combinatorics and Number Theory](#)” we give various implications of the recurrence results in combinatorics and number theory (► [Ergodic Theory: Interactions with Combinatorics and Number Theory](#)). Lastly, in Sect. “[Future Directions](#)” we give several open problems related to the material presented in Sects. “[Subsequence Recurrence](#)” to “[Connections with Combinatorics and Number Theory](#)”.

Quantitative Poincaré Recurrence

Early Results

For applications it is desirable to have quantitative versions of the results mentioned in the previous section. For example one would like to know how large $\mu(A \cap T^{-n}A)$ can be made and for how many n .

Theorem 4 (Khinchine [55]) *Let (X, \mathcal{B}, μ, T) be a measure preserving system and $A \in \mathcal{B}$. Then for every $\varepsilon > 0$ we*

have $\mu(A \cap T^{-n}A) > \mu(A)^2 - \varepsilon$ for a set of $n \in \mathbb{N}$ that has bounded gaps.

By considering the doubling map $Tx = 2x$ on \mathbb{T} and letting $A = \mathbf{I}_{[0,1/2]}$, it is easy to check that the lower bound of the previous result cannot be improved. We also remark that it is not possible to estimate the size of the gap by a function of $\mu(A)$ alone. One can see this by considering the rotations $R_kx = x + 1/k$ for $k \in \mathbb{N}$, defined on \mathbb{T} , and letting $A = \mathbf{I}_{[0,1/3]}$.

Concerning the second version of the Poincaré recurrence theorem, it is natural to ask whether for almost every $x \in X$ the set of return times $S_x = \{n \in \mathbb{N} : T^n x \in A\}$ has bounded gaps. This is not the case, as one can see by considering the doubling map $Tx = 2x$ on \mathbb{T} with the Lebesgue measure, and letting $A = \mathbf{I}_{[0,1/2]}$. Since Lebesgue almost every $x \in \mathbb{T}$ contains arbitrarily large blocks of ones in its dyadic expansion, the set S_x has unbounded gaps. Nevertheless, as an easy consequence of the Birkhoff ergodic theorem [19], one has the following:

Theorem 5 *Let (X, \mathcal{B}, μ, T) be a measure preserving system and $A \in \mathcal{B}$ with $\mu(A) > 0$. Then for almost every $x \in X$ the set $S_x = \{n \in \mathbb{N} : T^n x \in A\}$ has well defined density and $\int d(S_x) d\mu(x) = \mu(A)$. Furthermore, for ergodic measure preserving systems we have $d(S_x) = \mu(A)$ a. e.*

Another question that arises naturally is, given a set A with positive measure and an $x \in A$, how long should one wait until some iterate $T^n x$ of x hits A ? By considering an irrational rotation R_α on \mathbb{T} , where α is very near to, but not less than, $\frac{1}{100}$, and letting $A = \mathbf{I}_{[0,1/2]}$, one can see that the first return time is a member of the set $\{1, 50, 51\}$. So it may come as a surprise that the average first return time does not depend on the system (as long as it is ergodic), but only on the measure of the set A .

Theorem 6 (Kac [51]) *Let (X, \mathcal{B}, μ, T) be an ergodic measure preserving system and $A \in \mathcal{B}$ with $\mu(A) > 0$. For $x \in X$ define $R_A(x) = \min\{n \in \mathbb{N} : T^n x \in A\}$. Then for $x \in A$ the expected value of $R_A(x)$ is $1/\mu(A)$, i. e. $\int_A R_A(x) d\mu = 1$.*

More Recent Results

As we mentioned in the previous section, if the space X is endowed with a μ -compatible metric d , then for almost every $x \in X$ we have that $\liminf_{n \rightarrow \infty} d(x, T^n x) = 0$. A natural question is, how much iteration is needed to come back within a small distance of a given typical point? Under some additional hypothesis on the metric d we have the following answer:

Theorem 7 (Boshernitzan [20]) *Let (X, \mathcal{B}, μ, T) be a measure preserving system endowed with a μ -compatible metric d . Assume that the Hausdorff a -measure $\mathcal{H}_a(X)$ of X is σ -finite (i. e., X is a countable union of sets X_i with $\mathcal{H}_a(X_i) < \infty$). Then for almost every $x \in X$,*

$$\liminf_{n \rightarrow \infty} \{n^{\frac{1}{a}} \cdot d(x, T^n x)\} < \infty .$$

Furthermore, if $\mathcal{H}_a(X) = 0$, then for almost every $x \in X$,

$$\liminf_{n \rightarrow \infty} \{n^{\frac{1}{a}} \cdot d(x, T^n x)\} = 0 .$$

One can see from rotations by “badly approximable” vectors $\alpha \in \mathbb{T}^k$ that the exponent $1/a$ in the previous theorem cannot be improved. Several applications of Theorem 7 to billiard flows, dyadic transformations, symbolic flows and interval exchange transformations are given in [20]. For a related result dealing with mean values of the limits in Theorem 7 see [67].

An interesting connection between rates of recurrence and entropy of an ergodic measure preserving system was established by Ornstein and Weiss [62], following earlier work of Wyner and Ziv [73]:

Theorem 8 (Ornstein and Weiss [62]) *Let (X, \mathcal{B}, μ, T) be an ergodic measure preserving system and \mathcal{P} be a finite partition of X . Let $P_n(x)$ be the element of the partition $\bigvee_{i=0}^{n-1} T^{-i} \mathcal{P} = \{\bigcap_{i=0}^{n-1} T^{-i} P^{(i)} : P^{(i)} \in \mathcal{P}, 0 \leq i < n\}$ that contains x . Then for almost every $x \in X$, the first return time $R_n(x)$ of x to $P_n(x)$ is asymptotically equivalent to $e^{h(T, \mathcal{P})n}$, where $h(T, \mathcal{P})$ denotes the entropy of the system with respect to the partition \mathcal{P} . More precisely,*

$$\lim_{n \rightarrow \infty} \frac{\log R_n(x)}{n} = h(T, \mathcal{P}) .$$

An extension of the above result to some classes of infinite measure preserving systems was given in [42].

Another connection of recurrence rates, this time with the local dimension of an invariant measure, is given by the next result:

Theorem 9 (Barreira [4]) *Let (X, \mathcal{B}, μ, T) be an ergodic measure preserving system. Define the upper and lower recurrence rates*

$$\underline{R}(x) = \liminf_{r \rightarrow 0} \frac{\log \tau_r(x)}{-\log r} \quad \text{and}$$

$$\overline{R}(x) = \limsup_{r \rightarrow 0} \frac{\log \tau_r(x)}{-\log r} ,$$

where $\tau_r(x)$ is the first return time of $T^k x$ to $B(x, r)$, and the upper and lower pointwise dimensions

$$\underline{d}_\mu(x) = \liminf_{r \rightarrow 0} \frac{\log \mu(B(x, r))}{\log r} \quad \text{and} \\ \bar{d}_\mu(x) = \limsup_{r \rightarrow 0} \frac{\log \mu(B(x, r))}{\log r}.$$

Then for almost every $x \in X$, we have

$$\underline{R}(x) \leq \underline{d}_\mu(x) \quad \text{and} \quad \bar{R}(x) \leq \bar{d}_\mu(x).$$

Roughly speaking, this theorem asserts that for typical $x \in X$ and for small r , the first return time of x to $B(x, r)$ is at most $r^{-d_\mu(x)}$. Since $\underline{d}_\mu(x) \leq \mathcal{H}_d(X)$ for almost every $x \in X$, we can conclude the first part of Theorem 7 from Theorem 9. For related results the interested reader should consult the survey [5] and the bibliography therein.

We also remark that the previous results and related concepts have been applied to estimate the dimension of certain strange attractors (see [49] and the references therein) and the entropy of some Gibbsian systems [25].

We end this section with a result that connects “wandering rates” of sets in infinite measure preserving systems with their “recurrence rates”. The next theorem follows easily from a result about lower bounds on ergodic averages for measure preserving systems due to Leibman [57]; a weaker form for conservative, ergodic systems can be found in Aaronson [1].

Theorem 10 *Let (X, \mathcal{B}, μ, T) be an infinite measure preserving system, and $A \in \mathcal{B}$ with $\mu(A) < \infty$. Then for all $N \in \mathbb{N}$,*

$$\left(\frac{\mu \left(\bigcup_{n=0}^{N-1} T^{-n} A \right)}{N} \cdot \sum_{n=0}^{N-1} \mu(A \cap T^{-n} A) \right) \geq \frac{1}{2} \cdot (\mu(A))^2.$$

Subsequence Recurrence

In this section we discuss what restrictions one can impose on the set of return times in the various versions of the Poincaré recurrence theorem. We start with:

Definition 11 Let $R \subset \mathbb{Z}$. Then R is a set of:

- Recurrence if for any invertible measure preserving system (X, \mathcal{B}, μ, T) , and $A \in \mathcal{B}$ with $\mu(A) > 0$, there is some nonzero $n \in R$ such that $\mu(A \cap T^{-n} A) > 0$.
- Topological recurrence if for every compact metric space (X, d) , continuous transformation $T: X \rightarrow X$

and every $\varepsilon > 0$, there are $x \in X$ and nonzero $n \in R$ such that $d(x, T^n x) < \varepsilon$.

It is easy to check that the existence of a single $n \in R$ satisfying the previous recurrence conditions actually guarantees the existence of infinitely many $n \in R$ satisfying the same conditions. Moreover, if R is a set of recurrence then one can see from existence of some T -invariant measure μ that R is also a set of topological recurrence. A (complicated) example showing that the converse is not true was given by Kriz [56].

Before giving a list of examples of sets of (topological) recurrence, we discuss some necessary conditions: A set of topological recurrence must contain infinitely many multiples of every positive integer, as one can see by considering rotations on \mathbb{Z}_d , $d \in \mathbb{N}$. Hence, the sets $\{2n + 1, n \in \mathbb{N}\}$, $\{n^2 + 1, n \in \mathbb{N}\}$, $\{p + 2, p \text{ prime}\}$ are not good for (topological) recurrence. If $(s_n)_{n \in \mathbb{N}}$ is a lacunary sequence (meaning $\liminf_{n \rightarrow \infty} (s_{n+1}/s_n) = \rho > 1$), then one can construct an irrational number α such that $\{s_n \alpha\} \in [\delta, 1 - \delta]$ for all large $n \in \mathbb{N}$, where $\delta > 0$ depends on ρ (see [54], for example). As a consequence, the sequence $(s_n)_{n \in \mathbb{N}}$ is not good for (topological) recurrence.

Lastly, we mention that by considering product systems, one can immediately show that any set of (topological) recurrence R is partition regular, meaning that if R is partitioned into finitely many pieces then at least one of these pieces must still be a set of (topological) recurrence. Using this observation, one concludes for example that any union of finitely many lacunary sequences is not a set of recurrence.

We present now some examples of sets of recurrence:

Theorem 12 *The following are sets of recurrence:*

- Any set of the form $\bigcup_{n \in \mathbb{N}} \{a_n, 2a_n, \dots, na_n\}$ where $a_n \in \mathbb{N}$.
- Any IP-set, meaning a set that consists of all finite sums of the members of some infinite set.
- Any difference set $S - S$, meaning a set that consists of all possible differences of the members of some infinite set S .
- The set $\{p(n), n \in \mathbb{N}\}$ where p is any nonconstant integer polynomial with $p(0) = 0$ [35,66] (In fact we only have to assume that the range of the polynomial contains multiples of an arbitrary positive integer [53]).
- The set $\{p(n), n \in S\}$, where p is an integer polynomial with $p(0) = 0$ and S is any IP-set [12].
- The set of values of an admissible generalized polynomial (this class contains in particular the

smallest function algebra G containing all integer polynomials having zero constant term and such that if $g_1, \dots, g_k \in G$ and $c_1, \dots, c_k \in \mathbb{R}$ then $\|\sum_{i=1}^k c_i g_i\| \in G$, where $\llbracket x \rrbracket = [x + \frac{1}{2}]$ denotes the integer nearest to x [13].

- (vii) The set of shifted primes $\{p - 1, p \text{ prime}\}$, and the set $\{p + 1, p \text{ prime}\}$ [66].
- (viii) The set of values of a random non-lacunary sequence. (Pick $n \in \mathbb{N}$ independently with probability b_n where $0 \leq b_n \leq 1$ and $\lim_{n \rightarrow \infty} nb_n = \infty$. The resulting set is almost surely a set of recurrence. If $\limsup_{n \rightarrow \infty} nb_n < \infty$ then the resulting set is almost surely a finite union of sets, each of which is the range of some lacunary sequence, hence is not a set of recurrence). Follows from [22].

Showing that the first three sets are good for recurrence is a straightforward modification of the argument used to prove Theorem 1. Examples (iv) – (viii) require more work.

A criterion of Kamae and Mendés-France [53] provides a powerful tool that may be used in many instances to establish that a set R is a set of recurrence. We mention a variation of their result:

Theorem 13 (Kamae and Mendés-France [53]) *Suppose that $R = \{a_1 < a_2 < \dots\}$ is a subset of \mathbb{N} such that:*

- (i) *The sequence $\{a_n \alpha\}_{n \in \mathbb{N}}$ is uniformly distributed in \mathbb{T} for every irrational α .*
- (ii) *The set $R_m = \{n \in \mathbb{N} : m|a_n\}$ has positive density for every $m \in \mathbb{N}$.*

Then R is a set of recurrence.

We sketch a proof for this result. First, recall Herglotz’s theorem: if $(a_n)_{n \in \mathbb{Z}}$ is a positive definite sequence, then there is a unique measure σ on the torus \mathbb{T} such that $a_n = \int e^{2\pi i n t} d\sigma(t)$. The case of interest to us is $a_n = \int_{\mathbb{T}} f(x) \cdot f(T^n x) d\mu$, where T is measure preserving and $f \in L^\infty(\mu)$; (a_n) is positive definite, and we call $\sigma = \sigma_f$ the spectral measure of f .

Let now (X, \mathcal{B}, μ, T) be a measure preserving system and $A \in \mathcal{B}$ with $\mu(A) > 0$. Putting $f = \mathbf{1}_A$, one has

$$\begin{aligned} \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \int f(x) \cdot f(T^{a_n} x) d\mu \\ = \int_{\mathbb{T}} \lim_{N \rightarrow \infty} \left(\frac{1}{N} \sum_{n=1}^N e^{2\pi i a_n t} \right) d\sigma_f(t). \end{aligned} \quad (1)$$

For t irrational the limit inside the integral is zero (by condition (i)), so the last integral can be taken over the ratio-

nal points in \mathbb{T} . Since the spectral measure of a function orthogonal to the subspace

$$\mathcal{H} = \overline{\{f \in L^2(\mu) : \text{there exists } k \in \mathbb{N} \text{ with } T^k f = f\}} \quad (2)$$

has no rational point masses, we can easily deduce that when computing the first limit in (1), we can replace the function f by its orthogonal projection g onto the subspace \mathcal{H} (g is again nonnegative and $g \neq 0$). To complete the argument, we approximate g by a function g' such that $T^m g' = g'$ for some appropriately chosen m , and use condition (ii) to deduce that the limit of the average (1) is positive.

In order to apply Theorem 13, one uses the standard machinery of uniform distribution. Recall *Weyl’s criterion*: a real-valued sequence $(x_n)_{n \in \mathbb{N}}$ is uniformly distributed mod 1 if for every non-zero $k \in \mathbb{Z}$,

$$\lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N e^{2\pi i k x_n} = 0.$$

This criterion becomes especially useful when paired with van der Corput’s so-called third principal property: if, for every $h \in \mathbb{N}$, $(x_{n+h} - x_n)_{n \in \mathbb{N}}$ is uniformly distributed mod 1, then $(x_n)_{n \in \mathbb{N}}$ is uniformly distributed mod 1. Using the foregoing criteria and some standard (albeit non-trivial) exponential sum estimates, one can verify for example that the sets (iv) and (vii) in Theorem 12 are good for recurrence.

In light of the connection elucidated above between uniform distribution mod 1 and recurrence, it is not surprising that van der Corput’s method has been adapted by modern ergodic theorists for use in establishing recurrence properties *directly*.

Theorem 14 (Bergelson [7]) *Let $(x_n)_{n \in \mathbb{N}}$ be a bounded sequence in a Hilbert space. If*

$$D\text{-}\lim_{m \rightarrow \infty} \left(\lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \langle x_{n+m}, x_n \rangle \right) = 0,$$

then

$$\lim_{N \rightarrow \infty} \left\| \frac{1}{N} \sum_{n=1}^N x_n \right\| = 0.$$

Let us illustrate how one uses this “van der Corput trick” by showing that $S = \{n^2 : n \in \mathbb{N}\}$ is a set of recurrence. We will actually establish the following stronger

fact: If (X, \mathcal{B}, μ, T) is a measure preserving system and $f \in L^\infty(\mu)$ is nonnegative and $f \neq 0$ then

$$\liminf_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \int f(x) \cdot f(T^{n^2} x) \, d\mu > 0. \tag{3}$$

Then our result follows by setting $f = \mathbf{1}_A$ for some $A \in \mathcal{B}$ with $\mu(A) > 0$.

The main idea is one that occurs frequently in ergodic theory; split the function f into two components, one of which contributes zero to the limit appearing in (3), and the other one being much easier to handle than f . To do this consider the T -invariant subspace of $L^2(X)$ defined by

$$\mathcal{H} = \overline{\{f \in L^2(\mu) : \text{there exists } k \in \mathbb{N} \text{ with } T^k f = f\}}. \tag{4}$$

Write $f = g + h$ where $g \in \mathcal{H}$ and $h \perp \mathcal{H}$, and expand the average in (3) into a sum of four averages involving the functions g and h . Two of these averages vanish because iterates of g are orthogonal to iterates of h . So in order to show that the only contribution comes from the average that involves the function g alone, it suffices to establish that

$$\lim_{N \rightarrow \infty} \left\| \frac{1}{N} \sum_{n=1}^N T^{n^2} h \right\|_{L^2(\mu)} = 0. \tag{5}$$

To show this we will apply the Hilbert space van der Corput lemma. For given $h \in \mathbb{N}$, we let $x_n = T^{n^2} h$ and compute

$$\begin{aligned} & \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \langle x_{n+m}, x_n \rangle \\ &= \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \int T^{n^2+2nm+m^2} h \cdot T^{n^2} h \, d\mu \\ &= \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \int T^{2nm} (T^{m^2} h) \cdot h \, d\mu. \end{aligned}$$

Applying the ergodic theorem to the transformation T^{2m} and using the fact that $h \perp \mathcal{H}$, we get that the last limit is 0. This implies (5).

Thus far we have shown that in order to compute the limit in (3) we can assume that $f = g \in \mathcal{H}$ (g is also nonnegative and $g \neq 0$). By the definition of \mathcal{H} , given any $\varepsilon > 0$, there exists a function $f' \in \mathcal{H}$ such that $T^k f' = f'$ for some $k \in \mathbb{N}$ and $\|f - f'\|_{L^2(\mu)} \leq \varepsilon$. Then the limit in (3) is at least $1/k$ times the limit

$$\liminf_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \int f(x) \cdot f(T^{(kn)^2} x) \, d\mu.$$

Applying the triangle inequality twice we get that this is greater or equal than

$$\begin{aligned} & \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \int f'(x) \cdot f'(T^{(kn)^2} x) \, d\mu - c \cdot \varepsilon \\ &= \int (f'(x))^2 \, d\mu - 2\varepsilon \\ &\geq \left(\int f'(x) \, d\mu \right)^2 - c \cdot \varepsilon, \end{aligned}$$

for some constant c that does not depend on ε (we used that $T^k f' = f'$ and the Cauchy–Schwartz inequality). Choosing ε small enough we conclude that the last quantity is positive, completing the proof.

Multiple Recurrence

Simultaneous multiple returns of positive measure sets to themselves were first considered by H. Furstenberg [34], who gave a new proof of Szemerédi’s theorem [69] on arithmetic progressions by deriving it from the following theorem:

Theorem 15 (Furstenberg [34]) *Let (X, \mathcal{B}, μ, T) be a measure preserving system and $A \in \mathcal{B}$ with $\mu(A) > 0$. Then for every $k \in \mathbb{N}$, there is some $n \in \mathbb{N}$ such that*

$$\mu(A \cap T^{-n} A \cap \dots \cap T^{-kn} A) > 0. \tag{6}$$

Furstenberg’s proof came by means of a new structure theorem allowing one to decompose an arbitrary measure preserving system into component elements exhibiting one of two extreme types of behavior: *compactness*, characterized by regular, “almost periodic” trajectories, and *weak mixing*, characterized by irregular, “quasi-random” trajectories. On \mathbb{T} , these types of behavior are exemplified by rotations and by the doubling map, respectively. To see the point, imagine trying to predict the initial digit of the dyadic expansion of $T^n x$ given knowledge of the initial digits of $T^i x$, $1 \leq i < n$. We use the case $k = 2$ to illustrate the basic idea.

It suffices to show that if $f \in L^\infty(\mu)$ is nonnegative and $f \neq 0$, one has

$$\liminf_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \int f(x) \cdot f(T^n x) \cdot f(T^{2n} x) \, d\mu > 0. \tag{7}$$

An ergodic decomposition argument enables us to assume that our system is ergodic. As in the earlier case of the squares, we split f into “almost periodic” and “quasi-random” components. Let \mathcal{K} be the closure in L^2 of the subspace spanned by the eigenfunctions of T , i.e. the functions $f \in L^2(\mu)$ that satisfy $f(Tx) = e^{2\pi i \alpha} f(x)$ for some

$\alpha \in \mathbb{R}$. We write $f = g + h$, where $g \in \mathcal{K}$ and $h \perp \mathcal{K}$. It can be shown that $g, h \in L^\infty(\mu)$ and g is again nonnegative with $g \neq 0$. We expand the average in (7) into a sum of eight averages involving the functions g and h . In order to show that the only non-zero contribution to the limit comes from the term involving g alone, it suffices to establish that

$$\lim_{N \rightarrow \infty} \left\| \frac{1}{N} \sum_{n=1}^N T^n g \cdot T^{2n} h \right\|_{L^2(\mu)} = 0, \tag{8}$$

(and similarly with h and g interchanged, and with $g = h$, which is similar). To establish (8), we use the Hilbert space van der Corput lemma on $x_n = T^n g \cdot T^{2n} h$. Some routine computations and a use of the ergodic theorem reduce the task to showing that

$$D\text{-}\lim_{m \rightarrow \infty} \left(\int h(x) \cdot h(T^{2m} x) \, d\mu \right) = 0.$$

But this is well known for $h \perp \mathcal{K}$ (in virtue of the fact that for $h \perp \mathcal{K}$ the spectral measure σ_h is continuous, for example).

We are left with the average (7) when $f = g \in \mathcal{K}$. In this case f can be approximated arbitrarily well by a linear combination of eigenfunctions, which easily implies that given $\varepsilon > 0$ one has $\|T^n f - f\|_{L^2(\mu)} \leq \varepsilon$ for a set of $n \in \mathbb{N}$ with bounded gaps. Using this fact and the triangle inequality, one finds that for a set of $n \in \mathbb{N}$ with bounded gaps,

$$\int f(x) \cdot f(T^n x) \cdot f(T^{2n} x) \, d\mu \geq \left(\int f \, d\mu \right)^3 - c \cdot \varepsilon$$

for a constant c that is independent of ε . Choosing ε small enough, we get (7).

The new techniques developed for the proof of Theorem 15 have led to a number of extensions, many of which have to date only ergodic proofs. To expedite discussion of some of these developments, we introduce a definition:

Definition 16 Let $R \subset \mathbb{Z}$ and $k \in \mathbb{N}$. Then R is a set of *k-recurrence* if for every invertible measure preserving system (X, \mathcal{B}, μ, T) and $A \in \mathcal{B}$ with $\mu(A) > 0$, there is some nonzero $n \in R$ such that

$$\mu(A \cap T^{-n} A \cap \dots \cap T^{-kn} A) > 0.$$

The notions of k -recurrence are distinct for different values of k . An example of a difference set that is a set of 1-recurrence but not a set of 2-recurrence was given in [34]; sets of k -recurrence that are not sets of $(k + 1)$ -recurrence for general k were given in [31] ($R_k = \{n \in \mathbb{N} : \{n^{k+1} \sqrt{2}\} \in [1/4, 3/4]\}$ is such).

Aside from difference sets, the sets of (1-)recurrence given in Theorem 12 may well be sets of k -recurrence for every $k \in \mathbb{N}$, though this has not been verified in all cases. Let us summarize the current state of knowledge. The following are sets of k -recurrence for every k : Sets of the form $\bigcup_{n \in \mathbb{N}} \{a_n, 2a_n, \dots, na_n\}$ where $a_n \in \mathbb{N}$ (this follows from a uniform version of Theorem 15 that can be found in [15]). Every IP-set [37]. The set $\{p(n), n \in \mathbb{N}\}$ where p is any nonconstant integer polynomial with $p(0) = 0$ [16], and more generally, when the range of the polynomial contains multiples of an arbitrary integer [33]. The set $\{p(n), n \in S\}$ where p is an integer polynomial with $p(0) = 0$ and S is any IP-set [17]. The set of values of an admissible generalized polynomial [60]. Moreover, the set of shifted primes $\{p - 1, p \text{ prime}\}$, and the set $\{p + 1, p \text{ prime}\}$ are sets of 2-recurrence [32].

More generally, one would like to know for which sequences of integers $a_1(n), \dots, a_k(n)$ it is the case that for every invertible measure preserving system (X, \mathcal{B}, μ, T) and $A \in \mathcal{B}$ with $\mu(A) > 0$, there is some nonzero $n \in \mathbb{N}$ such that

$$\mu(A \cap T^{-a_1(n)} A \cap \dots \cap T^{-a_k(n)} A) > 0. \tag{9}$$

Unfortunately, a criterion analogous to the one given in Theorem 13 for 1-recurrence is not yet available for k -recurrence when $k > 1$. Nevertheless, there have been some notable positive results, such as the following:

Theorem 17 (Bergelson and Leibman [16]) Let (X, \mathcal{B}, μ, T) be an invertible measure preserving system and $p_1(n), \dots, p_k(n)$ be integer polynomials with zero constant term. Then for every $A \in \mathcal{B}$ with $\mu(A) > 0$, there is some $n \in \mathbb{N}$ such that

$$\mu(A \cap T^{-p_1(n)} A \cap \dots \cap T^{-p_k(n)} A) > 0. \tag{10}$$

Furthermore, it has been shown that the n in (10) can be chosen from any IP set [17], and the polynomials p_1, \dots, p_k can be chosen to belong to the more general class of admissible generalized polynomials [60].

Very recently, a new boost in the area of multiple recurrence was given by a breakthrough of Host and Kra [50]. Building on work of Conze and Lesigne [26,27] and Furstenberg and Weiss [41] (see also the excellent survey [52], exploring close parallels with [45] and the seminal paper of Gowers [43]), they isolated the structured component (or factor) of a measure preserving system that one needs to analyze in order to prove various multiple recurrence and convergence results. This allowed them, in particular, to prove existence of L^2 limits for the so-called ‘‘Furstenberg ergodic averages’’ $\frac{1}{N} \sum_{n=1}^N \prod_{i=0}^k f(T^{in} x)$,

which had been a major open problem since the original ergodic proof of Szemerédi's theorem. Subsequently Ziegler in [75] gave a new proof of the aforementioned limit theorem and established minimality of the factor in question. It turns out that this minimal component admits of a purely algebraic characterization; it is a *nilsystem*, i. e. a rotation on a homogeneous space of a nilpotent Lie group. This fact, coupled with some recent results about nilsystems (see [58,59] for example), makes the analysis of some otherwise intractable multiple recurrence problems much more manageable. For example, these developments have made it possible to estimate the size of the multiple intersection in (6) for $k = 2, 3$ (the case $k = 1$ is Theorem 4):

Theorem 18 (Bergelson, Host and Kra [14]) *Let (X, \mathcal{B}, μ, T) be an ergodic measure preserving system and $A \in \mathcal{B}$. Then for $k = 2, 3$ and for every $\varepsilon > 0$,*

$$\mu(A \cap T^{-n}A \cap \dots \cap T^{-kn}A) > \mu^{k+1}(A) - \varepsilon \quad (11)$$

for a set of $n \in \mathbb{N}$ with bounded gaps.

Based on work of Ruzsa that appears as an appendix to the paper, it is also shown in [14] that a similar estimate fails for ergodic systems (with any power of $\mu(A)$ on the right hand side) when $k \geq 4$. Moreover, when the system is nonergodic it also fails for $k = 2, 3$, as can be seen with the help of an example in [6]. Again considering the doubling map $Tx = 2x$ and the set $A = [0, 1/2]$, one sees that the positive results for $k \leq 3$ are sharp. When the polynomials $n, 2n, \dots, kn$ are replaced by linearly independent polynomials p_1, p_2, \dots, p_k with zero constant term, similar lower bounds hold for every $k \in \mathbb{N}$ without assuming ergodicity [30]. The case where the polynomials $n, 2n, 3n$ are replaced with general polynomials p_1, p_2, p_3 with zero constant term is treated in [33].

Connections with Combinatorics and Number Theory

The combinatorial ramifications of ergodic-theoretic recurrence were first observed by Furstenberg, who perceived a correspondence between recurrence properties of measure preserving systems and the existence of structures in sets of integers having positive upper density. This gave rise to the field of ergodic Ramsey theory, in which problems in combinatorial number theory are treated using techniques from ergodic theory. The following formulation is from [8].

Theorem 19 *Let A be a subset of the integers. There exists an invertible measure preserving system (X, \mathcal{B}, μ, T) and*

a set $A \in \mathcal{B}$ with $\mu(A) = \overline{d}(A)$ such that

$$\begin{aligned} & \overline{d}(A \cap (A - n_1) \cap \dots \cap (A - n_k)) \\ & \geq \mu(A \cap T^{-n_1}A \cap \dots \cap T^{-n_k}A), \quad (12) \end{aligned}$$

for all $k \in \mathbb{N}$ and $n_1, \dots, n_k \in \mathbb{Z}$.

Proof The space X will be taken to be the sequence space $\{0, 1\}^{\mathbb{Z}}$, \mathcal{B} is the Borel σ -algebra, while T is the shift map defined by $(Tx)(n) = x(n+1)$ for $x \in \{0, 1\}^{\mathbb{Z}}$, and A is the set of sequences x with $x(0) = 1$. So the only thing that depends on A is the measure μ which we now define. For $m \in \mathbb{N}$ set $\Lambda^0 = \mathbb{Z} \setminus \Lambda$ and $\Lambda^1 = \Lambda$. Using a diagonal argument we can find an increasing sequence of integers $(N_m)_{m \in \mathbb{N}}$ such that $\lim_{m \rightarrow \infty} |\Lambda \cap [1, N_m]|/N_m = \overline{d}(A)$ and such that

$$\lim_{m \rightarrow \infty} \frac{|\Lambda^{i_1 - n_1} \cap \Lambda^{i_2 - n_2} \cap \dots \cap \Lambda^{i_r - n_r} \cap [1, N_m]|}{N_m} \quad (13)$$

exists for every $n_1, \dots, n_r \in \mathbb{Z}$, and $i_1, \dots, i_r \in \{0, 1\}$. For $n_1, n_2, \dots, n_r \in \mathbb{Z}$, and $i_1, i_2, \dots, i_r \in \{0, 1\}$, we define the measure μ of the cylinder set $\{x(n_1) = i_1, x(n_2) = i_2, \dots, x(n_r) = i_r\}$ to be the limit (13). Thus defined, μ extends to a premeasure on the algebra of sets generated by cylinder sets and hence by Carathéodory's extension theorem [24] to a probability measure on \mathcal{B} . It is easy to check that $\mu(A) = \overline{d}(A)$, the shift transformation T preserves the measure μ and (12) holds. \square

Using this principle for $k = 1$, one may check that any set of recurrence is *intersective*, that is intersects $E - E$ for every set E of positive density. Using it for $n_1 = n, n_2 = 2n, \dots, n_k = kn$, together with Theorem 15, one gets an ergodic proof of Szemerédi's theorem [69], stating that every subset of the integers with positive upper density contains arbitrarily long arithmetic progressions (conversely, one can easily deduce Theorem 15 from Szemerédi's theorem, and that intersective sets are sets of recurrence). Making the choice $n_1 = n^2$ and using part (iv) of Theorem 13, we get an ergodic proof of the surprising result of Sárközy [66] stating that every subset of the integers with positive upper density contains two elements whose difference is a perfect square. More generally, using Theorem 19, one can translate all of the recurrence results of the previous two sections to results in combinatorics. (This is not straightforward for Theorem 18 because of the ergodicity assumption made there. We refer the reader to [14] for the combinatorial consequence of this result). We mention explicitly only the combinatorial consequence of Theorem 17:

Theorem 20 (Bergelson and Leibman [16]) *Let $\Lambda \subset \mathbb{Z}$ with $\bar{d}(\Lambda) > 0$, and p_1, \dots, p_k be integer polynomials with zero constant term. Then Λ contains infinitely many configurations of the form $\{x, x + p_1(n), \dots, x + p_k(n)\}$.*

The ergodic proof is the only one known for this result, even for patterns of the form $\{x, x + n^2, x + 2n^2\}$ or $\{x, x + n, x + n^2\}$.

Ergodic-theoretic contributions to the field of geometric Ramsey theory were made by Furstenberg, Katznelson, and Weiss [40], who showed that if E is a positive upper density subset of \mathbb{R}^2 then: (i) E contains points with any large enough distance (see also [21] and [29]), (ii) Every δ -neighborhood of E contains three points forming a triangle congruent to any given large enough dilation of a given triangle (in [21] it is shown that if the three points lie on a straight line one cannot always find three points with this property in E itself). Recently, a generalization of property (ii) to arbitrary finite configurations of \mathbb{R}^m was obtained by Ziegler [76].

It is also worth mentioning some recent exciting connections of multiple recurrence with some structural properties of the set of prime numbers. The first one is in the work of Green and Tao [45], where the existence of arbitrarily long arithmetic progressions of primes was demonstrated, the authors, in addition to using Szemerédi's theorem outright, use several ideas from its ergodic-theoretic proofs, as appearing in [34] and [39]. The second one is in the recent work of Tao and Ziegler [70], where a quantitative version of Theorem 17 was used to prove that the primes contain arbitrarily long polynomial progressions. Furthermore, several recent results in ergodic theory, related to the structure of the minimal characteristic factors of certain multiple ergodic averages, play an important role in the ongoing attempts of Green and Tao to get asymptotic formulas for the number of k -term arithmetic progressions of primes up to x (see for example [46] and [47]). This project has been completed for $k = 3$, thus verifying an interesting special case of the Hardy–Littlewood k -tuple conjecture predicting the asymptotic growth rate of $N_{a_1, \dots, a_k}(x) =$ the number of configurations of primes having the form $\{p, p + a_1, \dots, p + a_k\}$ with $p \leq x$.

Finally, we remark that in this article we have restricted attention to multiple recurrence and Furstenberg correspondence for \mathbb{Z} actions, while in fact there is a wealth of literature on extensions of these results to general commutative, amenable and even non-amenable groups. For an excellent exposition of these and other recent developments the reader is referred to the surveys [9] and [11]. Here, we give just one notable combinatorial corollary to

some work of this kind, a density version of the classical Hales–Jewett coloring theorem [48].

Theorem 21 (Furstenberg and Katznelson [38]) *Let $W_n(A)$ denote the set of words of length n with letters in the alphabet $A = \{a_1, \dots, a_k\}$. For every $\varepsilon > 0$ there exists $N_0 = N_0(\varepsilon, k)$ such that if $n \geq N_0$ then any subset S of $W_n(A)$ with $|S| \geq \varepsilon k^n$ contains a combinatorial line, i.e., a set consisting of k n -letter words, having fixed letters in l positions, for some $0 \leq l < n$, the remaining $n - l$ positions being occupied by a variable letter x , for $x = a_1, \dots, a_k$. (For example, in $W_4(A)$ the sets $\{(a_1, x, a_2, x) : x \in A\}$ and $\{(x, x, x, x) : x \in A\}$ are combinatorial lines).*

At first glance, the uninitiated reader may not appreciate the importance of this “master” density result, so it is instructive to derive at least one of its immediate consequences. Let $A = \{0, 1, \dots, k - 1\}$ and interpret $W_n(A)$ as integers in base k having at most n digits. Then a combinatorial line in $W_n(A)$ is an arithmetic progression of length k – for example, the line $\{(a_1, x, a_2, x) : x \in A\}$ corresponds to the progression $\{m, m + n, m + 2n, m + 3n\}$, where $m = a_1 + a_2 d^2$ and $n = d + d^3$. This allows one to deduce Szemerédi's theorem. Similarly, one can deduce from Theorem 21 multidimensional and IP extensions of Szemerédi's theorem [36,37], and some related results about vector spaces over finite fields [37]. Again, the only known proof for the density version of the Hales–Jewett theorem relies heavily on ergodic theory.

Future Directions

In this section we formulate a few open problems relating to the material in the previous three sections. It should be noted that this selection reflects the authors' interests, and does not strive for completeness.

We start with an intriguing question of Katznelson [54] about sets of topological recurrence. A set $S \subset \mathbb{N}$ is a set of Bohr recurrence if for every $\alpha_1, \dots, \alpha_k \in \mathbb{R}$ and $\varepsilon > 0$ there exists $s \in S$ such that $\{\alpha_i s\} \in [0, \varepsilon] \cup [1 - \varepsilon, 1)$ for $i = 1, \dots, k$.

Problem 1 *Is every set of Bohr recurrence a set of topological recurrence?*

Background for this problem and evidence for a positive answer can be found in [54,72]. As we mentioned in Sect. “Subsequence Recurrence”, there exists a set of topological recurrence (and hence Bohr recurrence) that is not a set of recurrence.

Problem 2 *Is the set $S = \{l!2^m 3^n : l, m, n \in \mathbb{N}\}$ a set of recurrence? Is it a set of k -recurrence for every $k \in \mathbb{N}$?*

It can be shown that S is a set of Bohr recurrence. Theorem 13 cannot be applied since the uniform distribution condition fails for some irrational numbers α . A relevant question was asked by Bergelson in [9]: “Is the set $S = \{2^m 3^n : m, n \in \mathbb{N}\}$ good for single recurrence for weakly mixing systems?”

As we mentioned in Sect. “Multiple Recurrence”, the set of primes shifted by 1 (or -1) is a set of 2-recurrence [32].

Problem 3 Show that the sets $\mathbb{P} - 1$ and $\mathbb{P} + 1$, where \mathbb{P} is the set of primes, are sets of k -recurrence for every $k \in \mathbb{N}$.

As remarked in [32], a positive answer to this question will follow if some uniformity conjectures of Green and Tao [47] are verified.

We mentioned in Sect. “Subsequence Recurrence” that random non-lacunary sequences (see definition there) are almost surely sets of recurrence.

Problem 4 Show that random non-lacunary sequences are almost surely sets of k -recurrence for every $k \in \mathbb{N}$.

The answer is not known even for $k = 2$, though, in unpublished work, Wierdl and Lesigne have shown that the answer is positive for random sequences with at most quadratic growth. We refer the reader to the survey [65] for a nice exposition of the argument used by Bourgain [22] to handle the case $k = 1$.

It was shown in [31] that if S is a set of 2-recurrence then the set of its squares is a set of recurrence for circle rotations. The same method shows that it is actually a set of Bohr recurrence.

Problem 5 If $S \subset \mathbb{Z}$ is a set of 2-recurrence, is it true that $S^2 = \{s^2 : s \in S\}$ is a set of recurrence?

A similar question was asked in [23]: “If S is a set of k -recurrence for every k , is the same true of S^2 ?”

One would like to find a criterion that would allow one to deduce that a sequence is good for double (or higher order) recurrence from some uniform distribution properties of this sequence.

Problem 6 Find necessary conditions for double recurrence similar to the one given in Theorem 13.

It is now well understood that such a criterion should involve uniform distribution properties of some generalized polynomials or 2-step nilsequences.

We mentioned in Sect. “Connections with Combinatorics and Number Theory” that every positive density subset of \mathbb{R}^2 contains points with any large enough distance. Bourgain [21] constructed a positive density subset E of \mathbb{R}^2 , a triangle T , and numbers $t_n \rightarrow \infty$, such that

E does not contain congruent copies of all t_n -dilations of T . But the triangle T used in this construction is degenerate, which leaves the following question open:

Problem 7 Is it true that every positive density subset of \mathbb{R}^2 contains a triangle congruent to any large enough dilation of a given non-degenerate triangle?

For further discussion on this question the reader can consult the survey [44].

The following question of Aaronson and Nakada [1] is related to a classical question of Erdős concerning whether every $K \subset \mathbb{N}$ such that $\sum_{n \in K} 1/n = \infty$ contains arbitrarily long arithmetic progressions:

Problem 8 Suppose that (X, \mathcal{B}, μ, T) is a $\{1/n\}$ -conservative ergodic measure preserving system. Is it true that for every $A \in \mathcal{B}$ with $\mu(A) > 0$ and $k \in \mathbb{N}$ we have $\mu(A \cap T^{-n}A \cap \dots \cap T^{-kn}A) > 0$ for some $n \in \mathbb{N}$?

The answer is positive for the class of Markov shifts, and it is remarked in [1] that if the Erdős conjecture is true then the answer will be positive in general. The converse is not known to be true. For a related result showing that multiple recurrence is preserved by extensions of infinite measure preserving systems see [61].

Our next problem is motivated by the question whether Theorem 21 has a polynomial version (for a precise formulation of the general conjecture see [9]). Not even this most special consequence of it is known to hold.

Problem 9 Let $\varepsilon > 0$. Does there exist $N = N(\varepsilon)$ having the property that every family \mathcal{P} of subsets of $\{1, \dots, N\}^2$ satisfying $|\mathcal{P}| \geq \varepsilon 2^{N^2}$ contains a configuration $\{A, A \cup (\gamma \times \gamma)\}$, where $A \subset \{1, \dots, N\}^2$ and $\gamma \subset \{1, \dots, N\}$ with $A \cap (\gamma \times \gamma) = \emptyset$?

A measure preserving action of a general countably infinite group G is a function $g \rightarrow T_g$ from G into the space of measure preserving transformations of a probability space X such that $T_{gh} = T_g T_h$. It is easy to show that a version of Khintchine’s recurrence theorem holds for such actions: if $\mu(A) > 0$ and $\varepsilon > 0$ then $\{g : \mu(A \cap T_g A) > (\mu(A))^2 - \varepsilon\}$ is syndetic. However it is unknown whether the following ergodic version of Roth’s theorem holds.

Problem 10 Let (T_g) and (S_g) be measure preserving G -actions of a probability space X that commute in the sense that $T_g S_h = S_h T_g$ for all $g, h \in G$. Is it true that for all positive measure sets A , the set of g such that $\mu(A \cap T_g A \cap S_g A) > 0$ is syndetic?

We remark that for general (possibly amenable) groups G not containing arbitrarily large finite subgroups nor elements of infinite order, it is not known whether one can

find a *single* such $g \neq e$. On the other hand, the answer is known to be positive for general G in case $(T_g^{-1}S_g)$ is a G -action [18]; even under such strictures, however, it is unknown whether a triple recurrence theorem holds.

Glossary

Differentiable rigidity Differentiable rigidity refers to finding invariants to the differentiable conjugacy of dynamical systems, and, more general, group actions.

Local rigidity Local rigidity refers to the study of perturbations of homomorphisms from discrete or continuous groups into diffeomorphism groups.

Global rigidity Global rigidity refers to the classification of all group actions on manifolds satisfying certain conditions.

Measure rigidity Measure rigidity refers to the study of invariant measures for actions of abelian groups and semigroups.

Lattice A lattice in a Lie group is a discrete subgroup of finite covolume.

Conjugacy Two elements g_1, g_2 in a group G are said to be conjugated if there exists an element $h \in G$ such that $g_1 = h^{-1}g_2h$. The element h is called conjugacy.

C^k Conjugacy Two diffeomorphisms ϕ_1, ϕ_2 acting on the same manifold M are said to be C^k -conjugated if there exists a C^k diffeomorphism h of M such that $\phi_1 = h^{-1} \circ \phi_2 \circ h$. The diffeomorphism h is called C^k conjugacy.

Definition of the Subject

As one can see from this volume, chaotic behavior of complex dynamical systems is prevalent in nature and in large classes of transformations. Rigidity theory can be viewed as the counterpart to the generic theory of dynamical systems which often investigates chaotic dynamics for a typical transformation belonging to a large class. In rigidity one is interested in finding obstructions to chaotic, or generic, behavior. This often leads to rather unexpected classification results. As such, rigidity in dynamics and ergodic theory is difficult to define precisely and the best approach to this subject is to study various results and themes that developed so far. A classification is offered below in local, global, differentiable and measurable rigidity. One should note that all branches are strongly intertwined and, at this stage of the development of the subject, it is difficult to separate them.

Rigidity is a well developed and prominent topic in modern mathematics. Historically, rigidity has two main origins, one coming from the study of lattices in semi-simple Lie groups, and one coming from the theory of hyperbolic dynamical systems. From the start, ergodic theory was an important tool used to prove rigidity results, and a strong interdependence developed between these fields. Many times a result in rigidity is obtained by combining techniques from the theory of lattices in Lie groups with techniques from hyperbolic dynamical systems and ergodic theory. Among other mathematical disciplines using results and contributing to this field one can mention representation theory, smooth, continuous and mea-

surable dynamics, harmonic and spectral analysis, partial differential equations, differential geometry, and number theory. Additional details about the appearance of rigidity in ergodic theory as well as definitions for some terminology used in the sequel can be found in the articles ► [Ergodic Theory on Homogeneous Spaces and Metric Number Theory](#) by Kleinbock, ► [Ergodic Theory: Recurrence](#) by Frantzikinakis, McCutcheon, and ► [Ergodic Theory: Interactions with Combinatorics and Number Theory](#) by Ward. The theory of hyperbolic dynamics is presented in the article ► [Hyperbolic Dynamical Systems](#) by Viana and in the article ► [Smooth Ergodic Theory](#) by Wilkinson.

Introduction

The first results about classification of lattices in semi-simple Lie groups were local, aimed at trying to understand the space of small perturbations of a given linear representation. A major contributor was Weil [110,111,112], who proved local rigidity of linear representations for large classes of groups, in particular lattices. Another breakthrough was the contribution of Kazhdan [66], who introduced property (T), allowing to show that large classes of lattices are finitely generated. Rigidity theory matured due to the remarkable global rigidity results obtained by Mostow [90] and Margulis [82], leading to a complete classification of lattices in large classes of semi-simple Lie groups.

Briefly, a hyperbolic (Anosov) dynamical system is one that exhibits strong expansion and contraction along complementary directions. An early contribution introducing this class of objects is the paper of Smale [106], in which basic examples and techniques are introduced. A breakthrough came with the results of Anosov [1], who proved structural stability of the Anosov systems and ergodicity of the geodesic flow on a manifold of negative curvature. Motivated by questions arising in mathematical physics, chaos theory and other areas, hyperbolic dynamics emerged as one of the major fields of contemporary mathematics. From the beginning, a major unsolved problem in the field was the classification of Anosov diffeomorphisms and flows.

In the 80s a change in philosophy occurred, partially motivated by a program introduced by Zimmer [114]. The goal of the program was to classify the smooth actions of higher rank semi-simple Lie groups and of their (irreducible) lattices on compact manifolds. It was expected that any such lattice action that preserves a smooth volume form and is ergodic can be reduced to one of the following standard models: isometric actions, linear actions on infranilmanifolds, and left translations on compact ho-

mogeneous spaces. This original conjecture was disproved by Katok, Lewis (see [56]): by blowing up a linear nilmanifold-action at some fixed points they exhibit real-analytic, volume preserving, ergodic lattice actions on manifolds with complicated topology.

Nevertheless, imposing extra assumptions on a higher rank action, for example the existence of some hyperbolicity, allows local and global classification results. The concept of *Anosov action*, that is, an action that contains at least one Anosov diffeomorphism, was introduced for general groups by Pugh, Shub [99]. The significant differences between the classical \mathbb{Z} and \mathbb{R} cases and those of higher rank lattices, or at a more basic level, of higher rank abelian groups, went unnoticed for a while. The surge of activity in the 80s allowed these differences to surface: for lattices in the work of Hurder, Katok, Lewis, Zimmer (see [43,55,56,63]); and for higher rank abelian groups in the work of Katok, Lewis [55] and Katok, Spatzier [59]. As observed in these papers, local and global rigidity are typical for such Anosov actions. This generated additional research which is summarized in Sects. “[Local Rigidity](#)” and “[Global Rigidity](#)”.

Differentiable rigidity is covered in Sect. “[Differentiable Rigidity](#)”. An interesting problem is to find moduli for the C^k conjugacy, $k \geq 1$, of Anosov diffeomorphisms and flows. This was tackled so far only for low dimensional cases ($n = 2$ for diffeomorphisms and $n = 3$ for flows). Another direction that can be included here refers to finding obstructions for higher transverse regularity of the stable/unstable foliation of a hyperbolic system. A spin-off of the research done so far, which is of high interest by itself, and has applications to local and global rigidity, consists of results lifting the regularity of solutions of cohomological equations over hyperbolic systems. In turn, these results motivated a more careful study of analytic questions about lifting the regularity of real valued continuous functions that enjoy higher regularity along webs of foliations. We also include in this section rigidity results for cocycles over higher rank abelian actions. These are crucial to the proof of local rigidity of higher rank abelian group actions. A more detailed presentation of the material relevant to differentiable rigidity can be found in the forthcoming monograph [58].

Measure rigidity refers to the study of invariant measures under actions of abelian groups and semigroups. If the actions are hyperbolic, higher-rank, and satisfy natural algebraic and irreducibility assumptions, one expects the invariant measures to be rare. This direction was started by a question of Furstenberg, asking if any nonatomic probability measure on the circle, invariant and ergodic under multiplications by 2 and 3, is the Lebesgue measure. An

early contribution is that of Rudolph [103], who answered positively if the action has an element of strictly positive entropy. Katok, Spatzier [61] extended the question to more general higher rank abelian actions, such as actions by linear automorphisms of tori and Weyl chamber flows. A related direction is the study of the invariant sets and measures under the action of horocycle flows, where important progress was made by Ratner [100,101] and earlier by Margulis [16,81,83]. An application of these results present in the last papers is the proof of the long standing Oppenheim’s conjecture, about the density of the values of the quadratic forms at integer points. Recent developments due to Einsiedler, Katok, Lindenstrauss [20] give a partial answer to another outstanding conjecture in number theory, Littlewood’s conjecture, and emphasize measure rigidity as one of a more promising directions in rigidity. More details are shown in Sect. “[Measure Rigidity](#)”.

Four other recent surveys of rigidity theory, each one with a fair amount of overlap but also complementary in part to the present one, that discuss various aspects of the field and its significance are written by Fisher [23], Lindenstrauss [68], Nițică, Török [95], and Spatzier [107]. Among these, [23] concentrates mostly on local and global rigidity, [95] on differentiable rigidity, [68] on measure rigidity, and [107] gives a general overview.

Here is a word of caution for the reader. Many times, instead of the most general results, we present an example that contains the essence of what is available. Also, several important facts that should have been included, are left out. This is because stating complete results would require more space than allocated to this material. The limited knowledge of the author also plays a role here. He apologizes for any obvious omissions and hopes that the bibliography will help fill the gaps.

Basic Definitions and Examples

A detailed introduction to the theory of Anosov systems and hyperbolic dynamics is given in the monograph [51]. The proofs of the basic results for diffeomorphisms stated below can be found there. The proofs for flows are similar. Surveys about hyperbolic dynamics in this volume are the article ▶ [Hyperbolic Dynamical Systems](#) by Viana and the article ▶ [Smooth Ergodic Theory](#) by Wilkinson.

Consider a compact differentiable manifold M and $f: M \rightarrow M$ a C^1 diffeomorphism. Let TM be the tangent bundle of M , and $Df: TM \rightarrow TM$ be the derivative of f . The map f is said to be an *Anosov diffeomorphism* if there is a smooth Riemannian metric $\|\cdot\|$ on M , which induces a metric d_M called *adapted*, a number $\lambda \in (0, 1)$, and

a continuous Df invariant splitting $TM = E^s \oplus E^u$ such that

$$\|Df v\| \leq \lambda \|v\|, v \in E^s, \quad \|Df^{-1} v\| \leq \lambda \|v\|, v \in E^u.$$

For each $x \in M$ there is a pair of embedded C^1 discs $W_{loc}^s(x), W_{loc}^u(x)$, called the local stable manifold and the local unstable manifold at x , respectively, such that:

1. $T_x W_{loc}^s(x) = E^s(x), T_x W_{loc}^u(x) = E^u(x)$;
2. $f(W_{loc}^s(x)) \subset W_{loc}^s(fx), f^{-1}(W_{loc}^u(x)) \subset W_{loc}^u(f^{-1}x)$;
3. For any $\mu \in (\lambda, 1)$, there exists a constant $C > 0$ such that for all $n \in \mathbb{N}$,

$$d_M(f^n x, f^n y) \leq C \mu^n d_M(x, y), \quad \text{for } y \in W_{loc}^s(x),$$

$$d_M(f^{-n} x, f^{-n} y) \leq C \mu^n d_M(x, y), \quad \text{for } y \in W_{loc}^u(x).$$

The local stable (unstable) manifolds can be extended to global stable (unstable) manifolds $W^s(x)$ and $W^u(x)$ which are well defined and smoothly injectively immersed. These global manifolds are the leaves of global foliations W^s and W^u of M . In general, these foliations are only continuous, but their leaves are differentiable.

Let $\phi: \mathbb{R} \times M \rightarrow M$ be a C^1 flow. The flow ϕ is said to be an *Anosov flow* if there is a Riemannian metric $\|\cdot\|$ on M , a constant $0 < \lambda < 1$, and a continuous Df invariant splitting $TM = E^s \oplus E^0 \oplus E^u$ such that for all $x \in M$ and $t > 0$:

1. $\frac{d}{dt}|_{t=0} \phi^t \in E_x^c \setminus \{0\}, \dim E_x^c = 1$,
2. $\|D\phi^t v\| \leq \lambda^t \|v\|, v \in E^s$,
3. $\|D\phi^{-t} v\| \leq \lambda^t \|v\|, v \in E^u$.

For each $x \in M$ there is a pair of embedded C^1 discs $W_{loc}^s(x), W_{loc}^u(x)$, called the local (strong) stable manifold and the local (strong) unstable manifold at x , respectively, such that:

1. $T_x W_{loc}^s(x) = E^s(x), T_x W_{loc}^u(x) = E^u(x)$;
2. $\phi^t(W_{loc}^s(x)) \subset W_{loc}^s(\phi^t x),$
 $\phi^{-t}(W_{loc}^u(x)) \subset W_{loc}^u(\phi^{-t} x)$ for $t > 0$;
3. For any $\mu \in (\lambda, 1)$, there exists a constant $C > 0$ such that for all $n \in \mathbb{N}$,

$$d_M(\phi^t x, \phi^t y) \leq C \mu^t d_M(x, y),$$

$$\text{for } y \in W_{loc}^s(x), t > 0,$$

$$d_M(\phi^{-t} x, \phi^{-t} y) \leq C \mu^t d_M(x, y),$$

$$\text{for } y \in W_{loc}^u(x), t > 0.$$

The local stable (unstable) manifolds can be extended to global stable (unstable) manifolds $W^s(x)$ and $W^u(x)$. These global manifolds are the leaves of global foliations W^s and W^u of M . One can also define weak stable and

weak unstable foliations with leaves given by $W^{cs}(x) = \cup_{t \in \mathbb{R}} (W^s(x))$ and $W^{cu}(x) = \cup_{t \in \mathbb{R}} (W^u(x))$, which have as tangent distributions $E^{cs} = E^c \oplus E^s$ and $E^{cu} = E^c \oplus E^u$. In general, all these foliations are only continuous, but their leaves are differentiable.

Any Anosov diffeomorphism is *structurally stable*, that is, any C^1 diffeomorphism that is C^1 close to an Anosov diffeomorphism is topologically conjugate to the unperturbed one via a Hölder homeomorphism. An Anosov flow is structurally stable in the orbit equivalence sense: any C^1 small perturbation of an Anosov flow has the orbit foliation topologically conjugate via a Hölder homeomorphism to the orbit foliation of the unperturbed flow.

Let $SL(n, \mathbb{R})$ be the group of all n -dimensional square matrices with real valued entries of determinant 1. Let $SL(n, \mathbb{Z}) \subset SL(n, \mathbb{R})$ be the subgroup with integer entries. Basic examples of Anosov diffeomorphisms are automorphisms of the n -torus $\mathbb{T}^n = \mathbb{R}^n/\mathbb{Z}^n$ induced by hyperbolic matrices in $SL(n, \mathbb{Z})$. A hyperbolic matrix is one that has only nonzero eigenvalues, all away in absolute value from 1. A specific example of such matrix in $SL(2, \mathbb{Z})$ is

$$\begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}.$$

Basic examples of Anosov flows are given by the geodesic flows of surfaces of constant negative curvature. The unitary bundle of such a surface can be realized as $M = \Gamma \backslash PSL(2, \mathbb{R})$, where $PSL(2, \mathbb{R}) = SL(2, \mathbb{R})/\{\pm 1\}$ and Γ is a cocompact lattice in $PSL(2, \mathbb{R})$. The action of the geodesic flow on M is induced by right multiplication with elements in the diagonal one-parameter subgroup

$$\left\{ \begin{pmatrix} e^{t/2} & 0 \\ 0 & e^{-t/2} \end{pmatrix}, t \in \mathbb{R} \right\}.$$

A related transformation, which is not hyperbolic, but will be of interest in this presentation, is the *horocycle flow* induced by right multiplication on M by elements in the one parameter subgroup

$$\left\{ \begin{pmatrix} 1 & t \\ 0 & 1 \end{pmatrix}, t \in \mathbb{R} \right\}.$$

Of interest in this survey are also actions of more general groups than \mathbb{Z} and \mathbb{R} . Typical examples of higher rank \mathbb{Z}^k Anosov actions are constructed on tori using groups of units in number fields. See [65] for more details about this construction. A particular example of Anosov \mathbb{Z}^2 -action on \mathbb{T}^3 is induced by the hyperbolic matrices:

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 8 & 2 \end{pmatrix}, \quad B = \begin{pmatrix} 2 & 1 & 0 \\ 0 & 2 & 1 \\ 1 & 8 & 4 \end{pmatrix}.$$

One can check, by looking at the eigenvalues, that A and B are not multiples of the same matrix. Moreover, A and B commute.

Typical examples of higher rank Anosov \mathbb{R}^k -actions are given by Weyl chamber flows, which we now describe using some notions from the theory of Lie groups. A good reference for the background in Lie group theory necessary here is the book of Helgason [40]. Note that for a hyperbolic element of such an action the center distribution is k -dimensional and coincides with the tangent distribution to the orbit foliation of \mathbb{R}^k .

Let G be a semi-simple connected real Lie group of the noncompact type, with Lie algebra \mathfrak{g} . Let $K \subset G$ be a maximal compact subgroup that gives a Cartan decomposition $\mathfrak{g} = \mathfrak{k} + \mathfrak{p}$, where \mathfrak{k} is the Lie algebra of K and \mathfrak{p} is the orthogonal complement of \mathfrak{k} with respect to the Killing form of \mathfrak{g} . Let $\alpha \subset \mathfrak{p}$ be a maximal abelian subalgebra and $A = \exp \alpha$ be the corresponding subgroup. The simultaneous diagonalization of $ad_{\mathfrak{g}}(\alpha)$ gives the decomposition

$$\mathfrak{g} = \mathfrak{g} + \sum_{\lambda \in \Lambda} \mathfrak{g}_{\lambda}, \quad \mathfrak{g}_0 = \alpha + \mathfrak{m},$$

where Λ is the set of restricted roots. The spaces \mathfrak{g}_{λ} are called *root spaces*. A point $H \in \alpha$ is called *regular* if $\lambda(H) \neq 0$ for all $\lambda \in \Lambda$. Otherwise it is called *singular*. The set of regular elements consists of the complement of a union of finitely many hyperplanes. Its components are cones in α called *Weyl chambers*. The faces of the Weyl chambers are called *Weyl chamber walls*.

Let M be the centralizer of A in K . Suppose Γ is an irreducible torsion-free cocompact lattice in G . Since A commutes with M , the action of A by right translations on $\Gamma \backslash G$ descends to an A -action on $N := \Gamma \backslash G/M$. This action is called a *Weyl chamber flow*. Any Weyl chamber flow is an Anosov action, that is, has an element that acts hyperbolically transversally to the orbit foliation of A . Note that all maximal connected \mathbb{R} diagonalizable subgroups of G are conjugate and their common dimension is called the \mathbb{R} -rank of G . If the \mathbb{R} -rank k of G is higher than 2, then the Weyl chamber flow is a higher rank hyperbolic \mathbb{R}^k -action.

An example of semi-simple Lie group is $SL(n, \mathbb{R})$. Let A be the diagonal subgroup of matrices with positive entries in $SL(n, \mathbb{R})$. An example of Weyl chamber flow that will be discussed in the sequel is the action of A by right translations on $\Gamma \backslash SL(n, \mathbb{R})$, where Γ is a cocompact lattice. In this case the centralizer M is trivial. The rank of this action is $n - 1$. The picture of the Weyl chambers for $n = 3$ is shown in Fig. 1. The signs that appear in each chamber are the signs of half of the Lyapunov exponents of a regular element from the chamber with respect

ERGODIC THEORY: RIGIDITY

Ergodic Theory: Rigidity, Figure 1
Weyl chambers for $SL(3, \mathbb{R})$

to a certain fixed basis. For this action, the Lyapunov exponents appear in pairs of opposite signs.

An example of higher rank lattice Anosov action that will be discussed in the sequel is the standard action of $SL(n, \mathbb{Z})$ on the torus \mathbb{T}^n , $(A, x) \mapsto Ax, A \in SL(n, \mathbb{Z}), x \in \mathbb{T}^n$. $SL(n, \mathbb{Z})$ is a (noncocompact!) lattice in $SL(n, \mathbb{R})$. As shown in [55], this action is generated by Anosov diffeomorphisms.

We describe now a class of dynamical systems more general than the hyperbolic one. A C^1 diffeomorphism f of a compact differentiable manifold M is called *partially hyperbolic* if there exists a continuous invariant splitting of the tangent bundle $TM = E^s \oplus E^0 \oplus E^u$ such that the derivative of f expands E^u much more than E^0 , and contracts E^s much more than E^0 . See [9,41] and [10] for the theory of partially hyperbolic diffeomorphisms. E^s and E^u are called stable, respectively unstable distributions, and are integrable. E^0 is called center distribution and, in general, it is not integrable. A structural stability result proved by Hirsch, Pugh, Shub [41], that is a frequently used tool in rigidity, shows that, if E^0 is integrable to a smooth foliation, then any perturbation \tilde{f} of f is partially hyperbolic and has an integrable center foliation. Moreover, the center foliations of \tilde{f} of f are mapped one into the other by a homeomorphism that conjugates the maps induced on the factor spaces of the center foliations by \tilde{f} of f respectively.

We review now basic facts about cocycles. These basic definitions refer to several regularity classes: measurable, continuous, or differentiable. Let G be a group acting on a set M , and denote the action $G \times M \rightarrow M$ by $(g, x) \mapsto gx$; thus $(g_1 g_2)x = g_1(g_2 x)$. Let Γ be a group with unit 1_{Γ} . M is usually endowed with a measurable, continuous, or differentiable structure. A *cocycle* β over

the action is a function $\beta: G \times M \rightarrow \Gamma$ such that

$$\beta(g_1 g_2, x) = \beta(g_1, g_2 x) \beta(g_2, x), \quad (1)$$

for all $g_1, g_2 \in G, x \in M$. Note that any group representation $\pi: G \rightarrow \Gamma$ defines a cocycle called *constant cocycle*. The trivial representation defines the *trivial cocycle*.

A natural equivalence relation for the set of cocycles is given by cohomology. Two cocycles $\beta_1, \beta_2: G \times M \rightarrow \Gamma$ are cohomologous if there exists a map $P: M \rightarrow \Gamma$, called *transfer map*, such that

$$\beta_1(g, x) = P(gx) \beta_2(g, x) P(x)^{-1}, \quad (2)$$

for all $g \in G, x \in M$.

Differentiable Rigidity

We start by reviewing cohomological results. Several basic notions are already defined in Sect. “[Basic Definitions and Examples](#)”. In this section we assume that the cocycles are at least continuous. A cocycle $\beta: G \times M \rightarrow \Gamma$ over an action $(g, x) \mapsto gx, g \in G, x \in M$, is said to satisfy *closing conditions* if for any $g \in G$ and $x \in M$ such that $gx = x$, one has $\beta(g, x) = 1_\Gamma$. Note that closing conditions are necessary in order for a cocycle to be cohomologous to the trivial one. Since a \mathbb{Z} -cocycle is determined by a function $\beta: M \rightarrow \Gamma, \beta(x) := \beta(1, x)$, the closing conditions become

$$f^n x = x \text{ implies } \beta(f^{n-1}x) \dots \beta(x) = 1_\Gamma, \quad (3)$$

where $f: M \rightarrow M$ is the function that implements the \mathbb{Z} -action.

The first cohomological results for hyperbolic systems were obtained by Livshits [70,71]. Let M be a compact Riemannian manifold with a \mathbb{Z} -action implemented by a topologically transitive Anosov C^1 diffeomorphism f . Then an α -Hölder function $\beta: M \rightarrow \mathbb{R}$ determines a cocycle cohomologous to a trivial cocycle if and only if β satisfies the closing conditions (3). The transfer map is α -Hölder. Moreover, for each Hölder class α and each finite dimensional Lie group Γ , there is a neighborhood U of the identity in Γ such that an α -Hölder function $\beta: M \rightarrow \Gamma$ determines a cocycle cohomologous to the trivial cocycle if and only if β satisfies the closing conditions (3). The transfer map is again α -Hölder. Similar results are true for Anosov flows.

Using Fourier analysis, Veech [108] extended Livshits’s result to real valued cocycles over \mathbb{Z} -actions induced by ergodic endomorphisms of an n -dimensional torus, not necessarily hyperbolic. For cocycles with values in abelian groups, the question of two arbitrary cocycles being cohomologous reduces to the question of an

arbitrary cocycle being cohomologous to a trivial one. This is not the case for cocycles with values in non-abelian groups. Parry [98] extended Livshits’s criteria to one for cohomology of two arbitrary cocycles with values in compact Lie groups. Parry’s result was generalized by Schmidt [104] to cocycles with values in Lie groups that, in addition, satisfy a center bunching condition. Nițică, Török [92] extended Livshits’s result to cocycles with values in the group $\text{Diff}^k(M)$ of C^k diffeomorphism of a compact manifold M with stably trivial bundle, $k \geq 3$. Examples of such manifolds are the tori and the spheres. In this case, the transfer map takes values in $\text{Diff}^{k-3}(M)$, and it is Hölder with respect to a natural metric on $\text{Diff}^{k-3}(M)$. In [92] one can also find a generalization of Livshits’s result to generic Anosov actions, that is, actions generated by families of Anosov diffeomorphisms that do not interchange the stable and unstable directions of elements in the family. An example of such an action is the standard action of $SL(n, \mathbb{Z})$ on the n -dimensional torus.

A question of interest is the following: if two C^k cocycles, $1 \leq k \leq \omega$, over a hyperbolic action, are cohomologous through a continuous/measurable transfer map P , what can be said about the higher regularity of P ? For real valued cocycles the question can be reduced to one about cohomologically trivial cocycles. Livshits showed that for a real valued C^1 cocycle cohomologous to a constant the transfer map is C^1 . He also obtained C^∞ regularity results if the action is given by hyperbolic automorphisms of a torus. After preliminary results by Guillemin and Kazhdan for geodesic flows on surfaces of negative curvature, for general hyperbolic systems the question was answered positively by de la Llave, Marco, Moriyon [76] in the C^∞ case and by de la Llave [74] in the real analytic case. Nițică, Török [93] considered the lift of regularity for a transfer map between two cohomologous cocycles with values in a Lie group or a diffeomorphism group. In contrast to the case of cocycles cohomologous to trivial ones, here one needs to require for the transfer map a certain amount of Hölder regularity that depends on the ratio between the expansion/contraction that appears in the base and the expansion/contraction introduced by the cocycle in the fiber. This assumption is essential, as follows from a counterexample found by de la Llave’s [73].

Useful tools in this development have been results from analysis that lift the regularity of a continuous real valued function which is assumed to have higher regularity along pairs of transverse Hölder foliations. Many times the foliations are the stable and unstable ones associated to a hyperbolic system. Journé [46] proved the $C^{n,\alpha}$ regularity of a continuous function that is $C^{n,\alpha}$ along two transverse continuous foliations with $C^{n,\alpha}$ leaves. If one

is interested only in C^∞ regularity, a convenient alternative is a result of Hurder, Katok [44]. This has a simpler proof and can be applied to the more general situation in which the function is regular along a web of transverse foliations. A real analytic regularity result along these lines belongs to de la Llave [74]. In certain problems, for example when working with Weyl chamber flows, it is difficult to control the regularity in enough directions to span the whole tangent space. Nevertheless, the tangent space can be generated if one consider higher brackets of good directions. A C^∞ regularity result for this case belongs to Katok, Spatzier [60]. In order to apply this result, the foliations need to be C^∞ not only along the leaves, but also transversally.

An application of the above regularity results is to questions about transverse regularity of the stable and unstable foliations of the geodesic flow on certain C^∞ surfaces of nonpositive curvature. For compact negatively curved C^∞ surfaces, E. Hopf showed that these foliations are C^1 , and it follows from the work of Anosov that individual leaves are C^∞ . Hurder, Katok [44] showed that once the weak-stable and weak-unstable foliations of a volume-preserving Anosov flow on a compact 3-manifold are C^2 , they are C^∞ .

Another application of the regularity results is to the study of invariants for C^k conjugacy of hyperbolic systems. By structural stability, a small C^1 perturbation of a hyperbolic system is C^0 conjugate to the unperturbed one. The conjugacy, in general, is only Hölder. If the conjugacy is C^1 then it preserves the eigenvalues of the derivative at the periodic orbit. The following two results describe the invariants of smooth and real analytic conjugacy of low dimensional hyperbolic systems. They are proved in a series of papers written in various combinations by de la Llave, Marco, Moryion [72,74,75,79,80].

Let X, Y be two $C^\infty(C^\omega)$ transitive Anosov vector fields on a compact three-dimensional manifold. If they are C^0 conjugate and the eigenvalues of the derivative at the corresponding periodic orbits are the same, then the conjugating homeomorphism is $C^\infty(C^\omega)$. In particular, any C^1 conjugacy is $C^\infty(C^\omega)$.

Assume now that f, g are two $C^\infty(C^\omega)$ Anosov diffeomorphisms on a compact two dimensional manifold. If they are C^0 conjugate and the eigenvalues of the derivative at the corresponding periodic orbits are the same, then the conjugating diffeomorphism is $C^\infty(C^\omega)$. In particular, any C^1 conjugacy is $C^\infty(C^\omega)$.

An important direction was initiated by Katok, Spatzier [59] who studied cohomological results over hyperbolic \mathbb{Z}^k or \mathbb{R}^k -actions, $k \geq 2$. They show that real valued smooth/Hölder cocycles over typical classes of hyper-

bolic \mathbb{Z}^k or \mathbb{R}^k , $k \geq 2$, actions are smoothly/Hölder cohomologous to constants. These results cover, in particular, actions by hyperbolic automorphisms of a torus, and Weyl chamber flows. The proofs rely on harmonic analysis techniques, such as Fourier transform and group representations for semi-simple Lie groups.

A geometric method for cocycle rigidity was developed in [64]. One constructs a differentiable form using invariant structures along stable/unstable foliations, and the commutativity of the action. The form is exact if and only if the cocycle is cohomologous to a constant one. The method covers actions on nilmanifolds satisfying a condition called TNS (Totally Non-Symplectic). This condition means that the action is higher rank abelian hyperbolic, and that the tangent space is a direct sum of invariant distributions, with each pair of these included in the stable distribution of a hyperbolic element of the action. The method was also applied to small (i. e. close to identity on a set of generators) Lie group valued cocycles. A related paper is [96] which contains rigidity results for cocycles over (TNS) actions with values in compact Lie groups. In this situation the number of cohomology classes is finite. An example of (TNS) action is given by the action of a maximal diagonalizable subgroup of $SL(n, \mathbb{Z})$ on \mathbb{T}^n .

Recently Damjanović, Katok [14] developed a new method that was applied to the action of the matrix diagonal group on $\Gamma \backslash SL(n, \mathbb{R})$. They use techniques from [54], where one finds cohomology invariants for cocycles over partially hyperbolic actions that satisfy accessibility property. Accessibility means that one can connect any two points from the manifold supporting the partially hyperbolic dynamical system by transverse piecewise smooth paths included in stable/unstable leaves. This notion was introduced by Brin, Pesin [9] and it is playing a crucial role in the recent surge of activity in the field of partially hyperbolic diffeomorphisms. See [10] for a recent survey of the subject. The cohomology invariants described in [54] are heights of the cocycle over cycles constructed in the base out of pieces inside stable/unstable leaves. They provide a complete set of obstructions for solving the cohomology equation. A new tool introduced in [14] is algebraic K -theory [88]. The method can be extended to cocycles with non-abelian range. In [57] one finds related results for small cocycles with values in a Lie group or the diffeomorphism group of a compact manifold.

The equivalent of the Livshits theorem in the higher-rank setting appears to be a description of the highest cohomology rather than the first cohomology. Indeed, for higher rank partially hyperbolic actions of the torus, the intermediate cohomologies are trivial, while for the high-

est one the closing conditions characterize the cohomology classes. This behavior provides a generalization of Veech cohomological result and of Katok, Spatzier cohomological result for toral automorphisms, and was discovered by A. Katok, S. Katok [52,53].

Flaminio, Forni [27] studied the cohomological equation over the horocycle flow. It is shown that there are infinitely many obstructions to the existence of a smooth solution. Moreover, if these obstructions vanish, then one can solve the cohomological equation. In [28] it is shown a similar result for cocycles over area preserving flows on compact higher-genus surfaces under certain assumptions that hold generically. Mieczkowski [87] extended these techniques and studied the cohomology of parabolic higher rank abelian actions. All these results rely on non-commutative Fourier analysis, more specifically representation theory of $SL(2, \mathbb{R})$ and $SL(2, \mathbb{C})$.

Local Rigidity

Let Γ be a finitely (or compactly) generated group, G a topological group, and $\pi: \Gamma \rightarrow G$ a homomorphism. The target of local rigidity theory is to understand the space of perturbations of various homomorphisms π . Trivial perturbations of a homomorphism arise from conjugation by an arbitrary element of G . In order to rule them out, one says that π is *locally rigid* if any nearby homomorphism π' , (that is, π' close to π on a finite or compact set of generators of Γ), is conjugate to π by an element $g \in G$, that is, $\pi(\gamma) = g\pi'(\gamma)g^{-1}$ for all $\gamma \in \Gamma$. If G is path-wise connected, one can also consider *deformation rigidity*, meaning that any nearby continuous path of homomorphisms is conjugated to the initial one via a continuous path of elements in G that has an end in the identity.

Initial results on local rigidity are about embeddings of lattices into semi-simple Lie groups. The main results belong to Weil [110,111,112]. He showed that if G is a semi-simple Lie group that is not locally isomorphic to $SL(2, \mathbb{R})$ and if $\Gamma \subset G$ is an irreducible cocompact lattice, then the natural embedding of Γ into G is locally rigid. Earlier results were obtained by Selberg [105], Calabi, Vesentini [12], and Calabi [11]. Selberg proved the local rigidity of the natural embedding of cocompact lattices into $SL(n, \mathbb{R})$. His proof used the dynamics of iterates of matrices, in particular the existence of singular directions, or walls of Weyl chambers, in the maximal diagonalizable subgroups of $SL(n, \mathbb{R})$. Selberg's approach inspired Mostow [90] to use the boundaries at infinity in his proof of strong rigidity of lattices, which in turn was crucial to the development of superrigidity due to Margulis [82]. See Sect. "Global Rigidity" for more details.

Recall that hyperbolic dynamical systems are structurally stable. Thus they are, in a certain sense, locally rigid. We introduce now a precise definition of local rigidity in the infinite-dimensional setup. The fact that for general group actions one needs to consider different regularities for the actions, perturbations and conjugacies is apparent from the description of structural stability for Anosov systems.

A C^k action α of a finitely generated discrete group Γ on a manifold M , that is, a homomorphism $\alpha: \Gamma \rightarrow \text{Diff}^k(M)$, is said to be $C^{k,l,p,r}$ *locally rigid* if any C^l perturbation $\tilde{\alpha}$ which is C^p close to α on a family of generators, is C^r conjugate to α , i.e there exists a C^r diffeomorphism $H: M \rightarrow M$ which conjugates $\tilde{\alpha}$ to α , that is, $H \circ \alpha(g) = \tilde{\alpha}(g) \circ H$ for all $g \in \Gamma$. Note that for Anosov \mathbb{Z} -actions, $C^{1,1,1,0}$ rigidity is known as *structural stability*. One can also introduce the notion of *deformation rigidity* if the initial action and the perturbation are conjugate by a continuous path of diffeomorphisms that has an end coinciding to the identity.

A weaker notion of local rigidity can be defined in the presence of invariant foliations for the initial group action and for the perturbation. The map H is now required to preserve the leaves of the foliations and to conjugate only after factorization by the invariant foliations. The importance of this notion is apparent from the leafwise conjugacy structural stability theorem of Hirsch, Pugh, Shub [41]. See Sect. "Basic Definitions and Examples". Moreover, for Anosov flows this is the natural notion of structural stability, and appears by taking the invariant foliation to be the one-dimensional orbit foliation. For more general actions, of lattices or higher rank abelian groups, this property is often used in combination to cocycle rigidity in order to show local rigidity. We discuss more about this when we review local rigidity results for partially hyperbolic actions.

We summarize now several developments in local rigidity that emerged in the 80s. Initial results [67,115] were about *infinitesimal rigidity*, that is, a weaker version of local rigidity suitable for discrete groups representations in infinite-dimensional spaces of smooth vector fields. Then Hurder [43] proved $C^{\infty,\infty,1,\infty}$ deformation rigidity and Katok, Lewis, Zimmer [55,56,63] proved $C^{\infty,\infty,1,\infty}$ local rigidity of the standard action of $SL(n, \mathbb{Z})$, $n \geq 3$, on the n -dimensional torus. In these results crucial use was made of the presence of an Anosov element in the action. Due to the uniqueness of the conjugacy coming from structural stability, one has a continuous candidate for the conjugacy between the actions. Margulis, Qian [85] used the existence of a spanning family of directions that are hyperbolic for certain elements of the action to show lo-

cal rigidity of partially hyperbolic actions that are not hyperbolic. Another important tool present in many proofs is Margulis and Zimmer superrigidity. These results allow one to produce a measurable conjugacy for the perturbation. Then one shows that the conjugacy has higher regularity using the presence of hyperbolicity. Having enough directions to span the whole tangent space is essential to lift the regularity. A cocycle to which superrigidity can be applied is the derivative cocycle.

The study of local rigidity of partially hyperbolic actions that contain a compact factor was initiated by Nițică, Török [92,94]. Let $n \geq 3$ and $d \geq 1$. Let ρ be the action of $SL(n, \mathbb{Z})$ on $\mathbb{T}^{n+d} = \mathbb{T}^n \times \mathbb{T}^d$ given by $\rho(A)(x, y) = (Ax, y)$, $x \in \mathbb{T}^n$, $y \in \mathbb{T}^d$, $A \in SL(n, \mathbb{Z})$. Then, for $K \geq 1$, [92] shows that ρ is $C^{\infty, \infty, 5, K-1}$ deformation rigid. The proof is based on three results in hyperbolic dynamics: the generalization of Livshits's cohomological results to cocycles with values in diffeomorphism groups, the extension of Livshits's result to general Anosov actions, and a version of the Hirsch, Pugh, Shub structural stability theorem improving the regularity of the conjugacy.

Assume now $n \geq 3$ and $K \geq 1$. If ρ is the action of $SL(n, \mathbb{Z})$ on $\mathbb{T}^{n+1} = \mathbb{T}^n \times \mathbb{T}$ given by $\rho(A)(x, y) = (Ax, y)$, $x \in \mathbb{T}^n$, $y \in \mathbb{T}$, $A \in SL(n, \mathbb{Z})$, [94] shows that the action ρ is $C^{\infty, \infty, 2, K-1}$ locally rigid. Ingredients in the proof are two rigidity results, one about TNS actions, and one about actions of property (T) groups. A locally compact group has property (T) if the trivial representation is isolated in the Fell topology. This means that if G acts on a Hilbert space unitarily and it has almost invariant vectors, then it has invariant vectors. Hirsch–Pugh–Shub theorem implies that perturbations of abelian partially hyperbolic actions of product type are conjugated to skew-products of abelian Anosov actions via cocycles with values in diffeomorphism groups. In addition, the TNS property implies that the sum of the stable and unstable distributions of any regular element of the perturbation is integrable. The leaves of the integral foliation are closed, covering the base simply. Thus one obtains a conjugacy between the perturbation and a product action. Property (T) is used to show that the conjugacy reduces the perturbed action to a family of perturbations of hyperbolic actions. But the last ones are already known to be conjugate to the hyperbolic action in the base.

Recent important progress in the question of local rigidity of lattice actions was made by Fisher, Margulis [24,25,26]. Their proofs are modeled along the proof of Weil's local rigidity result [112] and use an analog of Hamilton's [39] hard implicit function theorem. Let G be a connected semi-simple Lie group with all simple factors of rank at least two, and $\Gamma \subset G$ a lattice. The main result

shows that a volume preserving affine action ρ of G or Γ on a compact smooth manifold X is $C^{\infty, \infty, \infty, \infty}$ locally rigid. Lower regularity results are also available. A component of the proof shows that if Γ is a group with property (T), X a compact smooth manifold, and ρ a smooth action of Γ on X by Riemannian isometries, then ρ is $C^{\infty, \infty, \infty, \infty}$ locally rigid. An earlier local rigidity result for this type of actions by cocompact lattices was obtained by Benveniste [5].

Many lattices act naturally on “boundaries” of type G/P , where G is a semi-simple algebraic Lie group and P is a parabolic subgroup. An example is given by $G = SL(2, \mathbb{R})$ and P the subgroup in G consisting of upper triangular matrices. Local rigidity results for this type of actions were found by Ghys [34], Kanai [50] and Katok, Spatzier [62].

Starting with the work of Katok and Lewis, a related direction was the study of local rigidity for higher rank abelian actions. They prove in [55] the $C^{\infty, \infty, 1, \infty}$ local rigidity of the action of a \mathbb{Z}^n maximal diagonalizable (over \mathbb{R}) subgroup of $SL(n+1, \mathbb{Z})$, $n \geq 2$, acting on the torus \mathbb{T}^{n+1} . These type of results were later pushed forward by Katok, Spatzier [62]. Using the theory of nonstationary normal forms developed in [38] and [37] by Katok, Guysinsky, they proved several local rigidity results. The first one assumes that G is a semisimple Lie group with all simple factors of rank at least two, Γ a lattice in G , N a nilpotent Lie group and Λ a lattice in N . Then any Anosov affine action of Γ on N/Λ is $C^{\infty, \infty, 1, \infty}$ locally rigid. Second, let \mathbb{Z}^d be a group of affine transformations of N/Λ for which the derivatives are simultaneously diagonalizable over \mathbb{R} with no eigenvalues on the unit circle. Then the \mathbb{Z}^d -action on N/Λ is $C^{\infty, \infty, 1, \infty}$ locally rigid. A related result for continuous groups is the $C^{\infty, \infty, 1, \infty}$ local rigidity (after factorization by the orbit foliation) of the action of a maximal abelian \mathbb{R} -split subgroup in an \mathbb{R} -split semi-simple Lie group of real rank at least two on G/Λ , where Λ is a cocompact lattice in G .

One can also study rigidity of higher rank abelian partially hyperbolic actions that are not hyperbolic. Natural examples appear as automorphisms of tori and as variants of Weyl chamber flows. For the case of ergodic actions by automorphisms of a torus, this was investigated using a version of the KAM (Kolmogorov, Arnold, Moser) method by Damianović, Katok [15]. As usual in the KAM method, one starts with a linearization of the conjugacy equation. At each step of the iterative KAM scheme, some twisted cohomological equations are solved. The existence of the solutions is forced by the ergodicity of the action and the higher rank assumptions. Diophantine conditions present in this case allow to control the fixed loss of rigidity.

larity which is necessary for the convergence of these solutions to a conjugacy.

Global Rigidity

The first remarkable result in global rigidity belongs to Mostow [90]. For G a connected non-compact semi-simple Lie group not locally isomorphic to $SL(2, \mathbb{R})$, and two irreducible cocompact lattices $\Gamma_1, \Gamma_2 \subset G$, Mostow showed that any isomorphism θ from Γ_1 into Γ_2 extends to an isomorphism of G into itself. G has an involution σ whose fixed set is a maximal compact subgroup K . One constructs the symmetric Riemannian space $X = G/K$. To each chamber of X corresponds a parabolic group and these parabolic groups are endowed with a Tits geometry similar to the projective geometry of lines, planes etc. formed in the classical case when $G = PGL(n, \mathbb{R})$. The proof of Mostow's result starts by building a θ -equivariant pseudo-isometric map $\phi: G/K_1 \rightarrow G/K_2$. The map ϕ induces an incidence preserving θ -equivariant isomorphism ϕ_0 of the Tits geometries. By Tits' generalized fundamental theorem of projective geometry, ϕ_0 is induced by an isomorphism of G . Finally, $\theta(\gamma) = \phi_0 \cdot \gamma \cdot \phi_0^{-1}$ gives the desired conclusion.

The next remarkable result in global rigidity is Margulis' superrigidity theorem. An account of this development can be found in the monograph [82]. For large classes of irreducible lattices in semi-simple Lie groups, this result classifies all finite dimensional representations. Let G be a semi-simple simply connected Lie group of rank higher than two and $\Gamma < G$ an irreducible lattice. Then any linear representation π of Γ is almost the restriction of a linear representation of G . That is, there exists a linear representation π_1 of G and a bounded image representation π_2 of Γ such that $\pi = \pi_1 \pi_2$. The possible representations π_2 are also classified by Margulis up to some facts concerning finite image representations. As in the case of Mostow's result, the proof involved the analysis of a map defined on the boundary at infinity. In this case the map is studied using deep results from dynamics like the multiplicativity ergodic theorem of Osledec [97] or the theory of random walks on groups developed by Furstenberg [31]. An important consequence of Margulis superrigidity result is the arithmeticity of irreducible lattices in connected semi-simple Lie groups of rank higher than two. A basic example of arithmetic lattice can be obtained by taking the integer points in a semi-simple Lie group that is a matrix group, like taking $SL(n, \mathbb{Z})$ inside $SL(n, \mathbb{R})$. Special cases of superrigidity theorems were proved by Corlette [13] and Gromov, Schoen [36] for the rank one groups $Sp(1, n)$ and respec-

tively F_4 using the theory of harmonic maps. A consequence is the arithmeticity of lattices in these groups. Some of these results are put into differential geometric setting in [89].

Margulis superrigidity result was extended to cocycles by Zimmer. A detailed exposition, including a self contained presentation of several rigidity results of Margulis, can be found in the monograph [113]. We mention here a version of this result that can be found in [24]. Let M be a compact manifold, H a matrix group, $P = M \times H$, and Γ a lattice in a simply connected, semi-simple Lie group with all factors of rank higher than two. Assume that Γ acts on M and H in a way that makes the projection from P to M equivariant. Moreover, the action of Γ on P is measure preserving and ergodic. Then there exists a measurable map $s: M \rightarrow H$, a representation $\pi: G \rightarrow H$, a compact subgroup $K < H$ which commute with $\pi(G)$ and a measurable map $k: \Gamma \times M \rightarrow K$ such that $\gamma \cdot s(m) = k(\gamma, m) \cdot \pi(\gamma) \cdot s(\gamma \cdot m)$. One can easily check from the last equation that k is a cocycle. So, up to a measurable change of coordinates given by the map s , the action of Γ on P is a compact extension via a cocycle of a linear representation of G .

Developing further the method of Mostow for studying the Tits building associated to a symmetric space of non-positive curvature led Ballman, Brin, Eberlein, Spatzier [2,3] to a number of characterizations of symmetric spaces. In particular, they showed that if M is a complete Riemannian manifold of non-positive curvature, finite volume, with simply connected cover, irreducible and of rank at least two, then M is isometric to a symmetric space with the connected component of $\text{Isom}(M)$ having no compact factors.

A topological rigidity theorem has been proved by Farrell, Jones [21]. They showed that if N is a complete connected Riemannian manifold whose sectional curvature lies in a closed interval included in $(-\infty, 0]$, and M is a topological manifold of dimension greater than 5, then any proper homotopy equivalence $f: M \rightarrow N$ is properly homotopic to a homeomorphism. In particular, if M and N are both compact connected negatively curved Riemannian manifolds with isomorphic fundamental groups, then M and N are homeomorphic.

Likewise to the case of local rigidity, a source of inspiration for results in global rigidity was the theory of hyperbolic systems, in particular their classification. The only known examples of Anosov diffeomorphisms are hyperbolic automorphisms of infranilmanifolds. Moreover, any Anosov diffeomorphism on an infranilmanifold is topologically conjugate to a hyperbolic automorphism [29,78]. It is conjectured that any Anosov diffeomorphism is topo-

logically conjugate to a hyperbolic automorphism of an infranilmanifold. Partial results are obtained in [91], where the conjecture is proved for Anosov diffeomorphisms with codimension one stable/unstable foliation. The proof of the general conjecture eluded efforts done so far. It is not even known if any Anosov diffeomorphism is topologically transitive, that is, if it has a dense orbit. A few positive results are available. Let M be a C^∞ compact manifold endowed with a C^∞ affine connection. Let f be a topologically transitive Anosov diffeomorphism preserving the connection and such that the stable and unstable distributions are C^∞ . Then Benoist, Labourie [4] proved that f is C^∞ conjugate to a hyperbolic automorphism of an infranilmanifold.

The situation for Anosov flows is somehow different. As shown in [30], there exist Anosov flows that are not topologically transitive, so a general analog of the conjecture is false. Nevertheless, for the case of codimension one stable or unstable foliation, it is conjectured in [109] that any Anosov flow on a manifold of dimension greater than three admits a global cross-section. This would imply that the flow is topologically conjugate to the suspension of a linear automorphism of a torus.

For actions of groups larger than \mathbb{Z} , or \mathbb{R} , global classification results are more abundant. A useful strategy in these type of results, which are quite technical, is to start by obtaining a measurable description of the action, most of the time using Margulis–Zimmer superrigidity results, and then use extra assumptions on the action, such as the presence of a hyperbolic element, or the presence of an invariant geometric structure, or both, in order to show that the measurable model is actually continuous or even differentiable. For actions of higher rank Lie groups and their lattices some representative papers are by Katok, Lewis, Zimmer [63] and Goetze, Spatzier [35]. For actions of higher rank abelian groups see Kalinin, Spatzier [49].

Measure Rigidity

Measure rigidity is the study of invariants measures for actions of one parameter and multiparameter abelian groups and semigroups acting on manifolds. Typical situations when interesting rigidity phenomena appear are for one parameter unipotent actions and higher rank hyperbolic actions, discrete or continuous.

A unipotent matrix is one all of whose eigenvalues are one. An important case where the action of a unipotent flow appears is that of the horocycle flow. The invariant measures for it were studied by Furstenberg [33], who showed that the horocycle flow on a compact surface is uniquely ergodic, that is, the ergodic measure is unique.

Dani and Smillie [17] extended this result to the case of non-compact surfaces, with the only other ergodic measures appearing being those supported on compact horocycles. An important breakthrough is the work of Margulis [81], who solved a long standing question in number theory, Oppenheim’s conjecture. The conjecture is about the density properties of the values of an indefinite quadratic form in three or more variables, provided the form is not proportional to a rational form. The proof of the conjecture is based on the study of the orbits for unipotent flows acting by translations on the homogenous space $SL(n, \mathbb{Z}) \backslash SL(n, \mathbb{R})$. All these results were special cases of the Raghunathan conjecture about the structure of the orbits of the actions of unipotent flows on homogenous spaces. Raghunathan’s conjecture was proved in full generality by Ratner [100,101]. Borel, Prasad [8] raised the question of an analog of Raghunathan’s conjecture for S -algebraic groups. S -algebraic groups are products of real and p -adic algebraic groups. This was answered independently by Margulis, Tomanov [86] and Ratner [102].

A basic example of higher rank abelian hyperbolic action is given by the action of $S_{m,n}$, the multiplicative semigroup of endomorphisms generated by the multiplication by m and n , two nontrivial integers, on the one dimensional torus \mathbb{T}^1 . In a pioneering paper [32] Furstenberg showed that for m, n that are not powers of the same integer the action of $S_{m,n}$ has a unique closed, infinite invariant set, namely \mathbb{T}^1 itself. Since there are many closed, infinite invariant sets for multiplication by m , and by n , this result shows a remarkable rigidity property of the joint action. Furstenberg’s result was generalized later by Berend for other group actions on higher dimensional tori and on other compact abelian groups in [6] and [7].

Furstenberg further opened the field by raising the following question:

Conjecture 1 *Let μ be a $S_{m,n}$ -invariant and ergodic probability measure on \mathbb{T}^1 . Then μ is either an atomic measure supported on a finite union of (rational) periodic orbits or μ is the Lebesgue measure.*

While the statement appears to be simple, proving it has been elusive. The first partial result was given by Lyons [77] under the strong additional assumption that the measure makes one of the endomorphisms generating the action exact. Later Rudolph [103] and Johnson [45] weaken the exactness assumption and proved that μ must be the Lebesgue measure provided that multiplication by m (or multiplication by n) has positive entropy with respect to μ . Their results have been proved again using slightly different methods by Feldman [22]. A further extension was given by Host [42].

Katok proposed another example for which measure rigidity can be fruitfully tested, the \mathbb{Z}^2 -action induced by two commuting hyperbolic automorphisms on the torus \mathbb{T}^3 . An example of such action is shown in Sect. “[Basic Definitions and Examples](#)”. One can also consider the action induced by a \mathbb{Z}^{n-1} maximal abelian group of hyperbolic automorphisms acting on the torus \mathbb{T}^n . Katok, Spatzier [61] developed a more geometric technique allowing to prove measure rigidity for these actions if they have an element acting with positive entropy. Their technique can be applied in higher generality if the action is irreducible in a strong sense and, in addition, it has individual ergodic elements or it is TNS. See also [47]. This method is based on the study of conditional measures induced by the invariant measure on certain invariant foliations that appear naturally in the presence of a hyperbolic action. Besides stable and unstable foliations, one can also consider various intersections of them. Einsiedler, Lindenstrauss [19] were able to eliminate the ergodicity and TNS assumptions.

Yet another interesting example of higher rank abelian action is given by Weyl chamber flows. These do not satisfy the TNS condition. Einsiedler, Katok [18] proved that if G is $SL(n, \mathbb{R})$, $\Gamma \subset G$ is a lattice, H is the subgroup of positive diagonal matrices in G , and μ a H -invariant and ergodic measure on G/Γ such that the entropy of μ with respect to all one parameter subgroups of H is positive, then μ is the G invariant measure on G/Γ .

These results are useful in the investigation of several deep questions in number theory. Define $X = SL(3, \mathbb{Z}) \setminus SL(3, \mathbb{R})$ the diagonal subgroup of matrices with positive entries in $SL(3, \mathbb{R})$. This space is not compact but is endowed with a unique translation invariant probability measure. The diagonal subgroup

$$H = \left\{ \begin{pmatrix} e^s & 0 & 0 \\ 0 & e^t & 0 \\ 0 & 0 & e^{-s-t} \end{pmatrix} : s, t \in \mathbb{R} \right\}$$

acts naturally on X by right translations. It was conjectured by Margulis [83] that any compact H -invariant subset of X is a union of compact H -orbits. A positive solution to this conjecture implies a long standing conjecture of Littlewood:

Conjecture 2 *Let $\|x\|$ denote the distance between the real number x and the closest integer. Then*

$$\liminf_{n \rightarrow \infty} n \|n\alpha\| \|n\beta\| = 0 \quad (4)$$

for any real numbers α and β .

A partial result was obtained by Einsiedler, Katok, Lindenstrauss [20] who proved that the set of pairs $(\alpha, \beta) \in \mathbb{R}^2$

for which (4) is not satisfied has Hausdorff dimension zero. Applications of these techniques to questions in quantum ergodicity were found by Lindenstrauss [69].

A current direction in measure rigidity is attempting to classify the invariant measures under rather weak assumptions about the higher rank abelian action, like the homotopical data for the action. Kalinin and Katok [48] proved that any \mathbb{Z}^k , $k \geq 2$, smooth action α on a $k + 1$ -dimensional torus whose elements are homotopic to the corresponding elements of an action by hyperbolic automorphisms preserves an absolutely continuous measure.

Future Directions

An important open problem in differential rigidity is to find invariants for the C^k conjugacy of the perturbations of higher dimensional hyperbolic systems. For Anosov diffeomorphisms, de la Llave counterexample [73] shows that this extension is not possible for a four dimensional example that appears as a direct product of two dimensional Anosov diffeomorphisms. Indeed, there are C^∞ perturbations of the product that are only C^k conjugate to the unperturbed system for any $k \geq 1$. In the positive direction, Katok conjectured that generalizations are possible for the diffeomorphism induced by an irreducible hyperbolic automorphism of a torus. One can also investigate this question for Anosov flows.

Examples of higher rank Lie groups can be obtained by taking products of rank one Lie groups. Many actions of irreducible lattices in these type of groups are believed to be locally rigid, but the techniques available so far cannot be applied. A related problem is to study local rigidity in low regularity classes, for example the local rigidity of homomorphisms from higher rank lattices into homeomorphism groups. More problems related to local rigidity can be found in [23].

An important problem in global rigidity, emphasized by Katok and Spatzier, is to show that, up to differentiable conjugacy, any higher rank Anosov or partially hyperbolic action is algebraic under the assumption that it is sufficiently irreducible. The irreducibility assumption is needed in order to exclude actions obtained by successive application of products, extensions, restrictions and time changes from basic ingredients which include some rank one actions.

Another problem of current research in measure rigidity is to develop a counterpart of Ratner’s theory for the case of actions by hyperbolic higher rank abelian groups on homogeneous spaces. It was conjectured by Katok, Spatzier [61] that the invariant measures for such actions given by toral automorphisms or Weyl chamber flows are

essentially algebraic, that is, supported on closed orbits of connected subgroups. Margulis in [84] extended this conjecture to a rather general setup addressing both the topological and measurable aspects of the problem. More details about actions on homogenous spaces, as well as connections to diophantine approximation, can be found in the article ► [Ergodic Theory on Homogeneous Spaces and Metric Number Theory](#) by Kleinbock.

Glossary

Community A group of neighbors or people with a commonality of association and generally defined by location, shared experience, or function [59].

Community empowerment Internally and externally nurtures a community to accept that residents live in a hazard zone, and they choose to do things as a group to maximize their safety.

Community safety group Existing community groups (such as Neighborhood Watch) and individuals, working with formal response organizations form a coherent affiliation in and near a hazard zone, to help maximize safety and care for all community members.

Disaster The interface between an extreme physical event and a vulnerable human population [81].

Disaster lead time The time taken from first detection of a natural disaster threat to the likely time of impact on humans or human structures.

Disaster threat A natural extreme event which may impact on a community.

Effective risk communication . That which motivates people to maximize their own safety.

Emergency An actual or imminent event which endangers or threatens to endanger life, property or the environment, and which requires a significant and coordinated response [55].

Evacuation People relocating to safely escape hazardous disaster impacts. To move from a high danger zone to relative safety.

Hazard A source of potential harm or a situation with a potential to cause loss. A situation or condition with potential for loss or harm to the community or environment [55]. Hazard is synonymous with 'source of risk' [25].

Hazard zone Defined geographic areas which may be subject to a natural disaster impact of flood, bushfire, storm surge, destructive winds, earthquake, landslide or damaging hail. Hazard zones include major accident sites, including industrial, transport or mining precincts; or biological or terrorist threat or impact, or from-source predicted area(s) of pandemic spread.

Mitigation Any efforts taken which may reduce the impact of a threat.

Prevention Measures to eliminate or reduce the incidence or severity of emergencies [55].

Ramp-up preparations The final set of preparations and precautionary evacuations taken ahead of a forecast disaster impact. This includes earlier final actions than precipitated by formal organizations.

Risk treatment options Measures that modify the characteristics of hazards, communities and environments to reduce risk, e. g. prevention, preparedness, response and recovery [55].

Vulnerability comprises 'resilience' and 'susceptibility'. 'Resilience' is related to 'existing controls' and the capacity to reduce or sustain harm. 'Susceptibility' is related to 'exposure' [25].

Definition of the Subject

This article intends to show how system and complexity science can contribute to an understanding and improvement of evacuation processes, especially considering the roles of engaged communities at risk, the concepts of community self-help, and clear communication about local threats and remedies.

This article shows researchers in Complexity and Systems Science (CSS) a social sciences approach to maximize effective and precautionary evacuation, maximize safety, minimize loss and speed full recovery. The computational and analytical modeling tools of CSS may be considered to apply to a complex interaction of community awareness, inclination to accept the reality of a natural disaster threat, along with achieving background and final preparations to maximize safety and recovery from a natural disaster impact. This article may stimulate CSS researchers to develop detailed models of the complex systems and complexity of melding information from Weather Bureaus and Disaster Managers, via contacts and intervening media to communities at risk, with the shared social goal of maximizing safety. This social sciences task requires cross-disciplinary approaches of respect and response.

The old disaster management model lacked the predictive and rapid communication systems now available and developing in disaster predictive models (such as a flood maps). An approach to modeling the great complexity of human behavior responding to threat is provided. Such a model must include people's prior knowledge of a threat type, and consider such fine detail as the overarching language used in a country with threat zones, and the dominant languages of all under threat. It is hoped this article stimulates CSS models to further engage in this social good of helping people get safe and stay safe through natural disasters by providing predictive tool to Authorities to better inform and encourage those at risk to action, including the possible need for precautionary evacuations ahead of a predicted impact.

Disaster management in Australia, and increasingly, globally, is focused on mitigation as part of a 'threat continuum', from acceptance that some locations are vulner-

able to a hazard impact, through to recovery [13]. Emergency warnings and a possible need to evacuate are embedded as ‘spikes’ on that continuum. Thus, this article stresses the importance of developing ways; incentives, to mobilize aware at-risk community members to precautionary self-evacuation. For this to happen, people need to know and internalize the reality that they are in a hazard zone.

Thus, in the cost-effective philosophy of engendering self-help, the process of understanding the complexity of achieving the shared social goal in maximizing safety and minimizing loss is to engender creation of empowered communities with a high motivation for safety-oriented and precautionary action. This is likely to lead to minimized loss and disruption, and maximized recovery. This article details many elements of that process, and invites detailed development of the Sustainability Implementation Research to achieve that goal through CSS.

To model the path to collective safety, the complexity of the dynamics at play need to be clarified: impact preparedness, including possible evacuation, is a communication and social issue.

This article demonstrates that acknowledgment of hazard zones, developing community acceptance of threat and needed action needs to be at the individual, household and community levels. Evacuation modeling is needed only for those whose homes may be at real threat of a disaster impact. For those living in a hazard zone, a fully informed community, who have internalized the reality of the threat and have worked for maximum background preparation, and have mechanisms to receive alerts and warnings of a looming threat; a community predisposed to precautionary evacuations will result.

Capturing this complexity is the challenge for modelers. Evacuation is about hazard zone residents actively monitoring a looming threat via refined communication channels detailed in this article, within a developed social predisposition to act. Some examples are given. For consideration by scientists and students internationally, this article introduces the Communication Safety Triangle and the Seven Steps to Community Safety on the Preparedness Continuum, within the new research frame of Sustainability Implementation Research (SIR).

Introduction

The purpose of this article is to share with modelers and complexity and system scientists the social and communication issues of modeling effective safety strategies to a natural disaster threat. It is hoped, through the approaches and processes described in this article, that mod-

elers will more clearly link physical threats with warnings and community engagement.

This article first looks at the definitions and language used in risk communication and effective warnings, leading to informal and formal evacuations, then considers some Australian policies relating to emergency management. Theories related to risk communication are presented, with examples of evacuation issues provided from Indigenous communities, and from non English speaking households. The needed conceptual shift to self-help is placed within the larger theoretical frame of paradigms and paradigms shifts.

An example of including residents to internalize threats is given, followed by a more general example of transport evacuation.

A discussion of international evacuation issues precedes a broader view of some of the institutional barriers which may restrict the uptake of the seven step approach to an aware, informed community, relying on accurate information and choosing to self evacuate as a precaution. These issues are discussed, considering effective ways of allowing people to know that they are at risk so they are inclined to evacuate themselves, as a practice. These approaches can be used or tested by other scholars. Recommendations and a summary of the key issues to maximize voluntary and safe evacuations finish this article.

Some Key Evacuation Issues

In an era of increasing social self-help [7,55] and community empowerment [13,25,26], a part of global efforts to embrace Ecologically Sustainable Development [8,62] is to increasingly see evacuation as a social phenomenon.

This article provides a conceptual frame, the Communication Safety Triangle (CST) which includes responsible media telling people at risk what they need to know and *seven steps to community safety* (7SCS). The 7SCS help guide emergency managers and modelers to treat the possible need for evacuation as a decision-making process where the community should be aware of the potential threats and receive clear, detailed and reliable information on the possible need to evacuate, so most residents in a high impact zone self-evacuate in a precautionary way, as a practice. Examples provided in this article illustrate this new, *sustainability implementation research* (SIR) approach to disaster management.

Warnings precede a perceived need to evacuate. In the USA, the need for an integrative approach to warnings is identified: “There is a major need for better coordination among the warning providers, more effective delivery mechanisms, better education of those at risk, and new

ways for building partnerships among the many public and private groups involved” [63].

Sustainability implementation is the way to achieve a sustainable future. Disaster management, effective risk communication and community self-help provide a stark and comprehensible example of what sustainability implementation means, how it will benefit societies, and will help channel us into a safer, more sustainable future. Within this approach, scientists and students become major agents for sustainability implementation, as models can illustrate the needed paths to achievement.

Evacuation Overview

There are three types of disasters which may require evacuation: human induced and natural disasters with and without lead times. This article is focused on precautionary evacuations ahead of natural disasters with lead times (Table 1). The research and conceptual frames draw on and are applicable to all communities in hazard zones. Defining, modeling and effectively communicating to at-risk residents and travelers about specific geographic hazards and safety-oriented behaviors are core elements of successful precautionary evacuations.

Within Table 1, evacuation may be a response to an emerging hazard of indicated intensity, direction and speed. This article advocates development of informed and directed communities which will actively respond to a communicated threat, with the vulnerable moving them-

selves early to places of safety, or being helped by other community members to move.

Concepts, Language and Mathematically Modeling the Propensity to Evacuate

Precautionary self evacuation pivots on knowing who is at risk. With the help of researchers, modelers; planning and community involvement can prepare people and their valuables to minimize loss. Very public hazard maps will help people internalize that they are in a hazard zone, and what they should do. The concept is not new or alarming: every public building has emergency exit routes marked, with all that implies. Air flight comes with the mandatory emergency preparation presentation. Minute or recurrent risks to where we live or travel to should be no less public, nor more alarming than a fire drill in a public building.

Hazard Types – Little or Considerable Warning Times

Hazards may or may not have lead times (Table 1). Sudden onset threats include: tsunami, earthquake, major eruption, major toxic spill or discharge, mine disaster, terrorist threat or attack. Signaled threats include: – cyclone, flood, fire and destructive winds. This article focuses on disasters with sufficient warning periods to be able to evacuate the vulnerable away from the predicted worst impact areas. Table 1 that with sudden onset impacts, sheltering to sur-

Evacuation as a Communication and Social Phenomenon, Table 1
Evacuation decision matrix – short to long warning times

Evacuation decision matrix, Evacuation around <i>sudden onset impact</i>			
Hazard:	Landslide	Earthquake	Tsunami
Possible safety-oriented response	Stay in strong structure. Move across slope as soon as possible.	Get into the open or shelter under strong structure.	Immediately flee to higher ground.

Precautionary Evacuation (PE) decisions with lead time – signaled threats			
Considerations for evacuation decision	Hazard		
	Destructive wind/cyclone	Fire	Flood
1. Vulnerability of present environment	If likely to be in a storm surge, must PE; If shelter weak, must PE	House material, surrounds, water available. If poor, PE	May be inundated= PE; may be cut off, consider PE
2. If 1 OK: vulnerability of individuals (e. g. weak)	PE first	Asthmatics and less able: PE	Judgments of flood height. If in any doubt, PE
3a. Distance to safe shelter	The further, PE earlier	The further, PE earlier	The further, PE earlier
3b. Safety along exit route	Know in preparation	Know in preparation	Know in preparation
3c. Means of travel	Reliability and suitability	Reliability and suitability	Reliability and suitability
4. Community cohesion	Help available	Help available	Help available

vive the first few minutes is critical, then moving to open; stable ground is important to avoid further aftershocks or landslide. Always take direction from local authorities. For natural disasters with lead times, Table 1 shows that, if you will clearly be safe where you are, stay put, and prepare as best you can. If, in the worst case, you may not be safe, move early (Table 1). The vulnerability of individuals needs to be considered. In a bush fire, for instance, the general advice is: if the property is well prepared [7], stay and defend. If, however, you may not be able to cope with the psychological terror of staying through the fire front, fully prepare your property, and then leave early (Table 1). If the exit route may be blocked by flood waters, or by dense smoke or fire, evacuation needs to precede that obstruction. In the ‘background’ phase of community disaster preparation, all such possible obstacles to a clear escape route (including gridlock congestion) need to be factored in to the timing of precautionary evacuation (Table 1).

Finally, as seen in the Woodgate Beach example of Sect. “[Experiences and Lessons – Some Case Studies](#)”, the level of community support in ensuring all residents are aware of and prepared for the ‘ramp-up’ phase of a possible disaster impact, and receive the warning as soon as possible, the able-bodied will help the less able to get out of harm’s way early in the threat period, as a safety-oriented practice, minimizing the demands of the formal response groups as the likelihood of impact increases.

All effective communication involves sending signals and having them received and processed, then incorporated into the receiver’s world view [27,40,41,76,81,82]. Effective risk communication [4,13], Sect. “[Effective Risk Communication](#)”, motivates people to act to maximize their own safety. This may not happen if people have not internalized that the threat is real. They are in denial. Alternatively, people may be ignorant of the threat, or why it should be taken seriously. Salter [77] categorizes ignorance from pure ignorance to acts of ignoring.

Disaster Definitions

A disaster may be seen as a negative impact of a hazard on a community as measure of vulnerability. The language of disaster mitigation evolved and is increasingly practiced since the late 1990s i. e. [13,96]. Risk is seen as a function of probability and consequence, related to exposure and the level of force embedded in the threatening hazard.

Boughton [6] points out that natural disasters are usually extremely rare for the individuals concerned but they can cause massive impacts. Because Australia is so vast, overall there are reasonably frequent natural disas-

ters. However, in most locations they are rare indeed. Boughton [6] argues that a “natural disaster” is a natural event in which the community life is seriously and traumatically disrupted. Embracing the way forward with ‘structural mitigation’, “... a key step in preventing natural disasters is to prevent building damage.” [6]. Like “disasters”, “community” is difficult to define [84]. As developed in Sect. “[Integrating Theory and Implementation](#)”, “community” is the collection of people in a close geographic area, particularly focused on near neighbors and supportive friends of those in or near a known hazard zone.

What to Communicate

Having the right words or approaches in place *as policy* does not automatically guarantee community safety-oriented responses to disruptive warnings. Since 1989 the approach to cope with disasters has been *prevention, preparedness, response and recovery* training courses. This helps focus all concerned on the temporal sequence. The language could perhaps be refined to talk about acceptance that a threat exists, background, then ‘ramp-up’ (final) preparations to safe shelter; impact, then orderly return and recovery. Classically, ‘response’ was seen as the final, near impact flurry of ‘lock down’ activity [57].

Deeper than language is our conceptual frame (Sect. “[Integrating Theory and Implementation](#)”). If researchers encouraged disaster managers to move ‘response’ behavior back a day; a few hours to ‘precautionary, early response’, many of Lewis’s [57] legitimate concerns would be addressed. Some disaster managers may see themselves as dramatic figures in the early impact phase of a disaster, rather than calm, precautionary minimizers of risk. This culture has changed greatly over the last decade (Sect. “[Integrating Theory and Implementation](#)”). For many reasons, there is a clear divide between the US Federal response to Cyclone Katrina (2005) and to the California fires (October, 2007). This shift from passive to active can be encouraged by modelers. As part of effective risk communication to encourage precautionary impact preparedness, research with remote Indigenous communities and recently arrived, non-English speaking refugees (Sect. “[Integrating Theory and Implementation](#)”) showed the importance of accurate, plain English, and the use of images.

Yates [93] argues mitigation efforts need to be refined to make sure they are focused on issues from the relevant local communities. Much of the problem of non response seems that ‘the message’ to take care does not effectively get through to the target [68]. It is to do with communica-

tion, with signals sent, signals received, and their interpretation.

The types of received and interpreted messages are explored specifically in Sect. “[Integrating Theory and Implementation](#)”, which develops the intellectual foundation to more fully understand the semiotics of risk communication. The following outlines the concepts and relevance of semiotics.

Semiotics is the study of signs including words, sounds and such things as ‘body language’. By the ‘message conveying’ principles of semiotics we can understand how various authors on disasters and evacuations approach the topic, and which cultural signs and symbols they manipulate. For example, a sign showing a person running up-slope ahead of an exaggerated tsunami wave contains all the preferred imagery to tell people what to do in a tsunami warning. Images, as seen for locating oneself in airports or finding evacuation stairs, do not use words.

The next section lays the foundations for a mathematical modeling of propensity for householder self-evacuation, centered on knowledge and refined communications acting on residents in hazard zones who are predisposed to act in their own safety.

Mathematical Modeling

Foundations of the Household Safety Preparedness and Action Index: the HSPA Index

This section does not consider refined algorithms to define how successfully people may respond to *Authority’s Perceived Need to Evacuate (APNE)*. This section considers the form and ingredients of how this could be done; the elements and their possible interactions to predict the success of APNE. Unfortunately, in the previously cited Canberra 2003 bush fires, the APNE did not appear universally, nor was it properly conveyed to the residents in dire risk.

Rohrman [75] has clearly mapped a process from the warning signal to the hoped-for response. The information and processing flow to internalized inferences is called intuitive heuristics [74]. Renn & Rohrman [74] basically argue that people process probabilistic information on the likelihood of them needing to move, aligned and convergent with researchers like Thompson [87]. Hence the need for the seven step process (Fig. 8) to trigger a paradigm shift for people in danger zones.

As seen in formula 1, there are finite evacuation triggers (ET), ranging from no lead time LT_0 , such as an earthquake, to a LT of days (LT_{xd}), such as a cyclone. So a key component of a successful response to an APNE is the time

in which to disseminate the warning (LT_{0-xd} ; Table 1) Also, Impact Severity (IS) is central to safety and loss.

As detailed in Sect. “[Integrating Theory and Implementation](#)” and Fig. 8; *The seven steps to community safety*, there is a convincing body of research which indicated that People’s Propensity to Respond (PPR) to an emergency warning (whether that response be to finalize preparation to stay and defend the property or evacuate as a precaution) is strongly linked to their Acceptance they are In a Hazard Zone (AIHZ).

Community Resilience (linkage and inter-support and communication – CR) is also important; along with a potential evacuee’s Knowledge Base of the hazard and safety-maximizing behavior (KB). Thinking Through to Recovery (TR) is also important. As per points 6 and 7 in the 7SCS; Fig. 8, the medium of warning delivery, and the quality of the warning information (Medium & Message: MM) is a factor in the response of those under threat. Overall, Sorenson and Mileti [81] believe that increased credibility of the warning source means the specific warning will be more effective. They also provide evidence that the electronic mass media produced the most believable public warnings. This underlines why development of formal links between all types and levels of media information about hazards and preparation from the weather bureau and emergency managers is so important. Having formal links with the media, coupled with web-delivered ‘real-terrain’ simulations of the hazard will help produce a powerful and effective ‘active warning’ regime.

Issues of Exit Route(s) (ER), Possible Travel Mode (PTM) may be crucial. A normally free-flowing exit route may be blocked by the disaster itself, or others trying to flee. This may involve accidents. People’s psychological and physical states of Well-Being (WB) will also affect potential effective evacuation decisions and accomplishment. Authors like Rohrman [75] have attempted to stylistically model some of this complexity.

Many of the earlier recognized impediments to full preparedness, like unrealistic optimism (Heller et al., [46]) are incorporated into one overarching factor of formula (1): People’s Propensity to Respond (PPR), including the centrally important feature of individual households fully accepting they are in a hazard zone, and that they need to engage in background preparation, ‘listen up’ around a hazard threat, and undertake their own, precautionary final preparations.

Cutter et al. [17] developed 11 factors indicating vulnerability caused by a major disaster, using principal components analysis within factor analysis. The resultant Social Vulnerability Index (SoVI), necessarily weights the 11 components according to the percentage of variation

of analysis of counties on the USA as to resident’s vulnerability. Personal wealth, age and housing density head up the contributions of the 11 variables used to determine the SoVI of USA counties. Cutter’s SoVI contributes to the likelihood that proper preparations; including for a timely evacuation, would occur, either at a broad regional or more individual level. This SoIV is included in the HPSAI below. Its weighting remains to be tested. A final issue overarching many others is Institutional Barriers to change (IB), detailed in Sect. “[Institutional Barriers to Greater Community Self-Help](#)”. The support or otherwise of the media can play a critical role in effective crisis communication – most messages are likely to be through the media, so the media is part of the systems complexity blend: Media Support (MS).

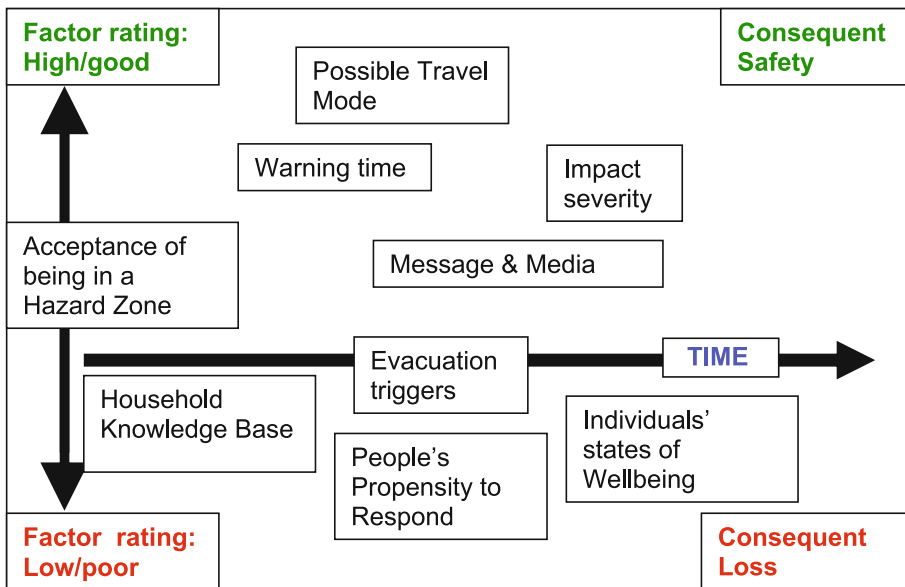

From the weight of SIR and the conceptual framework described in this article, the following generic formula expressing the above factors likely to impact on householder propensity for precautionary evacuations may entice other, more theoretical researchers, to develop the needed algorithms. What follows is purely a design base for others to develop predictive modeling of *People’s Propensity and Capacity to Successfully Evacuate (PPCSE – or safely and actively stay)* PPCSE is better named the *Household Preparedness and Safety Action Index: the HPSA Index*. The following is a synthesis of Bayesian Logic (Hoeting et al. [45]) and Eigenvalues.

People’s Propensity and Capacity to Successfully Evacuate (PPCSE) or Household Preparedness and Safety Actions Index (HPSAI):

$$\begin{aligned}
 &HPSAI \propto \\
 &f(PPR)(AIHZ)(LT_{0-xd}) \\
 &(APNE)(ET)(IS)(AIHZ)(CR)(TR)(MM)(ER) \\
 &(PTM)(WB)(SoIV)(IB)(MS)
 \end{aligned}
 \tag{1}$$

Formula (1) anticipates constants to ‘weigh’ each factor according to its contributing importance on the resultant HPSAI (see [45] p 384) for detail of the Bayesian modeling approach.

Resultant safety (*safety* being a combination of successfully evacuating to a safe place, or sheltering within the impact zone in a safe place) of those under threat will be greatest (Fig. 1) where the factors of formula (1) tend to intersect in the positive quadrant of an Eigen plane (Fig. 1) [94]. Equally, outcomes of loss will occur with, for example, short lead times, insufficient warnings of evacuation triggers or lack of belief that residents or travelers are in a hazard zone. A journal search showed few links between disasters and Eigenvalues. An exception is Fowler et al. (2007, [32]). With global warming and increased populations increasingly encroaching into obvious hazard zones, modeling to influence planning and to maximize HPSAI must be a major growth industry.

Evacuation as a Communication and Social Phenomenon, Figure 1
 Factors in the Eigen plane determining Household Preparedness and Safety Action Index

Calibrating the Model: the Greek Fires, August '07

[98] or California in late October '07 [99] show that if various of the above variables or likely variable clusters or Eigenvalues from factor analysis have low values, people will not be placed in a strong, precautionary position of safety. This was true of fire-threatened residents in Canberra in 2003 (<http://www.abc.net.au/canberra/bushfires/>), all ultimately leading back to the mathematical weight which needs to be given to each point on in the 7SCS: especially accepting that the threat is real (and possibly imminent).

Once the above-described preparedness paradigm is internalized, it is difficult to experience any disasters news coverage without feeling some despair: cars submerged or floating in flood waters; people fleeing for their lives ahead of imminent immolation; any reports of lost lives through natural disasters with lead times of hours or longer. There are few excuses for this to remain so. In most parts of the developed world, there are prevailing technologies to detect and rapidly convey threat. Researchers are well placed to conceive, trial and link the threat information directly to prepared populations; to close the gap between knowing and acting to maximize safety, as a social exercise of community engagement and communication refinement.

Cyclone Larry [54] showed that, with general community acceptance of the reality of the threat, good warnings and a lead time of about 20 h, combined with well developed disaster management and media cooperation in getting the needed messages to people well primed to the 7SCS, there was no loss of life, although about 5000 people were directly subjected to destructive winds of a category 4/5 cyclone. Residents of the impact zone generally followed the 7SCS, supporting the general approach of formula (1): the community was prepared and acted in a precautionary way to maximize their own safety.

The above model design offers elements/factors to maximize *People's Propensity and Capacity to Successfully Evacuate (PPCSE – or safely and actively stay)*; the *Household Safety Preparedness and Action Index (HSPA1)*, so strengthening a paradigm among Agencies and hazard-zone residents of 'self-help' and 'community engagement' approaches; less passive than earlier approaches used in considering people's vulnerability. This generic approach is supported by model testing by Schadschneider et al. (► [Evacuation Dynamics: Empirical Results, Modeling and Applications](#)).

The Australian examples detailed in this article, including the national shift to mitigation (COAG 2004 [13]), best illustrated in the Woodgate Beach example (Sect. "[Experiences and Lessons – Some Case Studies](#)"), show that

the conceptual frame and thus variables chosen to mathematically model evacuation propensity and capacity are more important than the results of any model using 'passive' variables or variable clusters. The advantages and means of achieving this shift from community passivity to partnerships; place- and people-based community empowerment and self-help, form the basis of this article. The above mathematical approach may help validate and guide this necessary conceptual shift.

The next section considers policy, laws, concepts and possible safety-oriented actions that words, images and stories convey to vulnerable residents in hazard zones. In Australia, policy and legislative requirements are indicated, which aim to responsibly maximize community safety [13,24,25,26,27,28,44,70]. Some new concepts, epitomized by new language phrases (with their embedded meanings) are discussed in Sect. "[Integrating Theory and Implementation](#)", especially *Community safety groups*. New phrases include 'Social Burnoffs' and 'Practice evacuations'. Like "The Communication Safety Triangle" and "Seven steps to community safety", it is hoped these expressions enter local, state and national lexicons and modeling in disaster management.

Effective Risk Communication

Policy and Laws on Hazard Preparedness and Evacuation

All risk communication operates within government policies and legislation. Forced evacuation may be normal in some jurisdictions for all threats; outlawed in others. Policy may encourage passivity, or be energetically pro-active in achieving the 7SCS, both in urban planning and building materials, and community engagement. In Australia, for instance, there are many federal and regional guides to urban growth, e. g. [2]. A new urban paradigm is, perhaps, best expressed as: "Think globally, act locally, respond personally" ([2] pnp, [3] p 1). This paradigm shift can easily embrace and be informed by computer modeling of individual's behavior, demonstrated in recent Springer's *Journal of Systems Science and Complexity* articles, such as Kikuchi T & Nakamori Y [97]. Agent model analysis to explore effects of interaction and environment on individual performance [97]

From all decisions of urban development being in the hands of 'experts', government policy increasingly requires a dialog with local residents, through public participation. The first barrier to ecologically sustainable urban development is "... belief systems – doubting a problem exists, or supporting the status quo. [Solutions include] ... consciousness raising campaigns, public partici-

pation in decision-making, demonstration projects and incentives and disincentives” ([76] p 46). This is the KB of formula (1).

This article stresses that response models, Authorities and all residents are constrained (and empowered) by national and regional laws and policies. Research can only work within a prevailing frame, and will be welcomed by or influence prevailing policy. It is thus useful to have clear goals to achieve social or environmental ‘good’ [13,44,70]. This requires greater community involvement in mitigation, and responsible media helping to mitigate disaster impacts (MS of formula 1). In Australia, the national radio broadcaster has a binding agreement with the weather bureau and disaster managers to read issued warnings verbatim; report and engage community members in safety oriented behavior, by providing relevant information. Local community media are often willing to develop the same responsible functions.

Risk Communication’s Core Goals

Risk communicators advise “individuals and communities to respond appropriately to a threat in order to reduce the risk of death, injury, property loss and damage.” [42]. Risk communicators and disaster managers need to formally work closely with the media to maximize social benefit.

Although it may be intended that information flows and is received accurately; that desired behavior will result, and that only communication techniques are important [49], humans tend to be irrational and optimistic, and only hear what they want to hear. It is not what our message *is*, but what, if anything, the listener *does* with our message. To have any chance of ‘success’, information needs to have meaning which is shared between those who construct and send the warning, and those for whom the warning is meant to inform and motivate to action.

‘Action statements’ (what the at-risk person, family or community should actually do to minimize damage) are seen as central to the whole purpose of risk communication [78]. Kaspersen & Stallen [49], along with Salter [77,78] and others detail risk communication messages in terms of content, clarity, understandability, consistency, relevance, accuracy, certainty, frequency, channel, credibility, public participation, ethnicity, age, gender, roles, responsibility, elements, sequencing, synopsis, prognosis, location, action, warning timing, and action statements. It is not a case of saying: “a category three cyclone will pass over Smithfield”. It is more a case of making sure the members of Smithfield hear that message, and feel moved to and competent to take well-understood personal risk-minimizing actions.

Knowledge, Self, World Views and Messages

For precautionary evacuations to be successful, the seven steps to safety (Sect. “[Integrating Theory and Implementation](#)”) have occurred; or people have been coerced by authorities, or they have seen others depart, and felt insecure, so they leave as a follower of the ‘innovation’ of the ‘norm’: precautionary evacuation. This occurred in the desktop exercise in an isolated settlement in March 2007, detailed in Sect. “[Experiences and Lessons – Some Case Studies](#)”.

It is now difficult to understand why people needed prompting to take evasive action against the forecast Brisbane floods in 1974, but many ignored the prompts. Authorities believed houses and roads would be flooded, so people should finalize travel or evacuation early [10]. For those in the flood zone, 88% of a later survey sample reported evacuating their home. Some took this step very early, but 67% of respondents only made preparations immediately before leaving home. Twelve percent only left on foot or in boats *after waters entered the main living areas of their homes*. Almost 22% of respondents said they made no preparations, mainly because the threat was not recognized in time [10]. This well documented ‘poor’ crisis communication can help calibrate formula 1.

A key safety message surrounding floods is not to enter flood waters. Figure 2 is one example of using images to help convey the reality of a threat, and the pitfalls of belated action.

Effectively Conveying Meaning

Because language is pivotal to acceptance of risk and conveyed warnings of need for evacuations, it is important that all participants reasonably agree on word meanings. This section starts in the comfort zone of simple definitions, then considers semiotics, considers core issues of world views (paradigms), and finishes with the uneasy realities of our knowledge base, our epistemological orientation. Sect. “[Integrating Theory and Implementation](#)” shows that some cultures do not carry the background cultural experience to absorb the meaning of cyclone or bushfire – there is no shared experience or ‘stories’ of the power of these extreme forces of nature. Some of the underlying knowledge foundations of context, intent and behavioral motivation need to be considered – how humans construct, transfer, acquire and use knowledge.

Imparting meteorological knowledge, then warnings, to target audiences to engender safety-oriented responses is a complex exercise in social empowerment, explored in Sect. “[Experiences and Lessons – Some Case Studies](#)”. As information promulgators, information and warning

Evacuation as a Communication and Social Phenomenon, Figure 2
 What flood-threatened residents need to consider (Photos courtesy Townsville City Council)

sources should understand a little of *Perception* (the raw data from the outside world entering an organism via any of the five senses), *Cognition* (internal processing, analyzing, information storage and processing), *Attitudes* (how we think and feel about particular issues, implying a predisposition to specific action), *Language use* and links to *Behavior*.

An intellectual framework to risk communication is provided by Rohrman [75]. It considers ‘the message features’: the recipient features, social influences and context which influences individual risk assessment and management, including preventative action. Rohrman and Handmer’s publications [41,42,43,75] inform the Communication Safety Triangle and *the seven steps to community safety* provided in this article.

Philosophy for Policy Review: Crying Wolf or Worse – Applying the Precautionary Principle

From the 1990s a strong issue of debate in risk communication has been “the right to know” [4]. Some disaster managers wish to avoid false alarms, which may cause ‘concern fatigue’. This can be seen as an institutional barrier to change (Sect. “[Institutional Barriers to Greater Community Self-Help](#)”). ‘Avoiding undue alarm’ is in conflict with the right to know, and the precautionary principle of ESD.

The ‘precautionary’ approach is supported by the Economic Commission for Asia and the Pacific (ECAP), the World Meteorological Organization and the Red Cross Societies. The alerting of the community and its responsible authorities must begin, at least provisionally, as soon as the existence of a tropical cyclone over the seas bordering the country is known ([24] p 16). According to ECAP et al. [24], the warning challenge is less clear for predicted localized downpours and flash flooding – how much effort should be taken to warn – what is the message, how do you

keep it to the affected area, and what do you want people to do? These questions resonated in Australia after billion dollar hail damage in Sydney in April 1999, or damaging flash floods in Melbourne in December 2003.

Precautionary Evacuations

Handmer [43] reports an evacuation of 250,000 Dutch ahead of a flood threat in 1995. Eighty-eight percent of people surveyed in broad post-emergency surveys “believe that evacuation was appropriate.” [43] p 24. In part this may be because of floods experienced two years prior. Good skills in dealing with the mass media appear to have helped in the effective precautionary evacuation. The Dutch experience showed a willingness to evacuate again in future, even though the threatening flood waters did not inundate to the level feared. This compares favorably with the 2005 boat owners’ responses to Cyclone Ingrid in Port Douglas, North Queensland (Sect. “[Institutional Barriers to Greater Community Self-Help](#)”). Both Handmer and Goudie’s research [33,36,38,41,42,43,52,53,54] show clearly that people would rather practice (make a precautionary evacuation) than incur loss. It was treated as a learning experience. The ‘boy who cried wolf’ argument is not acceptable. This is an important message researchers can test and convey to partnering Disaster Managers.

Have Clear, Consistent Messages

Part of the *seven steps to community safety* is clear, reliable, explicit languages and images. Salter et al. [78] point out that the use of meteorological category systems such as ‘minor’, ‘moderate’ or ‘major’ carry unambiguous information about the level of disruption likely from a particular flood. Language used should not be for the convenience of the warning agencies. Its function is to convey clear unambiguous messages to the threatened public.

Use Past Events to ‘Make the Threat Real’

The purpose of risk communication is to make people perceive the threat as real, and to successfully motivate safety-oriented action. Boughton (1992, p 6) argues that awareness of hazards and disasters can be fostered by “drawing attention to media coverage of hazards in other places”. Images of large scale floods and evacuation in Holland in 1995 [42] may help prompt a future flood evacuation.

The Changing Politics of Risk Communication

Risk communication is often laden with values and political implications (Sect. “[Institutional Barriers to Greater Community Self-Help](#)”). For instance, in the 1990s in Cairns, north Queensland, it was argued that the reason for not having detailed local cyclone surge inundation maps made available at the corner store level was that such information may have a negative impact on local land prices. This appeared more a political decision than an attempt at effective risk communication. In 2007, such maps are freely available on the local Council web site [9].

Sirens or Not

No or short lead time disasters are a powerful argument for warning sirens to alert people, perhaps at 2 am, to “listen to local media now”. Lives will be saved in future tsunamis and bush fires with the reintroduction of sirens, as insistent triggers to “find out more now”. However, “large numbers of sirens are needed to cover populated areas and to be loud enough to be heard indoors by most people. Sirens are expensive to install and maintain and can only provide limited information” [63] p 33. Fixed public address systems or those on vehicles may be used. People who hear such sirens will be encouraged to tune to local media, and to phone others in the threat zone, to warn them of the alert. Sorenson and Mileti [81] believe sirens are most effective if used on populations without other ways of receiving the warning. Wider use would appear prudent, especially with short lead-time threats.

Media Roles

As community media moves from ‘sensationalism’ [13, 71], 2007 research by Goudie confirms that community media organizations now want to become responsible conveyors of safety-oriented information to people at risk. After the Canberra fires of 2003, where 300 homes and four lives were lost in the nation’s ‘bush capital’, all local media signed binding agreements with emergency authorities to faithfully convey provided safety information.

The Communication Safety Triangle envisages local media and householders drawing detailed local threat information from the internet, with media conveying that directly to readers, watchers and listeners. This forms the basis of future ‘world best practice’ risk communication. In the preparation for threat impact, the reliable information will help people make informed decisions, rather than remaining trapped and inactive in uncertainty.

Risk communication is complex, involving many values, predispositions and distorting lenses. Rohrmann’s [75] fine risk communication explanations show that we may tell the people at risk, but they may not interpret as intended. Clear, consistent warnings in plain English, with clear images of the threat, showing safety-oriented behavior are needed from reliable sources. Warnings, seen on a continuum of risk and preparation actions, should be able to be discussed and reinforced with information from other sources. This is most likely to produce safety-oriented behavior, with the constrained and clear assistance of the media, as responsible agents for community safety.

Given the previously fraught nature of risk communication, Sect. “[Institutional Barriers to Greater Community Self-Help](#)” provides a conceptual framework, with Australian examples of current community safety theory and implementation, preceding some detailed examples.

Integrating Theory and Implementation

This section introduces a triangular model to best ensure community safety. With disaster managers central, the three elements are the community, local media and the internet. Also, there is a continuous spectrum of seven steps, from accepting there is a risk, through early preparation, final (ramp up) preparation, which may include evacuation, surviving the hazard impact and achieving smooth recovery. An exploration of motivation leads to a discussion of ‘world view’, including some insights into remote Indigenous communities [36], and recently arrived, non-English speaking immigrants. The conceptual frame and steps are intended to help guide risk communicators and potential modelers through the issues of acceptance, preparations, evacuation and functional recovery. Within CSS, all these factors have some bearing on consequent behavior.

Changing Values and Roles

In an attempt to understand why we support or ignore certain messages relevant to our safety, and thus facilitate modeling, this section considers the Dominant Social Paradigm and the New Environmental Paradigm.

A paradigm is a coherent world view, “a mental image of social reality that guides expectations in a society” ([23] p 10, [29]). Shared paradigms change. The underlying philosophy shift toward disaster mitigation generates a distinct policy move toward safe, self-helping communities. Thus, the goal of disaster managers, effective risk communicators and computer modelers becomes one of championing or demonstrating the efficacy of self-help techniques and information to and within communities.

World Views Which Accept Responsibilities of Living in a Hazard Zone

‘Why do we do what we do?’ has long been a central exploration of psychology. Precautionary safety behavior, including self-evacuations, may depend on a person’s world view. Stern et al. [83] developed a simple and elegant model to help explain human behavior, starting with a person’s position in a social structure, with constraints and incentives which generate values. Values determine general beliefs, leading to a consistent world view, specific beliefs and attitudes, which predisposes intent and helps explain behavior ([83] Fig. 3). Loosely translated, behavior results from a linked sequence starting with: the where, when and to whom of an individual’s birth, the surrounding circumstances and ‘cultural sheath’ of their early childhood experiences, leading to acceptance or rebellion against prevailing social norms, determining an evolving world view. Once we have our coherent world view, beliefs and values give us our ‘predisposition to act’, our ‘intent’ which precedes action/behavior.

Many things now mold and modify world views, including the media, and normative world views are muta-

Behavior is explained by:

1. a person’s *position in a social structure*,
2. with *constraints and incentives* as generators of *values*, which lead to
3. *general beliefs*,
4. *world view*,
5. *specific beliefs and attitudes*, generating
6. *intent*, which helps explain
7. *Behavior*.

Evacuation as a Communication and Social Phenomenon, Figure 3
Stern’s 1995 behavioral explanation model

ble, changeable. Aligned starkly with our shared and collective biological survival urge, and much concerted efforts by scientists and conservationists for decades; publicizing by people like Al Gore, and the authority of England’s uptake of the 2006 Stern Report, there is now a global paradigm shift to the urgent need for behavioral and technological change to minimize the gross impacts of global warming, pertinent to increased disasters and needed evacuation readiness. Modeling specific hazard zones’ strengths and weaknesses and broadcasting prediction simulations to the internet and TV will help mobilize those at risk.

Why We Do What We Do

A behavioral model of causality ([91] Fig. 4) shows relationships between reported attitudes and actual behavior. However, a complex model proposed by Kitchin [51], with the strength of including social and environmental interactions shows why we do what we do: Kitchin’s model includes a person’s ‘working and long term’ memory. Internal information is processed within ‘real world’ context, such as cost [82], which may be processed within the ‘it can’t happen to me’ cognitive frame [61] of subjective reality. These complex but quantifiable attributes will contribute to modeling maximum likelihood to accept, prepare and act to maximize safety.

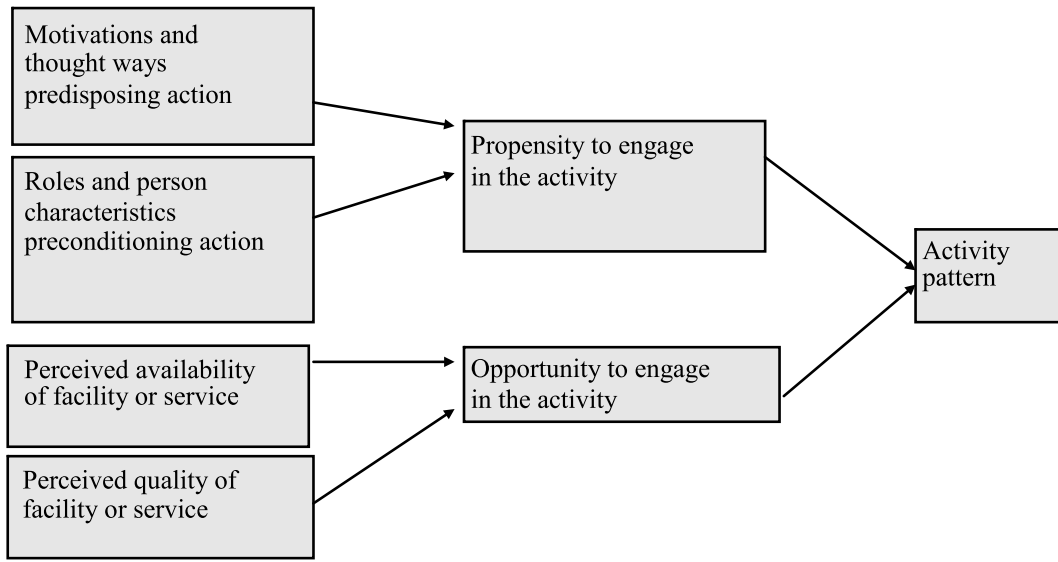

Learning from 18 Remote Indigenous Communities

Much of the rest of this section underlines why modelers will need to deal in great detail with ‘cultural’ aspects of massed responses to safety threats.

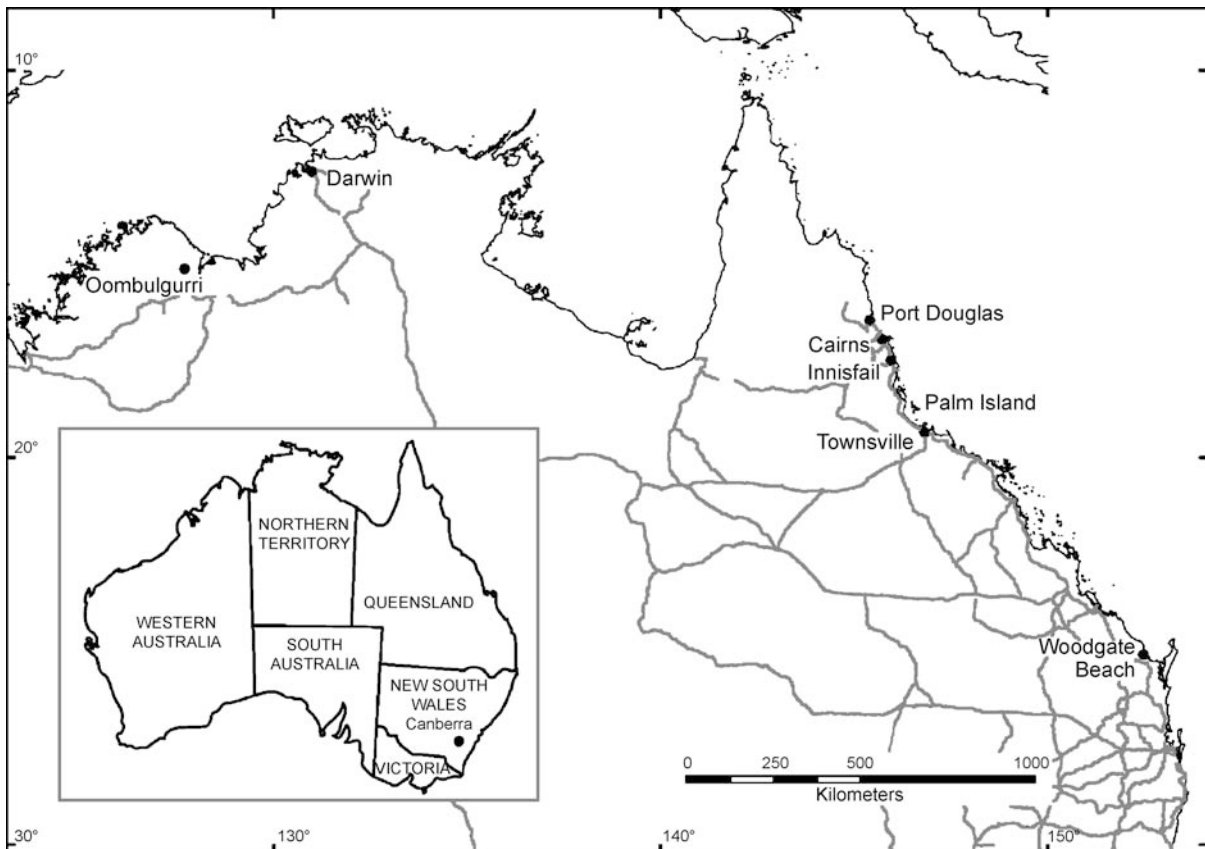

The Stern model (Fig. 3) helps explain why there is such a strong sense of self-help in remote Indigenous communities [27,29,80,94] helps explain why there is such a strong sense of self-help in remote Indigenous communities [27,29,80,94]. Elders decide responses to threats, there are historic and immediate constraints, generating a value system where community members need to look out for each other.

In many traditional Australian Aboriginal stories, most people drown in flood disasters, often as punishment when people do not take care of each other [36,39,64,87,88]. If general beliefs embrace self help, including the felt need to ensure safety, and a resultant intent to achieve community safety, this should lead to safety-centered behavior.

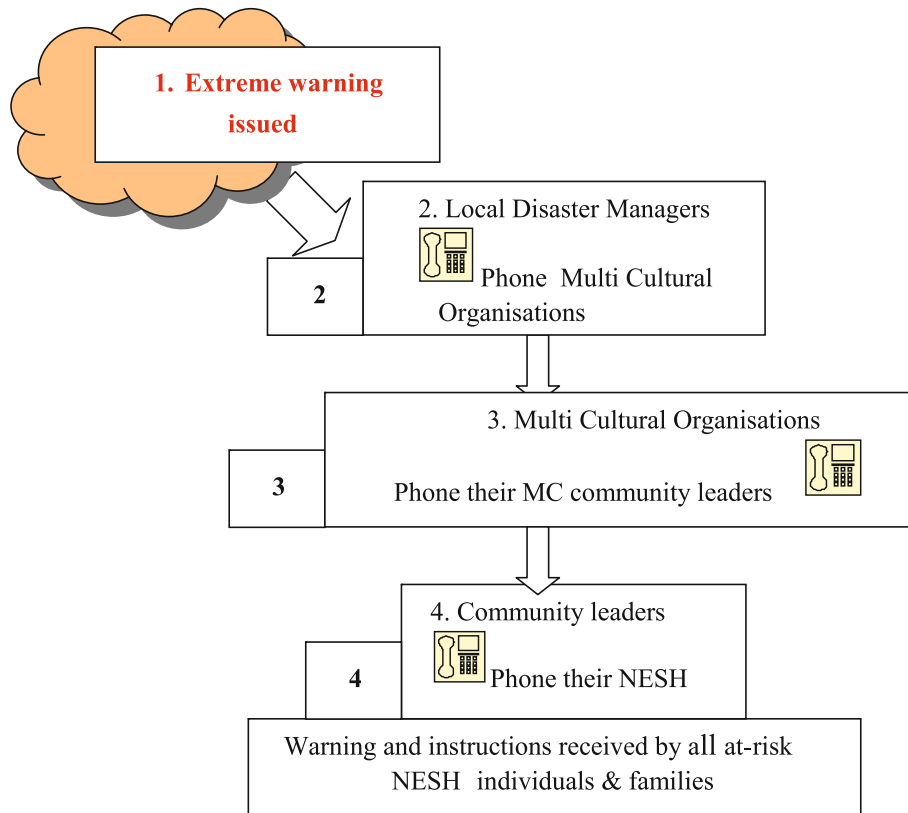

Each community ([36] Fig.5) was not greatly concerned by weather extremes (values), but each relied on and respected their traditional reading of threats, and information from the Bureau of Meteorology (the Bureau).

Evacuation as a Communication and Social Phenomenon, Figure 4
Possible determinants of activity patterns (from [91])

Evacuation as a Communication and Social Phenomenon, Figure 5
Australian study sites

Evacuation as a Communication and Social Phenomenon, Figure 6
Multicultural phone tree disaster warnings model

The world view is that flooding or worse may happen, and that the Bureau will provide adequate warning. Responses may be inhibited by the Social Vulnerability Index (SoVI) of formula 1.

Community Links, Phone Trees and the Web in Risk Communication for Non-English Speaking Households (NESH)

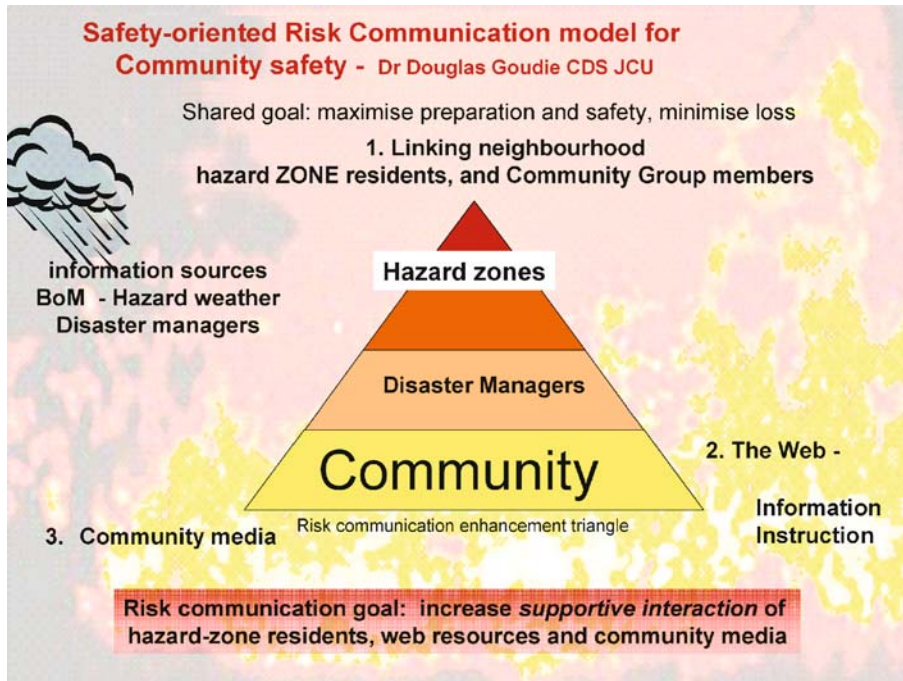

Many multicultural organizations and focus group meetings in 2005 helped develop the warnings phone tree model for NESH in Fig. 6. NESH rarely listen to the English language media. With about 30,000 NES people arriving in Australia each year [18], there is Federal government recognition of special emergency management needs [28]. This way of getting evacuation warnings through was developed once interviews revealed that practically all NESH have a mobile phone, and are closely connected with their nearest government funded Multicultural Organization and their 'community leader'; hence the phone tree. Modeling is of and for the real world, so re-

search like this reported NESH study is needed to see what 'complex systems' may be possible. Further recommendations to develop a multilingual warning web site with a simple guide to the seven steps, in relevant languages, to be accessed and used by MCO and NESH training sessions is being considered by authorities. This provides another example of the internet's latent role in effective risk communication.

The Australian Northern Territory has cyclone preparedness kits with action guides in 8 languages; the NSW Rural Fire Service has information in 27 languages. This shows the importance of modeling all possible communication avenues, encapsulated as Medium & Message: MM in the general formula for Household Preparedness and Safety Actions Index (HPSAI).

An Holistic Approach to Community Risk Management

The seven steps for effective warnings involves community networking, 'responsible' media, and, increased web

Evacuation as a Communication and Social Phenomenon, Figure 7
The Communication Safety Triangle

use. A ‘continuum’ approach to hazards which may lead to a need to evacuate is important to modelers because it is important to all people in hazard zones: they will be able to access more accurate, detailed and timely information of any looming threat, assisting Emergency Managers because a self-help public will decrease demands on formal evacuation, rescue and property protection [93]. Recovery will be less arduous [67] if hazard impact is minimized. Reducing disaster impacts will reduce costs, to national benefit. This gives strength to supporting the very demanding goal of developing the model of formula 1.

Risk Managers

Researchers can work with risk managers to achieve “... better, timely warnings and advice on safe action during fire events” [3]. With risk managers central, Fig. 7 suggests that enhancing community links [7]; web information for residents and media outlets, and cooperation of community media with fire managers [89] will more empower householders to embrace self-help in fire safety. Figure 7, the Community Safety Triangle, with the “Seven steps to community safety” (Fig. 8) provides the conceptual frame to enable maximum safety modeling.

Core of Risk Communication for Community Safety Through Natural Disasters

Building Community Links and Refining Media Delivery will Change the Household Preparedness and Safety Actions Index

The disaster safety benefits of enhanced community links fit positively with broader social policy [47]. Stronger community links will help ensure that threat information is easily accessed and shared; and the need to actively self-protect is internalized at the neighborhood level. Residents will benefit by enhanced community links (with such innovations as social burn offs and Community Safety Groups) in improving their general quality of local social interaction. Changing Community Resilience (CR of the formula) will then change overall preparedness, so pilot tests of change to CR will show quantifiable changes to the Household Preparedness and Safety Actions Index. Disaster web site managers will be providing a product which is rationalized to reduce national duplication of core information. This will positively change Medium & Message, MM, of the formula. Residents with few English language skills will benefit by having disaster information delivered,

Goal: Maximise safety and recovery, and minimise loss in hazard zones.

1. Encourage those in hazard zones to accept that the risks are real.
2. Help create an aware, informed community, predisposed to safety-oriented action, as a precaution; as a practice.
3. Encourage information-sharing and support among friends, neighbours, family.
4. Provide ‘what to do’ (action) information, via reliable sources, including web and community media delivered for background and preparation.
5. Encourage people to think right through to impact and recovery.
6. When a threat is closing in, warning messages will clearly convey: *this is real, this is coming at me. I need to make safe where I am, or move early to somewhere much safer. I will not travel during the impact period.*
7. Provide timely, effective threat warnings and fine location and forecast weather detail, and recommended local responses.

Evacuation as a Communication and Social Phenomenon, Figure 8
Seven steps to community safety

via the web, in language and concepts that can be internalized and acted upon.

Handmer [43] suggests that a flood, for instance is actually ‘owned’ by the communities at risk. Individuals and organizations within these communities actively seek out information and mobilize their personal networks for action. In this way of looking at the warning process, the warning specialists act as mediators between the threat and the threatened. Local knowledge is used and the whole response process remains focused on safety and loss-minimization. For this plausible vision to become fact, local capacity building will need to proceed apace with these more formal efforts to inform and maximize community safety.

The importance of ‘informal’ information sources and community links are shown in Table 2, from about 200 people interviewed immediately after Cyclone Larry in 2006 [53], showing that about 90% are deeply dependent on social and family support, if only for reassurance.

Finally for community enhancement within the CST model, there is current and lucid national disaster mitigation policy [13] <http://www.dotars.gov.au/localgovt/ndr/>

[nat_disaster_report/naturaldis.pdf](#): in the statement of the paradigm shift [13], p 13, “Principle 7 – Reform Commitment 7: develop jointly improved national practices in community awareness, education, and warnings which can be tailored to suit State, Territory and local circumstances.”

Community Media

“The Media: Media organizations, particularly public and private radio and television organizations, have responsibilities in ensuring that timely and appropriate warnings and advice on disasters is broadcast to communities at the request of relevant authorities. They also have a role to play in educating the community about natural disaster issues” ([13] p. 18).

The Web

Rationalized web information delivery: One national generic provider and up keeper of core information, known to all, is recommended; to which state and local government will add their unique detail. A rationalized disaster information web delivery can properly incorporate broad contents, fine (and zoom-in findable) and multi lingual information.

Simulations of predicted near-term fire or other threat movement based on the above, akin to micro scale modeling of cyclone impact forecasts will help revolutionize the way people react to fire and flood threat. With about one in three households having the internet, prior to likely power loss residents can draw on enhanced fine detail of the current fire situation, to assist in their actual decision making. Before Cyclone Larry struck, residents with web access to the Bureau copied cyclone forecast maps and distributed

The stages of change from the Diffusion of Innovations theory. The vortex shape has no mathematical basis. Its purpose is to illustrate the point.

Evacuation as a Communication and Social Phenomenon, Figure 9
O'Neil's 2004 innovation uptake model

them to neighbors [53]. All the preceding is encapsulated in Figs. 8 and 9.

Images Tell a Story

Images such as cyclone forecast track maps in risk communication convey more information than words alone [36,53]. With this feedback from real residents, it becomes clear that linking fire zone residents, for instance, to educative web fire images becomes an important goal (e. g. [100]).

Community Story Telling Bonds Neighbors

The multi-pronged approach [33,52,54] fosters community 'story-telling' links [50,59,90] relating to community self-help and safety. Strengthening community bonds, working with enhanced web resources and community media [14,72] will increase community internalization of risk [31], enhancing the likelihood of safety-oriented responses, leading to and possibly including evacuation. People need to accept the reality of the threat, indeed, feel some anxiety about the threat to help drive the intent to seek more information, or the intent to prepare [68].

With easier access to relevant web information; with greater detail of current fire behavior and *nowcasts*; fire zone residents and community radio announcers can describe the looming threat, helping timely preparations and the monumental 'stay or go' decision. Community radio, like the National public radio, the ABC, will deliver authoritative and timely risk communication directly from the refined web information.

Theory and emerging practice converge on using refined web-delivered material to households and their neighbors, and to local media, to inform and motivate res-

idents through the whole continuum of the seven steps to community safety. The next section considers institutional barriers to change, followed by extensive research findings and lessons from Australia in disaster management to develop effective warnings and self evacuations.

Institutional Barriers to Greater Community Self-Help

Institutional barriers to change take many forms, from 'unconsciously' avoiding consideration of the extreme event as 'too hard', to a misuse of the power relationships within bureaucracies because of fear of change, or malice. Clear examples of the 'too hard syndrome' mingled with entrenched vested interests has been denial of links between smoking and cancer, or delayed uptake of global warming mitigation.

There were Institutional Barriers for disaster managers to consider land-based flooding from torrential rains preceding a cyclone (hurricane/typhoon) [34] in many cyclone-prone areas. The Queensland State Planning policy [70] now explicitly refers to Probable Maximum Flood. Including maximum flooding is now part of emergency manager's internal planning base. This means the Exit Routes (ER, formula 1) are now considered in planned evacuations.

Since the early 90s researchers like Boughton [6] have suggested having drills for schools and other institutions in readiness for possible earthquakes, cyclones or other hazards. This author supports precautionary evacuation practices. There are, of course, liability barriers to easily undertaking practice evacuations. There is also uncertainty of threat, which may restrain some risk managers [86].

Institutions have cultures which may passively express antipathy to a paradigm shift toward sustainability, whilst being required to usher in sustainability [19,37]. Emergency Management Australia, the peak national body, has the slogan: *Safe, sustainable communities*. However, there is a multitude of conservative forces representing the Dominant Social Paradigm restricting innovation, despite sustainability policy. People engaging in sustainability implementation may come into conflict with institutional representatives of the old paradigm.

With most development taking place in urban settings, concepts of urban sustainability attempt to merge two different fields of human endeavor – how we modify our landscape, our built environment, and how we behave in that environment. Disaster mitigation is obliged to fuse these two seemingly disparate fields. There may be resistance to that. That resistance needs to be included in any mass disaster movement modeling. The following subsections indicate some reasons for IBs which modelers may need to consider in the IB factor.

Political Insecurity, Real Estate Values, or Undue Alarm

The tension between people's right to know, government duty of care and politicians' perceptions of probability of risk on 'their shift' form a complex interplay. If maximizing safety is the shared goal, all risk communication theory suggests people will behave appropriately with the realistic threat information, motivation and 'how to' instruction on safety-oriented behavior leading into, through and recovering from a natural disaster impact.

Paradigms of Politics: the Real Estate Industry and Vested Interests

Broughton [6] argues that if people know of the threats, they are likely to support politicians who make sound decisions for community survival. Some plans are made but they are hidden away for various financial and political reasons. This is a case in which attitudinal changes on the part of those communities may change the priorities of the decision makers and promote the interests of the community.

Those most empowered to assist in implementing projects that require independence, initiative, local links and knowledge may be the ones who prove most obstructive to innovation [1,48,56,69].

Action Research [16] sets out to research, develop and document socially and environmentally desired outcomes within sustainability principles. In this inclusive and 'engagement-focused' research, gaining support from the top

is crucial to the success of any organizations' efforts at 'social change' [66]. If innovation uptake is viewed as a normative uptake process [12,65] and Fig. 9, then the gradual, long term paradigm shift to sustainability [30] is plausible and has a conceptual frame.

Uptake of the Communication Safety Triangle and the seven steps to community safety (Figs. 7 and 8) will make them the disaster managers' 'norm' over time, simply because that is the direction of social evolution in disaster management. It fits social policy and advanced disaster management approaches, and the technology and willingness of regional media and residents is there. All that is needed is the testing and roll-out by more innovative disaster managers. The same applies for Community Safety Groups and variants of *over-managed, locally controlled near-house "social burn-offs"* in the case of fire risk management.

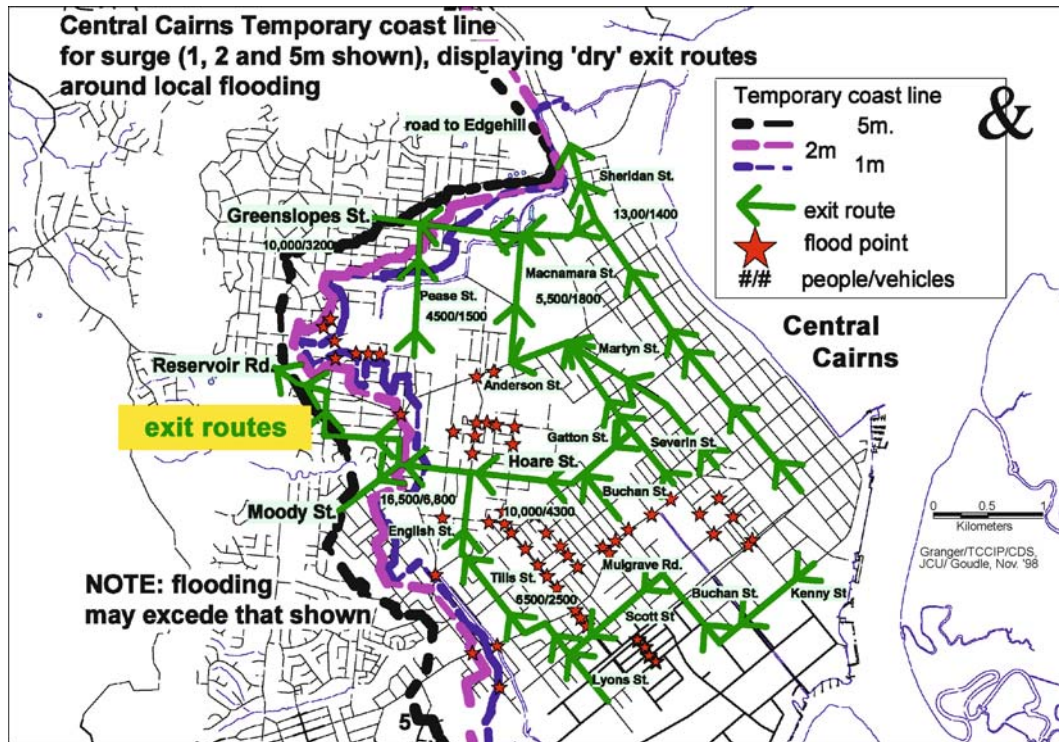

Bureaucratic processes need to support the stated goals of their own work units, but individuals may be ambiguous, contradictory, belated, bullying, ill informed and, due perhaps to time pressure or arrogance, quite destructive. Such individuals may be 'corporate psychopaths' (<http://www.abc.net.au/catalyst/stories/s1360571.htm>). Instead, innovators may be seen as threatening; troublesome. Any innovative pilot project must develop strategies that will maximize change within their unique situation. Ideally, that happens within a supportive parent organization. The next section discusses the emergent issues of effective risk communication and precautionary self-evacuations.

Experiences and Lessons – Some Case Studies

This section considers disaster impacts and impacts from north Queensland and from fire zones in SE Australia to illustrate the generally positive points of approaches already outlined: living flesh for modelers to understand how subtle, complex but do-able successful community preparedness and willingness to act for maximum safety can be. Researching these events, gaining community and disaster managers feedback on risk communication; working closely with the Australian Bureau of Meteorology over 15 years, through the Federal disaster 'paradigm shift' to mitigation ([13] p 13) all inform the emergent CST and seven steps to community safety.

Cairns and Storm Surge Considering Exit Routes (ER, Formula 1)

Cairns City, North Queensland, is centered on land less than 2 m above high tide, and subject to cyclone (storm) surge of up to 5 m. A storm surge tracks just behind the eye of a cyclone, a low mound of sea water, perhaps 50 km

Evacuation as a Communication and Social Phenomenon, Figure 10
 Cairns flood prone evacuation routes and schemata of wave reach and temporary coast line from 1998 information

wide and up to 3 m above normal sea level. It may flow overland for perhaps 4 h, as destructive winds to 280 km/h tear at structures, and churning seas; both laden with pounding debris, behave as battering rams and missiles. Because cyclones have such long lead times from modern electronic detection to landfall, results of this deadly combination [60] will be widespread destruction and loss of infrastructure, but not life, with precautionary evacuations [38,72]. At the macro-observation scale, people and vehicles in motion within confining environments tend to behave like fluids, capable of modeling. Constrictions of flow paths cause congestion, as described by Helbing et al., (► *Pedestrian, Crowd and Evacuation Dynamics*), so early and precautionary evacuation will help minimize the likelihood of grid-lock.

Land-based flooding may be a core issue to effective evacuation [34,38,95], with up to 40,000 people in the vulnerable central city area and northern beach suburbs needing early, precautionary evacuation [79], Fig. 10. Cairns City Council now has a storm surge map on its public web site ([101], posted in 2006), like the public and informative flood map for the Redlands Shire, SE of Brisbane, Queensland ([102]).

Within the philosophical and moral frame of people's "right to know", these local governments are using the internet to inform people they are in a hazard zone, the first step in making the threat real to those residents. They have made the paradigm shift to providing fine-detailed background information which says to residents: "you are in a hazard zone, you may need to do things. Listen for warnings and be prepared to act in a precautionary way."

Figure 11 shows that after a devastating flood in 1997, the flood-affected residents of Cloncurry, NW Queensland town would do things differently, with better warnings, when faced with rising flood waters. Remote automatic flood monitoring devices were requested, but the local downpour over a fully flooded, vast and flat landscape appeared to be the cause of the flood rising 2 m higher than any flood in the prior hundred years. Precautionary evacuation of the low-lying homes would have prevented much heartache and loss of valued possessions [52].

In 2005, north Queensland was threatened by cyclone Ingrid. Newspaper-reading residents were left in no doubt about the threat (Fig. 12); a good example of the clear warning role played by the media, and non-language image used to convey meaning (Sect. "Discussion").

Evacuation as a Communication and Social Phenomenon, Figure 11
Cloncurry reflective of likely responses to future floods

A portion of a Weather Bureau warning media bulletin for Cyclone Ingrid follows, showing, verbatim, what the nation radio broadcaster, the Indigenous Radio Network and most responsible media outlet relayed on. This is clear information, including the possible impacts (M&M of formula 1).

Media: For immediate broadcast. Transmitters in the area Cape Grenville to Cooktown are requested to use the Standard Emergency Warning Signal.

TOP PRIORITY

TROPICAL CYCLONE ADVICE NUMBER 14

Issued by the Bureau of Meteorology, Brisbane

Issued at 10:56 am on Wednesday the 9th of March 2005

A Cyclone WARNING is current for communities between Cape Grenville and

Cooktown. The warning extends inland across central Cape York Peninsula.

A Cyclone WATCH is current for coastal and island communities on the eastern Gulf of Carpentaria between Weipa and Kowanyama.

The watch south to the Gilbert River Mouth has been canceled.

At 10:00 am EST SEVERE TROPICAL CYCLONE Ingrid, Category 4, with central pressure 935 hPa, was located near latitude 13.5 south longitude 145.5 east, which is about 140 km northeast of Cape Melville and 260 km east of Coen. The cyclone was moving westward at 11 km/h.

Severe Tropical Cyclone Ingrid poses a serious threat to the far north.

Queensland coast with very destructive wind gusts to 280 km/hr near the center. Gales are expected to develop between Cape Grenville and Cooktown during the afternoon. Destructive winds are expected between Coen and Cape Flattery overnight. The very destructive core of the cyclone is expected near the coast between Coen and Cape Melville on Thursday morning.

Coastal residents between Coen and Cape Flattery are specifically warned of the dangerous storm tide as the cyclone crosses the coast early Thursday. The sea is likely to rise steadily to a level significantly above the highest tides of the year with damaging waves, strong currents and flooding of low-lying areas extending some way inland. People living in areas likely to be affected by this flooding should be prepared to evacuate if advised to do so.

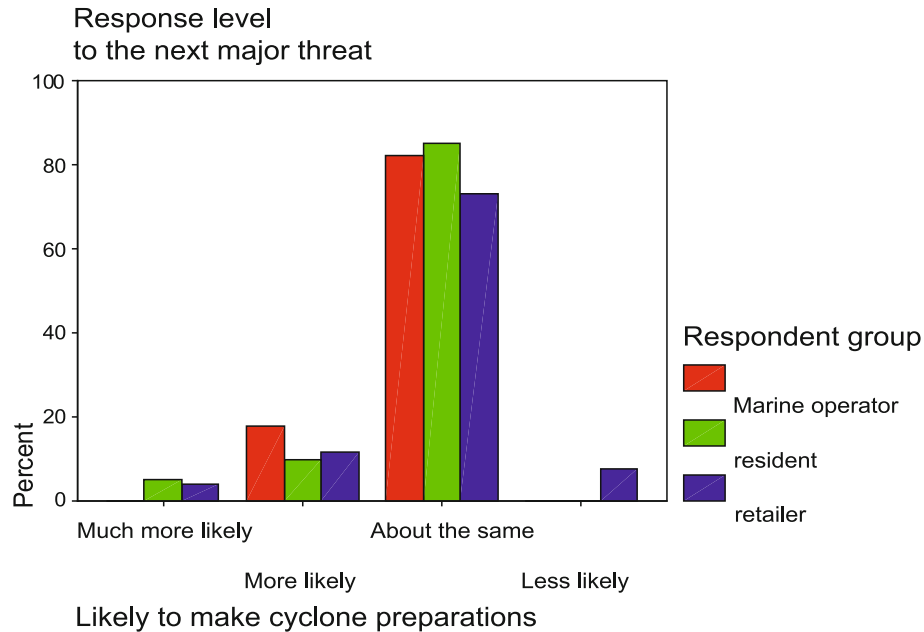

Evacuation as a Communication and Social Phenomenon, Figure 12
Media coverage of threatening Cyclone Ingrid, 2005

Very heavy rain can be expected to develop on the coast and ranges north of Cooktown.

Research in Port Douglas, NQ was conducted immediately following Cyclone Ingrid, to help clarify the 'Boy

who cried wolf' hypothesis about 'concern fatigue' over precautionary evacuations (Sect. "Institutional Barriers to Greater Community Self-Help"). Feedback from marine tourist operators and tourist businesses that removed about 60 large vessels to safe, up-creek moorings, or fully

Evacuation as a Communication and Social Phenomenon, Figure 13
People of Port Douglas appreciated a precautionary evacuation

shuttered their premises and raised all stock. These preparations were arduous, and costly. The cyclone veered away from Port Douglas, with virtually no impact. Despite that, people were glad of the precautionary evacuation, as a practice (Fig. 13), reinforcing the findings of the Netherlands flood study [43]. People appreciate practice, as part of the new paradigm of a precautionary approach to hazards.

From Those Impacted by Larry, 2006

After Cyclone Larry, a powerful Category 4/5 severe cyclone which damaged the Innisfail region, Goudie led a social science research team into the impact area, interviewing households for 4 days (King et al. [53,54]), from the 150 householders survey, focused on risk communication, we learned: as with fire zone residents and those who experienced Cyclone Larry, that most people, once they have experienced a major disaster, maintain a healthy respect and inclination to act ahead of any future such threat. Hence the advocated merit of encouraging people with experience to 'tell their story'; and community (Media and Message and Community Resilience of formula 1) to help make the threat real to others. The next section is, perhaps, at the leading edge of where disaster management will go: living community self-help. Such communities can provide pilot locations to 'calibrate' formula 1.

Woodgate Beach and Community Safety Groups (CSGs)

This section reports a collaborative process between the author and many others, mainly residents of Woodgate Beach, Queensland (Fig. 5), to develop a *Preparation and Evacuation Plan* for residents, formal response groups, the Local Government Disaster Management Group (LDMG) and Shire Council.

Through the 18 month consultation and development process, the plan needed to be realistic and achievable, relying mainly on locals working together under the LDMG and local SES group, aiming to optimize each element of formula 1.

Community networking and self-responsibility for community safety is profoundly developed in the isolated, 700 strong, Central-coast Queensland settlement. The volunteer community safety groups were made up of dedicated people. Goudie led development of a community-based evacuation plan, aiming to: ensure maximum preparation and minimum impact on property and residents; optimizing formula 1.

There were 5 meetings, of up to 80 residents and representatives of all formal response groups, weather and earthquake experts. Meetings included researcher-led two-day 'table-top' evacuation exercise. Woodgate Beach did not develop an evacuation plan, but a preparations and evacuation plan:

Preparations and Evacuation Self-Help Approach

To nurture aware, informed residents preparing to be safe through, and recover from natural disaster impacts.

Overarching Evacuation Approach

- Identify vulnerable areas or houses
- Evacuate caravan park, visitors, people at risk unable to easily move themselves

The Planning Process:

1. DEFINE THE THREATS – Fire, flood, wind, cyclone surge, earth movement, tsunami.
2. MOVE FROM WHERE TO WHERE? Fires can be fought; floods, storm surge and cyclonic winds, tsunami or earthquake cannot be. In all threats, make sure your property is as secure from impact as possible.
3. IDENTIFY THE VULNERABLE – Which buildings, infrastructure and people may be in the threat zone.

Threats and Treatments An all-of-community approach has developed an annual round of public education projects, press releases and pamphlets to inform residents and tourists of the annual cycle of dangers to be wary of, from cyclones to fire care and management. The Council newsletter will be a consistent source of information on threats and how to minimize risks (M & M), from the flying debris of a wind storm to being patient at a flood-swollen creek crossing.

A sequenced approach, where the aged and vulnerable are moved first from the highest risk areas will be taken, as a practice, as a precaution. To highlight the stages of disaster and possible evacuation planning, the background preparations phase is included in this article:

Background Preparations

1. Woodgate Beach residents recognize and act on the need for background preparations to minimize the impacts of all hazard impacts. This includes property maintenance and upkeep. This maximizes PPR of formula 1.
2. Provide newcomers with an information pack, including a copy of extracts of this Community preparations and evacuation plan (CPEP). All community members, including tourists, the elderly, infirm, and needy are incorporated into this CPEP. This enhances the KB of formula 1.
3. Provide dot points on evacuation for local residents in the *Disaster Preparedness Information Kit*, delivered to each household.

4. Expose tourists to the essence of local threats and what will be expected of them: leave early, unless they or their vehicles can actively help, under direction.
5. Define safe shelters – preferably with friends or compatible households. Organizing possible billets for any major impact on portions or all of Woodgate Beach can form a key function of the Community Safety Group. This is the CR of formula 1.
6. Go through whole plan, and address matters like the caravan park needing auxiliary power for fuel pumping before the cyclone season.

The Community Safety Group Approach to Disaster Management This approach is detailed to provide a guide for researchers to use as a framework for other communities:

The Community Safety Group

Purpose encourage:

1. Early Warning Alert The CSG is an affiliation of existing community groups and neighborhood-level residents who make first contact with ‘walking-distance’ neighbors as soon as anyone hears of a warning that a natural disaster may be approaching their area.

2. Final Preparations (Ramp-Up) Activation The neighbor-level CSG will provide early local motivation for final safety preparations.

Recovery – Thinking Through to Recovery (TR) of formula 1.

Recovery is now seen as part of the preparations package, rather than just looking to minimizing impact. The developing approach is to see the whole threat event as one continuous process: from awareness and structural preparedness, through initial communication of threat, to final precautionary preparations and impact and rapid recovery to a fully functional community.

International Snaps

The Center for Disaster Development within The Northumbria University, Newcastle on Tyne, coastal north east England specializes in recovery and response with an emphasis on development long term recovery and resilience-building. Embedded in this approach is to undertake mitigation. Interviewed by Goudie in May 2005, the Director reported “We use the approach that local knowledge is always drawn on, and that people involved should be in control”, KB and CR of formula (1) and agrees “all disaster management is under the umbrella of sustainable development”. Other interviewed staff support precautionary

evacuation as a practice, and, independent of the media, an alert signal for people to tune in to the media.

The Shetland Islands

Like Australia's emerging approach to self-help communities, The Shetland Council's Emergency Management Planner (2005 interview) gave strong practical support to the approach of an informed, aware, self-activating community ready to act on reliable, clear, how-to emergency warnings, ranging from making safe if intrinsically out of the main impact zones, to early 'self-evacuation'. This convergence from differently evolved and slightly different disaster management systems is grounds for optimism that the evacuation approach and formula expounded in this article has widely applicable merit.

Remote communities like the Shetlands have lessons for the mainstream in taking responsibility and perforce being self-reliant and oriented to robust self-help. Such isolated communities represent matured examples of the informed, aware communities, predisposed to precautionary action that mainstream populations now aspire to. Community-building is an international aspiration, achievable in urban settings.

Hurricane Katrina

Hurricane Katrina, USA late August, 2005 (Fig. 14) has deliberately not been included in this evacuation analy-

sis. With days of clear warning, general formal approaches to precautionary action which underpin the CST and the seven steps to safety and recovery were underplayed.

Figure 14 is included to remind all readers that hazards are real threats to real people in real hazard zones. If all the parameters to maximizing formula 1, such as Institutional Barriers are not optimal to safety, great distress and loss can ensue.

This section has provided a cross-section of disaster threats, evolving reasons to empower communities, and some factors to include in modeling greater community safety. After discussion in the following section, some recommendations and future directions are provided.

Modeling not only the natural hazard but the various social and communication parameters will provide a good basis for not only simulating impact; say, of the extent of flood waters; but will also highlight which impact areas are the most and least likely to properly act in their own best safety.

Discussion

Risk Communication Theory and Residents in Hazard Zones

People need to know that an impact is possible before they will willingly evacuate. The concept of risk characterization [42,46,68,75,77,83] makes clear that people need a practical understanding (*the possibility of impact is real,*

Evacuation as a Communication and Social Phenomenon, Figure 14

What no-one should have to stay through – Katrina '05 http://news.bbc.co.uk/1/hi/in_pictures/4194032.stm

I fully accept that) to then illuminate practical choices. ‘Internalizing’ that *a threat is real and what you need to do to maximize your safety* may be the core goal of risk communication. This internalization and safety-oriented action may lead to a choice of precautionary evacuations. People need to make informed decisions, thus leading to decision-driven activity.

Delivering Real-Time Warnings

The idea of subjective uncertainty [74] is well displayed by fire-zone residents who, despite all authority efforts to have them commit to an early decision to stay and defend or to leave their properties early, recurrently reported that they would decide on the day whether they would stay or go. There are tragic and recent international examples of resident’s decisions made on too little understanding or information.

The bushfire ‘stay or go’ decision point explored in 2007 research by the author with Australian fire-zone residents clarifies that decision impact on those under threat – packing up their valuables, children and pets and fleeing their house, almost certainly putting it at risk of burning down; as opposed to staying in their house and experiencing the terror of the developing bushfire, was a decision many preferred to delay. Further, many acknowledged that to leave early with all of the disruption, only to learn that the fire was not an actual threat to their property helped induces people to delay that decision point.

Subjective uncertainty is a psychological problem. The outcome of current research is to encourage the threat information gatherers and providers; the weather bureau and disaster managers, to refine information detail and use all currently available modes of dissemination to provide the threatened with the maximum amount of fine details to make that evacuation decision in an informed and timely manner. This is a clear example of where theory and the practical views of hazard zone residents converge.

The 2007 southeast Australian fire zone research shows that people who are more obviously at risk from bushfire are far more prepared than people who are at risk from an occasional but as potentially destructive bushfire. The literature [13,24,31] shows that the less frequent the event, the less prepared people are likely to be. Aligned to the goals of this publication, the formula explained in this article on the realities and complex elements of combining physical with human geography to the ‘social good’ of maximizing safety around disaster impacts is a great potential application of complexity and systems science. This complexity includes the Media (Media Support MS of formula 1).

The Media

The media plays an ongoing role in socialization and the development of normative values. Dominick [20] argues that the media plays a key role in the cognitive development of individuals. Cognition is the act of coming to know something. Mass media can play a defining role in people’s awareness and responses to disaster threats. The CST embraces local media as an active agent in providing needed local information. Local media outlets can draw on and enhance Internet information to inform readers and listeners of ‘how to’ actions to maximize their safety. In this way the mass media can help clarify facts to help make contentious decisions (which may result in life or major property loss) by providing the fine details to reduce the uncertainty surrounding decisions that householders under threat need to make. The seven steps to community safety (Sect. “[Integrating Theory and Implementation](#)”) underline this core need for individuals in hazard zones to accept they are at risk and for the Internet and local media to act as providers of relevant, local, timely information for informed decision-making.

The media can play a powerful role in mobilizing communities [58], but they need to have accurate and timely information from disaster managers. The information which fire zone residents in southeastern Australia in 2007 asked for from the Internet is in full keeping with theory, and a recognition that greater access to current facts will reduce uncertainty in decision-making.

Triggering Action: Modeling and Simulating This Geographic, Communications and Psychological Complexity

The reason step one in the seven step process is so important is to counteract a psychological defense against accepting threat. We need to have a sense of personal invulnerability to get us through each day [75]. If we were scared of all possible problems we would cease to operate. The risk literature from Handmer, Goudie, Rohrmann, Salter [34,42,75,77] and many others underlines the importance of the clarity in the description of the threat and safety oriented action. Thus Acceptance they are In a Hazard Zone (AIHZ) of formula 1 is central to possible consequent safety-oriented behavior.

One reason given for risk communication failing is that it is not clear what should be done. The seven steps include a requirement that ‘what to do’ information be an integral part of any warning as a prelude to evacuation. The clear message is that the process of people accepting that a risk is real needs to well precede any actual impact. This is underlined by Kasperon & Stallen [49], who also

stress the importance of time perception and time horizons. Hence the importance of Knowledge Base of the hazard and safety-maximizing behavior (KB) of formula 1.

Timely Preparation, Final Actions and Evacuations

Timeliness of warnings is paramount to the effectiveness of warnings [85]. In the early 1990s there was much psychology research on perceptions of risk probabilities, individual psychometric studies on perceptions of future time, time orientation, planning horizons, and prediction of future events. In 2007 Australian fire zone residents say they want fine, detailed information as a threat approaches, so the uncertainty of what they may face is minimized. Their planning horizons are generally well oriented to maximum safety, but the crucial 'stay or go' decision will be based on information as close to impact as allows them adequate time to act safely.

Svenson [85] and others make clear that it is not only what you may choose to do, but also when you do it. In the case of remote area warnings of flooding, for instance, when flood waters may take a week to block down-catchment roads, traveling earlier than planned may be the best way to avoid the fate of the truck shown in Fig. 15. This is an example of an 'Active warning image', along with the image of the person standing on the car roof in the flooded road crossing (Fig. 16). Images like these are of use to remind people to travel before or after expected flooding – not during the flood.

In 2007, in a two day threat and evacuation exercise in Woodgate Beach operated on the underlined imperative, from the outset, that evacuation ahead of a storm surge would need to be completed not as cyclonic winds struck, but six hours before landfall. Once the winds gusted above 100 km per hour, all peoples, including disaster managers, must be in safe shelter above cyclone surge height.

Disasters and evacuations are issues of people, information, time and space. People in threat zones are entitled to accurate and timely localized information, detailing the threat and likely time-linked movement. People also want to know, via the internet or battery operated radios, what authorities are doing. That information may influence their own actions. What they ask for is the enhancement of their 'risk decision landscape' [83].

In 1974 communication management of and responses to disasters in Darwin and Brisbane shocked Australians. Darwin's Cyclone Tracy killed 65 people, and the Brisbane floods killed 16 [10,11]. These catastrophes taught Australian emergency planners much about the importance of effective warnings, sharing honest, complete and open information in a timely way to emergency managers, emer-

Conveying weather threat information - flood

Evacuation as a Communication and Social Phenomenon, Figure 16

An image dissuading people from driving in to flood waters

gency workers, and those at risk to ensure sound preparation and responses. The Australian natural disasters of 1974, with major flooding elsewhere in Australia that year, also reinforced the importance of community and family ties to get people through the often profound emotional trauma allied with major natural disasters. The detailed documentation of Cyclone Tracey can help guide development of predictive models of disaster preparedness, communications and responses. With so few well documented cases, a Bayesian Logic approach could be used, some well documented disasters, communications and response cases to develop the model, others to test and refine it.

The more recent and current disaster impacts all point to the importance of communities being properly informed. Indeed, the literature on knowledge, risk and inclusion of residents in the bushfire planning process is well described by Goldammer [32]. Issues of increased encroachment on to bush edges along with climate change are causing increased international concern over fire threats, often to places without much collective wisdom over the reality of those fire threats, or the nature of the strategies needed to maximize community safety.

South Eastern Australia is seen as one of the most bushfire-prone environments in the world [92]. Boura [7], an Australian fire manager, describes the development of community fireguard groups in Victoria. These groups are managed and instructed by the Country Fire Authority, but they are residents within very localized neighborhoods. They have their counterparts in the ACT and some other Australian States. They draw on detailed, often technically advanced information from the weather bureau and fire agencies to increase local awareness and action. This is a real playing out of the theories of social amplification developed by psychologists and risk communication theorists [73]; advanced planning techniques [16] and aligned with the way many feel about the direction of emergency management in Australia [15].

Linking the People with the Message

The foci on culture, community and social frameworks, either formal or informal neighborly links, is considered by Douglas [21]. Douglas argues that there is a need for people to understand that risk and danger exist where they live, despite a low probability that an impact may occur in any given hazard season. There is a large body of psychology which considers why people ignore clear messages

which may maximize their safety [12]. Douglas speaks of artificially distorted world views. Douglas posits such bias is rooted in over-simple views of heroic and bourgeois fiction. Changing such a normative world view has been discussed in this article in terms of a paradigm shift, well displayed by the Australian Government [13]. A model constructed from formula 1 needs to include all the subtle complex issues of social profiling.

Woodgate Beach (Sect. “Experiences and Lessons – Some Case Studies”), perhaps because of physical isolation, is fully embracing self-help, also displaying a deep culture of volunteerism that can be nurtured and emulated in ‘urban villages’. Sustainable urban planning concepts of nodes or activity centers are now well evolved as the hub of ‘urban villages’ [35]. What is happening in Woodgate Beach can be used as a model for any formula of developed social collective will to self-help, ultimately whether urban and surrounded by other neighborhoods, or more physically isolated.

Like the Ferny Creek (Victoria) community who agitated for a fixed bushfire siren after three of their neighbors were burned to death in the flash fire of 1997, community action needs a few individuals of vision and drive, residents of ‘neighborhoods’ can initiate and embrace safety-oriented behaviors and structures. The best thing the insti-

Evacuation as a Communication and Social Phenomenon, Figure 17
Initiatives to empower residents to be prepared for fire

tutional systems can do is draw out, nurture and encourage these individuals to mobilize a focus on gaining threat knowledge and acting to increase community responses. Part of the community engagement in the fact they are in a threat zone, as step 1 to action, is shown in Fig. 17; a great road-side banners initiative by one section of the Victorian Country Fire Authority to make the fire threat and implications real for fire-prone residents. Figure 17 shows, in few words, that if you intend to evacuate, do it early. Figure 17 says that the support and creativity to maximize communication effectiveness (the opposite of Institutional Barriers) helps contribute to a positive Medium and Message (MM) of formula 1.

Traditional Weather Warnings

Traditional weather warning signs include ant movement for looming flood, and general bird movement for strong winds, including cyclones [64,87,88]. On Palm Island, when the birds and animals go quiet, it signals that a major storm may be on the way [36,39]. The buildup to the summer monsoon rains is the universal experience of still, humid and hot conditions, continuing in intensity and cloud until the rains come. All cultures in all hazard zones have their traditional knowledge. Cultural Knowledge Bases (KB of formula 1) needs to be modeled into any mathematical prediction of likely propensity to respond to a natural disaster threat.

Words and Images

Word and image use are critical to effective communication. A newspaper graphic ahead of the terrorist-threatened 2004 Olympic Games (Fig. 18) conveys much about the world we now occupy, and uses no words.

The need for clear messages, most likely to provoke a precautionary response, is supported by the risk communication literature of Sect. “Effective Risk Communication” and the communication and cognitive theory of

Evacuation as a Communication and Social Phenomenon, Figure 18

An image of terror in 2004 – Source: Townsville Bulletin

Sect. “Integrating Theory and Implementation”. If this knowledge is melded to requests of remote Indigenous peoples and NESH, the safety goal of clear, plain words and images will become the risk communication norm. There are many examples of images conveying meaning, such as the internationally used figure running upstairs, with an arrow; signifying an evacuation route. The symbol for tsunami; a stylized figure racing up a steep slope with a very large wave following, threatening to engulf them is also without words, but conveys all we need to know about evacuating ahead of a tsunami: get up slope immediately.

Images and Warning Maps

Risk communication is usually about attempts to prompt considered action by a person or community. Effective communication should make the future threat real in present thinking. Alternative responses should be outlined, along with likely consequences. To further prompt a considered and active response to the ‘action warning’, the consequences of inaction or a range of defensive actions should be made lucid. ‘Preferred’ behavior should seem reasonably attractive to ‘target individuals’ [85]. The theoretical overview of risk communication in Sect. “Effective Risk Communication” explains why the message must be clear to the target audience. It needs to have some cognitive content to get people thinking about how it may impact on them, and what the alternative outcomes for them may be if the predicted impact strikes where they are. Stimulus and local risk simulations, as embedded in the Redlands shire flood map [102], should be saturation broadcast into all hazard zones. The CST should be attempted with at-risk groups; people in threat zones, encouraging them to properly think about the real threat and to indicate to people what inaction may bring. A range of safety-oriented actions should also be presented.

Modeling Risk Communication into and Through Communities

Efforts have been made since the 1960s to see how well people understood the hazard. These studies continue [5]. The model of hearing, understanding, believing and feeling that the information is personalized so that those at risk will act has been well understood since the early 90s [81]. The general issues of credibility [18,69,70] still apply. Studies reported by Sorenson and Mileti [81] show increased knowledge as a result of risk communication efforts. People do become more aware of hazards and their personal place within the hazard threats. Unfortunately the link between knowledge and behavior remains tenuous [35].

Knowing that the normal first warning of major disruptive weather comes via the evening TV news in remote settlements, simulations will carry a high embedded likelihood of safety-oriented community response.

Sorenson and Mileti [81] showed that the believability of warnings increases as people get more warnings from officials with high credibility, and that women tend to believe emergency warnings more than men. They also showed that people higher up the socioeconomic ladder tend to believe warnings more than their counterparts. Minority groups have lower than average belief in warnings while people with a high knowledge of the hazard tend to find warnings more credible.

New Cultures to Hazard Zones

The issues discussed in this article from remote Indigenous communities and from non-English-speaking households make clear the importance of using plain English. Work with representatives of both groups made clear that plain English and images were necessary to convey the concept of danger to people in hazard zones, concurring with the expositions of Douglas [21]. The simpler the language the better. Douglas argues that even the word 'risk' could be dropped and 'danger' used instead. Goudie's work with recent Somali arrivals in Australia showed that, like Japanese tourists and many other people from non-English-speaking backgrounds, they understood the word and concept of 'danger', but did not, for instance, understand the word 'severe'. The importance of language clarity to the intended audiences in the MM expression of formula 1 needs emphasis.

For risk communication and evacuation advice to penetrate to all people in hazard zones, the language and images must be clear, simple, and compelling. If risk communicators construct campaigns of engagement which work for such 'marginalized' groups, the 'mainstream' can be easily included in that campaign.

Playing the Odds

Renn and Rohrmann [74] make clear that the assumption that risk judgments and evaluations are universal processes independent of social status or national heritage are unreasonable. Goudie's Australian research with multicultural organizations shows most clearly that there are many populations in hazard zones and that each of those groups must be addressed in ways that make the hazard real to them. Findings from the Cyclone Larry research [53] also show that there are many groups other than cultural, such as 'social isolates' – the socially disenfranchised, who need

special attention around disaster threats to ensure their safety.

Douglas [21] argues that risk perception and thus response is also an issue of moral and political issues. Westerners tend to consider the probability of an impact in terms of gambling whereas other cultures may need other triggers to internalize the threat and motivate them to action. The concept of a low probability event needing to be taken seriously is discussed by Douglas and others. Residents of Florida are well used to a near-annual evacuation ahead of frequent cyclones. Residents of the coastal communities of Queensland may be less likely to take the warning seriously, because they believe that there is no real chance that they will be personally affected by a cyclone. The whole issue of low probability and high impact events needs to be stressed to relevant impact zone residents.

The first and hardest step in an effective community evacuation remains convincing people in the projected impact zone that the looming threat is real. Renn and Rohrmann [74] suggest that to help make that threat real, project the expected number of fatalities or the catastrophic potential or where the threat may come from.

Spreading the Warning

Handmer [43] recommends that the professional warning agencies should attempt to harness the "personal informational networks of individuals within formal communication systems, and by assuring that formal warning advice is consistent with local norms and behavior" ([43] p 27). Shifting the normative values of recalcitrant disaster managers, and residents in ignorance or denial in urban risk zones becomes the key task of the *seven steps to community safety*, along with the amalgamating approach of the *community safety triangle*.

Part of the strength of the CST is that it taps into and informs an existing social predisposition for people to talk to each other, particularly in times of common threat (King and Goudie 2006). Using emergent technologies to provide real-time information to community media and households helps realize aware informed communities, predisposed to action.

With literature and research results discussed throughout this article, this discussion underlines the importance of modeling local norms, and interactive, safety-focused behavior. Emerging concepts which may be tested in further research are Community Safety groups (Sect. "Experiences and Lessons – Some Case Studies") and Social Burnoffs or flood evacuation practices. The main thrust of this work is to encourage interested modelers to accurately simulate how communities understand and act on

the need for safety-oriented action, where people are inclusive at the neighborhood level, acting as a self-preserving group, no matter what the ethnicity or state of surrounding populations. Neighborhood cohesion and empowerment is current social policy consistent with ESD philosophies and principles, enshrined in current planning laws such as IPA 1997 [46].

To illustrate the power of the internet, consider that any online reader globally can click on [103] and see the social aspects of Queensland's sustainability planning law. Indeed, click on and draw from any of the web sites given. If we were not suffering from information overload and time paucity, the paradigm shift to sustainability implementation would be rapid, the modeling acted on by disaster managers and financial cost-benefit analysts. Until that time, models will help convince and guide people in testable and demonstrable ways to increase community safety. Our very busyness is perhaps the main barrier to reducing global warming and natural disaster impacts. An alternative way into a more sustainable future is centered on local needs-meeting, including nurturing more local community cohesion and sharing of reliable, safety-oriented information and safety-oriented actions.

Future Directions in Modeling Disaster Preparedness and Evacuations as a Social Issue

As global warming and climate change intensifies, the need to model for preparedness and evacuations will increase with more frequent and extreme weather events. The total and fine detail of all needed background preparations and ramp-up preparations are too numerous and arduous for formal disaster management organizations to implement alone, hence the increased need to promote and strongly support the role of community engagement, of community empowerment and nurturing self-help in maximizing effective natural disaster preparation, including evacuations.

Australia has matured disaster policy, law and evolving practice, all embedded in concepts of ecologically sustainable development. Researchers can access, model and test local applicability of some of the Australian experiences and culture of community self-help. Sustainability Implementation Research will become universal as the era of last-minute organizational flurries whilst goading an ignorant and passive population at threat is superseded by prepared and bonded communities who are primed to receive well-delivered warnings, often sourced from the web, and who move themselves to safety in plenty of time. Modeling this will help sell the approach to conservative disaster managers.

The Sustainability Implementation Research, including data-based simulations introduced in this article, is the logical next step to 'action research' of the social sciences and will become the norm in approaching all issues of sustainability where the policies are mature, but agencies are unsure how to implement the paradigm shift; the behavioral and technological shift, to agreed long-term goals.

Meaningful consultation is a defining requirement of sustainability planning and good modeling, so all future social research of merit will take the Human Geographer's approach and "ask the local residents, involve the local residents." Community empowerment, and its modeling means local residents are entitled to help mold their own future. With hazard management, the shared SIR goal is to empower hazard-zone communities to be aware of the threat, be basically prepared for any warning, and act, as a community, in a precautionary way to maximize safety, minimize loss, and speed recovery.

As we move forward, plain language(s), clear, widely displayed hazard maps and images of like hazard impacts will help energize hazard-zone residents to the threats and their own needed safety-oriented behavior.

Researchers and Complexity and Systems Scientists have a moral if onerous obligation to challenge any layer of government clearly exercising or imposing barriers to helping people internalize any threats, then be supported in getting safe and staying safe, recognizing that change may threaten some individuals or sections within bureaucracies. As disaster management moves from a militaristic model of command and control to community empowerment and self help, the developing potential of the web as a key information source into hazard zones – ultimately web-to-air – will bear the fruit of greater community safety and minimized loss. Web-to-TV in disaster warning will be a fine conduit for showing residents-at-risk where the threat may be in relation to their home in a few hours. That immediacy of moving images is a compelling motivator for safety-oriented action.

In future, researchers, modelers and others involved in maximizing community safety will embrace some variations of the *communications safety triangle* and *the seven steps to community safety*, simply because they make sense; are highly cost-effective and easily web-refined from international to local conditions, populations and threats.

Acknowledgment

I most thank my research guardian and mentor over 15 years, Prof. David King, Director of both the Australian Center for Disaster Studies and of the Center for Tropi-

cal Urban and Regional Planning. David allowed me freedom to develop as an 'evidence-based' scientist, to conceive core approaches to sustainability implementation research; productive in helping render positive change in both disaster management and sustainability planning.

Thanks to Australian Bureau of Meteorology staff for their interactive support to improve risk communications, listening to what real people in real hazard zones experience, how they hear warnings, and how the medium and the messages can be and are optimized. The Bureau embraces the core goal to motivate safety-oriented action by people in hazard zones. The Bureau listens and improves the message and the delivery.

The bushfire research of '06 & 07 was funded by the Australian Bushfire Cooperative Research Center, supported by the University of Tasmania.

The 14 years of research reported in this article was not possible without the contributions of Authorities and more than 1000 Australians, old and new, who opened their organizations or doors to myself or research team members and shared their hazard experiences and specific warning needs. Thanks all.

Glossary

Pedestrian A person traveling on foot. In this article, other characterizations are used depending on the context, e. g., agent or particle.

Crowd A large group of pedestrians moving in the same area, but not necessarily in the same direction.

Evacuation The movement of persons from a dangerous place due to the threat or occurrence of a disastrous event. In normal situations this is called “egress” instead.

Flow The flow or current J is defined as the number of persons passing a specified cross-section per unit time. The common unit of flow is “persons per second”. Specific flow is the flow per unit cross-section. The maximal flow supported by a facility (or a part of it) is called “capacity”.

Fundamental diagram In traffic engineering (and physics): density-dependence of the flow: $J(\rho)$. Due to the hydrodynamic relation $J = \rho v b$ equivalent representations used frequently are $v = v(\rho)$ or $v = v(J)$. The fundamental diagram is probably the most important quantitative characterization of traffic systems.

Lane formation In bidirectional flows, lanes are often dynamically formed in which all pedestrians move in the same direction.

Bottleneck A limited resource for pedestrian flows, for example a door, a narrowing in a corridor, or stairs, i. e., a location of reduced capacity. At bottlenecks jamming occurs if the inflow is larger than the capacity. Other phenomena that can be observed are the formation of lanes and the zipper-effect.

Microscopic models Models which represent each pedestrian separately with individual properties like walking velocity or route choice behavior and the interactions between them. Typical models that belong to this class are cellular automata and the social-force model.

Macroscopic models Models which do not distinguish individuals. The description is based on aggregate quantities, e. g., appropriate densities. Typical models belonging to this class are fluid-dynamic approaches. Hand calculation methods which are based on related ideas and are often used in the field of (fire-safety) engineering belong to this class as well.

Crowd disaster An accident in which the specific behavior of the crowd is a relevant factor, e. g., through competitive and non-adaptive behavior. In the media, it is often called “panic” which is a controversial concept in crowd dynamics and should thus be avoided.

Definition of the Subject

Today, there are many occasions on which a large number of people gathers in a rather small area. Office buildings and apartment houses grow larger and more complex. Very large events related to sports, entertainment or cultural and religious events are held all over the world on a regular basis. This brings about serious safety issues for

the participants and for the organizers who must be prepared for any case of emergency or critical situation. Usually in such cases the participants must be guided away from the dangerous area as quickly as possible. Therefore the understanding of the dynamics of large groups of people is very important.

In general, evacuation is egress from an area, a building or a vessel due to a potential or actual threat. In the cases described above, the dynamics of the evacuation processes are quite complex due to the large number of people and their interaction, external factors such as fire, complex building geometries, etc. Evacuation dynamics must be described and understood on different levels: physical, physiological, psychological, and social. Accordingly, the scientific investigation of evacuation dynamics involves many research areas and disciplines. The system “evacuation process” (i. e., the population and the environment) can be modeled on many different levels of detail, ranging from hydro-dynamic models to artificial intelligence and multi-agent systems. There are at least three aspects of evacuation dynamics that motivate its scientific investigation:

- 1) As in most many-particle systems several interesting collective phenomena can be observed that need to be explained;
- 2) Models need to be developed that are able to reproduce pedestrian dynamics in a realistic way, and
- 3) Pedestrian dynamics must be applied to facility design and to emergency preparation and management.

The investigation of evacuation dynamics is a difficult problem that requires close collaboration between different fields. The origin of the apparent complexity lies in the fact that one is concerned with a many-‘particle’ system with complex interactions that are not fully understood. Typically the systems are far from equilibrium and so are, e. g., sensitive to boundary conditions. Motion and behavior are influenced by several external factors and often crowds can be rather inhomogeneous.

In this article we want to deal with these problems from different perspectives and will not only review the theoretical background, but will also discuss some concrete applications.

Introduction

The awareness that emergency exits are one of the most important factors to ensure the safety of persons in buildings can be traced back more than 100 years. Disasters due to the fires in the Ring theater in Vienna and the urban theater in Nizza in 1881 resulted in several hundred fatal-

ities and led to a rethinking of the safety in buildings [24]. First, attempts were made to improve safety by using non-flammable building materials. However, the disaster at the Troquois Theater in Chicago with more than 500 fatalities, where only the decorations burned, demonstrated the need for more effective measures. This was a starting point for studying the influences of emergency exits and thus the dynamics of pedestrian streams [24,32].

In recent years there have been two major evacuation incidents which gained immense global attention. First, there was the capsizing of the Baltic Sea ferry MV Estonia (September 28, 1994, 852 casualties) [100] and, of course, the terrorist attacks of 9/11 (2,749 casualties). Other prominent examples of the possible tragic outcomes of the dynamics of pedestrian crowds are the Hillsborough stadium disaster in Sheffield (April 15, 1989, 96 casualties) [182], the accident at Bergisel (December 4, 1999, 5 casualties) [189], the stampede in Baghdad (August 30, 2005, 1,011 casualties), the tragedy at the concert of “The Who” (December 3, 1979, 11 casualties) [73] and – very early – the events at the crowning ceremony of Tsar Nicholas II in St. Petersburg in May 1896 with 1,300 to 3,000 fatalities (sources vary considerably) [168]. In the past, tragic accidents have happened frequently in Mecca during the Hajj (1990: 1,426, 1994: 270, 1997: 343, 1998: 107, 2001: 35, 2003: 14, 2004: 244, and 2006: 364 casualties). What stands out is that the initiating events are very diverse and range from external human aggression (terrorism) to external physical dangers (fire) and rumors to various shades of greedy behavior in absence of any external danger.

Many authors have pointed out that the results of experts’ investigations and the way the media typically reports about an accident very often differ strongly [17,77,109,155,156,178]. Public discussion has a much greater tendency to identify “panic” as the cause of a disaster, while expert commissions often conclude that there either was no panic at all, or panic was merely a result of some other preceding phenomenon.

This article first discusses the empirical basis of pedestrian dynamics in Sect. “[Empirical Results](#)”. Here we introduce the basic observables and describe the main qualitative and quantitative results, focusing on collective phenomena and the fundamental diagram. It is emphasized that even for the most basic quantities, no consensus about basic behavior has been reached.

In Sect. “[Modeling](#)” various model approaches that have been applied to the description of pedestrian dynamics are reviewed.

Section “[Applications](#)” discusses more practical issues and gives a few examples for applications to safety analysis.

In this regard, prediction of evacuation times is an important problem as legal regulations must often be fulfilled. Here, commercial software tools are available. A comparison shows that the results must be interpreted with care.

Empirical Results

Overview

Pedestrians are three-dimensional objects and a complete description of their highly developed and complicated motion sequence is rather difficult. Therefore, in pedestrian and evacuation dynamics, pedestrian motion is usually treated as two-dimensional by considering the vertical projection of the body.

In the following sections we review the present knowledge of empirical results. These are relevant not only as a basis for the development of models, but also for applications such as safety studies and legal regulations.

We start with the phenomenological description of collective effects. Some of these are known from everyday experience and will serve as benchmark tests for any kind of modeling approach. Any model that does not reproduce these effects is missing some essential part of the dynamics. Next, the foundations of a quantitative description are laid by introducing the fundamental observables of pedestrian dynamics. Difficulties arise from different conventions and definitions. Then pedestrian dynamics in several simple scenarios (corridor, stairs etc.) are discussed. Surprisingly, even for these simple cases no consensus about the basic quantitative properties exists. Finally, more complex scenarios are discussed which are combinations of the simpler elements. Investigations of scenarios such as evacuations of large buildings or ships suffer even more from lack of reliable quantitative and sometimes even qualitative results.

Collective Effects

One of the reasons why the investigation of pedestrian dynamics is attractive for physicists is the large variety of interesting collective effects and self-organization phenomena that can be observed. These macroscopic effects reflect the individuals’ microscopic interactions and thus give important information for any modeling approach.

Jamming Jamming and clogging typically occur for high densities at locations where the inflow exceeds capacity. Locations with reduced capacity are called *bottle-necks*. Typical examples are exits (Fig. 1) or narrowings. This kind of jamming phenomenon does not depend strongly on the microscopic dynamics of the

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 1

Clogging near a bottleneck. The shape of the clog is discussed in more detail in Subsect. “Theoretical Results”

particles. Rather it is a consequence of an exclusion principle: space occupied by one particle is not available for others.

This clogging effect is typical for a bottleneck situation. It is important for practical applications, especially evacuation simulations.

Other types of jamming occur in the case of counterflow where two groups of pedestrians mutually block each other. This happens typically at high densities and when it is not possible to turn around and move back, e. g., when the flow of people is large.

Density waves Density waves in pedestrian crowds can be generally characterized as quasi-periodic density variations in space and time. A typical example is the movement in a densely crowded corridor (e. g., in subway-stations close to the density that causes a complete halt of motion) where phenomena similar to stop-and-go vehicular traffic can be observed, e. g., density fluctuations in a longitudinal direction that move backwards (opposite to the movement direction of the crowd) through the corridor. More specifically, for the situation on the Jamarat Bridge in Makkah (during the Hajj pilgrimage 2006), stop-and-go waves have been

reported. At densities of 7 persons per m^2 upstream, moving stop-and-go waves of period 45 s have been observed that lasted for 20 minutes [59]. Fruin reports, that “at occupancies of about 7 persons per square meter the crowd becomes almost a fluid mass. Shock waves can be propagated through the mass sufficient to lift people off their feet and propel them distances of 3 m (10 ft) or more.” [36].

Lane formation In counterflow, i. e., two groups of people moving in opposite directions, (dynamically varying) lanes are formed where people move in just one direction [135,139,197]. In this way, strong interactions with oncoming pedestrians are reduced which is more comfortable and allows higher walking speeds. The occurrence of lane formation does not require a preference of moving on one side. It also occurs in situations without left- or right-preference. However, cultural differences for the preferred side have been observed. Although this preference is not essential for the phenomenon itself, it has an influence on the kind of lanes formed and their order.

Several quantities for the quantitative characterization of lane formation have been proposed. Yamori [197] has introduced a band index which is basically the ratio of pedestrians in lanes to their total number. In [13] a characterization of lane formation through the (transversal) velocity profiles at fixed positions has been proposed. Lane formation has also been predicted to occur in colloidal mixtures driven by an external field [15,28,158]. Here, an order parameter $\phi = \frac{1}{N} \langle \sum_{j=1}^N \phi_j \rangle$ has been introduced where $\phi_j = 1$ if the lateral distance to all other particles of the other type is larger than a typical density-dependent length scale, and $\phi_j = 0$ otherwise.

The number of lanes can vary considerably with the total width of the flow. Figure 2 shows a street in the city center of Cologne during World Youth Day in Cologne (August 2005) where two comparatively large lanes have been formed.

The number of lanes usually is not constant and might change in time, even if there are relatively small changes in density. The number of lanes in opposite directions is not always identical. This can be interpreted as a sort of spontaneous symmetry breaking.

Quantitative empirical studies of lane formation are rare. Experimental results have been reported in [94] where two groups with varying relative sizes had to pass each other in a corridor with a width of 2 m. On one hand, similar to [197] a variety of different lane patterns were observed, ranging from 2 to 4 lanes. On the other hand, in spite of this complexity, surprisingly

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 2

The “Hohe Straße” in Cologne during World Youth Day 2005. The yellow line is the border of the two walking directions

large flows could be measured: the sum of (specific) flow and counterflow was between 1.8 and 2.8 persons per meter per second and exceeded the specific flow for one-directional motion (≈ 1.4 P/ms).

Oscillations In counterflow at bottlenecks, e. g., doors, one can sometimes observe oscillatory changes of the direction of motion. Once a pedestrian is able to pass the bottleneck it becomes easier for others to follow in the same direction until somebody is able to pass the bottleneck (e. g., through a fluctuation) in the opposite direction.

Patterns at intersections At intersections, various collective patterns of motion can be formed. A typical example is short-lived roundabouts which make motion more efficient. Even if these are connected with small detours, the formation of these patterns can be favorable since they allow for “smoother” motion.

Emergency situations, “panic” In emergency situations various collective phenomena have been reported that have sometimes misleadingly been attributed to *panic behavior*. However, there is strong evidence that this is not the case. Although a precise accepted definition of *panic* is missing, usually certain aspects are associated with this concept [77]. Typically “panic” is assumed to occur in situations where people compete for scarce or dwindling resources (e. g., safe space or access to an exit) which leads to selfish, asocial or even completely irrational behavior and contagion that affects large groups. A closer investigation of many crowd disasters has revealed that most of the above characteristics have played almost no role and most of the time have not been observed at all (see e. g. [73]). Often

the reason for these accidents is much simpler, e. g., in several cases the capacity of the facilities was too small for the actual pedestrian traffic, e. g., Luschniki Stadium Moskau (October 20, 1982), Bergisel (December 4, 1999), pedestrian bridge Kobe (Akashi) (July 21, 2001) [186]. Therefore the term “panic” should be avoided, *crowd disaster* being a more appropriate characterization. Also it should be kept in mind that in dangerous situations it is *not* irrational to fight for resources (or for your own life), if everybody else does this [18,113]. Only from the outside is this behavior perceived as irrational since it might lead to a catastrophe [178]. The latter aspect is therefore better described as *non-adaptive behavior*. We will discuss these issues in more detail in Subsect. “Evacuations: Empirical Results”.

Observables

Before we review experimental studies in this section, the commonly used observables are introduced.

The flow J of a pedestrian stream gives the number of pedestrians crossing a fixed location of a facility per unit of time. Usually it is taken as a scalar quantity since only the flow normal to some cross-section is considered. There are various methods to measure flow. The most natural approach is to determine the times t_i at which pedestrians pass a fixed measurement location. The time gaps $\Delta t_i = t_{i+1} - t_i$ between two consecutive pedestrians i and $i + 1$ are directly related to the flow

$$J = \frac{1}{\langle \Delta t_i \rangle} \quad \text{with} \quad \langle \Delta t_i \rangle = \frac{1}{N} \sum_{i=1}^N (t_{i+1} - t_i) = \frac{t_{N+1} - t_1}{N}. \quad (1)$$

Another possibility for measuring the flow of a pedestrian stream is borrowed from fluid dynamics. The flow through a facility of width b is determined by the average density ρ and the average speed v of a pedestrian stream as

$$J = \rho v b = J_s b. \quad (2)$$

where the *specific flow*¹

$$J_s = \rho v \quad (3)$$

gives the flow per unit-width. This relation is also known as *hydrodynamic relation*.

There are several problems concerning the way in which velocities, densities or time gaps are measured and

¹In strictly one-dimensional motion often a line density (dimension: 1/length) is used. Then the *flow* is given by $J = \rho v$.

the conformance of the two definitions of flow. The flow according to Eq. (1) is usually measured as a mean value over time at a certain location, while the measurement of the density in Eq. (2) is connected with an instantaneous mean value over space. This can lead to a bias caused by underestimation of fast moving pedestrians at the average over space compared to the mean value of the flow over time at a single measurement line (see the discussion for vehicular traffic e. g., in [51,81,102]). Furthermore, most experimental studies measuring the flow according to Eq. (2) combine for technical reasons an *average* velocity of a single pedestrian over time with an *instantaneous* density. To ensure a correspondence of the mean values the average velocity of all pedestrians contributing to the density at a certain instant has to be considered. However this procedure is very time consuming and not realized in practice up to now. Moreover, the fact that the dimension of the test section has usually the same order of magnitude as the extent of the pedestrians can influence the averages over space. These all are possible factors why different measurements can differ in a large way, see discussion in Subsect. “Fundamental Diagram”.

Another way to quantify the pedestrian load of facilities has been proposed by Fruin [35]. The “pedestrian area module” is given by the reciprocal of the density. Thompson and Marchant [184] introduced the so-called “inter-person distance” d , which is measured between center coordinates of the assessing and obstructing persons. According to the “pedestrian area module” Thompson and Marchant call $\sqrt{1/\rho}$ the “average inter-person distance” for a pedestrian stream of evenly spaced persons [184]. An alternative definition is introduced in [58] where the local density is obtained by averaging over a circular region of radius R ,

$$\rho(\mathbf{r}, t) = \sum_j f(\mathbf{r}_j(t) - \mathbf{r}), \quad (4)$$

where $\mathbf{r}_j(t)$ are the positions of the pedestrians j encompassed by \mathbf{r} and $f(\dots)$ is a Gaussian, distance-dependent weight function.

In contrast to the density definitions above, Predtechenskii and Milinskii [151] consider the ratio of the sum of the projection area f_j of the bodies and the total area of the pedestrian stream A , defining the (dimensionless) density $\bar{\rho}$ as

$$\bar{\rho} = \frac{\sum_j f_j}{A}, \quad (5)$$

a quantity known as *occupancy* in the context of vehicular traffic. Since the projection area f_j depends strongly on the

type of person (e. g., it is much smaller for a child than for an adult), the densities for different pedestrian streams consisting of the same number of persons and the same stream area can be quite different.

Beside technical problems due to camera distortions and camera perspective there are several conceptual problems, such as the association of averaged with instantaneous quantities, the need to choose an observation area in the same order of magnitude as the extent of a pedestrian together with the definition of the density of objects with nonzero extent and much more. A detailed analysis of the ways in which measurement influences the relations is necessary but still lacking.

Fundamental Diagram

The fundamental diagram describes the empirical relation between density ρ and flow J . The name indicates its importance and naturally it has been the subject of many investigations. Due to the hydrodynamic relation (3) there are three equivalent forms: $J_s(\rho)$, $v(\rho)$ and $v(J_s)$. In applications the relation is a basic input for engineering methods developed for the design and dimensioning of pedestrian facilities [35,136,150]. Furthermore, it is a quantitative benchmark for models of pedestrian dynamics [21,86,112,175].

In this section we will concentrate on planar facilities such as sidewalks, corridors and halls. For various facilities such as floors, stairs or ramps, the shape of the diagrams differ, but in general it is assumed that the fundamental diagrams for the same type of facilities but having different widths merge into one diagram for the specific flow J_s . In first order this is confirmed by measurements on different widths [49,135,139,142]. However, Navin and Wheeler observed in narrow sidewalks more orderly movement leading to slightly higher specific flows than for wider sidewalks [135]. A natural lower bound for the independence of the specific flow from the width is given by the body size and the asymmetry in movement possibilities of the human body. Surprisingly, Kretz et al. found an increase of the specific flow for bottlenecks with $b \leq 0.7$ m [93]. This will be discussed in more detail later. For the following discussion we assume facility widths larger than $b = 0.6$ m and use the most common representations $J_s(\rho)$ and $v(\rho)$.

Figure 3 shows various fundamental diagrams used in planning guidelines and measurements of two selected empirical studies representing the overall range of the data. The comparison reveals that specifications and measurements disagree considerably. In particular, the maximum of the function giving the capacity $J_{s,\max}$ ranges from 1.2 (ms)^{-1} to 1.8 (ms)^{-1} , the density value where the max-

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 3

Fundamental diagrams for pedestrian movement in planar facilities. The lines refer to specifications according to planning guidelines (SFPE Handbook [136]), Predtechenskii and Milinskii (PM) [150], Weidmann (WM) [192]. Data points give the range of experimental measurements (Older [142] and Helbing [58])

imum flow is reached (ρ_c) ranges from 1.75 m^{-2} to 7 m^{-2} and, most notably, the density ρ_0 , where the velocity approaches zero due to overcrowding, ranges from 3.8 m^{-2} to 10 m^{-2} .

Several explanations for these deviations have been suggested, including cultural and population differences [58,116], differences between uni- and multidirectional flow [99,135,154], short-ranged fluctuations [154], influence of psychological factors given by the incentive of the movement [150] and, partially related to the latter, the type of traffic (commuters, shoppers) [139].

It seems that the most elaborate fundamental diagram is given by Weidmann who collected 25 data sets. An examination of the data which were included in Weidmann's analysis shows that most measurements with densities larger than $\rho = 1.8 \text{ m}^{-2}$ are performed on multidirectional streams [135,139,140,142,148]. But data gained by measurements on strictly unidirectional streams has also been considered [35,49,188]. Thus Weidmann neglected differences between uni- and multidirectional flow in accordance with Fruin, who states in his often cited book [35] that the fundamental diagrams of multidirectional and unidirectional flow differ only slightly. This disagrees with results of Navin and Wheeler [135] and Lam et al. [99] who found a reduction of the flow in dependence of directional imbalances. Here lane formation in bidirectional flow has to be considered. Bidirectional pedestrian flow includes unordered streams as well as lane-separated and thus quasi-unidirectional streams in opposite directions. A more detailed discussion and data can be found

in [99,135,154]. A surprising finding is that the sum of flow and counterflow in corridors is larger than the unidirectional flow and for equally distributed loads it can be twice the unidirectional flow [94].

Another explanation is given by Helbing et al. [58] who argue that cultural and population differences are responsible for the deviations between Weidmann and their data. In contrast to this interpretation the data of Hanking and Wright [49] gained by measurements in the London subway (UK) are in good agreement with the data of Mori and Tsukaguchi [115] measured in the central business district of Osaka (Japan), both on strictly uni-directional streams. This brief discussion clearly shows that up to now there is no consensus about the origin of the discrepancies between different fundamental diagrams and how one can explain the shape of the function.

However, all diagrams agree in one characteristic: velocity decreases with increasing density. As the discussion above indicates there are many possible reasons and causes for the velocity reduction. For the movement of pedestrians along a line, a linear relation between speed and the inverse of the density was measured in [174]. The speed for walking pedestrians depends also linearly on the step size [192] and the inverse of the density can be regarded as the required length for one pedestrian to move. Thus it seems that smaller step sizes caused by a reduction of the available space with increasing density is, at least for a certain density region, one cause for the decrease of speed. However, this is only a starting point for a more elaborated modeling of the fundamental diagram.

Bottleneck Flow

The flow of pedestrians through bottlenecks shows a rich variety of phenomena, e. g., the formation of lanes at the entrance to the bottleneck [64,66,93,176], clogging and blockages at narrow bottlenecks [24,57,93,121,122,150] or some special features of bidirectional bottleneck flow [57]. Moreover, the estimation of bottleneck capacities by the maxima of fundamental diagrams is an important tool for the design and dimensioning of pedestrian facilities.

Capacity and Bottleneck Width One of the most important practical questions is how the capacity of a bottleneck rises with increasing width. Studies of this dependence can be traced back to the beginning of the last century [24,32] and, up to now, have been discussed controversially. As already mentioned in the context of the fundamental diagram there are multiple possible influences on pedestrian flow and thus on the capacity. In the following, the major findings are outlined, demonstrating the complexity of the system and documenting a controversial discussion over one hundred years.

At first sight, a stepwise increase of capacity with the width appears to be natural if lanes are formed. For independent lanes, where pedestrians in one lane are not influenced by those in others, the capacity increases only if an additional lane can be formed. This is reflected in the stepwise enlargement of exit width, which has been a requirement of several building codes and design recommendations. See e. g., the discussion in [146] for the USA and GB and [130] for Germany. e. g.; the German building code requires an exit width (e. g., for a door) to be at least 90 cm plus 60 cm for every 200 persons. Independently from this simple lane model, Hoogendoorn and Daamen [64,66] measured by a laboratory experiment the trajectories of pedestrians passing a bottleneck. The trajectories show that inside a bottleneck the formation of lanes occurs, resulting from the zipper effect occurring on entry to the bottleneck. Due to the zipper effect, a self-organization phenomenon leading to an optimization of the available space and velocity; the lanes are not independent and thus do not allow passing (Fig. 4). The empirical results of [64,66] indicate a distance between lanes of $d \approx 0.45$ m, independent of the bottleneck width b , implying a stepwise increase of capacity. However, the investigation was restricted to two values ($b = 1.0$ m and $b = 2.0$ m) of the width.

In contrast, the study [176] considered more values of the width and found that the lane distance increases continuously as illustrated in Fig. 4. Moreover it was shown that a continuous increase of the lane distance leads to

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 4

A sketch of the zipper effect with continuously increasing lane distances in x : The distance in the walking direction decreases with increasing lateral distance. Density and velocities are the same in all cases, but the flow increases continuously with the width of the section

a very weak dependence on its width of the density and velocity inside the bottleneck. Thus in reference to Eq. (2) the flow does not necessarily depend on the number of lanes. This is consistent with common guidelines and handbooks² which assume that the capacity is a linear function of the width [35,136,150,192]. It is given by the maximum of the fundamental diagram and in reference to the specific flow concept introduced in Subsect. “Observables”, Eqs. (2), (3), the maximum grows linearly with the facility width. To find a conclusive judgment on the question if the capacity grows continuously with the width the results of different laboratory experiments [93,121,122,132,176] are compared in [176].

In the following we discuss the data of flow measurement collected in Fig. 5. The corresponding setups are sketched in Fig. 6. First, note that all presented data are taken under laboratory conditions where the test persons are advised to move normally. The data by Muir et al. [121], who studied the evacuation of airplanes (see Fig. 6b), seem to support the stepwise increase of flow with the width. They show constant flow values for $b > 0.6$ m. But the independence of flow over the large range from $b = 0.6$ m to $b = 1.8$ m indicates that in this special setup the flow is not restricted by the bottleneck width. Moreover, it was shown in [176] by determination of the trajectories that the distance between lanes changes continuously, invalidating the basic assumption leading to a stepwise increasing flow. Thus all collected data for flow measurements in Fig. 5 are compatible with a continuous

²One exception is the German MVStättV [130], see above.

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 5

Influence of the width of a bottleneck on the flow. Experimental data [121,122,132,176] of different types of bottlenecks and initial conditions. All data are taken under laboratory conditions where the test persons are advised to move normally

and almost linear increase with the bottleneck width for $b > 0.6$ m.

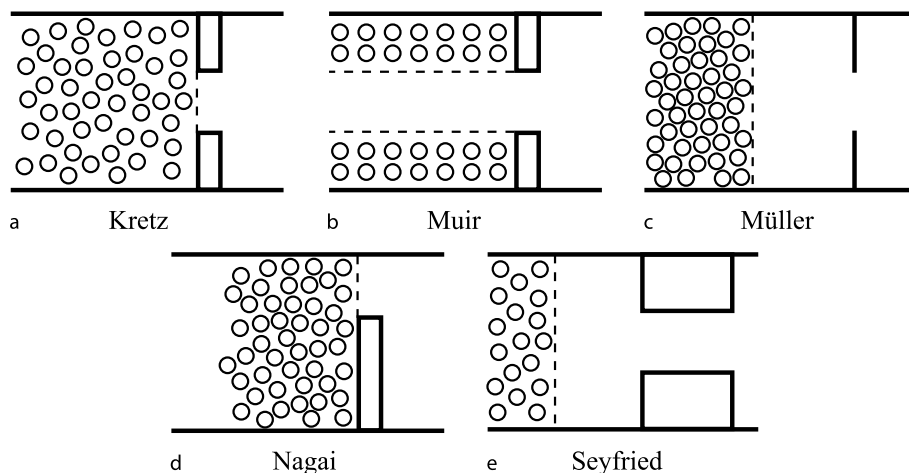

The data in Fig. 5 differ considerably in values of bottleneck capacity. In particular, the flow values of Nagai [132] and Müller [122] are much higher than the maxima of empirical fundamental diagrams (see Sub-

sect. “Fundamental Diagram”). The influence of “panic” or pushing can be excluded since in all experiments the participants were instructed to move normally. The comparison of the different experimental setups (Fig. 6) shows that the exact geometry of the bottleneck is of only minor influence on the flow, while a high initial density in front of the bottleneck can increase the resulting flow values. This is confirmed by the study of Nagai et al., see Figure 6 in [132]. There it is shown that for $b = 1.2$ m the flow grows from $J = 1.04 \text{ s}^{-1}$ to 3.31 s^{-1} when the initial density is increased from 0.4 m^{-2} to 5 m^{-2} .

The linear dependence of the flow on the width has a natural limitation due to the nonzero body-size and the asymmetry given by the sequence of movement in steps. Movement of pedestrians through bottlenecks smaller than shoulder width requires a rotation of the body. Kretz et al. found in their experiment [93] that the specific flow J_s increases if the width decreases from $b = 0.7$ m to $b = 0.4$ m.

Connection Between Bottleneck Flow and Fundamental Diagrams

An interesting question is how the bottleneck flow is connected to the fundamental diagram. General results for driven diffusive systems [149] show that boundary conditions only *select* between the states of the undisturbed system instead of creating completely different ones. Therefore it is surprising that the measured maximal flow at bottlenecks can exceed the maximum of the empirical fundamental diagram. These questions are related to the common jamming criterion. Generally, it is assumed that a jam occurs if the incoming flow exceeds the capacity of the bottleneck. In this case one expects the

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 6

Outlines of the experimental arrangements under which the data shown in Fig. 5 were taken

flow through the bottleneck to continue with the capacity (or lower values).

The data presented in [176] show a more complicated picture. While the density in front of the bottleneck amounts to $\rho \approx 5.0(\pm 1) \text{ m}^{-2}$, the density inside the bottleneck tunes around $\rho \approx 1.8 \text{ m}^{-2}$. The observation that the density inside the bottleneck is lower than in front of the bottleneck is consistent with measurements of Daamen and Hoogendoorn [20] and the description given by Predtechenskii and Milinskii in [150]. The latter assumes that in the case of a jam the flow through the bottleneck is determined by the flow in front of the bottleneck. The density inside the jam will be higher than the density associated with the capacity. Thus the reduced flow in front of the bottleneck causes a flow through the bottleneck smaller than the bottleneck capacity. Correspondingly the associated density is also smaller than that at capacity. But the discussion above cannot explain why the capacities measured at bottlenecks are significantly higher than the maxima of empirical fundamental diagrams and cast doubts on the common jamming criterion. Possible unconsidered influences are stochastic flow fluctuations, non-stationarity of the flow, flow interferences due to the necessity of local organization or changes of the incentive during the access into the bottleneck.

Blockages in Competitive Situations As stated above all data collected in Fig. 5 are gained by runs where the test persons were instructed to move normally. By definition a bottleneck is a limited resource and it is possible that under competitive situations pedestrian flow through bottlenecks is different from the flow in normal situations. One qualitative difference to normal situations is the occurrence of blockages. Regarding the term ‘panic’ one has to bear in mind that for the occurrence of blockages some kind of reward is essential, while the emotional state of the test persons is not. This was a result of a very interesting and often cited study by Mintz [113]. First experiments with real pedestrians have been performed by Dieckmann [24] in 1911 as a reaction to many fatalities in theater fires at the end of the 19th century. In these small scale experiments test persons were instructed to go through great trouble to pass the door as fast as possible. Even in the first run he observed a stable “wedging”. In [150] it is described how these obstruction occurs due to the formation of arches in front of the door under high pressure. This is very similar to the well-known phenomenon of *arching* occurring in the flow of granular materials through narrow openings [194].

Systematic studies including the influence of the shape and width of the bottleneck and comparisons with flow

values under normal situations have been performed by Müller and Muir et al. [121,122]. Müller found that funnel-like geometries support the formation of arches and thus blockages. For further discussion, one must distinguish between temporary blockages and stable blockages leading to a zero flow. For the setup sketched in Fig. 6c Müller found that temporary blockages occur only for $b < 1.8 \text{ m}$. For $b \leq 1.2 \text{ m}$ the flow shows strong pulsing due to unstable blockages. Temporal disruptions of the flow appear for $b \leq 1.0 \text{ m}$. In comparison to normal situations the flow is higher, and in general the occurrence of blockages decreases with width. However a surprising result is that for narrow bottlenecks, increasing the width can be counterproductive since it also increases the probability of blockages. Muir et al. for example note that in their setup (Fig. 6b) the enlargement of the width from $b = 0.5 \text{ m}$ to $b = 0.6 \text{ m}$ leads to an increase of temporary blockages. The authors explain this by differences in the perception of the situation by the test persons. While the smaller width is clearly passable only for one person, the wider width may lead to the perception that the bottleneck is sufficiently wide to allow two persons to pass through. How many people have direct access to the bottleneck is clearly influenced by the width of the corridor in front of the bottleneck. Also, Müller found hints that flow under competitive situations did not increase in general with the bottleneck width. He notes an optimal ratio of 0.75:1 between the bottleneck width and the width of the corridor in front of the bottleneck.

To reduce the occurrence of blockages, and thus evacuation times, Helbing et al. [54,55,83] suggested putting a column (asymmetrically) in front of a bottleneck. It should be emphasized that this theoretical prediction was made under the assumption that the system parameters, i. e., the basic behavior of the pedestrians, does not change in the presence of the column. This is highly questionable in real situations where a column can be perceived as an additional obstacle or can make it difficult to find the exit. In experiments [57] an increase of the flow of about 30% has been observed for a door with $b = 0.82 \text{ m}$. But this experiment was performed only for one width and the discussion above indicates the strong influence of the specific setup used. Independent of this uncertainty this concept is limited, as the occurrence of stable arches, to narrow bottlenecks. In practice narrow bottlenecks are not suitable for a large number of people and an opening in a room has other important functionalities, which would be restricted by a column.

Another finding is the observation that the total flow at bottlenecks with bidirectional movement is higher than it is for unidirectional flows [57].

Stairs

In most evacuation scenarios stairs are important elements that are a major determinant for the evacuation time. Due to their physical dimension, which is often smaller than other parts of a building, or due to a reduced walking speed, stairs generally must be considered as bottlenecks for the flow of evacuees. For the movement on stairs, just as for the movement on flat terrain, the fundamental diagram is of central interest. Compared to the latter there are more degrees of freedom, which influence the fundamental diagram:

- One has to distinguish between upward and downward movement.
- The influence of riser height and tread width (which determine the incline) has to be taken into account.
- For upward motion exhaustion effects lead to a strong time dependence of the free speed.

It is probably a consequence of the existence of a continuum of fundamental diagrams in dependence of the incline that there are no generally accepted fundamental diagrams for movement on stairs. However, there are studies on various details—mostly the free speed—of motion on stairs in dependence of the incline [35,38,39,46], conditions (comfortable, normal, dangerous) [151], age and sex [35], tread width [33], and the length of a stair [95]; and in consideration of various disabilities [11].

In addition there are some compilations or “meta studies”: Graat [46] compiled a list of capacity measurements and Weidmann [192] built an average of 58 single studies and found an average for the horizontal upstairs speed—the speed when the motion is projected to the horizontal level—of 0.610 m/s.

Depending on various parameters, the aforesaid studies report horizontal upward walking speeds varying over a wide range from 0.391 to 1.16 m/s. Interestingly, on one and the same short stairs it could be observed [95] that people on average walked faster up- than downwards.

There is also a model where the upstairs speed is calculated from the stair geometry (riser and tread) [183] and an empirical investigation of the collision avoidance behavior on stairs [37].

On stairs (up- as well as downward) people like to put their hand on the handrail, i. e., they tend to walk close to walls, even if there is no counterflow. This is in contrast to movement on flat terrain, where at least in situations of low density there is a tendency to keep some distance from walls.

The movement on stairs is typically associated with a reduction of the walking speed. For upward motion this

follows from the increased physical effort required. This has two aspects: first, there is the physical potential energy that a pedestrian has to supply if he wants to rise in height; second, the motion process itself is more exertive – the leg has to be lifted higher – than during motion on a level, even if this motion process is executed only on the spot. Concerning the potential energy there is no comparable effect for people going downstairs. But still one can observe jams forming at the upper end of downstairs streams. These are due to the slight hesitation that occurs when pedestrians synchronize their steps with the geometry of the (down-)stairs ahead. Therefore the bottleneck character of downstairs is less a consequence of the speed on the stairs itself and more of the transition from planar to downward movement, at least as long as the steps are not overly steep.

Evacuations: Empirical Results

Up to now this section has focused on empirical results for pedestrian motion in rather simple scenarios. As we have seen there are many open questions where no consensus has been reached, sometimes even about the qualitative aspects. This becomes even more relevant for full-scale descriptions of evacuations from large buildings or cruise ships. These are typically a combination of many of the simpler elements, so a lack of reliable information is not surprising. In the following we will discuss several complex scenarios in more detail.

Evacuation Experiments In the case of an emergency, the movement of a crowd usually is more straightforward than in the general case. Commuters in a railway station, for example, or visitors of a building might have complex itineraries which are usually represented by origin-destination matrices. In the case of an evacuation, however, the aims and routes are known and usually the same, i. e., the exits and the egress routes. This is the reason why an evacuation process is rather strictly limited in space and time, i. e., its beginning and end are well-defined: the sound of the alarm, initial position of all persons, safe areas (final position of all persons), and the time at which the last person reaches the safe area. When all people have left a building or vessel and reached a safe area (or the lifeboats or life rafts), then the evacuation is finished. Therefore, it is also possible to perform evacuation trials and measure overall evacuation times. Before we go into details, we will clarify three different aspects of data on evacuation processes:

- (1) The definition and parts of evacuation time,
- (2) The different sources of data, and
- (3) The application of these data.

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 7

Empirical data can be roughly classified according to controlled/uncontrolled and emergency/normal situations

Concerning the evacuation time, five different phases can be distinguished [48,118,153]:

- (1) Detection time,
- (2) Awareness time,
- (3) Decision time,
- (4) Reaction time, and
- (5) Movement time.

In IMO's regulations [118,119], the first four are grouped together into *response time*. Usually, this time is called *pre-movement time*

One possible scheme for the classification of data on evacuation processes is shown in the following Fig. 7.

Please note that not only data obtained from uncontrolled or emergency situations can be used in the context of evacuation assessment. Knowledge about bottleneck capacities (i. e., flows through doors and on stairs) is especially important when assessing the layout of a building with respect to evacuation. The purpose of empirical data in the context of evacuation processes (and modeling in general) is threefold [43,71]:

- (1) Identify parameters (factors that influence the evacuation process, e. g., bottleneck widths and capacities),
- (2) Quantify (calibrate) those parameters, e. g., flow through a bottleneck in persons per meter per second, and
- (3) Validate simulation results, e. g., compare the overall evacuation time measured in an evacuation with simulation or calculation results.

The validation is usually based on data from the evacuation of complete buildings, aircraft, trains or ships. These are available from two different sources:

- (1) Full scale evacuation trials and
- (2) Real evacuations.

Evacuation trials are usually observed and videotaped. Reports of real evacuation processes are obtained from eyewitness records and a posteriori incident investigations. Since the setting of a complete evacuation is not experimental, it is hardly possible to measure microscopic features of the crowd motion. Therefore, calibration of parameters is usually not the main purpose in evacuation trials; rather, they are carried out to gain knowledge about the overall evacuation process, the behavior of the persons, to identify the governing influences/parameters and to validate simulation results.

One major concern in evacuation exercises is the well-being of the participants. Due to practical, financial, and ethical constraints, an evacuation trial cannot be, by nature, realistic. Therefore, an evacuation exercise does not convey the increased stress of a real evacuation. To draw conclusions on the evacuation process, the walking speed observed in an exercise should not be assumed to be higher in a real evacuation [145]. Along the same lines of argument, a simplified evacuation analysis based on, e. g., a hydro-dynamic model can predict an evacuation exercise, and the same constraints apply for its results concerning the prediction of evacuation times and the evacuation process. If population parameters (such as gender, age, walking speed, etc.) are explicitly stated in the model, increased stress can be simulated by adapting these parameters.

In summary, evacuation exercises are just too expensive, time consuming, and dangerous to be a standard measure for evacuation analysis. An evacuation exercise organized by the UK Marine Coastguard Agency on the Ro-Ro ferry "Stena Invicta" held in Dover Harbor in 1996 cost more than 10,000 GBP [117]. This is one major argument for the use of evacuation simulations based on hydro-dynamic models and calculations.

Panic, Herding, and Similar Conjectured Collective Phenomena As already mentioned earlier in Subsect. "Collective Effects", the concept of "panic" and its relevance for crowd disasters is rather controversial. It is usually used to describe irrational and unsocial behavior. In the context of evacuations, empirical evidence shows that this type of behavior is rare [3,17,77,178]. On the other hand there are indications that fear might be "contagious" [22]. Related concepts like "herding" and "stampede" imply a certain similarity between the behavior of human crowds and animal behavior. This terminology is quite often used in the public media. *Herding* has been described in animal experiments [166] and is difficult to measure in human crowds. However, it seems to be natural that herding exists in certain situations, e. g., limited

visibility due to failing lights or strong smoke when exits are hard to find.

Panic As stated earlier, “panic” behavior is usually characterized by selfish and anti-social behavior which through contagion affects large groups and even leads to completely irrational actions. Often it is assumed, especially in the media, to occur in situations where people compete for scarce or dwindling resources, which in the case of emergencies are safe space or access to an exit. However, this point of view does not stand close scrutiny and it has turned out that this behavior has played no role at all in many tragic events [73,77]. For these incidents *crowd disaster* is a much more appropriate characterization.

Furthermore, lack of social behavior seems to be more frequent during so called “acquisitive panics” or “crazes” [179] than during “flight panics”. That is, social behavior seems to be less stable if there is something to gain than if there is some external danger which threatens all members of a group. Examples of crazes (acquisitive panics) include the Victoria Hall Disaster (1883) [150], the crowning ceremony of Tsar Nicholas II (1896) [168], a governmental Christmas celebration in Aracaju (2001), the distribution of free Saris in Uttar Pradesh (2004), and the opening of an IKEA store in Jeddah (2004). Crowd accidents which occur at rock concerts and religious events as well bear more similarities with crazes than with panics.

However, it is not the case that altruism and cooperation increase with danger. The events during the capsizing of the MV Estonia (see Sect. 16.6 of [100]) show some behavioral threshold: faced with immediate life-threatening danger, most people struggle for their own survival or that of close relatives.

Herding Herding in a broad context means “go with the flow” or “follow the crowd”. Like “panic”, the term “herding” is often used in the context of stock market crashes, i. e., causing an avalanche effect. Like “panic” the term is usually not well defined and is used in an allegoric way. Therefore, it is advisable to avoid the term in a scientific context (apart from zoology, of course). Furthermore, “herding”, “stampede”, and “panic” have a strong connotation of “deindividuation”. The conjecture of an automatic deindividuation caused by large crowds [101] has been replaced by a social attachment theory (“the typical response to a variety of threats and disasters is not to flee but to seek the proximity of familiar persons and places”) [109].

Stampede Stampede is – like herding – a term from zoology where herds of large mammals, such as buffalo, collectively run in one direction and might overrun any obsta-

cles. This is dangerous for human observers if they cannot get out of the way. The term “stampede” is sometimes used for crowd accidents [73], too. It is furthermore assumed to be highly correlated with panic. When arguing along those lines, a stampede might be the result of “crowd panic” or vice versa.

Shock or Density Waves Shock waves are reported for rock concerts [180] and religious events [2,58]. They might result in people standing close to each other falling down. Pressures in dense crowds of up to 4, 450 N/m² have been reported.

Although empirical data on crowd disasters exist, e. g., in the form of reports from survivors or even video footage, it is almost impossible to derive quantitative results from them. Models that aim at describing such scenarios make predictions for certain counter-intuitive phenomena that should occur. In the faster-is-slower effect [54] a higher desired velocity leads to a slower movement of a large crowd. In the freezing-by-heating effect [53] increasing the fluctuations can lead to a more ordered state. For a thorough discussion we refer to [54,55] and references therein. However, from a statistical point of view there is insufficient data to decide the relevance of these effects in real emergency situations, not least because it is almost impossible to perform “realistic” experiments.

Sources of Empirical Data on Evacuation Processes

The evacuation of a building can either be an isolated process (due to fire restricted to this building, a bomb threat, etc.) or it can be part of the evacuation of a complete area. We will focus on the single building evacuation, here. For the evacuation of complete areas, e. g., because of flooding or hurricanes, cf. [157] and references therein.

For passenger ships, a distinction between High Speed Craft (HSC), Ro-Ro passenger ferries, and other passenger vessels (cruise ships) is made. High Speed Craft do not have cabins and the seating arrangement is similar to aircraft. Therefore, there is a separate guideline for HSC [119]. A performance-based evacuation analysis at an early stage of design is required for HSC and Ro-Pax. There is currently no such requirement for cruise ships. For an overview of IMO’s requirements and the historical development up to 2001 cf. [27]. In addition to the five components for the overall evacuation time listed above, there are three more specific to ships:

- (6) Preparation time (for the life-saving appliances, i. e., lifeboats, life-rafts, davits, chutes),
- (7) Embarkation time, and
- (8) Launching time.

Therefore, the evacuation procedure on ships is more complex than for buildings. Additionally, SAR (Search And Rescue) is an integral part of ship evacuation.

For High Speed Craft, the time limit is 17 minutes for evacuation [70], for Ro-Ro passenger ships it is 60 minutes [118], and for all other passenger ships (e. g., cruise ships) it is 60 minutes if the number of main vertical zones is less or equal to five and 80 minutes otherwise [118]. For HSC, no distinction is made between assembly and embarkation phases.

For aircraft, the approach can be compared to that of HSC. First, an evacuation test is mandatory and there is a time limit of 90 seconds that has to be complied to in the test [31].

In many countries there is no strict criterion for the maximum evacuation time of buildings. The requirements are based on minimum exit widths and maximum escape path lengths.

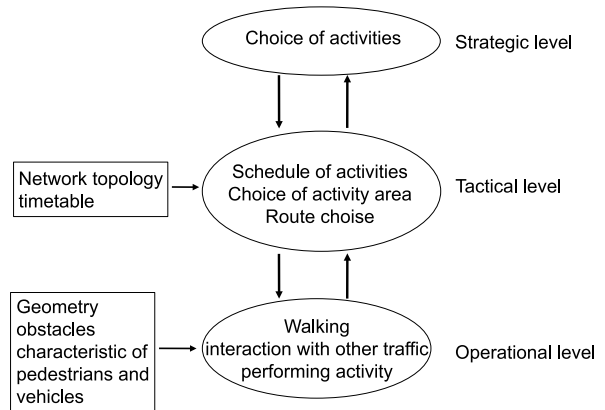

A number of real evacuations has been investigated and reports are publicly available. Among the most recent ones are: Beverly Hills Club [12], MGM Grand Hotel, [12], retail store [4], department store [1], World Trade Center [47] and www.wtc.nist.gov, high-rise buildings [144, 173], theater [191] for buildings, High Speed Craft “Sleipner” [138] for HSC, an overview up to 1998 [143], exit width variation [121], double deck aircraft [74], another overview for aircraft [120], and for trains [43,169].

Modeling

A comprehensive theory of pedestrian dynamics has to take into account three different levels of behavior (Fig. 8). At the *strategic level*, pedestrians decide which activities they like to perform and the order of these activities. With the choices made at the strategic level, the *tactical level* concerns the short-term decisions made by the pedestrians, e. g., choosing the precise route taking into account obstacles, density of pedestrians etc. Finally, the *operational level* describes the actual walking behavior of pedestrians, e. g., their immediate decisions necessary to avoid collisions etc.

Processes at the strategic and tactical level are usually considered to be exogenous to pedestrian simulation. Here information from other disciplines (sociology, psychology etc.) is required. In the following we will mostly be concerned with the operational level, although some of the models that we are going to describe allow us to take into account certain elements of behavior at the tactical level as well.

Modeling on the operational level is usually based on variations of models from physics. Indeed the motion of

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 8

The different levels of modeling pedestrian behavior (after [19, 65])

pedestrian crowds shares certain similarities with fluids and the flow of granular materials. The goal is to find models which are as simple as possible, but at the same time can reproduce “realistic” behavior in the sense that the empirical observations are reproduced. Therefore, based on the experience from physics, pedestrians are often modeled as simple “particles” that interact with each other.

There are several characteristics which can be used to classify the modeling approaches:

Microscopic vs. macroscopic In microscopic models each individual is represented separately. Such an approach allows us to introduce different types of pedestrians with individual properties as well as issues such as route choice. In contrast, in macroscopic models, individuals cannot be distinguished. Instead the state of the system is described by densities, usually a mass density derived from the positions of the persons and a corresponding locally averaged velocity.

Discrete vs. continuous Each of the three basic variables for a description of a system of pedestrians, namely space, time and state variable (e. g., velocities), can be either discrete (i. e., an integer number) or continuous (i. e., a real number). Here all combinations are possible. In a cellular automaton approach all variables are by definition discrete, whereas in hydrodynamic models all are continuous. These are the most common choices, but other combinations are used as well. Sometimes for a cellular automata approach a continuous time variable is also allowed. In computer simulation this is realized through a *random-sequential update* where at each step the particle or site to be up-

dated (moved) is chosen randomly (from *all* particles or sites, respectively). A discrete time is usually realized through a *parallel* or *synchronous update* where all particles or sites are moved at the same time. This introduces a timescale. In so-called coupled map lattices time is discrete, whereas space and state variables are continuous.

Deterministic vs. stochastic The dynamics of pedestrians can either be deterministic or stochastic. In the first case the behavior at a certain time is completely determined by the present state. In stochastic models, behavior is controlled by certain probabilities such that the agents can react differently in the same situation. This is one of the lessons learnt from the theory of complex systems where it has been shown for many examples that through introduction of stochasticity into rather simple systems very complex behavior can be generated. On the other hand, the stochasticity in the models reflects our lack of knowledge of the underlying physical processes that, e. g., determine the decision-making of the pedestrians. Through stochastic behavioral rules it often becomes possible to generate a rather realistic representation of complex systems such as pedestrian crowds.

This “intrinsic” stochasticity should be distinguished from “noise”. Sometimes external noise terms are added to the *macroscopic* observables, such as position or velocity. Often the main effect of these terms is to avoid certain special configurations which are considered to be unrealistic, like completely blocked states. Otherwise the behavior is very similar to the deterministic case. For true stochasticity, on the other hand, the deterministic limit usually has very different properties from the generic case.

Rule-based vs. force-based Interactions between the agents can be implemented in at least two different ways: In a rule-based approach agents make “decisions” based on their current situation, the nature of their neighborhood as well as their goals, etc. It focuses on the *intrinsic properties* of the agents and thus the rules are often justified from psychology. In force-based models, agents “feel” a force exerted by others and the infrastructure. They therefore emphasize *extrinsic properties* and their relevance for the motion of the agents. This is a physical approach based on the observation that the presence of others leads to deviations from a straight motion. In analogy to Newtonian mechanics a force is made responsible for these accelerations.

Cellular automata are typically rule-based models, whereas, e. g., the social-force model belongs to the

force-based approaches. However, sometimes a clear distinction cannot be made; many models combine aspects of both approaches.

High vs. low fidelity *Fidelity* here refers to the apparent realism of the modeling approach. High fidelity models try to capture the complexity of decision making, actions, etc. that constitute pedestrian motion in a realistic way. In contrast, in the simplest models pedestrians are represented by particles without any intelligence. Usually the behavior of these particles is determined by “forces”. This approach can be extended, e. g., by allowing different “internal” states of the particles so that they react differently to the same force depending on the internal state. This can be interpreted as some kind of “intelligence” and leads to more complex approaches, like multi-agent models. Roughly speaking, the number of parameters in a model is a good measure for fidelity in the sense introduced here, but note that higher fidelity does not necessarily mean that empirical observations are reproduced better!

It should be mentioned that a clear classification according to the characteristics outlined here is not always possible. In the following we will describe some model classes in more detail.

Fluid-dynamic and Gas kinetic Models

Pedestrian dynamics has some obvious similarities with fluids. For example, the motion around obstacles appears to follow “streamlines”. Motion at intermediate densities is restricted (short-ranged correlations). Therefore it is not surprising that, very much like for vehicular dynamics, the earliest models of pedestrian dynamics took inspiration from hydrodynamics or gas-kinetic theory [50,61,68,69]. Typically these macroscopic models are deterministic, force-based and of low fidelity.

Henderson [60,61] has tried to establish an analogy of large crowds with a classical gas. From measurements of motion in different crowds in a low density (“gaseous”) phase he found good agreement of the velocity distribution functions with Maxwell–Boltzmann distribution [60].

Motivated by this observation, he later developed a fluid-dynamic theory of pedestrian flow [61]. Describing the interactions between the pedestrians as a collision process where the particles exchange momenta and energy, a homogeneous crowd can be described by the well-known kinetic theory of gases. However, the interpretation of the quantities is not entirely clear, e. g., what the analogues of pressure and temperature are in the context of pedestrian

motion. Temperature could be identified with the velocity variance, which is related to the distribution of desired velocities, whereas the pressure expresses the desire to move against a force in a certain direction.

The applicability of classical hydrodynamic models is based on several conservation laws. The conservation of mass, corresponding to conservation of the total number of pedestrians, is expressed through a continuity equation of the form

$$\frac{\partial \rho(\mathbf{r}, t)}{\partial t} + \nabla \cdot \mathbf{J}(\mathbf{r}, t) = 0, \quad (6)$$

which connects the local density $\rho(\mathbf{r}, t)$ with the current $\mathbf{J}(\mathbf{r}, t)$. This equation can be generalized to include source and sink terms. However, the assumption of conservation of energy and momentum is not true for interactions between pedestrians which in general do not even satisfy Newton's Third Law ("actio = reaction"). In [50] several other differences to normal fluids were pointed out, e. g., the anisotropy of interactions or the fact that pedestrians usually have an individual preferred direction of motion.

In [50] a better founded fluid-dynamical description was derived on the basis of a gas kinetic model which describes the system in terms of a density function $f(\mathbf{r}, \mathbf{v}, t)$. The dynamics of this function are determined by Boltzmann's transport equation that describes its change for a given state as difference of inflow and outflow due to binary collisions.

An important new aspect in pedestrian dynamics is the existence of desired directions of motion which allows us to distinguish different groups μ of particles. The corresponding densities f_μ change in time due to four different effects:

1. A relaxation term with characteristic time τ describes tendency of pedestrians to approach their intended velocities.
2. The interaction between pedestrians is modeled by a Stosszahlansatz as in the Boltzmann equation. Here, pair interactions between types μ and ν occur with a total rate that is proportional to the densities f_μ and f_ν .
3. Pedestrians are allowed to change from type μ to ν which, e. g., accounts for turning left or right at a crossing.
4. Additional gain and loss terms allow us to model entrances and exits where pedestrian can enter or leave the system.

The resulting fluid-dynamic equations derived from this gas kinetic approach are similar to that of ordinary fluids.

However, due to the different types of pedestrians, corresponding to individuals who have approximately the same desired velocity, one actually obtains a set of coupled equations describing several interacting fluids. These equations contain additional characteristic terms describing the approach to the intended velocity and the change of fluid-type due to interactions in avoidance maneuvers.

Equilibrium is approached through the tendency to walk with the intended velocity, not through interactions as in ordinary fluids. Momentum and energy are not conserved in pedestrian motion, but the relaxation towards the intended velocity describes a tendency to restore these quantities.

Unsurprisingly for a macroscopic approach, the gas-kinetic models have problems at low densities. For a discussion, see e. g. [50].

Hand Calculation method For practical applications effective engineering tools have been developed from the hydrodynamical description. In engineering these are often called *hand calculation methods*. One could also classify some of them as queuing models since the central idea is to describe pedestrian dynamics as flow on a network with links of limited capacities. These methods allow us to calculate evacuation times in a relatively simple way that does not require any simulations. Parameters entering in the calculations can be adapted to the situation that is studied. Often they are based on empirical results, e. g., evacuation trials. Details about this kind of model can be found in Subsect. "Calculation of Evacuation Times".

Social-Force Models

The social-force model [52] is a deterministic continuum model in which interactions between pedestrians are implemented by using the concept of a *social force* or *social field* [103]. It is based on the idea that changes in behavior can be understood in terms of fields or forces. Applied to pedestrian dynamics, the social force $\mathbf{F}_j^{(\text{soc})}$ represents the influence of the environment (other pedestrians, infrastructure) and changes the velocity \mathbf{v}_j of pedestrian j . Thus it is responsible for acceleration which justifies the interpretation as a force. The basic equation of motion for a pedestrian of mass m_j is then of the general form

$$\frac{d\mathbf{v}_j}{dt} = \mathbf{f}_j^{(\text{pers})} + \mathbf{f}_j^{(\text{soc})} + \mathbf{f}_j^{(\text{phys})} \quad (7)$$

where $\mathbf{f}_j^{(\text{soc})} = \frac{1}{m_j} \mathbf{F}_j^{(\text{soc})} = \sum_{l \neq j} \mathbf{f}_{jl}^{(\text{soc})}$ is the total (specific) force due to other pedestrians. $\mathbf{f}_j^{(\text{pers})}$ denotes a "personal" force which makes a pedestrian attempt to move with his or her own preferred velocity $\mathbf{v}_j^{(0)}$ and thus acts as a driving

term. It is given by

$$\mathbf{f}_j^{(\text{pers})} = \frac{\mathbf{v}_j^{(0)} - \mathbf{v}_j}{\tau_j} \quad (8)$$

where τ_j is reaction or acceleration time. In high density situations, physical forces $\mathbf{f}_{jl}^{(\text{phys})}$ also become important, e. g., friction and compression when pedestrians make contact.

The most important contribution to the social force $\mathbf{f}_j^{(\text{soc})}$ comes from the territorial effect, i. e., the private sphere. Pedestrians feel uncomfortable if they get too close to others, which effectively leads to a repulsive force between them. Similar effects are observed for the environment, e. g., people prefer not to walk too close to walls.

Since social forces are difficult to determine empirically, some assumptions must be made. Usually an exponential form is assumed. Describing the pedestrians as disks of radius R_j and position (of the center of mass) \mathbf{r}_j , the typical structure of the force between the pedestrians is described by [54]

$$\mathbf{f}_{jl}^{(\text{soc})} = A_j \exp\left[\frac{R_{jl} - \Delta r_{jl}}{\xi_j}\right] \mathbf{n}_{jl} \quad (9)$$

with $R_{jl} = R_j + R_l$, the sum of the disk radii, $\Delta r_{jl} = |\mathbf{r}_j - \mathbf{r}_l|$, the distance between the centers of mass, $\mathbf{n}_{jl} = \mathbf{r}_j - \mathbf{r}_l / \Delta r_{jl}$, the normalized vector pointing from pedestrian l to j . A_j can be interpreted as strength, ξ_j as the range of the interactions.

The appeal of the social-force model is given mainly by analogy to Newtonian dynamics. For the solution of the equations of motion of Newtonian many-particle systems, well-founded molecular dynamics techniques exist. However, in most studies so far the distinctions between pedestrian and Newtonian dynamics are not discussed in detail. A straightforward implementation of the equations of motion neglecting these distinctions can lead to unrealistic movement of single pedestrians. For example, negative velocities in the main moving direction cannot be excluded in general even if asymmetric interactions (violating Newton's Third Law) between the pedestrians are chosen. Another effect is the occurrence of velocities higher than the preferred velocity $v_j^{(0)}$ due to the forces on pedestrians in the moving direction. To prevent this effect, additional restrictions for the degrees of freedom must be introduced, see for example [52], or the superposition of forces has to be discarded [175]. A general discussion of the limited analogy between Newtonian dynamics and the social-force model as well as the consequences for model implementations is still missing.

Apart from the ad hoc introduction of interactions, the structure of the social-force model can also be derived from an extremal principle [62,63]. It follows under the assumption that pedestrian behavior is determined by the desire to minimize a certain cost function which takes into account not only kinematic aspects and walking comfort, but also deviations from a planned route.

Cellular Automata

Cellular automata (CA) are rule-based dynamical models that are discrete in space, time and state variable which in the case of traffic usually corresponds to velocity. Discreteness in time means that the positions of the agents are updated in well defined steps. In computer simulations this is realized through a *parallel* or *synchronous* update where all pedestrians move at the same time. The time step corresponds to a natural timescale Δt which could be identified, e. g., with some reaction time. This can be used for the calibration of the model which is essential for making quantitative predictions. A natural space discretization can be derived from the maximal densities observed in dense crowds which gives the minimal space requirement of one person. Usually each cell in the CA can be occupied by only one particle (exclusion principle) so that this space requirement can be identified with the cell size. In this way, a maximal density of 6.25 P/m^2 [192] leads to a cell size of $40 \times 40 \text{ cm}^2$. Sometimes finer discretizations are more appropriate (see Subsect. "Theoretical Results"). In this case pedestrians correspond to extended particles that occupy more than one cell (e. g., four cells). The exclusion principle and the modeling of humans as non-compressible particles mimics short-range repulsive interactions, i. e., the "private-sphere".

The dynamics are usually defined by rules which specify transition probabilities for motion to one of the neighboring cells (Fig. 9). The models differ in the specification of these probabilities as well in that of the "neighborhood". For deterministic models, all but one are of probability zero.

The first cellular automata (CA) models [7,41,89,129] for pedestrian dynamics can be considered two-dimensional variants of the asymmetric simple exclusion process (ASEP) (for reviews, see [9,23,172]) or models for city or highway traffic [6,16,133] based on it. Most of these models represent pedestrians by particles without any internal degrees of freedom. They can move to one of the neighboring cells based on certain transition probabilities which are determined by three factors:

- (1) The desired direction of motion, e. g., to find the shortest connection,

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 9

A particle, its possible directions of motion and the corresponding transition probabilities p_{ij} for the case of a von Neumann neighborhood

- (2) Interactions with other pedestrians, and
- (3) Interactions with the infrastructure (walls, doors, etc.).

Fukui–Ishibashi Model One of the first CA models for pedestrian dynamics was proposed by Fukui and Ishibashi [40,41] and is based on a two-dimensional variant of the ASEP. They studied bidirectional motion in a long corridor where particles moving in opposite directions were updated alternately. Particles move deterministically in their desired direction; only if the desired cell is occupied by an oppositely moving particle do they make a random sidestep.

Various extensions and variations of the model have been proposed, e.g., an asymmetric variant [129] where walkers prefer lane changes to the right, different update types [193], simultaneous (exchange) motion of pedestrians standing “face-to-face” [72], or the possibility of backstepping [107]. The influence of the shape of the particles has been investigated in [131]. Also other geometries [128, 181] and extensions to full 2-dimensional motion have been studied in various modifications [106,107,127]

Blue–Adler Model The model of Blue and Adler [7,8] is based on a variant of the Nagel–Schreckenberg model [133] of highway traffic. Pedestrian motion is considered in analogy to a multi-lane highway. The structure of the rules is similar to the basic two-lane rules suggested in [159]. The update is performed in four steps which are applied to all pedestrians in parallel. In the first step each pedestrian chooses a preferred lane. In the second step the lane changes are performed. In the third step the velocities are determined based on the available gap in the new lanes. Finally, in the fourth step the pedestrians move forward according to the velocities determined in the previous step.

In counterflow situations head-on-conflicts occur. These are resolved stochastically and with some probability opposing pedestrians are allowed to exchange positions within one time step. Note that the motion of a sin-

gle pedestrian (not interacting with others) is deterministic otherwise.

Unlike the Fukui–Ishibashi model, motion is not restricted to nearest-neighbor sites. Instead, pedestrians can have different velocities v_{\max} which correspond to the maximal number of cells they are allowed to move forward. In contrast to vehicular traffic, acceleration to v_{\max} can be assumed to be instantaneous in pedestrian motion.

In order to study the effects of inhomogeneities, the pedestrians are assigned different maximal velocities v_{\max} . Fast walkers have $v_{\max} = 4$, standard walkers $v_{\max} = 3$ and slow walkers $v_{\max} = 2$. The cell size is assumed to be 50 cm \times 50 cm. The best agreement with empirical observations has been achieved with 5% slow and 5% fast walkers [8]. Furthermore the fundamental diagram in more complex situations, such as bi- or four-directional flows, has been investigated.

Gipps–Marksjös Model A more sophisticated discrete model was suggested by Gipps and Marksjös [45] in 1985. One motivation for developing a discrete model was the limited computer power at that time. Therefore a discrete model, which reproduces the properties of pedestrian motion realistically, was in many respects a real improvement over the existing continuum approaches.

Interactions between pedestrians are assumed to be repulsive, anticipating the idea of social forces (see Subsect. “Social-Force Models”). The pedestrians move on a grid of rectangular cells of size 0.5 \times 0.5 m. To each cell a score is assigned based on its proximity to other pedestrians. This score represents the repulsive interactions and actual motion is then determined by the competition between these repulsions and the gain of approaching the destination. Applying this procedure to all pedestrians, a potential value is assigned to each cell which is the sum of the individual contributions. The pedestrian then selects the cell of its nine neighbors (Moore neighborhood) which leads to the maximum benefit. This benefit is defined as the difference between the gain of moving closer to the destination and the cost of moving closer to other pedestrians as represented by the potential. This requires a suitable chosen gain function P .

The updating is done sequentially to avoid conflicts of several pedestrians trying to move to the same position. In order to model different velocities, faster pedestrians are updated more frequently. Note that the model dynamics are deterministic.

Floor Field CA Floor field CA [13,14,83,167] can also be considered as an extension of the ASEP. However, the transition probabilities to neighboring cells are no longer

fixed but vary dynamically. This is motivated by the process of chemotaxis (see [5] for a review) used by some insects (e. g., ants) for communication. They create a chemical trace to guide other individuals to food sources. In this way a complex trail system is formed that has many similarities with human transport networks.

In the approach of [13] the pedestrians also create a trace. In contrast to chemotaxis, however, this trace is only virtual, although one could assume that it corresponds to some abstract representation of the path in the mind of the pedestrians. Although this is mainly a technical trick which reduces interactions to local ones that allow efficient simulations in arbitrary geometries, one could also think of the trail as representation of the paths in the mind of a pedestrian. The locality becomes important in complex geometries as no algorithm is required to check whether the interaction between particles is screened by walls, etc. The number of interaction terms always grows linearly with the number of particles.

The translation into local interactions is achieved by the introduction of so-called *floor fields*. The transition probabilities for all pedestrians depend on the strength of the floor fields in their neighborhood in such a way that transitions in the direction of larger fields are preferred. The *dynamic floor field* D_{ij} corresponds to a virtual trace which is created by the motion of the pedestrians and in turn influences the motion of other individuals. Furthermore it has its own dynamics, namely through diffusion and decay, which leads to a dilution and finally the vanishing of the trace after some time. The *static floor field* S_{ij} does not change with time since it only takes into account the effects of the surroundings. Therefore it exists even without any pedestrians present. It allows us to model, e. g., preferred areas, walls and other obstacles. Figure 10 shows the static floor field used for the simulation of evacuations from a room with a single door. Its strength decreases with increasing distance from the door. Since the pedestrians prefer motion into the direction of larger fields, this is already sufficient to find the door.

Coupling constants control the relative influence of both fields. For a strong coupling to the static field pedestrians will choose the shortest path to the exit. This corresponds to a ‘normal’ situation. A strong coupling to the dynamic field implies a strong herding behavior where pedestrians try to follow the lead of others. This often happens in emergency situations.

The model uses a fully parallel update. Therefore conflicts can occur where different particles choose the same destination cell. This is relevant for high density situations and happens in all models with parallel update if motion in different directions is allowed. Conflicts have been con-

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 10

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 11

Refused movement due to the friction parameter μ (for $m = 4$)

sidered a technical problem for a long time and usually the dynamics have been modified in order to avoid them. The simplest method is to update pedestrians sequentially instead of using fully parallel dynamics. However, this leads to other problems, e. g., the identification of the relevant timescale. Therefore it has been suggested in [84,85] to take these conflicts seriously as an important part of the dynamics.

For the floor field model it has been shown in [85] that the behavior becomes more realistic if not all conflicts are resolved by allowing one pedestrian to move while the others stay at their positions. Instead with probability $\mu \in [0, 1]$, which is called the friction parameter, the movement of *all* involved pedestrians is denied [85] (see Fig. 11).

This allows one to describe clogging effects between the pedestrians in a much more detailed way [85]. μ works as some kind of local pressure between the pedestrians.

If μ is high, the pedestrians handicap each other trying to reach their desired target sites. This local effect can have enormous influence on macroscopic quantities like flow and evacuation time [85]. Note that the kind of friction introduced here only influences interacting particles, not the average velocity of a freely moving pedestrian.

Surprisingly, the qualitative behaviors of the floor field model and the social-force models are very similar despite the fact that the interactions are very different. In the floor field model interactions are attractive, whereas in the social-force model they are repulsive. However, in the latter interactions are between particle densities. In contrast, in the floor field model the particle density interacts with the velocity density.

Other Approaches

Lattice-gas models In 1986, Frisch, Hasslacher, and Pomeau [34] showed that one does not have to take into account detailed molecular motion within fluids in order to obtain a realistic picture of (2d) fluid dynamics. They proposed a lattice gas model [164,165] on a triangular lattice with hexagonal symmetry, which is similar in spirit to CA models, but the exclusion principle is relaxed: particles with different velocities are allowed to occupy the same site. Note that the allowed velocities differ only in the direction, not absolute value. The dynamics are based on a succession of collision and propagation that can be chosen in such a way that the coarse-grained averages of this microscopic dynamic is asymptotically equivalent to the Navier–Stokes equations of incompressible fluids.

In [108] a kind of mesoscopic approach inspired by these lattice gas models has been suggested as a model for pedestrian dynamics. In analogy with the description of transport phenomena in fluids (e. g., the Boltzmann equation) the dynamics are based on a succession of collision and propagation.

Pedestrians are modeled as particles, moving on a triangular lattice, which have a preferred direction of motion \mathbf{c}_F . However, the particles do not strictly follow this direction but also have a tendency to move with the flow. Furthermore, at high densities the crowd motion is influenced by a kind of friction which slows down the pedestrians. This is achieved by reducing the number of individuals allowed to move to neighboring sites.

As in a lattice gas model [165], the dynamics now consists of two steps. In the *propagation step* each pedestrian moves to the neighbor site in the direction of its velocity vector. In the *collision step* the particles interact and new velocities (directions) are determined. In contrast to physical systems, momentum, etc., does not need to be con-

served during the collision step. These considerations lead to a collision step that takes into account the favorite direction \mathbf{c}_F , the local density (the number of pedestrians at the collision site), and a quantity called mobility at all neighbor sites which is a normalized measure of the local flow after the collision.

Optimal-Velocity Model The optimal velocity (OV) model originally introduced for the description of highway traffic can be generalized to higher dimensions [134] which allows its application to pedestrian dynamics.

In the two-dimensional extension of the OV model the equation of motion for particle i is given by

$$\frac{d^2}{dt^2} \mathbf{x}_i(t) = a \left\{ \mathbf{V}_0 + \sum_j \mathbf{V}(\mathbf{x}_j(t) - \mathbf{x}_i(t)) - \frac{d}{dt} \mathbf{x}_i(t) \right\}, \quad (10)$$

where $\mathbf{x}_i = (x_i, y_i)$ is the position of particle i . It can be considered as a special case of the general social-force model (7) without physical forces. The optimal-velocity function

$$\mathbf{V}(\mathbf{x}_j - \mathbf{x}_i) = f(r_{ij})(1 + \cos \varphi) \mathbf{n}_{ij}, \quad (11)$$

$$f(r_{ij}) = \alpha \{ \tanh \beta(r_{ij} - b) + c \}, \quad (12)$$

where $r_{ij} = |\mathbf{x}_j - \mathbf{x}_i|$, $\cos \varphi = (x_j - x_i)/r_{ij}$ and $\mathbf{n}_{ij} = (\mathbf{x}_j - \mathbf{x}_i)/r_{ij}$ is determined by interactions with other pedestrians. \mathbf{V}_0 is a constant vector that represents a ‘desired velocity’ at which an isolated pedestrian would move. The strength of the interaction depends on the distance r_{ij} between the i th and j th particles, and on the angle φ between the directions of $\mathbf{x}_j - \mathbf{x}_i$ and the current velocity $d\mathbf{x}_i/dt$. Due to the term $(1 + \cos \varphi)$, a particle reacts more sensitively to particles in front than to those behind.

Now two cases can be distinguished: repulsive and attractive interactions. The former is relevant for pedestrian dynamics whereas the latter is more suitable for biological motion. Therefore, for pedestrian motion one chooses $c = 1$ which implies $f < 0$.

A detailed analysis [134] shows that the model exhibits a rich phase diagram including the formation of various patterns.

Other Models We briefly mention a few other model approaches that have been suggested. In [10] a discretized version of the social-force model has been introduced and shown to reproduce qualitatively the observed collective phenomena.

In [141] a magnetic force model has been proposed where pedestrians and their goals are treated as magnetic poles of opposite sign.

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 12

The dynamics of lattice gas models proceed in two steps. Pedestrians coming from neighboring sites interact in the collision step where velocities are redistributed. In the propagation step the pedestrians move to neighbor sites in directions determined by the collision step

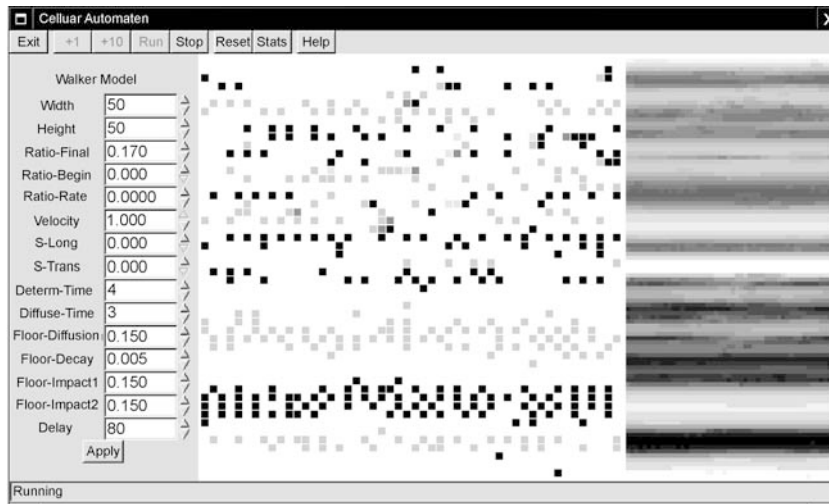

Another class of models is based on ideas from queuing theory. In principle, some hand calculation methods can be considered as macroscopic queuing models. Typically, rooms are represented as nodes in the queuing network and links correspond to doors. In microscopic approaches, in the movement process each agent chooses a new node, e. g., according to some probability [105].

Theoretical Results

As emphasized in Subject. “Collective Effects”, the collective effects observed in the motion of pedestrian crowds are a direct consequence of microscopic dynamics. These effects are reproduced quite well by some models, e. g., the social-force and floor-field model, at least on a qualitative level. As mentioned before, the qualitative behavior of the two models is rather similar despite the very different im-

plementation of the interactions. This indicates a certain robustness of the collective phenomena observed.

As an example we discuss the formation of lanes in counterflow formation. Empirically one observes a strong tendency to follow immediately in the “wake” of another person heading in the same direction. Such lane formation was reproduced in the social-force model [52,53] as well as in the floor-field model [13,76] (see Fig. 13). While the formation of lanes in general is essential to avoid deadlocks and thus keep the chance of reproducing realistic fluxes, the number of direction changes per meter cross section is a parameter which in reality crucially depends on the situation [76]: the longer a counterflow situation is assumed to persist, the fewer lanes per meter cross section can be found. The correct reproduction of counterflow is an issue for an accommodating animation, but more or less unimportant for macroscopic observables. This is probably the

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 13

Lane formation in the floor-field model. The central window is the corridor and the light and dark squares are right- and left-moving pedestrians, respectively. In the bottom part well-separated lanes can be observed whereas in the top part the motion is still disordered. The right part of the figure shows the floor fields for the right-movers (*upper half*) and left-movers (*lower half*)

main reason why there seems to have been little effort put into the attempt to reproduce different “kinds” of lane formation in a controlled, situation-dependent manner.

On the quantitative side, the fundamental diagram is the first and most serious test for any model. Since most quantitative results rely on the fundamental diagram, it can be considered the most important characteristic of pedestrian dynamics. It is not only relevant for movement in a corridor or through a bottleneck, but also as an important determinant of evacuation times. However, as emphasized earlier, there is currently no consensus on the empirical form of the fundamental diagram. Therefore, a calibration of the model parameters is currently difficult.

Most cellular automata models are based on the asymmetric simple exclusion process. This strictly one-dimensional stochastic process has a fundamental diagram which is symmetric around density $\rho = 1/2$. Lane changes in two-dimensional extensions lead to only a small shift towards smaller densities. Despite the discrepancies in the empirical results, an almost symmetric fundamental diagram can be excluded.

Based on the experience with modeling of highway traffic [16,133], models with higher speeds have been introduced which naturally lead to an asymmetric fundamental diagram. Typically this is implemented by allowing the agents to move more than one cell per update step [82, 86,87,92,195,196]. These model variants have been shown to be flexible enough to reproduce, e. g., Weidmann’s fundamental diagram for the flow in a corridor [192] with high precision. Usually in the simulations a homogeneous population is assumed. However, in reality, different pedestrians have different properties such as walking speed, motivation, etc. This is easily taken into account in every microscopic model. There are many parameters that could potentially have an influence on the fundamental diagram. However, the current empirical situation does not allow to decide this question.

Another problem occurring in CA models has its origin in the discreteness of space. Through the choice of the lattice discretization, space is no longer isotropic. Motion in directions not parallel to the main axis of the lattice are difficult to realize and can only be approximated by a sequence of steps parallel to the main directions.

Higher velocities also require the extension of the neighborhood of a particle which is no longer identical to the cells adjacent to the current position. A natural definition of “neighborhood” corresponds to those cells that could be reached within one time step. In this way the introduction of higher velocities also reduces the problem of space isotropy as the neighborhoods become more isotropic for large velocities.

Other solutions to this problem have been proposed. One way is to count the number of diagonal steps and let the agent suspend from moving following certain rules which depend on the number of diagonal steps [171]. A similar idea is to sum up the real distance that an agent has moved during one round: a diagonal step counts $\sqrt{2}$ and a horizontal or vertical step counts 1. An agent has to finish its round as soon as this sum is bigger than its speed [87]. A third possibility – which works for arbitrary speeds – is to assign selection probabilities to each of the four lattice positions adjacent to the exact final position [195,196]. Naturally these probabilities are inversely proportional to the square area between the exact final position and the lattice point, as in this case the probabilities are normalized by construction if one has a square lattice with points on all integer number combinations. However, one also could think of other methods to calculate the probability.

For the social-force model, the specification of the repulsive interaction (with and without hard core, exponential or reciprocal with distance) as well as the parameter sets for the forces changes in different publications [52,53, 54,114]. In [55] the authors state that “most observed self-organization phenomena are quite insensitive to the specification of interaction forces”. However, at least for the fundamental diagram, a relation connected with all phenomena in pedestrian dynamics, this statement is questionable. As remarked in [56] the reproduction of the fundamental diagram “requires a less simple specification of the repulsive interaction forces”. Indeed in [175] it was shown that the choice of hard-core forces or repulsive soft interactions as well as the particular parameter set can strongly influence the resulting fundamental diagram regarding qualitative as well as quantitative effects.

Also a more realistic behavior at higher densities requires a modification of the basic model. Here the use of density-dependent desired velocities leads to a reduction of the otherwise unrealistically large number of collisions [10].

The particular specification of forces and the previously mentioned problem with Newton’s Third law can lead in principle to some unwanted effects, such as momentary velocities larger than the preferred velocity [52] or the penetration of pedestrians into each other or into walls [98]. It is possible that these effects can be suppressed for certain parameter sets by contact or friction forces, but the general appearance is not excluded. Only in the first publication [52] are restrictions for the velocity explicitly formulated to prevent velocities larger than the intended speed; other authors tried to improve the model by introducing more parameters [98]. But additional paramete-

ter and artificial restrictions of variables diminish the simplicity and thus the attractiveness of the model. A general discussion of how to deal with these problems of the social-force model and a verification that the observed phenomena are not limited to a certain specification of the interaction and a special parameter set is up to now still missing.

While realistic reproduction within the empirical range of these macroscopic observables, especially the fundamental diagram, is absolutely essential to guarantee safety standards in evacuation simulations, and while a user should always be distrustful of models where no fundamental diagram has ever been published, it is by no means sufficient to exclusively check for the realism of macroscopic observables. On the microscopic level there are a large number of phenomena which need to be reproduced realistically, be it just to make a simulation animation look realistic or because microscopic effects can often easily influence macroscopic observables.

If one compares simulations of bottleneck flows with real events, one observes that in simulations the form of the queue in front of bottlenecks is often a half-circle, while in reality it is drop- or wedge-shaped. In most cases this discrepancy probably does not have an influence on the simulated evacuation time, but it is interesting to note where it originates from. Most simulation models implicitly or explicitly use some kind of utility maximization to steer the pedestrians – with the utility being foremost inversely proportional to the distance from the nearest exit. This obviously leads to half-circle-shaped queues in front of bottlenecks. So wherever one observes queues different than half-circles, people have exchanged their normal “utility function based on the distance” with something else. One such alternative utility function could be that people are just curious about what is inside or behind the bottleneck, so they seek a position where they can look into it. A more probable explanation would be that in any case it is the time distance not the spatial distance which is sought to be minimized. As anyone knows what the inescapable loss in time a bottleneck means for the whole waiting group, the precise waiting spot is not that important. However, in societies with a strong feeling for equality, people would strongly wish to equally distribute the waiting time and keep a first-in-first-out principle, which can best be accomplished and controlled when the queue is more or less one-dimensional, respectively just as wide as the bottleneck itself.

Finally it should be mentioned that theoretical investigations based on simulations of models for pedestrian dynamics have led to the prediction of some surprising and counter-intuitive collective phenomena, such as the

reduction of evacuation times through additional columns near exits (see Subsect. “[Bottleneck Flow](#)”) or the faster-is-slower [54] and freezing-by-heating effect [53]. However, so far the empirical evidence for the relevance or even the occurrence of these effects in real situations is rather scarce.

Applications

In the following section we discuss more practical aspects of based on the modeling concepts presented in Sect. “[Modeling](#)”. Tools of different sophistication have been developed that are nowadays routinely used in safety analysis. The latter becomes more and more relevant since many public facilities must fulfill certain legal standards. As an example we mention aircrafts which must be evacuated within 90 seconds. The simulations etc. are already used in the planning stages because changes of the design at a later stage are difficult and expensive.

For this kind of safety analysis tools of different sophistication have been developed. Some of them mainly are able to predict just evacuation times whereas others are based on microscopic simulations which allow also to study various external influences (fire, smoke, ...) in much detail.

Calculation of Evacuation Times

The basic idea of hand calculation methods has already briefly been described at the end of Subsect. “[Fluid-Dynamic and Gas Kinetic Models](#)”. Here we want to discuss its practical aspects in more detail.

The approach has been developed since the middle of the 1950s [185]. The basic idea of these methods is the assumption that people can be modeled to behave like fluids. Knowledge of the flow (see Eq. 1) and the technical data of the facility are then sufficient to evaluate evacuation times, etc.

Hand calculation method can be divided into two major approaches: methods with “dynamic” flow [35,42,78,79,80,136,151,152,163,192] and methods with “fixed” flow [110,123,124,125,126,137,145,173,185]. As methods with “dynamic” flow we cite methods where the pedestrian flow is dependent on the density of the pedestrian stream (see Subsect. “[Observables](#)”) in the selected facility, thus the flow can be obtained from fundamental diagrams (see Subsect. “[Fundamental Diagram](#)”) or it is explicitly prescribed in the chosen method. This flow can change during movement through the building, e. g., by using stairs, thus the pedestrian stream has a “dynamic” flow. Methods with “fixed” flow do not use this concept of relationship between density and flow. In these methods selected

facilities (e. g., stairs or doors) have a fixed flow which is independent from the density, which is usually not used in these methods. The “fixed” flow is usually based upon empirical and measured data of flow, which are specified for a special type of building, such as high-rise buildings or railway stations, for example. Because of much simplification, in these “fixed” flow methods a calculation can always be done very quickly.

Methods with “dynamic” flow allow one to describe the condition of the pedestrian flow in every part of a selected building or environment, because they are mostly based upon the continuity equation, thus it is possible to calculate different kinds of buildings. This allows the user to calculate transitions from wide to narrow, floor to door, floor to stair, etc. The disadvantage is that some these methods are very elaborate and time-intensive. But in general, a method with “dynamic” flow is not complicated to calculate, thus we want to divide hand calculation methods in simple [35,42,110,123,124,125,126,136,137,145,152,163,173,185,192] and complex [78,79,80,151] for evacuation calculation. All of these hand calculation methods are able to predict total evacuation times for a selected building, but differences between different methods still exist. Thus the user has to ensure that he is familiar with assumptions made by each method to ensure that a result is interpreted in a correct way [161].

Simulation of Evacuation Processes

Before we go into the details of evacuation simulation, let us briefly clarify its scope and limitations and contrast it to other methods used in evacuation analysis. When analyzing evacuation processes, three different approaches can be identified:

- (1) Risk assessment,
- (2) Optimization, and
- (3) Simulation.

The aim and result of risk-assessment is a list of events and their consequences (e. g., damage, financial loss, loss of life), i. e., usually an event tree with probabilities and expectation values for financial loss. Optimization aims at, roughly speaking, minimizing the evacuation time and reducing the area and duration of congestion. And finally, simulation describes a system with respect to its function and behavior by investigating a model of the system. This model is usually non-analytic, so does not provide explicit equations for the calculation of, e. g., evacuation time. Of course, simulations are used for “optimization” in a more general sense, too, i. e., they can be part of an optimization. This holds for risk assessment, too, if simulations are used

to determine the outcomes of the different scenarios in the event tree.

In evacuation analysis the system is, generally speaking, a group of persons in an environment. More specifically, four components (sub-systems/sub-models) of the system *evacuation process* can be identified:

- (1) Geometry,
- (2) Environment,
- (3) Population, and
- (4) Hazards [43].

Any evacuation simulation must at least take into account (1) and (3). The behavior of the persons (which can be described on the strategic, tactical, and operational level—see Sect. “Modeling”) is part of the population sub-model. An alternative way of describing behavior is according to its algorithmic representation: no behavior modeling – functional analogy – implicit representation (equation) – rule based – artificial intelligence [43].

In the context of evacuation, hazards are first of all fire and smoke, which then require a toxicity sub-model, e. g., the fractional effective dose model (FED), to assess the physiological effect of toxic gases and temperature [25]. Further hazards to take into account might be earthquakes, flooding, or in the case of ships, list, heel, or roll motion. The sub-model environment comprises all other influences that affect the evacuation process, e. g., exit signs, surface texture, public address system, etc.

In summary, aims of an evacuation analysis and simulation are to provide feedback and hints for improvement at an early stage of design, information for safer and more rigorous regulations, improvement of emergency preparedness, training of staff, and accident investigation [43]. They usually do not provide direct results on the probability of a scenario or a systematic search for optimal geometries.

Calculation of Overall Evacuation Time, Identification of Congestion, and Corrective Actions

The scope of this section is to show general results that can be obtained by evacuation simulations. They are general in the sense that they can basically be obtained by any stochastic and microscopic model, i. e., apart from these two requirements, the results are not model specific. In detail, five different results of evacuation simulations can be distinguished:

- (1) Distribution of evacuation times,
- (2) Evacuation curve (number of persons evacuated vs. time),

- (3) Sequence of the evacuation (e. g., snapshots/screenshots at specific times, e. g., every minute), and
- (4) Identification of congestion, usually based on density and time.

The last point (4), in particular, needs some more explanation: congestion is defined based on density. Notwithstanding the difficulties of measuring density, we suggest density as the most suitable criterion for the identification of congestion. In addition to the mere occurrence of densities exceeding a certain threshold (say 3.5 persons per square meter), the time this threshold is exceeded is another necessary condition for a sensible definition of congestion. In the case presented here, 10% of the overall evacuation time is used. Both criteria are in accordance with the IMO regulations [118].

Based on these results, evacuation time and areas of congestion, corrective actions can be taken. The most straightforward measure would be a change of geometry, i. e., shorter or wider escape paths (floors, stairs, doors). This can be directly put into the geometry sub-model, the simulation can be re-run, and the result checked. Secondly, the signage, and therefore the orientation capability, can be improved. This is not as straightforward as geometrical changes. It does depend more heavily on the model characteristics as to how these changes influence the evacuation sequence.

We will not go into these details in the following two sections but rather show two typical examples for evacuation simulations and the results obtained. We will also not discuss the results in detail, since they are of an illustrative nature in the context of this article. The following examples are based on investigations that have been performed using a cellular automaton model which is described along with the simulation program in [90,111].

Simulation Example 1 – Hotel The first example we show is a hotel with 8069 persons. In Fig. 15 only the ground floor is shown. There are nine floors altogether. The upper floors influence the ground floor only via the stair landings and the exits adjacent to them. Most of the 8069 persons are initially located in the ground floor, since the theater and conference area is located there. The upper floors are mainly covering bedrooms and some small conference areas.

The first step in our example (which might well be a useful recipe for evacuation analyses in general and is again in accordance with [118]) is to perform a statistical analysis. To this end, 500 samples are simulated. The evacuation time of a single run is the time it takes for all persons to get out. In this context, no fire or smoke are

taken into account. Since there are stochastic influences in the model used, the significant overall evacuation time is taken to be the 95-percentile (cf. Fig. 14). Finally, the maximum, minimum, mean, and significant values for the evacuation curve (number of persons evacuated vs. time) are also shown in Fig. 14.

The next figure (Fig. 16) shows the cumulated density. The thresholds (red areas) are 3.5 persons per square meter and 10% of the overall evacuation time (in this case 49 seconds). The overall evacuation time is 8:13 minutes (493 seconds). This value is obtained by taking the 95-percentile of the frequency distribution for the overall evacuation times (cf. Fig. 14).

Of course, a distribution of overall evacuation times (for one scenario, i. e., the same initial parameters) can only be obtained by a stochastic model. In a deterministic model only one single value is calculated for the overall evacuation time. The variance of the overall evacuation times is due to two effects in the model used here: the initial position of the persons is determined anew at the beginning of each simulation run since only the statistical properties of the overall population are set and the motion of the persons is governed by partially stochastic rules (e. g., probabilistic parameters).

Simulation Example 2 – Passenger Ship The second example we will show is a ship. The major difference from the previous example is the addition of (1) the assembly phase and (2) embarkation and launching.

$$\begin{aligned}
 T &= A + \frac{2}{3}(E + L) \\
 &= f_{\text{safety}} \cdot (t_{\text{react}} + t_{\text{walk}}) + \frac{2}{3}(E + L) \\
 &\leq 60 \text{ minutes} .
 \end{aligned}$$

Embarkation and launching time ($E + L$) are required to be less than 30 minutes. For the sake of the evacuation analysis at an early design stage, the sum of embarkation and launching time can be assumed to be 30 minutes. Therefore, the requirement for A is 40 minutes. Alternatively, the embarkation and launching time can be determined by an evacuation trial.

Figure 17 shows the layout, initial population distribution (night case), density plot for the day case, and density plot for the night case. The reaction times are different for the day and the night case: 3 to 7 minutes (equally distributed) in the one and 7 to 13 minutes in the other. The longer reaction time in the night case results in less congestion (cf. Fig. 17). Both cases must be done in the analysis according to [118]. Additionally, a secondary night and day case are required (making up four cases altogether). In these secondary cases the main vertical zone (MVZ) lead-

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 14
 Frequency distribution for the overall evacuation time (a) and evacuation curve (b)

ing to the longest overall individual assembly time is identified, and then either half of the stairway capacity in this zone is assumed to be not available, or 50% of the persons initially located in this zone must be led via one neighboring zone to the assembly station.

In the same way as shown for the two examples, simulations can be performed for other types of buildings and vessels. This technique has been applied to various passen-

gers ships [112] to football stadiums [88] and the World Youth Day 2005 [88], the Jamarat Bridge in Makkah [88], a movie theater and schools (mainly for calibration and validation) [90] and airports [171]. Of course, many examples of applications based on various models can be found in the literature. For an overview, the proceedings of the PED conference series are an excellent starting point [44, 170,190].

Initial population distribution and situation after two minutes

Comparison of Commercial Software Tools

From a practical point of view, application of models for pedestrian dynamics and evacuation processes becomes more and more relevant in safety analysis. This has led to the development of a number of software tools that, with different sophistication, help us study many aspects without risking the health of test persons in evacuation trials.

There are commercial, as well as non-commercial software tools. All tools might be based on different models [97,187]. They have become very popular since the middle of the 1990s. A first comparison of different com-

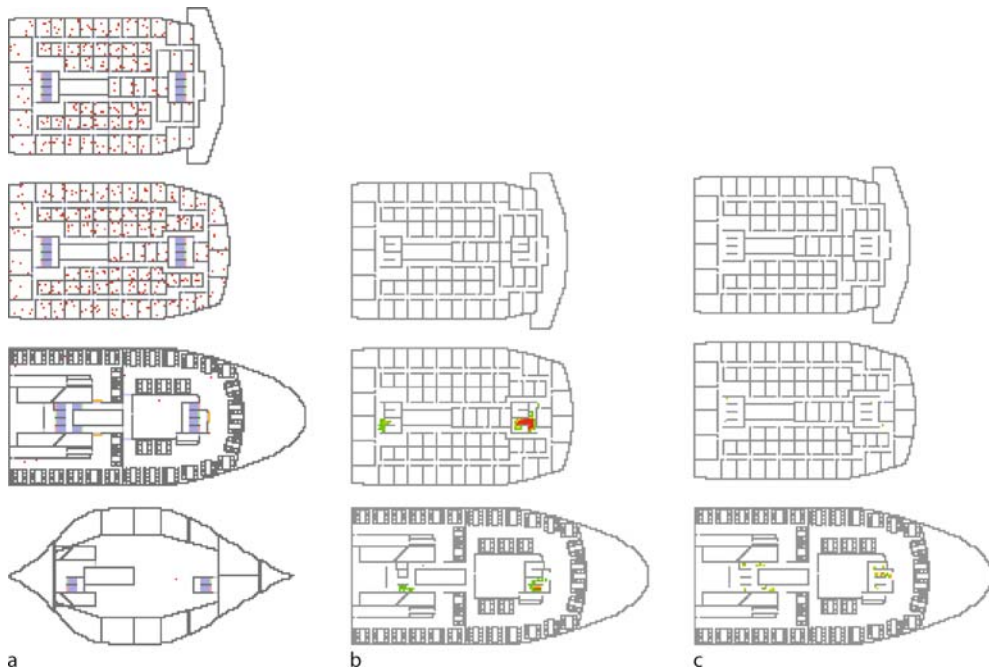

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 16

Density plot, i.e., cumulated person density exceeding 3.5 persons per square meter and 10% of overall evacuation time

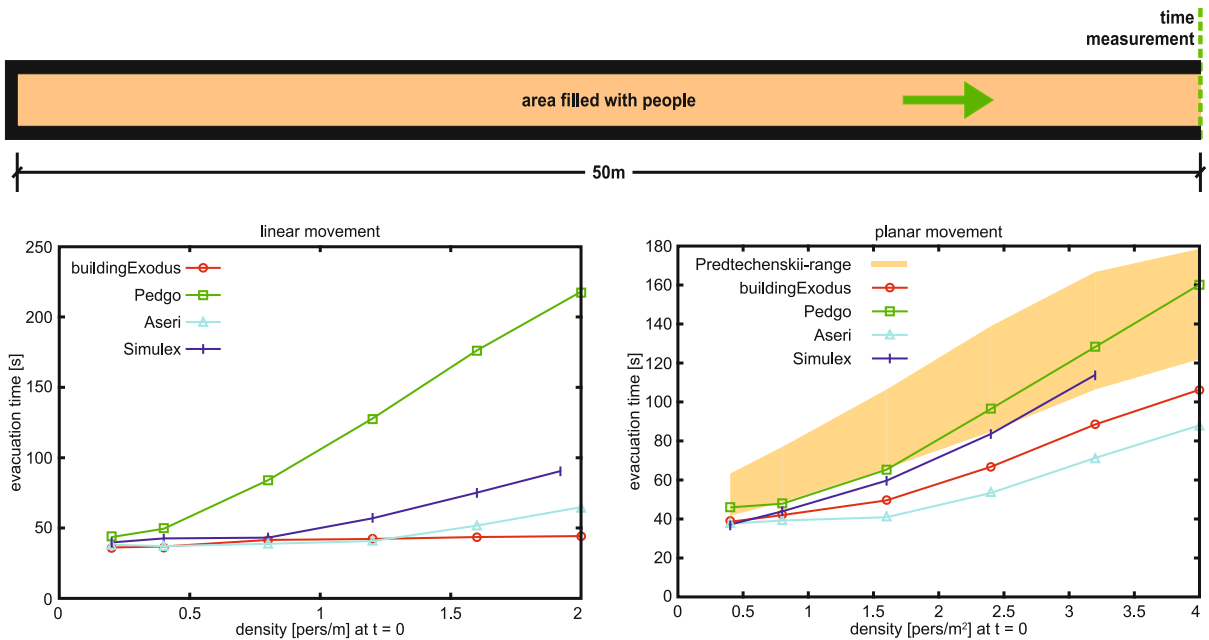

mercial software tools can be found in [191], where they were said to produce “reasonable results”. Further comparisons of real evacuation data with software tools or hand calculation methods can be found in [29,67,91,96,104,160,161,177]. But results predicted by different commercial software tools can differ by up to 40% for the same building [96]. Results may differ, too, when calculating with different assumptions, e.g., different reaction times, use of more or less detailed stair models, or when calculating with a real occupant load in contrast to an uncertainty analysis [96,104]. Contrary to these results, another study [161] shows that calculations with different software tools are able to predict total evacuation times for high-rise buildings and there are no large differences as shown in [96]. In [161] the results of an evacuation trial and simulations with different commercial software tools differed for selected floors of a highrise building. The densities were very low in this instance. In this case human behavior has a very large influence on the evacuation time. By contrast, evacuations at medium or high densities, human behavior has a smaller influence on the evacuation time of selected areas because congestion appears and continues larger than in low density situations – thus people reach the exit while congestion is still a factor [162]. In low density situations congestions are very rare, thus people move narrowly with free walking velocity through the building [162].

But the results presented in [161] also show that commercial software tools sometimes have problems with the

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 17

Initial distribution for the night case, density plot for the day case, and density plot for the night case for the “AENEAS steamliner”

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 18

Comparison of different software tools by simulating linear (left, narrow floor) and planar (right, 2 m wide floor) movement [162]

empirical relationship of density and walking speed (see Fig. 18). Furthermore, it is very important how boundary conditions are implemented in these tools (see Fig. 19), and the investigation of a simple scenario of a single room

using different software tools shows results differing by about a factor of two (see Fig. 19) [161]. In this case all software tools predict a congestion at the exit. Furthermore it is possible that the implemented algorithm fails [161].

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 19
Comparison of different software tools by simulating a simple room geometry [162]

Thus for the user it is hard to know which algorithms are implemented in closed-source tools so that such a tool must be considered as “black box” [147]. It is also quite difficult to compare results about density and appearing congestions calculated by different software tools [162] and so it is questionable how these results should be interpreted. But, as pointed out earlier, reliable empirical data are often missing so that a validation of software tools or models is quite difficult [162].

Future Directions

The discussion has shown that the problem of crowd dynamics and evacuation processes is far from being well understood. One big problem is experimental basis. As in many human systems, it is difficult to perform controlled experiments on a sufficiently large scale. This would be necessary since data from actual emergency situations is usually not available, at least in sufficient quality. Progress should be possible by using modern video and computer technology which should allow us, in principle, to extract precise data even for the trajectories of individuals.

The full understanding of the complex dynamics of evacuation processes requires collaboration between engineering, physics, computer science, psychology, etc. Engineering in cooperation with computer science will lead to an improved empirical basis. Methods from physics allow us to develop simple but realistic models that capture the main aspects of the dynamics. Psychology is then needed to understand the interactions between individuals in sufficient detail to get a reliable set of ‘interaction’ parameters for the physical models.

In the end, we hope these joint efforts will lead to realistic models for evacuation processes that not only allow us to study these in the planning stages of facilities, but

even allow for dynamical real-time evacuation control in case an emergency occurs.

Acknowledgments

The authors would like to acknowledge the contribution of Tim Meyer-König (the developer of PedGo) and Michael Schreckenberg, Ansgar Kirchner, Bernhard Steffen for many fruitful discussions and valuable hints.

Glossary

Deterministic evolutionary dynamic A deterministic evolutionary dynamic is a rule for assigning population games to ordinary differential equations describing the evolution of behavior in the game. Deterministic evolutionary dynamics can be derived from *revision protocols*, which describe choices (in economic settings) or births and deaths (in biological settings) on an agent-by-agent basis.

Evolutionarily stable strategy (ESS) In a symmetric normal form game, an evolutionarily stable strategy is a (possibly mixed) strategy with the following property: a population in which all members play this strategy is resistant to invasion by a small group of mutants who play an alternative mixed strategy.

Normal form game A normal form game is a strategic interaction in which each of n players chooses a strategy and then receives a payoff that depends on all agents' choices of strategy. In a *symmetric two-player normal form game*, the two players choose from

the same set of strategies, and payoffs only depend on own and opponent's choices, not on a player's identity.

Population game A population game is a strategic interaction among one or more large populations of agents. Each agent's payoff depends on his own choice of strategy and the distribution of others' choices of strategies. One can generate a population game from a normal form game by introducing random matching; however, many population games of interest, including congestion games, do not take this form.

Replicator dynamic The replicator dynamic is a fundamental deterministic evolutionary dynamic for games. Under this dynamic, the percentage growth rate of the mass of agents using each strategy is proportional to the excess of the strategy's payoff over the population's average payoff. The replicator dynamic can be interpreted biologically as a model of natural selection, and economically as a model of imitation.

Revision protocol A revision protocol describes both the timing and the results of agents' decisions about how to behave in a repeated strategic interaction. Revision protocols are used to derive both deterministic and stochastic evolutionary dynamics for games.

Stochastically stable state In Game-theoretic models of stochastic evolution in games are often described by irreducible Markov processes. In these models, a population state is stochastically stable if it retains positive weight in the process's stationary distribution as the level of noise in agents' choices approaches zero, or as the population size approaches infinity.

Definition of the Subject

Evolutionary game theory studies the behavior of large populations of agents who repeatedly engage in strategic interactions. Changes in behavior in these populations are driven either by natural selection via differences in birth and death rates, or by the application of myopic decision rules by individual agents.

The birth of evolutionary game theory is marked by the publication of a series of papers by mathematical biologist John Maynard Smith [137,138,140]. Maynard Smith adapted the methods of traditional game theory [151,215], which were created to model the behavior of rational economic agents, to the context of biological natural selection. He proposed his notion of an *evolutionarily stable strategy (ESS)* as a way of explaining the existence of ritualized animal conflict.

Maynard Smith's equilibrium concept was provided with an explicit dynamic foundation through a differential

equation model introduced by Taylor and Jonker [205]. Schuster and Sigmund [189], following Dawkins [58], dubbed this model the *replicator dynamic*, and recognized the close links between this game-theoretic dynamic and dynamics studied much earlier in population ecology [132,214] and population genetics [73]. By the 1980s, evolutionary game theory was a well-developed and firmly established modeling framework in biology [106].

Towards the end of this period, economists realized the value of the evolutionary approach to game theory in social science contexts, both as a method of providing foundations for the equilibrium concepts of traditional game theory, and as a tool for selecting among equilibria in games that admit more than one. Especially in its early stages, work by economists in evolutionary game theory hewed closely to the interpretation set out by biologists, with the notion of ESS and the replicator dynamic understood as modeling natural selection in populations of agents genetically programmed to behave in specific ways. But it soon became clear that models of essentially the same form could be used to study the behavior of populations of active decision makers [50,76,133,149,167,191]. Indeed, the two approaches sometimes lead to identical models: the replicator dynamic itself can be understood not only as a model of natural selection, but also as one of imitation of successful opponents [35,188,216].

While the majority of work in evolutionary game theory has been undertaken by biologists and economists, closely related models have been applied to questions in a variety of fields, including transportation science [143,150,173,175,177,197], computer science [72,173,177], and sociology [34,62,126,225,226]. Some paradigms from evolutionary game theory are close relatives of certain models from physics, and so have attracted the attention of workers in this field [141,201,202,203]. All told, evolutionary game theory provides a common ground for workers from a wide range of disciplines.

Introduction

This article offers a broad survey of the theory of evolution in games. Section “[Normal Form Games](#)” introduces normal form games, a simple and commonly studied model of strategic interaction. Section “[Static Notions of Evolutionary Stability](#)” presents the notion of an evolutionarily stable strategy, a static definition of stability proposed for this normal form context.

Section “[Population Games](#)” defines population games, a general model of strategic interaction in large populations. Section “[Revision Protocols](#)” offers the notion of a revision protocol, an individual-level description

of behavior used to define the population-level processes of central concern.

Most of the article concentrates on these population-level processes: Section “[Deterministic Dynamics](#)” considers deterministic differential equation models of game dynamics; Section “[Stochastic Dynamics](#)” studies stochastic models of evolution based on Markov processes; and Sect. “[Local Interaction](#)” presents deterministic and stochastic models of local interaction. Section “[Applications](#)” records a range of applications of evolutionary game theory, and Sect. “[Future Directions](#)” suggests directions for future research. Finally, Sect. “[Bibliography](#)” offers an extensive list of primary references.

Normal Form Games

In this section, we introduce a very simple model of strategic interaction: the symmetric two-player normal form game. We then define some of the standard solution concepts used to analyze this model, and provide some examples of games and their equilibria. With this background in place, we turn in subsequent sections to evolutionary analysis of behavior in games.

In a *symmetric two-player normal form game*, each of the two players chooses a (pure) strategy from the finite set S , which we write generically as $S = \{1, \dots, n\}$. The game’s *payoffs* are described by the matrix $A \in \mathbf{R}^{n \times n}$. Entry A_{ij} is the payoff a player obtains when he chooses strategy i and his opponent chooses strategy j ; this payoff does not depend on whether the player in question is called player 1 or player 2.

The fundamental solution concept of noncooperative game theory is Nash equilibrium [151]. We say that the pure strategy $i \in S$ is a *symmetric Nash equilibrium* of A if

$$A_{ii} \geq A_{ji} \quad \text{for all } j \in S. \quad (1)$$

Thus, if his opponent chooses a symmetric Nash equilibrium strategy i , a player can do no better than to choose i himself.

A stronger requirement on strategy i demands that it be superior to all other strategies regardless of the opponent’s choice:

$$A_{ik} > A_{jk} \quad \text{for all } j, k \in S. \quad (2)$$

When condition (2) holds, we say that strategy i is *strictly dominant* in A .

Example 1 The game below, with strategies C (“cooperate”) and D (“defect”), is an instance of a *Prisoner’s*

Dilemma:

	C	D
C	2	0
D	3	1

(To interpret this game, note that $A_{CD} = 0$ is the payoff to cooperating when one's opponent defects.) Since $1 > 0$, defecting is a symmetric Nash equilibrium of this game. In fact, since $3 > 2$ and $1 > 0$, defecting is even a strictly dominant strategy. But since $2 > 1$, both players are better off when both cooperate than when both defect.

In many instances, it is natural to allow players to choose *mixed* (or *randomized*) strategies. When a player chooses mixed strategy from the simplex $X = \{x \in \mathbb{R}_+^n : \sum_{i \in S} x_i = 1\}$, his behavior is stochastic: he commits to playing pure strategy $i \in S$ with probability x_i .

When either player makes a randomized choice, we evaluate payoffs by taking expectations: a player choosing mixed strategy x against an opponent choosing mixed strategy y garners an expected payoff of

$$x' Ay = \sum_{i \in S} \sum_{j \in S} x_i A_{ij} y_j. \tag{3}$$

In biological contexts, payoffs are *fitnesses*, and represent levels of reproductive success relative to some baseline level; Eq. (3) reflects the idea that in a large population, expected reproductive success is what matters. In economic contexts, payoffs are *utilities*: a numerical representation of players' preferences under which Eq. (3) captures players' choices between uncertain outcomes [215].

The notion of Nash equilibrium extends easily to allow for mixed strategies. Mixed strategy x is a *symmetric Nash equilibrium* of A if

$$x' Ax \geq y' Ax \quad \text{for all } y \in X. \tag{4}$$

In words, x is a symmetric Nash equilibrium if its expected payoff against itself is at least as high as the expected payoff obtainable by any other strategy y against x . Note that we can represent the pure strategy $i \in S$ using the mixed strategy $e_i \in X$, the i th standard basis vector in \mathbb{R}^n . If we do so, then definition (4) restricted to such strategies is equivalent to definition (1).

We illustrate these ideas with a few examples.

Example 2 Consider the *Stag Hunt* game:

	H	S
H	h	h
S	0	s

Each player in the Stag Hunt game chooses between hunting hare (H) and hunting stag (S). A player who hunts hare always catches one, obtaining a payoff of $h > 0$. But hunting stag is only successful if both players do so, in which case each obtains a payoff of $s > h$. Hunting stag is potentially more profitable than hunting hare, but requires a coordinated effort.

In the Stag Hunt game, H and S (or, equivalently, e_H and e_S) are symmetric pure Nash equilibria. This game also has a symmetric mixed Nash equilibrium, namely $x^* = (x_H^*, x_S^*) = (\frac{s-h}{s}, \frac{h}{s})$. If a player's opponent chooses this mixed strategy, the player's expected payoff is h whether he chooses H, S, or any mixture between the two; in particular, x^* is a best response against itself.

To distinguish between the two pure equilibria, we might focus on the one that is *payoff dominant*, in that it achieves the higher joint payoff. Alternatively, we can concentrate on the *risk dominant* equilibrium [89], which utilizes the strategy preferred by a player who thinks his opponent is equally likely to choose either option (that is, against an opponent playing mixed strategy $(x_H, x_S) = (\frac{1}{2}, \frac{1}{2})$). In the present case, since $s > h$, equilibrium S is payoff dominant. Which strategy is risk dominant depends on further information about payoffs. If $s > 2h$, then S is risk dominant. But if $s < 2h$, H is risk dominant: evidently, payoff dominance and risk dominance need not agree.

Example 3 In the *Hawk–Dove* game [139], the two players are animals contesting a resource of value $v > 0$. The players choose between two strategies: display (D) or escalate (E). If both display, the resource is split; if one escalates and the other displays, the escalator claims the entire resource; if both escalate, then each player is equally likely to claim the entire resource or to be injured, suffering a cost of $c > v$ in the latter case.

The payoff matrix for the Hawk–Dove game is therefore

	D	E
D	$\frac{1}{2}v$	0
E	v	$\frac{1}{2}(v - c)$

This game has no symmetric Nash equilibrium in pure strategies. It does, however, admit the symmetric mixed equilibrium $x^* = (x_D^*, x_E^*) = (\frac{c-v}{c}, \frac{v}{c})$. (In fact, it can be shown that every symmetric normal form game admits at least one symmetric mixed Nash equilibrium [151].)

In this example, our focus on symmetric behavior may seem odd: rather than randomizing symmetrically, it seems more natural for players to follow an asymmetric Nash equilibrium in which one player escalates and the

other displays. But the symmetric equilibrium is the most relevant one for understanding natural selection in populations whose members are randomly matched in pairwise contests –;see Sect. “Static Notions of Evolutionary Stability”.

Example 4 Consider the class of *Rock–Paper–Scissors* games:

	R	P	S
R	0	−l	w
P	w	0	−l
S	−l	w	0

Here $w > 0$ is the benefit of winning the match and $l > 0$ the cost of losing; ties are worth 0 to both players. We call this game *good RPS* if $w > l$, so that the benefit of winning the match exceeds the cost of losing, *standard RPS* if $w = l$, and *bad RPS* if $w < l$. Regardless of the values of w and l , the unique symmetric Nash equilibrium of this game, $x^* = (x_R^*, x_P^*, x_S^*) = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$, requires uniform randomization over the three strategies.

Static Notions of Evolutionary Stability

In introducing game-theoretic ideas to the study of animal behavior, Maynard Smith advanced this fundamental principle: that the evolutionary success of (the genes underlying) a given behavioral trait can depend on the prevalences of all traits. It follows that natural selection among the traits can be modeled as random matching of animals to play normal form games [137,138,139,140]. Working in this vein, Maynard Smith offered a stability concept for populations of animals sharing a common behavioral trait – that of playing a particular mixed strategy in the game at hand. Maynard Smith’s concept of evolutionary stability, influenced by the work of Hamilton [87] on the evolution of sex ratios, defines such a population as stable if it is resistant to invasion by a small group of mutants carrying a different trait.

Suppose that a large population of animals is randomly matched to play the symmetric normal form game A . We call mixed strategy $x \in X$ an *evolutionarily stable strategy* (ESS) if

$$x'A((1 - \varepsilon)x + \varepsilon y) > y'A((1 - \varepsilon)x + \varepsilon y) \text{ for all } \varepsilon \leq \bar{\varepsilon}(y) \text{ and } y \neq x. \quad (5)$$

To interpret condition (5), imagine that a population of animals programmed to play mixed strategy x is invaded by a group of mutants programmed to play the alternative mixed strategy y . Equation (5) requires that regardless of the choice of y , an incumbent’s expected payoff from

a random match in the post-entry population exceeds that of a mutant so long as the size of the invading group is sufficiently small.

The definition of ESS above can also be expressed as a combination of two conditions:

$$x'Ax \geq y'Ax \text{ for all } y \in X; \quad (4)$$

$$\text{For all } y \neq x, [x'Ax = y'Ax] \text{ implies that } [x'Ay > y'Ay]. \quad (6)$$

Condition (4) is familiar: it requires that the incumbent strategy x be a best response to itself, and so is none other than our definition of symmetric Nash equilibrium. Condition (6) requires that if a mutant strategy y is an alternative best response against the incumbent strategy x , then the incumbent earns a higher payoff against the mutant than the mutant earns against itself.

A less demanding notion of stability can be obtained by allowing the incumbent and the mutant in condition (6) to perform equally well against the mutant:

$$\text{For all } y \in X, [x'Ax = y'Ax] \text{ implies that } [x'Ay \geq y'Ay]. \quad (7)$$

If x satisfies conditions (4) and (7), it is called a *neutrally stable strategy* (NSS) [139].

Let us apply these stability notions to the games introduced in the previous section. Since every ESS and NSS must be a Nash equilibrium, we need only consider whether the Nash equilibria of these games satisfy the additional stability conditions, (6) and (7).

Example 5 In the Prisoner’s Dilemma game (Example 1), the dominant strategy D is an ESS.

Example 6 In the Stag Hunt game (Example 2), each pure Nash equilibrium is an ESS. But the mixed equilibrium $(x_H^*, x_S^*) = (\frac{s-h}{s}, \frac{h}{s})$ is not an ESS: if mutants playing either pure strategy enter the population, they earn a higher payoff than the incumbents in the post-entry population.

Example 7 In the Hawk–Dove game (Example 3), the mixed equilibrium $(x_D^*, x_E^*) = (\frac{c-v}{c}, \frac{v}{c})$ is an ESS. Maynard Smith used this and other examples to explain the existence of ritualized fighting in animals. While an animal who escalates always obtains the resource when matched with an animal who merely displays, a population of escalators is unstable: it can be invaded by a group of mutants who display, or who merely escalate less often.

Example 8 In Rock–Paper–Scissors games (Example 4), whether the mixed equilibrium $x^* = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ is evolutionarily stable depends on the relative payoffs to winning

and losing a match. In good RPS ($w > l$), x^* is an ESS; in standard RPS ($w = l$), x^* is a NSS but not an ESS, while in bad RPS ($w < l$), x^* is neither an ESS nor an NSS. The last case shows that neither evolutionary nor neutrally stable strategies need exist in a given game.

The definition of an evolutionarily stable strategy has been extended to cover a wide range of strategic settings, and has been generalized in a variety of directions. Prominent among these developments are set-valued versions of ESS: in rough terms, these concepts consider a set of mixed strategies $Y \subset X$ to be stable if the no population playing a strategy in the set can be invaded successfully by a population of mutants playing a strategy outside the set. [95] provides a thorough survey of the first 15 years of research on ESS and related notions of stability; key references on set-valued evolutionary solution concepts include [15,199,206].

Maynard Smith's notion of ESS attempts to capture the dynamic process of natural selection using a static definition. The advantage of this approach is that his definition is often easy to check in applications. Still, more convincing models of natural selection should be explicitly dynamic models, building on techniques from the theories of dynamical systems and stochastic processes. Indeed, this thoroughgoing approach can help us understand whether and when the ESS concept captures the notion of robustness to invasion in a satisfactory way.

The remainder of this article concerns explicitly dynamic models of behavior. In addition to being dynamic rather than static, these models will differ from the one considered in this section in two other important ways as well. First, rather than looking at populations whose members all play a particular mixed strategy, the dynamic models consider populations in which different members play different pure strategies. Second, instead of maintaining a purely biological point of view, our dynamic models will be equally well-suited to studying behavior in animal and human populations.

Population Games

Population games provide a simple and general framework for studying strategic interactions in large populations whose members play pure strategies. The simplest population games are generated by random matching in normal form games, but the population game framework allows for interactions of a more intricate nature.

We focus here on games played by a single population (i. e., games in which all agents play equivalent roles). We suppose that there is a unit mass of agents, each of whom chooses a pure strategy from the set $S = \{1, \dots, n\}$. The

aggregate behavior of these agents is described by a *population state* $x \in X$, with x_j representing the proportion of agents choosing pure strategy j . We identify a *population game* with a continuous vector-valued payoff function $F: X \rightarrow \mathbf{R}^n$. The scalar $F_i(x)$ represents the payoff to strategy i when the population state is x .

Population state x^* is a *Nash equilibrium* of F if no agent can improve his payoff by unilaterally switching strategies. More explicitly, x^* is a Nash equilibrium if

$$x_i^* > 0 \quad \text{implies that } F_i(x) \geq F_j(x) \quad \text{for all } j \in S. \quad (8)$$

Example 9 Suppose that the unit mass of agents are randomly matched to play the symmetric normal form game A . At population state x , the (expected) payoff to strategy i is the linear function $F_i(x) = \sum_{j \in S} A_{ij}x_j$; the payoffs to all strategies can be expressed concisely as $F(x) = Ax$. It is easy to verify that x^* is a Nash equilibrium of the population game F if and only if x^* is a symmetric Nash equilibrium of the symmetric normal form game A .

While population games generated by random matching are especially simple, many games that arise in applications are not of this form. In the biology literature, games outside the random matching paradigm are known as *playing the field* models [139].

Example 10 Consider the following model of highway congestion [17,143,166,173]. A pair of towns, Home and Work, are connected by a network of *links*. To commute from Home to Work, an agent must choose a *path* $i \in S$ connecting the two towns. The payoff the agent obtains is the negation of the delay on the path he takes. The delay on the path is the sum of the delays on its constituent links, while the delay on a link is a function of the number of agents who use that link.

Population games embodying this description are known as a *congestion games*. To define a congestion game, let Φ be the collection of links in the highway network. Each strategy $i \in S$ is a route from Home to Work, and so is identified with a set of links $\Phi_i \subseteq \Phi$. Each link ϕ is assigned a *cost function* $c_\phi: \mathbf{R}_+ \rightarrow \mathbf{R}$, whose argument is link ϕ 's *utilization level* u_ϕ :

$$u_\phi(x) = \sum_{i \in \rho(\phi)} x_i, \quad \text{where } \rho(\phi) = \{i \in S: \phi \in \Phi_i\}$$

The payoff of choosing route i is the negation of the total delays on the links in this route:

$$F_i(x) = - \sum_{\phi \in \Phi_i} c_\phi(u_\phi(x)).$$

Since driving on a link increases the delays experienced by other drivers on that link (i.e., since highway congestion involves *negative externalities*), cost functions in models of highway congestion are increasing; they are typically convex as well. Congestion games can also be used to model positive externalities, like the choice between different technological standards; in this case, the cost functions are decreasing in the utilization levels.

Revision Protocols

We now introduce foundations for our models of evolutionary dynamics. These foundations are built on the notion of a revision protocol, which describes both the timing and results of agents’ myopic decisions about how to continue playing the game at hand [24,35,96,175,217]. Revision protocols will be used to derive both the deterministic dynamics studied in Sect. “**Deterministic Dynamics**” and the stochastic dynamics studied in Sect. “**Stochastic Dynamics**”; similar ideas underlie the local interaction models introduced in Sect. “**Local Interaction**”.

Definition

Formally, a *revision protocol* is a map $\rho: \mathbf{R}^n \times X \rightarrow \mathbf{R}_+^{n \times n}$ that takes the payoff vectors π and population states x as arguments, and returns nonnegative matrices as outputs. For reasons to be made clear below, scalar $\rho_{ij}(\pi, x)$ is called the *conditional switch rate* from strategy i to strategy j .

To move from this notion to an explicit model of evolution, let us consider a population consisting of $N < \infty$ members. (A number of the analyzes to follow will consider the limit of the present model as the population size N approaches infinity – see Sects. “**Mean Dynamics**”, “**Deterministic Approximation**”, and “**Stochastic Stability via Large Population Limits**”.) In this case, the set of feasible social states is the finite set $\mathcal{X}^N = X \cap \frac{1}{N}\mathbf{Z}^n = \{x \in X: Nx \in \mathbf{Z}^n\}$, a grid embedded in the simplex X .

A revision protocol ρ , a population game F , and a population size N define a continuous-time evolutionary process – a Markov process $\{X_t^N\}$ – on the finite state space \mathcal{X}^N . A one-size-fits-all description of this process is as follows. Each agent in the society is equipped with a “stochastic alarm clock”. The times between rings of of an agent’s clock are independent, each with a rate R exponential distribution. The ringing of a clock signals the arrival of a revision opportunity for the clock’s owner. If an agent playing strategy $i \in S$ receives a revision opportunity, he switches to strategy $j \neq i$ with probability ρ_{ij}/R . If a switch occurs, the population state changes accordingly,

from the old state x to a new state y that accounts for the agent’s change in strategy.

While this interpretation of the evolutionary process can be applied to any revision protocol, simpler interpretations are sometimes available for protocols with additional structure. The examples to follow illustrate this point.

Examples

Imitation Protocols and Natural Selection Protocols

In economic contexts, revision protocols of the form

$$\rho_{ij}(\pi, x) = x_j \hat{\rho}_{ij}(\pi, x) \tag{9}$$

are called *imitation protocols* [35,96,216]. These protocols can be given a very simple interpretation: when an agent receives a revision opportunity, he chooses an opponent at random and observes her strategy. If our agent is playing strategy i and the opponent strategy j , the agent switches from i to j with probability proportional to $\hat{\rho}_{ij}$. Notice that the value of the population share x_j is not something the agent need know; this term in (9) accounts for the agent’s observing a randomly chosen opponent.

Example 11 Suppose that after selecting an opponent, the agent imitates the opponent only if the opponent’s payoff is higher than his own, doing so in this case with probability proportional to the payoff difference:

$$\rho_{ij}(\pi, x) = x_j [\pi_j - \pi_i]_+.$$

This protocol is known as *pairwise proportional imitation* [188].

Protocols of form (9) also appear in biological contexts, [144], [153,158], where in these cases we refer to them as *natural selection protocols*. The biological interpretation of (9) supposes that each agent is programmed to play a single pure strategy. An agent who receives a revision opportunity dies, and is replaced through asexual reproduction. The reproducing agent is a strategy j player with probability $\rho_{ij}(\pi, x) = x_j \hat{\rho}_{ij}(\pi, x)$, which is proportional both to the number of strategy j players and to some function of the prevalences and fitnesses of all strategies. Note that this interpretation requires the restriction

$$\sum_{j \in S} \rho_{ij}(\pi, x) \equiv 1.$$

Example 12 Suppose that payoffs are always positive, and let

$$\rho_{ij}(\pi, x) = \frac{x_j \pi_j}{\sum_{k \in S} x_k \pi_k}. \tag{10}$$

Understood as a natural selection protocol, (10) says that the probability that the reproducing agent is a strategy j player is proportional to $x_j\pi_j$, the aggregate fitness of strategy j players.

In economic contexts, we can interpret (10) as an imitative protocol based on repeated sampling. When an agent's clock rings he chooses an opponent at random. If the opponent is playing strategy j , the agent imitates him with probability proportional to π_j . If the agent does not imitate this opponent, he draws a new opponent at random and repeats the procedure.

Direct Evaluation Protocols In the previous examples, only strategies currently in use have any chance of being chosen by a revising agent (or of being the programmed strategy of the newborn agent). Under other protocols, agents' choices are not mediated through the population's current behavior, except indirectly via the effect of behavior on payoffs. These *direct evaluation protocols* require agents to directly evaluate the payoffs of the strategies they consider, rather than to indirectly evaluate them as under an imitative procedure.

Example 13 Suppose that choices are made according to the *logit choice rule*:

$$\rho_{ij}(\pi, x) = \frac{\exp(\eta^{-1}\pi_j)}{\sum_{k \in S} \exp(\eta^{-1}\pi_k)}. \quad (11)$$

The interpretation of this protocol is simple. Revision opportunities arrive at unit rate. When an opportunity is received by an i player, he switches to strategy j with probability $\rho_{ij}(\pi, x)$, which is proportional to an exponential function of strategy j 's payoffs. The parameter $\eta > 0$ is called the *noise level*. If η is large, choice probabilities under the logit rule are nearly uniform. But if η is near zero, choices are optimal with probability close to one, at least when the difference between the best and second best payoff is not too small.

Additional examples of revision protocols can be found in the next section, and one can construct new revision protocols by taking linear combinations of old ones; see [183] for further discussion.

Deterministic Dynamics

Although antecedents of this approach date back to the early work of Brown and von Neumann [45], the use of differential equations to model evolution in games took root with the introduction of the replicator dynamic by Taylor and Jonker [205], and remains an vibrant area of re-

search; Hofbauer and Sigmund [108] and Sandholm [183] offer recent surveys. In this section, we derive a deterministic model of evolution: the *mean dynamic* generated by a revision protocol and a population game. We study this deterministic model from various angles, focusing in particular on local stability of rest points, global convergence to equilibrium, and nonconvergent limit behavior.

While the bulk of the literature on deterministic evolutionary dynamics is consistent with the approach we take here, we should mention that other specifications exist, including discrete time dynamics [5,59,131,218], and dynamics for games with continuous strategy sets [41,42,77,100,159,160] and for Bayesian population games [62,70,179]. Also, deterministic dynamics for extensive form games introduce new conceptual issues; see [28,30,51,53,55] and the monograph of Cressman [54].

Mean Dynamics

As described earlier in Sect. "Definition", a revision protocol ρ , a population game F , and a population size N define a Markov process $\{X_t^N\}$ on the finite state space \mathcal{X}^N . We now derive a deterministic process – the *mean dynamic* – that describes the expected motion of $\{X_t^N\}$. In Sect. "Deterministic Approximation", we will describe formally the sense in which this deterministic process provides a very good approximation of the behavior of the stochastic process $\{X_t^N\}$, at least over finite time horizons and for large population sizes. But having noted this result, we will focus in this section on the deterministic process itself.

To compute the expected increment of $\{X_t^N\}$ over the next dt time units, recall first that each of the N agents receives revision opportunities via a rate R exponential distribution, and so expects to receive Rdt opportunities during the next dt time units. If the current state is x , the expected number of revision opportunities received by agents currently playing strategy i is approximately $Nx_i Rdt$. Since an i player who receives a revision opportunity switches to strategy j with probability ρ_{ij}/R , the expected number of such switches during the next dt time units is approximately $Nx_i \rho_{ij}dt$. Therefore, the expected change in the number of agents choosing strategy i during the next dt time units is approximately

$$N \left(\sum_{j \in S} x_j \rho_{ji}(F(x), x) - x_i \sum_{j \in S} \rho_{ij}(F(x), x) \right) dt. \quad (12)$$

Dividing expression (12) by N and eliminating the time differential dt yields a differential equation for the rate of

change in the *proportion* of agents choosing strategy i :

$$\dot{x}_i = \sum_{j \in S} x_j \rho_{ji}(F(x), x) - x_i \sum_{j \in S} \rho_{ij}(F(x), x). \quad (M)$$

Equation (M) is the *mean dynamic* (or *mean field*) generated by revision protocol ρ in population game F . The first term in (M) captures the inflow of agents to strategy i from other strategies, while the second captures the outflow of agents to other strategies from strategy i .

Examples

We now describe some examples of mean dynamics, starting with ones generated by the revision protocols from Sect. “Examples”. To do so, we let

$$\bar{F}(x) = \sum_{i \in S} x_i F_i(x)$$

denote the *average payoff* obtained by the members of the population, and define the *excess payoff* to strategy i ,

$$\hat{F}_i(x) = F_i(x) - \bar{F}(x),$$

to be the difference between strategy i 's payoff and the population's average payoff.

Example 14 In Example 11, we introduced the pairwise proportional imitation protocol $\rho_{ij}(\pi, x) = x_j[\pi_j - \pi_i]_+$. This protocol generates the mean dynamic

$$\dot{x}_i = x_i \hat{F}_i(x). \quad (13)$$

Equation (13) is the *replicator dynamic* [205], the best-known dynamic in evolutionary game theory. Under this dynamic, the percentage growth rate \dot{x}_i/x_i of each strategy currently in use is equal to that strategy's current excess payoff; unused strategies always remain so. There are a variety of revision protocols other than pairwise proportional imitation that generate the replicator dynamic as their mean dynamics; see [35,96,108,217].

Example 15 In Example 12, we assumed that payoffs are always positive, and introduced the protocol $\rho_{ij} \propto x_j \pi_j$, which we interpreted both as a model of biological natural selection and as a model of imitation with repeated sampling. The resulting mean dynamic,

$$\dot{x}_i = \frac{x_i F_i(x)}{\sum_{k \in S} x_k F_k(x)} - x_i = \frac{x_i \hat{F}_i(x)}{\bar{F}(x)}, \quad (14)$$

is the *Maynard Smith replicator dynamic* [139]. This dynamic only differs from the standard replicator dynamic

(13) by a change of speed, with motion under (14) being relatively fast when average payoffs are relatively low. (In multipopulation models, the two dynamics are less similar, and convergence under one does not imply convergence under the other – see [183,216].)

Example 16 In Example 13 we introduced the logit choice rule $\rho_{ij}(\pi, x) \propto \exp(\eta^{-1} \pi_j)$. The corresponding mean dynamic,

$$\dot{x}_i = \frac{\exp(\eta^{-1} F_i(x))}{\sum_{k \in S} \exp(\eta^{-1} F_k(x))} - x_i, \quad (15)$$

is called the *logit dynamic* [82].

If we take the noise level η to zero, then the probability with which a revising agent chooses the best response approaches one whenever the best response is unique. At such points, the logit dynamic approaches the *best response dynamic* [84]:

$$\dot{x} \in B^F(x) - x, \quad (16)$$

where

$$B^F(x) = \operatorname{argmax}_{y \in X} y'F(x)$$

defines the (*mixed*) *best response correspondence* for game F . Note that unlike the other dynamics we consider here, (16) is defined not by an ordinary differential equation, but by a differential inclusion, a formulation proposed in [97].

Example 17 Consider the protocol

$$\rho_{ij}(\pi, x) = \left[\pi_j - \sum_{k \in S} x_k \pi_k \right]_+.$$

When an agent's clock rings, he chooses a strategy at random; if that strategy's payoff is above average, the agent switches to it with probability proportional to its excess payoff. The resulting mean dynamic,

$$\dot{x}_i BM = [\hat{F}_i(x)]_+ - x_i \sum_{k \in S} [\hat{F}_k(x)]_+,$$

is called the *Brown–von Neumann–Nash (BNN) dynamic* [45]; see also [98,176,194,200,217].

Example 18

Consider the revision protocol

$$\rho_{ij}(\pi, x) = [\pi_j - \pi_i]_+.$$

When an agent's clock rings, he selects a strategy at random. If the new strategy's payoff is higher than his cur-

Evolutionary Game Theory, Table 1
Five basic deterministic dynamics

Revision Protocol	Mean Dynamic	Name and source
$\rho_{ij} = x_j[\pi_j - \pi_i]_+$	$\dot{x}_i = x_i \hat{F}_i(x)$	Replicator [205]
$\rho_{ij} = \frac{\exp(\eta^{-1} \pi_j)}{\sum_{k \in S} \exp(\eta^{-1} \pi_k)}$	$\dot{x}_i = \frac{\exp(\eta^{-1} F_i(x))}{\sum_{k \in S} \exp(\eta^{-1} F_k(x))} - x_i$	Logit [82]
$\rho_{ij} = 1_{\{j = \operatorname{argmax}_{k \in S} \pi_k\}}$	$\dot{x} \in B^F(x) - x$	Best response [84]
$\rho_{ij} = [\pi_j - \sum_{k \in S} x_k \pi_k]_+$	$\dot{x}_i = [\hat{F}_i(x)]_+ - x_i \sum_{j \in S} [F_j(x)]_+$	BNN [45]
$\rho_{ij} = [\pi_j - \pi_i]_+$	$\dot{x}_i = \sum_{j \in S} x_j [F_i(x) - F_j(x)]_+ - x_i \sum_{j \in S} [F_j(x) - F_i(x)]_+$	Smith [197]

rent strategy’s payoff, he switches strategies with probability proportional to the difference between the two payoffs. The resulting mean dynamic,

$$\dot{x}_i = \sum_{j \in S} x_j [F_i(x) - F_j(x)]_+ - x_i \sum_{j \in S} [F_j(x) - F_i(x)]_+, \tag{17}$$

is called the *Smith dynamic* [197]; see also [178].

We summarize these examples of revision protocols and mean dynamics in Table 1.

Figure 1 presents phase diagrams for the five basic dynamics when the population is randomly matched to play standard Rock–Paper–Scissors (Example 4). In the phase diagrams, colors represent speed of motion: within each diagram, motion is fastest in the red regions and slowest in the blue ones.

The phase diagram of the replicator dynamic reveals closed orbits around the unique Nash equilibrium $x^* = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$. Since this dynamic is based on imitation (or on reproduction), each face and each vertex of the simplex X is an invariant set: a strategy initially absent from the population will never subsequently appear.

The other four dynamics pictured are based on direct evaluation, allowing agents to select strategies that are currently unused. In these cases, the Nash equilibrium is the sole rest point, and attracts solutions from all initial conditions. (In the case of the logit dynamic, the rest point happens to coincide with the Nash equilibrium only because of the symmetry of the game; see [101,104].) Under the logit and best response dynamics, solution trajectories quickly change direction and then accelerate when the best response to the population state changes; under the BNN and especially the Smith dynamic, solutions approach the Nash equilibrium in a less angular fashion.

Evolutionary Justification of Nash Equilibrium

One of the goals of evolutionary game theory is to justify the prediction of Nash equilibrium play. For this justification to be convincing, it must be based on a model that makes only mild assumptions about agents’ knowledge about one another’s behavior. This sentiment can be captured by introducing two desiderata for revision protocols:

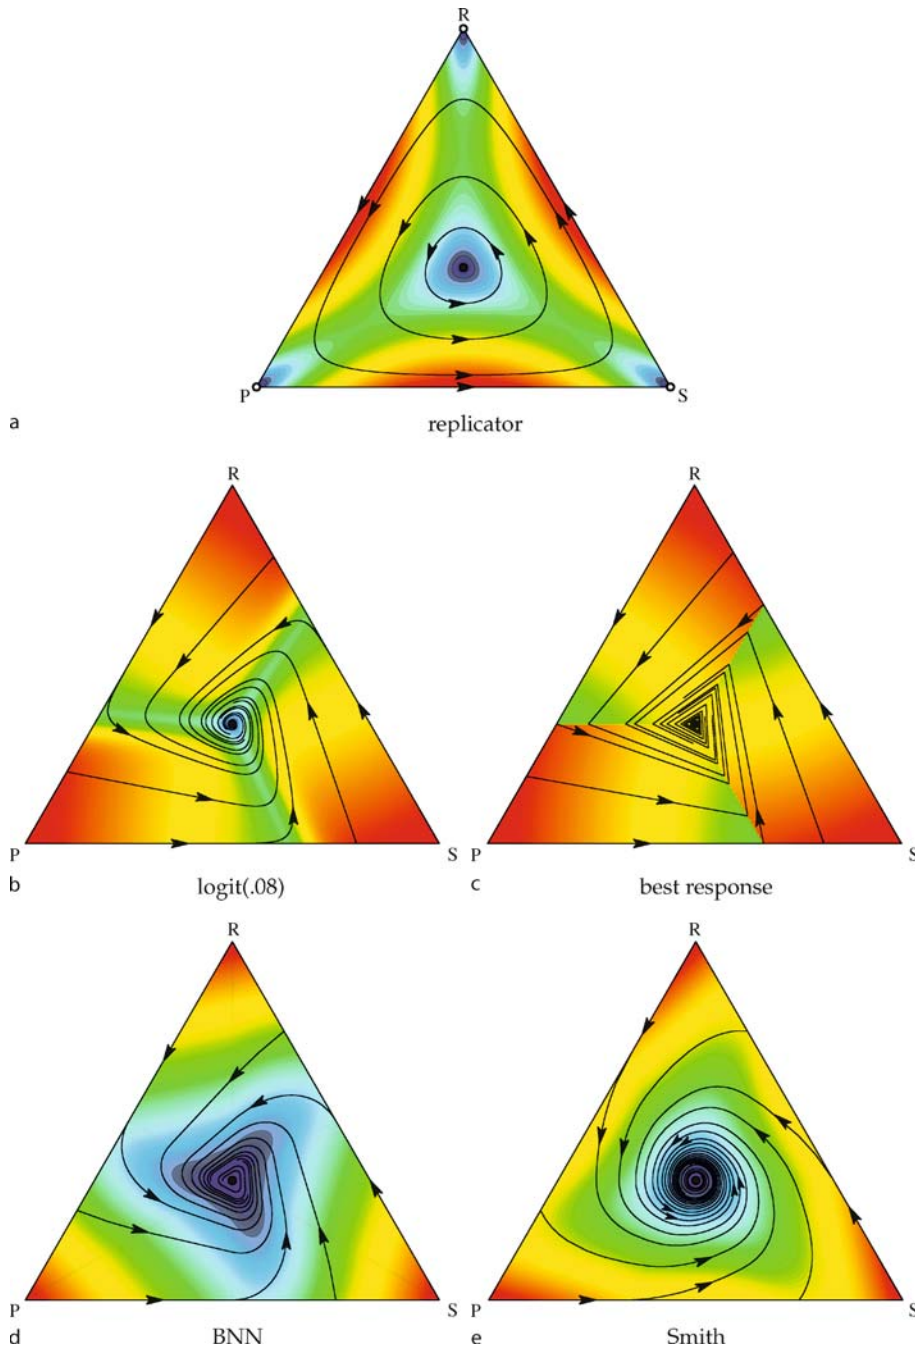

- (C) *Continuity*: ρ is Lipschitz continuous.
- (SD) *Scarcity of data*: ρ_{ij} only depends on π_i, π_j , and x_j .

Continuity (C) asks that revision protocols depend continuously on their inputs, so that small changes in aggregate behavior do not lead to large changes in players’ responses. *Scarcity of data* (SD) demands that the conditional switch rate from strategy i to strategy j only depend on the payoffs of these two strategies, so that agents need only know those facts that are most germane to the decision at hand [183]. (The dependence of ρ_{ij} on x_j is included to allow for dynamics based on imitation.) Protocols that respect these two properties do not make unrealistic demands on the amount of information that agents in an evolutionary model possess.

Our two remaining desiderata impose restrictions on mean dynamics $\dot{x} = V^F(x)$, linking the evolution of aggregate behavior to incentives in the underlying game.

- (NS) *Nash stationarity*:
 $V^F(x) = \mathbf{0}$ if and only if $x \in NE(F)$.
- (PC) *Positive correlation*:
 $V^F(x) \neq \mathbf{0}$ implies that $V^F(x)'F(x) > 0$.

Nash stationarity (NS) is a restriction on stationary states: it asks that the rest points of the mean dynamic be pre-

Evolutionary Game Theory, Figure 1

Five basic deterministic dynamics in standard Rock–Paper–Scissors. Colors represent speeds: red is fastest, blue is slowest

cisely the Nash equilibria of the game being played. *Positive correlation* (PC) is a restriction on disequilibrium adjustment: it requires that away from rest points, strategies’ growth rates be positively correlated with their pay-

offs. Condition (PC) is among the weakest of the many conditions linking growth rates of evolutionary dynamics and payoffs in the underlying game; for alternatives, see [76,110,149,162,170,173,200].

Evolutionary Game Theory, Table 2

Families of deterministic evolutionary dynamics and their properties; yes* indicates that a weaker or alternate form of the property is satisfied

Dynamic	Family	(C)	(SD)	(NS)	(PC)
Replicator	Imitation	yes	yes	no	yes
Best response		no	yes*	yes*	yes*
Logit	Perturbed best response	yes	yes*	no	no
BNN	Excess payoff	yes	no	yes	yes
Smith	Pairwise comparison	yes	yes	yes	yes

In Table 2, we report how the the five basic dynamics fare under the four criteria above. For the purposes of justifying the Nash prediction, the most important row in the table is the last one, which reveals that the Smith dynamic satisfies all four desiderata at once: while the revision protocol for the Smith dynamic (see Example 18) requires only limited information on the part of the agents who employ it, this information is enough to ensure that rest points of the dynamic and Nash equilibria coincide.

In fact, the dynamics introduced above can be viewed as members of families of dynamics that are based on similar revision protocols and that have similar qualitative properties. For instance, the Smith dynamic is a member of the family of *pairwise comparison* dynamics [178], under which agents only switch to strategies that outperform their current choice. For this reason, the exact functional forms of the previous examples are not essential to establishing the properties noted above.

In interpreting these results, it is important to remember that Nash stationarity only concerns the rest points of a dynamic; it says nothing about whether a dynamic will converge to Nash equilibrium from an arbitrary initial state. The question of convergence is addressed in Sects. “Global Convergence” and “Nonconvergence”. There we will see that in some classes of games, general guarantees of convergence can be obtained, but that there are some games in which no reasonable dynamic converges to equilibrium.

Local Stability

Before turning to the global behavior of evolutionary dynamics, we address the question of local stability. As we noted at the onset, an original motivation for introducing game dynamics was to provide an explicitly dynamic foundation for Maynard Smith’s notion of ESS [205]. Some of the earliest papers on evolutionary game dynamics [105,224] established that being an ESS is a sufficient condition for asymptotically stability under the replicator dynamic, but that it is not a necessary condition. It is cu-

rious that this connection obtains despite the fact that ESS is a stability condition for a population whose members all play the same mixed strategy, while (the usual version of) the replicator dynamic looks at populations of agents choosing among different pure strategies.

In fact, the implications of ESS for local stability are not limited to the replicator dynamic. Suppose that the symmetric normal form game A admits a symmetric Nash equilibrium that places positive probability on each strategy in S . One can show that this equilibrium is an ESS if and only if the payoff matrix A is negative definite with respect to the tangent space of the simplex:

$$z'Az < 0 \quad \text{for all } z \in TX = \left\{ \hat{z} \in \mathbf{R}^n : \sum_{i \in S} \hat{z}_i = 0 \right\}. \quad (18)$$

Condition (18) and its generalizations imply local stability of equilibrium not only under the replicator dynamic, but also under a wide range of other evolutionary dynamics: see [52,98,99,102,111,179] for further details.

The papers cited above use linearization and Lyapunov function arguments to establish local stability. An alternative approach to local stability analysis, via index theory, allows one to establish restrictions on the stability properties of all rest points at once – see [60].

Global Convergence

While analyses of local stability reveal whether a population will return to equilibrium after a small disturbance, they do not tell us whether the population will approach equilibrium from an arbitrary disequilibrium state. To establish such global convergence results, we must restrict attention to classes of games defined by certain interesting payoff structures. These structures appear in applications, lending strong support for the Nash prediction in the settings where they arise.

Potential Games A *potential game* [17,106,143,166,173,181] is a game that admits a *potential function*: a scalar val-

ued function whose gradient describes the game’s payoffs. In a full potential game $F: \mathbf{R}_+^n \rightarrow \mathbf{R}^n$ (see [181]), all information about incentives is captured by the potential function $f: \mathbf{R}_+^n \rightarrow \mathbf{R}$, in the sense that

$$\nabla f(x) = F(x) \quad \text{for all } x \in \mathbf{R}_+^n. \tag{19}$$

If F is smooth, then it is a full potential game if and only if it satisfies *full externality symmetry*:

$$\frac{\partial F_i}{\partial x_j}(x) = \frac{\partial F_j}{\partial x_i}(x) \quad \text{for all } i, j \in S \text{ and } x \in \mathbf{R}_+^n. \tag{20}$$

That is, the effect on the payoff to strategy i of adding new strategy j players always equals the effect on the payoff to strategy j of adding new strategy i players.

Example 19 Suppose a single population is randomly matched to play the symmetric normal form game $A \in \mathbf{R}^{n \times n}$, generating the population game $F(x) = Ax$. We say that A exhibits *common interests* if the two players in a match always receive the same payoff. This means that $A_{ij} = A_{ji}$ for all i and j , or, equivalently, that the matrix A is symmetric. Since $DF(x) = A$, this is precisely what we need for F to be a full potential game. The full potential function for F is $f(x) = \frac{1}{2}x'Ax$, which is one-half of the average payoff function $\bar{F}(x) = \sum_{i \in S} x_i F_i(x) = x'Ax$. The common interest assumption defines a fundamental model from population genetics, this assumption reflects the shared fate of two genes that inhabit the same organism [73,106,107].

Example 20 In Example 10, we introduced congestion games, a basic model of network congestion. To see that these games are potential games, observe that an agent taking path $j \in S$ affects the payoffs of agents choosing path $i \in S$ through the marginal increases in congestion on the links $\phi \in \Phi_i \cap \Phi_j$ that the two paths have in common. But since the marginal effect of an agent taking path i on the payoffs of agents choosing path j is identical, full externality symmetry (20) holds:

$$\frac{\partial F_i}{\partial x_j}(x) = - \sum_{\phi \in \Phi_i \cap \Phi_j} c'_\phi(u_\phi(x)) = \frac{\partial F_j}{\partial x_i}(x).$$

In congestion games, the potential function takes the form

$$f(x) = - \sum_{\phi \in \Phi} \int_0^{u_\phi(x)} c_\phi(z) dz,$$

and so is typically unrelated to aggregate payoffs,

$$\bar{F}(x) = \sum_{i \in S} x_i F_i(x) = - \sum_{\phi \in \Phi} u_\phi(x) c_\phi(u_\phi(x)).$$

However, potential is proportional to aggregate payoffs if the cost functions c_ϕ are all monomials of the same degree [56,173].

Population state x is a Nash equilibrium of the potential game F if and only if it satisfies the Kuhn–Tucker first order conditions for maximizing the potential function f on the simplex X [17,173]. Furthermore, it is simple to verify that any dynamic $\dot{x} = V^F(x)$ satisfying positive correlation (PC) ascends the potential function:

$$\frac{d}{dt} f(x_t) = \nabla f(x_t)' \dot{x}_t = F(x_t)' V^F(x_t) \geq 0.$$

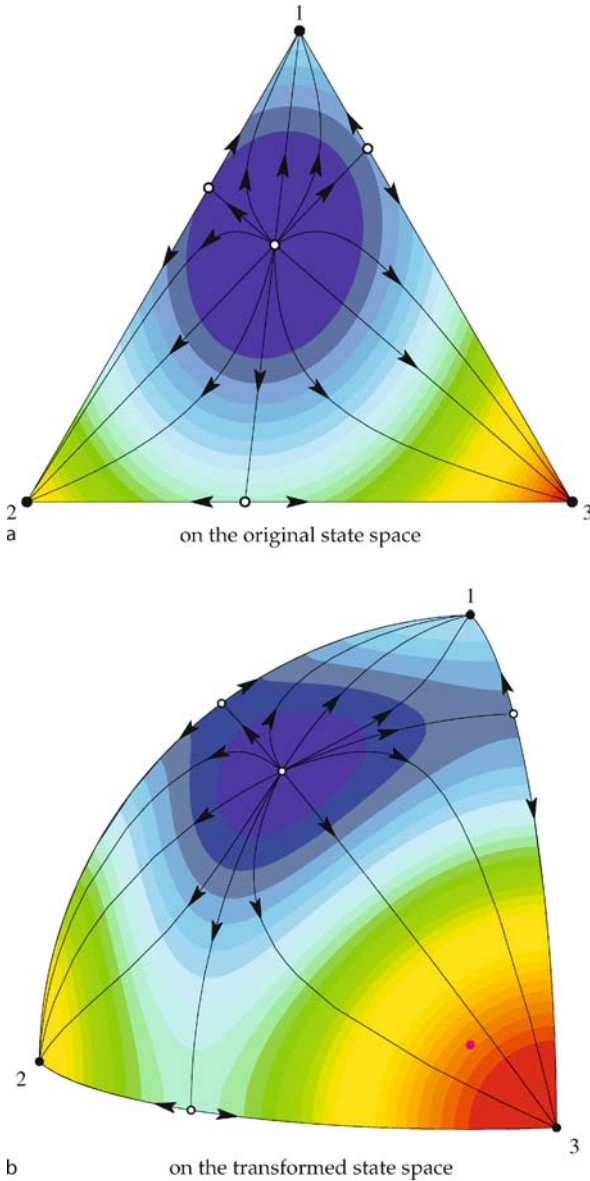

It then follows from classical results on Lyapunov functions that any dynamic satisfying positive correlation (PC) converges to a connected set of rest points. If the dynamic also satisfies Nash stationarity (NS), these sets consist entirely of Nash equilibria. Thus, in potential games, very mild conditions on agents’ adjustment rules are sufficient to justify the prediction of Nash equilibrium play.

In the case of the replicator dynamic, one can say more. On the interior of the simplex X , the replicator dynamic for the potential game F is a *gradient system* for the potential function f (i. e., it always ascends f in the direction of maximum increase). However, this is only true after one introduces an appropriate Riemannian metric on X [123,192]. An equivalent statement of this result, due to [2], is that the replicator dynamic is the gradient system for f under the usual Euclidean metric if we stretch the state space X onto the radius 2 sphere. This stretching is accomplished using the *Akin transformation* $H_i(x) = 2\sqrt{x_i}$, which emphasizes changes in the use of rare strategies relative to changes in the use of common ones [2,4,185]. (There is also a dynamic that generates the gradient system for f on X under the usual metric: the so-called *projection dynamic* [130,150,185].)

Example 21 Consider evolution in 123 Coordination:

	1	2	3
1	1	0	0
2	0	2	0
3	0	0	3

Figure 2a presents a phase diagram of the replicator dynamic on its natural state space X , drawn atop of a contour plot of the potential function $f(x) = \frac{1}{2}((x_1)^2 + 2(x_2)^2 + 3(x_3)^2)$. Evidently, all solution trajectories ascend this function and converge to one of the seven symmetric Nash equilibria, with trajectories from all but a measure

Evolutionary Game Theory, Figure 2
 The replicator dynamic in 123 Coordination. Colors represent the value of the game’s potential function

zero set of initial conditions converging to one of the three pure equilibria.

Figure 2b presents another phase diagram for the replicator dynamic, this time after the solution trajectories and the potential function have been transported to the surface of the radius 2 sphere using the Akin transformation. In this case, solutions cross the level sets of the potential function orthogonally, moving in the direction that increases potential most quickly.

Stable Games A population game F is a *stable game* [102] if

$$(y - x)'(F(y) - F(x)) \leq 0 \quad \text{for all } x, y \in X. \quad (21)$$

If the inequality in (21) always holds strictly, then F is a *strictly stable game*.

If F is smooth, then F is a stable game if and only if it satisfies *self-defeating externalities*:

$$z'DF(x)z \leq 0 \quad \text{for all } z \in TX \text{ and } x \in X, \quad (22)$$

where $DF(x)$ is the derivative of $F: X \rightarrow \mathbf{R}^n$ at x . This condition requires that the improvements in the payoffs of strategies to which revising agents are switching are always exceeded by the improvements in the payoffs of strategies which revising agents are abandoning.

Example 22 The symmetric normal form game A is *symmetric zero-sum* if A is skew-symmetric (i. e., if $A = -A'$), so that the payoffs of the matched players always sum to zero. (An example is provided by the standard Rock–Paper–Scissors game (Example 4).) Under this assumption, $z'Az = 0$ for all $z \in \mathbf{R}^n$; thus, the population game generated by random matching in A , $F(x) = Ax$, is a stable game that is not strictly stable.

Example 23 Suppose that A satisfies the interior ESS condition (18). Then (22) holds strictly, so $F(x) = Ax$ is a strictly stable game. Examples satisfying this condition include the Hawk–Dove game (Example 3) and any good Rock–Paper–Scissors game (Example 4).

Example 24 A *war of attrition* [33] is a symmetric normal form game in which strategies represent amounts of time committed to waiting for a scarce resource. If the two players choose times i and $j > i$, then the j player obtains the resource, worth v , while both players pay a cost of c_i ; once the first player leaves, the other seizes the resource immediately. If both players choose time i , the resource is split, so payoffs are $\frac{v}{2} - c_i$ each. It can be shown that for any resource value $v \in \mathbf{R}$ and any increasing cost vector $c \in \mathbf{R}^n$, random matching in a war of attrition generates a stable game [102].

The flavor of the self-defeating externalities condition (22) suggests that obedience of incentives will push the population toward some “central” equilibrium state. In fact, the set of Nash equilibria of a stable game is always convex, and in the case of strictly stable games, equilibrium is unique. Moreover, it can be shown that the replicator dynamic converges to Nash equilibrium from all interior initial conditions in any strictly stable

Evolutionary Game Theory, Table 3

Lyapunov functions for five basic deterministic dynamics in stable games

Dynamic	Lyapunov function for stable games
Replicator	$H_{x^*}(x) = \sum_{i \in S(x^*)} x_i^* \log \frac{x_i}{x_i^*}$
Logit	$\tilde{G}(x) = \max_{y \in \text{int}(X)} (y' \hat{F}(x) - \eta \sum_{i \in S} y_i \log y_i) + \eta \sum_{i \in S} x_i \log x_i$
Best response	$G(x) = \max_{i \in S} \hat{F}_i(x)$
BNN	$\Gamma(x) = \frac{1}{2} \sum_{i \in S} [\hat{F}_i(x)]_+^2$
Smith	$\Psi(x) = \frac{1}{2} \sum_{i \in S} \sum_{j \in S} x_i [F_j(x) - F_i(x)]_+^2$

game [4,105,224], and that the direct evaluation dynamics introduced above converge to Nash equilibrium from all initial conditions in all stable games, strictly stable or not [98,102,104,197]. In each case, the proof of convergence is based on the construction of a Lyapunov function that solutions of the relevant dynamic descend. The Lyapunov functions for the five basic dynamics are presented in Table 3.

Interestingly, the convergence results for direct evaluation dynamics are not restricted to the dynamics listed in Table 3, but extend to other dynamics in the same families (cf Table 2). But compared to the conditions for convergence in potential games, the conditions for convergence in stable games demand additional structure on the adjustment process [102].

Perturbed Best Response Dynamics in Supermodular Games

Supermodular games are defined by the property that higher choices by one’s opponents (with respect to the natural ordering on $S = \{1, \dots, n\}$) make one’s own higher strategies look relatively more desirable. Let the matrix $\Sigma \in \mathbf{R}^{(n-1) \times n}$ satisfy $\Sigma_{ij} = 1$ if $j > i$ and $\Sigma_{ij} = 0$ otherwise, so that $\Sigma x \in \mathbf{R}^{n-1}$ is the “decumulative distribution function” corresponding to the “density function” x . The population game F is a *supermodular game* if it exhibits *strategic complementarities*:

If $\Sigma y \geq \Sigma x$, then

$$F_{i+1}(y) - F_i(y) \geq F_{i+1}(x) - F_i(x)$$

for all $i < n$ and $x \in X$. (23)

If F is smooth, condition (23) is equivalent to

$$\frac{\partial(F_{i+1} - F_i)}{\partial(e_{j+1} - e_j)}(x) \geq 0 \quad \text{for all } i, j < n \text{ and } x \in X. \quad (24)$$

Example 25 Consider this model of *search with positive externalities*. A population of agents choose levels of search effort in $S = \{1, \dots, n\}$. The payoff to choosing effort i is

$$F_i(x) = m(i) b(a(x)) - c(i),$$

where $a(x) = \sum_{k \leq n} kx_k$ is the aggregate search effort, b is some increasing benefit function, m is an increasing multiplier function, and c is an arbitrary cost function. Notice that the benefits from searching are increasing in both own search effort and in the aggregate search effort. It is easy to check that F is a supermodular game.

Complementarity condition (23) implies that the agents’ best response correspondence is monotone in the stochastic dominance order, which in turn ensures the existence of minimal and maximal Nash equilibria [207]. One can take advantage of the monotonicity of best responses in studying evolutionary dynamics by appealing to the theory of monotone dynamical systems [196]. To do so, one needs to focus on dynamics that respect the monotonicity of best responses and that also are smooth, so that the theory of monotone dynamics can be applied. It turns out that the logit dynamic satisfies these criteria; so does any perturbed best response dynamic defined in terms of stochastic payoff perturbations. In supermodular games, these dynamics define cooperative differential equations; consequently, solutions of these dynamics from almost every initial condition converge to an approximate Nash equilibrium [104].

Imitation Dynamics in Dominance Solvable Games

Suppose that in the population game F , strategy i is a strictly dominated by strategy j : $F_i(x) < F_j(x)$ for all $x \in X$. Consider the evolution of behavior under the repli-

cator dynamic (13). Since for this dynamic we have

$$\begin{aligned} \frac{d}{dt} \frac{x_i}{x_j} &= \frac{\dot{x}_i x_j - \dot{x}_j x_i}{(x_j)^2} \\ &= \frac{x_i \hat{F}_i(x) x_j - x_j \hat{F}_j(x) x_i}{(x_j)^2} \\ &= \frac{x_i}{x_j} (\hat{F}_i(x) - \hat{F}_j(x)), \end{aligned}$$

solutions from every interior initial condition converge to the face of the simplex where the dominated strategy is unplayed [3]. It follows that the replicator dynamic converges in games with a strictly dominant strategy, and by iterating this argument, one can show that this dynamic converges to equilibrium in any game that can be solved by iterative deletion of strictly dominated strategies. In fact, this argument is not specific to the replicator dynamic, but can be shown to apply to a range of dynamics based on imitation [110,170]. Even in games which are not dominance solvable, arguments of a similar flavor can be used to restrict the long run behavior of imitative dynamics to better-reply closed sets [162]; see Sect. “Convergence to Equilibria and to Better-Reply Closed Sets” for a related discussion.

While the analysis here has focused on imitative dynamics, it is natural to expect that elimination of dominated strategies will extend to any reasonable evolutionary dynamic. But we will see in Sect. “Survival of Dominated Strategies” that this is not the case: the elimination of dominated strategies that obtains under imitative dynamics is the exception, not the rule.

Nonconvergence

The previous section revealed that when certain global structural conditions on payoffs are satisfied, one can establish global convergence to equilibrium under various classes of evolutionary dynamics. Of course, if these conditions are not met, convergence cannot be guaranteed. In this section, we offer examples to illustrate some of the possibilities for nonconvergent limit behavior.

Conservative Properties of the Replicator Dynamic in Zero-Sum Games In Sect. “Stable Games”, we noted that in strictly stable games, the replicator dynamic converges to Nash equilibrium from all interior initial conditions. To prove this, one shows that interior solutions descend the function

$$H_{x^*}(x) = \sum_{i \in S(x^*)} x_i^* \log \frac{x_i}{x_i^*},$$

until converging to its minimizer, the unique Nash equilibrium x^* .

Now, random matching in a symmetric zero-sum game generates a population game that is stable, but not strictly stable (Example 22). In this case, for each interior Nash equilibrium x^* , the function H_{x^*} is a constant of motion for the replicator dynamic: its value is fixed along every interior solution trajectory.

Example 26 Suppose that agents are randomly matched to play the symmetric zero-sum game A , given by

	1	2	3	4
1	0	-1	0	1
2	1	0	-1	0
3	0	1	0	-1
4	-1	0	1	0

The Nash equilibria of $F(x) = Ax$ are the points on the line segment NE connecting states $(\frac{1}{2}, 0, \frac{1}{2}, 0)$ and $(0, \frac{1}{2}, 0, \frac{1}{2})$, a segment that passes through the barycenter $x^* = (\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$. Figure 3 shows solutions to the replicator dynamic that lie on the level set $H_{x^*}(x) = .58$. Evidently, each of these solutions forms a closed orbit.

Although solution trajectories of the replicator dynamic do not converge in zero-sum games, it can be proved that the the time average of each solution trajectory converges to Nash equilibrium [190].

The existence of a constant of motion is not the only conservative property enjoyed by replicator dynamics for symmetric zero-sum games: these dynamics are also vol-

Evolutionary Game Theory, Figure 3 Solutions of the replicator dynamic in a zero-sum game. The solutions pictured lie on the level set $H_{x^*}(x) = .58$

ume preserving after an appropriate change of speed or change of measure [5,96].

Games with Nonconvergent Dynamics The conservative properties described in the previous section have been established only for the replicator dynamic (and its distant relative, the projection dynamic [185]). Inspired by Shapley [193], many researchers have sought to construct games in which large classes of evolutionary dynamics fail to converge to equilibrium.

Example 27 Suppose that players are randomly matched to play the following symmetric normal form game [107,109]:

	1	2	3	4
1	0	0	-1	ε
2	ε	0	0	-1
3	-1	ε	0	0
4	0	-1	ε	0

When $\varepsilon = 0$, the payoff matrix $A^\varepsilon = A^0$ is symmetric, so F^0 is a potential game with potential function $f(x) = \frac{1}{2}x'A^0x = -x_1x_3 - x_2x_4$. The function f attains its minimum of $-\frac{1}{4}$ at states $v = (\frac{1}{2}, 0, \frac{1}{2}, 0)$ and $w = (0, \frac{1}{2}, 0, \frac{1}{2})$, has a saddle point with value $-\frac{1}{8}$ at the Nash equilibrium $x^* = (\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$, and attains its maximum of 0 along the closed path of Nash equilibria γ consisting of edges $e_1e_2, e_2e_3, e_3e_4,$ and e_4e_1 .

Let $\dot{x} = V^F(x)$ be an evolutionary dynamic that satisfies Nash stationarity (NS) and positive correlation (PC), and that is based on a revision protocol that is continuous (C). If we apply this dynamic to game F^0 , then the foregoing discussion implies that all solutions to $\dot{x} = V^{F^0}(x)$ whose initial conditions ξ satisfy $f(\xi) > -\frac{1}{8}$ converge to γ . The Smith dynamic for F^0 is illustrated in Fig. 4a.

Now consider the same dynamic for the game F^ε , where $\varepsilon > 0$. By continuity (C), the attractor γ of V^{F^0} continues to an attractor γ^ε of V^{F^ε} whose basin of attraction approximates that of γ under $\dot{x} = V^{F^0}(x)$ (Fig. 4b). But since the unique Nash equilibrium of F^ε is the barycenter x^* , it follows that solutions from most initial conditions converge to an attractor far from any Nash equilibrium.

Other examples of games in which many dynamics fail to converge include monocyclic games [22,83,97,106], Mismatching Pennies [91,116], and the hypnodisk game [103]. These examples demonstrate that there is no evolutionary dynamic that converges to Nash equilibrium regardless of the game at hand. This suggests that in general, analyses of long run behavior should not restrict attention to equilibria alone.

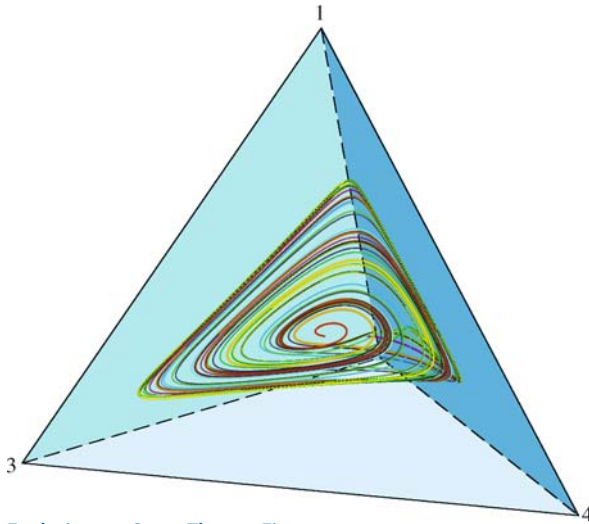

Evolutionary Game Theory, Figure 4
Solutions of the Smith dynamic in **a** the potential game F^0 ; **b** the perturbed potential game $F^\varepsilon, \varepsilon = \frac{1}{10}$

Chaotic Dynamics We have seen that deterministic evolutionary game dynamics can follow closed orbits and approach limit cycles. We now show that they also can behave chaotically.

Example 28 Consider evolution under the replicator dynamic when agents are randomly matched to play the symmetric normal form game below [13,195], whose lone interior Nash equilibrium is the barycenter $x^* = (\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$:

	1	2	3	4
1	0	-12	0	22
2	20	0	0	-10
3	-21	-4	0	35
4	10	-2	2	0

Evolutionary Game Theory, Figure 5
Chaotic behavior under the replicator dynamic

Figure 5 presents a solution to the replicator dynamic for this game from initial condition $x_0 = (.24, .26, .25, .25)$. This solution spirals clockwise about x^* . Near the right-most point of each circuit, where the value of x_3 gets close to zero, solutions sometimes proceed along an “outside” path on which the value of x_3 surpasses .6. But they sometimes follow an “inside” path on which x_3 remains below .4, and at other times do something in between. Which of these alternatives occurs is difficult to predict from approximate information about the previous behavior of the system.

While the game in Example 28 has a complicated payoff structure, in multipopulation contexts one can find chaotic evolutionary dynamics in very simple games [187].

Survival of Dominated Strategies In Sect. “Imitation Dynamics in Dominance Solvable Games”, we saw that dynamics based on imitation eliminate strictly dominated strategies along solutions from interior initial conditions. While this result seems unsurprising, it is actually extremely fragile: [25,103] prove that dynamics that satisfy continuity (C), Nash stationarity (NS), and positive correlation (PC) and that are not based exclusively on imitation must fail to eliminate strictly dominated strategies in some games. Thus, evolutionary support for a basic rationality criterion is more tenuous than the results for imitative dynamics suggest.

Example 29 Figure 6a presents the Smith dynamic for “bad RPS with a twin”:

a bad RPS with a twin

b bad RPS with a feeble twin

Evolutionary Game Theory, Figure 6
The Smith dynamic in two games

	R	P	S	T
R	0	-2	1	1
P	1	0	-2	-2
S	-2	1	0	0
T	-2	1	0	0

The Nash equilibria of this game are the states on line segment $NE = \{x^* \in X : x^* = (\frac{1}{3}, \frac{1}{3}, c, \frac{1}{3} - c)\}$, which is a repeller under the Smith dynamic. Under this dynamic, strategies gain players at rates that depend on their payoffs, but lose players at rates proportional to their current usage levels. It follows that when the dynamics are not at rest, the proportions of players choosing strategies 3 and 4 become equal, so that the dynamic approaches the plane $P = \{x \in X : x_3 = x_4\}$ on which the twins receive equal

weight. Since the usual three-strategy version of bad RPS, exhibits cycling solutions here on the plane P approach a closed orbit away from any Nash equilibrium.

Figure 6b presents the Smith dynamic in “bad RPS with a feeble twin”,

	R	P	S	T
R	0	-2	1	1
P	1	0	-2	-2
S	-2	1	0	0
T	-2 - ϵ	1 - ϵ	- ϵ	- ϵ

with $\epsilon = \frac{1}{10}$. Evidently, the attractor from Fig. 6a moves slightly to the left, reflecting the fact that the payoff to Twin has gone down. But since the new attractor is in the interior of X , the strictly dominated strategy Twin is always played with probabilities bounded far away from zero.

Stochastic Dynamics

In Sect. “Revision Protocols” we defined the stochastic evolutionary process $\{X_t^N\}$ in terms of a simple model of myopic individual choice. We then turned to the study of deterministic dynamics, which we claimed could be used to approximate the stochastic process $\{X_t^N\}$ over finite time spans and for large population sizes. In this section, we turn our attention to the stochastic process $\{X_t^N\}$ itself. After offering a formal version of the deterministic approximation result, we investigate the long run behavior of $\{X_t^N\}$, focusing on the questions of convergence to equilibrium and selection among multiple stable equilibria.

Deterministic Approximation

In Sect. “Revision Protocols”, we defined the Markovian evolutionary process $\{X_t^N\}$ from a revision protocol ρ , a population game F , and a finite population size N . In Sect. “Mean Dynamics”, we argued that the expected motion of this process is captured by the mean dynamic

$$\dot{x}_i = V_i^F(x) = \sum_{j \in S} x_j \rho_{ji}(F(x), x) - x_i \sum_{j \in S} \rho_{ij}(F(x), x). \tag{M}$$

The basic link between the Markov process $\{X_t^N\}$ and its mean dynamic (M) is provided by Kurtz’s Theorem [127], variations and extensions of which have been offered in a number of game-theoretic contexts [24,29,43, 44,175,204]. Consider the sequence of Markov processes $\{\{X_t^N\}_{t \geq 0}\}_{N=N_0}^\infty$, supposing that the initial conditions X_0^N

Evolutionary Game Theory, Figure 7
 Deterministic approximation of the Markov process $\{X_t^N\}$

converge to $x_0 \in X$. Let $\{x_t\}_{t \geq 0}$ be the solution to the mean dynamic (M) starting from x_0 . Kurtz’s Theorem tells us that for each finite time horizon $T < \infty$ and error bound $\epsilon > 0$, we have that

$$\lim_{N \rightarrow \infty} P \left(\sup_{t \in [0, T]} |X_t^N - x_t| < \epsilon \right) = 1. \tag{25}$$

Thus, when the population size N is large, nearly all sample paths of the Markov process $\{X_t^N\}$ stay within ϵ of a solution of the mean dynamic (M) through time T . By choosing N large enough, we can ensure that with probability close to one, X_t^N and x_t differ by no more than ϵ for all times t between 0 and T (Fig. 7).

The intuition for this result comes from the law of large numbers. At each revision opportunity, the increment in the process $\{X_t^N\}$ is stochastic. Still, at most population states the expected number of revision opportunities that arrive during the brief time interval $I = [t, t + dt]$ is large – in particular, of order Ndt . Since each opportunity leads to an increment of the state of size $\frac{1}{N}$, the size of the overall change in the state during time interval I is of order dt . Thus, during this interval there are a large number of revision opportunities, each following nearly the same transition probabilities, and hence having nearly the same expected increments. The law of large numbers therefore suggests that the change in $\{X_t^N\}$ during this interval should be almost completely determined by the expected motion of $\{X_t^N\}$, as described by the mean dynamic (M).

Convergence to Equilibria and to Better-Reply Closed Sets

Stochastic models of evolution can also be used to address directly the question of convergence to equilibrium [61,78,117,118,125,143,172,219]. Suppose that a society of agents is randomly matched to play an (asymmetric) normal form game that is *weakly acyclic in better replies*: from each strategy profile, there exists a sequence of profitable unilateral deviations leading to a Nash equilibrium. If agents switch to strategies that do at least as well as their current one against the choices of random samples of opponents, then the society will eventually escape any better-response cycle, ultimately settling upon a Nash equilibrium.

Importantly, many classes of normal form games are weakly acyclic in better replies: these include potential games, dominance solvable games, certain supermodular games, and certain *aggregative games*, in which each agent's payoffs only depend on opponents' behavior through a scalar aggregate statistic. Thus, in all of these cases, simple stochastic better-reply procedures are certain to lead to Nash equilibrium play.

Outside these classes of games, one can narrow down the possibilities for long run behavior by looking at *better-reply closed sets*: that is, subsets of the set of strategy profiles that cannot be escaped without a player switching to an inferior strategy (cf. [16,162]). Stochastic better-reply procedures must lead to a cluster of population states corresponding to a better-reply closed set; once the society enters such a cluster, it never departs.

Stochastic Stability and Equilibrium Selection

To this point, we used stochastic evolutionary dynamics to provide foundations for deterministic dynamics and to address the question of convergence to equilibrium. But stochastic evolutionary dynamics introduce an entirely new possibility: that of obtaining unique long-run predictions of play, even in games with multiple locally stable equilibria. This form of analysis, which we consider next, was pioneered by Foster and Young [74], Kandori, Mailath, and Rob [119], and Young [219], building on mathematical techniques due to Freidlin and Wentzell [75].

Stochastic Stability To minimize notation, let us describe the evolution of behavior using a discrete-time Markov chain $\{X_k^{N,\varepsilon}\}_{k=0}^{\infty}$ on \mathcal{X}^N , where the parameter $\varepsilon > 0$ represents the level of "noise" in agents' decision procedures. The noise ensures that the Markov chain is irreducible and aperiodic: any state in \mathcal{X}^N can be reached

from any other, and there is positive probability that a period passes without a change in the state.

Under these conditions, the Markov chain $\{X_k^{N,\varepsilon}\}$ admits a unique *stationary distribution*, $\mu^{N,\varepsilon}$, a measure on the state space \mathcal{X}^N that is invariant under the Markov chain:

$$\sum_{x \in \mathcal{X}^N} \mu^{N,\varepsilon}(x) P(X_{k+1}^{N,\varepsilon} = y \mid X_k^{N,\varepsilon} = x) = \mu^{N,\varepsilon}(y) \quad \text{for all } y \in \mathcal{X}^N.$$

The stationary distribution describes the long run behavior of the process $\{X_t^{N,\varepsilon}\}$ in two distinct ways. First, $\mu^{N,\varepsilon}$ is the *limiting distribution* of $\{X_t^{N,\varepsilon}\}$:

$$\lim_{k \rightarrow \infty} P(X_k^{N,\varepsilon} = y \mid X_0^{N,\varepsilon} = x) = \mu^{N,\varepsilon}(y) \quad \text{for all } x, y \in \mathcal{X}^N.$$

Second, $\mu^{N,\varepsilon}$ almost surely describes the *limiting empirical distribution* of $\{X_t^{N,\varepsilon}\}$:

$$P\left(\lim_{K \rightarrow \infty} \frac{1}{K} \sum_{k=0}^{K-1} 1_{\{X_k^{N,\varepsilon} \in A\}} = \mu^{N,\varepsilon}(A)\right) = 1 \quad \text{for any } A \subseteq \mathcal{X}^N.$$

Thus, if most of the mass in the stationary distribution $\mu^{N,\varepsilon}$ were placed on a single state, then this state would provide a unique prediction of long run behavior.

With this motivation, consider a sequence of Markov chains $\{\{X_k^{N,\varepsilon}\}_{k=0}^{\infty}\}_{\varepsilon \in (0,\bar{\varepsilon})}$ parametrized by noise levels ε that approach zero. Population state $x \in \mathcal{X}^N$ is said to be *stochastically stable* if it retains positive weight in the stationary distributions of these Markov chains as ε becomes arbitrarily small:

$$\lim_{\varepsilon \rightarrow 0} \mu^{N,\varepsilon}(x) > 0.$$

When the stochastically stable state is unique, it offers a unique prediction of play that is relevant over sufficiently long time spans.

Bernoulli Arrivals and Mutations Following the approach of many early contributors to the literature, let us consider a model of stochastic evolution based on *Bernoulli arrivals of revision opportunities* and *best responses with mutations*. The former assumption means that during each discrete time period, each agent has probability $\theta \in (0, 1]$ of receiving an opportunity to update his strategy. This assumption differs than the one we proposed in Sect. "Revision Protocols"; the key new implication is

that all agents may receive revision opportunities simultaneously. (Models that assume this directly generate similar results.) The latter assumption posits that when an agent receives a revision opportunity, he plays a best response to the current strategy distribution with probability $1 - \varepsilon$, and chooses a strategy at random with probability ε .

Example 30 Suppose that a population of N agents is randomly matched to play the Stag Hunt game (Example 2):

$$\begin{array}{c}
 \begin{array}{cc}
 H & S \\
 \hline
 H & \begin{array}{cc} h & h \end{array} \\
 S & \begin{array}{cc} 0 & s \end{array}
 \end{array}
 \end{array}$$

Since $s > h > 0$, hunting hare and hunting stag are both symmetric pure equilibria; the game also admits the symmetric mixed equilibrium $x^* = (x_H^*, x_S^*) = (\frac{s-h}{s}, \frac{h}{s})$.

If more than fraction x_H^* of the agents hunt hare, then hare is the unique best response, while if more than fraction x_S^* of the agents hunt stag, then stag is the unique best response. Thus, under any deterministic dynamic that respects payoffs, the mixed equilibrium x^* divides the state space into two basins of attraction, one for each of the two pure equilibria.

Now consider our stochastic evolutionary process. If the noise level ε is small, this process typically behaves like a deterministic process, moving quickly toward one of the two pure states, $e_H = (1, 0)$ or $e_S = (0, 1)$, and remaining there for some time. But since the process is ergodic, it will eventually leave the pure state it reaches first, and in fact will switch from one pure state to the other infinitely often.

To determine the stochastically stable state, we must compute and compare the “improbabilities” of these transitions. If the current state is e_H , a transition to e_S re-

quires mutations to cause roughly Nx_S^* agents to switch to the suboptimal strategy S, sending the population into the basin of attraction of e_S ; the probability of this event is of order $\varepsilon^{Nx_S^*}$. Similarly, to transit from e_S to e_H , mutations must cause roughly $Nx_H^* = N(1 - x_S^*)$ to switch from S to H; this probability of this event is of order $\varepsilon^{N(1-x_S^*)}$.

Which of these rare events is more likely ones depends on whether x_S^* is greater than or less than $\frac{1}{2}$. If $s > 2h$, so that $x_S^* < \frac{1}{2}$, then $\varepsilon^{Nx_S^*}$ is much smaller than $\varepsilon^{N(1-x_S^*)}$ when ε is small; thus, state e_S is stochastically stable (Fig. 8a). If instead $s < 2h$, so that $x_S^* > \frac{1}{2}$, then $\varepsilon^{N(1-x_S^*)} < \varepsilon^{Nx_S^*}$, so e_H is stochastically stable (Fig. 8b).

These calculations show that *risk dominance* – being the optimal response against a uniformly randomizing opponent – drives stochastic stability 2×2 games. In particular, when $s < 2h$, so that risk dominance and payoff dominance disagree, stochastic stability favors the former over the latter.

This example illustrates how under Bernoulli arrivals and mutations, stochastic stability analysis is based on *mutation counting*: that is, on determining how many simultaneous mutations are required to move from each equilibrium into the basin of attraction of each other equilibrium. In games with more than two strategies, completing the argument becomes more complicated than in the example above: the analysis, typically based on the tree-analysis techniques of [75,219], requires one to account for the relative difficulties of transitions between all pairs of equilibria. [68] develops a streamlined method of computing the stochastically stable state based on radius-coradius calculations; while this approach is not always sufficiently fine

Evolutionary Game Theory, Figure 8
 Equilibrium selection via mutation counting in Stag Hunt games

to yield a complete analysis, in the cases where it works it can be considerably simpler to apply than the tree-analysis method.

These techniques have been employed successfully to variety of classes of games, including pure coordination games, supermodular games, games satisfying “bandwagon” properties, and games with equilibria that satisfy generalizations of risk dominance [68,120,121,134]. A closely related literature uses stochastic stability as a basis for evaluating traditional solution concepts for extensive form games [90,115,122,128,152,168,169].

A number of authors have shown that variations on the Bernoulli arrivals and mutations model can lead to different equilibrium selection results. For instance, [165,211] show that if choices are determined from the payoffs from a single round of matching (rather than from expected payoffs), the payoff dominant equilibrium rather than the risk dominant equilibrium is selected. If choices depend on strategies’ relative performances rather than their absolute performances, then long run behavior need not resemble a Nash equilibrium at all [26,161,171,198]. Finally, if the probability of mutation depends on the current population state, then any recurrent set of the unperturbed process (e. g., any pure equilibrium of a coordination game) can be selected in the long run if the mutation rates are specified in an appropriate way [27]. This last result suggests that mistake probabilities should be provided with an explicit foundation, a topic we take up in Sect. “Poisson Arrivals and Payoff Noise”.

Another important criticism of the stochastic stability literature concerns the length of time needed for its predictions to become relevant [31,67]. If the population size N is large and the mutation rate ε is small, then the probability ε^{cN} that a transition between equilibria occurs during given period is miniscule; the waiting time between transitions is thus enormous. Indeed, if the mutation rate falls over time, or if the population size grows over time, then ergodicity may fail, abrogating equilibrium selection entirely [163,186]. These analyses suggest that except in applications with very long time horizons, the unique predictions generated by analyses of stochastic stability may be inappropriate, and that modelers would do better to focus on history-dependent predictions of the sort provided by deterministic models. At the same time, there are frameworks in which stochastic stability becomes relevant much more quickly. The most important of these are local interaction models, which we discuss in Sect. “Local Interaction”.

Poisson Arrivals and Payoff Noise Combining the assumption of Bernoulli arrivals of revision opportunities

with that of best responses with mutations creates a model in which the probabilities of transitions between equilibria are easy to compute: one can focus on events in which large numbers of agents switch to a suboptimal strategy at once, each doing so with the same probability. But the simplicity of this argument also highlights the potency of the assumptions behind it.

An appealing alternative approach is to model stochastic evolution using *Poisson arrivals of revision opportunities* and *payoff noise* [29,31,38,39,63,135,145,209,210,222]. (One can achieve similar effects by looking at models defined in terms of stochastic differential equations; see [18,48,74,79,113].) By allowing revision opportunities to arrive in continuous time, as we did in Sect. “Revision Protocols”, we ensure that agents do not receive opportunities simultaneously, ruling out the simultaneous mass revisions that drive the Bernoulli arrival model. (One can accomplish the same end using a discrete time model by assuming that one agent updates during each period; the resulting process is a random time change away from the Poisson arrivals model.)

Under Poisson arrivals, transitions between equilibria occur gradually, as the population works its way out of basins of attraction one agent at a time. In this context, the mutation assumption becomes particularly potent, ensuring that the probabilities of suboptimal choices do not vary with their payoff consequences. Under the alternative assumption of payoff noise, one supposes that agents play best responses to payoffs that are subject to random perturbations drawn from a fixed multivariate distribution. In this case, suboptimal choices are much more likely near basin boundaries, where the payoffs of second-best strategies are not much less than those of optimal ones, than they are at stable equilibria, where payoff differences are larger.

Evidently, assuming Poisson arrivals and payoff noise means that stochastic stability cannot be assessed by way of mutation counting. To determine the unlikelihood of escaping from an equilibrium’s basin of attraction, one must not only account for the “width” of the basin of attraction (i. e., the number of suboptimal choices needed to escape it), but also for its “depth” (the unlikelihood of each of these choices). In two-strategy games this is not difficult to accomplish: in this case the evolutionary process is a birth-and-death chain, and its stationary distribution can be expressed using an explicit formula. Beyond this case, one can employ the Freidlin and Wentzell [75] machinery, although doing so tends to be computationally demanding.

This computational burden is less in models that retain Poisson arrivals, but replace perturbed optimization with decision rules based on imitation and mutation [80].

Because agents imitate successful opponents, the population spends the vast majority of periods on the edges of the simplex, implying that the probabilities of transitions between vertices can be determined using birth-and-death chain methods [158]. As a consequence, one can reduce the problem of finding the stochastically stable state in an n strategy coordination game to that of computing the limiting stationary distribution of an n state Markov chain.

Stochastic Stability via Large Population Limits The approach to stochastic stability followed thus far relies on small noise limits: that is, on evaluating the limit of the stationary distributions $\mu^{N,\varepsilon}$ as the noise level ε approaches zero. Binmore and Samuelson [29] argue that in the contexts where evolutionary models are appropriate, the amount of noise in agents decisions is not negligible, so that taking the low noise limit may not be desirable. At the same time, evolutionary models are intended to describe behavior in large populations, suggesting an alternative approach: that of evaluating the limit of the stationary distributions $\mu^{N,\varepsilon}$ as the population size N grows large.

In one respect, this approach complicates the analysis. When N is fixed and ε varies, each stationary distribution $\mu^{N,\varepsilon}$ is a measure on the fixed state space $\mathcal{X}^N = \{x \in X: Nx \in \mathbf{Z}^n\}$. But when ε is fixed and N varies, the state space \mathcal{X}^N varies as well, and one must introduce notions of weak convergence of probability measures in order to define stochastic stability.

But in other respects taking large population limits can make analysis simpler. We saw in Sect. “[Deterministic Approximation](#)” that by taking the large population limit, we can approximate the finite-horizon sample paths of the stochastic evolutionary process $\{X_t^{N,\varepsilon}\}$ by solutions to the mean dynamic (M). Now we are concerned with infinite horizon behavior, but it is still reasonable to hope that the large population limit will again reduce some of our computations to a calculus problems.

As one might expect, this approach is easiest to follow in the two-strategy case, where for each fixed population size N , the evolutionary process $\{X_t^{N,\varepsilon}\}$ is a birth-and-death chain. When one takes the large population limit, the formulas for waiting times and for the stationary distribution can be evaluated using integral approximations [24,29,39,222]. Indeed, the approximations so obtained take an appealing simple form [182].

The analysis becomes more complicated beyond the two-strategy case, but certain models have proved amenable to analysis. For instance [80], characterizes large population stochastic stability in models based on imitation and mutation. Imitation ensures that the population spends nearly all periods on the edges of the simplex X ,

and the large population limit makes evaluating the probabilities of transitions along these edges relatively simple.

If one supposes that agents play best responses to noisy payoffs, then one must account directly for the behavior of the process $\{X_t^{N,\varepsilon}\}$ in the interior of the simplex. One possibility is to combine the deterministic approximation results from Sect. “[Deterministic Approximation](#)” with techniques from the theory of stochastic approximation [20,21] to show that the large N limiting stationary distribution is concentrated on attractors of the mean dynamic. By combining this idea with convergence results for deterministic dynamics from Sect. “[Global Convergence](#)”, Ref. [104] shows that the limiting stationary distribution must be concentrated around equilibrium states in potential games, stable games, and supermodular games.

The results in [104] do not address the question of equilibrium selection. However, for the specific case of logit evolution in potential games, a complete characterization of the large population limit of the process $\{X_t^{N,\varepsilon}\}$ has been obtained [23]. By combining deterministic approximation results, which describe the usual behavior of the process within basins of attraction, with a large deviations analysis, which characterizes the rare escapes from basins of attraction, one can obtain a precise asymptotic formula for the large N limiting stationary distribution. This formula accounts both for the typical procession of the process along solutions of the mean dynamic, and for the rare sojourns of the process against this deterministic flow.

Local Interaction

All of the game dynamics considered so far have been based implicitly on the assumption of *global interaction*: each agent’s payoffs depend directly on all agents’ actions. In many contexts, one expects to the contrary that interactions will be local in nature: for instance, agents may live in fixed locations and interact only with neighbors. In addition to providing a natural fit for these applications, *local interaction* models respond to some of the criticisms of the stochastic stability literature. At the same time, once one moves beyond relatively simple cases, local interaction models become exceptionally complicated, and so lend themselves to methods of analysis very different from those considered thus far.

Stochastic Stability and Equilibrium Selection Revisited

In Sect. “[Stochastic Stability and Equilibrium Selection](#)”, we saw the prediction of risk dominant equilibrium play provided by stochastic stability models is subverted by the waiting-time critique: namely, that the length of time re-

quired before this equilibrium is reached may be extremely long. Ellison [67,68] shows that if interactions are local, then selection of the risk dominant equilibrium persists, and waiting times are no longer an issue.

Example 31 In the simplest local interaction model, a population of N agents are located at N distinct positions around a circle. During each period of play, each agent plays the Stag Hunt game (Examples 2 and 30) with his two nearest neighbors, following the same action against both of his opponents. If we suppose that $s \in (h, 2h)$, so that hunting hare is the risk dominant strategy, then by definition, an agent whose neighbors play different strategies finds it optimal to choose H himself.

Now suppose that there are Bernoulli arrivals of revision opportunities, and that decisions are based on best responses and rare mutations. To move from the all S state to the all H state, it is enough that a single agent mutates S to H . This one mutation begins a chain reaction: the mutating agent's neighbors respond optimally by switching to H themselves; they are followed in this by their own neighbors; and the contagion continues until all agents choose H . Since a single mutation is always enough to spur the transition from all S to all H , the expected wait before this transition is small, even when the population is large.

In contrast, the transition back from all H to all S is extremely unlikely. Even if all but one of the agents simultaneously mutate to S , the contagion process described above will return the population to the all- H state. Thus, while the transition from all- S to all- H occurs quickly, the reverse transition takes even longer than in the global interaction setting.

The local interaction approach to equilibrium selection has been advanced in a variety of directions: by allowing agents to choose their locations [69], or to pay a cost to choose different strategies against different opponents [86], and by basing agents' decisions on the attainment of aspiration levels [11], or on imitation of successful opponents [9,10]. A portion of this literature initiated by Blume develops connections between local interaction models in evolutionary game theory with models from statistical mechanics [36,37,38,124,141]. These models provide a point of departure for research on complex spatial dynamics in games, which we consider next.

Complex Spatial Dynamics

The local interaction models described above address the questions of convergence to equilibrium and selection among multiple equilibria. In the cases where convergence and selection results obtain, behavior in these models is

relatively simple, as most periods are spent with most agents coordinating on a single strategy. A distinct branch of the literature on evolution and local interaction focuses on cases with complex dynamics, where instead of settling quickly into a homogeneous, static configuration, behavior remains in flux, with multiple strategies coexisting for long periods of time.

Example 32 Cooperating is a dominated strategy in the Prisoner's Dilemma, and is not played in equilibrium in finitely repeated versions of this game. Nevertheless, a pair of Prisoner's Dilemma tournaments conducted by Axelrod [14] were won by the strategy Tit-for-Tat, which cooperates against cooperative opponents and defects against defectors. Axelrod's work spawned a vast literature aiming to understand the persistence of individually irrational but socially beneficial behavior.

To address this question, Nowak and May [153,154,155,156,157] consider a population of agents who are repeatedly matched to play the Prisoner's Dilemma

$$\begin{array}{c} C \quad D \\ \begin{array}{|cc|} \hline C & 1 \quad -\varepsilon \\ \hline D & g \quad 0 \\ \hline \end{array} \end{array},$$

where the greedy payoff g exceeds 1 and $\varepsilon > 0$ is small. The agents are positioned on a two-dimensional grid. During each period, each agent plays the Prisoner's Dilemma with the eight agents in his (Moore) neighborhood. In the simplest version of the model, all agents simultaneously update their strategies at the end of each period. If an agent's total payoff that period is as high as that of any of neighbor, he continues to play the same strategy; otherwise, he switches to the strategy of the neighbor who obtained the highest payoff.

Since defecting is a dominant strategy in the Prisoner's Dilemma, one might expect the local interaction process to converge to a state at which all agents defect, as would be the case in nearly any model of global interaction. But while an agent is always better off defecting himself, he also is better off the more of his neighbors cooperate; and since evolution is based on imitation, cooperators tend to have more cooperators as neighbors than do defectors.

In Figs. 9–11, we present snapshots of the local interaction process for choices of the greedy payoff g from each of three distinct parameter regions. If $g > \frac{5}{3}$ (Fig. 9), the process quickly converges to a configuration containing a few rectangular islands of cooperators in a sea of defectors; the exact configuration depending on the initial conditions. If instead $g < \frac{8}{5}$ (Fig. 10), the process moves towards a configuration in which agents other than those in a "web" of defectors cooperate. But for $g \in (\frac{8}{5}, \frac{5}{3})$ (Fig. 11), the sys-

Evolutionary Game Theory, Figure 9

Local interaction in a Prisoner's Dilemma; greedy payoff $g = 1.7$. In Figs. 9–11, agents are arrayed on a 100×100 grid with periodic boundaries (i. e., a torus). Initial conditions are random with 75% cooperators and 25% defectors. Agents update simultaneously, imitating the neighbor who earned the highest payoff. *Blue* cells represent cooperators who also cooperated last period, *green* cells represent new cooperators; *red* cells represent defectors who also defected last period, *yellow* cells represent new defectors. (Figs. 9–11 created using VirtualLabs [92])

Evolutionary Game Theory, Figure 10

Local interaction in a Prisoner's Dilemma; greedy payoff $g = 1.55$

Evolutionary Game Theory, Figure 11

Local interaction in a Prisoner's Dilemma; greedy payoff $g = 1.65$

tem evolves in a complicated fashion, with clusters of cooperators and of defectors forming, expanding, disappearing, and reforming. But while the configuration of behavior never stabilizes, the proportion of cooperators appears to settle down to about .30.

The specification of the dynamics considered above, based on simultaneous updating and certain imitation of the most successful neighbor, presents a relatively favorable environment for cooperative behavior. Nevertheless, under Poisson arrivals of revision opportunities, or probabilistic decision rules, or both, cooperation can persist for very long periods of time for values of g significantly larger than 1 [154,155].

The literature on complex spatial dynamics in evolutionary game models is large and rapidly growing, with the evolution of behavior in the spatial Prisoners' Dilemma being the single most-studied environment. While analyses are typically based on simulations, analytical results have been obtained in some relatively simple settings [71,94].

Recent work on complex spatial dynamics has considered games with three or more strategies, including Rock–Paper–Scissors games, as well as public good contribution games and Prisoner's Dilemmas with voluntary participation. Introducing more than two strategies can lead to qualitatively novel dynamic phenomena, including large-scale spatial cycles and traveling waves [93,202,203]. In addition to simulations, the analysis of complex spatial dynamics is often based on approximation techniques from non-equilibrium statistical physics, and much of the research on these dynamics has appeared in the physics literature. [201] offers a comprehensive survey of work on this topic.

Applications

Evolutionary game theory was created with biological applications squarely in mind. In the prehistory of the field, Fisher [73] and Hamilton [87] used game-theoretic ideas to understand the evolution of sex ratios. Maynard Smith [137,138,139,140] introduced his definition of ESS as a way of understanding ritualized animal conflicts. Since these early contributions, evolutionary game theory has been used to study a diverse array of biological questions, including mate choice, parental investment, parent-offspring conflict, social foraging, and predator-prey systems. For overviews of research on these and other topics in biology, see [65,88].

The early development of evolutionary game theory in economics was motivated primarily by theoretical concerns: the justification of traditional game-theoretic solu-

tion concepts, and the development of methods for equilibrium selection in games with multiple stable equilibria. More recently, evolutionary game theory has been applied to concrete economic environments, in some instances as a means of contending with equilibrium selection problems, and in others to obtain an explicitly dynamic model of the phenomena of interest. Of course, these applications are most successful when the behavioral assumptions that underlie the evolutionary approach are appropriate, and when the time horizon needed for the results to become relevant corresponds to the one germane to the application at hand.

Topics in economics theoretical studied using the methods of evolutionary game theory range from behavior in markets [1,6,7,8,12,19,64,112,129,212], to bargaining and hold-up problems [32,46,57,66,164,208,220,221,222], to externality and implementation problems [47,49,136,174,177,180], to questions of public good provision and collective action [146,147,148]. The techniques described here are being applied with increasing frequency to problems of broader social science interest, including residential segregation [40,62,142,222,223,225,226] and cultural evolution [34,126], and to the study of behavior in transportation and computer networks [72,143,150,173,175,177,197]. A proliferating branch of research extends the approaches described in this article to address the evolution of structure and behavior in social networks; a number of recent books [85,114,213] offer detailed treatments of work in this domain.

Future Directions

Evolutionary game theory is a maturing field; many basic theoretical issues are well understood, but many difficult questions remain. It is tempting to say that stochastic and local interaction models offer the more open terrain for further explorations. But while it is true that we know less about these models than about deterministic evolutionary dynamics, even our knowledge of the latter is limited: while dynamics on one and two dimensional state spaces, and for games satisfying a few interesting structural assumptions, are well-understood, the dynamics of behavior in the vast majority of many-strategy games are not.

The prospects for further applications of the tools of evolutionary game theory are brighter still. In economics, and in other social sciences, the analysis of mathematical models has too often been synonymous with the computation and evaluation of equilibrium behavior. The questions of whether and how equilibrium will come to be are often ignored, and the possibility of long-term disequilibrium behavior left unmentioned. For settings in which its

assumptions are tenable, evolutionary game theory offers a host of techniques for modeling the dynamics of economic behavior. The exploitation of the possibilities for a deeper understanding of human social interactions has hardly begun.

Glossary

Culture The attitudes, beliefs, and behaviors that, for a certain group, define their general way of life and that they have taken over from others.

Cultural evolution The development of culture over time, as conceptualized through the mechanisms of variation and natural selection of cultural elements.

Replicator An information pattern that is able to make copies of itself, typically with the help of another system. Examples are genes, memes, and (computer) viruses.

Meme A cultural replicator; a unit of imitation or communication.

Memeplex (or meme complex) A collection of mutually supporting memes, which tend to replicate together.

Memetics The theoretical and empirical science that studies the replication, spread and evolution of memes.

Fitness The overall success rate of a replicator, as determined by its degree of adaptation to its environment, and the three requirements of longevity, fecundity and copying-fidelity.

Longevity The duration that an individual replicator survives.

Fecundity The speed of reproduction of a replicator, as measured by the number of copies made per time unit.

Copying-fidelity The degree to which a replicator is accurately reproduced.

Vertical transmission Transmission of traits (memes or genes) from parents to offspring.

Horizontal transmission Transmission of traits between individuals of the same generation.

Memotype A meme in the form of information held in an individual's memory.

Mediotype A meme as expressed in an external medium, such as a text, an artefact, a song, or a behavior.

Sociotype The group or community of individuals who hold a particular meme in their memory.

Definition of the Subject

Cultural traits are transmitted from person to person, similarly to genes or viruses. Cultural evolution therefore can be understood through the same basic mechanisms of reproduction, spread, variation, and natural selection that underlie biological evolution. This implies a shift from genes as units of biological information to a new type of units of cultural information: *memes*. The concept of meme can be defined as an information pattern, held in an individual's memory, which is capable of being copied to another individual's memory. Memetics can then be defined as the theoretical and empirical science that studies the replication, spread and evolution of memes. Memes differ in their degree of fitness, i. e. adaptedness to the socio-cultural environment in which they propagate. Fitter memes will be more successful in being communicated, "infecting" more individuals, thus spreading over a larger population. This biological analogy allows us to apply Darwinian concepts and theories to model cultural evolution.

Introduction

The transmission of cultural traits is a process that in many ways resembles the spread of an infectious disease: the carrier of a certain idea, behavior or attitude directly or indirectly communicates this idea to another person, who now also becomes a carrier, ready to "infect" further people. For example, after you heard your neighbor whistling a catchy tune a couple of times, you may well start whistling it your-

self, thus being ready to infect some more people with the tune. Similarly, after you hear your friends recommend a new electronic tool they have bought, you may well buy one yourself, and, if you like it, start recommending it to those acquaintances who do not know it yet. Thus, cultural traits can be seen as analogous to *mind viruses* [18,28], *idea viruses* [41] or *thought contagions* [59], which are reproduced from mind to mind via imitation or communication. A truly successful trait is one that spreads like an epidemic, infecting the whole of the population, in order to end up as a stable, endemic component of that population's culture. For example, the tune may become part of the repertoire of "evergreens" that everyone knows, and the tool may become as widespread as the mobile phone or color television.

This virus metaphor is attractive in that it suggests a new perspective and new methods, such as epidemiology [4], for studying the dynamics of culture. However, in order to turn it into a well-founded scientific theory, we need a deeper understanding of the underlying assumptions and implications of this analogy. For this, we can turn to the science that studies viruses and other self-reproducing systems: biology.

It is an old idea to see a correspondence between cultural and biological evolution, with cultural entities undergoing similar processes of variation, reproduction and natural selection as organisms or genes. Around the end of the 18th century Western linguists discovered the similarities between different languages. Sir William Jones gave birth to the field of language evolution studies, more specifically in the search for the origin of languages, and their "common descent" [72]. The German linguist August Schlegel attempted to recreate this common ancestor of languages, publishing tree-diagrams of languages as early as 1853, six years before Darwin published his *Origin of Species*. In an 1870 article one can already read: "How does a new style of architecture prevail? How, again, does fashion change? (...) or take language itself (...) it is the idea of 'natural selection' that was wanted" [65]. The American philosopher and psychologist William James [55] pointed out in a presentation to the Harvard Natural History Society that: "A remarkable parallel, . . . , obtains between the facts of social evolution on the one hand, and of zoological evolution as expounded by Mr. Darwin on the other."

By the end of the 20th century, the parallel study of cultural and biological evolution got a new impetus with the introduction, by Richard Dawkins [27] (first edition 1976), of the concept of *meme* (for a review see [7]). A meme, named in analogy with a gene, is defined as a cultural replicator, i. e. an element of culture such as a tradition, belief, idea, melody, or fashion, that can be held in memory and

transmitted or copied to the memory of another person. The core idea of memetics is that memes differ in their degree of fitness, i. e. adaptedness to the socio-cultural environment in which they propagate [29,50]. Mutations and recombinations of existing ideas will produce a variety of memes that compete with each other for the attention of people. Fitter memes will be more successful in being communicated, “infecting” more individuals, thus spreading over a larger population. The resulting evolutionary dynamics is one of variation creating new meme variants, followed by natural selection retaining only the ones that are most fit. Thus, the Darwinian principle of the survival of the fittest can be seen to underlie cultural evolution as well as biological evolution [3,5,6,33,58].

The memetic perspective on culture is complementary to the traditional social science perspective, which focuses on the characteristics of the individuals and groups communicating rather than on the characteristics of the information being communicated. This does not imply a “memetic reductionism”, which would deny individual control over what you communicate. It just notes that in many cases the dynamics of information propagation and the ensuing evolution of culture can be modeled more simply from the “meme’s point of view” than by analyzing the conscious or unconscious intentions of the communicating agents.

Over the past thirty years, several models of cultural evolution have been proposed that study the propagation of memes or similarly defined cultural traits e.g. “culturgens” [58] or “mnemons” [21]. Most of those models are purely theoretical, proposing various conceptualizations, implications and speculations based on the memetic perspective e.g. [15,31,38,54,57]. Some studies are mathematical in nature, applying techniques from mathematical genetics or epidemiology to quantitatively estimate the spread of particular types of memes within a population e.g. [17,23,58,60]. Others are computational, simulating the transmission of knowledge or behaviors between software agents e.g. [12,19,39]. A few are observational case studies, where the spread of a particular cultural phenomenon, such as a chain letter, an urban legend, or a social stereotype, is investigated qualitatively or quantitatively e.g. [10,24,42,68].

However, in spite of these advances, the memetic perspective on culture is not very well developed yet, and remains controversial [2,3,34]. There are several reasons why memeticists have not yet been able to convince the bulk of social and cultural scientists of the soundness of their approach.

First, the analogy with the gene, and its embodiment as DNA, seems to indicate that a meme should have

a clear, well-delineated, stable structure. (Although one should note that natural selection was proposed by Darwin well before genes were postulated by Mendel, and a century before their structure was elucidated by Watson and Crick). Cultural entities, such as beliefs, ideas, fashions, and norms, on the other hand are typically ambiguous, difficult to delimit and constantly changing. Memetic models that are based on “hard”, explicitly defined units, therefore, only seem applicable to a very small subset of cultural phenomena, such as chain letters. However, the biological analogy does not imply such rigidity: unlike higher organisms, the genes of bacteria and viruses too are in a flux, constantly mutating and exchanging bits of DNA with other organisms, but that does not imply that they do not obey evolutionary principles.

A second criticism of the memetic approach is that people are not passive “vehicles” or “carriers” of ideas and beliefs, the way they may carry viruses. Individuals actively interpret the information they receive in the light of their existing knowledge and values, and on the basis of that may decide to reject, accept, or modify the information that is communicated to them. In other words, individuals and groups actively intervene in the formulation and propagation of culture. In that sense, cultural evolution is Lamarckian rather than purely Darwinian.

A final criticism is that memetic models have not yet been sufficiently subjected to empirical tests [25,34]. Part of the reason is that most memetic theories do not make sufficiently concrete predictions to be falsifiable by observation. Most of these theories remain very speculative—often hardly better than a form of “armchair philosophy”. Moreover, until now there simply have been very few empirical studies of how memes propagate, whether in the laboratory e.g. [62] or in real life e.g. [10], and even fewer links have been established between these observations and theoretical or mathematical models.

We will try to address these criticisms in the remainder of this article. First, we will discuss the issue of how to define a meme in an as accurate way as possible. Then we will review the process of transmission of memes between individuals, emphasizing the active role played by an individual’s cognitive structure. This will give us a basis to review the dynamics of memetic propagation across a population, and the mathematical and simulation models that have been used to study it. To introduce empirical tests, we will first discuss the criteria that determine the fitness of a meme, specifying which memes are most likely to spread. We will then summarize a few experiments and case studies in which the predictive value of such selection criteria was tested. Finally, we will discuss some potential future applications of memetic research.

Defining the Meme

Replicators

The original definition of a meme by Dawkins [27] was based on the concept of *replicator*. A replicator is a system that is able to make copies of itself, typically with the help of some other system. Examples include real and computer viruses, which need respectively a cell and a computer processor to make copies of themselves. The fundamental example discussed by Dawkins is the gene, the string of DNA that carries the information on how to make a protein, and that is copied with the help of the cellular machinery whenever a cell divides. A meme too is a replicator, as it is copied whenever information is transmitted from one individual to another via communication or imitation.

Because replicators can be reproduced in different quantities, they are subject to natural selection: the one that tends to produce the largest number of replicas over an extended time span will win the competition with less productive replicators. To succeed in this, according to Dawkins [27], a good replicator should exhibit the following characteristics:

- Longevity:** The longer any instance of the replicating pattern survives, the more copies can be made of it. A drawing made by etching lines in the sand is likely to be erased before anybody could have reproduced it.
- Fecundity:** The faster the rate of copying, the more the replicator will spread. An industrial printing press can churn out many more copies of a pamphlet than an office-copying machine.
- Copying-fidelity:** The more accurate or faithful the copy, the more will remain of the initial pattern after several rounds of copying. If a painting is reproduced by making photocopies from photocopies, the picture will quickly become unrecognizable.

Dawkins called memes the “new” replicators, in the sense that they appeared very recently compared to genes. The reason for this evolution is clear: the typically human ability of imitation, i. e. learning new ideas, knowledge or behavior by copying what another individual already learnt, provides a tremendous shortcut for the multiple experiences of trial-and-error that are otherwise necessary to discover a useful new behavior pattern [21]. While some other animals are capable of limited imitation—e. g. songbirds learn songs from each other, and apes can imitate simple behaviors [16]—this capability is best developed in humans [15]. This accounts for our ability to develop a culture that is passed on from generation to generation, thus accumulating ever more useful knowledge in the course

of its evolution. In that sense, memes can be seen to be responsible for the extremely fast development of human society and its subsequent dominance of the ecosystem.

Memes vs. Genes

When we compare the two most important replicators, genes and memes, we immediately notice a number of fundamental differences. Genes can only be transmitted from parent to offspring. Memes can in principle be transmitted between any two individuals. For genes to be transmitted, you need one generation. Memes can be transmitted in the span of minutes. Meme propagation is also much faster than gene spreading, because gene replication is restricted by the relatively small number of offspring a single parent can have, whereas the number of individuals that can take over a meme from a single individual is almost unlimited. Moreover, it seems much easier for memes to undergo variation, since the information in the nervous system is more plastic than that in the DNA, and since individuals can come into contact with many more different sources of novel memes. On the other hand, selection processes too are more efficient because of “vicarious” selection [21]: the carrier of a meme does not need to be killed in order to eliminate an inadequate meme; it suffices that he witnesses or hears about the troubles of another individual due to that same meme.

The conclusion is that cultural evolution will be several orders of magnitude faster and more efficient than genetic evolution. It should not surprise us then that during the last ten thousand years, humans have hardly changed on the genetic level, whereas their culture has undergone the most radical developments. In practice the superior *evolvability* of memes also means that in cases where genetic and memetic replicators are in competition, we would expect the memes to win, even though the genes would start with the advantage of a well-established, stable structure [15], as we will discuss further when reviewing computer simulations of such dual evolution.

While memes have a much higher fecundity than genes, their plasticity implies a much lower copying-fidelity: a message as received and understood by an individual will rarely be identical to the one that was expressed, as illustrated by the many misunderstandings and reinterpretations during communication. Yet, we should not conclude from this that effective communication is impossible: if you believed that, you would not be reading this article, hoping to assimilate the main ideas presented by its authors. The reason for such mixture of accurate transmission with creative reinterpretation is that, most fundamentally, humans are cognitive agents. This means that they

process incoming information depending on the knowledge they already have and the computing machinery they are endowed with, selectively retain some of that information in their memory, and selectively express some of that information to other agents. Generally, the transmission of information by an agent will change both the agent, who has learned something new, and the information, which will be affected by the knowledge the agent already had.

Therefore, a meme reaching an agent, if it is reproduced at all, will typically be transmitted in a changed form, possibly recombined with other information learned earlier. This explains why it is often so difficult to define or pinpoint an individual meme. In that sense, cultural evolution is Lamarckian: characteristics acquired during the lifetime of the meme's carrier can be transmitted to later carriers. Lamarckian evolution, while not being Darwinian in the strict sense, is still subject to the principle of natural selection: acquired characteristics too will be passed on selectively, depending on their fitness. Natural selection by definition will pick out the memes who survive this transmission process and are favorable among other memes thanks to possible variations they underwent in this process (although it is likely that most changes will not be beneficial to the favorability). Therefore, the fittest memes, such as certain songs, religious beliefs, scientific laws, or brand names, will have a stable, recognizable identity, even though they may differ in appearance, as exemplified by the many renditions of a song or joke. All such memes together define the culture shared by a community.

This identity will be reinforced by positive feedback that characterizes the non-linear interaction between meme and carrier: the more people encounter a particular version of a meme, the more they will tend to adapt their own version to this common prototype, the more commonly they will express this version, and thus the more people will encounter it. In this way, a variety of versions that are constantly being exchanged within the same group will tend to *converge* to a single, canonical version [8]. A newcomer to this group with a variant version will be extensively subjected to the accepted version, and is likely to eventually give in to this *conformist pressure* by adopting the majority version [17].

This *winner-takes-all* dynamics, where the initially most frequent variant comes to dominate all others, is elegantly illustrated by computer simulations of the evolution of language, in which many communicating individuals who use different words for the same concept quickly converge on a single word [69]. Similarly, most systems of ethics or religious belief tend to actively suppress any variant from their canonical version. This explains why in spite of the great variability of memes, we generally have

no problems determining whether an individual belongs to a certain religious or linguistic group [51]. Note that such non-linear reinforcement does not exist for genes, since genes are transmitted only once, from parent to offspring. Moreover, once a gene is given, it can no longer be affected by the presence of other versions in the population.

Another fundamental difference between memes and genes is that for memes there is no equivalent for the traditional distinction between *genotype* (the information carried by the genes and passed on to the next generation) and *phenotype* (the specific appearance of an organism as determined by genes and environmental influences). In biological evolution, the genotype is the site of evolutionary variation (since variations in the phenotype are not passed on during reproduction) and the phenotype the site of selection (since it is the organism as a whole that survives and reproduces, or is eliminated). In memetics, we can distinguish three levels:

1. The *memotype* denotes the information as held in an individual's memory;
2. The *mediotype* denotes that information as expressed in an external medium, such as a text, an artefact, a song, or a behavior;
3. The *sociotype* denotes the group or community of individuals who hold that information in their memory [15].

Variation and selection take place on all three levels. A memotype can vary or be eliminated (forgotten) while residing in an individual's brain. A mediotype can similarly mutate (e. g. via a printing error) or be lost, and a sociotype can change when new individuals are added to the group, who may introduce different memes, or be eliminated (as when an unsuccessful tribe dies out). In conclusion, the processes of variation and selection, while analogous at the deepest level, are much more complex for memes than for genes.

Delimiting the Memetic Unit

What are the elements that make up a meme? In order to analyze meme structure, we can use some concepts from cognitive science, the discipline that studies mental content. Perhaps the most popular unit used to represent knowledge in artificial intelligence is the *production rule*. It has the form "if condition, then action". The action leads in general to the activation of another condition or category. A production rule can thus be analyzed as a combination of even more primitive elements: two *concepts* or *categories* and a *connection* (the "then" part, which

makes the first category entail the second one). For example, a meme like “God is omnipotent” can be interpreted as “if a phenomenon is God (it belongs to the category of God-like entities), then that phenomenon is omnipotent (it belongs to the category of omnipotent entities)”.

Production rules are connected when the output condition (action) of the one matches the input condition of the other. This makes it possible to construct complex cognitive systems on the basis of simple rules. In memetics, such systems are called *meme complexes* or *memeplexes*. For example, a scientific theory or a religious system of belief may be represented as a collection of mutually connected propositions or production rules, such as “God is omnipotent”, “God is good”, “God punishes bad people”, “if you steal, you are bad”, etc. This collection of rules together determines a knowledge system that allows making inferences, such as “if you steal, God will punish you”. Even more concrete perceptual or behavioral memes, such as a tune, might be modeled in this way, as concatenations of production rules of the type “if C (musical note distinguished), then E (note produced and subsequently distinguished)”, “if E, then A”, and so on. (In fact, genetic information too can be modeled using networks of “if... then” productions: a DNA string is activated by the presence of certain proteins (condition) to which it responds by producing specific other proteins (action), see [56]).

Production rules—or at least a simplified, binary representation of them, called “classifiers”—can be used to build computer simulations of cognitive evolution, using genetic algorithms, i. e. algorithmically applied operators that perform the equivalents of mutation, recombination, and selection on the basis of “fitness” on such strings [53]. Although classifier models generally do not take into account distinct carriers, this looks like a promising road to study the evolution of memeplexes formally and computationally. As we will see later, though, simulations of cultural evolution are usually limited to the mutation and spread of simple memes, ignoring the cognitive structures and processes that support inferences and that create new meme(plex)es out of combinations of existing ones.

Even if we would model memes as connected sets of production rules, we still have the problem of how many production rules define a single meme(plex). If we call a religion or a scientific theory a meme, it is clear that this will encompass a very large number of interconnected rules. In practice it will be impossible to enumerate all rules, or to define sharp boundaries between the rules that belong to the meme and those that do not. For example, should you believe in the existence of Hell, the creation of the world in seven days, and the virginity of Mary to be called a Catholic?

A pragmatic criterion that can be used in this regard is to define a meme or memeplex as the smallest collection of propositions or memory items that tends to replicate as a whole cf. [73]. For example, a proposition like “God is omnipotent” on its own, without specification of God’s other characteristics, is much too abstract to be clearly understood or applied, and as such is unlikely to replicate well. However, in combination with a number of other propositions, like “God is good”, “God is the creator of the world”, etc., that flesh out, apply, and support this abstract idea, the package will make much more sense, and be more likely to be passed on to other individuals. Similarly, the first three notes of a melody are unlikely to be remembered as a unit, but the first eight, as in the beginning of Beethoven’s fifth symphony, may well be.

It remains that often we can add or subtract a few production rules (such as the virginity of Mary) from a memeplex without significantly changing its chances of replication. Therefore, in practice it will rarely be possible to determine the precise boundaries of a meme(plex). However, this should not detract us from considering memes while analyzing cultural evolution. Indeed, the same problem besets genetic models of biological evolution: as yet, it is in practice impossible to specify the exact combination of DNA codons that determine the gene for, say, fair skin, big ears or altruism. The biochemical definition of a gene as a string of DNA that codes for one protein is not very useful when studying evolution, since most practical functions require a combination of proteins, most proteins exhibit a combination of functions, and much of the DNA is non-coding, but therefore not necessarily useless, as it may contain control information that determines the activation of other DNA strings.

As Dawkins [27] notes, we do not need to know the constitutive elements or boundaries of a gene in order to explain the evolution of particular characteristics, such as altruism or fair skin, for which such a gene would be responsible. It is sufficient that we can distinguish the effects of that gene from the effects of its rival genes (alleles). If we can determine the fitness differences resulting from these effects, then we can make predictions about which type of genes will win the competition in a particular situation, and thus which characteristics the species is most likely to evolve. For example, knowing that people with lighter skin need less sunlight to produce sufficient vitamin D, we can predict that in Northern regions natural selection will favor genes for light skin over genes for dark skin—whatever DNA codons make up these respective genes.

The same applies to memes. If, for example, we observe that one meme (say Catholicism) induces its carriers to have more children than its competitors (say Anglican-

ism), and that the children tend to take over their memes from their parents, then, *all other things being equal*, we can predict that after sufficient time this meme will dominate in the population. This prediction does not require any explicit definition of the meme of Catholicism, but only the ability to distinguish it from its competitors. Of course, in practice it is never the case that all other things are equal, but that is the predicament of all scientific modeling: we must always simplify, and ignore potentially important influences. The question is to do that as wisely as possible, and to maximally include relevant variables without making the model too complex.

Dynamics of Meme Replication and Spread

To be replicated, a meme must pass successfully through four subsequent stages:

1. *Assimilation* by an individual, who thereby becomes a carrier or *host* of the meme;
2. *Retention* in that individual's memory;
3. *Expression* by the individual in language, behavior, or another form that can be perceived by others;
4. *Transmission* of the thus created message or mediotype to one or more other individuals.

This last stage is followed again by stage 1, thus closing the replication loop. At each stage there is selection, meaning that some memes will be eliminated. Let us look in more detail at the mechanisms governing these four stages.

Assimilation

A successful meme must be able to “infect” a new host, that is, enter into its memory, and thus acquire its *memotype* form. Let us assume that a meme is presented to a potential new host. “Presented” means either that the individual encounters an existing mediotype form of a meme, or that he or she independently discovers the meme, by observation of outside phenomena or by thought, i. e. recombination of existing cognitive elements. To be assimilated, the presented meme must be respectively *noticed*, *understood* and *accepted* by the host. Noticing requires that the mediotype be sufficiently salient to attract the host's attention. Understanding means that the host recognizes the meme as something that fits in with his or her cognitive system. The mind is not a blank slate on which any idea can be impressed. To be understood, a new idea or phenomenon must connect to cognitive structures that are already available to the individual. Finally, a host that has understood a new idea must also be willing to believe it or to take it seriously. For example, although you are likely to under-

stand the proposition that your car was built by little green men from Mars, you are unlikely to accept that proposition without very strong evidence. Therefore, you will in general not memorize it, and the meme will not manage to infect you.

Retention

The second stage of memetic replication is the retention of the meme in memory. The longer the meme stays, the more opportunities it will have to spread further by infecting other hosts. This is Dawkins's [27] *longevity* characteristic for replicators.

Just like assimilation, retention is characterized by strong selection, which few memes will survive. Indeed, most of the things we hear, see or understand during the day are not stored in memory for longer than a few hours. Although you may have clearly assimilated the news that the national party won the Swaziland elections with 54% of the votes, you are unlikely to remember this a week later—unless you live in Swaziland, perhaps. Retention will depend on how important the idea is to you, and how often it is repeated, either by recurrent encounter or by internal rehearsal.

Expression

To be communicated to other individuals, a meme must emerge from its storage as memory pattern or memotype and enter its mediotype phase, i. e. assume a physical shape that can be perceived by others. This process may be called “expression”. The most obvious medium for expression is speech. Other common means are text, pictures, behavior, and the creation of artifacts such as tools, buildings or works of art. Expression does not require the conscious decision of the host to communicate the meme. A meme can be expressed simply by the way somebody walks or manipulates an object, or by what he or she wears.

Some retained memes will never be expressed, for example because the host does not consider the meme interesting enough for others to know, uses it unconsciously without it showing up in his or her behavior, does not know how to express it, or wants to keep it secret. On the other hand, the host may be convinced that the meme is so important that it must be expressed again and again to everybody he or she meets.

Transmission

To reach another individual, an expression needs a physical carrier or medium that is sufficiently stable to transmit the expression without too much loss or deformation.

Speech, for example, uses sound to transmit an expression, while text will be transmitted through ink on paper or electrical impulses in a wire. The expression will take the form of a physical signal, modulating the carrier into a specific shape—the mediotype—from which the original meme can be re-derived. For example, mediotypes can be books, photographs, artifacts or CD-ROMs.

Selection at the transmission stage happens through either elimination of certain memes, when the mediotype is destroyed or gets corrupted before it is perceived by another individual, or through differential multiplication, when the mediotype is reproduced into many copies. For example, a manuscript may be put into the shredder or turned into a book that is printed in millions of copies. Especially since the emergence of mass media and mass manufacturing, the transmission stage is the one where the contrast between successful and unsuccessful memes is largest, and where selection can have the largest impact.

Meme Fitness

The overall survival rate of a meme m can be expressed as the meme *fitness* $F(m)$, which measures the expected number $N(m)$ of memes at the next time step or generation $t + 1$ divided by the average number of memes at the present time t . This fitness can be expressed in a simplified model as the product of the survival/multiplication rates for each of the four stages, respectively assimilation A , retention R , expression E and transmission T :

$$F(m) \equiv \frac{N(m, t + 1)}{N(m, t)} = A(m).P(m).E(m).T(m)$$

A denotes the proportion of mediotypes encountered by the host that are assimilated. R represents the proportion of these assimilated memes that are retained in memory. Therefore, $A \leq 1$, $R \leq 1$. E is the number of times a retained meme is expressed by the host. T is the number of potential new hosts reached by a copy of the expression. Unlike A and R , E and T do not have an upper bound, although E is likely to be more restricted than T . Note that F is zero as soon as one of its components (A , R , E , T) is zero. This expresses the fact that a meme must successfully pass through *all* four stages in order to replicate. Also note that for a meme to spread ($F > 1$), you must have at least $E > 1$ or $T > 1$.

Dynamics of Spread

From the standard definition of fitness F , we can derive the rate of growth for the number $N(t)$ of meme copies at time t . This determines the speed with which the meme

spreads through the population of carriers:

$$\frac{dN}{dt} \cong \frac{N(t + 1) - N(t)}{1} = (F - 1).N$$

This results in a traditional exponential growth if $F > 1$, exponential decay (and eventual extinction) if $F < 1$, and stability if $F = 1$. This model is too simple if the population is finite. In that case, we need to take into account the total size of the population of potential carriers K , which functions as the “carrying capacity” of the socio-cultural environment in which a meme proliferates. The increase in the number $N(t)$ of memes can be represented by the following Verhulst type of equation:

$$\frac{dN}{dt} = (F - 1).N \left(1 - \frac{N}{K} \right).$$

This equation expresses the fact that the growth in meme number (dN) is in first instance proportional to the number (N) that is already there—since more memes produce more copies of themselves—, but eventually limited by the number K of potential hosts in the population, so that growth becomes zero when the population reaches this limit ($N = K$). The function $N(t)$ that is the solution to this differential equation is the logistic function with its characteristic *sigmoid* (S-like) shape.

Interactions Between Memes

The dynamics of a single growing meme population $N(m)$ could be extended to several interacting memes $N_i = N(m_i)$. Here we should add an interaction term A_{ij} which describes the strength of the influence of meme i on meme j . This influence can be positive ($A_{ij} > 0$), which means that an increase in i produces an increase in j , i. e. i helps j to grow. A negative influence ($A_{ij} < 0$) means that the growth of i suppresses the growth of j . A neutral relation ($A_{ij} = 0$) means that the spread of the one does not influence the spread of the other. This applies to memes from independent domains, such as “God exists” and “apples are healthy”. If we now consider the reciprocal influence (A_{ji}), we can distinguish the following specific types of interaction:

- $A_{ij} > 0$, $A_{ji} > 0$: the memetic species i and j can be seen as *mutualists*, that help each other to spread, e. g. by reinforcing each others’ message. An example could be “God is good” and “God is great”.
- $A_{ij} < 0$, $A_{ji} < 0$: i and j are rivals or *competitors* [12]: an increase in the one produces a decrease in the other. Examples are “God is good” and “God does not exist”.

- $A_{ij} > 0$, $A_{ji} < 0$: i and j stand in a *predator-prey* type of relationship, i. e. i grows at the expense of j . This may happen when i (e. g. relativity theory) is a more advanced version of j (e. g. Newtonian mechanics), so that carriers of j would quickly convert to i , but non-carriers of j would be more difficult to convince of i 's value.

The overall dynamics can be represented by the following system of non-linear differential \sum_j equations:

$$\frac{dN_i}{dt} = N_i \left(\sum_j A_{ij} N_j + B_i \right)$$

A_{ii} , the influence of meme i on itself will here normally always be negative and equal to $(1 - F_i)/K$, while $B_i = F_i - 1$, as in the previous equation for a single meme. Such dynamical models quickly become very complex to solve, but are not fundamentally different from traditional growth and competition models used in population biology, epidemiology, or studies of the diffusion of innovations [12]. However, they do not take into account the dependence of a meme on its carrier, nor the specific communication channels between carriers.

Social Structures

One way to make the model more realistic without adding too much complication is to consider the structure of the social space in which the potential carriers of a meme reside. Here we make the additional assumption of continuity, namely that a meme cannot jump from one carrier to another without there being some form of proximity or relationship between the carriers.

Horizontal Transmission and the Evolution of Cooperation

The simplest form of relationship is the one between parents and their offspring. Parent-to-child transmission (or more generally transmission between generations) is called *vertical transmission* [23]. Memes belonging to domains such as religion, language, ethics, and general culture are commonly transmitted in this way. This form of propagation is analogous to the transmission of genes. Therefore “vertical” models of cultural evolution find results similar to those of biological evolution. This means that vertically transmitted memes, such as established religions, will typically reinforce or elaborate genetically transmitted behavioral patterns and thus directly contribute to biological fitness [26].

The same does not apply to *horizontally transmitted* culture, i. e. memes exchanged between members of the same generation [23]. Here what is good for a meme (e. g. slavish imitation of fads and fashions) is not necessarily good for the biological individual or gene pool, since genes and memes are subjected to different kinds of natural selection. This may promote the evolution of parasitic memes that are deleterious to their carriers, as we will discuss further.

However, in addition to the fact that it spreads new information more quickly, horizontal transmission also offers another benefit that vertical transmission lacks. A classic problem in biological evolution is the *evolution of cooperation* [27,51]: given that genes are selected to promote their own good, with a disregard or even hostility toward any rivals that compete for their scarce resources, how can we explain cooperative or altruistic behavior where an individual invests more in helping another than in his or her own good? In the animal world, cases of altruism, such as among social insects, are usually explained via *kin selection*: individuals will help others as long as these are related to them, i. e. share their genes. In human society, however, people often help strangers that are totally unrelated. The initially proposed explanation of *group selection*, namely that groups of individuals that help each other survive better than groups of selfish individuals, has the shortcoming that, within altruist groups, it are the selfish profiteers that do best, and thus spread their genes most [27].

Horizontal transmission of cooperation norms solves this problem, since the members of a cultural group are all *memetically related* to each other, sharing their memes rather than their genes. Therefore, cultural kin selection will extend to all members of the group [36]. This entails a selective pressure for memes to support the fitness of the whole group of their carriers, e. g. by promoting cooperation. Moreover, selfish profiteers will not be able to undermine the cooperation produced by such altruism-promoting memes because of conformist pressure [17,51], or what we have called “winner-takes-all”: when one meme establishes a majority position it will eventually get imposed on *all* members of the group, thus suppressing the appearance of selfish dissidents—or at least not allowing them to make any converts and thus spread their memes. This cultural solution to the cooperation paradox in biological evolution appears to have been developed more or less independently by different meme theorists [15,17,36,47].

Topologies of Communication

Horizontal transmission will generally follow existing social or geographical topologies. This can be modeled in

two different ways:

1. Individuals are situated in a *space* (typically a two-dimensional plane, or its discrete equivalent, a two-dimensional lattice of cells);
2. Individuals are considered as nodes in a (social) *network*, which are connected by ties of acquaintance or trust.

The basic assumption in these models is that memes diffuse *continuously* across the space or network. This means that, in first instance, communications are considered to be *local*, i. e. agents exchange memes only with their direct neighbors in the space or social network. The neighbor can pass on the meme to its neighbors, and so on, so that a meme eventually may spread across the whole population.

When a population consists of different clusters or local communities, that have little communication with each other, this will typically lead to different cultures establishing themselves in different communities [8,17]. The reason is that intense communication within each community will produce a “winner-takes-all” dynamics where by chance or local adaptation one of several variant memes becomes dominant. Memes from other communities, however, will only rarely be encountered, so that they will generally not receive enough reinforcement to displace the established memes.

Recent research in complex networks, including social networks, has shown that such networks commonly have a *scale-free structure* [1]. This means that a few agents, the so-called “hubs” of the network, have a great many social ties, while most agents only have a few links. The implication for cultural diffusion is that memes hosted by “hub” agents will have a disproportionately large effect, and are much more likely to spread widely. A similar effect has been observed in the spread of sexually transmitted diseases, such as AIDS, where the infection of a few hubs in the network (in this case individuals with a large number of sexual partners) may make the difference between a large-scale epidemic and a few isolated infections. This observation has provided inspiration to researchers in “viral” marketing, who look for methods to make publicity for a brand or product by creating a “buzz”, i. e. a positive message about their product that is propagated via word-of-mouth [63,64]. Their strategies focus on identifying and targeting the “opinion-leaders” within a community, i. e. those central individuals that many know and tend to imitate.

Although it is in principle possible to make analytical models of the propagation of memes across space or across networks, calculating the precise spread in a realistic envi-

ronment is far too difficult. Therefore, these processes are typically explored via multi-agent computer simulations.

Computer Simulations of Cultural Evolution

Cultural transmission of rules, norms or information is a common ingredient in many social simulations (e. g. [8,20,32,37,45]), that are based on an “artificial society” of interacting software agents [35]. However, such memetic propagation is often added merely as one of the many assumptions within a complicated model of a specific type of socio-cultural evolution, such as the evolution of a shared vocabulary [69] or of cooperation norms [45]. There have been relatively few simulations that have explored cultural evolution in the broadest sense. We will now discuss some typical examples that illustrate the wider issue.

Probably the first explicitly memetic simulation, *Meme and Variations*, was made by Gabora [39] (first written 1992). The assumptions underlying this, and related simulations of cultural diffusion e. g. [9,30] are the following: agents search the best solution for a particular problem. They can either find a solution on their own through trial-and-error, or they can take over a solution from another agent, by observing the solutions each of their neighbors has found and imitating the best one. The result of the simulation is that the agents collectively find the best solutions if they partially imitate others, partially explore individually. If they only imitate, there is no creativity and the best solution cannot be improved. If they only explore individually, lots of search is needed to merely rediscover what was already known elsewhere. In the ideal situation, which is achieved by trying out different parameter values for the simulation until one has found the optimal mix of innovation and imitation, good solutions will spread very quickly throughout the population, but this without preventing the discovery of even better solutions by certain agents.

This simulation investigated the relative effectiveness of, and interaction between, *individual learning* and *cultural diffusion*. An older classic simulation [52] investigated the relative effectiveness of, and interaction between, *individual learning* and *genetic evolution*. Inspired by this work, Best [14] studied the three-way interactions between individual learning, genetic evolution, and cultural evolution. In Best’s simulation, agents can acquire knowledge that allows them to maximize their fitness in three ways: 1) by inheriting it, possibly with variations, from their parents (vertical, genetic transmission); 2) by copying it from another, fitter agent (horizontal, cultural transmission); 3) by individually discovering it via trial-and-error. The sim-

ulation showed that cultural transmission, just like individual learning, can enhance genetic evolution, accelerating its convergence to the optimal solution. Moreover, cultural transmission appeared superior to individual learning in that it produced convergence more quickly.

Best [14] also examined the situation in which cultural and genetic evolution pursue opposite goals, and found that in this case genetic evolution normally wins the competition. However, Bull, Holland and Blackmore [19] further investigated this situation by allowing cultural evolution to be much more rapid than genetic evolution, as is normally the case. They found that under these conditions memetic effects are stronger than genetic effects, and the only way genes can still keep some control over the process is by evolving mechanisms to filter out particularly harmful memes.

These simulations of cultural evolution are still rather simplistic, in the sense that agents literally copy any knowledge exhibited by a fitter agent. In practice, individuals do not a priori know which individual is fitter, and when they receive a message, this information will interact with the knowledge they already had. Van Overwalle and Heylighen [71] have proposed a more realistic simulation model in which agents do not just copy a message, but actively “reinterpret” it, based on their previous experience. Agents are modeled as simple neural networks that learn from experience. A message corresponds to a pattern of activation over the nodes in such a network, and communication to the spread of that activation from agent to agent via variable inter-agent connections. The strength of the connection between two agents represents the degree of trust of the one in the information received from the other. This trust is learned on the basis of the degree to which information received previously from that agent is confirmed by own knowledge. Unlike most multi-agent simulations, the Van Overwalle and Heylighen [71] model is supported by solid empirical evidence, in that it manages to accurately reproduce the results of several classic communication experiments, including the Lyons and Kashima [61,62] study of meme transmission that we will discuss in a later section.

Selection Criteria for Memes

Since mathematical models and computer simulations of meme spread necessarily have to make plenty of simplifying assumptions, and cannot incorporate all the specific social, psychological, linguistic and cultural factors that influence the propagation of a meme, they are not very useful in predicting which concrete memes will be successful and which will not. Yet, such predictions are neces-

sary if we want to arrive at an empirically testable theory, which can be applied to practical problems. One way to arrive at a more practical, predictive model is to formulate general selection criteria that distinguish fitter memes from less fit ones. All other things being equal, *a meme that scores better on one of these criteria is predicted to become more numerous* than a meme that scores worse. This is a falsifiable hypothesis that can be tested through experiments or observations. It suffices to operationalize the criteria so that satisfaction of a criterion can be objectively measured.

Many authors have proposed criteria for memetic success, and a few (e. g. [22,44,48,49,50]) have compiled lists of such criteria. Since these proposals, while related, are all different, we need to examine more clearly what is needed for a good list of criteria. First, such criteria should be formulated to be as much as possible independent or non-overlapping, so that a piece of information can vary along one dimension of evaluation without varying along the others. Second, without becoming too restrictive, they should be defined as precisely, concretely and unambiguously as possible, so that different observers using these criteria can come to the same conclusions.

To illustrate the importance of these methodological considerations, let us review some proposed criteria, and point to their shortcomings. For example, one might naively propose that fit memes should be *attractive* to their receivers. While this is true in a general sense, it helps us very little in operationalizing meme fitness, as we cannot say what makes a meme attractive without becoming much more explicit about its properties. A somewhat more sophisticated hypothesis may propose that good memes should be *communicable* [68]. Again, this is obviously correct, but communicability has so many different aspects, depending on the meme itself, its audience, the used medium, etc., that we might as well say that it simply should be a good meme. A more specific criterion, used e. g. by [46], is *plausibility*. The problem here is that people may use very different procedures to estimate plausibility, e. g. by looking at the source of the information, the available evidence for it, or their own previous experience.

We will here summarize the criteria proposed by Heylighen [48,49,50], which are based on an extensive review of relevant cognitive, social and communicative mechanisms. At the most abstract level, there are three classes of entities that information depends on: the object that it refers to, the subject who assimilates and remembers it, and the communication process that is used to transmit it between subjects. These determine three categories of selection criteria, *objective*, *subjective* and *intersubjective*:

Objective Criteria

Distinctiveness Information that refers to something precise, distinct or detailed, can be confirmed more easily by observation.

Invariance Information that remains valid over a wide range of contexts or situations, is more stable and broadly applicable.

Evidence Information that is supported by independent observations, is more reliable.

Subjective Criteria

Utility Information that is valuable or useful to its carrier is more likely to be remembered and passed on.

Affectivity Information that provokes strong emotions is more likely to be remembered and passed on: this typically stimulates instinctive reactions, such as fear, desire or disgust [46].

Coherence The better information fits in with the knowledge that individuals already have, the more easily they will understand and accept it [70]

Simplicity Short, simple messages are easier to assimilate, remember and transmit.

Novelty Information that is unexpected will attract more attention.

Repetition Repeated exposure to the same message helps it to be assimilated and retained.

Intersubjective Criteria

Publicity The more effort an individual puts into spreading a message, the more people will receive it.

Formality Messages formulated explicitly and unambiguously are less likely to be misinterpreted.

Expressivity Information must be easy to express in a given language or medium.

Authority An authoritative, trustworthy source of the information makes it more likely to be accepted.

Conformity Information confirmed by many people is more easily accepted [17].

Collective utility Information, if adopted by a group, may help the group to function better, and therefore to grow or function as a model for others. Examples are standards, linguistic conventions, and traffic rules.

Parasitic Memes

Memes being communicated undergo natural selection. Some memes are transmitted easily, thus reaching a large number of people, while others are rejected, misunderstood, forgotten or otherwise eliminated from circulation.

This means that the memes best adapted to the underlying cognitive and communicative processes will spread farthest. We may assume that our brain, general culture, and social structures have evolved so as to maximize the fitness of society and its members. This means that they should be good at assimilating useful memes, and at rejecting bad ones, e. g. [15]. For example, we know that we should not accept things without evidence, and that some sources are more reliable than other. Insofar that these socio-cognitive guidelines, as exemplified by the above list of selection criteria, efficiently filter out poor-quality information, successful memes will also increase the fitness of their carriers.

However, since no system is foolproof, these mechanisms will not always be reliable. This leaves a niche for memes to evolve that propagate well, apparently satisfying the criteria that people intuitively use, but without delivering any benefit to their carriers. We may call such memes *selfish* [47] or *parasitic* cf. [26], as they free ride on the effort invested by individuals to gather and communicate useful information. Such information parasites succeed by faking the criteria that we use to recognize high-quality information. This is similar to the way many biological organisms mimic other phenomena, such as viruses that mimic the cell's own DNA, so that they are reproduced for free by the cellular machinery. Memes have therefore been described as "mind viruses" [18,28], since they similarly exploit our cognitive machinery to get themselves replicated.

There are plenty of examples of such parasitic memes. Perhaps the most studied from a memetic point of view are *chain letters*, whose only purpose is to have themselves replicated and sent to as many people as possible [11,42]. A more modern variant are *virus hoaxes* [24,25], i. e. email messages that warn the receivers for a non-existent type of computer virus, and urge them to pass on this warning to as many people as possible. Probably the most dangerous information parasites are certain *religious cults* [26], which indoctrinate their followers to make as many converts as possible, while isolating them from alternative sources of information, so that they tend to develop a view of reality that is so distorted that it may end fatally, as in the mass suicides of the Heaven's Gate cult. *Pseudosciences* too can be dangerous, parading as solid scientific theories, but asserting statements that at best are not supported by the facts, like in astrology, at worst fatally wrong, like in certain quack cures for cancer. Somewhat more benign are *urban legends* and various *rumors* and *fads*, which tend to spread in waves, being passed on from person to person but without any authoritative source or real evidence. Bangertner and Heath [10] have tracked the evolution of

one such legend, the *Mozart effect* (i. e. the unfounded belief that babies listening to classical music become more intelligent), starting from its source: a scientific experiment that merely found that after listening to music adults temporarily scored better on certain tests—perhaps simply because they were more relaxed.

Several memeticists, e. g. [18,28,60], have investigated the many tricks that memes use to appear more acceptable than they deserve to be, including the following. *Self-justification* means that the components of a memplex mutually justify each other, but without independent support. An example is: “God exists because the Bible says so”, and “You should believe the Bible because it is the word of God”. *Self-reinforcement* means that a meme stimulates its host to rehearse itself, e. g. by repeated study, meditation, prayer, etc. *Intolerance* means that a meme indoctrinates its host to a priori reject any potentially competing memes. *Proselytism* occurs when a meme urges its host to maximally spread the meme to other hosts, like in the case of chain letters. *Baiting* occurs when a meme promises its carriers a reward if they only accept and spread the meme. All these tactics are common in religious cults, which promise their adherents that they will go to Heaven if they believe the teachings, pray, and spread the word, while they will burn in Hell if they dare to doubt [28].

Parasitic memes have been the subject and inspiration of most empirical approaches to memetics, since their spread is relatively easy to track, and since they are prime illustrations of the way in which cultural evolution is fundamentally different from genetic evolution.

Empirical Tests

Memetics has often been challenged and has known some very virulent critics. One of the main criticisms is that there are no empirical data to back up the theories that were put forth, and in that sense memetics is merely a way of thinking rather than a scientific discipline [34,40,43]. This criticism is to some degree justifiable. The lack of a universally accepted meme definition and the vagueness of meme boundaries cf. [2] indeed make empirical studies less evident. Yet, there have already been a few empirical studies of meme propagation in different conditions, both in the laboratory, e. g. [61,62], and in real life, e. g. [11,24,42]. More generally, we must note that memetics is an approach that illuminates important aspects of culture, society and communication that more traditional approaches, such as sociology, psychology or history, tend to neglect. Empirical tests cannot confirm or falsify this perspective as a whole, but merely specific implementations of it. This is analogous to the observation that ex-

periments in psychology or sociology can test particular theories within their field, but not the field as such.

Within the memetics field, one simple way to test specific theories is by considering the memetic selection criteria they imply [25]. We can then measure the apparent success rate of different memes, and examine its correlation with the degree to which the memes fulfill the proposed selection criteria. Heath, Bell and Sternberg [46] applied this approach to investigate the criteria of *affectivity* (which they call *emotional selection*) and *plausibility*. From the affects, they focused on disgust because this is a relatively simple emotion whose strength is easy to measure. When comparing different urban legends that contained an element of disgust (e. g. the story of a man who discovers a dead rat in the cola bottle he has just been drinking from), they found that the more disgusting variations typically had spread more widely than the less disgusting ones. The same applied to more plausible variations. Chieles [24] used a similar method to examine the spread of virus hoaxes. He used both expert and non-expert surveys to score different hoaxes on different criteria, including novelty, simplicity, utility, authority and proselytism. In this case, the spread of the hoax correlated most strongly with its *novelty*. Schaller, Conway and Tanchuk [68] examined the correlation between the *communicability* of traits, i. e. the probability with which subjects would speak about a particular trait, and the frequency of these traits. They found that for traits used to describe different ethnic groups, the most communicable traits are also the ones that are most widely spread and persistent in society. Pocklington and Best [66] and [12,13] used automatic text analysis to measure how often a certain discussion subject was mentioned in a particular discussion group on the net. They found evidence for memetic competition between mutually *incoherent* subjects, meaning that an increase in the one correlated with a decrease in the other.

While these studies merely observed existing patterns of spread, Lyons and Kashima [61,62] performed a laboratory experiment in which they deliberately produced a memetic transmission chain. They created a fictional story and asked the participants in the experiment to subsequently tell the story from person 1 to person 2, from 2 to 3, and so on, like in the game of “telephone” or “Chinese Whispers.” The story involved a fictitious tribe, the Jamayans, about which all participants had received some background information. After several experiments, a statistical analysis of the story elements that remained at the end of the transmission chain (i. e. as reported by the last person to hear the story) found a number of systematic selection effects. These seem to confirm four of the previously mentioned criteria:

1. *Coherence*: Elements inconsistent with the background information were more likely to be left out;
2. *Novelty*: Elements that the speakers assumed were already known by the listeners were more likely to be left out;
3. *Simplicity*: Details or embellishments that did not affect the story line tended to be left out;
4. *Conformity*: When the participants were told that the majority of them believed that the Jamayans were, e. g., peaceful, they were more likely to leave out elements inconsistent with this fact than if they thought that this was only a minority opinion.

Experiments on memes “in the wild” are more difficult to control than in such a laboratory situation. Because of ethical concerns it is hardly possible to release a well-doctored meme upon the world to observe how it evolves. Another problem is that it is hard to track memes once they are released. Even when feedback is asked or if mechanical trackers are included in the meme (for example, images included in an email message that are automatically downloaded from a controlled server each time the message is opened), it is hard to see whether the meme has already been changed by the time these devices are triggered.

In conclusion, empirical memetics research remains in its infancy. However, experiments have already shown that one can quantitatively confirm or falsify a number of non-trivial memetic predictions. It is to be hoped that many more studies along these lines will be carried out. As long as memetics has not been thoroughly investigated empirically, it is likely to remain a theoretical niche framework used only for description rather than prediction.

Future Directions

The theory of memetics and cultural evolution holds out great promises for a better understanding, anticipation and control of fundamental social problems that depend on the propagation of ideas and behaviors. This will require more extensive empirical observations and tests, more detailed computer models of the interaction between memes and their hosts, and a better conceptualization of what a meme precisely is. A first basic result that should come out of such research is a concrete and reliable list of criteria that characterize successful memes, i. e. ideas or cultural traits that propagate widely and easily across large populations. This would allow us not only to recognize such memes, but to some degree to design or improve them.

The ability to create successful memes is the Holy Grail of marketing research [41], which is constantly on the look-out for techniques to create a “buzz” and have their

publicity message or brand name [63,64] become as widely known as possible. Another application of these principles lies in public education. For example, if the government makes a campaign to convince people to stop smoking, it would be very useful to have the campaign designed according to sound memetic principles. This should take into account both the characteristics of the message itself (e. g. being sufficiently simple and unambiguous), of the intended audience (e. g. being consistent with what the audience already believes, while being sufficiently novel to attract their attention), and of the way it is transmitted (e. g. having the meme expressed in a common medium by people considered trustworthy).

Memetic selection criteria can be applied not only positively, to help spread a beneficial idea, but negatively, to prevent or suppress harmful memes. Examples are the idea that it is cool to smoke, false rumors and scares that may promote panic or accentuate social prejudice, fundamentalist ideologies that incite hatred or terrorism, and dangerous superstitions, such as the belief that you can cure AIDS by having sex with a virgin. A better understanding of memetic dynamics may help us to understand how such mind viruses arise and spread. It may moreover help us to “immunize” the population by educating them about basic memetics, so as not to be misled by apparently plausible—but fundamentally misleading—cults, fads and superstitions [18,28].

Another basic result of future memetic research should be a complex dynamical model of the interactions between individuals, groups, and the memes they carry. This should allow making longer-term predictions about the interactions between different groups and subcultures within our globalizing society. A crucial issue in this regard is whether minority cultures will eventually be assimilated into the majority, or on the contrary become polarized, asserting their divergent habits and beliefs ever more forcefully [8,71]. Two concrete examples are minority languages, such as the Welsh still spoken in Britain, where there is a tendency for the subculture to be slowly erased by the majority culture, and the culture of Islamic immigrants in Europe, where there is a tendency towards polarization in the sense of increased radicalism. Neither complete assimilation nor polarization are desirable outcomes, but at first sight they seem like the most likely results of the “winner-takes-all” dynamics created by the pressure to conform to the group one has most contact with. A more detailed theory of cultural evolution may help us to find a middle way that preserves cultural diversity without exacerbating conflicts, and to pinpoint the crucial factors that can steer the dynamics in one direction rather than another.

Glossary

Evolutionary algorithm A computer algorithm loosely inspired by Darwinian evolution.

Generate-and-test The process of generating a potential solution to a computational problem and testing it to see how good a solution it is. The idea behind it is that no human ingenuity is employed to make good solutions more likely.

Genotype A string of information that encodes a potential solution instance of a problem and allows its suitability to be assessed.

Evolution in materio The method of applying computer controlled evolution to manipulate or configure a physical system.

Liquid crystal Substances that have properties between those of a liquid and a crystal.

Definition of the Subject

Evolution in materio refers to the use of computers running search algorithms, called evolutionary algorithms, to find the values of variables that should be applied to material systems so that they carry out useful computation. Examples of such variables might be the location and magnitude of voltages that need to be applied to a particular physical system. Evolution in materio is a methodology for programming materials that utilizes physical effects that the human programmer need not be aware of. It is a general methodology for obtaining analogue computation that is specific to the desired problem domain. Although a form of this methodology was hinted at in the work of Gordon Pask in the 1950s it was not convincingly demonstrated until 1996 by Adrian Thompson, who showed that physical properties of a digital chip could be exploited by computer controlled evolution. This article describes the first demonstration that such a method can be used to obtain specific analogue computation in a non-silicon based physical material (liquid crystal). The work is important for a number of reasons. Firstly, it proposes a general method for building analogue computational devices. Secondly it explains how previously un-

known physical effects may be utilized to carry out computations. Thirdly, it presents a method that can be used to *discover* useful physical effects that can form the basis of future computational devices.

Introduction

Physical Computation

Classical computation is founded on a mathematical model of computation based on an abstract (but physically inspired) machine called a Turing Machine [1]. A Turing machine is a machine that can write or erase symbols on a possibly infinite one dimensional tape. Its actions are determined by a table of instructions that determine what the machine will write on the tape (by moving one square left or right) given its state (stored in a state register) and the symbol on the tape. Turing showed that the calculations that could be performed on such a machine accord with the notion of computation in mathematics. The Turing machine is an abstraction (partly because it uses a possibly infinite tape) and to this day it is still not understood what limitations or extensions to the computational power of Turing's model might be possible using real physical processes. Von Neumann and others at the Institute for Advanced Study at Princeton devised a design for a computer based on the ideas of Turing that has formed the foundation of modern computers. Modern computers are digital in operation. Although they are made of physical devices (i. e. transistors), computations are made on the basis of whether a voltage is above or below some threshold. Prior to the invention of digital computers there have been a variety of analogue computing machines. Some of these were purely mechanical (e. g. an abacus, a slide-rule, Charles Babbage's difference engine, Vannevar Bush's Differential Analyzer) but later computing machines were built using operational amplifiers [2].

There are many aspects of computation that were deliberately ignored by Turing in his model of computation. For instance, speed, programmability, parallelism, openness, adaptivity are not considered. The speed at which an operation can be performed is clearly an important issue since it would be of little use to have a machine that can calculate any computable function but takes an arbitrarily large amount of time to do so. Programmability is another issue that is of great importance. Writing programs directly in the form of instruction tables that could be used with a device based on a Turing is extremely tedious. This is why many high-level computer languages have been devised. The general issue of how to subdivide a computer program into a number of parallel executing processes so that the intended computation is carried out as quickly as

possible is still unsolved. Openness refers to systems that can interact with an external environment during their operation. Openness is exhibited strongly in biological systems where new resources can be added or removed either by an external agency or by the actions taken by the system itself. Adaptivity refers to the ability of systems to change their characteristics in response to an environment.

In addition to these aspects, the extent to which the underlying physics affects both the abstract notion of computation and its tractability has been brought to prominence through the discovery of quantum computation, where Deutsch pointed out that Turing machines implicitly use assumptions based on physics [3]. He also showed that through ‘quantum parallelism’ certain computations could be performed much more quickly than on classical computers. Other forms of physical computation that have recently been explored are: reaction-diffusion systems [4], DNA computing [5,6] and synthetic biology [7].

In the UK a number of Grand Challenges in computing research have been proposed [8], in particular ‘Journeys in Non-Classical Computation’ [9,10] seeks to explore, unify and generalize many diverse non-classical computational paradigms to produce a mature science of computation.

Toffoli argued that ‘Nothing Makes Sense in Computation Except in the Light of Evolution’ [11]. He argues firstly that a necessary but not sufficient condition for a computation to have taken place, is when a novel function is produced from a fixed and finite repertoire of components (i. e. logic gates, protein molecules). He suggests that a sufficient condition requires *intention*. That is to say, we cannot argue that computation has taken place unless a system has arisen for a higher purpose (this is why he insists on intention as being a prerequisite for computation). Otherwise, almost everything is carrying out some form of computation (which is not a helpful point of view). Thus a Turing machine does not carry out computations unless it has been programmed to do so, and since natural evolution constructs organisms that have an increased chance of survival (the higher ‘purpose’) we can regard them as carrying out computations. It is in this sense that Toffoli points to the fundamental role of evolution in the definition of a computation as it has provided animals with the ability to have intention.

This brings us to one of the fundamental questions in computation. How can we program a physical system to perform a particular computation? The dominant method used to answer this question has been to construct logic gates and from these build a von Neumann machine (i. e. a digital computer). The mechanism that has been used to devise a computer program to carry out a particular com-

putation is the familiar top-down design process, where ultimately the computation is represented using Boolean operations. According to Conrad this process leads us to pay ‘The Price of Programmability’ [12], whereby in conventional programming and design we proceed by excluding many of the processes that may lead to us solving the problem at hand. Natural evolution does not do this. It is noteworthy that natural evolution has constructed systems of extraordinary sophistication, complexity and computational power. We argue that it is not possible to construct computational systems of such power using a conventional methodology and that complex software systems that directly utilize physical effects will require some form of search process akin to natural evolution together with a way of manipulating the properties of materials. We suggest that some form of evolution ought to be an appropriate methodology for arriving at *physical* systems that compute. In this chapter we discuss work that has adopted this methodology. We call it evolution in materio.

Evolutionary Algorithms

Firstly we propose that to overcome the limitations of a top-down design process, we should use a more unconstrained design technique that is more akin to a process of generate-and-test. However, a guided search method is also required that spends more time in areas of the search space that confer favorable traits for computation. One such approach is the use of evolutionary algorithms. These algorithms are inspired by the Darwinian concepts of survival of the fittest and the genetic inheritance of information. Using a computer, a population of randomly generated solutions is systematically tested, selected and modified until a solution has been found [13,14,15].

As in nature, a genetic algorithm optimizes a population of individuals by selecting the ones that are best suited to solving a problem and allowing their genetic make-up to propagate into future generations. It is typically guided only by the evolutionary process and often contains very limited domain specific knowledge. Although these algorithms are bio-inspired, it is important that any analogies drawn with nature are considered only as analogies.

Their lack of specialization for a problem makes genetic algorithms ideal search techniques where little is known about a problem. As long as a suitable representation is chosen along with a fitness function that allows for ease of movement around a search space, a GA can search vast problem spaces rapidly. Another feature of their behavior is that provided that the genetic representation chosen is sufficiently expressive the algorithm can explore potential solutions that are unconventional. A human de-

signer normally has a set of predefined rules and strategies that they adopt to solve a problem. These preconceptions may prevent trying a new method, and may prevent the designer using a better solution. A genetic algorithm does not necessarily require such domain knowledge. Evolutionary algorithms have been shown to be competitive or surpass human designed solutions in a number of different areas. The largest conference on evolutionary computation called GECCO has an annual session on evolutionary approaches that have produced human competitive scientific and technological results. Moreover the increase in computational power of computers makes such results increasingly more likely.

Many different versions of genetic algorithms exist. Variations in representations and genetic operators change the performance characteristics of the algorithm, and depending on the problem, people employ a variety of modifications of the basic algorithm. However, all the algorithms follow a similar basic set of steps.

Firstly the numbers or physical variables that are required to define a potential solution have to be identified and encoded into a data representation that can be manipulated inside a computer program. This is referred to as the encoding step. The representation chosen is of crucial importance as it is possible to inadvertently choose overly constrained representations which limits the portions of the space of potential solutions that will be considered by the evolutionary algorithm. Generally the encoded information is referred to as a genotype and genotypes are sometimes divided into a number of separate strings called chromosomes. Each entry in the chromosome string is an allele, and one or more of these make up a gene.

The second step is to create inside the computer a number of independently generated genotypes whose alleles have been chosen with uniform probability from the allowed set of values. This collection of genotypes is called a population.

In its most basic form, an individual genotype is a single chromosome made of 1s and 0s. However, it is also common to use integer and floating-point numbers if they more appropriate for the task at hand. Combinations of different representations can also be used within the same chromosome, and that is the approach used in the work described in this article. Whatever representation is used, it should be able to adequately describe the individual and provide a mechanism where its characteristics can be transferred to future generations without loss of information.

Each of these individuals is then decoded into its phenotype, the outward, physical manifestation of the individual and tested to see how well the candidate solution solves

the problem at hand. This is usually returned as a number that is referred to as the *fitness* of the genotype. Typically it is this phase in a genetic algorithm that is the most time consuming.

The next stage is to select what genetic information will proceed to the next generation. In nature the fitness function and selection are essentially the same – individuals that are better suited to the environment survive to reproduce and pass on their genes. In the genetic algorithm a procedure is applied to determine what information gets to proceed.

Genetic algorithms are often generational – where all the old population is removed before moving to the next generation, in nature this process is much less algorithmic. However, to increase the continuity of information between generations, some versions of the algorithm use elitism, where the fittest individuals are always selected for promotion to the next generation. This ensures that good solutions are not lost from the population, but it may have the side effect of causing the genetic information in the population to converge too quickly so that the search stagnates on a sub-optimal solution.

To generate the next population, a procedure analogous to sexual reproduction occurs. For example, two individuals will be selected and they will then have their genetic information combined together to produce the genotype for the offspring. This process is called recombination or crossover. The genotype is split into sections at randomly selected points called crossover points. A “simple” GA has only one of these points, however it is possible to perform this operation at multiple points.

Sections of the two chromosomes are then put together to form a new individual. This individual shares some of the characteristics of both parents. There are many different ways to choose which members of the population to breed with each other, the aim in general is to try and ensure that fit individuals get to reproduce with other fit individuals. Individuals can be selected with a probability proportional to their relative fitness or selected through some form of tournament, which may choose two or more chromosomes at random from the population and select the fittest.

In natural recombination, errors occur when the DNA is split and combined together. Also, errors in the DNA of a cell can occur at any time under the influence of a mutagen, such as radiation, a virus or toxic chemical. The genetic algorithm also has mutations. A number of alleles are selected at random and modified in some way. For a binary GA, the bit may be flipped, in a real-numbered GA a random value may be added to or subtracted from the previous allele.

Although GAs often have both mutation and crossover, it is possible to just use mutation. A mutation only approach has in some cases been demonstrated to work, and often crossover is seen as a macro mutation operator – effectively changing large sections of a chromosome.

After the previous operations have been carried out, the new individuals in the population are then retested and their new fitness scores calculated. Eventually this process leads to an increase in the average fitness of the population, and so the population moves closer toward a solution. This cycle of test, select and reproduce is continued until a solution is found (or some other termination condition is reached), at which point the algorithm stops. The performance of a genetic algorithm is normally measured in terms of the number of evaluations required to find a solution of a given quality.

Evolution in Materio: Historical Background

It is arguable that ‘evolution in materio’ began in 1958 in the work of Gordon Pask who worked on experiments to grow neural structures using electrochemical assemblages [16,17,18,19]. Gordon Pask’s goal was to create a device sensitive to either sound or magnetic fields that could perform some form of signal processing – a kind of ear. He realized he needed a system that was rich in structural possibilities, and chose to use a metal solution. Using electric currents, wires can be made to self-assemble in an acidic aqueous metal-salt solution (e. g. ferrous sulphate). Changing the electric currents can alter the structure of these wires and their positions – the behavior of the system can be modified through external influence. Pask used an array of electrodes suspended in a dish containing the metal-salt solution, and by applying current (either transiently or a slowly changing source) was able to build iron wires that responded differently to two different frequencies of sound – 50 Hz and 100 Hz.

Pask had developed a system whereby he could manually train the wire formation in such a way that no complete specification had to be given – a complete paradigm shift from previous engineering techniques which would have dictated the position and behavior of every component in the system. His training technique relied on making changes to a set of resistors, and updating the values with given probabilities – in effect a test-randomly modify-test cycle. We would today recognize this algorithm as some form of evolutionary, hill climbing strategy – with the test stage as the fitness evaluation.

In 1996 Adrian Thompson started what we might call the modern era of evolution in materio. He was investigating whether it was possible to build working electronic

Evolution in Materio, Figure 1

Pask’s experimental set up for growing dendritic wires in ferrous sulphate solution [17]

circuits using unconstrained evolution (effectively, generate-and-test) using a re-configurable electronic silicon chip called an Field Programmable Gate Array (FPGA). Carrying out evolution by defining configurations of actual hardware components is known as *intrinsic* evolution. This is quite possible using FPGAs which are devices that have a two-dimensional array of logic functions that a configuration bit string defines and connects together. Thompson had set himself the task of evolving a digital circuit that could discriminate between an applied 1 kHz or 10 kHz applied signal [20,21]. He found that computer controlled evolution of the configuring bit strings could relatively easily solve this problem. However, when he analyzed the successful circuits he found to his surprise that they worked by utilizing subtle electrical properties of the silicon. Despite painstaking analysis and simulation work he was unable to explain how, or what property was being utilized. This lack of knowledge of how the system works, of course, prevents humans from designing systems that are intended to exploit these subtle and complex physical characteristics. However, it does not prevent exploitation through artificial evolution. Since then a number of researchers have demonstrated the viability of intrinsic evolution in silicon devices [21,22,23,24,25,26,27].

The term *evolution in materio* was first coined by Miller and Downing [28]. They argued that the lesson that should be drawn from the work of [21] is that evolution may be used to exploit the properties of a wider range of materials than silicon.

In summary, evolution in materio can be described as:

Exploitation, using an unconstrained evolutionary algorithm, of the non-linear properties of a malleable or programmable material to perform a desired function by altering its physical or electrical configuration.

Evolution in materio is a subset of a research field known as evolvable hardware. It aims to exploit properties of physical systems with much fewer preconditions and constraints than is usual, and it deliberately tries to avoid paying Conrad's 'Price of Programmability'. However, to get access to physically rich systems, we may have to discard devices designed with human programming in mind. Such devices are often based on abstract idealizations of processes occurring in the physical world. For example, FPGAs are considered as digital, but they are fundamentally analogue devices that have been constrained to behave in certain, human understandable ways. This means that intrinsically complex physical processes are carefully manipulated to represent extremely simple effects (e.g. a rapid switch from one voltage level to another). Unconstrained evolution, as demonstrated by Thompson, allows for the analogue properties of such devices to be effectively utilized.

We would expect physically rich systems to exhibit non-linear properties – they will be complex systems. This is because physical systems generally have huge numbers of parts interacting in complex ways. Arguably, humans have difficulty working with complex systems, and the use of evolution enables us to potentially overcome these limitations when dealing with such systems.

When systems are abstracted, the relationship to the physical world becomes more distant. This is highly convenient for human designers who do not wish to understand, or work with, hidden or subtle properties of materials. Exploitation through evolution reduces the need for abstraction, as it appears evolution is capable of discovering and utilizing any physical effects it can find. The aim of this new methodology in computation is to evolve special purpose computational processors. By directly exploiting physical systems and processes, one should be able to build extremely fast and efficient computational devices. It is our view that computer controlled evolution is a universal methodology for doing this. Of course, von Neumann machines (i.e. digital computers) are *individually* universal and this is precisely what confers their great utility in modern technology, however this universality comes at a price. They ignore the rich computational possibilities of materials and try to create operations that are close to a mathematical abstraction. Evolution in materio is a universal methodology for producing specific, highly tuned computational devices.

It is important not to underestimate the real practical difficulties associated with using an unconstrained design process. Firstly the evolved behavior of the material may be extremely sensitive to the specific properties of the material sample, so each piece would require individual train-

ing. Thompson originally experienced this difficulty, however in later work he showed that it was possible to evolve the configuration of FPGAs so that they produced reliable behavior in a variety of environmental conditions [29].

Secondly, the evolutionary algorithm may utilize physical aspects of any part of the training set-up. Both of these difficulties have already been experienced [21,23]. A third problem can be thought of as "the wiring problem". This means to supply huge amounts of configuration data to a tiny sample. This problem is a very fundamental one. It suggests that if we wish to exploit the full physical richness of materials we might have to allow the material to grow its own wires and be self-wiring. This has profound implications for intrinsic evolution as artificial hardware evolution requires complete reconfigurability, this implies that one would have to be able to "wipe-clean" the evolved wiring and start again with a new artificial genotype. This might be possible by using nanoparticles that assemble into nanowires. These considerations bring us to an important issue in evolution in materio. Namely, the problem of choosing a suitable materials that can be exploited by computer controlled evolution.

Evolution in Materio: Defining Suitable Materials

The obvious characteristic required by a candidate material is the ability to reconfigure it in some way. Liquid crystal, clay, salt solutions etc can be readily configured either electrically or mechanically; their physical state can be adjusted, and readjusted, by applying a signal or force. In contrast (excluding its electrical properties) the physical properties of an FPGA would remain unchanged during configuration. It is also desirable to bulk configure the system. It would be infeasible to configure every molecule in the material, so the material should support the ability to be reconfigured over large areas using a small amount of configuration.

The material needs to perform some form of transformation (or computation) on incident signals that we apply. To do this, the material will have to interfere with the incident signal and perform a modification to it. We will need to be able to observe this modification, in order to extract the result of the computation. To perform a non-trivial computation, the material should be capable of performing complex operations upon the signal. Such capabilities would be maximized if the system exhibited non-linear behavior when interacting with input signals.

In summary, we can say that for a material to be useful to evolution in materio it should have the following properties:

- Modify incident signals in observable ways.
- The components of a system (i. e. the molecules within a material) interact with each other locally such that non-linear effects occur at either the local or global levels.
- It is possible to configure the state of the material locally.
- It is possible to observe the state of the material – either as a whole or in one or more locations.
- For practical reasons we can state that the material should be reconfigurable, and that changes in state should be temporary or reversible.

Miller and Downing [28] identified a number of physical systems that have some, if not all, of these desirable properties. They identified liquid crystal as the most promising in this regard as it digitally writable, reconfigurable and works at a molecular level. Most interestingly, it is an example of mesoscopic organization. Some people have argued that it is within such systems that emergent, organized behavior can occur [30]. Liquid crystals also exhibit the phenomenon of self-assembly. They form a class of substances that are being designed and developed in a field of chemistry called Supramolecular Chemistry [31]. This is a new and exciting branch of chemistry that can be characterized as ‘the designed chemistry of the intermolecular bond’. Supramolecular chemicals are in a permanent process of being assembled and disassembled. It is interesting to consider that conceptually liquid crystals appear to sit on the ‘edge of chaos’ [32] in that they are fluids (chaotic) that can be ordered, under certain circumstances.

Liquid Crystal

Liquid crystal (LC) is commonly defined as a substance that can exist in a mesomorphic state [33,34]. Mesomorphic states have a degree of molecular order that lies between that of a solid crystal (long-range positional and orientational) and a liquid, gas or amorphous solid (no long-range order). In LC there is long-range orientational order but no long-range positional order.

LC tends to be transparent in the visible and near infrared and quite absorptive in UV. There are three distinct types of LC: lyotropic, polymeric and thermotropic. Lyotropic LC is obtained when an appropriate amount of material is dissolved in a solvent. Most commonly this is formed by water and amphiphilic molecules: molecules with a hydrophobic part (water insoluble) and a hydrophilic part (strongly interacting with water). Polymeric LC is basically a polymer version of the aromatic LC discussed. They are characterized by high viscosity and include vinyls and Kevlar. Thermotropic LC (TLC) is the

most common form and is widely used. TLC exhibit various liquid crystalline phases as a function of temperature. They can be depicted as rod-like molecules and interact with each other in distinctive ordered structures. TLC exists in three main forms: nematic, cholesteric and smectic. In nematic LC the molecules are positionally arranged randomly but they all share a common alignment axis. Cholesteric LC (or chiral nematic) is like nematic however they have a chiral orientation. In smectic LC there is typically a layered positionally disordered structure. The three types A, B and C are defined as follows. In type A the molecules are oriented in alignment with the natural physical axes (i. e normal to the glass container), however in type C the common molecular axes of orientation is at an angle to the container. LC molecules typically are dipolar. Thus the organization of the molecular dipoles give another order of symmetry to the LC. Normally the dipoles would be randomly oriented. However in some forms the natural molecular dipoles are aligned with one another. This gives rise to ferroelectric and ferrielectric forms.

There is a vast range of different types of liquid crystal. LC of different types can be mixed. LC can be doped (as in Dye-Doped LC) to alter their light absorption characteristics. Dye-Doped LC film has been made that is optically addressable and can undergo very large changes in refractive index [35]. There are Polymer-Dispersed Liquid Crystals, which can have tailored, electrically controlled light refractive properties. Another interesting form of LC being actively investigated is Discotic LC. These have the form of disordered stacks (1-dimensional fluids) of disc-shaped molecules on a two-dimensional lattice. Although discotic LC is an electrical insulator, it can be made to conduct by doping with oxidants [36]. The oxidants are incorporated into the fluid hydrocarbon chain matrix (between disks). LC is widely known as useful in electronic displays, however, there are in fact, many non-display applications too. There are many applications of LC (especially ferroelectric LC) to electrically controlled light modulation: phase modulation, optical correlation, optical interconnects and switches, wavelength filters, optical neural networks. In the latter case a ferroelectric LC is used to encode the weights in a neural network [37].

Conducting and Electroactive Polymers

Conducting polymer composites have been made that rapidly change their microwave reflection coefficient when an electric field is applied. When the field is removed, the composite reverts to its original state. Experiments have shown that the composite can change from one state to the other in the order of 100 ms [38]. Also, some poly-

mers exhibit electrochromism. These substances change their reflectance when a voltage is applied. This can be reversed by a change in voltage polarity [39]. Electroactive polymers [40] are polymers that change their volume with the application of an electric field. They are particularly interesting as voltage controlled artificial muscle. Organic semiconductors also look promising especially when some damage is introduced. Further details of electronic properties of polymers and organic crystals can be found in [41].

Voltage Controlled Colloids

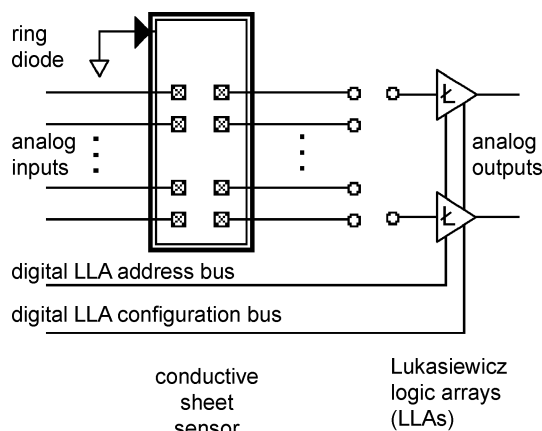

Colloids are suspensions of particles of sub-micron sizes in a liquid. The phase behavior of colloids is not fully understood. Simple colloids can self assemble into crystals, while multi-component suspensions can exhibit a rich variety of crystalline structures. There are also electrorheological fluids. These are suspensions of extremely fine non-conducting particles in an electrically insulating fluid. The viscosity of these fluids can be changed in a reversible way by large factors in response to an applied electric field in times of the order of milliseconds [42]. Also colloids can also be made in which the particles are charged making them easily manipulatable by suitable applied electric fields. Even if the particles are not charged they may be moved through the action of applied fields using a phenomenon known as dielectrophoresis which is the motion of polarized but electrically uncharged particles in nonuniform electric fields [43]. In work that echoes the methods of Pask nearly four decades ago, dielectrophoresis has been used to grow tiny gold wires through a process of self-assembly [44].

Langmuir–Blodgett Films

Langmuir–Blodgett films are molecular monolayers of organic material that can be transferred to a solid substrate [45]. They usually consist of hydrophilic heads and hydrophobic tails attached to the substrate. Multiple monolayers can be built and films can be built with very accurate and regular thicknesses. By arranging an electrode layer above the film it seems feasible that the local electronic properties of the layers could be altered. These systems look like feasible systems whose properties might be exploitable through computer controlled evolution of the voltages.

Kirchoff–Lukasiewicz Machines

Work by Mills [46,47] also demonstrates the use of materials in computation. He has designed an ‘Extended Analog Computer’ (EAC) that is a physical implementation of

Evolution in Materio, Figure 2
Kirchoff–Lukasiewicz Machine

a Kirchoff–Lukasiewicz Machine (KLM) [46]. The machines are composed of logical function units connected to a conductive media, typically a conductive polymer sheet. The logical units implement Lukasiewicz Logic – a type of multi-valued logic [47]. Figure 2 shows how the Lukasiewicz Logic Arrays (LLA) are connected to the conductive polymer. The LLA bridge areas of the sheet together. The logic units measure the current at one point, perform a transformation and then apply a current source to the other end of the bridge.

Computation is performed by applying current sinks and sources to the conductive polymer and reading the output from the LLAs. Different computations can be performed that are determined by the location of applied signals in the conducting sheet and the configuration of the LLAs. Hence, computation is performed by an interaction of the physics described by Kirchoff's laws and the Lukasiewicz Logic units. Together they form a physical device that can solve certain kinds of partial differential equations. Using this form of analogue computation, a large number of these equations can be solved in nanoseconds – much faster than on a conventional computer. The speed of computation is dependent on materials used and how they are interfaced to digital computers, but it is expected that silicon implementations will be capable of finding tens of millions of solutions to the equations per second.

Examples of computation so far implemented in this system include robot control, control of a cyclotron beam [48], models of biological systems (including neural networks) [49] and radiosity based image rendering.

One of the most interesting feature of these devices is the programming method. It is very difficult to understand the actual processes used by the system to perform

computation, and until recently most of the reconfiguration has been done manually. This is difficult as the system is not amenable to traditional software development approaches. However, evolutionary algorithms can be used to automatically define the parameters of the LLAs and the placement of current sinks and sources. By defining a suitable fitness function, the configuration of the EAC can be evolved – which removes the need for human interaction and for knowledge of the underlying system.

Although it is clear that such KLMs are clearly using the physical properties of a material to perform computation, the physical state of the material is not reconfigured (i. e., programmed), only the currents in the sheet are changed.

Evolution in Materio Is Verified with Liquid Crystal

Harding [50] has verified Miller's intuition about the suitability of liquid crystal as an evolvable material by demonstrating that it is relatively easy to configure liquid crystal to perform various forms of computation.

In 2004, Harding constructed an analogue processor that utilizes the physical properties of liquid crystal for computation. He evolved the configuration of the liquid crystal to discriminate between two square waves of many different frequencies. This demonstrated, for the first time, that the principle of using computer-controlled evolution was a viable and powerful technique for using non-silicon materials for computation. The analogue processor consists of a passive liquid crystal display mounted on a reconfigurable circuit, known as an evolvable motherboard. The motherboard allows signals and configuration voltages to be routed to physical locations in the liquid crystal.

Harding has shown that many different devices can be evolved in liquid crystal including:

- Tone discriminator. A device was evolved in liquid crystal that could differentiate many different frequencies of square wave. The results were competitive, if not superior to those evolved in the FPGA.
- Logic gates. A variety of two input logic gates were evolved, showing that liquid crystal could behave in a digital fashion. This indicates that liquid crystal is capable of universal computation.
- Robot controller. An obstacle avoidance system for a simple exploratory robot was evolved. The results were highly competitive, with solutions taking fewer evaluations to find compared to other work on evolved robot controllers.

One of the surprising findings in this work has been that it turns out to be relatively easy to evolve the configura-

tion of liquid crystal to solve tasks; i. e., only 40 generations of a modest population of configurations are required to evolve a very good frequency discriminator, compared to the thousands of generations required to evolve a similar circuit on an FPGA. This work has shown that evolving such devices in liquid crystal is easier than when using conventional components, such as FPGAs. The work is a clear demonstration that evolutionary design can produce solutions that are beyond the scope of human design.

Evolution in Materio Using Liquid Crystal: Implementational Details

An evolvable motherboard (EM) [23] is a circuit that can be used to investigate intrinsic evolution. The EM is a reconfigurable circuit that rewires a circuit under computer control. Previous EMs have been used to evolve circuits containing electronic components [23,51] – however they can also be used to evolve in materio by replacing the standard components with a candidate material.

An EM is connected to an Evolvatron. This is essentially a PC that is used to control the evolutionary processes. The Evolvatron also has digital and analog I/O, and can be used to provide test signals and record the response of the material under evolution.

The Liquid Crystal Evolvable Motherboard (LCEM) is a circuit that uses four cross-switch matrix devices to dynamically configure the circuits connecting to the liquid crystal. The switches are used to wire the 64 connections on the LCD to one of 8 external connections. The external connections are: input voltages, grounding, signals and connections to measurement devices. Each of the external connectors can be wired to any of the connections to the LCD.

The external connections of the LCEM are connected to the Evolvatron's analogue inputs and outputs. One connection was assigned for the incident signal, one for measurement and the other for fixed voltages. The value of the fixed voltages is determined by the evolutionary algorithm, but is constant throughout each evaluation.

In these experiments the liquid crystal glass sandwich was removed from the display controller it was originally mounted on, and placed on the LCEM. The display has a large number of connections (in excess of 200), however because of PCB manufacturing constraints we are limited in the size of connection we can make, and hence the number of connections. The LCD is therefore roughly positioned over the pads on the PCB, with many of the PCB pads touching more than one of the connectors on the LCD. This means that we are applying configuration voltages to several areas of LC at the same time.

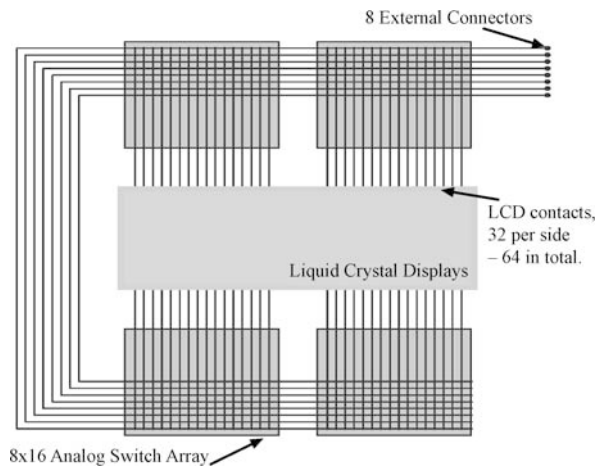

Evolution in Materio, Figure 3
Equipment configuration

Evolution in Materio, Figure 4
The LCEM

Unfortunately neither the internal structure nor the electrical characteristics of the LCD are known. This raises the possibility that a configuration may be applied that would damage the device. The wires inside the LCD are made of an extremely thin material that could easily be burnt out if too much current flows through them. To guard against this, each connection to the LCD is made through a 4.7 Kohm resistor in order to provide protection against short circuits and to help limit the current in the LCD. The current supplied to the LCD is limited to 100 mA. The software controlling the evolution is also responsible for avoiding configurations that may endanger the device (such as short circuits).

It is important to note that other than the control circuitry for the switch arrays there are no other active components on the motherboard – only analog switches, smoothing capacitors, resistors and the LCD are present.

Evolution in Materio, Figure 5
Schematic of LCEM

Stability and Repeatability Issues

When the liquid crystal display is observed while solving a problem it is seen that some regions of the liquid display go dark indicating that the local molecular direction has been changed. This means that the configuration of the liquid crystal is changing while signals are being applied. To draw an analogy with circuit design, the incident signals would be changing component values or changing the circuit topology, which would have an affect on the behavior of the system. This is likely to be detrimental to the measured performance of the circuit. When a solution is evolved, the fitness function automatically measures its stability over the period of the evaluation. Changes made by the incident signals can be considered part of the genotype-phenotype mapping. Solutions that cannot cope with

their initial configurations being altered will achieve a low score. However, the fitness function cannot measure the behavior beyond the end of the evaluation time. Therein lies the difficulty, in evolution in materio long term stability cannot be guaranteed.

Another issue concerns repeatability. When a configuration is applied to the liquid crystal the molecules are unlikely go back to exactly where they were when this configuration was tried previously. Assuming, that there is a strong correlation between genotype and phenotype, then it is likely that evolution will cope with this extra noise. However, if evolved devices are to be useful one needs to be sure that previously evolved devices will function in the same way as they did when originally evolved.

In [27] it is noted that the behavior of circuits evolved intrinsically can be influenced by previous configurations – therefore their behavior (and hence fitness) is dependent not only on the currently evaluated individual's configuration but on those that came before. It is worth noting that this is precisely what happens in natural evolution. For example, in a circuit, capacitors may still hold charge from a previously tested circuit. This charge would then affect the circuits operation, however if the circuit was tested again with no stored charge a different behavior would be expected and a different fitness score would be obtained. Not only does this affect the ability to evolve circuits, but would mean that some circuits are not valid. Without the influence of the previously evaluated circuits the current solution may not function as expected. It is expected that such problems will have analogies in evolution in materio. The configurations are likely to be highly sensitive to initial conditions (i. e. conditions introduced by previous configurations).

Dealing with Environmental Issues

A major problem when working with intrinsic evolution is separating out the computation allegedly being carried out by the target device, and that actually done by the material being used. For example, whilst trying to evolve an oscillator Bird and Layzell discovered that evolution was using part of the circuit for a radio antenna, and picking up emissions from the environment [22]. Layzell also found that evolved circuits were sensitive to whether or not a soldering iron was plugged in (not even switched on) in another part of the room [23]!

An evolved device is not useful if it is highly sensitive to its environment in unpredictable ways, and it will not always be clear what environmental effects the system is

using. It would be unfortunate to evolve a device for use in a space craft, only to find out it fails to work once out of range of a local radio tower!

To minimize these risks, we will need to check the operation of evolved systems under different conditions. We will need to test the behavior of a device using a different set up in a different location. It will be important to know if a particular configuration only works with one particular sample of a given material.

The Computational Power of Materials

In [52], Lloyd argued that the theoretical computing power of a kilogram of material is far more than is possible with a kilogram of traditional computer. He notes that computers are subject to the laws of physics, and that these laws place limits on the maximum speed they can operate and the amount of information it can process. Lloyd shows that if we were fully able to exploit a material, we would get an enormous increase in computing power. For example, with 1 kg of matter we should be able to perform roughly 5×10^{50} operations per second, and store 10^{31} bits. Amazingly, contemporary quantum computers do operate near these theoretical limits [52].

A small amount of material also contains a large number of components (regardless of whether we consider the molecular or atomic scale). This leads to some interesting thoughts. If we can exploit materials at this level, we would be able to do a vast amount of computation in a small volume. A small size also hints at low power consumption, as less energy has to be spent to perform an operation. Many components also provide a mechanism for reliability through redundancy. A particularly interesting observation, especially when considered in terms of non Von-Neumann computation, is the massive parallelism we may be able to achieve. The reason that systems such as quantum, DNA and chemical computation can operate so quickly is that many operations are performed at the same time. A programmable material might be capable of performing vast numbers of tasks simultaneously, and therefore provide a computational advantage.

In commercial terms, small is often synonymous with low cost. It may be possible to construct devices using cheaply available materials. Reliability may not be an issue, as the systems could be evolved to be massively fault tolerant using their intrinsic redundancy. Evolution is capable of producing novel designs. Koza has already rediscovered circuits that infringe on recent patents, and his genetic programming method has 'invented' brand new circuit designs [53]. Evolving in materio could produce many novel designs, and indeed given the infancy of pro-

grammable materials all designs may be unique and hence patentable.

Future Directions

The work described here concerning liquid crystal computational devices is at an early stage. We have merely demonstrated that it is possible to evolve configurations of voltages that allow a material to perform desired computations. Any application that ensues from this work is unlikely to be a replacement for a simple electronic circuit. We can design and build those very successfully. What we have difficulty with is building complex, fault tolerant systems for performing complex computation. It appears that nature managed to do this. It used a simple process of a repetitive test and modify, and it did this in a universe of unimaginable physical complexity. If nature can exploit the physical properties of a material and its surroundings through evolution, then so should we.

There are many important issues that remain to be addressed. Although we have made some suggestions about materials worthy of investigation, it is at present unclear which materials are most suitable. An experimental platform needs to be constructed that allows many materials to be tried and investigated. The use of microelectrode arrays in a small volume container would allow this. This would also have the virtue of allowing internal signals in the materials to be inspected and potentially understood.

We need materials that are rapidly configurable. They must not be fragile and sensitive to minute changes in physical setup. They must be capable of maintaining themselves in a stable configuration. The materials should be complex and allow us to carry out difficult computations more easily than conventional means. One would like materials that can be packaged into small volumes. The materials should be relatively easily interfaced with. So far, material systems have been configured by applying a constant configuration pattern, however this may not be appropriate for all systems. It may be necessary to put the physical system under some form of responsive control, in order to program and then keep the behavior stable.

We may or may not know if a particular material can be used to perform some form of computation. However, we can treat our material as a “black box”, and using evolution as a search technique, automatically discover what, if any, computations our black box can perform. The first step is to build an interface that will allow us to communicate with a material. Then we will use evolution to find a configuration we can apply using this platform, and then attempt to find a mapping from a given problem to an input suitable for that material, and a mapping from the ma-

terials response to an output. If this is done correctly, we might be automatically able to tell if a material can perform computation, and then classify the computation.

When we evolve in materio, using mappings evolved in software, how can we tell when the material is giving us any real benefit? The lesson of evolution in materio has been that the evolved systems can be very difficult to analyze, and the principal obstacle to the analysis is the problem of separating out the computational role that each component plays in the evolved system. These issues are by no means just a problem for evolution in materio. They may be an inherent part of complex evolved systems. Certainly the understanding of biological systems are providing immense challenges to scientists.

The single most important aspect that suggests that evolution in materio has a future is that natural evolution has produced immensely sophisticated material computational systems. It would seem foolish to ignore this and merely try to construct computational devices that operate according to one paradigm of computation (i. e. Turing). Oddly enough, it is precisely the sophistication of the latter that allows us to attempt the former.

Glossary

Cellular automaton (CA) Discrete-space and discrete-time spatially extended lattice of cells connected in a regular pattern. Each cell stores its state and a state-

transition function. At each time step, each cell applies the transition function to update its state based on its local neighborhood of cell states. The update of the system is performed in synchronous steps – i. e., all cells update simultaneously.

Cellular programming A variation of genetic algorithms designed to simultaneously evolve state transition rules and local neighborhood connection topologies for non-homogeneous cellular automata.

Coevolution An extension to the genetic algorithm in which candidate solutions and their “environment” (typically test cases) are evolved simultaneously.

Density classification A computational task for binary CAs: the desired behavior for the CA is to iterate to an all-1s configuration if the initial configuration has a majority of cells in state 1, and to an all-0s configuration otherwise.

Genetic algorithm (GA) A stochastic search method inspired by the Darwinian model of evolution. A population of candidate solutions is evolved by reproduction with variation, followed by selection, for a number of generations.

Genetic programming A variation of genetic algorithms that evolves genetic trees.

Genetic tree Tree-like representation of a transition function, used by genetic programming algorithm.

Lookup table (LUT) Fixed-length table representation of a transition function.

Neighborhood Pattern of connectivity specifying to which other cells each cell is connected.

Non-homogeneous cellular automaton A CA in which each cell can have its own distinct transition function and local neighborhood connection pattern.

Ordering A computational task for one-dimensional binary CAs with fixed boundaries: The desired behavior is for the CA to iterate to a final configuration in which all initial 0 states migrate to the left-hand side of the lattice and all initial 1 states migrate to the right-hand side of the lattice.

Particle Periodic, temporally coherent boundary between two regular domains in a set of successive CA configurations. Particles can be interpreted as carrying information about the neighboring domains. Collisions between particles can be interpreted as the processing of information, with the resulting information carried by new particles formed by the collision.

Regular domain Region defined by a set of successive CA configurations that can be described by a simple regular language.

Synchronization A computational task for binary CAs: the desired behavior for the CA is to iterate to a tem-

poral oscillation between two configurations: all cells have state 1 and all cells have state 0s.

Transition function Maps a local neighborhood of cell states to an update state for the center cell of that neighborhood.

Definition of the Subject

Evolving cellular automata refers to the application of evolutionary computation methods to evolve cellular automata transition rules. This has been used as one approach to automatically “programming” cellular automata to perform desired computations, and as an approach to model the evolution of collective behavior in complex systems.

Introduction

In recent years, the theory and application of cellular automata (CAs) has experienced a renaissance, due to advances in the related fields of reconfigurable hardware, sensor networks, and molecular-scale computing systems. In particular, architectures similar to CAs can be used to construct physical devices such as field configurable gate arrays for electronics, networks of robots for environmental sensing and nano-devices embedded in interconnect fabric used for fault tolerant nanoscale computing. Such devices consist of networks of simple components that communicate locally without centralized control. Two major areas of research on such networks are (1) *programming* – how to construct and configure the locally connected components such that they will collectively perform a desired task; and (2) *computation theory* – what types of tasks are such networks able to perform efficiently, and how does the configuration of components affect the computational capability of these networks?

This article describes research into one particular automatic programming method: the use of genetic algorithms (GAs) to evolve cellular automata to perform desired tasks. We survey some of the leading approaches to evolving CAs with GAs, and discuss some of the open problems in this area.

Cellular Automata

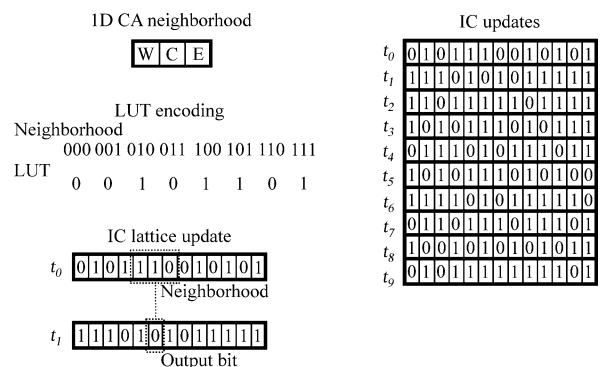

A *cellular automaton* (CA) is a spatially extended lattice of locally connected simple processors (cells). CAs can be used both to model physical systems and to perform parallel distributed computations.

In a CA, each cell maintains a discrete state and a transition function that maps the cell’s current state to its next state. This function is often represented as a lookup table (LUT). The LUT stores all possible configurations of

a cell’s local neighborhood, which consists of its own current state and the state of its neighboring cells. Change of state is performed in discrete time steps: the entire lattice is updated synchronously. There are many possible definitions of a *neighborhood*, but here we will define a neighborhood as the cell to be updated and the cells adjacent to it at a distance of radius r . The number of entries in the LUT will be s^N , where s is the number of possible states and N is the total number of cells in the neighborhood: $(2r + 1)^d$ for a square shaped neighborhood in a d -dimensional lattice, also known as a *Moore neighborhood*. CAs typically are given *periodic boundary conditions*, which treat the lattice as a torus.

To transform a cell’s state, the values of the cell’s state and those of its neighbors are encoded as a lookup index to the LUT that stores a value representing the cell’s new state (Fig. 1: left) [8,16,59]. For the scope of this article, we will focus on homogeneous binary CAs, which means that all cells in the CAs have the same LUT and each cell has one of two possible states, $s \in \{0, 1\}$. Figure 1 shows the mechanism of updates in a homogeneous one-dimensional two-state CA with a neighborhood radius $r = 1$.

CAs were invented in the 1940s by Stanislaw Ulam and John von Neumann. Ulam used CAs as a mathematical abstraction to study the growth of crystals, and von Neumann used them as an abstraction of a physical system with the concepts of a cell, state and transition function in order to study the logic of self-reproducing sys-

Evolving Cellular Automata, Figure 1

Left top: A one-dimensional neighborhood of three cells (radius 1): Center cell, West neighbor, and East neighbor. **Left middle:** A sample look-up table in which all possible neighborhood configurations are listed, along with the update state for the center cell in each neighborhood. **Left bottom:** Mechanism of update in a one dimensional binary CA of length 13: t_0 is the initial configuration at time 0 and t_1 is the initial configuration at next time step. **Right:** The sequence of synchronous updates starting at the initial state t_0 and ending at state t_9

tems [8,11,55]. Von Neumann’s seminal work on CAs had great significance. Science after the industrial revolution was primarily concerned with energy, force and motion, but the concept of CAs shifted the focus to information processing, organization, programming, and most importantly, control [8]. The universal computational ability of CAs was realized early on, but harnessing this power continues to intrigue scientists [8,11,32,55].

Computation in CAs

In the early 1970s John Conway published a description of his deceptively simple Game of Life CA [18]. Conway proved that the Game of Life, like von Neumann’s self-reproducing automaton, has the power of a universal Turing machine: any program that can be run on a Turing machine can be simulated by the Game of Life with the appropriate initial configuration of states. This initial configuration (IC) encodes both the input and the program to be run on that input. It is interesting that so simple a CA as the Game of Life (as well as even simpler CAs – see chapter 11 in [60]) has the power of a universal computer. However, the actual application of CAs as universal computers is, in general, impractical due to the difficulty of encoding a given program and input as an IC, as well as very long simulation times.

An alternative use of CAs as computers is to design a CA to perform a particular computational task. In this case, the initial configuration is the input to the program, the transition function corresponds to the program performing the specific task, and some set of final configurations is interpreted as the output of the computation. The intermediate configurations comprise the actual computation being done.

Examples of tasks for which CAs have been designed include location management in mobile computing networks [50], classification of initial configuration densities [38], pseudo-random number generation [51], multi-agent synchronization [47], image processing [26], simulation of growth patterns of material microstructures [5], chemical reactions [35], and pedestrian dynamics [45].

The problem of designing a CA to perform a task requires defining a cell’s local neighborhood and boundary conditions, and constructing a transition function for cells that produces the desired input-output mapping. Given a CA’s states, neighborhood radius, boundary conditions, and initial configuration, it is the LUT values that must be set by the “programmer” so that the computation will be performed correctly over all inputs.

In order to study the application of genetic algorithms to designing CAs, substantial experimentation has been done using the *density classification* (or *majority classification*) task. Here, “density” refers to the fraction of 1s in the initial configuration. In this task, a binary-state CA must iterate to an all-1s configuration if the initial configuration has a majority of cells in state 1, and iterate to an all-0s configuration otherwise. The maximum time allowed for completing this computation is a function of the lattice size.

One “naïve” solution for designing the LUT for this task would be *local majority voting*: set the output bit to 1 for all neighborhood configurations with a majority of 1s, and 0 otherwise. Figure 2 gives two space-time diagrams illustrating the behavior of this LUT in a one-dimensional binary CA with $N = 149$, and $r = 3$, where N denotes the number of cells in the lattice, and r is the neighborhood radius.

Evolving Cellular Automata, Figure 2

Two space-time diagrams illustrating the behavior of the “naïve” local majority voting rule, with lattice size $N = 149$, neighborhood radius $r = 3$, and number of time steps $M = 149$. *Left*: initial configuration has a majority of 0s. *Right*: initial configuration has a majority of 1s. Individual cells are colored black for state 1 and white for state 0. (Reprinted from [37] with permission of the author.)

Each diagram shows an initial configuration of 149 cells (horizontal) iterating over 149 time steps (vertical, down the page). The left-hand diagram has an initial configuration with a majority of 0 (white) cells, and the right-hand diagram has an initial configuration with a majority of 1 (black) cells. In neither case does the CA produce the “correct” global behavior: an all-0s configuration for the left diagram and an all-1s configuration for the right diagram. This illustrates the general fact that human intuition often fails when trying to capture emergent collective behavior by manipulating individual bits in the lookup table that reflect the settings of the local neighborhood.

Evolving Cellular Automata, Figure 4
 Reproduction applied to *Parent*₁ and *Parent*₂ producing *Child*₁ and *Child*₂. The one-point crossover is performed at a randomly selected crossover point (bit 3) and a mutation is performed on bits 2 and 5 in *Child*₁ and *Child*₂ respectively

Evolving Cellular Automata with Genetic Algorithms

Genetic Algorithms (GAs) are a group of stochastic search algorithms, inspired by the Darwinian model of evolution, that have proved successful for solving various difficult problems [3,4,36].

A GA works as follows: (1) A population of individuals (“chromosomes”) representing candidate solutions to a given problem is initially generated at random. (2) The fitness of each individual is calculated as a function of its quality as a solution. (3) The fittest individuals are then selected to be the parents of a new generation of candidate solutions. Offspring are created from parents via copying, random mutation, and crossover. Once a new generation of individuals is created, the process returns to step two. This entire process is iterated for some number of generations, and the result is (hopefully) one or more highly fit individuals that are good solutions to the given problem.

GAs have been used by a number of groups to evolve LUTs for binary CAs [2,10,14,15,34,43,47,51]. The individuals in the GA population are LUTs, typically encoded as binary strings. Figure 3 shows a mechanism of encoding LUTs from a particular neighborhood configuration. For

example: the decimal value for the neighborhood 11010 is 26. The updated value for the neighborhood’s center cell 11010 is retrieved from the 26th position in the LUT, updating cell’s value to 1.

The fitness of a LUT is a measure of how well the corresponding CA performs a given task after a fixed number of time steps, starting from a number of *test* initial configurations. For example, given the density classification task, the fitness of a LUT is calculated by running the corresponding CA on some number *k* of random initial configurations, and returning the fraction of those *k* on which the CA produces the correct final configuration (all 1s for initial configurations with majority 1s, all 0s otherwise). The set of random test ICs is typically regenerated at each generation.

For LUTs represented as bit strings, crossover is applied to two parents by randomly selecting a crossover point, so that each child inherits one segment of bits from each parent. Next, each child is subject to a mutation, where the genome’s individual bits are subject to a bit complement with a very low probability. An example of the reproduction process is illustrated in Fig. 4 for a lookup

1D CA neighborhood $r=2$

Neighborhood values:

	00000	00001	00010	00011	00100	00101	11010	11011	11100	11101	11110	11111
LUT Offset:	0	1	2	3	4	5	26	27	28	29	30	31

LUT (length $2^{(2r+1)}$):

0	1	0	0	1	1	1	1	0	0	1	1
---	---	---	---	---	---	-----	-----	---	---	---	---	---	---

Evolving Cellular Automata, Figure 3

Lookup table encoding for 1D CA with neighborhood $r = 2$. All permutations of neighborhood values are encoded as an offset to the LUT. The LUT bit represents a new value for the center cell of the neighborhood. The binary string (LUT) encodes an individual’s chromosome used by evolution

table representation of $r = 1$. Here, one of two children is chosen for survival at random and placed in an offspring population. This process is repeated until the offspring population is filled. Before a new evolutionary cycle begins, the newly created population of offspring replaces the previous population of parents.

Previous Work on Evolving CAs

Von Neumann's self-reproducing automaton was the first construction that showed that CAs can perform universal computation [55], meaning that the CAs are capable, in principle, of performing any desired computation. However, in general it was unknown how to effectively "program" CAs to perform computations or what information processing dynamics CAs could best use to accomplish a task. In the 1980s and 1990s, a number of researchers attempted to determine how the generic dynamical behavior of a CA might be related to its ability to perform computations [18,19,21,33,58]. In particular, Langton defined a parameter on CA LUTs, λ , that he claimed correlated with computational ability. In Langton's work, λ is a function of the state-update values in the LUT; for binary CAs, λ is defined as the fraction of 1s in the state-update values.

Computation at the Edge of Chaos

Packard [40] was the first to use a genetic algorithm to evolve CA LUTs in order to test the hypothesis that LUTs with a critical value of λ will have maximal computational capability. Langton had shown that generic CA behavior seemed to undergo a sequence of phase transitions – from simple to "complex" to chaotic – as λ was varied. Both Langton and Packard believed that the "complex" region was necessary for non-trivial computation in CAs, thus the phrase "computation at the edge of chaos" was coined [33,40]. Packard's experiments indicated that CAs evolved by GAs to perform the density classification task indeed tended to exhibit critical λ values. However, this conclusion was not replicated in later work [38]. Correlations between λ (or other statistics of LUTs) and computational capability in CAs have been hinted at in further work, but have not been definitively established. A major problem is the difficulty of quantifying "computational capability" in CAs beyond the general (and not very practical) capability of universal computation.

Computation via CA "Particles"

While Mitchell, Hraber, and Crutchfield were not able to replicate Packard's results on λ , they were able to show

that genetic algorithms can indeed evolve CAs to perform computations [38]. Using earlier work by Hanson and Crutchfield on characterizing computation in CAs [20,21], Das, Mitchell and Crutchfield gave an information-processing interpretation of the dynamics exhibited by the evolved CAs in terms of *regular domains* and *particles* [21]. This work was extended by Das, Crutchfield, Mitchell, and Hanson [14] and Hordijk, Crutchfield and Mitchell [24].

In particular these groups showed that when regular domains – patterns described by simple regular languages – are filtered out of CA space-time behavior, the boundaries between these domains become forefront and can be interpreted as information-carrying "particles". These particles can characterize non-trivial computation carried out by CAs [15,21].

The information-carrying role of particles becomes clear when applied to CAs evolved by the GA for the density classification task. Figure 5, left, shows typical behavior of the best CAs evolved by the GA. The CA contains three regular domains: all white (0^*), all black (1^*), and checkerboard ($(01)^*$). Figure 5, right, shows the particles remaining after the regular domains are filtered out. Each particle has an origin and velocity, and carries information about the neighboring regions [37]. Hordijk et al. [24] showed that a small set of particles and their interactions can explain the computational behavior (i. e., the fitness) of the evolved cellular automata. Crutchfield et al. [13] describe how the analysis of evolved CAs in terms of particles can also explain how the GA evolved CAs with high fitness.

Land and Belew [31] proved that no two-state homogeneous CA can perform the density classification task perfectly. However, the maximum possible performance for CAs on this task is not known.

The density classification task remains a popular benchmark for studying the evolution of CAs with GAs, since the task requires collective behavior: the decision about the global density of the IC is based on information only from each local neighborhood. Das et al. [14] also used GAs to evolve CAs to perform a global synchronization task, which requires that, starting from any initial configuration, all cells of the CA will synchronize their states (to all 1s or 0s) and in the next time step all cells must change state to the opposite value. Again, this behavior requires global coordination based on local communication. Das et al. showed that an analysis in terms of particles and their interactions was also possible for this task.

Genetic Programming

Andre et al. [2] applied genetic programming (GP), a variation of GAs, to the density classification task. GP method-

Evolving Cellular Automata, Figure 5

Analysis of a GA evolved CA for density classification task. *Left*: The original spacetime diagram containing particle strategies in a CA evolved by GA. The regions of regular domains are all white, all black, or have a checkerboard pattern. *Right*: Spacetime diagram after regular domains are filtered out. (Reprinted from [37] with permission of the author.)

ology also uses a population of evolving candidate solutions, and the principles of reproduction and survival are the same for both GP and GAs. The main difference between these two methods is the encoding of individuals in the population. Unlike the binary strings used in GAs, individuals in a GP population have tree structures, made up of *function* and *terminal* nodes. The *function* nodes (internal nodes) are operators from a pre-defined function set, and the *terminal* nodes (leaves) represent operands from a terminal set. The fitness value is obtained by evaluating the tree on a set of test initial configurations. The crossover operator is applied to two parents by swapping randomly selected sub-trees, and the mutation operation is performed on a single node by creating a new node or by changing its value (Fig. 6) [29,30].

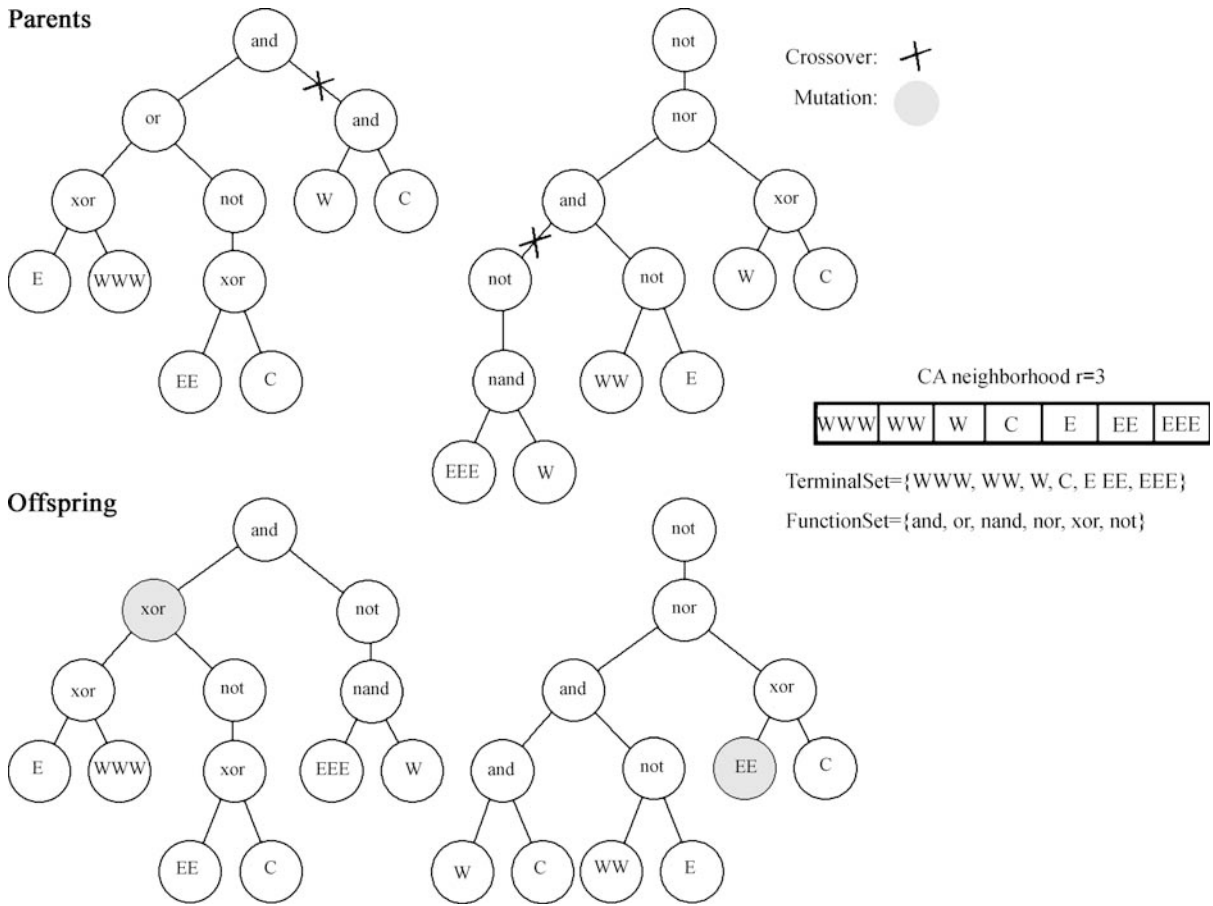

The GP algorithm evolved CAs whose performance is slightly higher than the performance of the best CAs evolved by a traditional GA.

Unlike traditional GAs that use crossover and mutation to evolve fixed length genome solutions, GP trees evolve to different sizes or shapes, and the subtrees can be substituted out and added to the function set as automatically defined functions. According to Andre et al., this allows GP to better explore the “regularities, symmetries, homogeneities, and modularities of the problem domain” [2]. The best-evolved CAs by GP revealed more complex particles and particle interactions than the CAs found by the EvCA group [13,24]. It is unclear whether the improved results were due to the GP representation or to the increased population sizes and computation time used by Andre et al.

Parallel Cellular Machines

The field of evolving CAs has grown in several directions. One important area is evolving non-homogeneous cellular automata [22,47,48,54]. Each cell of a non-homogeneous CA contains two independently evolving chromosomes. One represents the LUT for the cell (different cells can have different LUTs), and the second represents the neighborhood connections for the cell. Both the LUTs and the cell’s connectivity can be evolved at the same time. Since a task is performed by a collection of cells with different LUTs, there is no single best performing individual; the fitness is a measure of the collective behavior of the cells’ LUTs and their neighborhood assignments [46,48].

One of many tasks studied by Sipper was the global ordering task [47]. Here, the CA has fixed rather than periodic boundaries, so the “left” and “right” parts of the CA lattice are defined. The *ordering* in any given IC pattern will place all 0s on the left, followed by all 1s on the right. The initial density of the IC has to be preserved in the final configuration. Sipper designed a *cellular programming algorithm* to co-evolve multiple LUTs and their neighborhood topologies. Cellular programming carries out the same steps as the conventional GA (initialization, evaluation, reproduction, replacement), but each cell reproduces only with its local neighbors. The LUTs and connectivity chromosomes from the locally connected sites are the only potential parents for the reproduction and replacement of cell’s LUTs and the connectivity tables respectively. The cell’s limited connectivity results in genetically diverse population. If a current population has a cell with

Evolving Cellular Automata, Figure 6

An example of the encoding of individuals in a GP population, similar to one used in [2]. The function set here consists of the logical operators {and, or, not, nand, nor, and xor}. The terminal set represents the states of cells in a CA neighborhood, here {Center, East, West, EastOfEast, WestOfWest, EastOfEastOfEast, WestOfWestOfWest}. The figure shows the reproduction of *Parent₁* and *Parent₂* by crossover with subsequent mutation to produce *Child₁* and *Child₂*

a high-fitness LUT, its LUT will not be directly inherited by a given cell unless they are connected. The connectivity chromosome causes spatial isolation that allows evolution to explore multiple CA rules as a part of a collective solution [47,48].

Sipper exhaustively tested all homogeneous CAs with $r = 1$ on the ordering task, and found that the best performing rule (rule 232) correctly ordered 71% of 1000 randomly generated ICs. The cellular programming algorithm evolved a non-homogeneous CA that outperformed the best homogeneous CA. The evolutionary search identified multiple rules that the non-homogeneous CA used as the components in the final solution. The rules composing the collective CA solution were classified as state preserving or repairing the incorrect ordering of the neighborhood bits. The untested hypothesis is that the cellular

programming algorithm can discover multiple important rules (partial traits) that compose more complex collective behavior.

Coevolution

Coevolution is an extension of the GA, introduced by Hillis [23], inspired by host-parasite coevolution in nature. The main idea is that randomly generated test cases will not continually challenge evolving candidate solutions. Coevolution solves this problem by evolving two populations – candidate solutions and test cases – also referred to as hosts and parasites. The hosts obtain high fitness by performing well on many of the parasites, whereas the parasites obtain high fitness by being difficult for the hosts. Simultaneously coevolving both populations engages hosts

and parasites in a mutual competition to achieve increasingly better results [7,17,56].

Successful applications of coevolutionary learning include discovery of minimal sorting networks, training artificial neural networks for robotics, function induction from data, and evolving game strategies [9,23,41,44,56,57]. Coevolution also improved upon GA results on evolving CA rules for density classification [28].

In the context of evolving CAs, the LUT candidate solutions are hosts, and the ICs are parasites. The fitness of a host is a fraction of correctly evaluated ICs from the parasite population. The fitness of a parasite is a function of the number of hosts that failed to correctly classify it.

Pagie et al. and Mitchell et al. among others, have found that embedding the host and parasite populations in a spatial grid, where hosts and parasites compete and evolve locally, significantly improves the performance of coevolution on evolving CAs [39,41,42,57].

Other Applications

The examples described in previous sections illustrate the power and versatility of genetic algorithms used to evolve desired collective behavior in CAs. The following are some additional examples of applications of CAs evolved by GAs.

CAs are most commonly used for modeling physical systems. CAs evolved by GAs modeled multi-phase fluid flow in porous material [61]. A 3D CA represented a pore model, and the GA evolved the permeability characteristics of the model to match the fluid flow pattern collected from the sample data. Another example is the modeling of physical properties of material microstructures [5]. An alternative definition of CAs (*effector automata*) represented a 2D cross-section of a material. The rule table specified the next location of the neighborhood's center cell. The results show that the GA evolved rules that reconstructed microstructures in the sample superalloy.

Network theory and topology studies for distributed sensor networks rely on connectivity and communication among its components. Evolved CAs for location management in mobile computing networks is an application in this field [50]. The cells in the mobile networks are mapped to CA cells where each cell is either a reporting or non-reporting cell. Subrata and Zomaya's study used three network datasets that assigned unique communication costs to each cell. A GA evolved the rules that designate each cell as reporting or not while minimizing the communication costs in the network. The results show that the GA found optimal or near optimal rules to determine which cells in a network are reporting. Sipper also hinted at ap-

plying his cellular programming algorithm to non-homogeneous CAs with non-standard topology to evolve network topology assignments [47].

Chopra and Bender applied GAs to evolve CAs to predict protein secondary structure [10]. The 1D CA with $r = 5$ represents interactions among local fragments of a protein chain. A GA evolved the weights for each of the neighboring fragments that determine the shape of the secondary protein structure. The algorithm achieved superior results in comparison with some other protein-secondary-structure prediction algorithms.

Built-In Self-Test (BIST) is a test method widely used in the design and production of hardware components. A combination of a *selfish gene algorithm* (a GA variant) and CAs were used to program the BIST architecture [12]. The individual CA cells correspond to the circuitry's input terminals, and the transition function serves as a test pattern generator. The GA identified CA rules that produce input test sequences that detect circuitry faults. The results achieved are comparable with previously proposed GA-based methods but with lower overhead.

Computer vision is a fast growing research area where CAs have been used for low-level image processing. The cellular programming algorithm has evolved non-homogeneous CAs to perform image thinning, finding and enhancing an object's rectangle boundaries, image shrinking, and edge detection [47].

Future Directions

Initial work on evolving two-dimensional CAs with GAs was done by Sipper [47] and Jiménez-Morales, Crutchfield, and Mitchell [27]. An extension of domain-particle analysis for 2D CAs is needed in order to analyze the information processing of CAs and to identify the epochs of innovations in evolutionary learning.

Spatially extended coevolution was successfully used to evolve high performance CAs for density classification. Parallel cellular machines also used spatial embedding of their components and found better performing CAs than the homogeneous CAs evolved by a traditional GA. The hypothesis is that spatially extended search techniques are successful more often than non-spatial techniques because spatial embedding enforces greater genetic diversity and, in the case of coevolution, more effective competition between hosts and parasites. This hypothesis deserves more detailed investigation.

Additional important research topics include the study of the error resiliency and the effect of noise on both the information processing in CAs and evolution of CAs. How successful is evolutionary learning in noisy environment?

What is the impact of failing CA components on information processing and evolutionary adaptation? Similarly, to make CAs more realistic as models of physical systems, evolving CAs with asynchronous cell updates is an important topic for future research. A number of groups have shown that CAs and similar decentralized spatially extended systems using asynchronous updates can have very different behavior from those using synchronous updates (e. g., [1,6,25,49,53]). An additional topic for future research is the effect of connectivity network structure on the behavior and computational capability of CAs. Some work along these lines has been done by Teuscher [52].

Glossary

Evolving system In the context of this article the term ‘evolving’ is used in the sense of the self-development of a system (in terms of both its structure and parameters) based on the stream of data coming to the system on-line and in real-time from the environment and the system itself. The system is assumed to be mathematically described by a set of fuzzy rules of the form:

$$\begin{aligned}
 & \text{Rule}^i : \\
 & \text{IF } (Input_1 \text{ is close to prototype}_1^i) \\
 & \quad \text{AND } \dots \text{ AND } (Input_n \text{ is close to prototype}_n^i) \quad (1) \\
 & \text{THEN } (Output^i = \overline{Inputs}^T \text{ ConseqParams})
 \end{aligned}$$

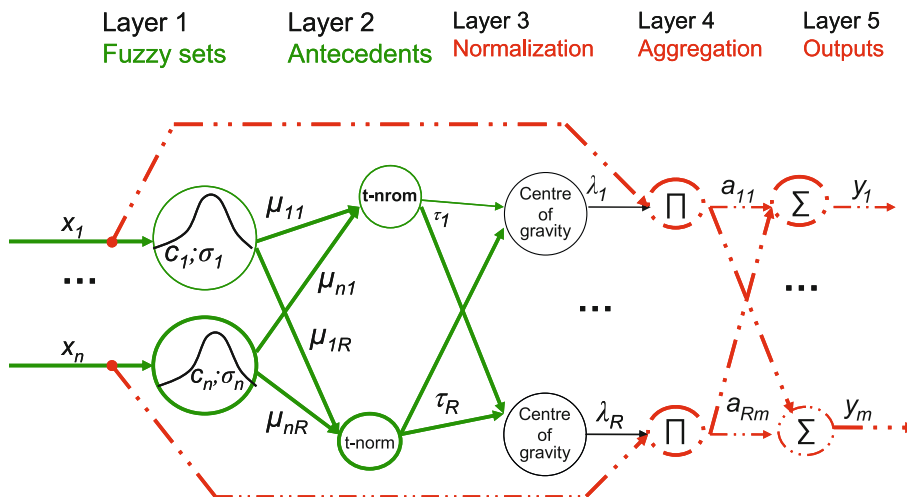

In this sense, this definition strictly follows the meaning of the English word “evolving” as described in [34], p. 294, namely “unfolding; developing; being developed, naturally and gradually”. Contrast this to the definition of “evolutionary” in the same source, which is “development of more complicated forms of life (plants, animals) from earlier and simpler forms”. The terms evolutionary or genetic are also associated with such phenomena (respectively operators that mimic these) as chromosome crossover, mutation, selection and reproduction, parents and off-springs [32]. Evolv-

ing (fuzzy and neuro-fuzzy) systems do not deal with such phenomena. They rather consider a *gradual development* of the underlying (fuzzy or neuro-fuzzy) system structure.

Fuzzy system structure Structure of a fuzzy (or neuro-fuzzy) system is constituted of a set of fuzzy rules (1). Each fuzzy rule is composed of antecedent (IF) and consequents (THEN) parts. They are linguistically expressed. The antecedent part consists of a number of fuzzy sets that are linked with fuzzy logic aggregators such as conjunction, disjunction, more rarely, negation [43]. In the above example, a conjunction (logical AND) is used. It can be mathematically described by so-called t-norms or t-conorms between membership functions. The most popular membership functions are Gaussian, triangular, trapezoidal [73]. The consequent part of the fuzzy rules in the so-called Takagi–Sugeno (TS) form is represented by mathematical functions (usually linear). The structure of the TS fuzzy system can also be represented as a neural network with a specific (five layer) composition (Fig. 1). Therefore, these systems are also called neuro-fuzzy (NF).

The number of fuzzy rules and inputs (which in case of classification problems are also called features or attributes) is also a part of the structure.

The first layer consists of neurons corresponding to the membership functions of a particular fuzzy set. This layer takes the inputs, x and gives as output the degree, μ to which these fuzzy descriptors are satisfied. The second layer represents the antecedent parts

Evolving Fuzzy Systems, Figure 1
Structure of the (neuro-fuzzy) system of TS type

of the fuzzy rules. It takes as inputs the membership function values and gives as output the firing level of the i th rule, τ_i . The third layer of the network takes as inputs the firing levels of the respective rule, τ_i and gives as output the normalized firing level, λ_i as “center of gravity” [43] of τ_i . As an alternative one can use the “winner takes all” operator. This operator is used usually in classification, while the “center of gravity” is preferred for time-series prediction and general system modeling and control. The fourth layer aggregates the antecedent and the consequent part that represents the local sub-systems (singletons or hyper planes). Finally, the last 5th layer forms the total output of the NF system. It performs a weighed summation of local sub-systems.

Fuzzy system parameters Parameters of the NF system of TS type include the center, c and spread, σ of the Gaussians or parameters of the triangular (or trapezoidal) membership functions. An example of a Gaussian type membership function can be given as:

$$\mu = e^{-\frac{1}{2}\left(\frac{d}{r}\right)^2} \quad (2)$$

where d denotes distance between a data sample (point in the data space) and a prototype/cluster center (focal point of a fuzzy set); r is the radius of the cluster (spread of the membership function).

Note that the distance can be represented by Euclidean (the most typical example), Mahalonobis [33], cosine etc. forms.

These parameters are associated with the antecedent part of the system. Consequent part parameters are coefficients of the (usually) linear functions, singleton coefficients or coefficients of more complex functions (e.g. exponential) if such ones are used.

$$y_i = a_{i0} + a_{i1}x_1 + \dots + a_{in}x_n \quad (3)$$

where a denotes parameters of the consequent part; x denote the inputs (features); i is the index of the i th fuzzy rule; n is the number (dimensionality) of the inputs (features).

Potential Potential is a mathematical measure of the data density. It is calculated at a data point, z and represents numerically the accumulated proximity (*density*) of the data surrounding this data point. It resembles the probability distribution used in so-called Parzen windows [33] and is described in [26,72] by a Gaussian-like function:

$$P(z) = e^{-\frac{1}{2r}\bar{\sigma}^2} \quad (4)$$

where $z = [x, y]$ denotes the joint (input/output) vector;

$\bar{\sigma}_k^2 = \frac{1}{k-1} \sum_{i=1}^{k-1} d^2(z_k, z_i)$ is the variance of the data in terms of the cluster center.

In [3,9] the Cauchy function is used which has the same properties as the Gaussian but is suitable for recursive calculations.

$$P(z) = \frac{1}{1 + \bar{\sigma}^2} \quad (5)$$

Age of a cluster or fuzzy rule The age of the (evolving) cluster is defined as the accumulated time of appearance of the samples that form the cluster which support that fuzzy rule.

$$A^i = k - \frac{\sum_{l=1}^{S_k^i} k_l}{S_k^i} \quad (6)$$

where k denotes the current time instant; S_k^i denotes the support of the cluster that is the number of data samples (points) that are in the zone of influence of the cluster (formed by its radius). It is derived by simple counting of data samples (points) at the moment of their arrival (when they are first read) and assigned to the nearest cluster [10].

The values of A vary from 0 to k and the derivative of A in respect to time is always less or equal to 1 [17]. An “old” cluster (fuzzy rule) has not been updated recently. A “young” cluster (fuzzy rule) is one that has predominantly new samples or recent ones. The (first and second) derivatives of the *age* are very informative and useful for detection of data “*shift*” and “*drift*” [17].

Definition of the Subject

Evolving Fuzzy Systems (EFS) are a class of Fuzzy Rule-based (FRB) and Neuro-Fuzzy (NF) systems that have both their parameters and underlying structure self-adapting, self-developing, self-learning from the data in on-line mode and, possibly, in real-time. The concept was conceived at the beginning of this century [2,5]. Parallel investigations have led to similar developments in neural networks (NN) [41,42]. EFS have the significant advantage compared to the evolving NN of being linguistically tractable and transparent. EFS have been instrumental in the emergence of new branches of *evolving* clustering algorithms [3], *evolving* classifiers [16,51], *evolving* time-series predictors [9,47], *evolving* fuzzy controllers [4], *evolving* fault detectors [30] etc. Over the last years EFS has demonstrated a wide range of applications spanning robotics [76]

and defense [24] to biomedical [70] and industrial process [29] data processing in real-time, new generations of self-calibrating, self-adapting sensors [52,53], speech [37] and image processing [56] etc. EFS have the potential to revolutionize such areas as autonomous systems [66], intelligent sensors [45], early cancer detection and diagnosis; they are instrumental in raising the so-called machine intelligence quotient [74] by developing systems that self-adapt in real-time to the dynamically changing environment and to internal changes that occur in the system itself (e. g. wearing, contamination, performance degradation, faults etc.). Although the terms *intelligent* and *artificial intelligence* have been used often during the last several decades the technical systems that claim to have such features are in reality far from true intelligence. One of the main reasons is that true intelligence is evolving, it is not fixed. EFS are the first mathematical constructs that combine the approximate reasoning typical for humans represented by the fuzzy inference with the dynamically evolving structure and respective formal mathematically sound learning mechanisms to implement it.

Introduction

Fuzzy Sets and Fuzzy Logic were introduced by Lotfi Zadeh in 1965 in his seminal paper [71]. During the last decade of the previous century there was an increase of the various applications of fuzzy logic-based systems mainly due to the introduction of fuzzy logic controllers (FLC) by Ebrahim Mamdani in 1975 [54], the introduction of the fuzzily blended linear systems construct called Takagi-Sugeno (TS) fuzzy systems in 1985 [65], and the theoretical proof that FRB systems are universal approximators (that is any arbitrary non-linear function in the $[0; 1]$ range can be asymptotically approximated by a FRB system [68]). Historically, the FRB systems were first being designed based entirely or predominantly on human expert knowledge [54,71]. This offers advantages and was a novel technique at that time for incorporating uncertain, subjective information, preferences, experience, intuition, which are difficult or impossible to be described otherwise. However, it poses enormous difficulties for the process of designing and routine use of these systems, especially in real industrial environments and in on-line and real-time modes. TS fuzzy systems made possible the development of efficient algorithms for their design not only in off-line, but also in on-line mode [14]. This is facilitated by their dual nature – they combine a fuzzy linguistic premise (antecedent) part with a functional (usually linear) consequent part [65]. With the invention of the concept of EFS [2,5] the problem of the design was completely

automated and data-driven. This means, EFS systems self-develop their model, respectively system structure as well as adapt their parameters “from scratch” on the fly using experimental data and efficient recursive learning mechanisms. Human expert knowledge is not compulsory, not limiting, not essential (especially if it is difficult to obtain in real-time). This does not necessarily mean that such knowledge is prohibited or not possible to be used. On the contrary, the concept of EFS makes possible the use of such knowledge in initialization stages, even during the learning process itself, but this is not essential, it is optional. Examples of EFS are intelligent sensors for oil refineries [52,53], autonomous self-localization algorithms used by mobile robots [75,76], smart agents for machine health monitoring and prognosis in the car industry [30], smart systems for automatic classification of images in CD production process [51] etc. This is a new promising area of research and new applications in different branches of industry are emerging.

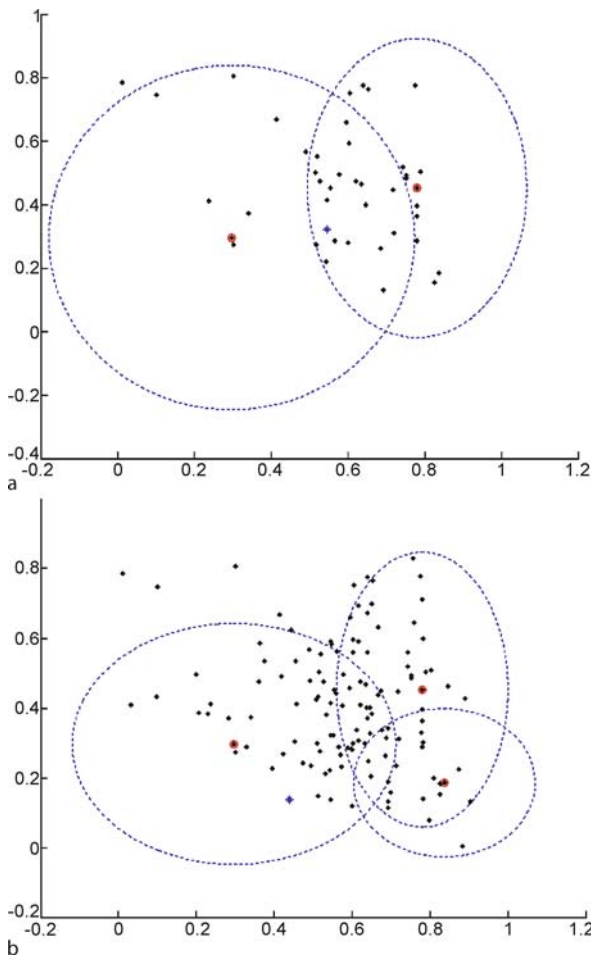

Evolving Clustering

Data Clustering and, Fuzzy Clustering in particular, are methods for grouping the data based on their similarity, density in the data space and proximity. Partitioning of the data into clusters can be done off-line (using a batch set of data, performing iterative computations over this set, minimizing certain criteria/cost function) or on-line, incrementally. Examples of incremental clustering approaches are self-organizing maps (SOM) conceived by Teuvo Kohonen in the early 1980s [44], adaptive resonance theory (ART) by Stephen Grossberg conceived in the same period [25] etc. Clustering is a type of unsupervised learning technique where the correct examples are not provided. Usually, the number of clusters is pre-specified, e. g. in SOM the number of nodes of the map is pre-defined; the number of neighbors, k in the k -nearest neighbor clustering method [33] is also supposed to be provided, the number C in the fuzzy c -means (FCM) fuzzy clustering algorithm by Jim Bezdek should also be provided [22]. Usually these approaches rely on a threshold and are very sensitive to the specific values of this threshold. Most of the existing approaches are also mean-based (i. e. they use the mean of all data or mean of groups of data). The problem is that the mean is a virtual (non-existing and possibly infeasible) point in the data space.

In contrast, the evolving clustering method eClustering conceived in the last decade [3] does not need the number of clusters, the threshold or any other parameter to be pre-specified. It is parameter-free and starts “from scratch” to cluster the data based on their density distri-

bution alone. It is based on the recursive calculation of the potential (5). eClustering is prototype-based (some of the data points are used as prototypes of cluster centers). The procedure of the evolving clustering approach starts from scratch assuming that the first available data point is a center of a cluster. This assumption is temporary and if a priori knowledge exists the procedure can start with an initial set of cluster centers that will be further refined. The coordinates of the first cluster center are formed from the coordinates of the first data point ($z_1^* \leftarrow z_1$). Its potential is set to the ideal value, $P_1(z_1) \rightarrow 1$. Starting from the **next** data point which is read in real-time, the following steps are performed for each new data point:

- calculate its potential, $P_k(z_k)$;

Evolving Fuzzy Systems, Figure 2

The Evolving Clustering method applied to data concerning NOx emissions; **a** top plot – after 43 samples are read (after 43 s because the sampling rate is 1 sample/second or 1 Hz); **b** bottom plot – after 124 samples are read (after 124 s)

- update the potential of the existing cluster centers (because their potential has been affected by adding a new data point);
- compare the potential of the new data point with the potential of the previously existing centers. On the basis of this comparison and the membership of the existing clusters one of the following actions is taken:
 - (**add** a new cluster center based on the new data point)
 - OR** (**remove** the cluster that describes well the new point which brings an increment to the potential)
 - AND** (**replace** it with a cluster formed around the new point)
 - OR** (**ignore** (do not change the cluster structure)).

The process is illustrated in Fig. 2 for the data of NOx emissions from a car exhaust [13].

One can see that the clustering evolves (number of clusters increases from two to three, their position and their radius has changed). Note that in this experiment only two normalized to the range [0; 1] inputs (features), namely the engine output torque in N/m, x_1 and pressure in the second cylinder in Pa, x_2 are used. For more details on eClustering, please, consult the papers from the bibliography, and especially [2,3,9,16].

Evolving TS Fuzzy Systems

TS fuzzy systems [as illustrated in Fig. 1 and described in a very general form in Eq. (1)] were first introduced in 1985 [65] in the form:

$$\mathfrak{R}_i: \text{IF } (x_1 \text{ is } A_{i1}) \text{ AND } \dots \text{ AND } (x_n \text{ is } A_{in}) \quad (7)$$

$$\text{THEN } (y_i = a_{i0} + a_{i1}x_1 + \dots + a_{in}x_n)$$

where A_i denotes the i th fuzzy rule ($i = [1, R]$); R is the number of fuzzy rules; \mathbf{x} is the input vector; $\mathbf{x} = [x_1, x_2, \dots, x_n]^T$; A_{ij} denotes the antecedent fuzzy sets, $j \in \{1, n\}$; y_i is the output of the i th linear subsystem; a_{il} are its parameters, $l \in \{0, n\}$.

The structure of the TS system (number of fuzzy rules), antecedent part of the rules, number of inputs etc., are supposed to be known and are fixed. The data may be provided to the TS system in off-line or in on-line manner. Different data-driven techniques were developed to identify the best in terms of certain (local or global) error minimization criteria such as using a (recursive) least squares technique [65], using genetic algorithms [7,62] etc. The overall output is found to be a weighted sum of local outputs produced by each fuzzy rule:

$$y = \sum_{i=1}^R \lambda^i y^i. \quad (8)$$

Where the weights, λ represent the normalized firing level of the respective fuzzy rule and can be determined by:

$$\lambda^i = \frac{\sum_{j=1}^n \mu_j^i(x_j)}{\sum_{l=1}^R \sum_{j=1}^n \mu_j^l(x_j)} . \quad (9)$$

In a vector form the above equations can be represented as:

$$y = \psi^T \theta \quad (10)$$

where $\psi = [\lambda_1 x_e^T, \lambda_2 x_e^T, \dots, \lambda_R x_e^T]^T$ is the vector of weighted extended inputs; $x_e^T = [1, x^T]$;

$\theta = [\pi_1^T, \pi_2^T, \dots, \pi_R^T]^T$ is the vector of parameters;

$$\pi^i = \begin{bmatrix} \alpha_{01}^i & \alpha_{02}^i & \dots & \alpha_{0m}^i \\ \alpha_{11}^i & \alpha_{12}^i & \dots & \alpha_{1m}^i \\ \dots & \dots & \dots & \dots \\ \alpha_{n1}^i & \alpha_{n2}^i & \dots & \alpha_{nm}^i \end{bmatrix}$$

are the parameters of the m local linear sub-systems.

The assumption that the TS fuzzy system structure has to be known a priori was for the first time questioned in [2,5] and ultimately in [9] with the proposal of evolving TS (eTS) systems. In [15] a further extension of the eTS system was proposed, namely that they can have many outputs. In this way, the multi-input-multi-output eTS systems were introduced (MIMO-eTS).

eTS is a very flexible and powerful tool for time-series prediction, prognosis, modeling non-stationary phenomena, intelligent sensors etc. The algorithm for its learning from streaming data in real-time has two basic phases, which can both be performed very quickly (in one time step between the arrival of two data samples – the current one and the next one). The learning mechanism proposed in [9] is computationally very efficient because it is fully recursive. The two phases include:

- Data space partitioning and based on this forming and update of the fuzzy rule-base structure;
- Learning parameters of the consequent part of the fuzzy rules.

Note that the partitioning of the data space serves in eTS identification a different purpose compared to the purpose of data space partitioning in eClustering. In eTS there are outputs and the aim is to find such (perhaps overlapping) clustering of the input-output joint data space that fragments the input-output relationship into locally valid simpler (possibly linear) dependences. In eClustering the aim is to cluster the input data space into distinctive

regions. Other than that, the first phase of the eTS model identification is the same as the procedure in the eClustering method described above.

The second phase of the learning is parameter identification. It can be performed using a fuzzily weighted version [9] of the well-known recursive least squares (RLS) method [50]. One can perform either local (11) or global (12) identification by minimizing different cost functions [9]:

$$J_L = \sum_{i=1}^R (Y - X^T \pi_i)^T \Lambda_i (Y - X^T \pi_i) \quad (11)$$

$$J_G = (Y - \Psi^T \theta)^T (Y - \Psi^T \theta) . \quad (12)$$

In one of the cases (when a local cost function is used) the result will be a better approximation locally of the overall non-linear function by the local linear sub-models. The pay-off is, however, a poorer overall approximation. This is, however, compensated by a simpler and computationally more efficient procedure (if we use a locally valid cost function the covariance matrices of much smaller size can be used and they require much less memory space and time to perform computations) [9].

Evolving Fuzzy Classifiers

Classification is a problem that has been well studied and a large number of conventional approaches exist to address this problem [33]. Most of them, however, are designed to operate in batch mode and do not change their structure on-line (do not capture new patterns that may be present in the streaming data once the classifier is built). Off-line pre-trained classifiers may be good for certain scenarios, but they need to be redesigned or retrained if the circumstances change. There are also so-called incremental (or on-line) classifiers which work on a “sample-by-sample” basis and only require the features of that sample plus a small amount of aggregated information (a rule-base, a small number of variables needed for recursive calculations). They do not require all the history of the data stream (all previously seen data samples). Sometimes they are also called one-pass (each sample is processed only once at a time and is then discarded from the memory).

FRB systems have been successfully applied to a range of classification tasks including, but not limited to, decision making, fault detection, pattern recognition, image processing [46]. FRB systems have become one of the alternative frameworks for classifier design together with the more established Bayesian classifiers, decision trees [33], neural network-based classifiers [57], and support-vector machines (SVM) [67]. The task of the classifier is to map

the set of features of the sample data onto the set of class labels. A particular advantage of the FRB classifiers is that they are linguistic in form while being also proven universal approximators [68].

In the framework of the concept of *evolving fuzzy systems* a family of evolving fuzzy classifiers, eClass was proposed in [16,17,51]. The first type of evolving fuzzy classifiers, eClass0 has the typical structure of a fuzzy classifier [46] that differs from structure (1) by the consequent part only:

$$\begin{aligned}
 R^i: & \text{ IF } (Feature_1 \text{ is close to prototype}_1^i) \\
 & \text{ AND } \dots \text{ AND } (Feature_n \text{ is close to prototype}_n^i) \\
 & \text{ THEN } (ClassLabel^i)
 \end{aligned} \quad (13)$$

The output of eClass0, in the same way as typical fuzzy classifiers [46] provides the label of the class (0, 1 etc.) directly. In this sense, it is not a TS fuzzy system, but is closer to the Mamdani-type fuzzy systems [54]. The main difference of the eClass0 from the typical classifiers [46] is its ability to evolve, to expand the set of fuzzy rules that enables it to capture new data patterns, to adapt to possibly changing characteristics of the streaming data [16,17]. The inference in eClass0 is produced using the so-called “winner takes all” rule [33,46]:

$$Label = Label^{i^*}; i^* = \arg \max_{i=1}^R \left(\sum_{j=1}^n \mu_j^i(x_j) \right). \quad (14)$$

It is much easier and faster to build and train eClass0 in real-time, but the results of the classification can be further significantly improved if the classifier structure is assumed to be of TS-type. eClass is designed for on-line applications with an evolving (self-developing) FRB structure. The antecedents of the FRB are formed from the data stream around highly descriptive focal points (prototypes) per class in the input-output space. The features vector, \mathbf{x} is augmented with the class label, L to form a joint input-output vector $\mathbf{z} = [\mathbf{x}^T, L]^T$. The eClustering algorithm is applied *per class* (not over all the data). In this way, information granules (primitive forms of knowledge) [36] are formed **in real-time** around descriptive data samples, represented linguistically by fuzzy sets. This on-line algorithm works similarly to adaptive control [19] and estimation [39] – in the period between two samples two phases are performed: (1) class prediction (classification); (2) classifier update or evolution. During the first phase the class label is not known and is being predicted; during the second phase, however, it is known and is used as supervisory

information to update the classifier (including its **structure evolution** as well as its parameters update).

An alternative structure of the fuzzy classifier, eClass1 is based on the TS-type fuzzy system which has a consequent part of functional type as described in (7). The architecture of eClass1 differs significantly from the architecture of eClass0 and the typical FRB [46]. It performs a regression over the features. Having in mind that the classification surface in a data stream changes dynamically the goal of the evolving fuzzy classifier eClass1 is to evolve a rule-base which takes these changes into account by adapting parameters of the FRB (spreads, consequent parameters) as well as the focal points and the size of the rule-base. The output of each rule is a real (not integer as in the typical fuzzy classifiers) value, which if normalized represents the possibility of a data sample to be of certain class [16,17]:

$$\bar{y}^i = \frac{y^i}{\sum_{i=1}^R y^i}. \quad (15)$$

The overall output of the classifier is then taken as a weighted average (not as winner takes all as in typical fuzzy classifiers) of the normalized outputs of each fuzzy rule:

$$y = \sum_{i=1}^R \frac{\sum_{j=1}^n \mu_j^i}{\sum_{l=1}^R \sum_{j=1}^n \mu_j^l} \bar{y}^i. \quad (16)$$

This output is then used to discriminate between the classes. If the problem has two classes (A and B) then the target values are, obviously, 0 for one of the two classes (e.g. Class A) and 1 for the other one (Class B) or vice versa. To discriminate in this case one can simply use a threshold of 0.5. All the outputs that are above 0.5 are being classified as Class B while all the outputs below 0.5 are classified as Class A or vice versa:

$$\begin{aligned}
 & \text{ IF } (y > 0.5) \\
 & \text{ THEN } (Class A) \\
 & \text{ ELSE } (Class B)
 \end{aligned} \quad (17)$$

When the problem has more than two classes, one can apply MIMO eTS where each of the K outputs corresponds to the possibility that a data sample belongs to a certain class (as discussed above). It is interesting to note that it is possible to use MIMO eTS for a two-class problem. In order to do this, one needs to have vectors that represent the target outputs, for example $\mathbf{y} = [1 \ 0]$ for Class A and

$y = [0 \ 1]$ for Class B or vice versa. In eClass1-MIMO the label is determined by the highest value of the discriminator, \bar{y}_l :

$$\text{Label} = \text{Label}^{i^*}; i^* = \arg \max_{l=1}^K \bar{y}_l \quad (18)$$

where K denotes the number of classes.

Evolving Fuzzy Controllers

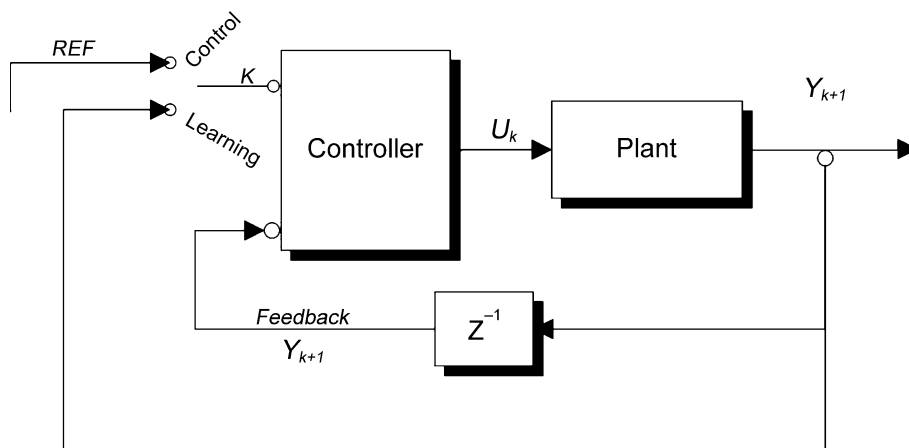

Fuzzy logic controllers have been applied in a range of industrial processes [48,59] around the word including in home appliances [21]. The structure of the controller, however, is often decided in an ad hoc manner [54,59] and parameters are tuned off-line using various numerical techniques such as genetic algorithms for example [27,32,63]. In reality, however, even if a validation test has been made beforehand, there is no guarantee that a controller designed in this way will perform satisfactorily if the object of control or its environment change [4]. The reasons could be aging, wearing, change in the mode of operation or development of a fault, seasonal changes in the environment etc. An effective mechanism for tackling such problems known from the classical control theory is adaptation [19]. It is well developed for the linear models and controllers [38], but not for a general (very often highly non-linear, complex and uncertain) case [2]. Adaptive control theory assumes a linear model with a fixed structure and applies to parameters only [19,38].

The concept of evolving fuzzy systems has been applied to the control problem in [2,4] in terms of self-developing the structure of a controller from experimental data in a data-driven manner based on the indirect adap-

tive learning scheme proposed initially by Psaltis [60] and developed further using NN by Anderson [1]. The indirect learning (IL) control scheme is based on the approximation of the inverse dynamics of the plant. The IL-based control scheme is a model-free concept. It feeds back the integrated (or delayed one-step back) output signal instead of feeding back the error between the plant output and the reference signal as represented in Fig. 3.

Figure 3 represents only the basic concept of the approach. It has two phases and the switching between them can be represented by an imaginary switch knob. When the imaginary knob, K is in position “1” the controller is used and we are in phase “Control”. When the imaginary knob is in position “2” the controller learns, self-develops and we are in phase “Learning”. During the supervisory learning phase, the true output signal (y_{k+1}) at the time-instant ($k + 1$) is fed back and the knob is in position “2”. The controller also receives a signal that is a delayed true output, y_k . The controller has as an output the value of the control signal, u_k . During the control phase (when the knob is in position “1”) the input is determined entirely based on the reference signal (ref) as an alternative to the predicted next step output, y_{k+1} . In this way, the controller already trained in the previous learning phases produces such a control signal (u_k), which brings the output of the plant at the next time step (y_{k+1}) close to the reference signal (ref).

The IL scheme was taken further in [2,4] by implementing the controller as an evolving FRB system of TS-type. The original works realized the controller as a NN that was trained *off-line* based on a batch set of training data for the control action and output triplets of the form [y_k, y_{k+1}, u_k] for $k = 1, 2, \dots, N$; where N denotes the

Evolving Fuzzy Systems, Figure 3
Indirect learning-based control scheme

number of training data samples. However, learning techniques for NN are iterative and, therefore training of the NN-controller as described in [1,60] is performed *off-line*. Additionally, NN suffers from the important disadvantage in comparison to the FRB systems that they are not transparent. In [2,4] the basic scheme of IL control is taken further by adding a disturbance and by using eTS to realize the controller. This scheme was implemented on temperature-control problems.

Application Case Studies

Self-Calibrating Intelligent Sensors for Process Industries

So-called intelligent or inferential sensors have been adopted by the process industries (chemical, petro-chemical, manufacturing) for several decades [31]. The main reason is that they provide accurate real time estimates of difficult to measure otherwise parameters or can replace (substitute) expensive measurements such as gas emissions, biomass, melt index, etc. They use as inputs the available (“hard”) sensors for easy to measure physical variables, such as temperatures, pressures, and flows which are also cheaper. The main disadvantage of the currently existing inferential or “soft” sensors is that significant efforts must be made based on batch sets of data to develop and maintain the mathematical models that support them (neural networks, statistical models etc.). Any process changes outside the conditions used for off-line model development can lead to significant performance

deterioration which, in turn, requires maintenance and recalibration.

Evolving Fuzzy Systems offer an effective opportunity to develop “soft” sensors that are more flexible, self-calibrating, and thus, more “intelligent” [45]. Several applications of EFS-based soft sensors, in particular for oil refineries [52,53] and propylene production [12] were reported. An important advantage of the evolving sensors is that they extract human-interpretable knowledge in the form of linguistic fuzzy rules. For example, Fig. 4 illustrates membership functions of the fuzzy sets (in values in the range [0;1] on the vertical axis) that describe the density of the crude, d in gram per liter (g/l) on the horizontal axis. The evolving fuzzy sensor (eSensor) implemented in the oil refinery at Santa Cruz, Tenerife, Spain predicts in real-time the temperature of the heavy naphtha (hn) T^{hn} , °C in degrees Celsius when it evaporates 95% liquid volume, according to the ASTM D86-04b standard based on real-time measurements of:

- The pressure of the tower, p , measured in $\text{kg}/\text{cm}^2\text{g}$
- The amount of the product taking off, P , represented in %
- The density of the crude, d in g/l (illustrated in Fig. 4)
- Temperature of the column overhead, T^{co} in °C
- Temperature of the naphtha extraction, T^{ne} in °C

An expert in the area of oil refining processes can easily visually distinguish between the heavy crude and light crude represented by respective membership functions derived automatically from the data in real-time.

Evolving Fuzzy Systems, Figure 4

Fuzzy sets for different fractions of the crude that contribute to the different quality of the end product (naphtha in this case) can be extracted automatically in real-time from the data stream using eSensor

Adaptive Real-Time Classifiers (Image, Land-Mark, Robotic)

Presently the data that are to be processed in industry, in defense and other real-life applications are not only huge in volume, but very often they are in the form of data *streams* [28]. This requires not only precise classifiers, but also dynamically evolvable classifiers. For example, in mobile robotics, an autonomous vehicle produces a video stream while operating in a completely unknown environment that needs to be processed [75,76]. The Evolving Clustering method was used to automatically generate a fuzzy rule-base that describes the landmarks discovered without any prior learning, “on the fly” by a mobile robot Pioneer 3DX [58] exploring a completely unknown environment [76]. The mobile robot is using its on-board pan-tilt zoom camera to produce a video stream. The frames were grasped and processed by the eClustering algorithm based on a 3-dimensional color-vector (R, G, B). Fuzzy rules of the following form were extracted from the data automatically:

Note that the landmarks that were identified automatically represented real objects on the route of the mobile robot such as the underpass of Lancaster University from the example. They were identified to be distinctive from the surrounding background by eClustering. The fuzzy rule base (Fig. 5) has evolved “from scratch” based on the video information and the data distribution only.

Predictive Models (Air-Conditioning, Financial Time-Series, Benchmark Data Sets)

There are different techniques that can be used for predictive models, such as ARMAX models [50], neural networks [34] non-evolving (fixed structure) fuzzy rule-based models [65,73]. Evolving fuzzy systems, however, offer additionally the capability to have a predictor that evolves

following the dynamic changes of the data by gradually adapting not only its parameters, but also its structure. In [6] the problem of predicting the characteristic temperature difference across a coil in a heat exchanger of an air-conditioning unit installed in a real building in Iowa, USA is considered. The evolving fuzzy rule-based model develops its structure and parameters based on the data of the flow rate entering the coil, moisture content of the air entering the coil, temperature of the chilled water, and control signal to the valve as illustrated in Fig. 6. The model proved to work satisfactorily in all season conditions due to its ability to adapt to the changes in the environment (different seasons) as demonstrated in Fig. 6c. When pre-trained (based on 400 samples) and fixed as both structure and parameters the performance deteriorated unacceptably in changing seasonal conditions as seen in Fig. 6a. A partial re-training improved significantly the results (Fig. 6b), but still this was less valid when the season changed (at around sample 912) and the model structure evolution has stopped (at sample 1000). When the model structure evolution continued uninterrupted the result was a satisfactory performance in all seasons as seen in Fig. 6c.

Fault Detection and Prognostics

Evolving clustering and eTS fuzzy systems were applied in Ford Motor Company to machine health monitoring and prognosis in [30]. The ability of the evolving clustering method to form new clusters that represent different operating modes of a machine was exploited and different types of faults (incipient or drastic) were automatically identified based on the difference in the cluster formation. A prediction of the direction of movement of the cluster centers was used for prediction of possible faults and of the end-of-life of the machine.

Rule_i: IF (μ_{il}^R is close to 123) AND... AND(μ_{in}^B is close to 84)

THEN the Frame_j is like the Landmark_i

Evolving Fuzzy Systems, Figure 5

Fuzzy rule describing a Landmark (underpass at Lancaster University campus) that was discovered automatically by eClustering using video streaming data

Evolving Fuzzy Systems, Figure 6

A predictive model of the characteristic temperature difference across a coil in a heat exchanger of an air-conditioning unit installed in a real building in Iowa, USA. **a** An off-line pre-trained model used in two different seasons (summer and spring); **b** Evolving FRB model trained and used during the summer (up to sample 1000) and then having its structure fixed during the spring season; **c** Evolving FRB model left to evolve (self-develop) during the whole period of usage (both spring and summer seasons)

Speech Signal Reconstruction

The ETS fuzzy system is used in [37] for error concealment in the next-generation Voice over Internet Protocol (VoIP) communication receivers. It is used in combination with parametric speech coders of analysis-by-synthesis-type. eTS MIMO [15] is used to predict the missing values of the linear spectral pairs (LSP) that will allow one

to reconstruct the lost in transmission packets. The eTS fuzzy model used ten inputs (current LSP parameter values) and ten outputs (predicted one step/20 milliseconds ahead LSP values). This research was a joint work between Lancaster University and Nokia-UK and aims the development of the next generation intelligent decoders at the receiver that will be able to conceal lost packets with a size of 80 to 160 ms without significant deterioration to the quality of service (QoS) in VoIP transmission.

Future Directions

The area of evolving fuzzy systems is in its infancy and has already demonstrated a remarkable success in addressing some of the most vibrating issues of the development, application and implementation of truly intelligent systems in a wide variety of branches of industry and real-life problems [11]. It opens the door for future developments that are related to the areas of autonomous systems, early cancer diagnosis and prognosis of the progression, even to the identification of structural changes in biological cells that correspond to the evolution of the disease. In the area of intelligent self-maintaining sensors the process industry can benefit from more flexible and smarter solutions. The problems that are yet to be addressed and can mark the future development of this vibrant area are; (1) collaboration aspects between two or more evolving fuzzy system-based intelligent systems (autonomous robots, intelligent sensors etc.); (2) further flexibility of the systems in terms of real-time self-analysis, optimal features and input selection, rule aggregation mechanism adaptation etc.; (3) even more flexible system structure architectures such as hierarchical, decentralized; (4) more robust learning algorithms that take care of missing data, different sampling intervals etc.

From a broader perspective, the future developments of this discipline will influence and are closely related to similar developments in the area of communication networks (self-adaptive networks [64]), self-validating soft sensors [61], autonomous aerial, ground-based, and underwater vehicles [20,40,49] etc. The area is closely related to the developments in the area of neural networks [34,48], so-called autonomous mental development [23] and cognitive psychology [55], mining data streams [28]. One can also expect more hardware implementations (the first hardware implementation of eClustering was reported in 2005 [8]). From the point of view of mathematical fundamentals and learning it is also closely related to adaptive filters theory [69] and the recent developments in particle filters [17] will certainly influence the future, more ef-

ficient techniques that will be developed in this emerging and highly potential branch of research.

Acknowledgments

The author would like to thank Mr. Xiaowei Zhou for his assistance in producing the illustrative material, Dr. Jose Macias Hernandez for kindly providing real data from the oil refinery CEPESA, Santa Cruz, Tenerife, Spain, Dr. Richard Buswell, Loughborough University and ASHRAE (RP-1020) for the real air conditioning data, and Dr. Edwin Lughofer from Johannes Kepler University of Linz, Austria for providing real data from car engines.

Glossary

Ordinary differential equation An ordinary differential equation is a relation between a (vector) function $u: I \rightarrow \mathbb{R}^m$, (I an interval in \mathbb{R} , $m \in \mathbb{N}$) and its derivatives. A function u , which satisfies this relation, is called a solution.

Initial value problem An initial value problem is an ordinary differential equation with a prescribed value for the solution at one instance of its variable, often called the initial time. The initial value is the pair consisting of the initial time and the prescribed value of the solution.

Vector field For an ordinary differential equation of the form $\frac{du}{dt} = f(t, u)$, the function $f: \mathbb{R} \times \mathbb{R}^m \rightarrow \mathbb{R}^m$ is called the vector field. Thus, at a solution, the vector field gives the tangent to the solution.

Flow map The flow map describes the solution of an ordinary differential equation for varying initial values. Hence, for an ordinary differential equation $\frac{du}{dt} = f(t, u)$, the flow map is a function $\Phi: \mathbb{R} \times \mathbb{R} \times \mathbb{R}^m \rightarrow \mathbb{R}^m$ such that $\Phi(t, t_0, u_0)$ is a solution of the ordinary differential equation, starting at $t = t_0$ in $u = u_0$.

Functions: bounded, continuous, uniformly Lipschitz continuous Let D be a connected set in \mathbb{R}^k with $k \in \mathbb{N}$ and let $f: D \rightarrow \mathbb{R}^m$ be a function on D :

- The function f is *bounded* if there is some $M > 0$ such that $|f(x)| \leq M$ for all $x \in D$.
- The function f is *continuous* on D if $\lim_{x \rightarrow x_0} f(x) = f(x_0)$, for every $x_0 \in D$. A continuous function on a bounded and closed set D is bounded. The function f is *equicontinuous* or *uniform continuous* if the convergence of the limits in the definition of continuity is uniform for all $x_0 \in D$, i. e., for every $\varepsilon > 0$, there is a $\delta > 0$, such that for all $x_0 \in D$ and all $x \in D$ with $|x - x_0| < \delta$ it holds that $|f(x) - f(x_0)| < \varepsilon$. A continuous function on a compact interval is equicontinuous.
- Let $D \subset \mathbb{R} \times \mathbb{R}^m$. The function $f: D \rightarrow \mathbb{R}^m$ is *uniformly Lipschitz continuous on D with respect to its second variable*, if f is continuous on D and there exists some constant $L > 0$ such that

$$|f(t, u) - f(t, v)| \leq L|u - v|,$$

for all $(t, u), (t, v) \in D$.

The constant L is called the *Lipschitz constant*.

Pointwise and uniform convergence A sequence of functions $\{u_n\}$ with $u_n: I \rightarrow \mathbb{R}^m$ is Pointwise con-

vergent if $\lim_{n \rightarrow \infty} u_n(t)$ exists for every $t \in I$. The sequence of functions $\{u_n\}$ is uniform convergent with limit function $u: I \rightarrow \mathbb{R}^m$ if $\lim_{n \rightarrow \infty} \sup\{|u - u_n| \mid t \in I\} = 0$. A sequence of pointwise convergent, equicontinuous functions is uniform convergent and the limit function is equicontinuous.

Notation

\dot{u}	Derivative of u , i. e., $\frac{du}{dt}$
$u^{(k)}$	The k th derivative of u , i. e., $\frac{d^k u}{dt^k}$
$I_a(t_0)$	The closed interval $[t_0, t_0 + a]$
$B_b(u_0)$	The closed ball with radius b about u_0 in \mathbb{R}^m , i. e., $B_b(u_0) := \{u \in \mathbb{R}^m \mid u - u_0 \leq b\}$
$\ u\ _\infty$	The supremum norm for a bounded function $u: I \rightarrow \mathbb{R}^m$, i. e., $\ u\ _\infty = \sup\{ u(t) \mid t \in I\}$

Definition of the Subject

Many problems in physics, engineering, biology, economics, etc., can be modeled as relations between observables or states and their derivatives, hence as differential equations. When only derivatives with respect to one variable play a role, the differential equation is called an ordinary differential equation. The field of differential equations has a long history, starting with Newton and Leibniz in the seventeenth century. In the beginning of the study of differential equations, the focus is on finding explicit solutions as the emphasis is on solving the underlying physical problems. But soon one starts to wonder: If a starting point for a solution of a differential equation is given, does the solution always exist? And if such a solution exists, how long does it exist and is there only one such solution? These are the questions of existence and uniqueness of solutions of initial value problems. The first existence result is given in the middle of the nineteenth century by Cauchy. At the end of the nineteenth century and the beginning of the twentieth century, substantial progress is made on the existence and uniqueness of solutions of initial value problems and currently the heart of the topic is quite well understood. But there are many open questions as soon as one considers delay equations, functional differential equations, partial differential equations or stochastic differential equations. Another area of intensive current research, which uses the existence and uniqueness of differential equations, is the area of finite- and infinite-dimensional dynamical systems.

Introduction

As indicated before, an initial value problem is the problem of finding a solution of an ordinary differential equation with a given initial condition. To be precise, let

D be an open, connected set in $\mathbb{R} \times \mathbb{R}^m$. Given are a function $f: D \rightarrow \mathbb{R}^m$ and a point $(t_0, u_0) \in D$. The initial value problem is the problem of finding an interval $I \subset \mathbb{R}$ and a function $u: I \rightarrow \mathbb{R}^m$ such that $t_0 \in I$, $\{(t, u(t)) \mid t \in I\} \subset D$ and

$$\frac{du}{dt} = f(t, u(t)), \quad t \in I, \quad \text{with } u(t_0) = u_0. \quad (1)$$

The function f is called the vector field and the point (t_0, u_0) the initial value. One often writes the derivative as $\frac{du}{dt} = \dot{u}$. If f is continuous, then the initial value problem (1) is equivalent to finding a function $u: I \rightarrow \mathbb{R}^m$ such that

$$u(t) = u_0 + \int_{t_0}^t f(\tau, u(\tau))d\tau, \quad \text{for } t \in I. \quad (2)$$

If f is continuous and a solution exists, then clearly this solution is continuously differentiable on I .

It might seem restrictive to only consider first-order systems; however, most higher-order equations can be written as a system of first-order equations. Consider for example the n th order differential equation for $v: I \rightarrow \mathbb{R}$

$$v^{(n)}(t) = F(t, v, \dot{v}, \dots, v^{(n-1)}),$$

with initial conditions

$$v^{(k)}(t_0) = v_k, \quad k = 0, \dots, n - 1.$$

This can be written as a first-order system by using the vector function $u: I \rightarrow \mathbb{R}^m$ defined as $u = (v, \dot{v}, \dots, v^{(n-1)})$. The equivalent initial value problem for u is

$$\dot{u} = f(t, u) = \begin{pmatrix} u_2 \\ \vdots \\ u_n \\ F(t, u_1, u_2, \dots, u_n) \end{pmatrix},$$

$$\text{with } u(t_0) = \begin{pmatrix} v_0 \\ v_1 \\ \vdots \\ v_{n-1} \end{pmatrix}.$$

Obviously, this system is not a unique representation, there are many other ways of obtaining first-order systems from the n th-order problem.

In the beginning of the study of differential equations, the focus is on finding explicit solutions. The first existence theorem is by Cauchy [3] in the middle of the nineteenth century and an initial value problem is also called a *Cauchy problem*. At the end of the nineteenth century

substantial progress is made on the existence of solutions of an initial value problem when Peano [20] shows that if f is continuous, then a solution exists near the initial value (t_0, u_0) , i. e., there is local existence of solutions. Global existence of solutions of initial value problems needs more than smoothness, as is illustrated by the following example.

Example 1 Consider the initial value problem on $D = \mathbb{R} \times \mathbb{R}$ given as

$$\dot{u} = u^2 \quad \text{and} \quad u(0) = u_0$$

for some $u_0 > 0$. As can be verified easily, the solution is $u(t) = u_0/(1 - tu_0)$, for $t \in (-\infty, 1/u_0)$. This solution cannot be extended for $t \geq 1/u_0$, even though the vector field $f(t, u) = u^2$ is infinitely differentiable on the full domain. As can be seen from later theorems, the lack of global existence is related to the fact that the vector field f is unbounded.

Once existence of solutions of initial value problems is known, the next question is if such a solution is unique. As can be seen from the following example, continuity of f is not sufficient for uniqueness of solutions.

Example 2 Consider the following initial value problem on $D = \mathbb{R} \times \mathbb{R}$:

$$\dot{u} = |u|^\alpha \quad \text{and} \quad u(0) = 0.$$

If $0 < \alpha < 1$, then there is an infinite number of solutions. Two obvious solutions for $t \in [0, \infty)$ are $\bar{u}(t) = 0$ and $\hat{u}(t) = ((1 - \alpha)t)^{\frac{1}{1-\alpha}}$. But these solutions are members of a large family of solutions. For any $c \geq 0$, the following functions are solutions for $I = \mathbb{R}$:

$$u_c(t) = \begin{cases} 0, & t < c \\ ((1 - \alpha)(t - c))^{\frac{1}{1-\alpha}}, & t \geq c. \end{cases}$$

A sufficient condition for uniqueness of solutions of the initial value problem is uniform Lipschitz continuity of the vector field f in its second variable u . Although the ideas behind this theorem go back to Cauchy and Lipschitz, Picard [21] and Lindelöf [18] are usually credited with this result. They used the so-called method of successive approximations to prove the uniqueness result; see Sect. “[Uniqueness](#)” for details.

Having determined existence and uniqueness, the next issue is the relation between a solution and its initial value. This is the topic of Sect. “[Continuous Dependence on Initial Conditions](#)”. The concept of a flow map is first introduced. Roughly speaking, the flow map is the solution,

with the initial value as an extra variable. If the vector field is uniformly Lipschitz continuous in its second variable, then the flow map is continuous. Thus, a small change in the initial value, will only give a small change in the solution (locally).

The concept of an initial value problem can be extended to noncontinuous vector fields f and existence theorems can be shown if the vector fields satisfy the so-called Carathéodory conditions. More details can be found in Sect. “[Extended Concept of Differential Equation](#)“. This chapter ends with a discussion of initial value problems in more general differential equations and the use of existence and uniqueness of solutions of initial value problems in dynamical systems.

Existence

Cauchy [3] seems to have been the first one to publish an existence result for differential equations, using an approximation of solutions by joined line segments. This work was extended considerably by Peano [20] in 1890.

Theorem 1 (Cauchy–Peano Theorem) *Let $a, b > 0$, define $I_a(t_0) := [t_0, t_0 + a]$ and $B_b(u_0) := \{u \in \mathbb{R}^m \mid |u - u_0| \leq b\}$ and assume that the cylinder $S := I_a(t_0) \times B_b(u_0) \subset D$. Let the vector field f be a continuous function on the cylinder S . This implies that f is bounded on S , say, $M = \max\{|f(t, u)| \mid (t, u) \in S\}$.*

Define the parameter $\rho = \min\left(a, \frac{b}{M}\right)$. Then there exists a solution $u(t)$, with $t_0 \leq t \leq t_0 + \rho$, which solves the initial value problem (1).

The theorem can also be phrased for an interval $[t_0 - \rho, t_0]$ or $[t_0 - \rho, t_0 + \rho]$. The parameter ρ gives a time interval such that that the solution $(t, u(t))$ is guaranteed to be within S . From the integral formulation of the initial value problem (2), it follows that

$$|u(t) - u_0| \leq \int_{t_0}^t |f(\tau, u(\tau))| d\tau \leq M(t - t_0).$$

To guarantee that $u(t)$ is within S , the condition $t - t_0 \leq \rho$ is sufficient as it gives $M(t - t_0) \leq b$ and $t - t_0 \leq a$. In Fig. 1, this is illustrated in the case $D \subset \mathbb{R} \times \mathbb{R}$.

To prove the Cauchy–Peano existence theorem, a construction which goes back to Cauchy is used. This so-called Cauchy–Euler construction of approximate solutions uses joined line segments which are such that the tangent of each line segment is given by the vector field evaluated at the start of the line segment. To be specific, for any $N \in \mathbb{N}$, the interval $I_\rho(t_0) = [t_0, t_0 + \rho]$ is divided in N equal parts with intermediate points $t_k := t_0 + \frac{k}{N}\rho$, $k = 1, \dots, N$. The approximate solution is the function $u_N: I_\rho(t_0) \rightarrow \mathbb{R}$, with

$$\begin{aligned} u_N(t_0) &= u_0, \\ u_N(t) &= u_N(t_{k-1}) + f(t_{k-1}, u_N(t_{k-1}))(t - t_{k-1}), \quad (3) \\ t_{k-1} < t \leq t_k, \quad k &= 1, \dots, N, \end{aligned}$$

see also Fig. 2. One sees immediately that function u_N is continuous and piecewise differentiable and, using the bound on the vector field f ,

$$|u_N(t) - u_N(s)| \leq M|t - s|, \quad \text{for all } t, s \in I_\rho(t_0). \quad (4)$$

Existence and Uniqueness of Solutions of Initial Value Problems, Figure 1

The parameter $\rho = \min\left(\frac{b}{M}, a\right)$ guarantees that the solution is within the shaded area S , on the left in the case $a < \frac{b}{M}$ and on the right if $a > \frac{b}{M}$

Existence and Uniqueness of Solutions of Initial Value Problems, Figure 2

The approximate solution u_N , with $N = 5$, and the solution $u(t)$. The dotted lines show the tangent given by the vector field $f(t, u)$ at the points (t_i, u) for various values of u and $i = 0, \dots, 5$

This estimate implies that the sequence of functions $\{u_N\}$ is uniformly bounded and that the functions u_N are equicontinuous. Indeed, the estimate above gives that for any $t \in I_\rho(t_0)$ and any $N \in \mathbb{N}$,

$$|u_N(t)| \leq |u_N(t_0)| + M|t - t_0| \leq |u_0| + M\rho.$$

And equicontinuity follows immediately from (4) as M does not depend on N .

Arzela-Ascoli’s lemma states that a sequence of functions which is uniformly bounded and equicontinuous on a compact set has a subsequence which is uniformly convergent on this compact set [5]. As the sequence $\{u_N\}$ is uniformly bounded and equicontinuous on the compact set $I_\rho(t_0)$, it follows immediately that it has a convergent subsequence. This convergent subsequence is denoted by u_{N-k} and its limit by u . To prove the Cauchy-Peano theorem, we will show that this limit function u satisfies the integral equation (2) and hence is a solution of the initial value problem (1).

Proof First it will be shown that if N is sufficiently large, then the functions u_N are close to solutions of the differential equation in the following sense: for all $\varepsilon > 0$, there is some N_0 such that for all $N > N_0$

$$|\dot{u}_N(t) - f(t, u_N(t))| < \varepsilon, \tag{5}$$

$$t \in I_\rho(t_0), \quad t \neq t_k, \quad k = 0, \dots, N.$$

Let $\varepsilon > 0$. As f is a continuous function on the compact set S , it follows that f is uniform continuous. Thus, there is some δ_ε such that for all $(t, u), (s, v) \in S$ with $|t - s| + |u - v| < \delta_\varepsilon$

$$|f(t, u) - f(s, v)| < \varepsilon. \tag{6}$$

Now define $N_0 = \left\lceil \frac{(M+1)\rho}{\delta_\varepsilon} \right\rceil$ and let $N > N_0$. Then for any $t \in I_\rho(t_0)$, $t \neq t_k$, $k = 0, \dots, N$, we have $\dot{u}_N(t) = f(t_l, u_N(t_l))$, where l is such that $t_l < t < t_{l+1}$. Hence, (6) gives

$$|\dot{u}_N(t) - f(t, u_N(t))| = |f(t_l, u_N(t_l)) - f(t, u_N(t))| < \varepsilon$$

as (4) shows that $|t_l - t| + |u_N(t_l) - u_N(t)| < (1 + M)|t_l - t| < \frac{(1+M)\rho}{N} \leq \frac{(1+M)\rho}{N_0} \leq \delta_\varepsilon$.

Next it will be shown that (5) implies that the functions u_N almost satisfy the integral equation (2) for N sufficiently large. From (5), it follows that $f(t, u_N(t)) - \varepsilon < \dot{u}_N(t) < f(t, u_N(t)) + \varepsilon$ for all $N > N_0$ and all $t \in I_\rho(t_0)$, except at the special points t_k , $k = 0, \dots, N$. Hence, for any $k = 1, \dots, N$ and all $t_{k-1} < t \leq t_k$, this gives

$$u_N(t) < u_N(t_{k-1}) + \int_{t_{k-1}}^t (f(\tau, u_N(\tau)) + \varepsilon) d\tau$$

$$\leq u_N(t_{k-1}) + \int_{t_{k-1}}^t f(\tau, u_N(\tau)) d\tau + \frac{\varepsilon\rho}{N}.$$

Thus, also for any $k = 1, \dots, N$, $u_N(t_k) - u_N(t_{k-1}) < \int_{t_{k-1}}^{t_k} f(\tau, u_N(\tau)) d\tau + \frac{\varepsilon\rho}{N}$ and hence

$$u_N(t_k) - u_N(t_0) = \sum_{j=1}^k [u_N(t_j) - u_N(t_{j-1})]$$

$$< \int_{t_0}^{t_k} f(\tau, u_N(\tau)) d\tau + \varepsilon\rho.$$

Combination of the last two results gives that for any $t \in I_\rho(t_0)$

$$u_N(t) < u_N(t_0) + \int_{t_0}^t (f(\tau, u_N(\tau)) + \varepsilon) d\tau + \varepsilon\rho.$$

In a similar way it can be shown that $u_N(t) > u_N(t_0) + \int_{t_0}^t f(\tau, u_N(\tau)) d\tau - \rho\varepsilon$ and hence for all $N > N_0$, the following holds:

$$\left| u_N(t) - u_N(t_0) - \int_{t_0}^t f(\tau, u_N(\tau)) d\tau \right| < \varepsilon\rho,$$

for all $t \in I_\rho(t_0)$. (7)

Thus, the function u_N satisfies the integral equation (2) up to an order ε error if N is sufficiently large.

As the subsequence u_{N_k} converges uniformly to u and f is continuous, this implies that $\int_{t_0}^t f(\tau, u_{N_k}(\tau)) d\tau \rightarrow \int_{t_0}^t f(\tau, u(\tau)) d\tau$. Thus, from (7), it can be concluded that u satisfies the integral equation (2) exactly. □

Note that the full sequence $\{u_N\}$ does not necessarily converge. A counterexample can be found in exercise 12 in Chap. 1 of [5]. It is based on the initial value problem $\dot{u} = |u|^{\frac{1}{4}} \operatorname{sgn}(u) + t \sin(\pi/t)$ with $u(0) = 0$, and shows that on a small interval near $t_0 = 0$, the even approximations are bounded below by a strictly positive constant, while the odd approximations are bounded above by a strictly negative constant.

However, if it is known that the solution of the initial value problem is unique, then the full sequence of approximate solutions $\{u_N\}$ must converge to the solution. This can be seen by a contradiction argument. If there is a unique solution, but the sequence $\{u_N\}$ is not convergent, then there is a convergent subsequence and a remaining set of functions which does not converge to the unique solution. But Arzelà–Ascoli’s lemma can be applied to the remaining set as well; thus, there exists a convergent subsequence in the remaining set, which must converge to a different solution. This is not possible as the solution is unique.

In case of the initial value problem as presented in Example 2, the sequence of Cauchy–Euler approximate solutions $\{u_N\}$ converges to the zero function; hence, no subsequence is required to obtain a solution. As there are many solutions of this initial value problem, this implies that not all solutions of the initial value problem in Example 2 solutions can be approximated by the Cauchy–Euler construction of approximate solutions as defined in (3). As indicated in exercise 2.2 in Chap. 2 of [13], it is possible to get any solution by using appropriate Lipschitz continuous approximations of the vector field f , instead of the original vector field itself, in the Cauchy–Euler construction. In the example below this is illustrated for the vector field $f(t, u) = \sqrt{|u|}$.

Example 3 Let $f: \mathbb{R} \times \mathbb{R}$ be defined as $f(t, u) = \sqrt{|u|}$. First we define the approximate functions $\hat{f}_n: [0, 2] \times [0, \infty) \rightarrow [0, \infty)$ as

$$\hat{f}_n(t, u) = \begin{cases} \sqrt{u}, & u > \frac{1}{n} \\ \frac{1}{\sqrt{n}} - \frac{1}{2}\sqrt{n}\left(\frac{1}{n} - u\right), & u \leq \frac{1}{n} \end{cases}$$

and the definition of the Euler–Cauchy approximate functions is modified to

$$u_N(t) = u_N(t_{k-1}) + \hat{f}_N(t_{k-1}, u_N(t_{k-1}))(t - t_{k-1}), \\ t_{k-1} < t \leq t_k, \quad k = 1, \dots, N.$$

This sequence converges to the solution $u(t) = 4t^2$ for $t \in [0, 2]$.

Next define the approximate functions $\tilde{f}_n: [0, 2] \times [0, \infty) \rightarrow [0, \infty)$ as

$$\tilde{f}_n(t, u) = \begin{cases} \sqrt{u}, & t \leq 1, \quad u > \frac{1}{n}, \\ \frac{1}{2n} - \left(\frac{1}{2n} - u\right) + a_2 \left(\frac{1}{2n} - u\right)^2 + a_3 \left(\frac{1}{n} - u\right)^3, & t \leq 1, \quad \frac{1}{2n} < u \leq \frac{1}{n}, \\ u, & t \leq 1, \quad u \leq \frac{1}{2n}, \end{cases}$$

with $a_2 = 4n(\sqrt{n}-1)$ and $a_3 = 12n^3(3\sqrt{n}-2)$, $\tilde{f}_n(t, u) = \hat{f}_n(t, u)$, for $t \geq 1 + \frac{1}{n}$ and a smooth connection between those two components of the approximation for $a < t < 1 + \frac{1}{n}$. Then the related approximate solutions will converge to the solution $u(t) = 4(t-1)^2$, $1 \leq t \leq 2$ and $u(t) = 0$, $0 \leq t < 1$. In a similar way all other solutions presented in Example 2 can be obtained.

Example 2 gives a connected and closed family of solutions to the initial value problem. The following theorem shows this is typical.

Theorem 2 ([15]) Assume that the assumptions of Theorem 1 are satisfied. Let $t_0 < c \leq t_0 + \rho$ and define A_c to be the set of points that can be reached at time $t = c$ by some solution of the initial value problem. Then A_c is closed, bounded and connected.

If the initial value problem is one-dimensional, i. e., $u \in \mathbb{R}$, then this implies that the set of points reached by possible solutions at time $t = c$ is the empty set, a point or a closed interval.

A proof of this theorem, based on [19], can be found in Theorem 4.1 in Chap. 2 of [13].

The existence theorems presented so far give existence of solutions near the initial value (t_0, u_0) . But this local result can be extended to a global one.

Theorem 3 (Extension Theorem) Let f be continuous on D . If $u(t)$ is a solution of the initial value problem (1) on some interval, then the solution can be extended to a maximal interval of existence (t_-, t_+) such that $(t, u(t))$ converges to the boundary of D as $t \uparrow t_+$ or $t \downarrow t_-$ (where $t_{\pm} = \pm\infty$ is possible).

Proof Let D_n be open subsets of D such that $\bigcup_{n \in \mathbb{N}} D_n = D$, the closures \bar{D}_n are compact and $\bar{D}_n \subset D_{n+1}$ (e. g., $D_n = \{(t, u) \in \mathbb{R} \mid |(t, u)| < n, \operatorname{dist}((t, u), \partial D) > 1/n\}$, see [13]). First it will be shown that for all $n \in \mathbb{N}$, there is some ρ_n such that for each $(t_0, u_0) \in D_n$, the initial value problem has a solution on the interval

$[t_0 - \rho_n, t_0 + \rho_n]$. Indeed, for each $n \in \mathbb{N}$, the function f is continuous on the compact set $\overline{D_n}$. Hence, there is some $M_n > 0$ such that $|f(t, u)| \leq M_n$ for all $(t, u) \in \overline{D_n}$. Furthermore, for each $n \in \mathbb{N}$, the distance $d_n := \text{dist}(\overline{D_n}, D_{n+1}) > 0$. Thus, the Cauchy–Peano theorem implies that for each $(t_0, u_0) \in \overline{D_n}$, the solution of the initial value problem exists on the interval $[t_0 - \rho_n, t_0 + \rho_n]$, with $\rho_n = 1/2 \min(d_n/M_{n+1}, d_n)$.

If the solution $u(t)$ is defined on an interval I , which is not a right maximal interval, then the argument above shows that the right endpoint of I can be included in the interval of existence. So it can be assumed that the interval I is of the form $[a_1, a_2]$. The continuity of the solution u gives that the set $\{(t, u(t)) \mid t \in [a_1, a_2]\}$ is a compact set in the open set D ; hence, there is some $n \in \mathbb{N}$ such that $\{(t, u(t)) \mid t \in [a_1, a_2]\} \subset D_n \subset \overline{D_n}$. But this implies that the solution can be extended to the interval $[a_1, a_2 + \rho_n]$. And if $\{(t, u(t)) \mid t \in [a_1, a_2 + \rho_n]\} \subset D_n$, then this can be repeated. Since $\overline{D_n}$ is compact, there is some $k \in \mathbb{N}$ such that $\{(t, u(t)) \mid t \in [a_1, a_2 + k\rho_n]\} \not\subset D_n$; hence, there exists some $(t_n, u(t_n))$ such that $(t_n, u(t_n)) \in D_{n+1} \setminus D_n$. This argument can be repeated for each $n \in \mathbb{N}$ to give sequence $(t_n, u(t_n)) \in D_{n+1} \setminus D_n$, with $t_n < t_{n+1}$. Thus, the sequence t_n is monotone increasing. Either it is unbounded, which implies that the solution exists on an interval $[a_1, \infty)$ and hence $t_+ = \infty$ or it is bounded and hence is convergent to some limit t_+ . Similarly, the sequence $(t_n, u(t_n))$ is either an unbounded sequence in D or has a cluster point on the boundary of D . In either case it is clear that the solution cannot be extended outside the interval $[a_1, t_+)$. A similar argument can be used for the left endpoint and it can be concluded that there exists a maximal interval of existence of the form (t_-, t_+) .

Finally it will be shown that the solution converges to the boundary of D by a contradiction argument. Assume that the solution does not converge to the boundary if $t \uparrow t_+$. Then there is some $\varepsilon_0 > 0$ and a sequence $\{\tau_n\}$ with $t_+ - \tau_n < \frac{1}{n}$ and $d(\tau_n, u(\tau_n), D) > \varepsilon_0$. This implies that there is some $N \in \mathbb{N}$ such that the sequence $\{(\tau_n, u(\tau_n))\} \subset D_N$. With the arguments above, this implies that the solution can be extended to an interval including t_+ , which contradicts t_+ being the maximal right point. \square

Example 1 gives an example of a solution for which $u(t) \rightarrow \infty$ if $t \rightarrow \frac{1}{u_0}$, the boundary of its interval of existence. Example 2 gives an example of a solution with an unbounded interval of existence. Example 4 shows that the endpoint can also be related to the failure of continuity of f .

Example 4 Consider the initial value problem with $D = \mathbb{R} \times (0, \infty)$ and

$$\dot{u} = -\frac{1}{u}, \quad \text{and} \quad u(0) = 2.$$

Then the solution is $u(t) = \sqrt{4 - 2t}$ for $t \in (-\infty, 2)$. If $t \rightarrow 2$, then $(t, u(t)) \rightarrow (2, 0)$, hence the boundary of D and the point where the continuity of f fails.

If the initial value problem has a nonunique solution, then the maximal interval of extension in the extension theorem will in general depend on the initial solution $u(t)$.

Uniqueness

Uniqueness follows if the vector field f is Lipschitz continuous with respect to its second variable u as shown first by Picard [21] and Lindelöf [18]. Their proof is based again on approximate solutions, but the approximate solutions are smoother than the Cauchy–Euler ones. The approximate solutions are obtained by successive iterations and are defined as

$$u_0(t) := u_0 \quad \text{and} \\ u_{n+1}(t) := u_0 + \int_{t_0}^t f(\tau, u_n(\tau))d\tau, \quad n \in \mathbb{N}, \quad t \in I. \tag{8}$$

Sometimes this iteration is called Picard iteration. Clearly, this iteration is based on the integral formula (2). The iteration process fails if $u_n(\tau) \notin D$ for some $\tau \in I$. If f is continuous, then there is some interval I for which the sequence is well-defined, as follows from the proof below.

Theorem 4 (Picard–Lindelöf Theorem) *Let $a, b > 0$ be such that the cylinder $S := I_a(t_0) \times B_b(u_0) \subset D$. Let the vector field f be a uniformly Lipschitz continuous function on the cylinder S with respect to its second variable u and let M be the upper bound on f , i.e., $M = \max\{f(t, u) \mid (t, u) \in S\}$.*

Define the parameter $\rho = \min\left(a, \frac{b}{M}\right)$. For $t \in [t_0, t_0 + \rho]$, there exists a unique solution $u(t)$ of the initial value problem (1).

Successive iterations play an important role in proving existence for more general differential equations. Thus, although the existence of solutions already follows from the Cauchy–Peano theorem, we will prove again existence by using the successive iterations instead of the Cauchy–Euler approximations as the ideas in the proof can be extended to more general differential equations.

Proof By using the bound on the vector field f , we will show that if $(t, u_n(t)) \in S$ for all $t \in [t_0, t_0 + \rho_0]$, then $(t, u_{n+1}(t)) \in S$ for all $t \in [t_0, t_0 + \rho_0]$. Indeed, for any $t \in [t_0, t_0 + \rho_0]$,

$$\begin{aligned} |u_{n+1}(t) - u_0| &\leq \int_{t_0}^t |f(\tau, u_n(\tau))| d\tau \\ &\leq \int_{t_0}^t M d\tau \leq M(t - t_0) \leq b; \end{aligned} \quad (9)$$

thus, $|u_{n+1}(t) - u_0| \leq M\rho \leq b$ and therefore $u_{n+1}(t) \in B_b(u_0)$.

The boundedness of f also ensures that the functions $\{u_n\}$ are equicontinuous as for any $n \in \mathbb{N}$ and any $t_0 \leq t_1 < t_2 \leq \rho + t_0$:

$$|u_n(t_1) - u_n(t_2)| \leq \int_{t_1}^{t_2} |f(\tau, u_n(\tau))| d\tau \leq M|t_2 - t_1|.$$

Up to this point, we have only used the boundedness of f (which follows from the continuity of f). But for the next part, in which it will be shown that for any $t \in [t_0, t_0 + \rho_0]$ the sequence $\{u_n(t)\}$ is a Cauchy sequence in \mathbb{R}^m , we will need the Lipschitz continuity. Let L be the Lipschitz constant of f on S , then for any $n \in \mathbb{N}$ and $t \in [t_0, t_0 + \rho_0]$, we have

$$\begin{aligned} |u_{n+1}(t) - u_n(t)| &\leq \int_{t_0}^t |f(\tau, u_n(\tau)) - f(\tau, u_{n-1}(\tau))| d\tau \\ &\leq \int_{t_0}^t L |u_n(\tau) - u_{n-1}(\tau)| d\tau \\ &\leq L \|u_n - u_{n-1}\|_\infty \int_{t_0}^t d\tau \\ &= L \|u_n - u_{n-1}\|_\infty (t - t_0), \end{aligned}$$

where $\|u_n - u_{n-1}\|_\infty = \sup\{|u_n(\tau) - u_{n-1}(\tau)| \mid t_0 \leq \tau \leq t_0 + \rho\}$. This implies that

$$\begin{aligned} |u_{n+2}(t) - u_{n+1}(t)| &\leq \int_{t_0}^t L |u_{n+1}(\tau) - u_n(\tau)| d\tau \\ &\leq L^2 \|u_n - u_{n-1}\|_\infty \int_{t_0}^t (\tau - t_0) d\tau \\ &= \frac{L^2}{2} \|u_n - u_{n-1}\|_\infty (t - t_0)^2. \end{aligned}$$

Repeating this process, it follows for any $k \in \mathbb{N}$ that

$$\begin{aligned} |u_{n+k+1}(t) - u_{n+k}(t)| &\leq \frac{L^k}{k!} \|u_n - u_{n-1}\|_\infty (t - t_0)^k \\ &\leq \frac{L^k \rho^k}{k!} \|u_n - u_{n-1}\|_\infty. \end{aligned}$$

By using the triangle inequality repeatedly this gives for any $n, k, \in \mathbb{N}$ and $t \in [t_0, t_0 + \rho_0]$,

$$\begin{aligned} |u_{n+k+1}(t) - u_n(t)| &\leq \sum_{i=0}^k |u_{n+i+1}(t) - u_{n+i}(t)| \\ &\leq \sum_{i=0}^k \frac{L^{n+i} \rho^{n+i}}{(n+i)!} \|u_1 - u_0\|_\infty \\ &\leq \frac{(L\rho)^n}{n!} \|u_1 - u_0\|_\infty \sum_{i=0}^k \frac{L^i \rho^i}{i!} \\ &\leq \frac{(L\rho)^n}{n!} b e^{L\rho}. \end{aligned}$$

Thus, for any $t \in [t_0, t_0 + \rho_0]$, the sequence $\{u_n(t)\}$ is a Cauchy sequence in \mathbb{R}^m ; hence, the sequence has a limit, which will be denoted by $u(t)$. In other words, the sequence of functions $\{u_n\}$ is pointwise convergent in $I_\rho(t_0)$. We have already seen that the functions u_n are equicontinuous; hence, the convergence is uniform and the limit function $u(t)$ is equicontinuous [23].

To see that u satisfies the integral equation (2), observe that for any $t \in [t_0, t_0 + \rho_0]$

$$\begin{aligned} \left| u(t) - u_0 - \int_{t_0}^t f(\tau, u(\tau)) d\tau \right| &\leq |u(t) - u_{n+1}(t)| \\ &\quad + \left| \int_{t_0}^t |f(\tau, u_n(\tau)) - f(\tau, u(\tau))| d\tau \right| \\ &\leq |u(t) - u_{n+1}(t)| + L \|u - u_n\|_\infty (t - t_0) \\ &\leq (1 + L\rho) (\|u - u_{n+1}\|_\infty + \|u - u_n\|_\infty) \end{aligned}$$

for any $n \in \mathbb{N}$. As the sequence $\{u_n\}$ is uniformly convergent, this implies that $u(t)$ satisfies the integral equation (2).

Finally the uniqueness will be proved using techniques similar to those in ‘‘Existence.’’ Assume that there are two solutions u and v of the integral equation (2). Hence, for any $t_0 \leq t \leq t_0 + \rho$,

$$\begin{aligned} |u(t) - v(t)| &\leq \int_{t_0}^t |f(\tau, u(\tau)) - f(\tau, v(\tau))| d\tau \\ &\leq L \|u - v\|_\infty (t - t_0). \end{aligned}$$

Thus, for $k = 1$, it holds that

$$\begin{aligned} |u(t) - v(t)| &\leq \frac{L^k \|u - v\|_\infty (t - t_0)^k}{k!}, \\ &\text{for any } t_0 \leq t \leq t_0 + \rho. \end{aligned} \quad (10)$$

For the induction step, assume that (10) holds for some $k \in \mathbb{N}$. Then for any $t_0 \leq t \leq t_0 + \rho$,

$$\begin{aligned} |u(t) - v(t)| &\leq L \int_{t_0}^t \frac{L^k \|u - v\|_{\infty} (\tau - t_0)^k}{k!} d\tau \\ &= \frac{L^{k+1} \|u - v\|_{\infty} (t - t_0)^{k+1}}{(k + 1)!} . \end{aligned}$$

By using the principle of induction, it follows that (10) holds for any $k \in \mathbb{N}$. This implies that for any $t_0 \leq t \leq t_0 + \rho$, the solutions satisfy $|u(t) - v(t)| \leq \frac{(L\rho)^{k+1} \|u - v\|_{\infty}}{(k+1)!}$ for any $k \in \mathbb{N}$. Since the expression on the right converges to 0 for $k \rightarrow \infty$, this implies that $u(t) = v(t)$ for all $t \in [t_0, t_0 + \rho]$ and hence the solution is unique. \square

Implicitly, the proof shows that the integral equation gives rise to a contraction on the space of continuous functions with the supremum norm and this could also have been used to show existence and uniqueness; see [11,25], where Schauder’s fixed-point theorem is used to prove the Pi-

card–Lindelöf theorem. With Schauder’s fixed-point theorem, existence and uniqueness can be shown for much more general differential equations than ordinary differential equations.

The iteration process in (8) does not necessarily have to start with the initial condition. It can start with any continuously differentiable function $u_0(t)$ and the iteration process will still converge. In specific problems, there are often obvious choices for the initial function u_0 which give a faster convergence or are more efficient, for instance, when proving unboundedness.

Techniques similar to those in the proof can be used to derive a bound on the difference between the successive approximations and the solution, showing that

$$|u_n(t) - u(t)| \leq \frac{ML^n(t - t_0)^n}{(n + 1)!} , \quad t \in [t_0, t_0 + \rho] ;$$

see [13]. This illustrates that the convergence is fast for t near t_0 , but might be slow further away: see Fig. 3 for an example.

Continuous Dependence on Initial Conditions

In this section, the vector field f is uniformly Lipschitz continuous on D with respect to its second variable u and its Lipschitz constant is denoted by L . By combining the Picard–Lindelöf theorem (Theorem 4) and the extension theorem (Theorem 3), it follows that for every $(t_0, u_0) \in D$, there exists a unique solution of (1) passing through (t_0, u_0) with a maximal interval of existence $(t_-(t_0, u_0), t_+(t_0, u_0))$. The trajectory through (t_0, u_0) is the set of points $(t, u(t))$, where $u(t)$ solves (1) and $t_-(t_0, u_0) < t < t_+(t_0, u_0)$. Now define the set $E \subset \mathbb{R}^{n+2}$ as

$$E := \{ (t, t_0, u_0) \mid t_-(t_0, u_0) < t < t_+(t_0, u_0), (t_0, u_0) \in D \} .$$

The flow map $\Phi: E \rightarrow \mathbb{R}^m$ is a mapping which describes the solution of the initial value problem with the initial condition varying through D , i. e.,

$$\begin{aligned} \frac{d}{dt} \Phi(t, t_0, u_0) &= f(t, \Phi(t, t_0, u_0)) \quad \text{and} \\ \Phi(t_0, t_0, u_0) &= u_0 , \quad \text{for } (t, t_0, u_0) \in E . \end{aligned}$$

From the integral equation (2), it follows that the flow map satisfies

$$\begin{aligned} \Phi(t, t_0, u_0) &= u_0 + \int_{t_0}^t f(\tau, \Phi(\tau, t_0, u_0)) d\tau , \\ &\text{for } (t, t_0, u_0) \in E . \end{aligned}$$

Existence and Uniqueness of Solutions of Initial Value Problems, Figure 3

The first four iterations for initial value problem with the vector field $f(t, u) = t \cos u + \sin t$ and the initial value $u(0) = 0$. Note that the convergence in the interval $[0, 1]$ is very fast (two steps seem sufficient for graphical purposes), but near $t = 2$, the convergence has not yet been reached in three steps

Existence and Uniqueness of Solutions of Initial Value Problems, Figure 4

The flow map $\Phi(t, t_0, u_0)$. Note the group property $\Phi(t, s, \Phi(s, t_0, u_0)) = \Phi(t, t_0, u_0)$. The lightly shaded area is the tube U_{δ_1} and the darker shaded area is the tube U_δ as used in the proof of Theorem 6. If a solution starts from within U_δ , then it will stay within the tube U_{δ_1} for $t_1 \leq t \leq t_2$, as the solution $\Phi(t, s_0, v_0)$ demonstrates

Furthermore, the uniqueness implies for the flow map that starting at the point (t_0, u_0) , flowing to $(t, \Phi(t, t_0, u_0))$ is the same as starting at the point (t_0, u_0) and flowing to the intermediate point $(s, \Phi(s, t_0, u_0))$ and continuing to the point $(t, \Phi(t, t_0, u_0))$. This implies that the flow map has a group structure: for any $(t_0, u_0) \in D$ and any $s, t \in (t_-(t_0, u_0), t_+(t_0, u_0))$, the flow map satisfies $\Phi(t, s, \Phi(s, t_0, u_0)) = \Phi(t, t_0, u_0)$; the identity map is given by $\Phi(t_0, t_0, u_0) = u_0$; and by combining the last two results, it follows that $\Phi(t_0, t, \Phi(t, t_0, u_0)) = \Phi(t_0, t_0, u_0) = u_0$, and hence there is an inverse. See also Fig. 4 for a sketch of the flow map for $D \subset \mathbb{R} \times \mathbb{R}$.

To show that the flow map is continuous in all its variables, Gronwall’s lemma [9] will be very useful. There are many versions of Gronwall’s lemma; the one presented here follows [1].

Lemma 5 (Gronwall’s Lemma) Let $\psi : [a, b] \rightarrow \mathbb{R}$ and $\phi : [a, b] \rightarrow \mathbb{R}$ be nonnegative continuous functions on an interval $[a, b]$. Let $K \geq 0$ be some nonnegative constant such that

$$\phi(t) \leq K + \int_a^t \psi(\tau)\phi(\tau)d\tau, \quad \text{for all } a \leq t \leq b.$$

Then

$$\phi(t) \leq K \exp \left[\int_a^t \psi(\tau)d\tau \right], \quad \text{for all } a \leq t \leq b.$$

Proof Define $F(t) = K + \int_a^t \psi(\tau)\phi(\tau)d\tau$, for $a \leq t \leq b$. Then the assumption in the lemma gives $\phi(t) \leq F(t)$ for $a \leq t \leq b$. Furthermore, F is differentiable, with $\dot{F} = \phi\psi$; hence, for $a \leq t \leq b$

$$\begin{aligned} & \frac{d}{dt} \left(F(t) \exp \left[- \int_a^t \psi(\tau)d\tau \right] \right) \\ &= \psi(t)\phi(t) \exp \left[- \int_a^t \psi(\tau)d\tau \right] \\ & \quad - F(t)\psi(t) \exp \left[- \int_a^t \psi(\tau)d\tau \right] \leq 0 \end{aligned}$$

as $\phi(t) \leq F(t)$. Integrating the left-hand side gives

$$F(t) \exp \left[- \int_a^t \psi(\tau)d\tau \right] \leq F(a) = K,$$

which implies for ϕ that $\phi(t) \leq F(t) \leq K \exp \left[\int_a^t \psi(\tau)d\tau \right]$. \square

Gronwall’s lemma will be used to show that small variations in the initial conditions give locally small variations in the solution, or

Theorem 6 The flow map $\Phi : E \rightarrow \mathbb{R}^{n+2}$ is continuous in E .

Proof Let $(t, t_0, u_0) \in E$. As $t, t_0 \in (t_-(t_0, u_0), t_+(t_0, u_0))$, there is some $t_1 < t_2$ such that $t, t_0 \in (t_1, t_2)$, $[t_1, t_2] \subset (t_-(t_0, u_0), t_+(t_0, u_0))$ and the solution $\Phi(s, t_0, u_0)$ exists for any $s \in [t_1, t_2]$. First we will show that there is some tube around the solution curve $\{(s, \Phi(s, t_0, u_0)) \mid t_1 \leq s \leq t_2\}$ such that for any (s_0, v_0) in this tube, the solution $\Phi(s, s_0, v_0)$ exists for $t_1 \leq s \leq t_2$.

As D is open, there is some $\delta_1 > 0$ such that the closed tube $U_{\delta_1} := \{(s, v) \mid |\Phi(s, t_0, u_0) - v| \leq \delta_1, t_1 \leq s \leq t_2\} \subset D$. As f is Lipschitz continuous, hence continuous, there is some $M > 0$ such that $|f(s, v)| \leq M$ for all $(s, v) \in U_{\delta_1}$. Recall that the Lipschitz constant of f on D is denoted by L . Now define $\delta := \delta_1 e^{-L(t_2-t_1)} < \delta_1$ and the open tube

$$U_\delta = \{(s, v) \mid |\Phi(s, t_0, u_0) - v| < \delta, t_1 < s < t_2\},$$

thus, $U_\delta \subset U_{\delta_1} \subset D$. Thus, for every $(s_0, v_0) \in U_\delta$, the solution $\Phi(s, s_0, v_0)$ exists for s in some closed interval in $[t_1, t_2]$ around s_0 and the solution in this interval satisfies

$$\Phi(s, s_0, v_0) = v_0 + \int_{s_0}^s f(\tau, \Phi(\tau, s_0, v_0))d\tau,$$

see also Fig. 4. Furthermore, for any $s \in [t_1, t_2]$, we have

$$\begin{aligned} \Phi(s, t_0, u_0) &= \Phi(s, s_0, \Phi(s_0, t_0, u_0)) \\ &= \Phi(s_0, t_0, u_0) + \int_{s_0}^s f(\tau, \Phi(\tau, s_0, \Phi(s_0, t_0, u_0)))d\tau \\ &= \Phi(s_0, t_0, u_0) + \int_{s_0}^s f(\tau, \Phi(\tau, t_0, u_0))d\tau . \end{aligned}$$

Subtracting these expressions gives

$$\begin{aligned} |\Phi(s, s_0, v_0) - \Phi(s, t_0, u_0)| &\leq |v_0 - \Phi(s_0, t_0, u_0)| \\ &\quad + \int_{s_0}^s |f(\tau, \Phi(\tau, s_0, v_0)) - f(\tau, \Phi(\tau, t_0, u_0))| d\tau \\ &\leq \delta + \int_{s_0}^s L |\Phi(\tau, s_0, v_0) - \Phi(\tau, t_0, u_0)|d\tau , \end{aligned}$$

so Gronwall's lemma implies that $|\Phi(s, s_0, v_0) - \Phi(s, t_0, u_0)| \leq \delta e^{L(s-s_0)} \leq \delta_1$. Hence, for any s , $\Phi(s, s_0, v_0) \in U_{\delta_1} \subset D$, and hence this solution can be extended to its maximal interval of existence, which contains the interval $[t_1, t_2]$. So it can be concluded that for any $(s_0, v_0) \in U_\delta$, the solution $\Phi(s, s_0, v_0)$ exists for any $s \in [t_1, t_2]$.

Next we will show continuity of the flow map in its last two variables, i. e., in the initial value. For any $(s_0, v_0) \in U_\delta$ and $t_1 \leq t \leq t_2$, we have

$$\begin{aligned} |\Phi(t, s_0, v_0) - \Phi(t, t_0, u_0)| &\leq |v_0 - u_0| \\ &\quad + \left| \int_{s_0}^t f(\tau, \Phi(\tau, s_0, v_0))d\tau - \int_{t_0}^t f(\tau, \Phi(\tau, t_0, u_0))d\tau \right| \\ &\leq |v_0 - u_0| + \left| \int_{s_0}^{t_0} |f(\tau, \Phi(\tau, s_0, v_0))|d\tau \right| \\ &\quad + \left| \int_{t_0}^t |f(\tau, \Phi(\tau, t_0, u_0)) - f(\tau, \Phi(\tau, s_0, v_0))|d\tau \right| \\ &\leq |v_0 - u_0| + M|t_0 - s_0| \\ &\quad + \left| \int_{t_0}^t L|\Phi(\tau, t_0, u_0) - \Phi(\tau, s_0, v_0)|d\tau \right| . \end{aligned}$$

Thus, Gronwall's lemma implies that

$$\begin{aligned} |\Phi(t, s_0, v_0) - \Phi(t, t_0, u_0)| &\leq (|v_0 - u_0| + M|t_0 - s_0|) e^{L|t-t_0|} \\ &\leq (|v_0 - u_0| + M|t_0 - s_0|) e^{L|t_2-t_1|} , \end{aligned}$$

and it follows that Φ is continuous in its last two arguments. The continuity of Φ in its first argument follows

immediately from the fact that the solution of the initial value problem is continuous. \square

If the vector field f is smooth, then the flow map Φ is smooth as well.

Theorem 7 *Let $f \in C^1(D, R^m)$. Then the flow map $\Phi \in C^1(E, R^m)$ and*

$$\begin{aligned} \det(D_{u_0}\Phi(t, t_0, u_0)) &= \exp \left(\int_{t_0}^t \text{tr} (D_u f(\tau, \Phi(\tau, t_0, u_0))) d\tau \right) \end{aligned}$$

for any $(t, t_0, u_0) \in E$.

In this theorem, $\text{tr}(D_u f(\tau, \Phi(\tau, t_0, u_0)))$ stands for the trace of the matrix $D_u f(\tau, \Phi(\tau, t_0, u_0))$. For second-order linear systems, this identity is known as Abel's identity and $\det(D_{u_0}\Phi(t, t_0, u_0))$ is the Wronskian.

The proof of Theorem 7 uses the fact that $D_{u_0}\Phi(t, t_0, u_0)$ satisfies the linear differential equation

$$\frac{d}{dt} D_{u_0}\Phi(t, t_0, u_0) = D_u f(t, \Phi(t, t_0, u_0)) D_{u_0}\Phi(t, t_0, u_0),$$

with the initial condition $D_{u_0}\Phi(t_0, t_0, u_0) = I$. This last fact follows immediately from $\Phi(t_0, t_0, u_0) = u_0$. And the linear differential equation follows by differentiating the differential equation for $\Phi(t, t_0, u_0)$ with respect to u_0 . The full details of the proof can be found, for example, in [5,11].

Extended Concept of Differential Equation

Until now, we have looked for continuously differentiable functions $u(t)$, which satisfy the initial value problem (1). But the initial value problem can be phrased for less smooth functions as well. For example, one can define a solution as an absolute continuous function $u(t)$ which satisfies (1). A function $u: I \rightarrow \mathbb{R}^m$ is *absolutely continuous* on I if for every positive number ε , no matter how small, there is a positive number δ small enough so that whenever a sequence of pairwise disjoint subintervals $[s_k, t_k]$ of I , $k = 1, 2, \dots, N$ satisfies $\sum_{k=1}^N |t_k - s_k| < \delta$ then

$$\sum_{k=1}^n d(u(t_k), u(s_k)) < \varepsilon .$$

An absolute continuous function has a derivative almost everywhere and is uniformly continuous, thus continuous [24]. Thus, the initial value problem for an absolute continuous function can be stated almost everywhere.

For the existence of absolute continuous solutions, the continuity condition for the vector field in the Cauchy–

Peano theorem (Theorem 1) is replaced by the so-called Carathéodory conditions on the vector field. A function $f: D \rightarrow \mathbb{R}^m$ satisfies the Carathéodory conditions if [2]

- $f(t, u)$ is Lebesgue measurable in t for each fixed u ;
- $f(t, u)$ is continuous in u for each fixed t ;
- for each compact set $A \subset D$, there is a measurable function $m_A(t)$ such that $|f(t, u)| \leq m_A(t)$ for any $(t, u) \in A$.

Similar theorems to the ones in the previous sections about existence and uniqueness can be stated in this case.

Theorem 8 (Carathéodory) *If D is an open set in \mathbb{R}^{n+1} and $f: D \rightarrow \mathbb{R}^m$ satisfies the Carathéodory conditions on D , then for every $(t_0, u_0) \in D$ there is a solution of the initial value problem (1) through (t_0, u_0) .*

Theorem 9 *If D is an open set in \mathbb{R}^{n+1} , $f: D \rightarrow \mathbb{R}^m$ satisfies the Carathéodory conditions on D and $u(t)$ satisfies the initial value problem (1) on some interval, then there exists a maximal open interval of existence. Furthermore, if (t_-, t_+) denotes the maximal interval of existence, then the solution $u(t)$ tends to the boundary of D if $t \downarrow t_-$ or $t \uparrow t_+$.*

Theorem 10 *If D is an open set in \mathbb{R}^{n+1} , $f: D \rightarrow \mathbb{R}^m$ satisfies the Carathéodory conditions on D and for every compact set $U \subset D$ there is an integrable function $L_U(t)$ such that*

$$|f(t, u) - f(t, v)| \leq L_U |u - v|, \quad \text{for all } (t, u), (t, v) \in U,$$

then for every $(t_0, u_0) \in D$, there is a unique solution $\Phi(t, t_0, u_0)$ of the initial value problem (1). The domain E of the flow map Φ is open and Φ is continuous in E .

Proofs of those theorems can be found, for example, in Sect. I.5 in [11].

Many other generalizations are possible, for example, to vector fields which are discontinuous in u . Such vector fields play an important role in control theory. More details can be found in [6,7,17].

Further Directions

As follows from the previous sections, the theory of initial value problems for ordinary differential equations is quite well understood, at least for continuous vector fields. For more general differential equations, the situation is quite different. Consider for example a retarded differential equation, hence a differential equation with delay effects [12]. For retarded differential equations, there are local existence and uniqueness theorems which are quite similar to the ones for ordinary differential equations as

presented in the earlier sections and can be proved by using Schauder's fixed-point theorem. But not all solutions can be extended as in the extension theorem (Theorem 3); see Chap. 2 in [12].

If one considers differential equations with more variables, i. e., partial differential equations, then there are no straightforward general existence and uniqueness theorems. For partial differential equations, the existence and uniqueness depends very much on the details of the partial differential equation. One possible theorem is the Cauchy–Kowaleskaya theorem, which applies to partial differential equations of the form $\partial_t^m u = F(t, u, \partial_x u, \partial_t u, \partial_{tx}^2 u, \dots)$, where the total number of derivatives of u in F should be less than or equal to m [22]. But there are still many open questions as well. A famous open question is the existence and uniqueness of solutions of the three-dimensional Navier–Stokes equations, a system of equations which describes fluid motion. Existence and uniqueness is known for a fluid in a two-dimensional domain, but not in a three-dimensional domain. The question is one of the seven “Millennium Problems,” stated as prize problems at the beginning of the third millennium by the Clay Mathematics Institute [26].

Existence and uniqueness results are also used in dynamical systems. An area of dynamical systems is bifurcation theory and for bifurcation theory the smooth dependence on parameters is crucial. The following theorem gives sufficient conditions for the smooth dependence parameters; see Theorem 3.3 in Chap. 1 of [11].

Theorem 11 *If the vector field depends on parameters $\mu \in \mathbb{R}^k$, i. e., $f: D \times \mathbb{R}^k \rightarrow \mathbb{R}^m$ and $f \in C^1(D \times \mathbb{R}^k, \mathbb{R}^m)$, then the flow map is continuously differentiable with respect to its parameters μ . Furthermore, $D_\mu \Phi$ satisfies an inhomogeneous linear equation*

$$\begin{aligned} \frac{d}{dt} D_\mu \Phi(t, t_0, u_0, \mu) \\ = D_u f(t, \Phi(t, t_0, u_0, \mu), \mu) D_\mu \Phi(t, t_0, u_0, \mu) \\ + D_\mu f(t, \Phi(t, t_0, u_0, \mu), \mu) \end{aligned}$$

with initial condition $D_\mu \Phi(t_0, t_0, u_0, \mu) = 0$.

Results and overviews of bifurcation theory can be found, for example, in [4,8,10,14,16].

Another area of dynamical systems is stability theory. Roughly speaking, a solution is called stable if other solutions which start near this solution stay near it for all time. Note that the local continuity result in Theorem 6 is not a stability result as it only states that nearby solutions will stay nearby for a short time. For stability results, long-time existence of nearby solutions is a crucial property [10,14].

Glossary

Complexity A state of intricacy, complication, variety, or involvement, as in the interconnected parts of a system – a quality of having many interacting, different components.

Cosmic evolution A grand synthesis of the many varied changes in the assembly and composition of radiation, matter, and life throughout the history of the Universe.

Cosmology The study of the structure, evolution, and destiny of the Universe.

Energy The ability to do work or to cause change.

Energy rate density The amount of energy flowing through a system per unit time per unit mass.

Evolution Any process of growth and change with time, including an accumulation of historical information; in its broadest sense, both developmental and generational change.

Exobiology The study of the origin, evolution, and distribution of past and present life in the Universe; also known as astrobiology or bioastronomy.

Thermodynamics The study of the macroscopic changes in the energy of a system, for which temperature is a central property.

Definition of the Subject

Recent research, guided by theoretical searches for unification as much as by compilation of huge new databases, suggests that complex systems throughout Nature are localized, temporary islands of ordered structures within vastly larger, disordered environments beyond those systems. All such complex systems – including, for example, stars, life, and society – can be shown to obey quantitatively the principles of non-equilibrium thermodynamics, and all can be modeled in a common, integral manner by analyzing the energy passing through those systems. The concept of energy flow does seem to be as universal a process as anything yet found in Nature for the origin, maintenance, and evolution of ordered, complex systems. The optimization of such energy flows acts as an agent of evolution broadly considered, thereby affecting, and to some extent unifying, all of physical, biological, and cultural evolution.

More specifically, non-equilibrium thermodynamics, especially the energy flows resulting from contrasting temporal behaviors of matter and radiation energy densities, can generally explain the cosmic environments needed for the emergence of increasingly ordered structures over time. Furthermore, a necessary (though perhaps not sufficient) condition for the natural flow of energy, and hence for the growth of complexity, is the expansion of the Universe itself. Among all of Nature's diverse systems, energy – acquired, stored, and expressed – is a principal driver of the rising complexity among galaxies, stars, planets and life-forms throughout the cosmos. Neither new science nor appeals to non-science are required to appreciate the outstanding hierarchy of evolutionary change, from atoms to galaxies, from cells to society.

One way to approach the topic of exobiology and complexity – also known as astrobiology or bioastronomy – is to place it within the grand context of cosmic evolution.

This interdisciplinary subject seeks to combine all the natural sciences into a unified whole, thereby effectively creating a new scientific worldview for the 21st century. Evolution, broadly considered, has indeed become a powerful unifying concept in all of science. Life itself, including complex life, seems to be a natural, but not necessarily inevitable, result of the way things complexify in an expanding Universe.

Introduction

Cosmic evolution is the study of the sum total of the many varied developmental and generational changes in the assembly and composition of radiation, matter, and life throughout all space and across all time. These are the physical, biological, and cultural changes that have produced, in turn and among many other complex systems, our Galaxy, our Sun, our Earth, and ourselves. The result is an inclusive evolutionary synthesis bridging a wide variety of scientific specialties – physics, astronomy, geology, chemistry, biology, and anthropology – a genuine scientific narrative of epic proportions extending from the beginning of time to the present, from big bang to humankind.

The general idea of evolution – change writ large – extends well beyond the subject of biology, granting it a powerful unifying potential in all of science. Unquestionably, change is widespread throughout all of Nature, much as the Greek philosopher Heraclitus asserted 25 centuries ago: “All flows ... nothing stays”. Yet questions remain: How realistic is the quest for interdisciplinary unification? Can we reconcile the observed constructiveness of cosmic evolution with the inherent destructiveness of thermodynamics? Specifically, how have the amazing examples of order all around us arisen from chaos – and how does all this fit into complexity science?

We especially seek to understand the origins of the many diverse structures spanning the Universe today, notably those characterized by the term “complexity” – a state of intricacy, complication, variety, or involvement, as in the interconnected parts of a system. (In this article, no definitional distinctions are made among the words “order”, “form”, and “complexity”; we address only a general understanding of an entire spectrum of structures often described by the intuitive usage of the term complexity.) Particularly intriguing is the increase of complexity over the course of time, indeed dramatically so (with some exceptions) within the past half-billion years since the Cambrian period on Earth. Perhaps some underlying principle, a general law, or an ongoing process does create, organize, and maintain all complex structures in the

Universe, enabling us to study Nature's many changes on uniform, common ground – in the same quantitative way and with the same mental tools, in other words “on the same page”.

Both theory and experiment, as well as computer simulations, suggest affirmative answers to some of the above questions: Islands of ordered complexity – namely, open systems that are galaxies, stars, planets, and life-forms – are numerically more than balanced by great seas of increasing disorder elsewhere in the environments beyond those systems. All quantitatively agrees with the valued principles of thermodynamics, especially non-equilibrium thermodynamics. Furthermore, energy flows produced largely by the expanding cosmos do seem to be as universal a factor in the origin of structured systems as anything yet found in Nature. The optimization of such energy flows might well act as the motor of evolution broadly conceived, thereby affecting all of physical, biological, and cultural evolution, the combination of which constitutes cosmic evolution.

Therefore, a general outline for this article is:

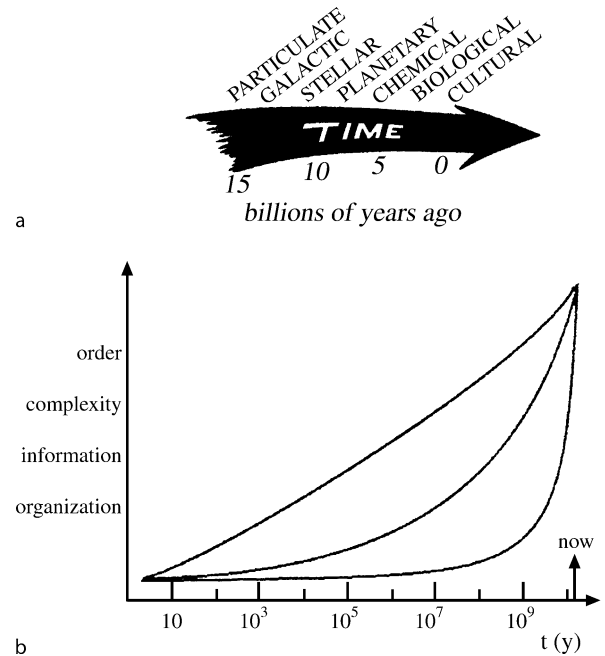

Cosmic Evolution

- Subsets in time: physical evolution → biological evolution → cultural evolution.

Other researchers have addressed life and complexity in a cosmic setting, originally Chambers [16], who anonymously wrote a pre-Darwinian study of wide interdisciplinary insight, and notably Shapley [62], who pioneered a “cosmography” that classified all known structures according to increasing dimensions. Among others, Spencer [64] championed the idea of growing complexity in biological and cultural evolution, Henderson [31] regarded the whole evolutionary process, both physical and organic, as one and the same, Whitehead [72] sought to broaden scientific thinking with his “organic philosophy”, von Bertalanffy [75] championed a systems theoretic approach to physical, biological, and social studies, and Sagan [57], Reeves [56], Jantsch [33] and Chaisson [7] widely advanced the concept of complex (intelligent) life within a cosmological framework.

Arrow of Time

Figure 1a sketches Nature's main historical epochs diagonally atop the so-called arrow of time [3]; these 7 epochs correspond to the major evolutionary phases comprising the whole of cosmic evolution [14]. Regardless of its shape or orientation, such an arrow symbolizes a *sequence* of events that have changed systems from simplicity to complexity, from inorganic to organic, from chaos in the early

Exobiology and Complexity, Figure 1

a An arrow of time symbolically chronicles the principal epochs of cosmic history, from the beginning of the Universe ~14 billion years ago (at left) to the present (at right). Labeled diagonally across the top are 7 major evolutionary phases (corresponding to the main historical epochs) that have produced, in turn, increasing amounts of order and complexity among all material systems: particulate, galactic, stellar, planetary, chemical, biological, and cultural. Cosmic evolution encompasses all of these phases, each of which represents a coarse temporal duration when the emergence of key systems flourished in Nature. Time is assumed to flow linearly and irreversibly, much as other basic tenets are presumed, including the fixed character of physical law and the idea that $2 + 2 = 4$ everywhere. **b** Sketched here qualitatively is the rise of order, form, and complexity typifying the evolution of *localized* material structures throughout the history of the Universe. This family of curves depicts a widespread, innate feeling, and not a rigid proof, that the complexity of ordered structures has *generally* increased over the course of time. It is unknown if this rise of complexity has been linear, exponential, or even faster (as drawn here for the 3 curves); current research aims to specify this curve and to describe it quantitatively

Universe to order more recently. That sequence, as determined by a large body of post-Renaissance data, accords well with the idea that a chain of knowledge – a loose continuity along an impressive hierarchy of complexity – links, in turn:

- The evolution of primal energy into elementary particles and then atoms
- The evolution of those atoms into galaxies and stars
- The evolution of stars into heavy elements

- The evolution of those elements into the molecular building blocks of life
- The evolution of those molecules into life itself
- The evolution of advanced life forms into intelligence
- The evolution of intelligent life into a cultured and technological civilization.

Despite the extreme specialization of modern science, evolution marks no disciplinary boundaries; complexity science is a truly interdisciplinary topic. A more specific outline for this article is then:

Cosmic Evolution

- Subsets: physical evolution → biological evolution → cultural evolution
- Phases: particulate → galactic → stellar → planetary → chemical → biological → cultural.

Accordingly, the most familiar kind of evolution – biological evolution, or neo-Darwinism – is just one, albeit important, subset of a broader evolutionary scenario including much more than life on Earth. In short, what Darwinian change does for plants and animals, cosmic evolution aspires to do for all things. And if Darwinism created a revolution in understanding by helping to free us from the anthropocentric belief that humans differ from other life-forms on our planet, then cosmic evolution extends that intellectual revolution by treating matter on Earth and in our bodies no differently from that in the stars and galaxies far beyond.

Note that time's arrow does not imply that primitive, "lower" life-forms have biologically changed directly into advanced, "higher" organisms, any more than galaxies have physically changed into stars, or stars into planets. Rather, with time – much time – the environmental conditions suitable for spawning simple life eventually changed into those favoring the biological origin and evolution of more complex species. Likewise, in the earlier Universe, the physical evolution of environments ripe for galactic formation eventually gave way more recently to conditions conducive to stellar and planetary formation. Now, at least on Earth, cultural evolution dominates, since our local planetary environment has once more changed to foster greater, societal complexity. Change in the surrounding environments usually precedes change in organized systems, and the resulting changes for those systems selected to endure have *generally* been toward greater amounts of diverse order and complexity.

Anthropocentrism is neither intended nor implied by the arrow of time; the arrow is not pointing at humankind. Anthropocentric principles notwithstanding, no logic supports

the idea that the Universe was conceived in order to produce specifically us. Humans are not the pinnacle or culmination of the cosmic-evolutionary scenario, nor are we likely to be the only technologically competent beings that have emerged in the organically rich Universe. The arrow merely provides a convenient symbol, artistically suggesting the building of increasingly complex structures, from spiral galaxies to rocky planets to thinking beings.

Figure 1b graphs the widespread impression that material systems have become more organized and complex, especially in relatively recent times. This family of curves graphs "islands" of complexity that comprise ordered systems per se – whether massive stars, colorful flowers, or busy urban centers – not their vastly, indeed increasingly disorganized surroundings. Modern science aims to explain this rise of complexity and to do so with accepted scientific principles and observational or experimental data.

Non-equilibrium Thermodynamics

Cosmic evolution, as understood today, is governed largely by the laws of physics, particularly those of thermodynamics. However, this does not mean classical reductionism, for here we seek to model change guided by a combination of randomness and determinism, of chance and necessity. Nor does the cosmic-evolutionary narrative employ mere equilibrium thermodynamics – the kind most often used to explain closed systems isolated from their surroundings and having maximum entropy states. All structures observed in Nature, among them most notably galaxies, stars, planets, and life-forms, are demonstrably open, non-equilibrium systems, with flows of energy in and out being an important feature. And it is this energy, often called available, or "free" energy that helps to build structures [27,28,38,54,60,74].

By utilizing energy, order can be achieved temporarily, or at least the environmental conditions made conducive for the potential rise of order within open systems ripe for growth. Energy flow plays a vital role in the creation, maintenance, and fate of complex systems – all quantitatively in accord with the second law of thermodynamics, which demands an overall rise in disorder. None of Nature's ordered structures, not even life itself, is a violation (or even a circumvention) of the second law. Considering both any ordered system as well as its disordered surroundings, non-equilibrium thermodynamics shows that the net entropy of the system and its environment always increases. (Quantitative details for many such systems can be found in [10].)

Energy is now recognized as a key ingredient, not only for biological systems such as plants and animals, but also

for physical systems such as stars and galaxies, indeed as well for social systems such as a city's inward flow of food and resources amidst its outward flow of products and wastes (Weber [69]; Dyke [21]). The analysis is much the same for all open systems, provided they are modeled in broad, interdisciplinary ways; energy flow seems indispensable for any system's origin and evolution.

Figure 2, adapted from the work of Prigogine et al. [55] and Salk [58], graphically diagrams the emergence of structure in the presence of energy flow. Physicists relate to the type of curves drawn in part (a); biologists are more familiar with those in part (b). By crossing certain energy thresholds that depend on a system's status, bifurcations can occur, fostering the origin of whole new structures that display surprising amounts of coherent behavior. Such "dissipative" structures can export some of their entropy (or expel some of their energy) into their external environments. Accordingly, order is created and sustained by routine consumption of substances rich in energy, followed by discharge of substances low in energy. This process, often misnamed, is not really *self-ordering*; it is ordering in the presence of energy. "Self-assembling" systems demonstrate an essential tension between energy inflow and dissipative outflow; such systems do no function magically by themselves.

The emergence of order from a condition where originally there was none (or less of it) is relatively straightforward [54,59]. Fluctuations – random deviations from some average, equilibrium value of, for example, density, temperature, or pressure – inevitably yet stochastically appear in any natural system having many degrees of freedom. Normally, as in equilibrium thermodynamics, such instabilities regress in time and disappear; they come and go by chance since the statistical fluctuations diffuse as quickly as they arise. Even in an isolated system, such internal fluctuations can generate local, microscopic reductions in entropy, but the second law ensures that they will always balance out. Microscopic temperature fluctuations, for instance, are said to be thermally relaxed, and entropy remains maximized in such systems. Nor can an open system *near* equilibrium change spontaneously to new and interesting structures. But should those fluctuations become too great for an open system to damp, that system can then depart far from equilibrium and have a chance to reorganize. Such restructuring generates a "dynamic steady state", provided the amplified fluctuations are continuously driven and stabilized by a flow of energy from the surroundings – namely, provided the energy flow rate exceeds the thermal relaxation rate. Systematic, coherent cycling is often the result, since under these conditions the spontaneous creation of macroscopic structures dissipates

Exobiology and Complexity, Figure 2

a The departure of an open system from equilibrium is drawn here as a function of both time, t , and energy, E . The time axis makes clear that this is an historical, evolutionary process, whereas the parallel energy axis tracks free energy flowing through the open system as a vital part of that process. At certain critical energies, labeled here E_c , a system can spontaneously change, or bifurcate, into new, non-equilibrium, dynamic steady states. Statistical fluctuations – that's chance – affect which fork the system selects – that's necessity – upon bifurcation (vertical arrows), namely which spatial structure is achieved. Not all new systems survive (solid curve); some are rejected (dashed curve). The process, as always, is a mixture of randomness and determinism, therefore the end result is inherently unpredictable, as with all of evolution. **b** Events in evolutionary biology mimic those of the diagram in **a**, although the results here are richer in structural detail, system function, and energy flow. In phases marked A, a species survives and thus persists until the environment changes (vertical arrows), after which further evolution occurs – along phase B toward renewed survival or phase C toward extinction. Both upwardly rising graphs (drawn by solid lines for both parts of this figure) imply neither progress nor inevitability, but they do suggest a *general trend* toward increasing complexity with time – a trend that cannot be denied among organized systems observed throughout Nature

energy more rapidly than the ensuing, and damaging, heat can damp the gradients and destroy those structures. Furthermore, since each successive reordering often causes more complexity than the preceding one, such systems become even more susceptible to fluctuations. Complexity itself consequently creates the conditions for greater instability, which in turn provides an opportunity for greater reordering. Nothing is guaranteed; thermodynamics specifies what can happen, not what actually does happen. The resulting phenomenon – termed “order through fluctuations” – is a distinctly evolutionary one, complete with feedback loops that help drive some systems further from equilibrium. And as the energy consumption and resulting complexity accelerate, so does the evolutionary process. This is the realm of true *thermodynamics*, the older, established subject of that name more properly labeled “thermostatics”.

Numerous examples abound throughout Nature, and not just among physical systems, but for biological and social systems as well. Naturally occurring phenomena such as convection cells, river eddies, atmospheric storms, and even artificially made devices such as kitchen refrigerators and coherent lasers among an array of many physical systems that experience coherent order when amply fed with sufficient energy, all display enhanced order when energy flows exceed some threshold. Biological systems also obey the rules of non-equilibrium thermodynamics, for we and our living relatives are demonstrable examples of dynamic steady states that emerge and function via energetically enhanced neo-Darwinism (though biologists often worry that such statements aim to reduce biology to physics – whereas in reality physics is broadened to include biology.) As are Lamarckian-type cultural systems of more recent times also dynamic steady states, for among the bricks and chips that civilization has built, energy has been a principal driver (although, again, sociologists and anthropologists often loathe their subjects being treated thermodynamically). The result is that life and its cultural inventions differ not in kind, but merely in degree – specifically, degree of complexity – among numerous ordered systems evident in Nature.

Big-Bang Cosmology

The origin of Nature’s many complex structures depends on the flow of free energy. And this, like the arrow of time itself, is a direct consequence of the expanding Universe – a much tested “standard cosmological model” based largely on three-fold observations of distant receding galaxies, microwave background radiation, and light-element abundances. Time marches on and free energies

flow because the cosmos dynamically evolves – building, maintaining, and often destroying systems. Indeed, it is cosmic expansion, and probably nothing more, that has caused the entire Universe to depart from its initial state of thermodynamic equilibrium. (Thus, the free energies are inevitable, not the resulting systems per se – which is why it’s called “available”, or potential, energy freely *capable* of doing work.) The stark contrast between localized hot stars and the vast, cold interstellar space surrounding them now guarantees a state of non-equilibrium, a cosmic condition that has pertained for billions of years [26,40].

Matter

Although modern cosmology stipulates that matter only later emerged from the primordial radiation of the early Universe, it is pedagogically useful to quantify first the role of matter and thereafter the primacy of radiation. In this way, perhaps the greatest change in the history of the Universe – the transformation from radiation to matter – can be mathematically justified.

Imagine an arbitrary shell of mass, m , and radius, r , expanding isotropically with the Universe at a velocity, v , from some central point. The sphere within the shell is not necessarily meant to represent the entire Universe, only an extremely large gas cloud within it – in fact, larger than the extent of a typical galaxy supercluster (~50 Mpc across), which comprises the highest rank in the known hierarchy of matter assemblages in the Universe. Invoking the principle of energy conservation, we find the Friedmann–Lemaître equation that describes a family of models for the Universe in bulk,

$$H^2 - \frac{8}{3}\pi G\rho_m = -kR^{-2}.$$

Here, H is Hubble’s constant (a measure of galaxy recession in the expanding Universe), G is the universal gravitational constant, ρ_m is the matter density, and k is a time-dependent curvature constant. R is a scale factor which relates the radius, r , at any time, t , in cosmic history to the current radius, r_0 , at the present time – namely, $r = Rr_0$. Solutions to the above equation specify three general models for the Universe:

- The Universe is “open” (i. e., k negative) and thus recedes forevermore
- The Universe is “closed” (i. e., k positive), meaning it eventually stops and thereafter contracts to a point much like that from which it began
- The Universe is precisely balanced between the open and closed models, in which case it eternally expands

and never contracts (because it can never reach infinity).

Even if the Universe is, as now suspected, accelerating in its outward expansion, the effect of “dark energy” (that supposedly causes the acceleration) on stars and galaxies is minimal, and that on smaller structures like planets and their organized living systems is inconsequential; cosmic acceleration likely affects only the dynamics of the Universe on the largest scales and not those of organized systems that are controlled by local energies within it.

The simplest case ($k = 0$, also known as the Einstein-deSitter solution) leads to the critical density for closure,

$$\rho_{m,c} = 3H^2/8\pi G ,$$

which, when evaluated for G and H (~ 70 km/s/Mpc), equals $\sim 10^{-29}$ g/cm³. This is ~ 6 atoms in each cubic meter of space, or about a million times thinner than in the region between Earth and the Moon. Whether the actual current density, on average everywhere, is smaller or larger than this value, making the Universe open or closed, respectively, is currently unknown; there is too much uncertainty concerning “dark (non-baryonic) matter” that is implied, but not found yet needed, to gravitationally bind galaxies and their clusters. However, the above-noted acceleration of the Universe does imply that it is expanding ever faster, thereby giving it an open geometry that will recede toward infinity forevermore.

To follow the evolution of matter throughout cosmic history (up to the present), we appeal to the conservation of material particles in the huge sphere postulated above, $\rho_m = \rho_{m,0}R^{-3}$, substitute into the special ($k = 0$) case of the Friedmann–Lemaître equation, and manipulate,

$$\int dt = \left(\frac{8}{3}\pi G\rho_{m,c}\right)^{-0.5} \int R^{0.5} dR .$$

The result suggests that the Universe is $\sim 14 \times 10^9$ y old ($\pm \sim 10\%$). This equation additionally stipulates how the average matter density thins with time,

$$\rho_m \approx 10^6 t^{-2} ,$$

where ρ_m is expressed in g/cm³ and t in seconds.

Figure 3 plots this evolution of matter throughout all of universal history. This run of density, ρ_m , in standard, big-bang cosmology demonstrates the essence of change on the largest scales – the broadest view of the biggest picture. Here displayed in this one plot is the thermodynamic history of the whole Universe, so the curve for ρ_m in this figure (as well as the curve for T discussed in the next section) pertain to nothing in particular, just everything in general.

Exobiology and Complexity, Figure 3

Log-log plot of the density (ρ_m) of matter on average and the temperature (T) of radiation on average, over the course of all time, to date. The thick width of the density curve displays the range of uncertainty in total mass density, whose true value depends on the amount of “dark matter” in the Universe. By contrast, the cold cosmic background temperature is very accurately measured today (2.7 K), and its thin curve here is equally accurately extrapolated back into the hot, early Universe. Recent findings that cosmic expansion is accelerating should not much affect these curves

Radiation

The same analysis regarding matter can be applied to radiation in order to follow the change of temperature with time. Again, for the simplest $k = 0$ case,

$$H^2 = \frac{8\pi G\rho_{r,c}}{3R^4} ,$$

where ρ_r is the equivalent mass density of radiation. Here the R^4 term derives from the fact that radiation scales not only as the volume ($\propto R^3$) but also by one additional factor of R because radiation (unlike matter) is also affected linearly by the Doppler shift. And noting that $\rho_r c^2 = aT^4$, where a is the universal radiation constant for any black-body emitter and T is the temperature of radiation, we find the temporal dependence of average temperature throughout all time (in seconds),

$$T \approx 10^{10} t^{-0.5} .$$

The universal radiation, having begun in a fiery expansion (popularly called the “big bang”), has now cooled to 2.7 K, the average value of the cosmic microwave back-

ground measured today by radio telescopes on the ground and satellites in orbit [2].

Figure 3 also plots this run of T versus t . Again, for emphasis, the two curves in this figure show the prime twin trends of big-bang cosmology: the cooling and thinning of radiation and matter, based largely on observations of the microwave background radiation and of the distant receding galaxies.

For the first few hundred millennia of the Universe, radiation reigned supreme over matter. Life was nonexistent and matter only a submicroscopic precipitate suspended in a glowing, chaotic fireball. All space was flooded with high-frequency photons, especially light, x-rays, and γ -rays, ensuring a non-structured, undifferentiated, (virtually) informationless, and highly uniform plasma. Matter and radiation were intimately coupled to each other – thermalized and equilibrated. Structure of any sort had yet to emerge; the energy density of radiation was too great. If single protons captured single electrons to form simple hydrogen atoms, the radiation was then so fierce as to destroy those atoms immediately. However, as the Universe expanded with time, the energy of radiation decreased faster than the energy equivalently contained in matter.

To confirm this statement, compare the energy densities of radiation and matter, and especially how these two quantities have change over time. First convert the matter density derived earlier to an equivalent energy density by invoking the Einsteinian mass (m)-energy (E) relation, $E = mc^2$ – that is, by multiplying the above equation for ρ_m by c^2 . Now, $\sim 14 \times 10^9$ y after the big bang, $\rho_{m,0}c^2 \approx 10^{-9}$ erg/cm³, whereas $aT_0^4 \approx 4 \times 10^{-13}$ erg/cm³; thus currently, $\rho_{m,0}c^2 > aT_0^4$ by several orders of magnitude, proving that matter is now in firm control (gravitationally) of cosmic changes, despite the Universe still being flooded today with long-wavelength radiation. However, given that $\rho_m c^2$ scales as R^{-3} and aT^4 scales as R^{-4} , there must have been a time in the past when $\rho_m c^2 = aT^4$, and an even earlier time when $\rho_m c^2 < aT^4$. Manipulation of the above equations shows that these two energy densities crossed at $t \approx 10^4$ y, well less than a million years after the big bang. Figure 4 is a graphical representation of this paragraph.

This crossover represents a preeminent change in all of cosmic history. The event, $\rho_m c^2 = aT^4$, separates the *Radiation Era* from the *Matter Era*, and designates the time ($\sim 10^4$ y) when the Universe gradually began to become transparent. Thermal equilibrium was destroyed and symmetry broken, causing the radiative fireball and disorganized matter to decouple; it was as though a fog had lifted. Photons, previously scattered aimlessly and destructively

Exobiology and Complexity, Figure 4

The temporal behavior of both matter energy density ($\rho_m c^2$) and radiation energy density (aT^4) illustrates perhaps the greatest change in all of natural history. Where the two curves intersect, neutral atoms began to form; by $t \approx 10^5$ y after the big bang the Radiation Era had changed into the Matter Era. A uniform, featureless state describing the early Universe was thus naturally transformed into one in which order and complexity were thereafter possible

by subatomic material particles (especially free electrons) in the expanding, hot, opaque plasma of the Radiation Era, were no longer so affected once the electrons were bound into atoms of the Matter Era. This crucial and dramatic change was over by $\sim 4 \times 10^5$ y, when the last remnants of the early ionized plasma state had finally transformed into neutral matter. The 2.7-K microwave radiation reaching Earth today is a relic of this critical phase transition, having streamed unimpeded (except for being greatly redshifted, $z \sim 10^3$) across space and time for most of the age of the Universe, granting a “view” of this grandest of all evolutionary events that occurred long ago.

With the onset of the Matter Era, matter literally began dominating radiation. Natural history became more interesting, for then structures could begin to form. The results of inevitable change, induced gradients, energy flows, and evolved systems, over billions of years and minus the details, are galaxies, stars, planets, and life-forms, one by-product of which is intelligence – at least on Earth. And this, in turn, has anthropogenically changed nearly everything on our planet.

Life

Now ~ 14 billion years after the beginning of space and time, the *Life Era* has begun, at least locally on Earth

(and possibly at many other places in the Universe). Here, the emergence of technologically intelligent life heralds a whole new era wherein life has gradually begun to dominate matter. This second of two great transformations was not caused by the origin of life per se several billion years ago; rather, it is technologically advanced life that differs significantly from primitive life and from other types of clustered inanimate matter scattered throughout the Universe. This is not an anthropocentric statement; we differ because we are the only species capable of knowing our past and worrying about our future, the only one able to control matter (albeit locally), much as matter evolved to control radiation long ago. Intelligent life on Earth is literally taking matter into its own hands – manipulating matter and energy, altering genes and terrestrial environments, indeed potentially changing evolution itself.

Some central questions before us are these: What caused the changes amid a wide spectrum of ordered structures throughout cosmic history and how has complexity increased with time? Have humans actually become the agents of change on Earth, able to tinker with both matter and energy, including now modifying genes and environments more than they affect us? How did the neural network within our human brains acquire the sophistication needed to fashion societies, weapons, cathedrals, philosophies, etc? In short, what caused us to become sentient enough to contemplate our complex selves?

Measuring Complexity

To appreciate the crux of the historical appearance of structured matter and life, we return to the greater cosmic environment and to some of the thermodynamic issues raised earlier. In brief, when the Universe broke its symmetry a few thousand centuries after the big bang, equilibrium was also destroyed. Temperature gradients were thereafter established naturally owing to the expansion of the cosmos. And that meant free energy began flowing, in fact increasingly so as the temperatures of matter and radiation diverged with time. These are the environmental conditions that are favorable for the potential growth of order, form, and complexity.

Cosmic Environment for the Growth of Complexity

When matter and radiation were still equilibrated in the Radiation Era, only a single temperature is needed to describe the thermal history of the Universe; the absence of any thermal gradients imply (virtually) zero information content, or zero macroscopic order, in the early Universe. However, once the Matter Era began, the gas-en-

ergy equilibrium was destroyed and a single temperature is insufficient to specify the bulk evolution of the cosmos. Since the random motions of the H and He atoms failed to keep pace with the rate of general expansion of the atoms away from one another [40], the matter cooled faster, $T_m \approx 6 \times 10^{16} t^{-1}$, than the radiation, $T_r \approx 10^{10} t^{-0.5}$. Figure 5a displays this thermal gradient, which has grown wider since $t \approx 10^5$ y.

Such a thermal gradient is the clear signature of a heat engine, and it is this ever-widening gradient that has enabled matter, in the main, to “build things” increasingly complex. Theoretically at least, the environmental conditions after 10^5 y naturally allowed a rise in “negentropy” [60] or “information content” [61] – both factors

Exobiology and Complexity, Figure 5

a In the expanding Universe, the temperatures of matter and radiation separated once these quantities became fully decoupled at $\sim 10^5$ y. Since that time, the Universe has been in a non-equilibrium state. **b** S increases less rapidly than S_{\max} , once the symmetry of equilibrium broke when matter and radiation decoupled at $\sim 10^5$ y. By contrast, in the early, equilibrated Universe, $S = S_{\max}$ for the prevailing conditions. **c** The potential for the growth of order, $S_{\max} - S$, has increased ever since the start of the Matter Era. This potential rise of order compares well with the subjectively drawn curves of Fig. 1b, thus providing a theoretical basis for the growth of system complexity

qualitatively synonymous with the term “complexity” [42]. But, as noted below, in practice both such terms are overly vague and subject to interpretation [5,73], so we resort here to a more conventional use of entropy, as agreed upon by most thermodynamicists. The important point – without getting lost in dubious semantics or contentious definitions – is that such non-equilibrium states are suitable, indeed apparently necessary, for the emergence of order, thus it can be reasoned that *cosmic expansion itself is the prime mover for the gradual construction of a hierarchy of structures throughout the Universe.*

Figure 5b plots the run of entropy, S , for a thermal gradient typical of a heat engine, but here graphed for the whole Universe. This is not a mechanical device running with idealized Newtonian precision, but a global engine capable of potentially doing work as locally emerging systems interact with their environments – especially those systems able to take advantage of increasing flows of free energy resulting from cosmic expansion and its naturally growing gradients. Although thermal and chemical (but not gravitational) entropy must have been maximized in the early Universe, hence complexity in the form of any structures then nonexistent, after decoupling the environmental conditions became favorable for the potential growth of order, taken here to mean a “lack of disorder.” At issue was timing: As ρ decreased, the equilibrium reaction rates ($\alpha\rho$) fell below the cosmic expansion rate ($\alpha\rho^{1/2}$) and non-equilibrium states froze in. Thus we have a paradoxical yet significant result that, in an expanding Universe, both the disorder (i. e. net entropy) and the order (maximum possible entropy minus actual entropy at any given time) can increase simultaneously – the former globally and the latter locally. All the more interesting when comparing the shape of this curve of potentially rising order, $S_{\max} - S$ in Fig. 5c, with our earlier intuited sketch of rising complexity in Fig. 1b [12,25,41].

Free Energy Rate Density

Theory aside, have the many diverse real structures known to exist in the Universe displayed this sort of progressive increase in order during the course of time? The answer is generally yes. At issue again is how to best characterize complexity numerically, given the varied connotations that this term presents for many researchers [46,47]. In biology alone, much as their inability to reach consensus on a definition of life, biologists cannot agree on a complexity metric. Some count non-junk genome size [66], others employ structural morphology or behavioral flexibility [4], while still others chart numbers of cell types in organisms [36] or appeal to cellular specialization [49]. All

these attributes of life have qualitative usefulness, yet all are hard to quantify in practical terms; nor do they apply to non-living things. If progress is to be made assessing a wide spectrum of complex systems in Nature, our analysis must extend beyond mere words, indeed beyond biology.

Putting aside as unhelpful (in the sense that it is too ambiguous and controversial) the above-noted concept of information content [32,34] as well as the concept of negative entropy (or negentropy, which Schroedinger [60] first adopted but then quickly abandoned), we return to the quantity with greatest appeal to physical intuition – energy. Given that energy – the ability to do work or to cause change – is the most universal currency known in the natural sciences, it might reasonably be expected to have a central role in any attempted unification of physical, biological, and cultural evolution.

Energy does act as an underlying, universal driver like no other in all of modern science. Whether living or non-living, dynamical systems need flows of energy to endure. If stars don't convert gravitational potential into heat and light, they would collapse; if plants don't photosynthesize sunlight, they would shrivel and decay; if humans don't eat, we too would die. Likewise, society's fuel is energy: Resources come in and wastes go out, all the while civilization goes about its daily business.

Not that energy has been ignored in previous studies of systems' origin and assembly. Physicists (e. g., Morrison [52] and Dyson [22]), biologists (Lotka [44]; Morowitz [51]; Fox [24]), and ecologists (Odum [53], Ulanowitz [68], and Smil [63]), to cite only a few researchers, have noted energy's organizational abilities. But the quantity of choice cannot be energy alone, for a star clearly has more energy than an amoeba, a galaxy much more than a single cell. Yet any living system is surely more complex than any inanimate object. Thus, absolute energies are not as suitable as normalized values, which depend on a system's size, composition, and efficiency. Nor are maximum energy principles or minimum entropy states [43] likely relevant; rather, organizational complexity is more likely governed by the *optimum* use of energy – not too little as to starve a system, yet not too much as to destroy it.

To characterize complexity objectively – that is, to normalize all such ordered systems on the same, level page – a kind of energy density is useful, much like the competing energy densities of radiation and matter that dictated changing events in the earlier Universe (Fig. 4). In fact, for a proper treatment of the thermodynamics of non-equilibrium open systems, it is the *rate* at which free energy flows through such systems of given mass that is most practical. Hence, *free energy rate density*, symbolized by Φ_m , is an

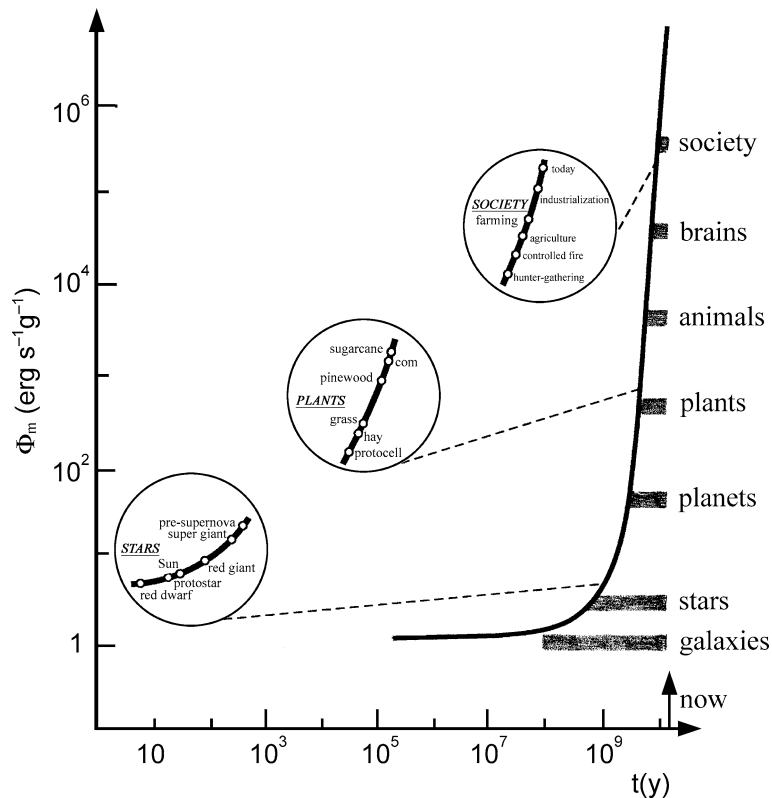

operational term whose meaning, measurement, and units are clearly understood. In this way, neither new science nor appeals to nonscience are needed to justify the impressive hierarchy of the cosmic-evolutionary story, from stars to plants to society.

Note that this complexity metric is not an original term; free energy rate density is a mere revision of an old one. Moreover, for years the same term has been labeled differently by specialized researchers: Φ_m is familiar to astronomers as the luminosity-to-mass ratio, to physicists as the power density, to geologists as the specific radiant flux, to biologists as the specific metabolic rate, and to engineers as the power-to-mass ratio. Free energy rate density is central to many varied subjects; all the more reason to use it to build a true interdisciplinary subject and to use it in search of unity across the spectrum of all the natural sciences [8,9,10,11].

Exobiology and Complexity, Table 1
Free energy rate densities for several representative systems

System	Duration (10^6 y)	Φ_m (erg/s/g)
Galaxy (Milky Way)	12,000	0.5
Star (main-sequence Sun)	10,000	2
Planet (Earth's climasphere)	5000	75
Plant (Earth's biosphere)	3000	900
Animal (hominid body)	10	20,000
Brain (human cranium)	1	150,000
Society (modern culture)	0	500,000

Table 1 lists values of Φ_m , in units of erg/sec/g, for seven representative systems (and their specific, computed cases in parentheses). Also listed is the duration, in millions of years, for each type of structure, dating back to their origins in the observational record. Clearly, Φ_m

Exobiology and Complexity, Figure 6

Increase in free energy rate density, Φ_m , plotted as horizontal histograms when various open structures prospered in Nature, has been especially rapid in the last few billion years, much as expected from subjective intuition (Fig. 1b) and objective thermodynamics (Fig. 5c). The drawn curve approximates the increase in normalized energy flows characterizing order, form, and structure for a range of systems throughout the history of the Universe. The circled insets show greater detail of further measurements or calculations of free energy rate density for three representative systems – stars, plants, and society – typifying physical, biological, and cultural evolution, respectively. The data in those circled insets are discussed in Sect. “Complexity and Evolution, Broadly Considered”. (Adapted from [9,10])

has increased as more intricately ordered systems have emerged throughout cosmic history, and dramatically so in relatively recent times.

The modeled flow of energy through a wide variety of open systems, alive or not, resembles the intuitive rise in complexity implied by Fig. 1b; it also mimics the potential rise of order in the above thermodynamic analysis of Fig. 5c. Complexity (at least as treated here energetically for localized structures) has indeed quantitatively increased over the course of natural history, and at a rate faster than exponential in more recent times ([9,11,13]; for details of energy computations and modeling, consult [10]).

Figure 6 plots the results listed in Table 1, where the Φ_m values are graphed as horizontal histograms for various systems' evolutionary durations to date. As expected:

- Stars and planets have small energy rate densities, $\Phi_m = 1-10^2$ erg/s/g
- Plants and animals have larger energy rate densities, 10^3-10^5 erg/s/g
- Human societies have the largest known energy rate densities, $\sim 10^6$ erg/s/g.

Note that, although the total energy flowing through a star or planet is much greater than that through our individual bodies or brains, the *specific* rate (per unit mass) is larger for the latter – in fact, roughly a million times greater Φ_m for the human body than for the Sun.

This is not to say, by any means, that galaxies evolved into stars, or stars into planets, or planets into life. Rather, this analysis contends that galaxies gave rise to environments suited to the birth of stars, that some stars spawned environments conducive to the formation of planets, and that countless planets likely fostered environments ripe for the origin of life. Cosmic evolution, to repeat, incorporates both developmental and generational change.

Nor do these evolutionary phases, or historical durations, have well-determined start and stop times – or stop times necessarily at all. The horizontal histograms of Fig. 6 serve to stress that each of these phases once begun did not end; stars and galaxies, for example, first emerged in the earlier Universe, as also implied by the diagonal phases atop the arrow of time in Fig. 1a, but both such system types continue on presently originating, developing, and evolving, as do plants and animals that emerged much later. As depicted by those histograms yet unlike customary geological periods that do have set time intervals, currently all evolutionary phases noted in Figs. 1 and 6 operate simultaneously and indefinitely.

We thus arrive at a comprehensible reconciliation of the evident destructiveness of thermodynamics with

the observed constructiveness of cosmic evolution. The sources and sinks of such energy flows passing through complex yet disparate entities such as stars, plants, and civilization all relate back to the time of thermal decoupling in the early Universe, when the conditions naturally emerged for the origin and evolution of order and organization.

Complexity and Evolution, Broadly Considered

Evolution should not be the sole province of biology, nor should its utility be of value only to life scientists. Darwin [19] never used the word “evolution” as a noun, in fact only once as a verb in the very last sentence of his classic book, *On the Origin of Species*. Nor need the principle of natural selection be the only mechanism of evolutionary change, past or present.

Actually, the term “selection” is itself a misnomer, for no known agent in Nature deliberately selects. Selection is not an active force or promoter of change as much as a passive mechanism that weeds out the unfit. As such, selected systems are simply those that remain after all the poorly adapted or less fortunate ones have been removed from a population of such systems. A better term might be “non-random elimination” [48]. What we really aim to explain are the adverse circumstances responsible for the deletion of some members of a group. Accordingly, selection can be generally taken to mean favorable interaction of any system with its environment – a more liberal interpretation that also helps widen the concept of evolution.

Selection works alongside the flow of resources into and out of all open systems, not just life-forms. Ordered systems are selected partly for their ability to utilize energy; and this energy is the “force”, if there is any at all, in evolution. Broadly considered, selection occurs in the inanimate world as well as among animate objects, often providing a formative step in the production of order. It is energy flow and natural selection that together, working in tandem, underlie the “self”-assembly sketched in Fig. 2 – the former driving initial systems beyond equilibrium, the latter aiding the emergence of higher order in those systems that survive.

A handful of cases will suffice, among many others so documented [14], to illustrate the action of this energy-selection duo among a spectrum of increasingly ordered systems in successive phases of cosmic evolution:

- Red-giant stars are more complex than main-sequence stars
- Eukaryotes are more complex than prokaryotes
- Plants are more complex than protists
- Animals are more complex than plants
- Mammals are more complex than reptiles

- Brains are more complex than bodies
- Industrial society is more complex than hunter-gatherers.

Whether physical evolution of galaxies, stars and planets, or biological evolution of plants and animals on Earth, or cultural evolution of our technological civilization, a rather remarkable ranking order is apparent among all known organized structures. Stars, life, and society, all share a significant, common conclusion: Basic differences, both within and among these categories, are in degree, not in kind – namely, in degree of complexity arising from ongoing cosmic evolution. To justify this, consider below in greater detail each of the three major subsets of cosmic evolution noted in Sect. “Introduction”.

Physical Evolution

Stars are good examples of physical evolution. Growing complexity can serve as an indicator of stellar aging – a developmental process – allowing stars to be judged as their interiors undergo cycles of nuclear fusion that result in greater thermal and chemical gradients. More data are needed to describe the increasingly differentiated, onion-like layers of fused heavy elements within highly evolved stars; more energy also flows per unit mass. Stellar size, color, brightness, and composition all change while passing on up the hierarchy of complexity for all stars, each stage using more free energy rate density:

- From protostars at “birth” ($\Phi_m \approx 0.5$ erg/s/g)
- To main-sequence stars at “mid-life” (~ 2)
- To red-giant stars in “old age” ($\sim 10^2$),
- To pre-supernovae near “death” ($\sim 5 \times 10^2$).

Those parenthetical values are the stars’ increased energy rate densities, plotted among other values in the lower circled inset of Fig. 6. At least as regards energy flow, material resources, and structural integrity while experiencing change, stars have much in common with life. This is not to say that stars are alive, which is an occasional misinterpretation of such a broad statement. Nor do stars evolve in the strict and limited biological sense; most researchers would agree that stars *develop*. Yet close parallels are apparent among stars, including selection, adaptation, and perhaps even a kind of stellar reproduction – a generational process – reminiscent of the following Malthusian-inspired scenario:

Galactic clouds spawn clusters of stars, only a few of which (the more massive ones unlike the Sun) enable other, subsequent populations of stars to emerge in turn, with each generation’s offspring showing slight variations, especially among the heavy elements contained

within. Waves of “sequential star formation” [23] propagate through many such clouds like slow-motion chain reactions over eons of time – shock waves from the death of old stars triggering the birth of new ones – neither any one kind of star displaying a dramatic increase in number nor the process of regeneration ever being perfect. Those massive stars selected by Nature to endure the fusion needed to produce heavy elements are in fact the very same stars that often produce shocks to create new populations of stars, thereby both episodically and gradually enriching the interstellar medium with greater elemental complexity on timescales measured in millions of millennia. As always, the necessary though perhaps not sufficient conditions for the growth of complexity depend on the environmental circumstances and on the availability of energy flows in such (here, galactic) environments. All of which is reminiscent of stellar “evolution”, minus any genes, inheritance, or overt function, for these are the value-added qualities of biological evolution that go well beyond physical evolution.

Continuing on and throughout the physical evolutionary subset of cosmic evolution, a *general* trend prevails, at least as pertains to Earth’s environment that set the stage for life:

- Young rocky planets have greater Φ_m (~ 10 erg/s/g) than normal stars and galaxies (~ 1)
- Hydrothermal vents on at least one of those planets have more (~ 50)
- Planetary climates, such as Earth’s ocean-air interface, have even more (~ 100).

Note that some physical systems seem to be exceptions to the above findings, but upon closer inspection they are not exceptional at all. For example, that supernovae have very high values of Φ_m ($\gg 10^6$ erg/s/g) does not violate our complexity metric. The reason is that supernovae are not organized systems, in fact just the opposite; as excellent examples of totally disorganized explosions of massive stars, they have too much energy flow that is well outside the optimal range for stars, and thus we should not expect to properly plot chaotic supernovae among other clearly ordered systems in Fig. 6. Pre-supernovae are noted there, representing an advanced stage of stellar evolution and growing complexity prior to explosion, but supernovae themselves are destructive events more typical of retreat from complexity toward simplicity. Likewise, bombs, flames, and many other damaging events do have large energy throughput yet do not belong on this curve, thus do not partake of a general trend toward rising complexity in Nature.

Biological Evolution

Plants are good examples of biological evolution. Here, we trace increasing complexity among plant life on Earth where neo-Darwinism is clearly at work, making use of free energy rate densities well higher than those for galaxies, stars, and planets. As shown in the middle circled inset of Fig. 6, energy-flow diagnostics display a definite increase in complexity among various plants that locally and temporarily decrease entropy. The most dominant process in Earth's biosphere – photosynthesis – well illustrates that complexity hierarchy [29]:

- From simple hay or grass ($\Phi_m \approx 5 \times 10^2$ erg/s/g)
- To inefficient pinewood ($\sim 3 \times 10^3$)
- To more efficient corn ($\sim 6 \times 10^3$)
- To well cultivated sugarcane ($\sim 10^4$).

System functionality and genetic inheritance are two factors, above and beyond mere system structure, which help to enhance order among animate systems that are clearly living compared to inanimate systems that are clearly not. Unsurprisingly, more complex life-forms require the acquisition of more energy per unit mass per unit time for their well being.

Energy flows through plants as captured solar energy during the act of photosynthesis converts H₂O and CO₂ into nourishing carbohydrates; the previous low-grade disordering sunlight becomes, in a relative sense, a higher-grade ordering form of energy compared to the even lower-grade (infrared) energy re-emitted by Earth. Likewise, as regards previously discussed physical evolution, energy flows through stars as gravitational potential energy during the act of star formation converts into radiation released by mature stars; high-grade energy produced by gravitational and nuclear events yield greater (thermal and elemental) organization, yet only at the expense of their environments into which stars emit low-grade light abundant in entropy. Either way, energy is a fuel for evolution, fostering some systems to utilize increased power densities while driving others to destruction and extinction.

Onward across the bush of life (or the arrow of time) – cells, tissues, organs, organisms – much the same metric holds for animals (all in units of erg/s/g):

- Cold-blooded reptiles have greater Φ_m ($\sim 10^4$) than globally averaged plants ($\sim 10^3$)
- Warm-blooded mammals typically have more ($\sim 5 \times 10^4$)
- Some birds, during complex flight, can achieve even more ($\sim 7 \times 10^4$).

Human life itself can also be examined on finer scale to show how energy usage continues upward (per unit mass) for more complex tasks [30,63]:

- Laboring humans have greater Φ_m ($\sim 6 \times 10^4$) than sedentary humans ($\sim 2 \times 10^4$)
- Vigorously bicycling and intricately sewing humans have more ($\sim 10^5$)
- Thinking human brains themselves have even more ($\sim 2 \times 10^5$).

Starting with life's precursor molecules (the realm of chemical evolution) and all the way to human brains exemplifying the most complex clump of animate matter known (neurological evolution), the same *general* trend characterizes the complexity of plants and animals as for stars and planets: The greater the perceived complexity of the system, the greater the flow of free energy density through that system – either to build it, or to maintain it, or both.

No strong distinctions are made here among Φ_m values for members of the animal kingdom, except to note that they are nearly all within a factor of ten of one another, confined between those for photosynthesizing plants on the one hand and central nervous systems on the other. The results are broadly consistent with measured specific metabolic rates scaling inversely with body mass, $M^{-1/4}$, among a wide variety of animal species [37,70]. Suffice it to say that animals in the main and in accord with Fig. 6 fit well within the complexity trends for the major evolutionary stages of life and for the intermediate phases of cosmic evolution.

Note, however, as for some non-living systems above, a minority of living systems seem exceptional, their values of Φ_m somewhat out of bounds among other equally advanced biological systems. Occasional life-forms also display retreat from complexity, such as some bats that move deeper into caves over generations and thus gradually lose their eyesight, or snakes and whales that eventually lost legs over time. Exceptions, real and apparent, to any rule will likely occur in a biosphere so rich in numbers and diversity as ours on Earth. For example, respiring bacteria are problematic at face value, having Φ_m values as much as 10^6 erg/s/g [45], thus comparable to higher forms of life. But microbes are so highly metabolic only when environmental resources warrant; none of them respire continuously. Measured rates are often quoted for peak periods of high reproductivity. By contrast, more than three-quarters of all soil bacteria are virtually dormant and thus have Φ_m values orders of magnitude less while eking out a living in nutrient-poor environments. When all microbial rates are time-weighted, microbes' average values range in the

thousands of erg/s/g, as expected for systems of intermediate complexity. Likewise and to note just one other seemingly exceptional animal, the Komodo Dragon can consume 80% of its body weight at one meal, yet not need another meal for a month – however, its time-averaged metabolic rate is much less than its maximum rate while eating.

Birds are another case in point, as they are well known to have high specific metabolic rates ($\sim 3 \times 10^4$ erg/s/g) during periods of peak activity, such as when earnestly foraging for food for their nestlings. But, once again, upon closer inspection, they are recognized not to be exceptions at all. That the smallest animals have the highest such rates is often taken [70] as an explanation of their frequent eating habits (hummingbirds ingest up to half of their body mass daily), extreme levels of activity (bumblebees flap their wings up to 160 times per second), and relatively short lifespans (few years typically, given the heavy toll on their metabolic functions); those are operational tasks, namely, function, not structure. Given that birds and bees normally function in a three-dimensional aerial environment while solving advanced tasks in spatial geometry, materials science, aeronautical engineering, molecular biochemistry, and social stratification, then perhaps they ought to have large values of Φ_m . That birds, while airborne, have higher values than for resting humans should not surprise us since we ourselves have not solved the art of flying, an admittedly complex task. By contrast, when bicycling vigorously or sewing intricately, our specific metabolic rates do exceed even those of birds in flight as noted above. Moreover, when humans do fly, aided by built aircraft, machine values of Φ_m are indeed higher ($\sim 10^7$ erg/s/g) than for even the most impressively ingesting hummingbirds, as discussed in the next section on cultural evolution.

Cultural Evolution

Society is a good example of cultural evolution. Here, the cosmic-evolutionary chronicle continues, yet with greater normalized energy flows to power our obviously complex civilization. As plotted in the upper circled inset of Fig. 6, social progress can be tracked, again in terms of energy consumption, for a variety of human-related cultural advances among our hominid ancestors. Quantitatively, that same energy rate density increases:

- From hunter-gatherers of a few million years ago ($\Phi_m \approx 10^4$ erg/s/g)
- To agriculturists of several thousand years ago ($\sim 10^5$)
- To industrialists of two hundred years ago ($\sim 5 \times 10^5$)
- To western society today, on average ($\sim 10^6$).

That a cluster of brainy organisms working collectively in a social group is more energy intensive per capita (and thus more complex) than each of its individual human members – at least as regards the present criterion for order of free energy rate usage per capita – is a good example of a “whole greater than the sum of its parts”, in this case for the open, non-equilibrated society that constitutes modern civilization [15].

The road to today’s technological society was unquestionably built with increased energy use, as has been earlier recognized by many cultural historians (e. g., White [71]; Cook [18]; Brown [6]; Jervis [35]; McNeill and McNeill [50]), who noted the importance of rising energy expenditure per capita, a factor also more recently emphasized by practitioners of “big history” (Christian [17]; Spier [65]; Aunger [1]), a newly emerging subject that treats conventional history more deeply, indeed parallels the scenario of cosmic evolution.

Machines, too, and not just computer chips, but also ordinary motors and engines that typified the fast-paced economy of the 20th century, can be cast in evolutionary terms – though here the mechanism is less Darwinian than Lamarckian [39], with the latter’s emphasis on accumulation of acquired traits. Either way, energy remains a driver, and with rapidly accelerating pace. Aircraft engines, for example, display clear evolutionary trends as engineering improvement and customer selection over generations of products have made engines more intricate, complex, and efficient, all the while utilizing enriched flows of energy density [63]:

- Gas-guzzling SUVs have greater Φ_m ($\sim 10^6$ erg/s/g) than model-T automobiles ($\sim 10^5$)
- Boeing-747 jumbo jets of the last few decades have more ($\sim 10^7$)
- Military F-117 stealth aircraft of the present have even more ($\sim 10^8$).

Finer-scale evolutionary analysis of many technological advancements display evident progress toward greater complexity, such as for the typical American passenger car over the past two decades that can be cast in terms of growing horsepower-to-weight ratios provided by the US Highway Traffic Safety Administration: $\Phi_m = 5.9 \times 10^5$ erg/s/g in 1978, 6.8×10^5 in 1988, and 8.3×10^5 in 1998. Not surprisingly, silicon chips – a cultural icon of today’s vibrant, digitized 21st-century economy – have immense flows of energy density, currently reaching values of $\sim 10^{10}$ erg/s/g mostly caused by chip miniaturization despite reduced power consumption.

Rare exceptions in cultural evolution’s apparent drive toward greater complexity sometimes cause regression to-

ward simpler systems, much as for minor aspects of the physical and biological subsets of cosmic evolution. Collapse of civilizations, either internally (because of societal conflict) or externally (owing to environmental change), that then resort to social chaos is are examples of infrequent retreat from society's overall drive toward greater complexity [20,67].

Occasional exceptions aside, increasingly sophisticated technological gadgets, under the Lamarckian pressure of dealer competition and customer selection, do in fact show increases in Φ_m values with product improvement over the years. Not only can the cultural evolution of machines be traced and their Φ_m values computed as noted above for engines, but similar advances can also be tracked for a whole array of silicon-based devices now undating our global economy. In keeping with the upper part of the curve in Fig. 6, many of these cultural devices do have complexity measures comparable to, and often greater than, biological systems, including brains. Technology clearly allows individual humans to accomplish things that cannot be done by us alone, and usually faster too, which partly explains why most of society continues to embrace technology, despite its pitfalls, to aid our senses and improve our increasingly complex lives.

Conclusions and Future Directions

This article has taken the liberty of extrapolating the word "evolution" in an intentionally broad way to analyze change on all spatial and temporal scales. Within the grand context of cosmic evolution, common threads have been identified linking a wide spectrum of ordered structures during an extremely long period of natural history, from big bang to humankind. More than any other single factor, energy flow seems to be a principal means whereby Nature's diverse systems naturally became increasingly complex in an expanding Universe, including not only galaxies, stars and planets, but also lives, brains and civilization.

The scenario of cosmic evolution accords well with observations demonstrating an entire hierarchy of structures to have emerged, in turn, throughout the history of the Universe: particles, galaxies, stars, planets, life, intelligence, and culture. As a general trend, an overall increase in complexity is apparent with the relentless march of time, without any progress, purpose or design implied. With cosmic evolution as our guide, we can begin to understand the environmental conditions needed for matter to have become increasingly ordered, organized, and complex. This rise in order, form, and structure violates no laws of physics, and certainly not those of modern thermodynamics. Nor is the idea of ubiquitous change novel to

modern worldviews. What is new and exciting is the way that frontier, non-equilibrium science now helps us unify a holistic cosmology wherein complex life plays an integral role – namely, to address the origin and evolution of all things by means of logic, rationality, and the methods of natural science.

When studying complexity in Nature, some researchers prefer the concept of information rather than energy, often becoming displeased when the former is put aside as done in this article. But information content has had a muddled history full of assorted interpretations – meaningful information, the value of information, Shannon information, algorithmic information, raw information. Furthermore, no one has yet shown quantitatively and unambiguously, that information content rises throughout the ages for physical, biological, and cultural systems. A useful future research direction would clarify the role of the information sciences in complexity studies and cosmic evolution, including the possibility that information is merely other forms of energy – energy acquired, energy stored, and energy expressed.

By contrast, it is encouraging that a single quantity such as free energy rate density, defined here clearly and with units well understood, affects all ordered systems, given that some systems are regulated by gravity and others practically not. Thermodynamics does pertain to all such systems universally, whether massive enough like stars subject to gravity or less so as for life-forms governed mostly by electromagnetism. Energy flow is a common feature of every open, non-equilibrium system, and it is insightful not only that one such quantity is uniformly applicable but also that it seems to map reasonably well the rise of complexity among many known systems. Gravitational force in physics, natural selection in biology, and technological innovation in culture are all examples of diversified actions that can give rise to accelerated rates of change at locales much smaller than the Universe per se – such as the islands of order that are stars, life, and civilization itself. Indeed, our use of energy wisely and optimally will likely guide our fate along the future arrow of time, for we humans are also part of the cosmic-evolutionary scenario.

Humankind is now moving toward a time, possibly as soon as within a few generations, when we shall no longer be able to expect Nature to easily provide for our own survival. Rather, civilization on Earth will either have to adapt to the natural environment with ever-accelerating speed, or to generate artificially controlled environments (either on or beyond Earth) needed for our ecological existence. From two of Nature's most advanced yet locally ordered systems – society and machines – will likely emerge

a symbiotic technoculture, the epitome (thus far as best we know) of complexity in the Universe – a new technology-based system that will likely require even greater values of energy rate density, as the curve in Fig. 6 continues racing upward. Can humanity endure despite its own increasing complexity? Or will our species transform into some other intricate entity as complexity continues to rise?

I thank *la Fondation Wright de Geneve* for support and encouragement of this research, which comprises the intellectual theme of the Wright Center for Science Education at Tufts University. The author is also associated with the Harvard College Observatory, where he teaches a course on the topic of cosmic evolution and complexity science, for which a multi-media web site has been built http://www.tufts.edu/as/wright_center/cosmic_evolution.

Chiral, achiral and racemic A molecule is chiral if its three-dimensional structure is different from its mirror image. Such molecules tend to be optically active and turn the polarization plane of linearly polarized light in the right- or left-handed sense. Correspondingly, they are referred to as D- and L-forms, which stand for dextrorotatory and levorotatory molecules. An achiral molecule is mirror-symmetric and does not have this property. A substance is racemic if it consists of equally many left- and right-handed molecules. A polymer is said to be isotactic if all its elements have the same chirality.

Enantiomers and enantiomeric excess Enantiomers are a pair of chiral molecules that have opposite handedness, but are otherwise identical. Enantiomeric excess, usually abbreviated as e.e., is a normalized measure of the degree by which one handedness dominates over the other one. It is defined as the ratio of the difference to the sum of the two concentrations, so e.e. always falls between -1 and $+1$.

Epimerization and racemization Epimerization is a spontaneous change of handedness of one sub-unit in a polymer. Racemization indicates the loss of a preferred handedness in a substance.

Catalysis and auto-catalysis Catalysts are agents that lower the reaction barrier. A molecule reacts with the catalyst, but at the end of the reaction, the catalyst emerges unchanged. This is called catalysis. In auto-catalysis the catalyst is a target molecule itself, so this process leads to exponential amplification of the concentration of this molecule by using some substrate. Biological catalysts are referred to as enzymes.

Nucleotides and nucleic acids Nucleotides are monomers of nucleic acids, e. g., of RNA (ribonucleic acid) or DNA (deoxyribonucleic acid). They contain one of four nucleobases (often just called bases) that can pair in a specific way. Nucleotides can form polymers, and their sequence carries genetic information. One speaks about a polycondensation reaction instead of polymerization because one water molecule is removed in this step. Other nucleotides of interest include peptide nucleic acid or PNA. Here the backbone is made of peptides instead of sugar phosphate.

Peptides and amino acids Amino acids are molecules of the general form $\text{NH}_3\text{-CHR-COOH}$, where R stands for the rest, which makes the difference between different amino acids. For glycine, the simplest amino acid, we have R=H , so two of the bonds on the central C atom are the same and the molecule is, therefore, chiral. For alanine, R=CH_3 , so all four bonds on the central C atom are different, therefore this molecule is chiral. A peptide is a polymer generated through a polycondensation reaction of amino acids. Peptides are also referred to as proteins.

Solar constant and albedo The solar constant is the total flux of energy from the Sun above the Earth's atmosphere. Its current value is $S = 1.37 \text{ kW m}^{-2}$, but it was about 30% lower when the solar system was young (10^8 yr ago, say), so S is not a constant. The albedo A is the fraction of the Sun's energy that is reflected from the surface of the Earth, e. g., by clouds and snow and, to a lesser extent, by land masses and oceans.

Photosynthesis and carbon fixation Photosynthesis uses light to reduce CO_2 and to produce oxygen either as free molecular oxygen or in some other chemical form. This process removes CO_2 from the atmosphere and produces biomass, which is written in simplistic form as $(\text{CH}_2\text{O})_n$. This process is referred to as carbon fixation.

Life A preliminary definition of life involves replication and death, coupled to a metabolism that utilizes any sort of available energy. Life is characterized further by natural selection to adapt to environmental changes and to utilize available niches. A proper definition of life is difficult given that all life on Earth can be traced back to a single common ancestor. Any definition of life may need to be adjusted if extraterrestrial or artificial life is discovered.

Definition of the Subject

Astrobiology is concerned with questions regarding possible origins of life on Earth and elsewhere in the Universe. Although to date there has been no detection of extraterrestrial life, it is generally assumed that life could be widespread, provided certain conditions of habitability are met. A common implicit hypothesis in astrobiology is that life can emerge spontaneously once certain environmental conditions are met. This implies that there may well have been multiple geneses, separated only by global extinction events, such as major impacts by other celestial bodies [11].

Four important discoveries can be named that have provided impetus to the field of astrobiology.

1. More than 300 extrasolar planets have been discovered since 1995, providing explicit targets for detecting life outside the solar system.
2. Recent Mars missions have provided evidence for liquid water on the surface of Mars in the past and possibly even in the present time. This has fostered the search for techniques to detect microbial life on Mars.
3. On earth the carbon in very old sedimentary rocks dating back 3.8 Gyr ago shows a consistently lower ^{13}C to ^{12}C abundance ratio, which is normally indicative of life. This lends support to the notion that life may have been present as soon as the Earth's surface became hospitable.
4. The discovery of extremophiles on Earth has considerably extended the definition of habitability to include extreme temperatures, pressures and pH values, high salinity as well as high radiation levels. This has raised hopes of finding life elsewhere in our solar system.

Astrobiology thus comprises several scientific disciplines: astronomy, geology, chemistry, and biology. Therefore, much of the original literature tends to appear in journals in these various fields. We should also mention that there are technological attempts being made to produce artificial life [35]. While this approach is not aimed at reproducing the origin of life on Earth, it may still be useful for prompting our imaginations in understanding the transition from nonliving to living matter.

Introduction

Since the early days of nonlinear dynamics and non-equilibrium thermodynamics, it has been clear that one of the ultimate applications of this theory might be to facilitate an understanding of the transition from non-living to living matter. The main reason is obviously that living systems are very far from equilibrium – as indicated by the high degree of order, and hence the low entropy, of living systems relative to their environment.

As early as 1952, Turing [44] proposed the idea that chemical reaction-diffusion systems might provide a tool for studying biochemical pattern formation, which has increased our understanding of the laws of nature far from equilibrium, where life occurs. This idea was followed up in the late 1960s by Prigogine [33,34] who suggested that dissipative structures have great importance in establishing a physical description of living matter. A general theory of autocatalytic molecular evolution was developed in 1971 by Eigen [15], who argued that in a single micro-environment, only a single handedness can result from a single event. In particular, the famous chicken and egg problem that occurs in biology at different levels was identi-

fied as a Hopf bifurcation. A Hopf bifurcation describes the spontaneous emergence of an oscillating solution once some stability threshold has been crossed. The mathematics of this is familiar to any physicist, but it requires that the equations describing the relevant physics are known. In biology, it is not even clear that the various phenomena can be described by equations. A first detailed attempt in this direction was, indeed, that of Eigen. However, the equations governing the emergence of life are only phenomenological ones. Nevertheless, these approaches are invaluable in that they help give the origin of life question a mathematical basis.

One of the earliest anticipated forms of life that is still similar to present life is the RNA world [21], whereby simple RNA molecules with functional behavior self-reproduce using genetic information encoded either in the same or in other participating RNA molecules. Obviously, there are tremendous difficulties, given that RNA is too complicated a molecule to be synthesized abiologically. A significantly simpler molecule is peptide nucleic acid or PNA [30], in which the backbone consists of peptide instead of sugar phosphate. Nevertheless, the difficulty of producing RNA remains.

There is no firm idea where on Earth such molecular replication may have originally taken place. Frequently discussed scenarios include hydrothermal vent systems [37], and also beach scenarios that are subject to tides leading to cyclic changes in concentration [24] as well as to repeated wetting and drying [7].

An early experiment that contributed significantly to the research into the origins of life was the Urey–Miller experiment [26], which demonstrated the spontaneous production of amino acids in a reducing atmosphere consisting of H₂O vapor, CH₄, NH₃, and H₂ with an energy supply in the form of sparks. More recent experiments also allow for the presence of CO₂, which now seems unavoidable on the early Earth, given that it is continuously replenished through outgassing by volcanoes.

In the following, we review some areas in which there has been considerable cross-fertilization between astrobiology and nonlinear dynamics. We begin by discussing a phenomenon that is believed to have taken place around the time of the origin of life, namely the establishment of a definitive handedness of biomolecules that is inherent in DNA and RNA (D-form) and in amino acids (L-form). Next, we discuss constraints on the evolution of hereditary information and, finally, we review some models that characterize the alteration of the terrestrial environment by early life. In addition to any of these physical effects, random fluctuations lead inevitably to local imbalances between the concentrations of molecules of D- and L-form.

In the following, we discuss mechanisms that can lead to an exponential amplification of enantiomeric excess. For a recent review of these ideas see [32].

Homochirality

Theories of a chemical origin of life involve polymerization of nucleotides that carry and utilize genetic information. Ribonucleotides possess chirality, i. e., they are different from their mirror images. All known life forms use ribonucleotides of the so-called D-form (right-handed), as opposed to the L-form (left-handed). These two molecules are referred to as opposite *enantiomers*. In most cases these different enantiomers are optically active, i. e., they turn the polarization plane of linearly polarized light in a right-handed or left-handed sense.

Any non-enzymatic synthesis of ribonucleotides would have produced a mixture of equally many right- and left-handed building blocks. Technically this is referred to as a *racemic* mixture of these molecules. However, it is known experimentally that, in a racemic mixture of mononucleotides, polymerization is quickly terminated after the first or second polymerization step [23]. This is generally referred to as *enantiomeric cross-inhibition*, which was long thought to be a serious obstacle to a chemical origin of life. It was therefore thought to be necessary that life evolved only in a homochiral environment. Moreover, it would then be necessary that the degree of enantiomeric purity must have been very high. This is important because it rules out a number of physical mechanisms based on the enantioselective effects of circularly polarized radiation, magnetic fields, and the parity-breaking property of the electroweak force.

The Frank-Mechanism

A general mechanism for producing complete homochirality was proposed in 1953 by Frank [19] based on the assumed effects of auto-catalysis and what he called mutual antagonism. In fact, the enantiomeric cross-inhibition mentioned above can be thought of as a possible example of mutual antagonism. Frank's model is characterized by the following set of three reactions:

where *D* and *L* denote monomers of the two enantiomers, *S* is a substrate from which monomers could be formed

via auto-catalysis, and DL are inactive dimers that are lost from the system. (At this level of simplification no distinction is made between DL and LD . This simplification will later be relaxed.) The parameters k_C and k_I characterize the reaction speeds. These reactions translate to the following set of equations for the concentrations of D , L , S , and DL ,

$$\frac{d}{dt}[D] = +k_C[S][D] - k_I[D][L], \quad (4)$$

$$\frac{d}{dt}[L] = +k_C[S][L] - k_I[D][L], \quad (5)$$

$$\frac{d}{dt}[S] = -k_C[S]([D] + [L]), \quad (6)$$

$$\frac{d}{dt}[DL] = +2k_I[D][L]. \quad (7)$$

These equations imply that the total mass of all building blocks (including the substrate), is constant, i.e. $[D] + [L] + [S] + [DL] = \text{const} \equiv M$.

This system of equations describes the continued autocatalytic production of DL , D and L until the substrate S is exhausted, i.e., $[S] = 0$. However, as long as $[S]$ is still finite, the asymmetry, $\mathcal{A} = [D] - [L]$, grows quasi-exponentially, proportional to $\exp(\int [S] dt)$. A numerical example of this is shown in Fig. 1.

Exobiology (theoretical), Complexity in, Figure 1

Solution of Eqs. (4)–(6) for $k_I = k_C$. Both D and L grow exponentially until $[D] + [L]$ becomes comparable to the constantly declining substrate concentration $[S]$. At the same time the production of DL removes an equal amount of D and L , but this effect primarily affects those enantiomers that are already in the minority. In this calculation an initial asymmetry (here 10%) of $[D] - [L]$ grows until saturation. At the end, $[D]$ has reached 100% enantiomeric excess, but this happened at the expense of producing a large number of inactive heterochiral dimers DL .

In the numerical example above, we started with very small initial concentrations. Another possibility is to start with a perturbed racemic solution. The racemic solution is given by $[D] = [L] = \lambda/k_I$, where $\lambda = k_C[S]$ is the instantaneous growth rate due to auto-catalysis. Under the assumption that λ can be treated as a constant (i.e., when the system is still nearly racemic), a linear stability analysis shows that the enantiomeric excess,

$$\text{e.e.} = \frac{[D] - [L]}{[D] + [L]} \quad (8)$$

grows exponentially. This means that the racemic solution is unstable and that the mechanism for achieving homochirality is based on a linear instability.

Continued Polymerization

There is a priori no good reason to permit the production of heterochiral dimers DL , but not homochiral dimers DD and LL , i.e.,

The importance of such reactions was stressed in a review by Blackmond [1], who also introduced an additional modification that consists in the assumption that, rather than monomers, the homochiral dimers DD and LL catalyze the production of monomers, i.e., reactions (1) and (2) are replaced by

This model is similar to the original Frank model provided there is a way of getting rid of those homochiral dimers that are in the minority. This requires enantiomeric cross-inhibition for dimers to form heterochiral trimers, i.e., we need the additional reactions

A solution to the corresponding reaction equations is given in Fig. 2. Reaction calorimetry supports the assumption that dimers and not monomers are the relevant catalysts [1]. This seems to apply, in particular, to the first autocatalytic reaction ever found that enhances enantiomeric excess [42]. In this reaction (sometimes referred to as the Soai reaction), the substrate is pyridine-3-carbaldehyde and the chiral molecule of either D- or L-form is 3-pyridyl

Exobiology (theoretical), Complexity in, Figure 2

Solution of Eqs. (4), (6) supplemented by kinetic equations corresponding to the reactions Eqs. (9), (14), for $k_S = k_I = k_C$. Again, an initial 10% asymmetry of $[D] - [L]$ grows until $[D] + [L]$ becomes comparable to the constantly declining substrate concentration $[S]$. The monomers polymerize into dimers DD and LL . Toward the end, $[DD]$ reaches 100% enantiomeric excess

alkanol, which thus acts as an asymmetric autocatalyst to produce more of itself. In this reaction, however, dialkylzinc acts as an additional achiral catalyst. While the Soai reaction is important as a first explicit example of an autocatalytic reaction that enhances the enantiomeric excess, it is not normally regarded as directly important for astrobiology.

The polymerization model was developed by Sanders [39], who included arbitrarily many polymerization steps of the form

The basic outcome of this and similar models is always the same as in the original Frank model, except that the polymerization model is also capable of displaying interesting wave-like dynamics in time-dependent histograms of different polymers [5].

Spatially Extended Models

In reality, there are limits as to the degree to which a system can be considered fully mixed. In general, $[D]$ and $[L]$

should be functions of time *and* space, i. e. $[D] = [D](t, \mathbf{x})$ and $[L] = [L](t, \mathbf{x})$. Assuming that there is only molecular diffusion, the relevant reaction equations are to be supplemented by additional diffusion terms,

$$\frac{d}{dt}[D_n] = R_n^{(D)} + \kappa \nabla^2 [D_n], \quad (19)$$

$$\frac{d}{dt}[L_n] = R_n^{(L)} + \kappa \nabla^2 [L_n], \quad (20)$$

where $R_n^{(D)}$ and $R_n^{(L)}$ are the right hand sides of the reaction equations.

If there were only one type of handedness, the resulting equation would be reminiscent of the Fisher equation [29],

$$\frac{df}{dt} = \lambda(1 - f)f + \kappa \nabla^2 f, \quad (21)$$

which admits propagating front solutions with front speed $v_{\text{front}} = 2\sqrt{\kappa\lambda}$. Here, f could represent the local concentration of some disease in models of the spread of epidemics, for example.

In the present case, there are two fields, one of each handedness. It is instructive to refer to these fields as populations, which is suggestive of their ability to replicate, migrate, become extinct, and to compete against a population of opposite handedness. Each population is able to expand into unpopulated space at a speed given approximately by v_{front} , but once two opposing handednesses come into contact, there is an impasse and the propagation comes to a halt. A snapshot of a one-dimensional model illustrating polymer length as a function of position is shown in Fig. 3 for populations of opposite handedness that have come into contact.

The overall dynamics of symmetry breaking are well characterized by a low order truncation, where the model is truncated at $n = 2$ and the evolution of the $n = 1$ modes is assumed to be enslaved by the evolution of the $n = 2$ modes [5]. An example of such a solution is shown in Fig. 4, which shows the evolution in a space-time diagram, where two populations of opposite handedness expand into unpopulated space until two opposite populations come into contact.

In two and three dimensions, a front between two opposing enantiomers is (in general) curved, in which case it can propagate diffusively in the direction of curvature. This is caused by the fact that the inner front between two populations is slightly shorter than the outer one. (Only the immediate proximity of a front matters; what lies behind it is irrelevant if it is of the same handedness.) Indeed, on a two-dimensional surface the inner front is shorter than the outer one by $2\pi d$ – independent of radius. Here, d is the front thickness, which is of the order of $d \approx (\kappa/\lambda)^{1/2}$.

Exobiology (theoretical), Complexity in, Figure 3

Color/gray scale plots of $[D_n]$ and $[L_n]$ for $t/\tau_{diff} = 0.8$ as a function of x and n , and the corresponding dependencies of $\sum_{n=1}^N n[D_n]$ and $\sum_{n=1}^N n[L_n]$ (solid line), compared with $\frac{1}{2}N \sum_{n=1}^N [D_n]$ and $\frac{1}{2}N \sum_{n=1}^N [L_n]$ (dashed line), and $\frac{1}{4}N^2 [D_1]$ and $\frac{1}{4}N^2 [L_1]$ (dotted line), all in units of $(Q/k_S)^{1/2}$. The normalized diffusivity is $\kappa/(L^2 \lambda_0) = 10^{-2}$ and $N = 20$. Adapted from [4]

It turns out that in two dimensions the rate of change of the integrated asymmetry, $\mathcal{A} = \int ([D] - [L]) d^2x$, depends only on the number of topologically distinct rings or islands. Once an island is wiped out, the rate of change of \mathcal{A} changes abruptly and then stays constant until the next island gets wiped out. So the enantiomeric excess,

$$e.e. = \frac{\int ([D] - [L]) d^2x}{\int ([D] + [L]) d^2x}, \tag{22}$$

increases with time in a piecewise linear fashion.

Even if at each point homochirality could be reached rapidly (time scale λ^{-1}), global homochirality requires that one population wipes out the other one completely. Diffusion is usually too slow to lead to any significant mixing and hence to global homochirality. However, there could be circumstances where such mixing is sped up by

Exobiology (theoretical), Complexity in, Figure 4

Profile of $[D](x, t_*)$ and space-time diagram of $[D](x, t)$ for the one-dimensional problem without advection and an initial perturbation corresponding to a weak (amplitude 0.01) right-handed excess at $x/L = 0.1$ (marked in white or yellow) and a somewhat stronger (amplitude 0.3) left-handed excess at $x/L = -0.1$ (marked in dark or blue). Note the propagation of fronts with constant speed if the exterior is racemic (i.e. $[D] = [L] = 1/2$, shown in medium shades or red) and a non-propagating front when the chirality is opposite on the two sides of the front. The normalized diffusivity is $\kappa/(L^2 \lambda_0) = 10^{-2}$, i.e. the same as in Fig. 3. Adapted from [4]

something like “turbulent” transport. In the case of the Earth, the slowest relevant transport is in the Earth’s mantle, part of which is now associated with what is called the deep biosphere. Assuming that multiple geneses of life is possible, this would raise the question of whether a simultaneous co-existence of different handednesses on different parts of the early Earth would have been possible. It is, however, unclear whether this possibility could have left any traces that would still be detectable today.

Another approach to solving the problem of spatially extended chemistry is by means of cellular automata. In this approach, points on a mesh can take different states corresponding to molecules of right or left handedness, achiral substrate molecules, or even empty states. An example of such a calculation by Shibata et al. [41] is shown in Fig. 5. Again, there are patches of populations of opposite handedness that grow and wipe each other out, such that in the end only one handedness survives.

Exobiology (theoretical), Complexity in, Figure 5

The evolution of molecules of D- and L-forms is shown in the upper and lower panels, respectively. Note the tendency toward complete homochiralization by gradually filling up isolated islands with the chirality of the surrounding molecules. The dimensionless times are 50, 250, and 1750 from left to right. Adapted from [41]

Epimerization

An interesting alternative to the Frank-type mechanism is a set of reactions based primarily on a phenomenon called epimerization, i. e., the spontaneous change of handedness in one part of the polymer. This mechanism is important in the chemistry of amino acids. Plasson et al. [31] identified four reactions: activation, polymerization, epimerization, and depolymerization as necessary ingredients that can, under certain conditions, lead to an instability of the racemic state with a bifurcation toward full homochirality. They called this the APED model, whose reactions can be summarized as follows:

A: activation:

P: polymerization:

E: epimerization:

D: depolymerization:

This minimal subset of reactions is shown in Fig. 6.

Compared with the Frank model, a major advantage of the APED model is that no hypothetical auto-catalysis is required. Indeed, all these reactions exist in principle, although it is as yet unclear what kind of manipulation of the environment is required to make all these reactions happen. Another advantage is that the system is closed, so no inflow or outflow of matter is required. The system is maintained away from equilibrium by energy input through the activation of amino acids.

Given that there is neither auto-catalysis nor enantiomeric cross-inhibition, one wonders whether the APED model still shares some similarities with Frank's original model. Some degree of similarity is immediately seen by writing the APED reactions in sequential form in one line, i. e.,

This shows that, as long as the reaction rates for epimerization and depolymerization are not limiting factors, we

Exobiology (theoretical), Complexity in, Figure 6
Representation of the minimal set of reactions necessary for allowing a spontaneous transition to homochirality. Adapted from [6]

have essentially the reactions

This way of writing these reactions emphasizes the roles of *L* and *D* in catalyzing the conversion of *D** into *L* and *L** into *D*, respectively. Just like the mechanism of mutual antagonism, these reactions disfavor a racemic state, but instead of producing unreactive waste, these reactions produce directly one of two possible homochiral states.

In addition, there are reactions of the form

These reactions simulate the autocatalytic conversion of *L** into *L* by *L* and of *D** into *D* by *D*. Again, linear analysis establishes that the racemic state is unstable provided α is in the range $0 < \alpha < 1$; see [6,31].

In conclusion we can say that the homochirality of life-bearing molecules might well have originated from the chemical reactions that led to their formation. Thus, the hypothetical RNA world may have been born into an environment surrounded by homochiral peptides (as described in Sect. “Epimerization”), or, alternatively, homochirality may have emerged as a consequence of enantiomeric cross-inhibition during the first stages of the RNA world (as discussed in Sect. “Continued Polymerization”).

In the next section we discuss some issues regarding possible strategies for establishing a primitive information-carrying system. This is also based on catalysis, but catalysis in the production of molecules other than itself.

Establishing Hereditary Information

So far, we have ignored the fact that polymers can consist of different amino acid or nucleotide units, even though they would all have the same handedness. Therefore, such molecules could, in principle, carry information. Once such polymers can replicate, the question arises as to how to prevent them from becoming extinct due to errors in the copying process, and, instead, how to allow them to compete against parasites. It is generally believed that early self-replicating systems had a substantial error rate associated with each replication event. A certain error rate is obviously necessary for facilitating Darwinian evolution by natural selection, but it must be small enough to prevent extinction.

Assuming that with each generation a species produces σ offspring where the length of the genome is *N* bits, and that the probability for a copying error at any position in the genome is *p*, the necessary condition for long-term survival is given by [15,16]

$$pN < \ln \sigma. \tag{33}$$

The significance of this formula is illustrated in Fig. 7 with the help of a numerical example where the selective advan-

Exobiology (theoretical), Complexity in, Figure 7
Number of survivors as a function of the number of generations in a numerical example with an error rate of $p = 0.01$. This initial number of survivors is 1000. Note that for a genome length of $N = 70$ and 71 , the population dies out after 1800 and 400 generations, respectively. For $N = 69$ and less the number of survivors increases exponentially. This is compatible with the survival criterion $N \lesssim (\ln 2)/0.01 = 69.3$, derived from Eq. (33)

tage (i. e., the multiplication factor) is chosen to be $\sigma = 2$, the error rate is $p = 0.01$, and four different values of N between 68 and 71 are used. In this numerical experiment, σ new offspring are produced, but with a probability p that an error is introduced at each of the N positions. Following an error, only the intact copies can produce further offspring.

According to Eq. (33) the maximum genome length is, with the parameters of our example, $(\ln 2)/0.01 = 69.3$. This is compatible with Fig. 7, which shows that the dividing line between extinction and long-term survival is between $N = 69$ and 70. For contemporary genomes N is of the order of 10^8 , and p is of the order of 10^{-8} [14], or below, depending on the efficiency of error-correcting mechanisms available in contemporary organisms.

The first replicating systems are likely to have rather high error rates and no correction mechanism, making it virtually impossible to carry sufficient information for building more complex replicators. This difficulty can be removed by invoking the concept of hypercycles [17], whereby the full genetic information is carried collectively by several smaller systems (smaller N), each one small enough to obey Eq. (33). Mathematically, such a system can be described by the following set of reactions [2]:

Assuming, furthermore, that resources are limited, the total number of molecules, $M = \sum_i [I_i]$, is taken to be constant, i. e., I_i is assumed to be siphoned off from the system at a rate ϕ that is independent of i . Mathematically, such a system can be described by the following set of ordinary differential equations:

$$\frac{d}{dt} [I_i] = r_i [I_i] + k_i [I_i][I_{i-1}] - \phi [I_i], \tag{36}$$

where

$$\phi = \sum_i (r_i [I_i] + k_i [I_i][I_{i-1}]) / \sum_i [I_i] \tag{37}$$

is the factor that keeps the total number of molecules constant. The kinetic coefficient r_i models the residual effects of birth and death, while k_i is the kinetic coefficient for the catalytic production of I_i , where I_{i-1} acts as a catalyst. The evolution of number densities in a model of five hypercycles is shown in Fig. 8 for a case in which all $k_i = k$ and $r_i = r$ are chosen to be the same for all values of i .

An interesting situation arises when the effects of parasites are included. Boerlijst & Hogeweg [2] considered an

Exobiology (theoretical), Complexity in, Figure 8
Evolution of the number densities of five hypercycles with equal parameters. Note that peaks of I_1 (solid line) are followed by peaks of I_2 (dotted line) and I_3 (dashed line), and so forth. Time is measured in units of r^{-1} and concentrations are measured in units of r/k

Exobiology (theoretical), Complexity in, Figure 9
Sketch showing the coupling of several hypercycles together with a parasite coupled to species I_2 . Adapted from [2]

example in which a parasite was coupled to I_2 ; see Fig. 9. The effect on the above model is shown in Fig. 10 where $k_{para} = 2k$ and $r_{para} = r$ have been chosen. One sees that not much happens for a long time when the parasite is turned on. This is because the parasite has to grow to a level at which it can affect the entire system. When this point is reached, all components of the system decay exponentially – including the parasite itself. Unfortunately, the system can never recover from this disaster, so the hypercycle theory seems to have a problem.

Again, spatial extent can significantly alter the situation. Using a cellular automata approach, Boerlijst & Hogeweg [2] and Boerlijst [3] showed that the nonlinear spatial dynamics of spiral waves gives the system stabil-

Spatial patterns in the cellular automata approach of Boerlijst and Hogeweg [2]. Courtesy of Boerlijst MC

ity against otherwise deadly parasitic species. Interestingly enough, this approach tends to produce spiraling interfaces between different species; see Fig. 11

These equations are, by nature, similar to other chemical reaction-diffusion equations where several different substances catalyze each other's reactions. A particularly exciting example is the famous Belousov-Zhabotinsky reaction, where malonic acid, $\text{CH}_2(\text{COOH})_2$ is oxidized in the presence of bromate ions, BrO_3^- . To initiate the reaction, cerium is used as a catalyst to donate ions, although other metal ions may also be used. The color depends on the state of the cerium as it changes from Ce^{3+} to Ce^{4+} or, if iron is used, from Fe^{2+} to Fe^{3+} . The resulting reactions are of the form [28]

where $X = \text{HBrO}_2$, $Y = \text{Br}^-$, $Z = \text{Ce}^{4+}$, $A = B = \text{BrO}_3^-$, P and Q are reaction products that do not contribute further to the reactions, and k_1, \dots, k_5 are known rate constants. The reactions above lead to kinetic equations of the form

$$\frac{\partial[X]}{\partial t} = k_1[A][Y] - k_2[X][Y] + k_3[A][X] - k_4[X]^2, \quad (43)$$

$$\frac{\partial[Y]}{\partial t} = -k_1[A][Y] - k_2[X][Y] + k_5[Z], \quad (44)$$

$$\frac{\partial[Z]}{\partial t} = 2k_3[A][X] - k_5[Z]. \quad (45)$$

This model of reaction equations is called the Oregonator, which refers to the affiliation of the authors at the time of publication [18].

If spatial extent is included via diffusion terms, this reaction exhibits, in certain cases, spiral patterns similar to those in the model of Boerlijst & Hogeweg [2]. In Fig. 12 we reproduce the pattern obtained by Zhang et al. [48] for a slightly modified model consisting of only two partial differential equations. Depending on the value of a certain control parameter in their model, spiral patterns of different size are produced. An extensive review of the physics of pattern formation in different settings is given by Cross and Hohenberg [10].

The connection between pattern formation and the origin of life may seem rather remote. However, the equations governing chemical pattern formation illustrate some of the critical steps that are thought to have played a role in the origins of life. In particular, the fact that different chemical compounds catalyze each other in a productive manner is an essential property behind the model proposed by Eigen. The Belousov-Zhabotinsky reaction also illustrates the phenomenon of auto-catalysis where, in the presence of A , the molecule X catalyzes the production of more X by using A as a substrate and producing Z as an additional side product.

The possibility of self-replication was demonstrated for simple RNA molecules by Spiegelman [27] back in the late 1960s. Now, there are examples of simple peptide chains that can catalyze the production of each other [38]. However, a serious shortcoming of any of the above examples is the fact that there is no possibility of natural selec-

Exobiology (theoretical), Complexity in, Figure 12

Spiral and ring-like patterns for the modified reaction equations by Zhang et al. [48]. On the boundaries a no-flux condition has been adopted, i. e., the normal components of all gradients vanish. Adapted from [48]

tion and hence Darwinian evolution. So, as far as the question of the origin of life is concerned, this pathway must be considered a dead end.

In summary, one can say that there are similarities in the mathematics of producing homochirality and in establishing hereditary information in the composition of the first replicating polymers. However, in the latter case, even less is known about the detailed nature of such polymers and their catalytic properties. A particularly important aspect is the possibility of spatial extent, which can substantially modify the behavior of any chemical system. In the present case, as shown in Ref. [2], the possibility of spatial extent is critical for stabilizing the system against destruction by parasites. The model also exhibits spiral pattern formation that has been at the heart of early work by Prigogine and others in connection with early ideas on biogenesis.

Alteration of the Environment by Early Life

In this last section, we discuss some physics problems within astrobiology that illustrate how life, once it has formed, might affect the environment of the early Earth and how it led to a planet so markedly different from a planet that does not harbour life.

Global Energy Balance of the Earth

The young Sun was about 30% fainter than today, and yet the young Earth was covered with liquid water and had temperatures higher than nowadays. This was caused by the presence of greenhouse gases such as water vapor, carbon dioxide, and probably methane. Life is responsible for reducing CO_2 to compounds of the form $(\text{CH}_2\text{O})_n$ and similar, and for oxidizing various minerals to produce O_2 . The resulting decrease of CO_2 weakens the greenhouse effect, so in this sense the emergence of life has an essentially cooling effect on the Earth's overall climate.

Without atmosphere, the planet would cool like a black body at a rate proportional to the local flux $\sigma_{\text{SB}} T^4$, where σ_{SB} is the Stefan–Boltzmann constant. Integrated over the entire surface of the planet, this corresponds to a loss of $4\pi R_{\text{E}}^2 \sigma_{\text{SB}} T^4$, which would need to be balanced against the rate of energy received by solar radiation. The solar “constant” is $S = 1.37 \text{ kW m}^{-2}$ and the total energy projected onto the disk of the Earth is $(1 - A)\pi R_{\text{E}}^2 S$, where A is the albedo, i. e., the fraction of energy reflected from the Earth. The resulting blackbody temperature would be

$$T_0 = \left[(1 - A) \frac{S}{4\sigma_{\text{SB}}} \right]^{1/4}. \quad (46)$$

Using $A = 0.3$ and $\sigma_{\text{SB}} = 5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-1}$, the temperature of the Earth would be 255 K or about -18°C .

In the presence of an atmosphere, the rate of cooling is modified to $\sigma_{\text{SB}} T_{\text{eff}}^4$, where T_{eff} is the effective temperature equivalent to that of a black body. A positive greenhouse effect corresponds to $T_{\text{eff}} < T$, so the cooling is reduced and the atmosphere heats up according to the vertically integrated energy equation

$$C \frac{dT_0}{dt} = (1 - A) \frac{S}{4} - \sigma_{\text{SB}} T_{\text{eff}}^4, \quad (47)$$

where C is the vertically integrated specific heat.

The value of the effective temperature can be obtained from a radiative transfer calculation. A simplified model calculation¹ yields

$$T_{\text{eff}}^4 = \frac{\ell}{\ell_{\text{crit}}} T_0^4, \quad (48)$$

¹Under the assumption of local isotropy (Eddington approximation) radiative equilibrium implies that the flux is proportional to the negative gradient of the radiative energy density aT^4 , where a is the radiation-density constant, so

$$F = -\frac{1}{3} c \ell \nabla(aT^4).$$

Here, c is the speed of light and ℓ is the mean free path of photons. The latter can be expressed in terms of the opacity κ and the density ρ

where T_0 is the surface temperature, ℓ is an averaged mean free path of photons and ℓ_{crit} is the critical value above which there is a positive greenhouse effect. Again, a simplified calculation suggests $\ell_{\text{crit}} = 3H/16 \approx 0.19H$, where $H = \mathcal{R}T/(\mu g) \approx 8 \text{ km}$ is the pressure scale height of the atmosphere. So, an increase in opacity leads to a decrease of the cooling and hence to an increase in the surface temperature.

Another interpretation is that the greenhouse gases shift the radiating surface by a certain amount, ℓ_g , upward. The value of ℓ_g is related to ℓ . Ditlevsen [13] uses $\ell_g = 3 \text{ km}$. He also noted that a more accurate lapse rate of the temperature is $dT/dz = 10 \text{ K km}^{-1}$ instead of $T_0/H = 40 \text{ K km}^{-1}$, so that the temperature gain caused by greenhouse gases is $\ell_g \times dT/dz = 30 \text{ K}$. The reason for a shallower temperature gradient is the presence of convection that causes the specific entropy s to be nearly constant with height. In that case the temperature gradient is just the adiabatic one, $(dT/dz)_{\text{ad}} = g/c_p$, where c_p is the specific heat at fixed pressure, which in turn is related to the universal gas constant and the specific weight via $\mathcal{R}/\mu = c_p - c_v$, where c_v is the specific heat at fixed volume and $c_p/c_v = \gamma$ is the ratio of specific heats. With these formulae one does indeed get ²

$$\left(\frac{dT}{dz}\right)_{\text{ad}} = \left(1 - \frac{1}{\gamma}\right) \frac{\mu g}{\mathcal{R}} \approx 10 \text{ K km}^{-1}, \quad (49)$$

where we have used $\gamma = 7/5$ for air molecules with 5 degrees of freedom (3 for translation and 2 for rotation).

At certain times over the history of the Earth, other greenhouse gases such as methane may have played an important role in keeping the Earth above freezing temperatures. Indeed, the burial of oxides in the crust allowed methane to build up in the atmosphere, which may have led to concentrations of a few thousand times greater than modern levels. UV radiation in the upper atmosphere

as $\ell = (\kappa\rho)^{-1}$. Hydrostatic equilibrium can be written in the form

$$g = -\frac{\mathcal{R}}{\mu} \nabla T,$$

where \mathbf{g} is the gravitational acceleration, \mathcal{R} is the universal gas constant, and μ is the mean molecular weight. These equations can be solved by a polytrope, i. e., $T = T_0(1 - z/H)$ and $\rho = \rho_0(1 - z/H)^3$, where z is the distance from the surface and H is the vertical pressure scale height. This leads to a condition of the form Eq. (48) where $\ell_{\text{crit}} = 3H/16 \approx 0.19H$ is the critical mean free path of photons

²Hydrostatic equilibrium can be written as $-\rho^{-1}\nabla p - \nabla\phi = 0$, where p is the pressure and $\phi = gz + \text{const}$ is the gravitational potential. Using the thermodynamic relation $-\rho^{-1}\nabla p = -\nabla h + T\nabla s = 0$, where $h = c_p T$ is the specific enthalpy and $\nabla s = 0$ for adiabatic stratification, we have $d(c_p T)/dz = g$

breaks up methane into its components, letting H_2 escape into space, leading to a net gain of oxygen, that comes ultimately from H_2O .

According to a model of Catling et al. [8] methane (CH_4) may have been important 2.7...2.3 Gyr ago, just before the famous Snowball Earth deep freeze of the planet [22]. As discussed above, the associated loss of hydrogen may have led to a gradual accumulation of oxygen in the atmosphere, which then terminated the methane era and led to the Snowball Earth event. This event lasted until the continuous CO_2 production from volcanoes accumulated to large amounts so that the resulting greenhouse effect became sufficient to initiate partial melting of the ice cover.

Response to Changes in Greenhouse Gases

As we knew first from global climate models [20] and later from simplified models [9] using Eq. (47), with a relatively simple piecewise linear temperature dependence of $A(T)$, there can be three different equilibrium temperatures. This is illustrated in Fig. 13, where we compare the graph of $\sigma_{\text{SB}} T_{\text{eff}}^4$ versus surface temperature T_0 with the net radiation $(1 - A)S/4$. Here, $A(T)$ has been arranged such that $A = A_{\text{hot}}$ for $T \geq T_{\text{max}}$ (corresponding to no ice coverage) $A = A_{\text{cold}}$ for $T \leq T_{\text{min}}$ (corresponding to full ice coverage).

Ditlevsen [13] used Eq. (47) to study the response of the system to variable greenhouse gas concentrations. As the amount of CO_2 increases, the equilibrium temperature increases. Obviously, when the system is on the lower fixed point initially, there must be a critical CO_2 concentration above which the solution will jump discontinuously to the upper branch; see Fig. 14.

It is generally accepted that the rate of weathering increases with increasing temperature. This provides a stabilizing effect on the climate. As T increases, the rate of weathering increases, removing more CO_2 from the atmosphere, reducing the greenhouse effect, and thus leading to cooling. Ditlevsen [13] introduced the assumption that there is a continuous source of CO_2 through outgassing from volcanoes and a temperature-dependent sink of CO_2 from weathering when T exceeds a critical temperature T_w , but no weathering for $T < T_w$ [46]. This leads to a self-regulating effect for $T < T_w$, which Ditlevsen calls a greenhouse thermostat. Whenever $T < T_w$, since there is then no weathering and hence no sink of CO_2 , greenhouse gases will build up until the Earth's temperature has reached the value T_w ; see Fig. 15. This is the mechanism that is believed to have caused the early Earth to be above freezing through most of its history – with the

Exobiology (theoretical), Complexity in, Figure 13

Plot of $\sigma_{SB} T_{\text{eff}}^4$ versus surface temperature T_0 for three different greenhouse temperature shifts, T_g , compared with the net radiation $\frac{1}{4}(1 - A)$ for a simple piecewise linear function $A(T)$. Courtesy of P. Ditlevsen [13]

Exobiology (theoretical), Complexity in, Figure 14

Equilibrium temperature as a function of CO_2 concentration. Courtesy of P. Ditlevsen [13]

exception of intermediate Snowball Earth-like events that are caused by the emergence of other sinks of greenhouse gases, such as the onset of aerobic photosynthesis or the enhanced formation of mountain topography that leads to an increase in the erosion rate and, hence, weathering.

The Daisyworld Model

Life can also affect the planet's albedo, as has been demonstrated by Lovelock [47] in his Daisyworld model. For a tutorial on the Daisyworld model see [45]. This model also makes use of Eq. (47), but now the planet's albedo A is af-

Exobiology (theoretical), Complexity in, Figure 15

Dependence of surface temperature on time under the assumption of a continuous source of outgassing of CO₂ and the onset of a CO₂ sink for $T > T_w$. Courtesy of P. Ditlevsen [13]

ected by the plant population which is simplistically represented by black and white plants or flowers (daisies) with local albedos A_1 and A_2 , respectively. So the total albedo is a weighted average of the form

$$A = \sum_{i=1}^3 \alpha_i A_i, \tag{50}$$

where A_3 is the albedo of the unpopulated surface. The weights α_i depend on the surface coverage of the respective regions and obey evolution equations that are, in turn, governed by a temperature-dependent growth term, $\beta(T_i)$, and a fixed death rate, γ . The resulting equations for the rate of change of the albedo are

$$\frac{d\alpha_i}{dt} = [\beta(T_i) - \gamma]\alpha_i, \tag{51}$$

where $i = 1$ for black and $i = 2$ for white plant populations, $\beta(T)$ is assumed to be different from zero in the range $T_{\min} < T < T_{\max}$ with a maximum at $T_{\text{aver}} = \frac{1}{2}(T_{\min} + T_{\max})$. The weight for the unpopulated surface follows from the normalization $\sum \alpha_i = 1$, so $\alpha_3 = 1 - \alpha_1 - \alpha_2$.

The temperatures are higher in the regions of black plants and lower in regions of white plants according to the formula

$$T_i^4 = (A - A_i)q + T_0^4, \tag{52}$$

where q is a parameter that must be smaller than a critical value,

$$q < q_{\text{crit}} = S/(4\sigma_{\text{SB}}), \tag{53}$$

in order that heat flows against the temperature gradient [40]. For $q = q_{\text{crit}}$ the temperature is uniform for different values of A_i , while for $q < q_{\text{crit}}$ the regions of high albedo are cooler and those of low albedo warmer. Note also that Eq. (52) preserves heat balance, i. e., $\sum \alpha_i T_i^4 = T_0^4$.

The important point in the Daisyworld model is the fact that, for a certain range of S , the surface temperature of the planet, T_0 , is stabilized in a certain temperature range around the optimal value close to T_{aver} ; see Fig. 16.

Saunders makes another remarkable point. He showed that by changing the model to allow for Darwinian evolution such that each plant species works with an optimized temperature dependence, so $\beta(T_i) \rightarrow \beta_i(T_i)$ is modified to become dependent on i , the overall result changes only very little. More importantly, the range over which the model can stabilize the planet's temperature shrinks, making the planet as a whole more vulnerable. Although the amount of shrinkage is small, it emphasizes the dangers associated with adopting changes that lead only to short-term benefits. Saunders emphasizes in his work that the ability of life to regulate the surface temperature of a planet is not associated with natural selection as in the concept of Darwinian evolution. More generally he warns, therefore,

Exobiology (theoretical), Complexity in, Figure 16

Temperature (in Celsius) versus relative irradiation (normalized to the average temperature). Note that the temperature is stabilized around the value T_{aver} , provided the energy input S is within a certain range. Adapted from [40]

that not everything that is to an advantage needs to be the result of natural selection [40].

Oxidation of the Earth's Crust

It has recently been proposed that, in addition to the effects discussed above, life may also have profound effects on the Earth's crust. A possible scenario has recently been discussed by Rosing et al. [36]. The idea is that photosynthetic life may tap large amounts of solar energy that were used to reduce carbon from CO_2 to compounds of the form $(\text{CH}_2\text{O})_n$ and similar, via reactions of the form

where $h\nu$ denotes the energy taken from solar radiation. Furthermore, and even more surprisingly, the oxygen produced by photosynthesis may have been critical in oxidizing iron in the continental crust. Although other factors also played a substantial role, it is clear that biological processes can speed up the oxidation process substantially. Comparing the oceanic crust with the continental crust, a major difference is the enhanced fraction of SiO_2 (57% in the continental crust compared to 50% in the oceanic crust).

Granite, being one of the lightest rock types, was eventually able to escape subduction and to produce stable continents about 3.8 Gyr ago. This is also the time of the oldest

rock findings on Earth. Given that the rise of continents on the early Earth is associated with granite formation, the presence of granite on silicon-bearing rocky planets might thus be a possible biomarker for photosynthesis [36].

Although this idea is speculative, it may be supported quantitatively as follows. Firstly, the present day production rate of organically fixated carbon is estimated to be $9 \times 10^{15} \text{ mol C yr}^{-1}$ [12,25]. The amount of energy required for this can be calculated by using the fact that it costs 477 kJ to transfer one mole of carbon to hexose. The energy required for this is then 300 mW m^{-2} . Rosing et al. [36] argue that this amount could be supplied by only 0.1% of the effective solar energy flux, $S/4$. Assuming that the amount of carbon burial, relevant to estimating the usable fraction of oxygen for iron oxidation, is also about 0.1%, this corresponds to about $10^{13} \text{ mol C yr}^{-1}$. This would yield a comparable iron oxidation rate. Rosing et al. [36] argue further that annual basalt production contributes about $10^{14} \text{ mol Fe yr}^{-1}$, so a fraction of the magmatic iron flux could be used for building up the mantle reservoir of ferric iron.

In conclusion, the presence of life can lead to significant alterations of the planet in a number of different ways, as is quite clearly demonstrated by some of the differences between Earth and its neighboring planets Venus and Mars. Only the Earth has extensive reservoirs of oxygen and of granite. Within limits, the presence of life on a planet can also have a stabilizing effect on its climate. The relevant mathematical modeling of some of these processes resembles, in many ways, those encountered earlier in studies of homochirality and of the spread of hereditary information on the early Earth.

Conclusions

Astrobiology has developed into a rapidly growing research field involving expertise from a number of neighboring disciplines. Nonlinear dynamics and nonequilibrium thermodynamics find applications in all these subfields. Here, we have elaborated on a few such aspects. Closest to the onset of life is, perhaps, the emergence of homochirality of biomolecules. Given that RNA has been proven to form longer polymers only in a homochiral environment, one would expect that homochirality must be a prerequisite to the emergence of life at the level of a replicating RNA world. On the other hand, the very mechanism causing the polymerization to terminate, namely enantiomeric cross-inhibition, can also be the mechanism responsible for causing 100% homochirality by destroying RNA molecules whose chirality is already in the minority. This would, however, require the possibility of auto-

catalysis, which can be avoided in another scenario where a closed peptide system is kept away from equilibrium by continuous activation of amino acids.

Chemically speaking, the stabilization of a definite chirality is in some models similar to the subsequent establishment of hereditary information, in that catalysis plays a crucial role. Furthermore, in both cases, the possibility of chemistry in an extended system is crucial. On the one hand, spatial extent gives rise to the possibility of coexistence of life forms of opposite handedness on the early Earth. On the other hand, spatial extent can be critical in allowing the system to find unpopulated locations fast enough to avoid being overwhelmed by the effects of parasites that tap the same resources that are required for the maintenance and development of hereditary information.

Finally, life is invariably coupled to some kind of metabolism that is ultimately powered by solar energy. This clearly affects the environment by reducing carbon and oxidizing the crust of the Earth and, over the last two billion years, the atmosphere. How much these alterations of the environment are due to biological processes is less obvious. However, it is clear that biological factors greatly speed up weathering on the Earth. The extent of biologically induced alterations of the continental crust, for example, may therefore best be tested using quantitatively accurate model calculations. The outcome may ultimately hinge on energetic considerations and on the efficiency of photosynthesis as a solar energy collector.

With the scope of being able to explore, in the near future, not only the planets and other celestial bodies in the solar system in much more detail, but also planets of other planetary systems, research in astrobiology quickly develops into a field that will be driven more and more by new data, making this field less susceptible to speculation. Therefore, it is important to be prepared for upcoming discoveries in this field. Finally, it should be emphasized that astrobiology is efficient in communicating science to the general public, which may provide an additional boost to the field.

Glossary

Complexity A definitive feature of nonlinear systems of interacting elements. It comprises high instability with respect to initial and boundary conditions, and complex but non-random behavior patterns (“order in chaos”).

Extreme events Rare events having a large impact. Such events are also known as critical phenomena, disas-

ters, catastrophes, and crises. They persistently reoccur in hierarchical complex systems created, separately or jointly, by nature and society.

Fast acceleration of unemployment (FAU) The start of a strong and lasting increase of the unemployment rate.

Pattern recognition of rare events The methodology of artificial intelligence' kind aimed at studying distinctive features of complex phenomena, in particular – at formulating and testing hypotheses on these features.

Premonitory patterns Patterns of a complex system's behavior that emerge most frequently as an extreme event approaches.

Recession The American National Bureau of Economic Research defines recession as “a significant decline in economic activity spread across the economy, lasting more than a few months”. A recession may involve simultaneous decline in coincident measures of overall economic activity such as industrial production, employment, investment, and corporate profits.

Start of the homicide surge (SHS) The start of a strong and lasting increase in the smoothed homicide rate.

Definition of the Subject

At stake in the development of accurate and reliable methods of prediction for social systems is the capacity of scientific reason to improve the human condition. Today's civilization is highly vulnerable to crises arising from extreme events generated by complex and poorly understood systems. Examples include external and civil wars, terrorist attacks, crime waves, economic downturns, and famines, to name just a few. Yet more subtle effects threaten modern society, such as the inability of democratic systems to produce policies responsive to challenges like climate change, global poverty, and resource depletion.

Our capacity to predict the course of events in complex social systems is inherently limited. However, there is a new and promising approach to predicting and understanding complex systems that has emerged through the integration of studies in the social sciences and the mathematics of prediction. This entry describes and analyzes that approach and its real-world applications. These include algorithmic prediction of electoral fortunes of incumbent parties, economic recessions, surges of unemployment, and outbursts of crimes. This leads to important inferences for averting and responding to impending crises and for improving the functioning of modern democratic societies.

That approach was successfully applied also to natural disasters such as earthquakes. Ultimately, improved pre-

diction methods enhance our capacity for understanding the world and for protecting and sustaining our civilization.

Extreme events. Hierarchical complex systems persistently generate extreme events – the rare fast changes that have a strong impact on the system. Depending on connotation they are also known as critical phenomena, disasters, catastrophes, and crises. This article examines the development and application of the algorithmic prediction of extreme socio-economic and political events.

The prediction problem is formulated as follows:

given are time series that describe dynamics of the system up to the current moment of time t and contain potential precursors of an extreme event;

to predict whether an extreme event will or will not occur during the subsequent time period $(t, t + \tau)$; if the answer is “yes”, this will be the “*period of alarm*”.

As the time goes by, predictions form a discrete sequence of alarms. The possible outcomes of such a prediction are shown in Fig. 1. The actual outcome is determined unambiguously, since the extreme events are identified independently of the prediction either by the actual happening (e. g. by an election result) or by a separate algorithm (e. g. homicide surge) after they occur.

Such “yes or no” prediction is aimed not at analyzing the whole dynamics of the system, but only at identifying the occurrence of rare extreme events. In a broad field of prediction studies this prediction is different from and complementary to the classical Kolmogoroff–Wiener prediction of continuous functions, and to traditional cause-and-effect analysis.

The problem includes estimating the predictions' accuracy: the rates of false alarms and failures to predict, and the total duration of alarms in relation to the total time considered. These characteristics represent the inevitable

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 1
Possible outcomes of prediction

probabilistic component of prediction; they provide for statistical validation of a prediction algorithm and for optimizing preparedness to predicted events (e. g. recessions or crime surges).

Twofold importance. The prediction problem is pivotal in two areas:

- *Fundamental understanding of complex systems.* Prediction algorithms quantitatively define phenomena that anticipate extreme events. Such quantitative definition is pivotal for fundamental understanding of a complex system where these events occur, including the intertwined mechanisms of system's development and its basic features, e. g. multiple scaling, correlation range, clustering, fragmentation etc. (see Sects. "Common Elements of Data Analyzes", "Elections", "US Economic Recessions", "Unemployment"). The understanding of complex systems remains a major unsolved problem of modern science, tantamount to transforming our understanding of the natural and human world.
- *Disaster preparedness.* On the practical side prediction is pivotal for coping with a variety of disasters, commonly recognized as major threats to the survival and sustainability of our civilization (e. g. [22]; see also materials of G8-UNESCO World Forum on "Education, Innovation and Research: New Partnership for Sustainable Development", <http://g8forum.ictp.it>). The reliable advance prediction of extreme events can save lives, contribute to social and economic stability, and to improving the governing of modern societies.

Introduction

Predictability vs. Complexity: The Need for Holistic Approach [7,12,13,15,17,27,32]

Natural science had for many centuries regarded the Universe as a completely predictable machine. As Pierre Simon de Laplace wrote in 1776, "... if we knew exactly the laws of nature and the situation of the universe at the initial moment, we could predict exactly the situation of the same universe at a succeeding moment." However, at the turn of the 20th century (1905) Jules Henry Poincare discovered, that "... this is not always so. It may happen that small differences in the initial conditions will produce very great ones in the final phenomena. Prediction becomes impossible".

This instability to initial conditions is indeed a definitive attribute of complex systems. Nonetheless, through the robust integral description of such systems, it is possible to discover regular behavior patterns that transcend the

inherent complexity. For that reason studying complexity requires the holistic approach that proceeds from the whole to details, as opposed to the reductionism approach that proceeds from details to the whole. It is in principle not possible "to understand a complex system by breaking it apart" [13].

Among the regular behavior patterns of complex systems are "premonitory" ones that emerge more frequently as an extreme event approaches. These premonitory patterns make complex systems predictable. The accuracy of predictions, however, is inevitably limited due to the systems' complexity and observational errors.

Premonitory patterns and extreme events are consecutive manifestations of a system's dynamics. These patterns may not trigger extreme events but merely signal the growth of instability, making the system ripe for the emergence of extreme events.

Methodology

The prediction algorithms described here are based on discovering premonitory patterns. The development of the algorithms requires the integration of complementary methods:

- Theoretical and numerical modeling of complex systems; this includes "universal" models considered in statistical physics and non-linear dynamics (e. g. [1,3,5,8,12,15,20,42]), and system-specific models, if available.
- Exploratory data analysis.
- Statistical analysis of limited samples, which is relevant since the prediction targets are by definition rare.
- Practical expertise, even if it is intuitive.
- Risk analysis and theory of optimal control for optimizing prediction strategy along with disaster preparedness.

Pattern Recognition of Rare Events This methodology provides an efficient framework for integrating diverse information into prediction algorithms [4,11,19]. This methodology has been developed by the artificial intelligence school of I. Gelfand for the study of rare phenomena of a highly complex origin. In terminology of pattern recognition, the "object of recognition" is the time moment t . The problem is to recognize whether it belongs to the period of alarm, i. e. to a time interval Δ preceding an extreme event. An alarm starts when certain combinations of premonitory patterns emerges.

Several features of that methodology are important for predicting extreme events in the absence of a complete

closed theory that would unambiguously define a prediction algorithm. First, this kind of pattern recognition relies on simple, robust parameters that overcome the bane of complexity analysis – incomplete knowledge of the system’s causal mechanisms and chronic imperfections in the available data. In its efficient robustness, pattern recognition of rare events is akin to exploratory data analysis as developed by J. Tukey [50]. Second, unlike other statistical methods, e. g. regression analysis, that methodology can be used for small samples such as presidential elections or economic recessions. Also, it integrates quantitative and judgmental parameters and thereby more fully captures the full dimensions of the prediction problem than procedures that rely strictly on quantitative variables.

Summing up, the methodology described here can help in prediction when there are (1) many causal variables, (2) qualitative knowledge about which variables are important, and (3) limited amounts of data [2].

Besides societal predictions, pattern recognition of rare events has been successfully applied in seismology and earthquake prediction (e. g. [11,19,20,44,46]), geological prospecting (e. g. [45]) and in many other fields. Review can be found in [21,47]. Tutorial materials are available at the web site of the Abdus Salam International Centre for Theoretical Physics (http://cdsagenda5.ictp.it/full_display.php?da=a06219).

Validation of Prediction Algorithms The algorithms include many adjustable elements, from selecting the data and defining the prediction targets, to specifying numerical parameters involved. In lieu of theory that would unambiguously determine these elements they have to be developed retrospectively, by “predicting” past extreme events. The application of the methodology to known events creates the danger of self-deceptive data-fitting: As J. von Neumann put it “with four exponents I can fit an elephant”. The proper validation of the prediction algorithms requires three consecutive tests.

- *Sensitivity analysis*: testing whether predictions are sensitive to variations of adjustable elements.
- *Out of sample analysis*: application of an algorithm to past data that has not been used in the algorithm’s development. The test is considered successful if algorithm retains its accuracy.
- *Predicting future events* – the only decisive test of a prediction algorithm (see for example Sect. “Elections” below).

A highly efficient tool for such tests is the error Diagram, showing major characteristics of prediction accuracy [33,

34,35,36,37,38,39]. Its example is given in Fig. 10. Exhaustive sets of these tests are described in [10,11,24,52].

Common Elements of Data Analyzes

The methodology discussed above was used for predicting various kinds of extreme events, as illustrated in the next four Sections. Naturally, from case to case this methodology was used in different ways, according to specifics of phenomena considered. However in all cases data analysis has essential common elements described below.

Sequence of analysis comprises four stages: (i) Defining prediction targets. (ii) Choosing the data (time series), where premonitory patterns will be looked for and summing up a priori constrains on these patterns. (iii) Formulating hypothetical definition of these patterns and developing prediction algorithm; determining the error diagram. (iv) Validating and optimizing that algorithm.

Preliminary transformation of raw data. In predicting recessions (Sect. “US Economic Recessions”), fast acceleration of unemployment (Sect. “Unemployment”) and crime surges (Sect. “Homicide Surges”) raw data were time series of relevant monthly indicators, hypothetically containing premonitory patterns. Let $f(m)$ be such an indicator, with integer m showing time in months. Premonitory behavior of some indicators is better captured by their linear trends.

Let $W^f(l/q, p)$ be the local linear least-squares regression of a function $f(m)$ within the sliding time window (q, p) :

$$W^f(l/q, p) = K^f(q, p)l + B^f(q, p), \quad q \leq l \leq p, \quad (1)$$

where integers $l, q,$ and p stand for time in months.

Premonitory behavior of most indicators was captured by the following two functions:

- The trend of $f(m)$ in the s months long window, $(m - s, m)$. For brevity we denote

$$K^f(m/s) = K^f(m - s, m) \quad (2)$$

- The deviation of $f(m)$ from extrapolation of its long-term regression (i. e. regression on a long time window $(q, m - 1)$):

$$R^f(m/q) = f(m) - W^f(m/q, m - 1). \quad (3)$$

Both functions can be used for prediction since their values do not depend on the information about the future (after the month m) which would be anathema in prediction.

Discretization. The prediction algorithms use one or several premonitory patterns. Each pattern is defined at

the lowest – binary – level of resolution, as 0 or 1, distinguishing only the presence of absence of a pattern at each moment of time. Then the objects of recognition are described by binary vectors of the same length. This ensures the robustness of the prediction algorithms.

Simple algorithm called Hamming distance is used for classification of binary vectors in applications considered here, [14,20,28]. Each vector is either premonitory or not. Analyzing the samples of vectors of each class (“the learning material”), the algorithm determines a reference binary vector (“kernel”) with components typical for the premonitory vector. Let D be the Hamming distance of a vector from the kernel (the number of non-coinciding binary components). The given vector is recognized as premonitory class, if D is below a certain threshold D^* . This criterion takes advantage of the clustering of precursors in time.

Summing up, these elements of the pattern recognition approach are common for its numerous applications, their diversity notwithstanding. Experience in the specific applications is described in Sects. “Elections”, “US Economic Recessions”, “Unemployment”, “Homicide Surges”. The conceptual summary of the accumulated experience is given in the final Sect. “Summary: Findings and Emerging Possibilities”.

Elections

This Section describes algorithms for predicting the outcome of the US Presidential and mid-term Senatorial elections [28,29,30,31]. Elections’ time is set by the law as follows.

- National elections are held every even-numbered year, on the first Tuesday after the first Monday in November (i. e., between November 2 and November 8, inclusively).
- Presidential elections are held once every 4 years, i. e. on every other election day. People in each of the 50 states and District of Columbia are voting separately for “electors” pledged to one or another of the Presidential candidates. These electors make up the “Electoral College” which directly elects the President. Since 1860, when the present two-party system was basically established, the Electoral College reversed the decision of the popular vote only three times, in 1888, 1912, and 2000. Algorithmic prediction of such reversals is not developed so far.
- A third of Senators are elected for a 6-year term every election day; “mid-term” elections held in the middle of a Presidential term are considered here.

Methodology

The prediction target is an electoral defeat of an “incumbent” party, i. e. the party holding the contested seat. Accordingly, the prediction problem is formulated as whether the incumbent party will retain this seat or lose it to the challenging party (*and not whether Republican or Democrat will win*). As is shown below, that formulation is crucial for predicting the outcomes of elections considered.

Data. The pre-election situation is described by robust common sense parameters defined at the lowest (binary) level of resolution, as the *yes* or *no* answers to the questionnaires given below (Tables 1, 2). The questions are formulated in such a way that the answer *no* favors the victory of the challenging party. According to the Hamming distance analysis (Sect. “Common Elements of Data Analyzes”) the victory of the challenging party is predicted when the number of answers *no* exceeds a threshold D^* .

Mid-term Senatorial Elections

The prediction algorithm was developed by a retrospective analysis of the data on three elections, 1974, 1978, and 1982. The questionnaire is shown in Table 1. Victory of the challenger is predicted if the number of answers *no* is 5 or more [28,29,30].

The meaning of these questions may be broader than their literal interpretation. For example, financial contributions (key 5 in Table 2) not only provide the resources required for an effective campaign, but may also constitute a poll in which the preferences are weighed by the money attached.

Predicting future elections. This algorithm (without any changes from year to year and from state to state) was applied in advance to the five subsequent elections, 1986–2002. Predictions are shown in Fig. 2. Altogether, 150 seats were put up for election. For each seat a separate prediction was made, 128 predictions were correct, and 22 – wrong.

Statistical significance of this score is 99.9%. In other words the probability to get such a score by chance is below 0.1% [28,29,30]. For some elections these predictions might be considered as trivial, since they coincide with prevailing expectation of experts. Such elections are identified by *Congressional Review*. Eliminating them from the score still results in 99% significance.

Presidential Elections

The prediction algorithm was developed by a retrospective analysis of the data on the past 31 elections, 1860–1980;

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Table 1
Questionnaire for mid-term Senatorial Elections [28]

1.	(Incumbency): The incumbent -party candidate is the sitting senator.
2.	(Stature): The incumbent -party candidate is a major national figure.
3.	(Contest): There was no serious contest for the incumbent -party nomination.
4.	(Party mandate): The incumbent party won the seat with 60% or more of the vote in the previous election.
5.	(Support): The incumbent -party candidate outspends the challenger by 10% or more.
6.	(Obscurity): The challenging -party candidate is not a major national figure or a past or present governor or member of Congress.
7.	(Opposition): The incumbent party is not the party of the President.
8.	(Contest): There is no serious contest for the challenging -party nomination (the nominee gains a majority of the votes cast in the first primary and beats the second-place finisher at least two to one).

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Table 2
Questionnaire for Presidential elections [29,30]

KEY 1	(Party Mandate): After the midterm elections, the incumbent party holds more seats in the US House of Representatives than it did after the previous midterm elections.
KEY 2	(Contest): There is no serious contest for the incumbent -party nomination.
KEY 3	(Incumbency): The incumbent -party candidate is the sitting president.
KEY 4	(Third party): There is significant third-party or independent campaign.
KEY 5	(Short-term economy): The economy is not in recession during the election campaign.
KEY 6	(Long-term economy): Real per -capita economic growth during the term equals or exceeds mean growth during the previous two terms.
KEY 7	(Policy change): The incumbent administration effects major changes in national policy.
KEY 8	(Social unrest): There is no sustained social unrest during the term.
KEY 9	(Scandal): The incumbent administration is unattained by a major scandal.
KEY 10	(Foreign/military failure): The incumbent administration suffers no major failure in foreign or military affairs.
KEY 11	(Foreign/military success): The incumbent administration achieves a major success in foreign or military affairs.
KEY 12	(Incumbent charisma): The incumbent -party candidate is charismatic or a national hero.
KEY 13	(Challenger charisma): The challenging -party candidate is not charismatic or a national hero.

that covers the period between victories of A. Lincoln and R. Reagan inclusively. The questionnaire is shown in Table 2. Victory for the challenger is predicted if the number of answers *no* is 6 or more [29,30].

Predicting of future elections. This algorithm (without any changes from year to year state) was applied in advance to the six subsequent elections, 1984–2004. Predictions are shown in Fig. 3. All of them happened to be correct. In 2000 the decision of popular majority was reversed by the Electoral College; such reversals are not targeted by this algorithm [29,30].

Understanding Elections

Collective behavior. The finding that aggregate-level parameters can reliably anticipate the outcome of both presidential and senatorial elections points to an electoral behavior highly integrated not only for the nation as a whole but also within the diverse American states.

- A presidential election is determined by the collective, integrated estimation of performance of incumbent administration during the previous four years.
- In case of senatorial elections the electorate has more diffused expectations of performance but puts more importance on political experience and status than in the case of presidential elections. Senate incumbents, unlike presidential ones, do not suffer from a bad economy or benefit from a good one. (This suggests that rather than punishing the party holding a Senate seat for hard times, the voters may instead regard the incumbent party as a safe port in a storm).

Similarity. For each election year in all states the outcomes of elections follow the same pattern that transcends the diversities of the situations in each of the individual elections.

The same pattern of the choice of the US President prevails since 1860, i. e. since election of A Lincoln, despite

all the overwhelming changes in the electorate, the economy, the social order and the technology of politics during these 130 years. (For example, the electorate of 1860 did not include the groups, which constitute 3/4 of present electorate, such as women, African Americans, or most of the citizens of the Latin American, South European, Eastern European, and Jewish descent [30].

An alternative (and more traditional) concept of American elections focuses on the division of voters into interest and attitudinal groups. By this concept the goal of the contestants is to attract the maximum number of voting blocks with minimal antagonism from other blocks. Electoral choice depends strongly on the factors irrelevant to the essence of the electoral dilemma (e.g. on the campaign tactics). The drawbacks of this concept are discussed in [18,30]. In sum, the work on presidential and senatorial elections described above suggests the following new ways of understanding American politics and perhaps the politics of other societies as well.

1. Fundamental shifts in the composition of the electorate, the technology of campaigning, the prevailing economic and social conditions, and the key issues of campaigns do not necessarily change the pragmatic basis on which voters choose their leaders.
2. It is governing not campaigning that counts in the outcomes of presidential elections.
3. Different factors may decide the outcome of executive as compared to legislative elections.
4. Conventional campaigning will not improve the prospects for candidates faced with an unfavorable

combination of fundamental historical factors. Disadvantaged candidates have an incentive to adopt innovative campaigns that break the pattern of conventional politics.

5. All candidates would benefit from using campaigns to build a foundation for governing in the future.

US Economic Recessions

US National Bureau of Economic Research (NBER) has identified the seven recessions that occurred in the US since 1960 (Table 3). The starting points of a recession and of the recovery from it follow the months marked by a peak and a trough of economic activity, respectively.

A peak indicates the last month before a recession, and a trough – the last month of a recession.

Prediction targets considered are the first month after the peak and after the trough (“the turns to the worst and to the best”, respectively). The start of the first recession, in 1960, is not among the targets, since the data do not cover a sufficient period of time preceding the recession.

The data used for prediction comprise the following six monthly leading economic indicators obtained from the CITIBASE data base, Jan. 1960–June 2000 (abbreviations are the same, as in [49]).

G10FF = FYGT10 – FEDFUN Difference between the annual interest rate on 10 year US Treasury bonds, and federal fund annual interest rate.

IP Industrial Production, total: index of real (constant dollars, dimensionless) output in the entire economy.

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Table 3

American Economic Recessions since 1960

#	Peaks	Troughs
1	1960:04	1961:02
2	1969:12	1970:11
3	1973:11	1975:03
4	1980:01	1980:07
5	1981:07	1982:11
6	1990:07	1991:03
7	2001:03	2001:11

This represents mainly the manufacturing industry, because of the difficulties in measuring the quantity of the output in services (such as travel agents, banking, etc.).

LHELL Index of “help wanted” advertising. This is put together by a private publishing company that measures the amount of job advertising (column-inches) in a number of major newspapers.

LUINC Average weekly number of people claiming unemployment insurance.

INVTMQ Total inventories in manufacturing and trade, in real dollars. Includes intermediate inventories (for example held by manufacturers, ready to be sent to retailers) and final goods inventories (goods on the shelves in stores).

FYGM3 Interest rate on 90 day US treasury bills at an annual rate (in percent).

These indicators were already known [48,49], as those that correlate with a recession’s approach.

Prediction of a Recession Start

Single indicators exhibit the following premonitory patterns:

G10FF: small value

IP and INVTMQ: small deviation from the long-term trend R^f (3)

FYGM3: large deviation from the long-term trend R^f

LHELL: small trend K^f (2)

LUINC: large trend K^f

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 4

Alarms (black bars) and recessions (gray bars)

The prediction algorithm triggers an alarm after a month when most of the patterns emerge simultaneously. It lasts Δ months and can be extended by the same rule, if premonitory patterns keep emerging. Formal quantitative definition of the algorithm can be found in [23] along with its validation by sensitivity and out-of-sample analyzes.

Alarms and recessions are juxtaposed in Fig. 4. We see that five recessions occurring between 1961 and 2000 were predicted by an alarm. The sixth recession started in April 2001, one month before the corresponding alarm. (Recession of 1960 was not considered for prediction, since data analyzed start just before it.)

Only the first six recessions listed in Table 1 were considered in the developing of the algorithm [23]. Duration of each alarm was between 1 and 14 months. Total duration of all alarms was 38 months, or 13.6% of the time interval considered. There were no false alarms. No alarms were yielded so far by subsequent prediction in advance and no recession was identified during that time.

Prediction of a Recession End

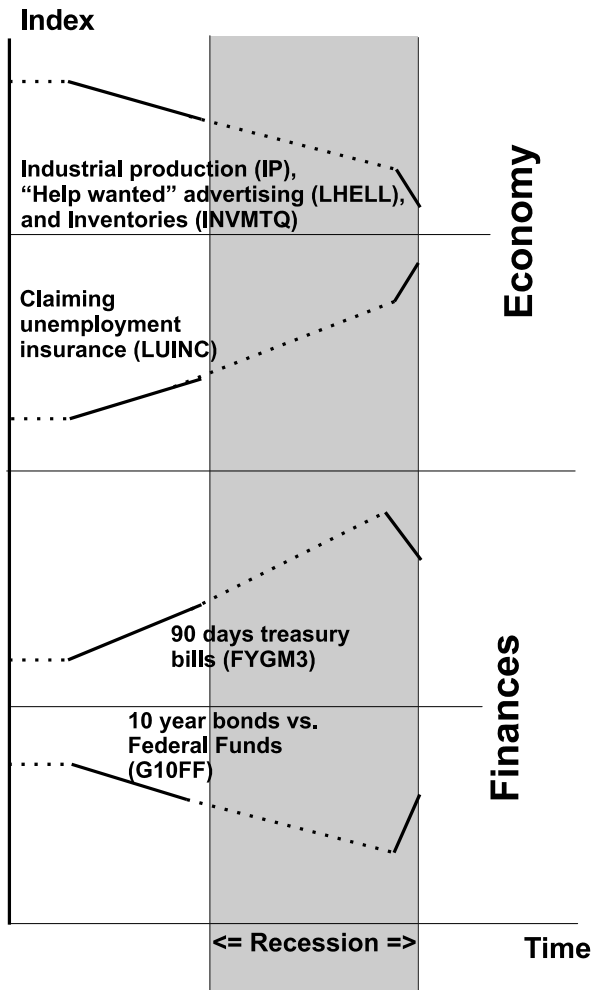

Prediction targets are the starting points of recovery from recessions; these points are indicated in the last column of Table 3.

The data comprise the same six indicators that indicate the approach of a recession (see Subsect. “Prediction of a Recession Start”); they are analyzed only within the recessions’ periods.

Data analysis shows intriguing regularity illustrated in Fig. 5:

- Financial indicators change in opposite directions before the recession and before the recovery.
- Economic indicators change in the same direction before the recession and the recovery; but the change is stronger before the recovery, i. e., the economic situation worsens.

Prediction algorithm is formulated in the same terms as in the previous case but an alarm is triggered after *three* consecutive months when most of the patterns emerge simultaneously. The alarms predict when the recovery will start. Alarms and prediction targets are juxtaposed in Fig. 6. Du-

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 5

Premonitory changes of indicators before the start of a recession and before its end. See explanations in the text

ration of a single alarm is one to five months. Total duration of alarms is 16 months, which is 22% of time covered by all recessions. There are neither false alarms nor failures to predict.

Unemployment

Here we describe uniform prediction of the sharp and lasting unemployment surge in France, Germany, Italy, and the USA [25].

Prediction Target

A prediction target is schematically illustrated in Fig. 7. Thin curve shows monthly unemployment with seasonal

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 6

Prediction of recovery from a recession. *Black bars* – periods of recessions. *Gray bars* – alarms preceding the end of a recession

variations. On the thick curve seasonal variations are smoothed away. The arrow indicates a sharp upward bend of the smoothed curve. The moment of that bend is the prediction target. It is called by the acronym *FAU*, for "Fast Acceleration of Unemployment".

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 7

Fast acceleration of unemployment (FAU): schematic definition. *Thin line* – monthly unemployment; with seasonal variations. *Thick line* – monthly unemployment, with seasonal variations smoothed away. The *arrow* indicates a FAU – the sharp bend of the smoothed curve. The moment of a FAU is the target of prediction

Smoothing was done as follows: Let $u(m)$ be number of unemployed in a month $m = 1, 2, \dots$. After smoothing out the seasonal variation we obtain time series $U(m) = W^u(m/m - 6, m + 6)$; this is the linear regression over the year-long time interval $(m - 6, m + 6)$. A natural robust measure of unemployment acceleration at the time m is the bend of the linear trend of U ; in notations used

in (1) this is the function $F(m/s) = K^U(m + s, m) - K^U(m, m - s)$. The FAUs are identified by the local maxima of $F(m)$ exceeding a certain threshold F . The time m^* and the height F^* of such a maximum are, respectively, the time and the magnitude of a FAU. Subsequent local minimum of $F(m)$ identifies the month m_e when acceleration ends. Figure 8 shows thus defined FAUs for France.

The Data

The analysis has been initially made for France and three groups of data have been analyzed.

- *Composite macroeconomic indicators of national economy*
 1. **IP:** Industrial production indicator, composed of weighted production levels in numerous sectors of the economy, in % relative to the index for 1990.
 2. **L:** Long-term interest rate on 10-year government bonds, in %.
 3. **S:** Short-term interest rate on 3-month bills, in %.
- *Characteristics of more narrow areas of French economy*
 4. **NC:** The number of new passenger car registrations, in thousands of units.

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 8

Unemployment in France. *Top:* Monthly unemployment, thousands of people. *Thin line:* $u(m)$, data from the OECD database; note the seasonal variations. *Thick line:* $U(m)$, data smoothed over one year. *Bottom:* Determination of FAUs. $F(m)$ shows the change in the linear trend of unemployment $U(m)$. FAUs are attributed to the local maxima of $F(m)$ exceeding threshold $F = 4.0$ shown by horizontal line. The thick vertical lines show moments of the FAUs

- 5. **EI**: Expected prospects for the national industrial sector.
 - 6. **EP**: Expected prospects for manufacturers.
 - 7. **EO**: Estimated volume of current orders.
- Indicators 5–7 distinguish only “good” and “bad” expectations determined polling 2,500 manufacturers, whose answers are by the size of their businesses.
- *Indicators related to US economy.*
 - 8. **FF/\$**: Value of US dollar in French francs.
 - 9. **AR**: The state of the American economy: is it close to a recession or not? This indicator shows the presence or absence of a current pre-recession alarm (see Subsect. “Prediction of a Recession Start”).

The data bases with above indicators for Europe are issued by the Organization for Economic Cooperation and Development [43] and the International Monetary Fund [16].

American analogues of indicators IP, L, and S are provided by CITIBASE; they are described in Sect. “US Economic Recessions>” under abbreviations IP, FYGM3 and FIGT10 respectively.

Prediction

Single indicators exhibit the following premonitory behavior.

- Steep upward trends of composite indicators (#1–#3). This behavior reflects “overheating” of the economy and may sound counterintuitive for industrial production (#1), since the rise of production is supposed to create more jobs. However, a particularly steep rise may create oversupply.
- Steep downward trends of economic expectations by general public (#4) and business community (#5–#8).
- Proximity of an American recession (#9). Before analysis was made such and opposite precursors might be expected for equally plausible reasons, so that this finding, if further confirmed, does provide a constraint on understanding unemployment’s dynamics.

Among different combinations of indicators the macroeconomic ones (#1–#3) jointly give relatively better predictions, with smallest rates of errors and highest stability in sensitivity tests.

Retrospective prediction. Macroeconomic indicators were used jointly in the Hamming distance prediction algorithm (Sect. “Common Elements of Data Analyzes”). Being robust and self-adjusting to regional conditions, this algorithm was applied without any changes to the four countries considered here.

Alarms and FAUs are juxtaposed in Fig. 9. Error diagram in Fig. 10 shows quality of prediction for different

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 9

Retrospective predictions for four countries: FAUs and alarms obtained by the prediction algorithm. The thick vertical lines show the moments of FAUs in a country. Bars – the alarms with different outcome: 1 – alarms that predict FAUs, 2 – alarms starting shortly after FAUs within the periods of unemployment surge, 3 – false alarms. Shaded areas on both sides indicate the times, for which data on economic indicators were unavailable

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 10

Error diagram for prediction of FAUs in different countries; τ is total duration of alarms in % to the time interval considered, f – total number of false alarms

countries. For US the quality is lower than for European countries, though still higher than in random predictions.

Prediction of the future FAUs was launched for USA. The results are shown in Fig. 11. It shows that by January 2008 two correct predictions have been made, without other false alarms or failures to predict. In November

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 11

Experiment in predicting future FAUs, September (1999)–January (2008). *Thin blue curve* shows monthly unemployment rate in USA, according to data of Bureau of Labor Statistics, US Department of Labor (<http://www.data.bls.gov>). *Thick curve* shows this rate with seasonal variation smoothed away. *Vertical red lines* show prediction targets – the moments of FAU, *gray bar* – the period of unemployment’s growth; *pink bars* – periods of alarms

2006 the second prediction was filed on the web site of the Anderson School of Management, University of California, Los Angeles (<http://www.uclaforecast.com/>). This started the documented experiment in testing the algorithm by predicting future FAUs on that website.

Homicide Surges

This section analyzes the prediction of homicide rates in an American megacity – Los Angeles, CA [24].

Prediction Target

A prediction target is the start of a sharp and lasting acceleration of the homicide rate; it is called by the acronym SHS, for “Start of the Homicide Surge.” It is formally determined by the analysis of monthly homicides rates, with seasonal variations smoothed out, as described in Subsect. “Prediction Target”. Prediction targets thus identified are shown by vertical lines in Figs. 12 and 14 below.

The Data

The analyzed data include monthly rates of the homicides and 11 types of lesser crimes, listed in Table 2. Definitions of these crimes are given in [6].

The data are taken from two sources:

- The National Archive of Criminal Justice Data, placed on the web site (NACJD), 1975–1993.

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 12

Target of prediction – the Start of the Homicide Surge (“SHS”); schematic definition. *Gray bar* marks the period of homicide surge

- Data bank of the Los Angeles Police Department (LAPD) Information Technology Division), 1990–2003.

The algorithm does not use socio-economic determinants of crime, or other data that might be also useful. The objective was to develop a simple, efficient prediction model; development of comprehensive causal model would be a complementary objective.

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 13
 Scheme of premonitory changes in crime statistics

Prediction

Premonitory behavior of indicators is illustrated in Fig. 13. The first phase is characterized by an escalation of burglaries and assaults, but not of robberies. Later on, closer to a homicide surge, robberies also increase.

The Prediction algorithm based on Hamming distance (see Sect. “Common Elements of Data Analyzes”) uses seven indicators listed in Table 4. Other five indicators marked by * are used in sensitivity tests; and the homicide rate is used for identification of targets SHS.

Alarms and homicide surges are juxtaposed in Fig. 14. The SHS episode in November 1994 has occurred simultaneously with the corresponding alarm. It is captured by an alarm, which starts in the month of SHS without a lead time. Prediction missed the October 1999 episode: it occurred two months before the start of the corresponding alarm. Such delays should be taken into account for validating the algorithm. Note, however, that the last prediction did remain informative.

Altogether alarms occupy 15% of the time considered. During phase 2 (as defined in Fig. 13) this rate might be reduced [24].

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 14
 Performance of prediction algorithm through 1975–2002. *Thin curve* – original time series, total monthly number of homicides in Los Angeles city, per 3,000,000 inhabitants. Data from NACJD [6] have been used for 1975–1993 and from the Data Bank of the Los Angeles Police Department (LAPD Information Technology Division) for subsequent 9 years. *Thick curve* – smoothed series, with seasonal variations eliminated. *Vertical lines* show the targets of prediction – episodes of SHS (Subsect. “Prediction Target”). *Gray bars* show the periods of homicide surge. *Red bars* show the alarms declared by the prediction algorithm [24]

	● Strong-arm robberies*	● Aggravated injury assaults*	

*Analyzed in sensitivity tests only

Summary: Findings and Emerging Possibilities

The findings described above enhance predictive understanding of extreme events and indicate yet untapped possibilities for further R&D in that field.

Pattern Recognition Approach

Information extracted from the already available data is indeed increased by this approach. To each problem considered here one may apply the following conclusion of J. Stock, a leading expert in the field: “Prediction/of recessions/requires fitting non-linear, high-dimensional models to a handful of observations generated by a possibly non-stationary economic environment... The evidence presented here suggests that these simple binary transformations of economic indicators have significant predictive content for recessions. It is striking that these models, in which the information in the data is reduced to binary indicators, have predictive contents comparable to or, in many cases, better than that of more conventional models.” Importantly, this is achieved by using not more detailed data and models, but more robust aggregation (Subsect. “Predictability vs. Complexity: The Need for Holistic Approach”).

Partial “universality” of premonitory patterns is established by broad research in modeling and data analysis. This includes the common definition of the patterns, their self-adjustment, scaling, and similarity [9,10,20,26,42]; see also references in Sects. “Elections”, “US Economic Recessions”, “Unemployment”, “Homicide Surges”).

Relation to “cause and effect” analysis (perpetrators or witnesses?). Premonitory patterns might be either “perpetrators” contributing to causing extreme events, or the “witnesses” – parallel manifestations of the system’s development. The cause that triggered a specific extreme event is usually identified, at least in retrospect. It may be, for example, a certain governmental decision, a change in the international situation, a natural disaster, the depletion of natural resources etc. However an actual extreme event

might materialize only if the system is destabilized and “ripe” for it. Patterns of each kind signal such a ripe situation.

What premonitory patterns to use for prediction? Existing theories and experience reduce the number of such patterns, but too many of them remain hypothetically promising and have to be chosen by a trial and error procedure. Inevitably a prediction algorithm begins with a limited number of promising patterns. They should be sufficient for prediction, but other patterns may be equally or more useful and should be considered in further development of the algorithm. Most relevant “perpetrators” might not be included in the most useful patterns (e.g. due to their sensitivity to too many factors).

Relation to policy-making: prediction and disaster preparedness. Reliable predictions of future extreme events in complex societal systems would allow policy-makers to take remedial action before rather than after the onset of such afflictions as economic disasters, crime surges, etc. As in case of military intelligence predictions would be useful if their accuracy is known, albeit not necessarily high. Analysis of error diagrams allows to regulate the tradeoff between the rates of failures to predict and false alarms according to the needs of a decision-maker.

Relation to governing and campaigning. The findings presented here for the USA elections show that top elected officials would have better chances for reelection, if they focus on effective governing, and not on rhetoric, packaging and image-making. Candidates will benefit themselves and their parties if they run substantive campaigns that build a foundation for governing during the next term.

Further Possibilities

A wealth of yet untapped data and models is readily available for the continuation of the kinds of studies described and analyzed in this article. Following are some immediate possibilities; specific examples can be found in the given references.

- *Continuing experiments in advance prediction*, for which the above findings set up a base (Sect. “[Elections](#)”). Successes and errors are equally important [37,38].
- *Incorporating other available data into the analysis* (Sects. “[US Economic Recessions](#)”, “[Unemployment](#)”)
- *Predicting the same kind of extreme events in different contexts* (Sect. “[Unemployment](#)”)
- *Predicting the end of a crisis* (Sect. “[US Economic Recessions](#)”).
- *Multistage prediction with several lead times* (Sect. “[Homicide Surges](#)”)

Less imminent, but within reach are:

 - “*Universal*” scenarios of extreme development and low-parametric definition of an ensemble of premonitory patterns [9,51,52].
 - *Validation of an algorithm and joint optimization of prediction and preparedness strategy* [38].
 - *Developing prediction algorithms for other types of extreme events.*

The authors would be glad to provide specific information upon request.

Generalizations

The problems considered here have the following common features:

- *The absence of a closed theory* that would unambiguously determine prediction methodology. This leads to the need for intense intertwining of mathematics, statistical physics and non-linear dynamics, a range of societal sciences, and practical experience (Subsect. “[Methodology](#)”). In reality this requires long-term collaboration of respective experts. As can be seen from the references to Sects. “[Elections](#)”, “[US Economic Recessions](#)”, “[Unemployment](#)”, “[Homicide Surges](#)” previous applications inevitably involved the teams of such experts.
- *Predictions in advance* is the only final validation of the results obtained.
- *The need for holistic analysis* driven to extreme robustness.
- *Considerable, albeit limited, universality* of the premonitory phenomena.

Two classical quotations shed the light on these features:

A. N. Kolmogoroff. “It became clear for me that it is unrealistic to have a hope for the creation of a pure theory [of the turbulent flows of fluids and gases] closed in itself. Due to the absence of such a theory we have to rely upon

the hypotheses obtained by processing of the experimental data.”

M. Gell-Mann: “... if the parts of a complex system or the various aspects of a complex situation, all defined in advance, are studied carefully by experts on those parts or aspects, and the results of their work are pooled, an adequate description of the whole system or situation does not usually emerge. ... The reason, of course, is that these parts or aspects are typically entangled with one another. ... We have to supplement the partial studies with a trans-disciplinary crude look at the whole.”

In the general scheme of things the problem considered belongs to a much wider field – the quest for a universal theory of complex systems extended to predicting extreme events – the Holy Grail of complexity studies. This quest encompasses the natural and human-made complex systems that comprise what some analysts have called “the global village”. It requires entirely new applications of modern science, such as algebraic geometry, combinatorics, and thermodynamics. As a means for anticipating, preventing and responding to natural and manmade disasters and for improving the outcomes of economic and political systems, the methods described here may hold one key for the survival and sustainability of our civilization.

Random variable When a coin is tossed two random outcomes are permitted: head or tail. These outcomes can be mapped to numbers in a process which defines a ‘random variable’: for instance, ‘head’ and ‘tail’ could be mapped respectively to +1 and –1. More generally, any function mapping the outcomes of a random process to real numbers is defined a random variable [15]. More technically, a random variable is any function from a probability space to some measurable

space, i. e., the space of admitted values of the variable, e. g., real numbers with the Borel σ -algebra. The amount of rainfall in a day or the daily price variation of a stock are two more examples. It’s worth to stress that, formally, the outcome of a given random experiment is not a random variable: the random variable is the function describing all the possible outcomes as numbers. Finally, two random variables are said independent when the outcome of either of them has no influence on the other.

Probability distribution The probability of either outcomes, ‘head’ and ‘tail’, in tossing a coin is 50%. Similarly, a discrete random variable, X , with values $\{x_1, x_2, \dots\}$ has an associate discrete probability distribution of occurrence $\{p_1, p_2, \dots\}$. More generally, for a random variable on real numbers, X , the corresponding probability distribution [15] is the function returning the probability to find a value of X within a given interval $[x_1, x_2]$ (where x_1 and x_2 are real numbers): $\Pr[x_1 \leq X \leq x_2]$. In particular, the random variable, X , is fully characterized by its cumulative distribution function, $F(x)$, which is: $F(x) = \Pr[X < x]$ for any x in \mathcal{R} . The probability distribution density, $f(x)$, can be often defined as the derivative of $F(x)$: $f(x) = dF(x)/dx$.

The probability distribution of two independent random variables, X and Y , is the product of the distributions, F_X and F_Y , of X and Y : $F(x, y) \equiv \Pr[X < x; Y < y] = \Pr[X < x] \cdot \Pr[Y < y] = F_X(x) \cdot F_Y(y)$.

Expected value The expected value [15] of a random variable is its average outcome over many independent experiments. Consider, for instance, a discrete random variable, X , with values in the set $\{x_1, x_2, \dots\}$ and the corresponding probability for each of these values $\{p_1, p_2, \dots\}$. In probability theory, the expected, or average, value of X (denoted $E(X)$) is just the sum: $E(X) = \sum x_i p_i$. For instance, if you have an asset which can give two returns $\{x_1, x_2\}$ with probability $\{p_1, p_2\}$, its expected return is $x_1 p_1 + x_2 p_2$.

In case we have a random variable defined on real numbers and $F(x)$ is its probability distribution function, the expected value of X is: $E(X) = \int X dF$. As for some $F(x)$ the above integral may not exist, the ‘expected value’ of a random variable is not always defined.

Variance and moments The variance [15] of a probability distribution is a measure of the average deviations from the mean of the related random variable. In probability theory, the variance is usually defined as the mean squared deviation, $E((X - E(X))^2)$, i. e., the expected value of $(X - E(X))^2$. The square root of the

variance is named the standard deviation and is a more sensible measure of fluctuations of X around $E(X)$. Alike $E(X)$, for some distributions the variance may not exist. In general, the expected value of the k th power of X , $E(X^k)$, is called the k th moment of the distribution.

The Central limit theorem The Central Limit Theorem [15] is a very important result in probability theory stating that the sum of N independent identically-distributed random variables, with finite average and variance, has a Gaussian probability distribution in the limit $N \rightarrow \infty$, irrespective of the underlying distributions of the random variables. The domain of attraction of the Gaussian as a limit distribution is, thus, very large and can explain why the Gaussian is so frequently encountered. The theorem is, in practice, very useful since many real random processes have a finite average and variance and are approximately independent.

Definition of the Subject

Extreme value theory is concerned with the statistical properties of the extreme events related to a random variable (see Fig. 1), and the understanding and applications of their probability distributions. The methods and the practical use of such a theory have been developed in the last 60 years, though, many complex real-life problems have only recently been tackled. Many disciplines use the tools of extreme value theory including meteorology, hydrology, ocean wave modeling, and finance to name just a few.

For example, in economics, extreme value theory is currently used by actuaries to evaluate and price insurance against the probability of rare but financially catastrophic events. An other application is for the estimation of Value at Risk. In hydrology, the theory is applied by environmental risk agencies to calculate, for example, the height of sea-walls to prevent flooding. Similarly, extreme value theory is also used to set strength boundaries in engineering materials, as well as for material fatigue and reliability in buildings (e. g., bridges, oil rigs), and estimating pollution levels.

This paper aims to give a simple, self contained, introduction to the motivations and basic ideas behind the development of extreme value theory, and briefly covers a few more technical topics such as extreme r order statistics and the generalization of extreme value distribution theory. We refer to textbooks on probability theory, such as [15] (or, for simplicity, to the Glossary), for the definition of the basic notions of probability used here.

Extreme Value Statistics, Figure 1

We show three samples, 1 to 3, each with N realizations of a random variable $X_i (i \in \{1, \dots, N\})$. Extreme value theory is concerned with the statistical properties of occurrence of the extreme values in those samples, such as the maxima (circled points)

The extensive research on extreme value statistics is reviewed in excellent books published over the past years, e. g., [6,11,12,13,14,17,18,21,24]; we provide here only an overview of the basic concepts and tools. To make this paper as self contained as possible, the Glossary gives a beginner introduction to all the elementary notions of probability theory encountered in the following sections.

Introduction

Extreme events, exceeding the typical expected value of a random variable, can have substantial relevance to problems raising in disciplines as diverse as sciences, engineering and economics.

Extreme value theory is a sub-field of applied statistics, early developed [13,14,17,18] by mathematician such as Fisher, Tippet, Gnedenko, and, in particular, Emil Julius Gumbel, dealing precisely with the problems related to extreme events (see Fig. 1). One of its key point is the so called ‘three types theorem’, relating the properties of

the distribution of probability of the underlying stochastic variable to its extreme value distributions, i. e., the limiting distributions for the extreme (minimum or maximum) value of a large collection of random observations. Interestingly, for a comparatively large class of random variables, the theory points out that only a few species of limit extreme value distributions are found.

In some respect, the ‘three types theorem’ can be considered the analogous of the well known central limit theorem applying to ordinary sums, or averages, of random variables. From a practical point of view it is as important, since it opens a way to estimate the asymptotic distribution of extreme values without any a priori knowledge, or guess assumption, on the parent distribution. In this way, we have a solid ground to estimate the parameters of the limit distributions along with their confidence intervals, an issue crucial, for instance, to proper risk assessment.

In Finance, for example, market regulators and financial institutions face the important and complex task to estimate and manage risk. Assessing the probability of rare and extreme events is, of course, a crucial issue and reliable measures of risk are needed to minimize undesirable effects on portfolios from large fluctuations in market conditions, e. g., exchange rates or prices of assets. Similar issues about risk and reliability are faced in insurance and banking, which are deeply concerned with unusually large fluctuations. Extreme value theory provides the solid theoretical foundation needed for the statistical modeling of such events and proper computation of risk and related confidence intervals.

The study of natural and environmental hazards is also strongly interested to extreme events; for instance, reported hydrology and meteorology applications of extreme event theory concern flood frequency analysis, estimation of precipitation probabilities, or extreme tide levels. Predictions of events such as strong heat waves, rain-fall, occurrence of huge sea waves are deeply grounded on such a theory as well. Analogous problems are found in telecommunications and transport systems, such as traffic data analysis, Internet traffic, queuing modeling; problems from material science, pollutants hazards on health add examples from a very long list of related phenomena.

It is impossible to summarize here the huge, often technical, literature on all these topics and we refer to the general books cited in the bibliography. Actually, to give an idea of the variety of applications of the theory, we only mention a few more example from still an other class of disciplines, Physical Sciences. In Physics, for instance, the equilibrium low-temperature properties of disordered systems are characterized by the statistics of ex-

remely low-energy states. Several problems in this class, including the Random Energy Model and models for decaying Burgers turbulence, have been connected to extreme value distributions [3]. In GaAs films, extreme values in Gaussian $1/f$ correlations of voltage fluctuations were shown to follow one of the limit distributions of extreme value theory, the Gumbel asymptote [1]. Hierarchically correlated random variables representing the energies of directed polymers [9] and maximal heights of growing self-affine surfaces [20] exhibits extreme value statistics as well. The Fisher–Tippett–Gumbel asymptote is involved in distribution of extreme height fluctuations for Edwards–Wilkinson relaxation of fluctuating interfaces on small-world-coupled interacting systems [16]. A connection was also established between the energy level density of a gas of non-interacting bosons and the distribution laws of extreme value statistics [7].

In case of systems with correlated variables, the application of the extreme value theory is far from trivial. A theorem states that the statistics of maxima of stationary Gaussian sequences, with suitable correlations, asymptotically converges to a Gumbel distribution [2]. Evidences supporting similar results were derived from numerical simulations and analysis of long-term correlated exponentially distributed signals [10]. In general, however, the scenario is non trivial. For instance, in Physics a variant of Gumbel distribution was observed in turbulence [4] and derived in the two-dimensional XY model [5], which are systems where correlations play an important role. Similarly, correlated extreme value statistics were discovered in the Sneppen depinning model [8]. In models for fluctuating correlated interfaces, such as Edwards–Wilkinson and Kardar–Parisi–Zhang equations, an exact solution for the distribution of maximal heights was recently derived and it turns out to be an Airy function [19].

After the above brief picture of the field, we illustrate next the general properties of extreme value distributions of independent random variables.

The Extreme Value Distributions

Extreme value distributions are the limit distributions of extremes (either maxima or minima) of a set of random variables (see Fig. 1). For definiteness, we will deal here with maxima, as minima can be seen as ‘maxima’ of a set of variables with opposite signs.

Consider a set $\{X_1, X_2, \dots, X_N\}$ of N independent identically distributed random variables, X_i , with a cumulative distribution function, $F(x) \equiv \Pr\{X_i \leq x\}$. The maximum in the set, $Y_N = \text{Max}\{X_1, X_2, \dots, X_N\}$, has a distribution function, $H_N(x)$, which is simply related to

Extreme Value Statistics, Figure 2

As an example, we plot in this figure the Gumbel density distribution, $h(x) = dH(x)/dx$, from Eq. (3), and the Fréchet and Weibull density distributions from Eqs. (4) and (5), for $\alpha = 2$

F , since by definition of Y_N , we have:

$$\begin{aligned} H_N(x) &\equiv \Pr\{Y_N \leq x\} \\ &= \Pr\{X_1 \leq x, X_2 \leq x, \dots, X_N \leq x\} \\ &= \Pr\{X_1 \leq x\} \cdot \Pr\{X_2 \leq x\} \cdot \dots \cdot \Pr\{X_N \leq x\} \\ &= F^N(x). \end{aligned} \tag{1}$$

In the limit of large samples, $N \rightarrow \infty$, it is possible to show that, under some general hypotheses on F described below, we can find a suitable sequence of scaling constants a_N and b_N , such that the scaled variable $y_N = (Y_N - b_N)/a_N$ has a non degenerate probability distribution function $H(y)$. Specifically, as $N \rightarrow \infty$, the distribution $\Pr\{y_N \leq y\}$ has a non trivial well defined limit $H(y)$:

$$\begin{aligned} \Pr\{y_N \leq y\} &= \Pr\{(Y_N - b_N)/a_N \leq y\} \\ &= \Pr\{Y_N \leq a_N y + b_N\} \\ &= F^N(a_N y + b_N) \rightarrow H(y) \text{ for } N \rightarrow \infty. \end{aligned} \tag{2}$$

For a given underlying distribution, F , the individuation of the precise sequence of scaling constants a_N and b_N required in Eq. (2) is a non trivial technical problem in the mathematics of extreme values [18], which we briefly discuss in the next sections. Such an issue is overshadowed by the simplicity of the result of the ‘three types theorem’, which states that there are only three types (apart from a scaling transformation of the variable) of limiting distribution $H(y)$ (see Fig. 2):

I) Gumbel type:

$$H(y) = \exp[-\exp(-y)] \tag{3}$$

with $-\infty < y < \infty$;

II) Fréchet type:

$$H(y) = \exp[-y^{-\alpha}] \tag{4}$$

where α is a fixed exponent and $0 < y < \infty$ (with $H(y) = 0$ for $y < 0$);

III) Weibull type:

$$H(y) = \exp[-(-y)^\alpha] \tag{5}$$

where α is a fixed exponent and $-\infty < y < 0$ (with $H(y) = 1$ for $y > 0$).

The Generalized Extreme Value Distribution

In the extreme value statistics literature, the three types of limiting distributions, Gumbel, Fréchet and Weibull, are often represented as a single family including all of them, the so called generalized extreme value distribution:

$$H(y; \mu, \sigma, \xi) = \exp \left[- \left(1 + \xi \frac{y - \mu}{\sigma} \right)^{-1/\xi} \right] \tag{6}$$

with support in the interval where $1 + \xi(y - \mu)/\sigma > 0$, as otherwise H is either zero or one. Out of the three parameters μ, σ, ξ of Eq. (6), ξ is called the ‘shape’ parameter and it is especially important as it selects the specific type of asymptote:

I) The case $\xi = 0$ corresponds to the Gumbel asymptote, since it is easy to show that

$$\lim_{\xi \rightarrow 0} H(y; \mu, \sigma, \xi) = \exp \left[- \exp \left(\frac{-y - \mu}{\sigma} \right) \right]; \tag{7}$$

II) Similarly, the case $\xi > 0$ corresponds to the Fréchet asymptote of Eq. (4), where the exponent is $\alpha = 1/\xi$;

III) And, finally, the case $\xi < 0$ corresponds to the Weibull asymptote of Eq. (5), where the exponent is $\alpha = -1/\xi$.

The parameters μ and σ of Eq. (6) are called the ‘location’ and the ‘scale’ parameters, since they are related to the moments of the generalized extreme value distribution of Eq. (6). Figure 3 plots the effects of changes in μ and σ on the form of $H(y)$ from Eq. (6) in the Gumbel case, $\xi = 0$. It is possible to show [18] that the k th moment is finite only if $\xi < 1/k$. The mean, which exists only if $\xi < 1$, can be expressed in the following general form

$$E(y) = \mu + \frac{\sigma}{\xi} [\Gamma(1 - \xi) - 1], \tag{8}$$

where $\Gamma(x)$ is the Gamma function. In the Gumbel limit, $\xi \rightarrow 0$, the above result is simplified to: $E(y) = \mu + \sigma\gamma$, where $\gamma = 0.577\dots$ is the Euler γ constant.

Extreme Value Statistics, Figure 3

In this figure we show the effects of the μ and σ parameters on the appearance of the generalized extreme value density distribution, $h(x) = dH(x)/dx$, from Eq. (6), in the case $\xi = 0$, i.e., the Gumbel type. In the upper panel, we plot $h(x)$ for $\sigma = 1$ and $\mu = 0, 1, 2$. In the lower panel, we plot $h(x)$ for $\mu = 0$ and $\sigma = 1/4, 1/2, 1$

Analogously, the variance, existing for $\xi < 1/2$, can be written as:

$$E([y - E(y)]^2) = \left(\frac{\sigma}{\xi}\right)^2 [\Gamma(1 - 2\xi) - \Gamma^2(1 - \xi)], \quad (9)$$

which in the $\xi \rightarrow 0$ limit becomes $E([y - E(y)]^2) = \sigma^2 \pi^2/6$.

The r Largest Order Statistics

The results on distributions of the maximum (or minimum) discussed above can be extended to the set of the r th largest value of an ensemble. Consider a set $\{X_1, X_2, \dots, X_N\}$ of N identically distributed random variables which, for simplicity of notation, are arranged in order of magnitude: $X_1 < X_2 < \dots < X_N$. As before,

$F(x) \equiv \Pr\{X_i \leq x\}$ is their common cumulative distribution function. The statistics of X_N and X_1 are the distribution of, respectively, the maximum and the minimum seen before. Similarly, X_r (with $r \in \{1, N\}$) is called the r (largest) order statistic.

The r order statistic has a distribution function, $H_r(x)$, simply related to F

$$\begin{aligned} H_r(x) &\equiv \Pr\{X_r \leq x\} \\ &= \Pr\{X_1 \leq x, X_2 \leq x, \dots, X_r \leq x\} \\ &\quad \cdot \Pr\{X_{r+1} > x, \dots, X_N > x\} \\ &= \sum_{i=r}^N \frac{N!}{(N-i)!i!} F^i(x)[1 - F(x)]^{N-i}. \end{aligned} \quad (10)$$

The theory of the generalized extreme value distribution can be extended to the r order statistic. Actually, in the limit $N \rightarrow \infty$, if a suitable sequence of scaling constants, a_N and b_N , can be found such that the scaled maximum variable $y_N = (X_N - b_N)/a_N$ has a limit distribution function $H(y)$ given in Eq. (6), then the r order statistic has a limit distribution which can be easily expressed in terms of $H(y)$ [18].

In order to describe a broader panorama of the available results in extreme value theory, we give here some details on the more general case of the limit probability distribution density of the vector of the first r largest values $(y_1, y_2, \dots, y_r) = ((X_N - b_N)/a_N, (X_{N-1} - b_N)/a_N, \dots, (X_{N-r+1} - b_N)/a_N)$. Such a limit distribution density can be shown to be [18]

$$\begin{aligned} h(y_1, \dots, y_r) &= \frac{1}{\sigma^r} \exp \left[- \left(1 + \xi \frac{y_r - \mu}{\sigma} \right)^{-\frac{1}{\xi}} \right. \\ &\quad \left. - \left(1 + \frac{1}{\xi} \right) \sum_{i=1}^r \ln \left(1 + \xi \frac{y_i - \mu}{\sigma} \right) \right]. \end{aligned} \quad (11)$$

Most of the other results of the previous sections can be generalized to the r order statistics, as shown for instance in [18].

Domains of Attraction and Examples

The problem of finding the domains of attraction of the classes of limiting distribution is a complex, partially still open, topic in extreme value theory [18]. Even in the case of independent identically distributed random variables, understanding which asymptote a given distribution, F , converges to and which is the sequence of scaling constants, a_N and b_N , can be a non trivial task. As the extreme events of a random variable are characterized by the tail of

F , a simple approximate approach to guess the domain of attraction F falls into is to consider its behavior for large x . We summarize below a few well known examples having a broad validity which can guide practical applications of the theory to the case where the random variables are independent and identically distributed.

E I) Many common distributions, $F(x)$, have exponential tails in x , very important examples being the Gaussian and the exponential distributions. In this case, their extreme value statistic is the Gumbel asymptote.

A more formal condition for F to belong to the domain of attraction of the Gumbel limiting distribution was established by von Mises. Take a function F and denote x_{\max} the largest value in its support, i. e., where $F(x_{\max}) = 1$ (the point x_{\max} can be also infinite). Consider the derivative $f(x) = dF(x)/dx$ and the rate of $F(x)$ in approaching 1 as $x \rightarrow x_{\max}$: when $x \rightarrow x_{\max}$, if

$$\frac{d}{dx} \left[\frac{1 - F(x)}{f(x)} \right] \rightarrow 0 \quad (12)$$

then $\Pr\{y_N \leq y\}$ tends to the Gumbel asymptote given in Eq. (3).

The above criterion can be rephrased in a more colloquial way: the Gumbel type is the limiting distribution when $1 - F(x)$ decays faster than a polynomial for $x \rightarrow x_{\max}$. Beyond the Gaussian and exponential distributions, the lognormal, the Gamma, the Weibull, the Benktander-type I and II, and many more common distributions, with x_{\max} either finite or infinite, belong to this class.

E II) Distributions such as the Pareto, Cauchy, Student, Burr have the Fréchet asymptote. More generally, when x_{\max} is infinite and F has a power law tail for $x \rightarrow \infty$

$$1 - F(x) \simeq x^{-\alpha} \quad (13)$$

with an exponent $\alpha > 0$, then the domain of attraction of the extreme value statistics is the Fréchet type given in Eq. (4), with precisely the same exponent α of Eq. (13).

E III) Finally, when x_{\max} is finite and F has a power law behavior for $x \rightarrow x_{\max}$

$$1 - F(x) \simeq (x_{\max} - x)^{-\alpha} \quad (14)$$

with an exponent $\alpha > 0$, then the domain of attraction of the extreme value statistics is the Weibull type of Eq. (5), with the same exponent α of

Eq. (14). The Uniform and Beta distributions have, for instance, the Weibull asymptote.

Extremes of Correlated Random Variables

When the underlying random variables are not independent, as in many cases of practical relevance ranging from Meteorology to Finance, the problem to individuate the form, or even the existence, of the limiting distribution is, in general, open. The existing broad technical literature on the topic [18] shows that the three types, Gumbel, Fréchet and Weibull, summarized in the generalized extreme value distribution of Eq. (6), often arise as well. For instance, a recent theorem has shown that in the case of stationary Gaussian sequences with suitable correlations the distribution of maxima asymptotically follows the Gumbel type [2]. Analysis of numerical simulations of long-term correlated exponentially distributed signals has given evidences supporting similar conclusions [10]. Sometimes, when considering ‘time’ series of N correlated variables, the approximate rule of thumb that N must be much bigger than the ‘correlation length’ of the sequence is used as a guide to decide whether Eq. (6) is likely to be the right asymptote.

Some of the example mentioned in the Introduction can help, however, in delineating the strong limits of the above approximate criteria and the lack of a general picture. For instance, in the XY model for magnetic systems used in Statistical Physics, in the Kosterlitz–Thouless low temperature phase the magnetization has a distribution which is a generalized Gumbel [5], but not the one in Eq. (3), a result expected to hold in a broad class of systems. In models for fluctuating interfaces, developing correlations, described by Edwards–Wilkinson and Kardar–Parisi–Zhang like equations, it has been derived that the exact distribution of maximal heights is an Airy function [19]. These examples show the variety of situations which can arise in practical cases and indicate that the theorems derived for independent identically distributed variables must be applied with caution.

Future Directions

In the sections above, we reviewed at an introductory level the mathematics of extreme value theory, with a special focus on the ‘three types theorem’ on the limiting distributions. We also discussed their domains of attraction and many examples on random extreme events. We have not covered, instead, other important, though, more technical and still evolving topics such as the theoretical approach to the problem of ‘exceedances over thresholds’, and the methodology for estimating from real sample data the

parameters of extreme distributions, such as maximum likelihood and Bayesian methods. These are covered, for instance, in the general references listed in the bibliography. Actually, there is a number of excellent textbooks on these topics, ranging from the original book by E.J. Gumbel [17], to more recent volumes illustrating in details extreme value theory in the formal framework of the theory of probability [11,13,14,18]. Volumes more focused on applications to Finance and Insurances are, e. g., [6,11,12,21], as applications to climate, hydrology and meteorology research are found in [6,12,21,24]. Finally, there is a number of more technical review papers on the topic, including [10,22,23].
