Glossary

Scaling limits A scaling limit denotes a procedure to reduce the degree of complexity of a large particle system. It consists in scaling the space-time variables and, possibly, other quantities (like the interaction potential or the density), in order to obtain a more handable description of the same system. The initial space-time coordinates are called **microscopic**, while the new ones, those well suited for the description of kinetic or hydrodynamical systems, are called **macroscopic**.

Boltzmann equation It is an integro-differential kinetic equation for the one particle distribution function in the classical phase space (see Eq. (64) below). It arises in some physical regimes, namely for a rarefied gas and for a weakly interacting quantum dense gas.

Uehling–Uhlenbeck equation It is a Boltzmann type equation taking into account corrections due to the Bose–Einstein or the Fermi–Dirac statistics (see Eq. (69) below). It holds in the weak-coupling limit.

Fokker–Planck–Landau equation It is a kinetic equation diffusive in velocity (see Eq. (28) below). It arises in the context of a weakly interacting classical dense gas.

Hydrodynamical equations They are evolution equations for macroscopic quantities like density, mean velocity, temperature, and so on.

Low density limit Sometimes called Boltzmann–Grad limit, it is a scaling limit in which the density is vanishing. Applied to classical particle systems it gives the Boltzmann equation.

Weak coupling limit It is a scaling limit in which the density is constant but the interaction vanishes suitably. Applied to a quantum particle systems it gives a Boltzmann equation. Applied to a classical particle systems it gives the Fokker–Planck–Landau equation.

Hydrodynamic limit In this scaling we simply pass from micro to macro variables. We look at the behavior of suitable mean values, which are functions of the space and the time. We expect them to behave in a hydrodynamical way, namely to satisfy a set of hydrodynamical equations.

Wigner transform It is the description of a quantum state as a function in the classical phase space.

Definition of the Subject

Many interesting systems in Physics and Applied Sciences are constituted by a large number of identical components so that they are difficult to analyze from a mathematical point of view. On the other hand, quite often, we are not interested in a detailed description of the system but rather to his global behavior. Therefore it is necessary to look for all procedures leading to simplified models, retaining all the interesting features of the original system, cutting away unnecessary informations. This is exactly the methodology of the Statistical Mechanics and the Kinetic Theory when dealing with large particle systems.

In this contribution we want to approach a problem of this type, namely we try to outline the difficulties in making rigorous the limiting procedure leading the microscopic description of a large particle system (based on the fundamental laws like Newton or Schrödinger equations) to a more handable kinetic or hydrodynamic picture. Such a transition depends on the space-time scale we choose to describe the phenomenon. To fix the ideas we start by considering a system constituted by N identical classical point particles of unitary mass. The Newton equations are:

$$\frac{d^2}{d\tau^2} q_i = \sum_{\substack{j=1\dots N:\\ j\neq i}} F(q_i - q_j) \,, \tag{1}$$

where $\{q_1 \dots q_N\}$, $q_i \in \mathbb{R}^3$ are the position of the particles and τ is the time. Here $F = -\nabla\phi$ denotes the interparticle (conservative) force and ϕ the two-body interaction potential.

We now introduce a small parameter $\varepsilon > 0$ expressing the ratio between the macroscopic and the microscopic scales. For instance ε could denote the inverse ratio of a typical distance between two molecules of a gas, measured in microscopic unities, and the same distance measured in meters. It can be as well the ratio between typical macroscopic and microscopic times. We now introduce the new variables

$$x = \varepsilon q \qquad t = \varepsilon\tau \,.$$

Since we are interested in the macroscopic properties of the system, namely in the evolution of macroscopic quantities that are those varying on the (x, t) scale and hence almost constant in the (q, τ) scale, it is natural to rescale also Eq. (1). We write

$$\frac{d^2}{dt^2} x_i = \frac{1}{\varepsilon} \sum_{\substack{j=1\dots N:\\ j\neq i}} F\left(\frac{x_i - x_j}{\varepsilon}\right) . \tag{2}$$

Up to now we did nothing else than an innocent change of variables. However to obtain a non trivial description, N has to diverge when $\varepsilon \to 0$, and we have to specify how. Also additional hypotheses on the strength of the interaction, according to the physical situation at hand, may be necessary. There are various possible scaling limits we shall discuss below.

- *The hydrodynamic limit*
  Here the system is dense, namely $N = O(\varepsilon^{-3})$. For all $x \in \Omega \subset \mathbb{R}^3$, we consider a small box Δ around x. In Δ there are a very large number of particles. We denote the initial density, mean velocity and temperature by $(\rho_0(x), u_0(x), T_0(x))$. At a positive time t the particles starts to interact. For a microscopic time τ the particles in Δ interact practically among themselves only (supposing a short range interaction) and, if an ergodic property would hold, we expect that they reach a thermal equilibrium state. We remind that $t = \varepsilon\tau$ is essentially vanishing, therefore we expect that at macroscopic time $t \approx 0$ the particle are distributed according to the Gibbs measure characterized by the parameters $(\rho_0(x), u_0(x), T_0(x))$, being mass momentum and energy locally conserved. On a larger time scale ($t > 0$) mass momentum and energy are not locally conserved anymore. If a local equilibrium structure is preserved, the parameters of the equilibria $(\rho(x, t), u(x, t), T(x, t))$ will evolve according to five equations which are the exactly the well known Euler equations for compressible gas.
  This complex mechanism is very far to be proven rigorously, even for short times and initial regular data. A heuristic derivation of the Euler equations in terms of particle dynamics was first given by Morrey [35]. We address the reader to [39] and [19] for further references and comments.
- *The low-density (Boltzmann–Grad) limit*
  Now we are dealing with a rarefied gas assuming $N = O(\varepsilon^{-2})$. This is the reason why this scaling is called low-density. We assume also, just for simplicity, that the interaction range of ϕ is one. Consider now a given test particle. If the gas is more or less homogeneous, the number of particles interacting with this particle in a given (macroscopic) time interval is $O(N\varepsilon^2) = O(1)$. Therefore we expect a finite number of collisions per unit time. Moreover each collision is almost instantaneous so that each particle undergoes a jump process in velocity.
  We also assume that initially the particles are independently distributed according to the one-particle distribution on the phase space $f_0(x, v)$ (v is the velocity). Of course the dynamics creates correlations so that, strictly speaking, we expect that the particles, for every positive time t, are not independently distributed anymore. However the probability that a given pair of particles interact is vanishing in the limit $\varepsilon \to 0$. Therefore the statistical independence (called propagation of chaos) is recovered in the same limit. In other words we expect, for the time evolved distribution $f(x, v, t)$, a nonlinear evolution equation, which is the celebrated Boltzmann equation discovered in 1872. This scaling limit, often called the Boltzmann–Grad limit [25], has been proved rigorously by Lanford [31] for a short time

interval (see also [28] for a special case in which the limit holds globally in time). We address the reader to refs. [14,39] and [19] for additional comments and references.

- *The weak-coupling limit*
  Now the gas is dense because we assume $N = O(\varepsilon^{-3})$, however the particles are weakly interacting. This condition is expressed by rescaling the interaction potential by setting

$$\phi \to \sqrt{\varepsilon}\phi \,.$$

After that the equation of motion (in macroscopic variables) become:

$$\frac{d^2}{dt^2}x_i = -\frac{1}{\sqrt{\varepsilon}} \sum_{\substack{j=1\dots N:\\ j\neq i}} \nabla\phi\left(\frac{x_i - x_j}{\varepsilon}\right) . \qquad (3)$$

To have a vague idea of the behavior of a test particle in this limit, we observe first that the velocity change due to a single collision is

$$\Delta v \approx F\Delta t \approx O(\varepsilon/\sqrt{\varepsilon}) = O(\sqrt{\varepsilon}) \,.$$

Here $\Delta t = O(\varepsilon)$ is the time in which the collision takes place, ϕ is assumed short-range in microscopic variables and then $1/\sqrt{\varepsilon}$ is the order of magnitude of the force F.
The number of collisions per unit time is $\varepsilon^2\varepsilon^{-3} = \varepsilon^{-1}$, so that

$$\sum |\Delta v|^2 = O(1) \,.$$

Therefore, provided that the propagation of chaos is ensured, $v = v(t)$ is expected to be not absolutely continuous in the limit and the one-particle distribution function to satisfy a diffusion equation in velocity, the Landau–Fokker–Planck equation.
The statistical independence at a positive time t is expected because the effect of the interaction between two given particle is going to vanish in the limit $\varepsilon \to 0$. Note that the physical meaning of the propagation of chaos here is quite different from that arising in the contest of the Boltzmann equation. Here two particles can interact but the effect of the collision is small, while in a low-density regime the effect of a collision between two given particles is large but quite unlikely.
The above scalings make sense as well for quantum systems. What we expect in this case? Notice that the transition from micro to macro variables increase the frequency of the quantum oscillations so that we are always in presence of a semiclassical limit as regards the kinetic energy part of the Hamiltonian. However the potential varies on the same scale of the oscillations. As a consequence we face the following scenario. The hydrodynamic limit of quantum systems yields the Euler equations for the equilibria parameters ρ, u, T. The only difference with the classical case is that the relationship between the pressure and the hydrodynamical fields, is that dictated by the Quantum Statistical Mechanics. Indeed the local equilibrium is achieved at a microscopic level and this is the only quantum effect we expect to survive in the limit.
The situation is conceptually similar for the low density limit: here we have the classical Boltzmann equation for the one-particle distribution function. The only quantum macroscopic effect is that the cross-section must be computed in terms of the quantum scattering process (see [6]).

Introduction

The hydrodynamical and the low density limits are relatively more popular then the weak-coupling limit, which will be, for that reason, the object of the present contribution. More precisely we analyze large classical and quantum particle systems in the weak-coupling regime. We show how we expect such systems to be well described by the Landau–Fokker–Planck and the Boltzmann equations, for the classical and the quantum case respectively. We also describe the effects of the Fermi–Dirac and Bose–Einstein statistics.

Unfortunately our arguments we present here are largely formal because the rigorous results we know up to now, are few. A rigorous proof of the validity of the weak-coupling limit, or a rigorous derivation of the corresponding kinetic equations, is a challenging and still open problem.

In Sect. “Weak-Coupling Limit for Classical Systems” we introduce and discuss the problem for classical systems, presenting a formal proof of the validity of the Landau equation.

In Sect. “Weak-Coupling Limit for Quantum Systems” we pass to analyze the case of a quantum system, neglecting the correlations due to the statistics. The case of Bosons and Fermions is discussed in Sect. “Weak-Coupling Limit in the Bose–Einstein and Fermi–Dirac Statistics”.

Finally, in Sect. “Weak-Coupling Limit for a Single Particle: the Linear Theory” we briefly introduce and discuss the corresponding linear problems, namely the behavior of a single (classical or quantum) particle in a random distribution of obstacles.

Section "Future Directions" is devoted to concluding remarks.

Weak-Coupling Limit for Classical Systems

We consider a classical system of N identical particles of unitary mass. Rescaled positions and velocities are denoted by $x_1 \dots x_N$ and $v_1 \dots v_N$. After having also rescaled the potential in the following way

$$\phi \to \sqrt{\varepsilon}\phi \, ,$$

the Newton equations reads as

$$\frac{\mathrm{d}}{\mathrm{d}t}x_i = v_i \qquad \frac{\mathrm{d}}{\mathrm{d}t}v_i = -\frac{1}{\sqrt{\varepsilon}} \sum_{\substack{j=1\dots N: \\ j\neq i}} \nabla\phi\left(\frac{x_i - x_j}{\varepsilon}\right) . \quad (4)$$

We also assume that $N = O(\varepsilon^{-3})$, namely the density is $O(1)$.

We are interested in the statistical behavior of the system so that we introduce a probability distribution on the phase space of the system, $W^N = W^N(X_N, V_N)$, that is the state at time zero. Here (X_N, V_N) denote the set of positions and velocities:

$$X_N = (x_1, \dots, x_N) \quad V_N = (v_1, \dots, v_N) \, .$$

Then from Eq. (4) we obtain the following Liouville equation

$$(\partial_t + V_N \cdot \nabla_N) W^N(X_N, V_N) = \frac{1}{\sqrt{\varepsilon}} \left(T^\varepsilon_N W^N\right)(X_N, V_N) \quad (5)$$

where $V_N \cdot \nabla_N = \sum_{i=1}^N v_i \cdot \nabla_{x_i}$ and $(\partial_t + V_N \cdot \nabla_N)$ is the usual free stream operator. Also, we have introduced the operator

$$\left(T^\varepsilon_N W^N\right)(X_N, V_N) = \sum_{0<k<\ell\leq N} \left(T^\varepsilon_{k,\ell} W^N\right)(X_N, V_N) , \quad (6)$$

with

$$T^\varepsilon_{k,\ell} W^N = \nabla\phi\left(\frac{x_k - x_\ell}{\varepsilon}\right) \cdot (\nabla_{v_k} - \nabla_{v_\ell}) W^N \, . \qquad (7)$$

To investigate the limit $\varepsilon \to 0\,,\ N = \varepsilon^{-3}$, it is convenient to introduce the BBKGY hierarchy (from Bogoliubov, Born, Green, Kirkwood and Yvon, see e. g. [2] and [19]), for the j-particle distributions defined as

$$f^N_j(X_j, V_j) = \int \mathrm{d}x_{j+1} \dots \int \mathrm{d}x_N \int \mathrm{d}v_{j+1} \dots \int \mathrm{d}v_N \\ W^N(X_j, x_{j+1} \dots x_N, V_j, v_{j+1} \dots v_N) \quad (8)$$

for $j = 1, \dots, N-1$. Obviously, we set $f^N_N = W^N$.

From now on we shall suppose that, due to the fact that the particles are identical, the function W^N and f^N_j which we have introduced are all symmetric in the exchange of particles.

A partial integration of the Liouville equation (5) and standard manipulations give us the following hierarchy of equations: (for $1 \leq j \leq N$):

$$\left(\partial_t + \sum_{k=1}^{j} v_k \cdot \nabla_k\right) f^N_j = \frac{1}{\sqrt{\varepsilon}} T^\varepsilon_j f^N_j + \frac{N-j}{\sqrt{\varepsilon}} C^\varepsilon_{j+1} f^N_{j+1} . \quad (9)$$

The operator C^ε_{j+1} is defined as:

$$C^\varepsilon_{j+1} = \sum_{k=1}^{j} C^\varepsilon_{k,j+1} \, , \qquad (10)$$

and

$$C^\varepsilon_{k,j+1} f_{j+1}(x_1 \dots x_j, v_1 \dots v_j) \\ = -\int \mathrm{d}x_{j+1} \int \mathrm{d}v_{j+1} F\left(\frac{x_k - x_\ell}{\varepsilon}\right) \qquad (11) \\ \cdot \nabla_{v_k} f_{j+1}(x_1, x_2, \dots, x_{j+1}, v_1, \dots, v_{j+1}) \, .$$

$C^\varepsilon_{k,j+1}$ describes the "collision" of particle k, belonging to the j-particle subsystem, with a particle outside the subsystem, conventionally denoted by the number $j+1$ (this numbering uses the fact that all particles are identical). The total operator C^ε_{j+1} takes into account all such collisions. The dynamics of the j-particle subsystem is governed by three effects: the free-stream operator, the "recollisions", i. e. the collisions "inside" the subsystem, given by the T term, and the "creations", i. e. the collisions with particles "outside" the subsystem, given by the C term.

We finally fix the initial value $\{f^0_j\}^N_{j=1}$ of the solution $\{f^N_j(t)\}^N_{j=1}$ assuming that $\{f^0_j\}^N_{j=1}$ is factorized, that is, for all $j = 1, \dots N$

$$f^0_j = f_0^{\otimes j} \, , \qquad (12)$$

where f_0 is a given one-particle distribution function. This means that any pair of particles are statistically uncorrelated at time zero. Of course such a statistical independence is destroyed at time $t > 0$ and Eq. (9) shows that the time evolution of f^N_1 is determined by the knowledge of f^N_2 which turns out to be dependent on f^N_3 and so on. However, since the interaction between two given particle is going to vanish in the limit $\varepsilon \to 0$, we can hope that such statistical independence, namely the factorization property (12), is recovered in the same limit.

Therefore we expect that in the limit $\varepsilon \to 0$ the one-particle distribution function f^N_1 converges to the solution of a suitable nonlinear kinetic equation f which we are going to investigate.

If we expand $f_j^N(t)$ as a perturbation of the free flow $S(t)$ defined as

$$(S(t)f_j)(X_j, V_j) = f_j(X_j - V_j t, V_j)\,, \tag{13}$$

we find

$$\begin{aligned} f_j^N(t) = S(t)f_j^0 + \frac{N-j}{\sqrt{\varepsilon}} \int_0^t S(t-t_1) C_{j+1}^{\varepsilon} f_{j+1}^N(t_1) \mathrm{d}t_1 \\ + \frac{1}{\sqrt{\varepsilon}} \int_0^t S(t-t_1) T_j^{\varepsilon} f_j^N(t_1) \mathrm{d}t_1\,. \end{aligned} \tag{14}$$

We now try to keep informations on the limit behavior of $f_j^N(t)$. Assuming for the moment that the time evolved j-particle distributions $f_j^N(t)$ are smooth (in the sense that the derivatives are uniformly bounded in ε), then

$$\begin{aligned} C_{j+1}^{\varepsilon} f_{j+1}^N(X_j, V_j, t_1) = -\varepsilon^3 \sum_{k=1}^{j} \int \mathrm{d}r \int \mathrm{d}v_{j+1} F(r) \\ \cdot \nabla_{v_k} f_{j+1}(X_j, x_k - \varepsilon r, V_j, v_{j+1}, t_1)\,. \end{aligned} \tag{15}$$

Assuming now, quite reasonably, that

$$\int \mathrm{d}r F(r) = 0\,, \tag{16}$$

we find that

$$C_{j+1}^{\varepsilon} f_{j+1}^N(X_j, V_j, t_1) = O(\varepsilon^4)$$

provided that $D_v^2 f_{j+1}^N$ is uniformly bounded. Since

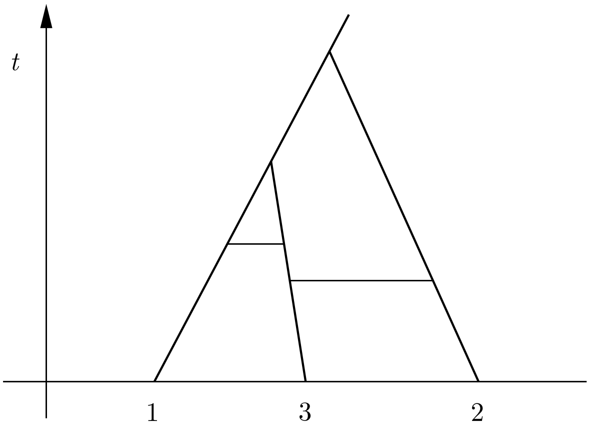
$$\frac{N-j}{\sqrt{\varepsilon}} = O(\varepsilon^{\frac{7}{2}})$$

we see that the second term in the right hand side of (14) does not give any contribution in the limit. Moreover

$$\begin{aligned} \int_0^t S(t-t_1) T_j^{\varepsilon} f_j^N(t_1) \mathrm{d}t_1 = \sum_{i \neq k} \int_0^t \mathrm{d}t_1 \\ \cdot F\left(\frac{(x_i - x_k) - (v_i - v_k)(t - t_1)}{\varepsilon} \right) g(X_j, V_j, t_1)\,, \end{aligned} \tag{17}$$

where g is a smooth function.

Obviously the above time integral is $O(\varepsilon)$ so that also the last term in the right hand side of (14) does not give any contribution in the limit. Then we are facing the alternative: either the limit is trivial or the time evolved distributions are not smooth. However we believe that the limit is not trivial (actually we expect to get a diffusion equation, according to the previous discussion) and a rigorous proof of this fact seems problematic.



Scaling Limits of Large Systems of Non-linear Partial Differential Equations, Figure 1
The collision sequence (1, 2), (1, 3), (1, 3), (2, 3)

The difficulty in obtaining a-priori estimates induce us to exploit the full series expansion of the solution, namely

$$\begin{aligned} & f_1^N(t) \\ & = \sum_{n \geq 0} \sum_{G_n} K(G_n) \int_0^t \mathrm{d}t_1 \int_0^{t_1} \mathrm{d}t_2 \ldots \int_0^{t_{n-1}} \mathrm{d}t_n \\ & \quad \cdot \left[S(t-t_1) O_1 S(t_1 - t_2) \ldots O_n S(t_n) \right] f_m^0\,. \end{aligned} \tag{18}$$

Here O_j is either an operator C or T expressing a creation of a new particle or a recollision between two particles respectively. G_n is a graph namely a sequence of indices

$$(r_1, l_1), (r_2, l_2), \ldots (r_n, l_n)$$

where (r_j, l_j), $r_j < l_j$ are the pair of indices of the particles involved in the interaction at time t_j. The number of particles created in the process is $m - 1$. It is convenient to represent the generic graph in the following way, as in Fig. 1.

The legs of the graph denotes the particles and the nodes the creation of new particles (operators C). Recollisions (operators T) are represented by horizontal link. For instance the graph in figure is $(1, 2)$, $(1, 3)$, $(1, 3)$, $(2, 3)$, $m = 3$ and the integrand in Eq. (18) is in this case

$$\begin{aligned} & \left[S(t-t_1) C_{1,2} S(t_1 - t_2) C_{1,3} S(t_2 - t_3) T_{1,3} \right. \\ & \quad \left. \cdot S(t_3 - t_4) T_{2,3} S(t_4) \right] f_3^0\,. \end{aligned} \tag{19}$$

Note that the knowledge of the graph determines completely the sequence of operators in the right hand side of (20).

Finally the factor $K(G_n)$ takes into account the divergences:

$$K(G_n) = O\left(\varepsilon^{-\frac{n}{2}}\varepsilon^{-3(m-1)}\right) . \tag{20}$$

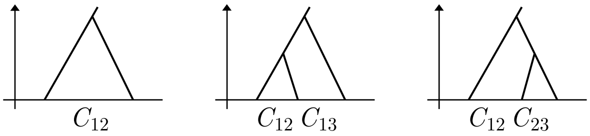
We are not able to analyze the asymptotic behavior of each term of the expansion (18) however we can compute the limit for $\varepsilon \to 0$ of the few terms up to the second order (in time). We have:

$$\begin{aligned} g^N(x_1, v_1, t) &= f^0(x_1 - v_1 t, v_1) + \frac{N-1}{\sqrt{\varepsilon}} \int_0^t S(t-t_1) \\ &\cdot C^{\varepsilon}_{1,2} S(t_1) f^0_2 \mathrm{d}t_1 + \frac{(N-1)}{\varepsilon}\frac{(N-2)}{\varepsilon} \sum_{j=1,2} \int_0^{t_1} \mathrm{d}t_2 \\ &\cdot S(t-t_1) C^{\varepsilon}_{1,2} S(t_1-t_2) C^{\varepsilon}_{j,3} S(t_2) f^0_3 + \frac{N-1}{\varepsilon} \int_0^t \mathrm{d}t_1 \\ &\cdot \int_0^{t_1} \mathrm{d}t_2\, S(t-t_1) C^{\varepsilon}_{1,2} S(t_1-t_2) T^{\varepsilon}_{1,2} S(t_2) f^0_2 . \end{aligned} \tag{21}$$

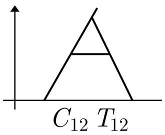
Here the right hand side of (21) defines g^N.

The second and third term in (21) corresponding to the graphs shown in Fig. 2 are indeed vanishing as follows by the use of the previous arguments.

The most interesting term is the last one, shown in Fig. 3.



Scaling Limits of Large Systems of Non-linear Partial Differential Equations, Figure 2
The vanishing terms in the expansion of g^N



Scaling Limits of Large Systems of Non-linear Partial Differential Equations, Figure 3
The first non vanishing terms in the expansion of g^N

To handle this term we denote by $w = v_1 - v_2$ the relative velocity and note that, for a given function u:

$$\begin{aligned} & S(t_1-t_2) T^{\varepsilon}_{1,2} u(x_1, x_2, v_1, v_2) \\ &= -F\left(\frac{(x_1-x_2) - w(t_1-t_2)}{\varepsilon}\right) \cdot [(\nabla_{v_1} - \nabla_{v_2})u] \\ &\quad \cdot (x_1 - v_1(t_1-t_2), x_2 - v_2(t_1-t_2), v_1, v_2) \\ &= -F\left(\frac{(x_1-x_2) - w(t-t_1)}{\varepsilon}\right) \cdot (\nabla_{v_1} - \nabla_{v_2} + (t_1-t_2) \\ &\quad \cdot (\nabla_{x_1} - \nabla_{x_2})) S(t_1-t_2) u(x_1, x_2, v_1, v_2) . \end{aligned} \tag{22}$$

Therefore the last term in the r.h.s. of (22) is

$$\begin{aligned} & \frac{N-1}{\varepsilon} \int_0^t \mathrm{d}t_1\, S(t-t_1) \int_0^{t_1} \mathrm{d}t_2 \int \mathrm{d}x_2 \int \mathrm{d}v_2 \\ & F\left(\frac{x_1-x_2}{\varepsilon}\right) \cdot \nabla_{v_1} F\left(\frac{(x_1-x_2) - w(t_1-t_2)}{\varepsilon}\right) \\ &\quad \cdot (\nabla_{v_1} - \nabla_{v_2} + (t_1-t_2)(\nabla_{x_1} - \nabla_{x_2})) \\ &\quad \cdot S(t_1) f^0_2(x_1, x_2, v_1, v_2) . \end{aligned} \tag{23}$$

Setting now $r = \frac{x_1-x_2}{\varepsilon}$ and $s = \frac{t_1-t_2}{\varepsilon}$ then

$$\begin{aligned} & g^N(x_1, v_1, t) = (N-1)\varepsilon^3 \int_0^t \mathrm{d}t_1 \int_0^{\frac{t_1}{\varepsilon}} \mathrm{d}s \int \mathrm{d}r \\ &\quad \cdot \int \mathrm{d}v_2\, F(r) \cdot \nabla_{v_1} \\ & F(r - ws) \cdot (\nabla_{v_1} - \nabla_{v_2} + \varepsilon s(\nabla_{x_1} - \nabla_{x_2})) \\ &\quad \cdot S(t_1 - \varepsilon s) f^0_2(x_1, x_2, v_1, v_2) + O(\sqrt{\varepsilon}) . \end{aligned} \tag{24}$$

The formal limit is of (21) is

$$\begin{aligned} g(x_1, v_1, t) = \int_0^t \mathrm{d}t_1 \int \mathrm{d}v_2\, S(t-t_1) \nabla_{v_1} a(v_1 - v_2) \\ \cdot (\nabla_{v_1} - \nabla_{v_2})\ S(t_1) f^0_2 , \end{aligned} \tag{25}$$

where (using $F(r) = -F(-r)$) the matrix a is given by:

$$\begin{aligned} a(w) &= \int \mathrm{d}r \int_0^{+\infty} \mathrm{d}s\, F(r) \otimes F(r - ws) = \frac{1}{2} \int \mathrm{d}r \\ &\cdot \int_{-\infty}^{+\infty} \mathrm{d}s\, F(r) \otimes F(r - ws) \frac{1}{2} \frac{1}{(2\pi)^3} \int_{-\infty}^{+\infty} \mathrm{d}s \\ &\cdot \int \mathrm{d}k\, k \otimes k\, \hat{\phi}(k)^2 \mathrm{e}^{i(w \cdot k)s} = \frac{1}{(8\pi)^2} \int \mathrm{d}k\, k \otimes k\, \hat{\phi}(k)^2 \\ &\cdot \delta(w \cdot k) = \frac{A}{|w|^3} (|w|^2 Id - w \otimes w), \end{aligned} \tag{26}$$

where $\hat{\phi}(k) = \int e^{-il\cdot x}\phi(x)\mathrm{d}x$. Here the interaction potential ϕ has been assumed spherically symmetric and:

$$A = \frac{1}{8\pi}\int_0^{+\infty} \mathrm{d}r\, r^3 \hat{\phi}(r)^2\,. \tag{27}$$

Looking at Eq. (25) we are led to introduce the following nonlinear equation:

$$(\partial_t + v\cdot\nabla_x)f = Q_L(f, f) \tag{28}$$

with the collision operator Q_L given by:

$$Q_L(f,f)(v) = \int \mathrm{d}v_1 \cdot \nabla_v\Big[a(v-v_1)\,(\nabla_v - \nabla_{v_1})\; f(v)f(v_1)\Big]. \tag{29}$$

Here x plays the role of a parameter and hence his dependence is omitted.

Equation (28) is called the Fokker–Planck–Landau equation (Landau equation in the sequel) and has been introduced by Landau in the study of a dense, weakly interacting gas (see [32]).

From (28) we obtain the following (infinite) hierarchy of equations

$$(\partial_t + V_j\cdot\nabla_{X_j})f_j = C_{j+1}f_{j+1} \tag{30}$$

for the quantities:

$$f_j(t) = f(t)^{\otimes j} \tag{31}$$

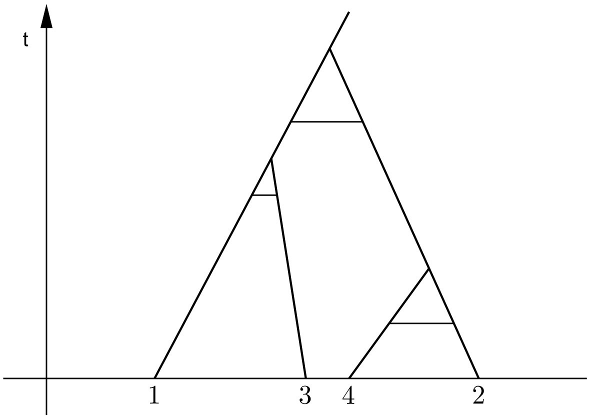
where $f(t)$ solves Eq. (28). Accordingly $C_{j+1} = \sum_k C_{k,j+1}$ where

$$\begin{aligned} &C_{k,j+1}f_{j+1}(x_1\dots x_j, v_1\dots v_j)\\ &= \prod_{r\neq k} f(x_r, v_r)Q_L(f,f)(x_k, v_k)\,. \end{aligned} \tag{32}$$

Therefore f has the following series expansion representation

$$\begin{aligned} f(t) = \sum_{n\geq 0}\int_0^t \mathrm{d}t_1 \int_0^{t_1}\mathrm{d}t_2 \dots \int_0^{t_{n-1}} \mathrm{d}t_n\\ \cdot\big[S(t-t_1)C_2S(t_1-t_2)C_3\dots C_{n-1}S(t_n)\big]f^0_{n+1}\,. \end{aligned} \tag{33}$$

The previous calculation shows the formal convergence of g^N to the term with $n = 1$ of the expansion (33), namely we have an agreement between the particle system (18) and the solution to the Landau equation (33) at least up to the first order in time (second order in the potential). Although the above arguments can be made rigorous, under suitable assumption on the initial condition f_0 and the potential ϕ, it seems difficult to show the convergence of the whole series. On the other hand it is clear that the graphs which should contribute in the limit are those formed by a collision-recollision sequence, like that shown in Fig. 4. For those terms it is probably possible to show the convergence. For instance the case in figure has the asymptotics



Scaling Limits of Large Systems of Non-linear Partial Differential Equations, Figure 4
The collision-recollision sequence $(1,2)$, $(1,2)$, $(1,3)$, $(1,3)$, $(2,4)$, $(2,4)$

$$\begin{aligned} \int_0^t \mathrm{d}t_1 \int_0^{t_1}\mathrm{d}t_2\int_0^{t_2}\mathrm{d}t_3\big[S(t-t_1)C_{1,2}S(t_1-t_2)\\ \cdot C_{1,3}S(t_2-t_3)C_{2,4}S(t_3)\big]f^0_4\,. \end{aligned} \tag{34}$$

However the proof that all other graphs are vanishing in the limit is not easy. Even more difficult is a uniform control of the series expansion (18), even for short times. As we shall see in the next section, something more can be obtained for quantum systems under the same scaling limit.

Some comments are in order.

In the present section we showed how the Landau equation is expected to be derived in the weak-coupling limit from a particle system. In doing this we essentially followed the monograph [2]. This is not however the usual way in which the Landau equation is introduced in the literature. Indeed it is usually recovered from the Boltzmann equation. when the density increases and the grazing collisions become dominant. In particular, the case of the homogeneous Boltzmann equation has been investigated in [1,24,44] (see also [15] for the Coulomb potential case, and see the general survey [43]). In [1] the authors show that, under suitable assumptions on the cross-section, the diffusion Fokker–Planck–Landau equation (28) can indeed be derived. The diffusion operator is the form (29) but with a matrix a given by

$$a(w) = \alpha(|w|)(|w|^2 Id - w \otimes w) ,$$

with α smooth function. Next in [24] and [44] steps forward were performed to arrive to cover the case $\alpha(|w|) \approx 1/|w|^\nu$ for small $|w|$, with $\nu < 1$. We remark that the diffusion coefficient found in this way is different from that derived here in (26).

We conclude by observing that the Landau equation describes a genuine kinetic evolution. Mass, momentum and energy are conserved, while the kinetic entropy is decreasing. The equilibrium is Maxwellian. The difficulties in the validation problem are certainly related to the transition from a reversible (hamiltonian) dynamics to an irreversible one, as for the Boltzmann equation. Here we tried to compare the two series expansions as in the Lanford's validation proof for the Boltzmann equation. This is a sort of Cauchy–Kowalevski brute force argument which works, as well, for negative times. It is clear that, in this way, we cannot go beyond a short time result and even this seems not trivial at all. Other approaches making use of the diffusive nature of the motion of a test particle are, at moment, absent. However the weak-coupling limit of a single particle in a random distribution of scatterers is well understood as we shall discuss later in Sect. "The Weak Coupling Limit for a Single Particle: the Linear Theory".

Weak-Coupling Limit for Quantum Systems

We consider the quantum analog of the system considered in Sect. "Introduction", namely N identical quantum particles with unitary mass in $\mathbb{R}^3$. In the present section the statistical nature of the particles will be ignored.

The interaction between particles is still a two-body potential ϕ so that the total potential energy is taken as

$$U(x_1 \dots x_N) = \sum_{i<j} \phi(x_i - x_j) . \tag{35}$$

The associated Schrödinger equation reads

$$i\partial_t \Psi(X_N, t) = -\tfrac{1}{2}\Delta_N \Psi(X_N, t) + U(X_N)\Psi(X_N, t), \tag{36}$$

where $\Delta_N = \sum_{i=1}^N \Delta_i$, Δ_i is the Laplacian with respect to the x_i variables, $X_N = (x_1, \dots, x_N)$ and $\hbar$ is normalized to unity.

As for the classical system considered in Sect." Introduction" we rescale the equation and the potential by

$$x \to \varepsilon x , \qquad t \to \varepsilon t , \qquad \phi \to \sqrt{\varepsilon}\phi . \tag{37}$$

The resulting equation is,

$$i\varepsilon\partial_t \Psi^\varepsilon(X_N, t) = -\frac{\varepsilon^2}{2}\Delta_N \Psi^\varepsilon(X_N, t) + U_\varepsilon(X_N)\,\Psi^\varepsilon(X_N, t), \tag{38}$$

where:

$$U_\varepsilon(x_1 \dots x_N) = \sqrt{\varepsilon}\sum_{i<j} \phi\left(\frac{x_i - x_j}{\varepsilon}\right) . \tag{39}$$

We want to analyze the limit $\varepsilon \to 0$ in the above equations, when $N = \varepsilon^{-3}$.

Note that this limit looks, at a first sight, similar to a semiclassical (or high frequency) limit. It is not so: indeed the potential varies on the same scale of the typical oscillations of the wave functions so that the scattering process is a genuine quantum process. Obviously, due to the oscillations, we do not expect that the wave function does converge to something in the limit. The right quantity to look at was introduced by Wigner in 1922 [45] to deal with kinetic problems. It is called the Wigner transform (of Ψ^ε) and is defined as

$$\begin{aligned} W^N(X_N, V_N) = \left(\frac{1}{2\pi}\right)^{3N} \int \mathrm{d}Y_N\, \mathrm{e}^{iY_N \cdot V_N}\overline{\Psi}^\varepsilon \\ \cdot (X_N + \frac{\varepsilon}{2}Y_N)\,\Psi^\varepsilon(X_N - \frac{\varepsilon}{2}Y_N) . \end{aligned} \tag{40}$$

The Wigner transform W^N satisfies a transport-like equation, completely equivalent to the Schrödinger equation:

$$(\partial_t + V_N \cdot \nabla_N)W^N(X_N, V_N) = \frac{1}{\sqrt{\varepsilon}}(T_N^\varepsilon W^N)(X_N, V_N). \tag{41}$$

The operator T_N^ε on the right-hand-side of (38) plays the same role of the classical operator denoted with the same symbol in Sect. "Introduction". It is

$$(T_N^\varepsilon W^N)(X_N, V_N) = \sum_{0<k<\ell\leq N} (T_{k,\ell}^\varepsilon W^N)(X_N, V_N), \tag{42}$$

where each $T_{k,\ell}^\varepsilon$ describes the interaction of particle k with particle ℓ

$$\begin{aligned} (T_{k,\ell}^\varepsilon W^N)(X_N, V_N) = \frac{1}{i}\Bigg(\frac{1}{(2\pi)^{3N}} \int \mathrm{d}Y_N \mathrm{d}V_N' \\ \cdot \mathrm{e}^{iY_N\cdot(V_N - V_N')}\left[\phi\left(\frac{x_k - x_\ell}{\varepsilon} - \frac{y_k - y_\ell}{2}\right)\right) \\ -\phi\left(\frac{x_k - x_\ell}{\varepsilon} + \frac{y_k - y_\ell}{2}\right)\right] W^N(X_N, V_N') . \end{aligned} \tag{43}$$

Equivalently, we may write

$$(T^{\varepsilon}_{k,\ell}W^N)(X_N,V_N) = -i\sum_{\sigma=\pm1}\sigma\int\frac{\mathrm{d}h}{(2\pi)^3}\,\hat{\phi}(h)\cdot \mathrm{e}^{i\frac{h}{\varepsilon}(x_k-x_\ell)}W^N(x_1,\dots,x_N;v_1,\dots,v_k-\sigma\frac{h}{2},\dots,v_\ell+\sigma\frac{h}{2},\dots,v_N)\,. \quad (44)$$

Note that $T^{\varepsilon}_{k,\ell}$ is a pseudodifferential operator which formally converge, at fixed ε, for $\hbar\to0$ (here $\hbar=1$) to its classical analog given by Eq. (7). Note also that in (44), "collisions" may take place between *distant* particles ($x_k\neq x_\ell$). However, such distant collisions are penalized by the highly oscillatory factor $\exp(ih(x_k-x_\ell)/\varepsilon)$. These oscillations turn out to play a crucial role throughout the analysis, and they explain why collisions tend to happen when $x_k=x_\ell$ in the limit $\varepsilon\to0$.

The formalism we have introduced is formally similar to the classical case so that we proceed as before by transforming Eq. (38) into a hierarchy of equations. We introduce the partial traces of the Wigner transform W^N, denoted by f^N_j. They are defined through the following formula, valid for $j=1,\dots,N-1$:

$$f^N_j(X_j,V_j)=\int\mathrm{d}x_{j+1}\dots\int\mathrm{d}x_N\int\mathrm{d}v_{j+1}\dots\int\mathrm{d}v_N\, W^N(X_j,x_{j+1}\dots x_N,V_j,v_{j+1}\dots v_N)\,. \quad (45)$$

Obviously, we set $f^N_N=W^N$. The function f^N_j is the kinetic object that describes the state of the j particles subsystem at time t.

As before, the wave function Ψ, as well W^N and f^N_j, are assumed to be symmetric in the exchange of particle, a property that is preserved in time.

Proceeding then as in the derivation of the BBKGY hierarchy for classical systems, we readily transform Eq. (38) into the following hierarchy:

$$(\partial_t+\sum_{k=1}^{j}v_k\cdot\nabla_k)f^N_j(X_j,V_j) = \frac{1}{\sqrt{\varepsilon}}T^{\varepsilon}_j f^N_j+\frac{N-j}{\sqrt{\varepsilon}}C^{\varepsilon}_{j+1}f^N_{j+1}\,, \quad (46)$$

where

$$C^{\varepsilon}_{j+1}=\sum_{k=1}^{j}C^{\varepsilon}_{k,j+1}\,, \quad (47)$$

and $C^{\varepsilon}_{k,j+1}$ is defined by

$$C^{\varepsilon}_{k,j+1}f^N_{j+1}(X_j,V_j) = -i\sum_{\sigma=\pm1}\sigma\int\frac{\mathrm{d}h}{(2\pi)^3}\int\mathrm{d}x_{j+1}\cdot\int\mathrm{d}v_{j+1}\,\hat{\phi}(h)\,\mathrm{e}^{i\frac{h}{\varepsilon}(x_k-x_{j+1})} f^N_{j+1}\Big(x_1,x_2,\dots,x_{j+1},v_1,\dots,v_k-\sigma\frac{h}{2},\dots,v_{j+1}+\sigma\frac{h}{2}\Big)\,. \quad (48)$$

As before the initial value $\{f^0_j\}^N_{j=1}$ is assumed completely factorized: for all $j=1,\dots,N$, we suppose

$$f^0_j=f_0^{\otimes j}\,, \quad (49)$$

where f_0 is a one-particle Wigner function, and f^0 is assumed to be a probability distribution.

In the limit $\varepsilon\to0$, we expect that the j-particle distribution function $f^N_j(t)$, that solves the hierarchy (46) with initial data (49), tends to be factorized for all times: $f^N_j(t)\sim f(t)^{\otimes j}$ (propagation of chaos).

As for the classical case, if f_{j+1} is smooth:

$$C^{\varepsilon}_{k,j+1}f^N_{j+1}(X_j,V_j) = -i\varepsilon^3\sum_{\sigma=\pm1}\sigma\int\frac{\mathrm{d}h}{(2\pi)^3}\hat{\phi}(h)\cdot\int\mathrm{d}r\int\mathrm{d}v_{j+1}\;\mathrm{e}^{ih\cdot r} f^N_{j+1}\Big(X_j,x_k-\varepsilon r,\ v_1,\dots,v_k-\sigma\frac{h}{2},\dots,v_{j+1}+\sigma\frac{h}{2}\Big) = O(\varepsilon^4)\,. \quad (50)$$

Indeed, setting $\varepsilon=0$ in the integrand, the integration over r produces $\delta(h)$. As a consequence the integrand is independent on σ and the sum vanishes. Therefore the integral is $O(\varepsilon)$. Also

$$\frac{1}{\sqrt{\varepsilon}}\int_0^t\mathrm{d}t_1\,S(t-t_1)T_{r,k}f^N_j(t_1) = -i\sum_{\sigma=\pm1}\sigma\int_0^t\mathrm{d}t_1\frac{\mathrm{d}h}{(2\pi)^3}\hat{\phi}(h)\mathrm{e}^{i\frac{h}{\varepsilon}\cdot(x_r-x_k)-(v_r-v_k)(t-t_1)}\cdot f^N_j(X_j-V_j(t-t_1),V_j,t_1) \quad (51)$$

is weakly vanishing, by a stationary phase argument (see [4]). Therefore, as for the classical case, we analyze the asymptotics of the collision-recollision term (shown in Fig. 1):

$$-\frac{N-1}{\varepsilon}\int_0^t \mathrm{d}t_1 \int_0^{t_1} \mathrm{d}\tau_1 \cdot S(t-t_1)C_{1,2}S(t_1-\tau_1)T_{1,2}S(\tau_1)f_2^0 . \tag{52}$$

Explicitly it looks as:

$$\begin{aligned}&-\frac{N-1}{\varepsilon}\sum_{\sigma,\sigma'=\pm 1}\sigma\sigma'\int_0^t \mathrm{d}t_1\int_0^{t_1}\mathrm{d}\tau_1\int \mathrm{d}x_2\int \mathrm{d}v_2\\ &\cdot\int\frac{\mathrm{d}h}{(2\pi)^3}\int\frac{\mathrm{d}k}{(2\pi)^3}\hat{\phi}(h)\,\hat{\phi}(k)\,\mathrm{e}^{i\frac{h}{\varepsilon}\cdot\left(x_1-x_2-v_1(t-t_1)\right)}\\ &\cdot\mathrm{e}^{i\frac{k}{\varepsilon}\cdot\left(x_1-x_2-v_1(t-t_1)-(v_1-v_2-\sigma h)(t_1-\tau_1)\right)}\,f_2^0\Bigg(x_1-v_1 t\\ &\quad+\sigma\frac{h}{2}t_1+\sigma'\frac{k}{2}\tau_1, x_2-v_2t_1-\sigma\frac{h}{2}t_1-\sigma'\frac{k}{2}\tau_1;\\ &\quad v_1-\sigma\frac{h}{2}-\sigma'\frac{k}{2}, v_2+\sigma\frac{h}{2}+\sigma'\frac{k}{2}\Bigg) .\end{aligned} \tag{53}$$

By the change of variables:

$$t_1-\tau_1=\varepsilon s_1 , \;(\text{i.e. } \tau_1=t_1-\varepsilon s_1) , \;\xi=(h+k)/\varepsilon , \tag{54}$$

we have

$$\begin{aligned}(54) &= -(N-1)\,\varepsilon^3\sum_{\sigma,\sigma'=\pm 1}\sigma\sigma'\int_0^t \mathrm{d}t_1\int_0^{t_1/\varepsilon}\mathrm{d}s_1\\ &\cdot\int \mathrm{d}x_2\,\mathrm{d}v_2\,\frac{\mathrm{d}\xi}{(2\pi)^3}\,\frac{\mathrm{d}k}{(2\pi)^3}\,\hat{\phi}(-k+\varepsilon\xi_1)\,\hat{\phi}(k)\\ &\cdot\mathrm{e}^{i\xi\cdot\left(x_1-x_2-v_1(t-t_1)\right)}\mathrm{e}^{-is_1k\cdot(v_1-v_2-\sigma(-k+\varepsilon\xi))}f_{j+1}^0(\ldots) ,\end{aligned} \tag{55}$$

In the limit $\varepsilon \to 0$, the above formula gives the asymptotics

$$\begin{aligned}(52) \underset{\varepsilon\to 0}{\sim} &-\sum_{\sigma,\sigma'=\pm 1}\sigma\sigma'\int_0^t \mathrm{d}t_1\int \mathrm{d}v_2\,\frac{\mathrm{d}k}{(2\pi)^3}\,|\hat{\phi}(k)|^2\\ &\cdot\left(\int_0^{+\infty}\mathrm{e}^{-is_1k\cdot(v_1-v_2+\sigma k)}\mathrm{d}s_1\right)\\ &\cdot f_2^0\Bigg(x_1-v_1t-(\sigma-\sigma')\frac{k}{2}t_1,\\ &x_1-v_1(t-t_1)-v_2t_1+(\sigma-\sigma')\frac{k}{2}t_1, v_1+(\sigma-\sigma')\frac{k}{2},\\ &v_2-(\sigma-\sigma')\frac{k}{2}\Bigg) .\end{aligned} \tag{56}$$

In [4], we completely justify formula (56) and its forthcoming consequences.

Now, we turn to identifying the limiting value obtained in (56). To do so, we observe that symmetry arguments allow us to replace the integral in s by its real part:

$$\operatorname{Re}\int_0^{\infty}\mathrm{e}^{-is_1k\cdot(v_1-v_2+\sigma k)}\mathrm{d}s_1=\pi\delta(k\cdot(v_1-v_2+\sigma k)) . \tag{57}$$

Using this we realize that the contribution $\sigma = -\sigma'$ in (56) gives rise to the gain term:

$$\begin{aligned}&\int_0^t \mathrm{d}t_1\int \mathrm{d}v_2\int \mathrm{d}\omega\,B(\omega, v_1-v_2)\,f_2^0\big(x_1-v_1(t-t_1)\\ &\quad-v_1't_1, x_2-v_2(t-t_1)-v_2't_1, v_1', v_2'\big) ,\end{aligned} \tag{58}$$

where the integral in ω is on the surface of the unitary sphere in $\mathbb{R}^3$, and

$$B(\omega, v)=\frac{1}{8\pi^2}|\omega\cdot v|\,|\hat{\phi}(\omega\,(\omega\cdot v))|^2, \tag{59}$$

and the velocities v_1', v_2' are

$$v_1'=v_1-\omega(\omega\cdot(v_2-v_1)) , \quad v_2'=v_2+\omega(\omega\cdot(v_2-v_1)) .$$

Similarly, the term $\sigma = \sigma'$ in (5) yields the loss term:

$$\begin{aligned}&\int_0^t \mathrm{d}t_1\int \mathrm{d}v_2\int \mathrm{d}\omega\,B(\omega, v_1-v_2)\\ &\cdot f_2^0(x_1-v_1t, x_2-v_2(t-t), v_1, v_2) .\end{aligned} \tag{60}$$

By the same arguments used in the previous section we can conclude that the full series expansion (20) (of course for the present quantum case) agrees, up to the second order in the potential, with

$$S(t)f_0+\int_0^t \mathrm{d}t_1\,S(t-t_1)Q(S(t_1)f_0, S(t_1)f_0) \tag{61}$$

where

$$\begin{aligned}Q(f,f)&=\frac{1}{4\pi^2}\int \mathrm{d}v_1\int \mathrm{d}h\,|\hat{\phi}(h)|^2\delta((h\cdot(v-v_1+h))\\ &\cdot[f(v+h)f(v_1-h)-f(v)f(v_1)]=\int \mathrm{d}v_1\int \mathrm{d}\omega\\ &\cdot B(\omega, v-v_1)[f'f_1'-ff_1] ,\end{aligned} \tag{62}$$

with

$$\begin{aligned}&f_1=f(v_1) ,\; f'=f(v') ,\; f_1'=f(v_1') ,\\ &v'=v+h=v-\omega(\omega\cdot(v-v_1)) ,\\ &v_1'=v_1-h=v_1+\omega(\omega\cdot(v-v_1)) .\end{aligned} \tag{63}$$

In other words the kinetic equation which comes out is the Boltzmann equation with cross-section B:

$$(\partial_t + v \cdot \nabla_x) f = Q(f, f) \,, \tag{64}$$

where Q is given by Eq. (62). We note once more that the δ function in Eq. (62) expresses the energy conservation, while the momentum conservation is automatically satisfied. Note also that the cross-section B is the only quantum factor in the purely classical expression (62). It retains the quantum features of the elementary "collisions".

An important comment is in order. Why the kinetic equation for quantum systems is of Boltzmann type in contrast with the classical case where we got a diffusion? The answer is related to the asymptotics of a single scattering (see [36,37] and [8]). For quantum systems we have a finite probability of having any angle scattering, while for a classical particle, we surely have a small deviation from the free motion. Therefore a quantum particle, in this asymptotic regime, is going to perform a jump process (in velocity) rather than a diffusion.

From a mathematical view point we observe that [4] proves more than agreement up to second order. We indeed consider the subseries (of the full series expansion expressing $f_j^N(t)$) formed by *all* the collision–recollision terms (as that shown in Fig. 3). In other words, we consider the subseries of $f_j^N(t)$ given by

$$\begin{aligned}\sum_{n\geq 1} \sum_{r_1,\ldots,r_n,l_1,\ldots,l_n} \varepsilon^{-4n} \int_0^t \mathrm{d}t_1 \int_0^{t_1} \mathrm{d}\tau_1 \, S(t-t_1) C^{\varepsilon}_{r_1,l_1} \\ \cdot S(t_1-\tau_1) T^{\varepsilon}_{r_1,l_1} \int_0^{\tau_{n-1}} \mathrm{d}t_n \int_0^{t_n} \mathrm{d}\tau_n \, S(\tau_{n-1}-t_n) C^{\varepsilon}_{r_n,l_n} \\ \cdot S(t_n-\tau_n) T^{\varepsilon}_{r_n,l_n} S(\tau_n) f^0_{j+n+1} \,.\end{aligned} \tag{65}$$

Here the sum runs over all possible choices of the particles number r's and l's, namely we sum over the subset of graph of the form in Fig. 4. We establish in [4] that the subseries (65) is indeed absolutely convergent, for short times, uniformly in ε. Moreover, we prove that it approaches the corresponding complete series expansion obtained by solving iteratively the Boltzmann equation with collision operator given by Eq. (62) extending and making rigorous the above argument.

Under reasonable smoothness hypotheses on the potential and on the initial distribution, assuming in addition that $\hat{\phi}(0) = 0$, we also proved in [7], that all other terms than those considered in the subseries (65) are indeed vanishing in the limit. The condition $\hat{\phi}(0) = 0$ is probably only technical: it takes care automatically of some divergences which are difficult to deal with differently.

Unfortunately this result, even under these severe assumptions on the potential, is not yet conclusive because we are not able to show a uniform bound on the full series. Thus a mathematical justification of the quantum Boltzmann equation is a still an open and difficult problem.

It is not surprising that we know more for the quantum case in comparison with the classical problem introduced in Sect. "Introduction". Now the operators involved are differences while, for the classical case, we have to deal with derivatives. Introducing explicitly the $\hbar$ dependence, we easily realize that the results discussed in the present section are not uniform in $\hbar$.

Weak-Coupling Limit in the Bose–Einstein and Fermi–Dirac Statistics

In this section we approach the same problem as in Sect. "Weak-Coupling Limit for Classical Systems", for Bosons or Fermions, namely for particles obeying the Fermi–Dirac or Bose–Einstein statistics. As we shall see, the kinetic equation we expect to hold in the limit, is the so called Uehling and Uhlembeck equation, which is a Boltzmann type equation, with cubic collision operator. We note that the effects of the quantum correction here, enter also in the structure of the operator.

In this case, the starting point is still the rescaled Schrödinger equation (38), or the equivalent hierarchy (46). The only new point is that we cannot take a totally decorrelated initial datum as in (49). Indeed, the Fermi–Dirac or Bose–Einstein statistics yield correlations even at time zero. In this perspective, the most uncorrelated states one can introduce, and that do not violate the Fermi–Dirac or Bose–Einstein statistics, are the so called quasi-free states. They have, in terms of the Wigner formalism, the following form

$$f_j(x_1, v_1, \ldots, x_j, v_j) = \sum_{\pi \in \mathcal{P}_j} \theta^{s(\pi)} f_j^{\pi}(x_1, v_1, \ldots, x_j, v_j) \,, \tag{66}$$

where each f_j^{π} has the value

$$\begin{aligned} f_j^{\pi}(x_1, v_1, \ldots, x_j, v_j) = \int \mathrm{d}y_1 \ldots \mathrm{d}y_j \int \mathrm{d}w_1 \ldots \mathrm{d}w_j \\ \cdot \, \mathrm{e}^{i(y_1 \cdot v_1 + \cdots + y_j \cdot v_j)} \prod_{k=1}^{j} \mathrm{e}^{-\frac{i}{\varepsilon} w_k \cdot (x_k - x_{\pi(k)})} \\ \cdot \, \mathrm{e}^{-\frac{i}{2} w_k \cdot (y_k + y_{\pi(k)})} f\left(\frac{x_k + x_{\pi(k)}}{2} + \varepsilon \frac{y_k - y_{\pi(k)}}{4}, w_k \right) , \end{aligned} \tag{67}$$

and f is a given one-particle Wigner function. Here $\mathcal{P}_j$ denotes the group of all the permutations of j objects and π its generic element.

Note that the uncorrelated case treated in Sect. "Weak-Coupling Limit for Classical Systems", is recovered by the contribution due the permutation $\pi = \text{identity}$.

To verify that (66) and (67) really describe admissible states for the statistics, consider the inverse Wigner transform of (66) and (67). The density matrix obtained in this way does verify the permutation invariance required by the statistics.

Moreover the quasi-free states converge weakly to the completely factorized states as $\varepsilon \to 0$. This is physically obvious because the quantum statistics become irrelevant in the semiclassical limit. However the dynamics take place on the scale ε so that the effects of the statistics are present in the limit. Indeed it is expected that the one-particle distribution function $f_1^N(t)$ converges to the solution of the following cubic Boltzmann equation:

$$(\partial_t + v \cdot \nabla_x)\, f(x,v,t) = Q_\theta(f)(x,v,t)\,, \tag{68}$$

$$\begin{aligned} Q_\theta(f)(x,v,t) &= \int \mathrm{d}v_1\, \mathrm{d}\omega\, B_\theta(\omega, v - v_1) \\ &\cdot \left[f(x,v')f(x,v_1')(1 + 8\pi^3\theta f(x,v))(1 + 8\pi^3\theta f(x,v_1)) \right. \\ &\left. - f(x,v)f(x,v_1)(1 + 8\pi^3\theta f(x,v')(1 + 8\pi^3\theta f(x,v_1'))\right]\,, \end{aligned} \tag{69}$$

(for the notations see Eq. (63)). Here $\theta = +1$ or $\theta = -1$, for the Bose–Einstein or the Fermi–Dirac statistics respectively. Finally, B_θ is the symmetrized or antisymmetrized cross-section derived from B (see (59)) in a natural way:

$$\begin{aligned} B_\theta(\omega, v) = \frac{1}{16\pi^2}|\omega \cdot v| \\ \cdot \left[\hat{\phi}(\omega\,(\omega \cdot v)) + \theta\hat{\phi}(v - \omega\,(\omega \cdot v))\right]^2 . \end{aligned}$$

As we see, the modification of the statistics transforms the quadratic Boltzmann equation of the Maxwell–Boltzmann case, into a cubic one (fourth order terms cancel). Also, the statistics affects the form of the cross-section and B has to be (anti)symmetrized into B_θ.

The collision operator (69) has been introduced by Nordheim in 1928 [38] and by Uehling–Uhlenbeck in 1933 on the basis of purely phenomenological considerations [42].

Plugging in the hierarchy (46) an initial datum satisfying (66), we can follow the same procedure as for the Maxwell–Boltzmann statistics, namely we write the full perturbative series expansion expressing $f_j^N(t)$ in terms of the initial datum and try to analyze its asymptotic behavior.

As we did before, we first restrict our attention to those terms of degree less than two in the potential.

The analysis up to second order is performed in [5]. We actually recover here Eq. (68), (69) with the suitable B_θ. Now the number of terms to control is much larger due to the sum over all permutations that enters the definition (66) of the initial state. Also, the asymptotics is much more delicate. In particular, we stress the fact that the initial datum brings its own highly oscillatory factors in the process, contrary to the Maxwell–Boltzmann case where the initial datum is uniformly smooth, and where the oscillatory factors simply come from the collision operators T and C.

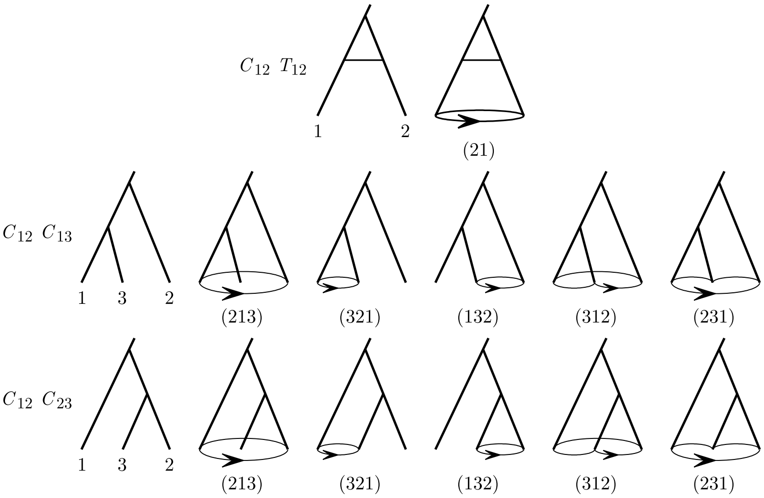
In [5] we consider the graphs of second order in $\hat{\phi}$, show in Fig. 5, which, because of the permutation of initial state, yields various terms: two of them are bilinear in the initial condition f_0 ($C_{12}T_{12}$), and give in the limit the part of Q_θ quadratic in f, twelve are cubic in $f_0(C_{12}C_{13},\ C_{12}C_{23})$. Due to a non-stationary phase argument the two terms with permutation $\pi = id = (123)$ vanish, as that the term with $\pi = (321)$ for $C_{12}C_{13}$, and the term with $\pi = (132)$ for $C_{12}C_{23}$. The two terms with $\pi = (321)$ give rise to truly diverging contributions (negative powers of ε), however their sum is seen to cancel. Last, permutations without fixed point ($\pi = (312), (231)$) and $\pi = (132)$ for $C_{12}C_{13}$, and $\pi = (321)$ for $C_{12}C_{23}$, give the part of Q_θ cubic in f. This ends up the analysis of terms up to second order in the potential.

The computation is heavy and hence we address the reader to [5] for the details.

We mention that a similar second order analysis, using commutator expansions in the framework of the second quantization formalism, has been performed in [27] (following [26]) in the case of the van Hove limit for lattice systems (that is the same as the weak-coupling limit, yet without rescaling the distances). For more recent formal results in this direction, but in the context of the weak-coupling limit, we also quote [21].

We finally observe that the initial value problem for Eq. (68) is somehow trivial for Fermions. Indeed we have the a priori bounds $f \leq 1/(8\pi)^3$ making everything easy. For Bosons the situation is much more involved even for the spatially homogeneous case. The statistics favor large value of f and it is not clear whether the equation can explain dynamical condensation. See, for the mathematical side, [33,34].

Under the weak coupling limit we derived two very different equations, the Fokker–Planck–Landau equation in the classical case, and a Boltzmann equation with a quantum cross section in the quantum case. For the original large particle system a classical or a quantum description



Scaling Limits of Large Systems of Non-linear Partial Differential Equations, Figure 5
The three graphs of second order with the statistical permutations

depends on the value of the physical scales of the macroscopic variables with respect to $\hbar$. The same happen for the two asymptotic equations. The dependence on $\hbar$ of the collision term (69) is given by

$$Q_{UU}(f)(v) = \frac{1}{16\pi^2\hbar^4}\int \mathrm{d}v_1 \int \mathrm{d}\omega \left[\hat{\phi}\left(\tfrac{\omega\,(\omega\cdot w)}{\hbar}\right) + \theta\hat{\phi}\left(\tfrac{w-\omega\,(\omega\cdot w)}{\hbar}\right)\right]^2 \{(1\pm(2\pi\hbar)^3 f)(1\pm(2\pi\hbar)^3 f_1) \cdot f' f_1' - (1\pm(2\pi\hbar)^3 f')(1\pm(2\pi\hbar)^3 f_1') f f_1\} \,. \tag{70}$$

The quantum-cross section term $\hat{\phi}(\omega\,(\omega\cdot(v-v_1))\,/\,\hbar)$ make $\omega\cdot(v-v_1) = O(\hbar)$, so that the collision operator concentrates on grazing collisions. In this sense, the classical limit $\hbar \to 0$ for (70) is a natural grazing collision limit. More formally, the operator (70) tends to the operator Q_L given in Eq. (29) (see [9]); nevertheless no results are available for the limit of the solutions of the equations.

We conclude this section with some consideration on the low-density limit.

In the classical case the low-density limit (or the Boltzmann–Grad limit) yields the usual Boltzmann equation for classical systems and this result has been proved for short times [31]. It is natural to investigate what happens, in the same scaling limit, to a quantum system. Here, due to the fact that the density is vanishing, the particles are too rare to make the statistical correlations effective. As a consequence, we expect that the Bose–Einstein, and Fermi–Dirac statistics, as well fully uncorrelated states, all give rise to the same Boltzmann equation along the low-density limit with the true quantum cross-section, given by the sum of the Born series, under smallness assumption for the potential. The analysis of the partial series of the dominant terms (uniform bounds and convergence as for the weak-coupling limit) has been performed in [6].

Weak-Coupling Limit for a Single Particle: The Linear Theory

Consider the time evolution of a single particle, in the low-density or in the weak-coupling regime, under the action of a random configuration of obstacles $\mathbf{c} = \{c_1 \dots c_N\} \subset \mathbb{R}^{3N}$.

More precisely, after the rescaling, the basic equations are:

$$\dot{x}(t) = v(t)\,, \quad \dot{v}(t) = -\sum_j \nabla\phi_\varepsilon(x(t)-c_j) \tag{71}$$

for a classical particle and, for a quantum particle,

$$i\varepsilon\partial_t\psi = -\frac{\varepsilon^2}{2}\Delta\psi + \sum_j \phi_\varepsilon(x(t)-c_j)\psi\,, \tag{72}$$

where $\phi_\varepsilon = \phi(\frac{x}{\varepsilon})$ and $\phi_\varepsilon = \sqrt{\varepsilon}\phi(\frac{x}{\varepsilon})$ for the low-density and weak-coupling limits respectively. Here ϕ denotes a given smooth potential.

We are interested in the behavior of

$$f_\varepsilon(x,v,t) = \mathbb{E}[f_{\mathbf{c}}(x,v,t)] \tag{73}$$

where $f_{\mathbf{c}}(t)$ is the time evolved classical distribution function or the Wigner transform of ψ according to Eq. (71)

or (72) respectively. Finally $\mathbb{E}$ denotes the expectation with respect to the obstacle distribution, for which, a natural choice could be the Poisson distribution of density μ_ε which is also scaled according to

$$\mu_\varepsilon = \varepsilon^{-2}\,, \quad \mu_\varepsilon = \varepsilon^{-3}$$

for the low-density and weak-coupling respectively.

For the low-density scaling (this is the so called Lorentz model), we obtain, for classical systems, a linear Boltzmann equation (see [3,13,17,23,40]). It is also known that the system does not homogenize to a jump process given by a linear Boltzmann equation in case of a periodic distribution of obstacles [10]. For recent results in this direction see [11].

For the weak-coupling limit of a classical particle we obtain a linear Landau equation as it is shown in [29] and [16].

Let us spend a few words on these results. Each solution $(x(t), y(t)) = (x_c(t), v_c(t))$ of Eq. (71) is a sample of a stochastic process. Looking at the behavior of $v_c(t)$ we suddenly realize that it does not enjoy the Markov property because, once an obstacle produces a change in velocity, we know its existence and this creates time correlations with the future behavior of the particle. However if a recollision with the same obstacle is an unlikely event, we could consider the velocity change due to the collisions, as independent and Poisson distributed (as the obstacles) random variables. In this case it is not difficult to prove the convergence to a diffusion process, solution to the following stochastic differential equation

$$\begin{aligned} dx &= v dt\,, \\ dv &= -2A\frac{v}{|v|^3}dt + \sqrt{\frac{2A}{|v|}}\left(I - \frac{v\otimes v}{|v|^2}\right) dw\,, \end{aligned} \tag{74}$$

where dw is a brownian motion, A is the constant given by Eq. (27), and $\sqrt{\frac{2A}{|v|}}\cdot\left(I - v\otimes v/|v|^2\right)$ is the matrix $\sqrt{2a}$, with a given by Eq. (26). Notice that each collision preserves the energy so that the above process lives on the surface of the sphere $|v| = \text{const}$.

Therefore the main point in the proof of the weak-coupling limit is to show that, in the same limit, the process under consideration is stochastically equivalent to a Markov process with the right properties. Moreover, as a consequence, we have also that $f_\varepsilon(t) \to f(t)$ being f solution to the following linear Landau equation

$$(\partial_t + v\cdot\nabla_x)\, f = \operatorname{div}_v[a(v)\nabla_v f]\,, \tag{75}$$

Alternatively we could proceed differently, in the same (Cauchy–Kovalevskii) spirit of our previous analysis for the nonlinear case. Namely we first represent the time evolved distribution $f_c(t)$ in terms of a series expansion. Then, taking the expectation of each term of the series, we exploit its limit by using the same arguments as in Sect. "Introduction". Finally the convergence of the series (uniformly in ε) should also be proven. This is certainly a possible program which is, however, conceptually and technically weaker than that based on the control of the particle trajectory illustrated above. Indeed the absolute control of the series expansion yielding the solution to Eq. (75) does not use the positivity of the diffusion coefficient so that, at best, we could recover the result for a short time only and in spaces of analytic functions, not at all natural in our context.

This remark applies as well to the nonlinear case for which, however, we do not have any result, even for short times.

As regards the corresponding weak-coupling quantum problem, the easiest case is when ϕ is a Gaussian process. The kinetic equation is still a linear Boltzmann equation. The first result, holding for short times, has been obtained in [41] (see also [30]). More recently this result has been extended to arbitrary times [22]. The technique of [22] can be also applied to deal with a Poisson distribution of obstacles [12] Obviously the cross section appearing in the Boltzmann equation is the one computed in the Born approximation. Finally in [20] the low-density case has been successfully approached. The result is a linear Boltzmann equation with the full cross-section.

Future Directions

The program of obtaining macroscopic equations from the microscopic dynamics is an ambitious and difficult problem. It arised in 1900 with the Hilbert's speech at the congress of mathematicians in Paris, as the sixth problem. After more than hundred years, such a program is far to be achieved.

It is probably true that new ideas and techniques are needed. As we said before in discussing the linear problems, it may be quite possible that classical ideas in the field of partial differential equations are not enough to approach this kind of problems successfully. On the other hand a deeper and more detailed analysis of the particle dynamics is technically difficult and philosophically paradoxical. Indeed from the practical side we introduce a partial differential equation to reduce the difficulties of the study of particle evolution, while its justification may require a deeper control of the underlying microscopic dynamics.

Scaling Properties, Fractals, and the Renormalization Group Approach to Percolation

DIETRICH STAUFFER
Institute for Theoretical Physics, Cologne University,
Köln, Germany

Article Outline

Glossary

Cluster Clusters are sets of occupied neighboring sites.

Critical exponent At a critical point or second-order phase transition, many quantities diverge or vanish with a power law of the distance from this critical point; the critical exponent is the exponent for this power law.

Fractals Fractals have a mass varying with some power of their linear dimension. The exponent of this power law is called the fractal dimension and is smaller than the dimension of the space.

Percolation Each site of a large lattice is randomly occupied or empty.

Renormalization A cell of several sites, atoms, or spins is approximated by one single site etc. At the critical point, these supersites behave like the original sites, and the critical point thus is a fixed point of the renormalization.

Definition of the Subject

Percolation theory mostly deals with large lattices where every site is randomly either occupied or empty. In particular it studies the resulting clusters which are sets of neighboring occupied sites.

Introduction

Paul Flory, who later got the Chemistry Nobel prize, published in 1941 the first percolation theory [1], to describe the vulcanization of rubber [2]. Others later applied and generalized it, in particular by dealing with percolation theory on lattices and by studying it with computers. Most of the theory presented here was known around 1980, though in the case of computer simulation with less accuracy than today. But on the questions of universality, of critical spanning probability and of the uniqueness of infinite clusters, the 1990's have shown some of our earlier opinions to be wrong. And even today it is questioned by some that the critical exponents of percolation theory can be applied to real polymer gelation, the application which Flory had in mind two-thirds of a century ago.

On a large lattice we assume that each site independently and randomly is occupied with probability p and empty with probability $1 - p$. Depending on applications, also other words can be used instead of occupied and empty, e. g. Republican and Democrat for the majority party in an electoral district of the USA. A *cluster* is now defined as set of occupied neighboring sites. Percolation theory deals with the number and structure of these clusters, as a function of their size s, i. e. of the number s of occupied sites in the cluster. In particular it asks whether an infinite cluster spans from one side of the lattice to the opposite side. Alternatively, and more naturally if one wants to describe chemical reactions for rubber vulcanization, this site percolation can be replaced by bond percolation, where every site is occupied but the link between neighboring sites is either present with probability p or absent with probability $1 - p$, again independently and ran-

Scaling Properties, Fractals, and the Renormalization Group Approach to Percolation, Table 1
Site and bond percolation thresholds for one dimension, three two-dimensional, four three-dimensional and four hypercubic lattices in higher dimensions [1,3]

p_c	Site	Bond
$d = 1$ chain	1	1
honeycomb	.697043	$1 - 2\sin(\pi/18)$
square	.592746	1/2
triangular	1/2	$2\sin(\pi/18)$
diamond	.4301	.3893
SC	.311608	.248813
BCC	.245691	.180287
FCC	.199236	.120163
$d = 4$ hypercubic	.196885	.160131
$d = 5$ hypercubic	.140797	.118172
$d = 6$ hypercubic	.109018	.094202
$d = 7$ hypercubic	.088951	.078675

domly for each link. A cluster is now a set of neighboring sites connected by links, and the size s of the cluster can be counted as the number of links, or as the number of sites, in that cluster. Because of this ambiguity we discuss here mainly site percolation; bond percolation is similar in the sense that it belongs to the same universality class (same critical exponents). One may also combine both choices and study site-bond percolation where each site is randomly occupied or empty, and where each bond between neighboring occupied sites is randomly present or absent.

Neither temperature nor quantum effects enter this standard percolation model, which is purely geometrical probability theory. However, to understand why percolation works the way it does it is helpful to understand thermal phase transitions like the vapor-liquid critical point; and for magnetic applications it is useful to know that some spins (atomic magnetic moments) have only two states, up or down, according to quantum mechanics. We will explain these physics aspects later.

For small p, most of the occupied sites are isolated $s = 1$, coexisting with only few pairs $s = 2$ and triplets $s = 3$. For large p, most of the occupied sites form one "infinite" cluster spanning the lattice from left to right, with a few small isolated holes in it. Thus there exists one percolation threshold p_c such that for $p < p_c$ we have no spanning cluster and for $p > p_c$ we have (at least) one spanning cluster. Inspite of decades of research in this seemingly simple problem, no exact solution for p_c is proven or guessed for site percolation on the square lattice with nearest-neighbor bonds; only numerically we know it to be about 0.5927462. For site percolation on the triangular lattice or bond percolation on the square lattice, $p_c = 1/2$ exactly. More thresholds are given in Table 1 [1]. They are valid in the limit of $L \to \infty$ for lattices with about L^d sites in d dimensions. For small L instead of a sharp transition at p_c one has a rounded changeover: with a very low probability one chain of L occupied sites at $p = 1/L^{d-1}$ spans from left to right. In one dimension, a small chain can easily be spanned if p is close to one, but for $L \to \infty$ the threshold approaches $p_c = 1$ since at smaller p a hole will appear about every $1/(1 - p)$ sites and prevent any cluster to span.

Methods

This section summarizes some of the methods employed to find percolation properties, first by pencil and paper, and then with the help of computers for which Fortran programs are published e. g. in [4,5]. More details on simulations are reviewed by Ziff in this percolation part of this encyclopedia.

Mean Field Limit

The Bethe lattice or Cayley tree neglects all cyclic links and allows a solution with paper and pencil. We start from one central site, and let z bonds emanate from that. At the end of each bond sits a neighbor. Then from each of these neighbors again z bonds emanate, one back to the central site and $z - 1$ to new sites further outward. They in turn lead again each to $z - 1$ new sites, and so on. None of the newly added sites agrees with one of the already existing sites, and so we can travel along the bonds only outwards or back, but never in a loop. It is quite plausible that an infinite cluster of bond percolation is formed if each site leads to at least one more outward site along an existing bond, that means if $(z - 1)p > 1$. This condition also holds for site percolation. Thus

$$p_c = 1/(z - 1) . \qquad (1)$$

In this way Flory calculated the threshold and other percolation properties. Today we call this the "mean field" universality class in analogy with thermal phase transitions. The critical exponents, to be discussed below, are integers or simple fractions. To this universality class belong also the Erdös-Rényi random graphs, where we connect in an assembly of N points each pair with a low probability $\propto 1/N$. And the same universality class is reached if we let the dimension d of the hypercubic lattice go to infinity (or at least take it above 6). A disadvantage of the Bethe lattice is its lack of realism: If the length of the bonds is constant, then the exponential increase of the number of sites and bonds with increasing radius leads to an infinite density.

Small Clusters

The probability of a site to be an isolated $s = 1$ cluster on the square lattice is $n_1 = p(1-p)^4$ since the site must be occupied and all its four neighbors be empty. The formula for pairs is $n_2 = 2p^2(1-p)^6$ since the pair can be oriented horizontally or vertically, resulting in the factor 2. Similar, only more difficult, is the evaluation of n_s with a maximum s usually 10 to 20; the general formula is

$$n_s = \sum_t g_{st}\, p^s\, (1-p)^t \tag{2}$$

where the perimeter t is the number of empty neighbors and g_{st} is the number of configurations (or lattice animals, or polyominoes) of size s and perimeter t. The King's College group in London published these results decades ago. With techniques borrowed from series expansions near thermal critical phenomena, these polynomials allow to estimate not only p_c but also many other quantities (see below) diverging or vanishing near p_c.

Leath Cluster Growth

In the cluster growth method of Leath (1976) one starts with one occupied site in the center of the lattice. Then a cluster is grown by letting each empty neighbor of an already occupied cluster site decide once and for all, whether it is occupied or empty. One needs to keep and to update a perimeter list of undecided neighbors. If that list becomes empty, the cluster growth is finished, and no boundary effects of the lattice influence this cluster. If, on the other hand, the cluster reaches the lattice boundary, one has to stop the simulation and can regard this cluster as spanning (from the center to one of the sides). Repeating many times this growth simulation one can estimate p_c as well as the cluster numbers. More precisely, the cluster statistics obtained in this way is not n_s but $n_s s$ since the original center site belongs with higher probability to a larger than to a smaller cluster.

Hoshen-Kopelman Labelling

To go regularly through a large lattice, which may even be an experimentally observed structure to be analyzed by computer, one could number consecutively each seemingly new cluster, and if no clusters merge later then one has a clear classification: All sites belonging to the first cluster have label 1, all sites of the second cluster have label 2, etc. Unfortunately, this does not work. In the later analysis it may turn out that two clusters which at first seemed separate actually merge and form one cluster:

```
* *     * *         1 1     2 2
  *   * * *           1   3 ? 2
* * * * *           4 ? ? x ?
```

Already in the simple structure shown on the left we have several such label conflicts. The labels to the right come from going through the lattice like a typewriter, from left to right, and after each line to the lower line. When we come to the right neighbor of the 3 we see that 3 is really part of the cluster with label 2. And at the right neighbor of 4 we see that 4 belongs to cluster 1. The stupid method is to go back and to relabel all 3 into 2, and all 4 into 1. If then we come to the site marked with x we see that the whole structure is really one single cluster, and thus all labels 2 have to be relabeled into a 1. This is inefficient for large lattices. Instead, Hoshen and Kopelman (1976) gave each site label $m = 1, 2, 3, \ldots$ another index $n(m)$. This label $n(m)$ of labels equals its argument, $n(m) = m$, if it is still a good "root label", and it equals another number k is the cluster with initial label m later turned out to be part of an earlier cluster k. By iterating the command `m = n(m)` until finally the new m equals $n(m)$ one finds this root label. For the above we make the following assignments and re-assignments to n: $n(1) = 1$, $n(2) = 2$, $n(3) = 3$, $n(3) = 2$, $n(4) = 4$, $n(4) = 1$, $n(2) = 1$. Clusters are now characterized by the same root label for all their labels.

An advantage if this method is that only one line of the square lattice, or one hyperplane of the d-dimensional lattice, needs to be stored at any time, besides the array $n(m)$. And that array can also be reduced in size by regular recycling no longer used labels n, just as beer bottles can be recycled. Lattices with more than 10^{13} sites were simulated, using parallel computers. However, understanding the details of the algorithms and finding errors in them can be very frustrating.

Sometimes one wants to determine the cluster numbers for numerous different p from 0 to 1. Instead of starting a new analysis for each different p one may also fill the lattice with new sites, and make the proper labeling of labels whenever a new site was added [6]. Similarly, one can determine the properties of various lattice sizes L by letting L grow one by one and relabeling the cluster after each growth step [7]. Unfortunately, these two methods came long after most of the percolation properties were already studied quite well by standard Hoshen-Kopelman analysis.

Relation to Ising and Potts Models

The relation between percolation and thermal physics was useful for both sides: Scaling theories for percolation could follow scaling theories for thermal physics from ten years earlier, and computer simulations for thermal physics could use the Leath and Hoshen-Kopelman algorithms of cluster analysis, leading to the Wolff and Swendsen-Wang methods, respectively, a decade later. A mathematical foundation is given by the Kasteleyn-Fortuin theorem [8] for the partition function Z of the Q-state Potts model at temperature T:

$$Z(Q) = \langle Q^N \rangle \tag{3}$$

where N is the total number $\sum_s n_s$ of clusters for bond percolation at probability $1 = \exp(-2J/k_B T)$, $\langle \ldots \rangle$ indicates an average over the configurations at this probability, k_B is Boltzmann's constant and 2J is the energy needed to break a bond between neighboring spins. (Each site i of a Potts lattice carries a variable $S_i = 1, 2, \ldots Q$; the energy of a neighbor pair is $-2J$ if the two variables agree, and zero otherwise.) For the special Ising case $Q = 2$ see also this author in this encyclopedia, "Opinion dynamics..." and "Phase transitions...".

Q values of 3 and larger are interesting since for increasing Q a second-order phase transition with a continuous order parameter changes into a first-order phase transition with a jumping order parameter, when T increases. The special case $Q = 2$ is the spin 1/2 Ising model (the model is pronounced EEsing, not EYEsing since Ernst Ising was born in Cologne, Germany, and became US citizen Ernest Ising only after publishing his theory in 1925 and surviving Nazi persecution 1933–1944). The limit $Q \to 0$ corresponds to some tree structures (no cyclic links, as in Flory's percolation theory, [9]). Percolation, on the other hand, corresponds to the limit $Q \to 1$, in the following way: The "free energy" in units of $k_B T$ is in this limit $\ln Z = \ln\langle \exp(N \ln Q)\rangle \simeq \ln\langle \exp[(Q-1)N]\rangle \simeq \ln\langle 1 + (Q-1)N\rangle \simeq (Q-1)N$. Thus for Q near unity this thermal free energy, divided by $Q - 1$, is the number of percolation clusters.

In this way thermal physics and percolation are related, and the cluster numbers N correspond to a free energy. In thermal physics, the negative derivative of the free energy with respect a conjugate field gives the order parameter (e.g magnetic field and magnetization), and the field derivative of the order parameter is called the susceptibility. For liquid-gas equilibria, the order parameter is the volume (or the density), the field is the pressure (or chemical potential), and the analog of the susceptibility is the compressibility. This result Eq. (3), not its derivation, we should keep in mind if we now look at the percolation quantities of interest.

Formally we may define for percolation a free energy F as a generating function of a ghost field h:

$$F(h) = \sum_s n_s \exp(-hs) \; . \tag{4}$$

Then its first h-derivative is $-\sum_s n_s s$, and the second one is $\sum_s n_s s^2$, sums which appear below in the percolation probability P_∞ (the order parameter) and the mean cluster size $S = \sum_s n_s s^2 / \sum_s n_s s$ (the susceptibility).

Quantities and Exponents

The basic quantity is n_s, the number (per site) of clusters containing s sites each, and often is an average over several realizations for the same occupation probability p in the same lattice. Several moments

$$M_k = \sum_s n_s s^k \tag{5}$$

are used to define other quantities of interest; in these sums the infinite (spanning) clusters are omitted. The following proportionalities are valid asymptotically in the limit of large lattice size L and for $p \to p_c$:

$$F = M_0 \propto |p - p_c|^{2-\alpha} + \ldots \tag{6a}$$

$$P_\infty = p - M_1 \propto (p - p_c)^\beta \tag{6b}$$

$$S = M_2/M_1 \propto |p - p_c|^{-\gamma} \; . \tag{6c}$$

Here F is the analog of the thermal free energy, where the three dots represent analytic background terms whose derivatives are all finite. Since every occupied site must belong either to a finite or to an infinite cluster, $P_\infty = p - \sum_s n_s s$ is the fraction of sites belonging to the infinite cluster and gives the probability that from a randomly selected site we can walk to a lattice boundary along a path of occupied sites. It is thus called the percolation probability but needs to be distinguished from the probability p that a single site is occupied and from the probability R, with $R(p < p_c) = 0, \;\; R(p > p_c) = 1$, that there is a spanning cluster in the lattice.

The quantity S is usually called the mean cluster size, and we follow this tradition even though it is very bad. There are many ways to define a mean size, and polymer chemists have the much more precise notation of a number average M_1/M_0, a weight average M_2/M_1 and a z average M_3/M_2 for the cluster size (= degree of polymerization). Physicists arbitrarily call the weight-averaged s the mean cluster size S. Numerically, the exponent γ is determined more easily from the "susceptibility" $\chi = M_2 \propto |p - p_c|^{-\gamma}$, since the denominator M_1 in Eq. (6c) approaches very slowly its asymptotic limit of 1.

Scaling Properties, Fractals, and the Renormalization Group Approach to Percolation, Table 2

Critical exponents for percolation clusters. The mean field values are valid for six and more dimensions and also apply to Flory's Bethe approximation and to Erdös-Rényi random graphs. The exponents α, δ, σ, τ can be derived from the scaling laws, Eq. (8)

d	β	γ	ν
2	5/36	43/18	4/3
3	0.41	1.796	0.88
≥ 6	1	1	1/2

The radius of a cluster R_s can be defined as the rms distance $r_i,\ i = 1, 2, \ldots, s$ of cluster sites from the center of mass r_c of the cluster (radius of gyration):

$$R_s^2 = \langle \sum_i (r_i - r_c)^2/s \rangle \tag{6d}$$

where the $\langle \ldots \rangle$ average over all cluster configurations at probability p. Then the correlation length ξ is related to the z-average cluster radius through

$$\xi^2 = \sum_s R_s^2 n_s s^2 / \sum_s n_s s^2 \propto |p - p_c|^{-\nu} \tag{6e}$$

with another critical exponent ν.

Finally, right at $p = p_c$, the cluster numbers decay as

$$n_s \propto 1/s^{2+1/\delta} \tag{7}$$

where δ must be positive to allow a finite density $\sum_s n_s s = p$.

These five critical exponents are not independent of each other but are related in d dimensions through the scaling laws:

$$2 - \alpha = \gamma + 2\beta = (\delta + 1)\beta = d\nu \tag{8a}$$

as known from thermal phase transitions; the last equation involving d is not valid in mean field theory (large d) but only for $d \leq 6$. Table 2 gives the numerical estimates of the exponents in three dimensions as well as their mean field values for $d \geq 6$ and their exact two-dimensional results [10,11]. Thus, for six and less dimensions, if you know two exponents you know them all; thus far.

These scaling laws (8a) can be derived by assuming

$$n_s = s^{-\tau} f[(p - p_c)s^{\sigma}] \quad (\tau = 2 + 1/\delta,\ 1/\sigma = \beta\delta) \tag{8b}$$

which was first postulated for the thermal Ising model, and then successfully applied to percolation. Here f is a suitable scaling function, which only in the mean-field limit approaches a Gaussian.

For both thermal critical phenomena and percolation, "universality" asserts that these critical exponents are independent of many details and (for the Potts model) depend only on the dimensionality d and the number Q of possible spin states. Since percolation corresponds to $Q \to 1$ this means that the exponents depend only on d. There are exceptions from this universality for thermal phase transitions, but for random percolation thus far it worked. However, the numerical value of the percolation threshold p_c is not a critical exponent, depends on the lattice structure, and is different for site and bond percolation.

This universality is one of the reasons why the investigation of exponents is important: They allow to classify models and materials. Similarly, in biology we have many birds of different colors, and many types of domestic animals. Biology became a systematic science only when it was found that all mammals share certain properties, which birds no not have. Thus there is the universality class of mammals.

(The proportionality factors in Eq. (6) are not universal, but some of their combinations are; for example, the ratio of the proportionality factors for S above to below p_c is universal. In some sense also the probability $R(p = p_c)$ of a lattice to contain one spanning cluster at the threshold is universal: same for bond and site percolation; however, that probability depends on the boundary conditions and the shape of the sample and thus is far less universal that the mentioned ratio for S.)

Unfortunately, there is another exponent which does not follow from the cluster numbers and radii and for which no scaling law is accepted which relates it to the other exponents above. This refers to the electrical conductivity

$$\Sigma \propto (p - p_c)^{\mu} \tag{9}$$

when each occupied site (or bond) conducts electrical current and each empty site (or deleted bond) is an insulator. The numerical values are 1.30, 2.0 and 3 in two, three and at least six dimensions. If bonds are realized by elastic springs with bending forces, the elastic exponent may be $\mu + 2\nu$ if entropy effects are negligible, or $2 - \alpha$ if entropy effects are dominant. Moreover, μ is less universal: the above lattice values do not hold on a continuum (conducting spheres which may overlap). Similarly, the kinetics of the Ising model determine a critical exponent which differs in different variants of the kinetics and may not be related to the static Ising exponents like β and γ.

Fractal Dimension; Incipient Infinite Cluster

Fractal Dimension D

Typical objects of geometry classes in school are one-dimensional lines, two-dimensional squares or circles, and three-dimensional cubes or spheres. They have a length (radius) L and a mass (volume for unit density) M with $M \propto L^d$ for d dimensions. In reality, mother nature produces much more complex objects, like trees, where the mass varies with a power of the tree height below 3:

$$M \propto L^D \quad (D < d,\ L \to \infty)\,. \tag{10a}$$

D is the fractal dimension, and such objects are called fractals, particularly if they also are self-similar in that a small twig looks like a big branch, etc. Finite-size scaling theory then relates D of the largest (spanning?) cluster at $p = p_c$ to the above percolation exponents through

$$D = d - \beta/\nu = (\gamma + \beta)/\nu = 1/(\sigma\nu) = d/(1 + 1/\delta) \tag{10b}$$

for $d \leq 6$. Thus the critical cluster is about 1.9-dimensional in two and 2.5-dimensional in three dimensions, while in the mean field regime for $d \geq 6$ we have $D = 4$. Why is this so? Any quantity X which is supposed to vary near $p = p_c$ as $|p - p_c|^x$ does so only for infinitely large systems. For a finite lattice size L, the transition is rounded, and neither X nor any of its p-derivatives diverges or becomes exactly zero. In particular, the typical cluster radius or correlation length $\xi \propto |p - p_c|^{-\nu}$ cannot become infinite but becomes of order L. Then the relation $X \propto \xi^{-x/\nu}$ is replaced by

$$X(p = p_c) \propto L^{-x/\nu} \tag{11a}$$

at the threshold, and

$$X(p \simeq p_c) = L^{-x/\nu} g[(p - p_c)L^{1/\nu}] \tag{11b}$$

near the threshold, with a suitable scaling function g. In particular, the fraction P_∞ of sites belonging to the largest cluster at $p = p_c$ vanishes as $L^{-\beta/\nu}$, and the total number M of sites in this cluster as

$$M \propto L^{d-\beta/\nu} \quad \text{or} \quad D = d - \beta/\nu \tag{11c}$$

as asserted in Eq. (10b).

Figure 1 shows the second moment $\chi = M_2 = \sum_s n_s s^2$ in small (curve) and large (+) simple cubic lattices, differing only for $p \simeq p_c$. Figure 2 shows right at $p = p_c$ the variation with lattice size of the number M of sites in the largest cluster and of the second moment M_2 (susceptibility).

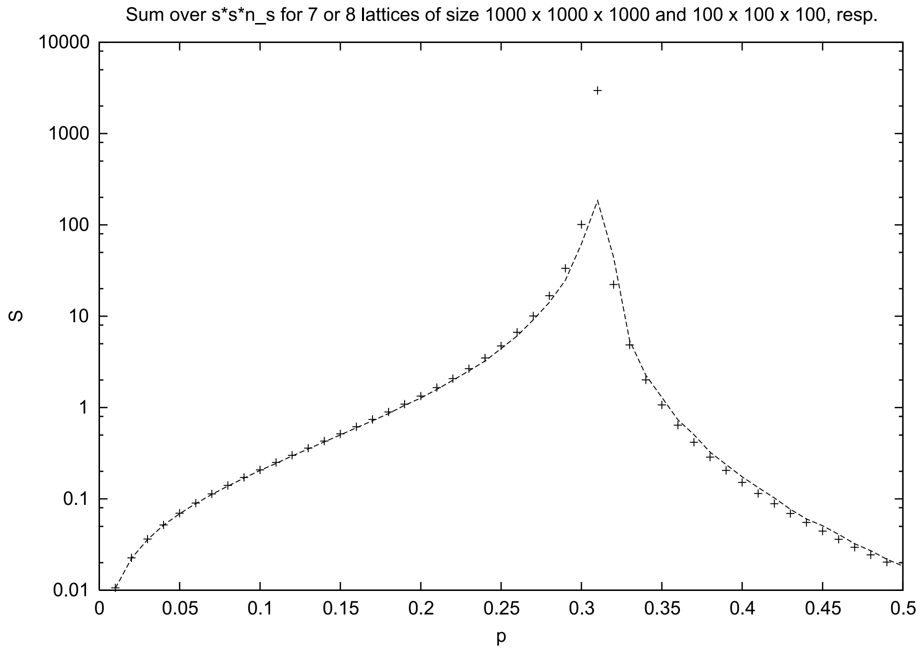
In a finite lattice, the probability $R(p)$ of a spanning cluster to exist goes from nearly zero to nearly unity in a p-interval proportional to $1/L^{1/\nu}$, according to Eq. (11b) with $x = 0$. The derivative $\mathrm{d}R/\mathrm{d}p$ is the probability that spanning first occurred at probability p. It is plausible that this probability, peaked around p_c, is a Gaussian, i. e. a normal distribution. Unfortunately, the Evil Empire, also known as the Departments of Chemical Engineering, destroyed [12] this beautiful idea: Since for $p \simeq p_c$ and $\xi \sim L$ every part of the lattice is correlated with the rest of the lattice, the central limit theorem does not hold.

(If for $p \ll p_c$ we let the cluster size s go to infinity, which requires a special algorithm, we get into the universality class of lattice animals, Sect. "Small Clusters". Most simply, in the limit $p \to 0$, Eq. (2) simplifies to $n_s/p^s = g_{st}$, that means we look at the distribution of configurations with s sites and perimeter t, where all configurations of a given s are weighted equally, whatever their perimeter t is. An important result for these animals is that in three dimensions their radius R_s varies as $\sqrt{s}$, i,e. their fractal dimension is exactly 2. In two dimensions, only numerical estimates exist with $D \simeq 1.56$. It is highly unusual that a problem has an exact solution in three but not in two dimensions.)

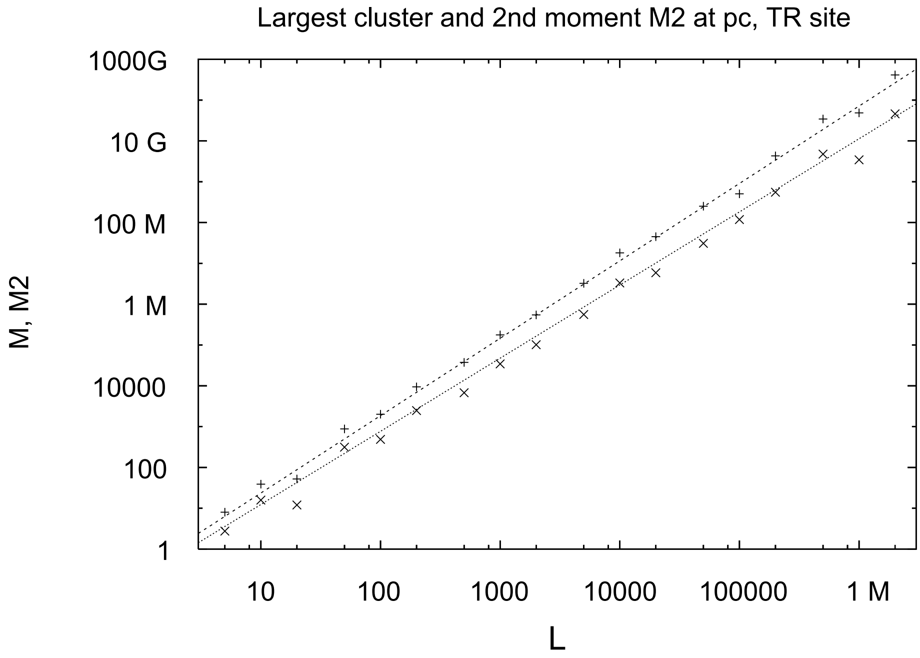
Incipient Infinite Cluster

Right at $p = p_c$ the largest cluster spans the lattice with a pseudo-universal probability $0 < R(p_c) < 1$, and then has a density P_∞ going to zero for L going to infinity. It is also called the incipient infinite cluster IIC. Most of the IIC consists of dangling ends which carry no current if the cluster is interpreted as a random resistor network with conductivity Σ, see Eq. (9) above. The remaining current carrying "backbone" has a fractal dimension 1.643 in two dimensions, 1.7 in three and 2 in at least six dimensions and mostly consists of blobs where current flows along several parallel though connected paths. The few "articulation" sites or bonds, the removal of which cuts the network into two or more parts, are also called "red" since all the current flows through them; they have a fractal dimension of only $1/\nu = 0.75$, 1.14 and 2 in two, three and $\geq$ six dimensions.

How many infinite clusters do we have? The easy answer is: none below, perhaps one at and always one above p_c in an infinite network. Indeed, this is what was claimed mathematically in the 1980's [13]: The number of infinite clusters is zero, one or infinite. Later mathematics excluded the last choice of infinitely many clusters, even though in seven dimensions scaling arguments, confirmed



Scaling Properties, Fractals, and the Renormalization Group Approach to Percolation, Figure 1
"Susceptibility" M_2 in simple-cubic lattice. For the smaller size the maximum is reduced appreciably



Scaling Properties, Fractals, and the Renormalization Group Approach to Percolation, Figure 2
Number M of sites in largest cluster (+) and susceptibility M_2 (x) at $p = p_c = 1/2$ for triangular site percolation. The two straight lines have the exact slopes $D = 91/48$ and $\gamma/\nu = 43/24$ predicted by finite-size scaling. The largest lattice took about 36 h on a workstation with 2 Gb memory. Tiggemann [7] simulated $L = 7 \times 10^6$, 25024, 1305, 225 for $d = 2, 3, 4, 5$ on a large parallel computer

by numerical studies [14], indicated the number of IIC to go to infinity for increasing L in seven dimensions. Only in 1995 and later Aizenman [15] predicted that in all dimensions one may have several spanning clusters at $p = p_c$, in agreement with simulations [16].

Why were the earlier uniqueness theorems irreproducible at p_c and for very elongated rectangles even above p_c [17]? A clear definition of "infinite" is missing in some of the mathematics, although [13] defined a cluster as infinite if its cardinality (= number of sites in it) is infinite for $L \to \infty$ in a hypercubic lattice of L^d sites. Clear definitions of infinity are, of course, needed for reliable proofs [18]. Measure theory as applied in some theorems may be based on some axioms which are not applicable for a fractal IIC. Very simply, imagine each line of an $L \times L$ square lattice to have one randomly selected site occupied and all others empty. The set of occupied site then has cardinality L which is infinite for infinite lattices, but its density becomes zero. Does your measure theory agree with this? More relevant for percolation, even for $p < p_c$ the largest cluster has a size increasing logarithmically with lattice size and thus can be described as infinite, invalidating the percolation threshold as the onset of infinite clusters. Thus infinite might be defined as increasing with a positive power of L, i. e. having a positive fractal dimension. Then we have infinitely many infinite clusters only at $p = p_c$, though in most cases only the largest of them is a spanning cluster. Using "spanning" as a definition of an infinite cluster seems to cause the smallest problems.

Thus one should not regard a question as settled if some mathematical theorem claims to have answered it. The mathematics may not apply to the same problem one is interested in, or (see bootstrap percolation in this encyclopedia) may apply only for unrealistically large lattices. On the other hand, also computer simulations should be relied upon only if confirmed independently. And in the interpretation of simulation results one should be objective and not try to agree with prevailing theories. For example, [14] might already have seen the multiplicity of infinite clusters in five dimensions, not only in seven, had she not followed her obviously incompetent postdoctoral mentor.

(On a more positive side, mathematicians [19] solved biased diffusion on percolating clusters above p_c only a few years after physicists still had controversies about their simulations.)

Simple Renormalization Group

Why are scaling laws and finite-size scaling so simple? Why is universality valid for the exponents? These question arose for thermal critical phenomena as well as for percolation. The main reason is that the correlation length ξ goes to infinity at the critical point. Thus all approximations which restrict the correlations to some finite lengths eventually become wrong, and instead the scaling ideas become correct. They were explained by Ken Wilson through what he called renormalization group, around 1970, and he got the physics Nobel prize for it in 1982. Basically, since correlations extend over long distances, the single atom or lattice point becomes irrelevant and can be averaged over. In politics, we have a similar effect: Many democracies are based on electoral districts, and the candidate winning most votes within this district represents this district in the national parliament. It is the cooperation of many people within the electoral district, not the single vote, which is decisive.

Returning to an $L \times L$ lattice, we can divide it into many blocks of linear dimension b, and treat a block analogously to an electoral district. Thus in an Ising model, if the majority of block spins point upward, the whole block is represented by a superspin pointing up, analogous to the single representative in politics. These block spins then act like the original spins, one can put $b \times b$ superspins into one superblock, and have just one super-representative following the majority opinion of the representatives within the superblock. This process can be continued: at each stage $b \times b$ lower representatives are normalized into a single higher representative.

Such a renormalization by majority rule works fine with Ising spins, but percolation deals with connections, not with up and down spins. Thus for percolation a $b \times b$ block is normalized into an occupied supersite if and only if there is a spanning cluster within the block; otherwise the superblock is defined empty. In this way, whole blocks are normalized into single sites via connectedness. And the renormalization is reduced to the standard question which was asked already before Wilson's invention: Does a $b \times b$ lattice have a spanning cluster? The supersite is thus occupied if and only if the block spans, which happens with probability $R_b(p)$. If we call p' the probability of the supersite to be occupied, we thus have

$$p' = R_b(p) \,. \tag{12a}$$

If we are at $p = p_c$, then the renormalization should not change anything drastic since ξ is larger than any b; thus if the renormalization would be exact we would have

$$p'_c = R_b(p_c) \,. \tag{12b}$$

Practically we determine a fixed point $p = p^*$ such that

$$p^* = R_b(p^*) \,. \tag{12c}$$

and then find p_c as the limit of p^* for $b \to \infty$, which again is similar to what percolation experts did before this renormalization theory.

A particularly simple example is the triangular site percolation problem with $p_c = 1/2$, if we do not divide the lattice into large $b \times b$ blocks but into small triangles of three sites which are nearest neighbors, as shown on the left:

```
   *              x              x
 *   *          x   x          x   .
```

The triangle contains a spanning cluster if either all three sites are occupied (x, central diagram) or two sites are occupied (x) and one site is empty (., right diagram). The first choice appears with probability p^3, the second with probability $p^2(1-p)$. However, this second choice has three possible orientations since each of the three sites can be the single empty site. Thus the total probability of the triangle to have a spanning cluster is

$$p' = p^3 + 3(1-p)p^2 \qquad (13a)$$

with three fixed points p^* where $p' = p$:

$$p^* = 0, \quad p^* = 1/2, \quad p^* = 1\,. \qquad (13b)$$

The second of these fixed points is the percolation threshold, while the first corresponds to lattice animals (Sect. "Small Clusters" and end of Sect. "Fractal Dimension D") and the third to compact non-fractal clusters. With somewhat more effort one can derive also a good approximation for ν.

This agreement of the fixed point p^* with the true threshold $p_c = 1/2$ is not valid for other lattices or block choices. Nevertheless there was a widespread fixed-point consensus that $R_b(p_c) = p_c$ for sufficiently large b. Regrettably, the Evil Empire [20] again destroyed this beauty and found $R_b(p_c) = 1/2$ for square site percolation where $p_c \simeq 0.593$. In general, $R(p_c)$ is a pseudo-universal quantity depending on boundary conditions and sample shape, while p_c for large samples is independent of these details but is different for site and bond percolation and depends on the size of the neighborhood. Life was much nicer before. Fortunately, if a fixed point is determined by Eq. (12c) and the block size goes to infinity, then the fixed point still approaches p_c.

Future Directions

This review summarized the basic theory, particularly when it was not yet contained in the earlier books [1]. Applications were left to the Sahimi book [1]; even for the very first application [2] there is not yet a complete consensus that the three-dimensional percolation exponents apply to polymer gelation. More recent applications are social percolation [21] for marketing by word-of-mouth, and stock market fluctuations due to herding among traders [22].

Percolation theory, similar to Fortran programming or capitalism, was thought to be finished but seems to be alive and kicking. Nevertheless I think the future is more in its applications.

The manuscript was improved by criticism of A. Aharony.

Scenario-Driven Planning with System Dynamics

NICHOLAS C. GEORGANTZAS
Fordham University Business Schools, New York, USA

Article Outline

Glossary

Mental model how one perceives cause and effect relations in a system, along with its boundary, i. e., exogenous variables, and the time horizon needed to articulate, formulate or frame a decision situation; one's implicit causal map of a system, sometimes linked to the reference performance scenarios it might produce.

Product either a physical good or an intangible service a firm delivers to its clients or customers.

Real option right and obligation to make a business decision, typically a tangible investment. The option to invest, for example, in a firm's store expansion. In contrast to financial 'call' and 'put' options, a *strategic real option* is not tradable. Any time it invests, a firm might be at once acquiring the *strategic real options* of expanding, downsizing or abandoning projects in future. Examples include research and development (abbreviated R&D), merger and acquisition (abbreviated M&A), licensing abroad and media options.

Scenario a postulated sequence or development of events trough time; via Latin *scena* '*scene*', from Greek *σκηνή*, *skēnē* '*tent, stage*'. In contrast to a forecast of what *will* happen in the future, a scenario shows what *might* happen. The term *scenario* must *not* be used loosely to mean situation. *Macro-environmental* as well as *industry-*, *task-* or *transactional-environmental* scenarios are merely inputs to the *strategic objectives* and *real options* a firm must subsequently explore through *strategic scenarios*, *computed* or simulated with an explicit, formal *system dynamics* (abbreviated SD) model of its strategic situation. *Computed strategic scenarios* create the multiple perspectives that strategic thinkers need to defeat the tyranny of dogmatism that often assails firms, governments and other social entities or organizations.

Scenario-driven planning (abbreviated SdP) to attain high performance through strategic flexibility, firms use the SdP *management technology* to create foresight and to anticipate the future with strategic real options, in situations where the business environment accelerates frequently and is highly complex or interdependent, thereby causing uncertainty.

Situation the set of circumstances in which a firm finds itself; its (strategic) state of affairs.

Strategic management process (abbreviated SMP) geared at detecting environmental threats and turning them into opportunities, it *proceeds from* a firm's mission, vision and environmental constraints *to* strategic goals and objectives *to* strategy design or formulation *to* strategy implementation or strategic action *to* evaluation and control *to* learning through feedback (background, Fig. 2).

SMP-1 environmental scanning monitors, evaluates and disseminates knowledge about a firm's internal and external environments to its people. The internal environment contains *s*trengths and *w*eaknesses within the firm; the external shows future *o*pportunities and *t*hreats (abbreviated SWOT).

SMP-2 mission a firm's purpose, *raison d'être* or reason for being.

SMP-3 objectives performance (P) goals that SMP often quantifies for some P metrics.

SMP-4 policy decision-making guidelines that link strategy design or formulation to action or implementation tactics.

SMP-5 strategy a comprehensive plan that shows how a firm might achieve its mission and objectives. The three strategy levels are: corporate, business and process or functional.

SMP-6 strategy design or formulation the interactive, as opposed to antagonistic, interplay of strategic content and process that creates flexible long-range plans to turn future environmental threats into opportunities; includes internal strengths and weaknesses as well as strategic mission and objectives, and policy guidelines.

SMP-7 strategic action or implementation the process by which strategies and policies are put into action through the development of programs, processes, budgets and procedures.

SMP-8 evaluation and control sub-process that monitors activities and performance, comparing actual results with desired performance.

SMP-9 learning through feedback occurs as knowledge about each SMP element enables improving previous SMP elements (background, Fig. 2).

System an organized group of interrelated components, elements or parts working together for a purpose; parts might be either goal seeking or purposeful.

System dynamics (abbreviated SD) a lucid modeling method born from the need to manage business performance through time. Thanks to Forrester [23], who discovered that all change propagates itself through stock and flow sequences, and user-friendly SD software (*iThink*®, *Vensim*®, etc.), SD models let managers see exactly how and why, like other biological and social organizations, business firms perform the way they do. Unlike other social sciences, SD shows exactly how *feedback loops*, i. e., circular cause and effect chains, each containing at least one time lag or delay, interact within a system to determine its performance through time.

Variable or metric something that changes either though time or among different entities at the same time. An *internal change lever* is a decision or policy variable that a strategy-design modeling, or client, team controls. An *external change trigger* is an environmental or policy variable that a strategy-design modeling team does not control. Both *trigger* and *lever* variables can initiate change and be either endogenous or exogenous to a model of a system.

However certain our expectation, the moment foreseen may be unexpected when it arrives
—T.S. Eliot

Definition of the Subject

Many of us live and work in and about business ecosystems with complex structures and behaviors. Some realize that poor performance often results from our very own past actions or decisions, which come back to haunt us. So business leaders in diverse industries and firms, such as *Airbus, General Motors, Hewlett-Packard, Intel* and *Merck*, use scenario-driven planning (SdP) with system dynamics (SD) to help them identify, design and apply high-leverage, sustainable solutions to dynamically complex strategic-decision situations. One must know, for example, if the effect of an environmental change or strategic action gets magnified through time or is dampened and smoothed away. What may seem insignificant at first might cause major disruption in performance. SdP with SD shows the causal processes behind such dynamics, so firms can respond to mitigate impacts on performance.

Accelerating change and complexity in the global business environment make firms and other social organizations abandon their *inactive, reactive* and *preactive* modes [2]. SdP with SD turns them *proactive*, so they can translate anticipation into action. To properly transform anticipation into action, computed with SD models, 'strategic scenarios' must meet four conditions: *consistency, likelihood, relevance* and *transparency* [37]. Combining SdP with SD for that purpose, with other tools, like actor and stakeholder purposes, morphological methods or probability might help avoid entertainment and explore all possible scenarios. Indeed, SdP with SD

> "does not stand alone… modeling projects are part of a larger effort… modeling works best as a complement to other tools, not as a substitute" (see p. 80 in [75]).

SdP with SD is a systematic approach to a vital top-management job: leading today's firm in the rapidly changing and highly complex global environment. Anticipating a world where product life cycles, technology and the mix of collective- and competitive-strategy patterns change at an unprecedented rate is hard enough. Moving ahead of it might prove larger than the talent and resources now available in leading firms. SdP with SD leads to a decisive integration of strategy design and operations, with the dividing line much lower than at present. As mid-level managers take on more responsibility, senior executives become free to give more time and attention to economic conditions, product innovation and the changes needed to enhance creativity toward strategic flexibility [23].

It is perhaps its capacity to reintegrate strategy content and process that turns SdP with SD into a new paradigm for competitive advantage [42], and simulation modeling in general [28], into a critical fifth tool, in addition to the four tools used in science: observation, logical-mathematical analysis, hypothesis testing and experiment [77]. But full-fledged SD models also allow computing scenarios to assess possible implications of strategic situations. Strategic scenarios are not merely hypothesized plausible futures, but computed by simulating combined changes in strategy and in the business environment [32].

Computed scenarios help managers understand what they do not know, enabling strategy design and implementation through the coalignment of timely tactics to improve long-term performance. Through its judicious use of resources, scenario-driven planning with system dynamics makes the tactics required for implementation clear [27]. And because computed scenarios reveal the required coalignment of tactics through time, SdP with SD helps firms become flexible, dependable and efficient, and save time!

Everyone's mind sees differently, but if there is truth in the adage 'a picture is worth a thousand words', then the complex interrelations that SdP with SD unearth and show must be worth billions. In a world where strategic chitchat dominates, one can only hope that SdP with SD will play a central role in public and private dialogues about dynamically complex opportunities and threats.

We shape our buildings; thereafter,
our buildings shape us
—Winston Churchill

Introduction

Following on the heels of Ackoff and Emery [3] and Christensen [10], respectively, Gharajedaghi [35] and Raynor [64] show how strategies with the best chances for brilliant success expose firms to debilitating uncertainty. Firms fail as their recipes for success turn bad through time. Gharajedaghi [35] shows, for example, five strategy scenarios that convert success to failure. Each scenario plays a critically different role. Together, however, these scenarios form a dynamically complex system. Through time, as each scenario plays, it enables the context for the next:

1. *Noble ape* or *copycat* strategy imitates and replicates advantage. Also called 'shadow marketing', it lets shadowy copycats instantly *shadow market* product technology, often disruptively.
2. *Patchy* or *sluggish* strategy delays responses to new technology. When this *second* scenario plays, then patching up wastes time, enabling competitors to deliver new technology and to dominate markets. Worse, it causes costs to rise as it drives down product quality.
3. *Satisficing* or *suboptimal* strategy scenarios take many forms. One entails a false assumption: if a policy lever helps produce desired performance, then pulling or pushing on that lever will push performance further.
4. *Gambling* or *changing the game* strategy scenario transforms a strategic situation by playing the game successfully. While dealing with a challenge, firms gradually transform their strategic situation and change the basis for competition, so a whole new game and set of issues emerge. Success marked, for example, the beginning of the *information era*. But competitive advantage has already moved away from having access to information. In our *systems era* [2], creating new knowledge and generating insight is the new game [81].

Lastly, the cumulative effects from these four strategy scenarios trickle down to the:

5. *Archetypal swing* or *paradigm shift* scenario. Both learning and unlearning can cause archetypal swings and paradigm shifts to unfold through time intentionally [76]. These also occur unintentionally when conventional wisdom fails to explain patterns of events that challenge prevailing mental models. The lack of a convincing explanation creates a twilight zone where acceptable ideas are not competent and competent ideas are not acceptable.

Beliefs about the future drive strategies. But the future is unpredictable. Worse, success demands commitments that make it impossible to adapt to a future that turns out surprising. So, strategies with great success potential also bear high failure probabilities. Raynor [64] calls this the *strategy paradox*. Dissolving it requires turning environmental uncertainty into strategic flexibility. To make it so, Raynor urges managers to: anticipate multiple futures with scenarios, formulate optimal strategies for each future, accumulate *strategic real options* [5] and manage the select options portfolio.

SdP with SD helps managers who operate in an uncertain world question their assumptions about how the world works, so they can see it more clearly. To survive, the human mind overestimates small risks and underestimates large risks. Likewise, it is much more sensitive to losses than to gains. So the capability to leverage opportunities and to mitigate risk might have become an economic value driver.

The purpose of computing scenarios is to help managers alter their view of reality, to match it up more closely with reality as is and as it might become. To become a leader, a manager must define reality. The SdP with SD purpose is *not*, however, to paint a more accurate picture of tomorrow, but to improve the quality of decisions about the future. Raynor says that the requisite strategic flexibility, which SdP with SD creates:

> "is not a pastiche of existing approaches. Integrating these tools and grounding them in a validated theory of organizational hierarchy creates something that is quite different from any of these tools on its own, or in mere combination with the others" (see p. 13 in [64]).

Indeed, knowledge of common purposes and the acceptable means of achieving them form and hold together a purposeful hierarchical system. Its members know and share values embedded in their culture, which knits parts into a cohesive whole. And because each part has a lot to say about the whole, consensus is essential to SdP with SD for the co-alignment of diverse interests and purposes.

Ackoff and Emery [3], Gharajedaghi [35] and Nicolis [55] concur that purpose offers the lens one needs to see a firm as a multi-minded social net. A purposeful firm produces either the same result differently in the same environment or different results in the same or different environments. Choosing among strategic real options is necessary but insufficient for purposefulness. Firms that behave differently but show only one result per environment are goal seeking, not purposeful. Servomechanisms are goal seeking but people are purposeful. As a purposeful system, the firm is part of purposeful sub-systems, such as its *industry value chain* [61] and the society. And firms have purposeful people as members. The result is a dynamically interdependent, i. e., complex, hierarchical purposeful system.

A firm's value chain is, along with its primary and support activities, at once a member of at least one industry value chain and of the society or *macro-environment*. Industry analysis requires looking at value chains independently from the society [61]. But people, the society and firm and industry value chains are so interdependent, so interconnected, that an optimal solution might not exist for any of them independently of the others. SdP with SD helps firms co-align the 'plural rationality' of purposeful stakeholder groups with each other and that of the system as a whole.

Seeing strategic management as a *strategies and tactics net* [27] is in perfect syzygy with the *plural rationality* that SdP with SD accounts for among individuals, groups and organizations. Singer [73,74] contrasts monothematic conventional universes of traditional rationality with the multiverse-directed view of plural rationality. In counterpoint, Morecroft's [52] computed scenarios trace the dysfunctional interactions among sales objectives, overtime and sales force motivation to the intended, i. e., stated, singular rationality that drove action in a large sales organization.

Because their superordinate purpose is neither to compete nor to collaborate, but to develop new wealth-creating capabilities, in unique ways that serve both current and future stakeholder interests, customers and clients included [51], firms can benefit from the multiverse-directed view of strategic management as a net of strategies and tactics. SdP with SD helps firms break free from the tradeoffs tyranny of the mass-production era. Evidently, adherents to tradeoffs-free strategy like *Bell Atlantic*, *Daimler-Benz*, *Hallmark* and *Motorola* "can have it all" [60].

A firm must serve the purposes of its people as well as those of its environment, not as a mindless mechanical system, but as a living, purposeful, *knowledge-bonded* hierarchical system [3,35,55,81]. To clarify, a bike always yields to its rider, for example, regardless of the rider's desire; even if that entails running into a solid brick wall. Ouch! But riding a horse is an entirely different story. Horse and rider form a knowledge-bonded system: the horse must know the rider and the rider must know exactly how to lead the horse.

SdP with SD History: Always Back, Always in Style, Always Practical

Herman Kahn introduced scenarios to planning while at RAND Corporation in the 1950s [45]. Scenarios entered military strategy studies conducted for the US government. In the 1960s, Ozbekhan [58] used urban planning scenarios in Paris, France. Organization theorists and even novelists were quick to catch on. The meaning of scenarios became literary. Imaginative improvisation produced flickering apocalyptic predictions of strikingly optimistic and pessimistic futures. Political and marketing experts use scenarios today to jazz up visions of favorable and unfavorable futures.

Wack [78,79] asserts it was Royal Dutch Shell that came up with the idea of scenarios in the early 1970s. Godet [36] points to the French OTAM team as the first to use scenarios in a futures study by DATAR in 1971. Brauers and Weber [8] claim that Battelle's scenarios method [49] was originally a German approach. In connection with planning, however, most authors see scenario methods as typically American.

Indeed, during the 1970s, US researchers Olaf Helmer and Norman Dalkey developed scenario methods at RAND for eliciting and aggregating group judgments via Delphi and cross-impact matrices [4]. They extended cross impact analysis within statistical decision theory [39]. A synthesis of scenario methods began in the 1970s that draws together multiple views, including those of professional planners, analysts and line managers.

Ansoff [6] and other strategy theorists state that the 1970s witnessed the transformation of global markets. Today, changes in the external sociopolitical environment become pivotal in strategy making. Combined with the geographical expansion of markets, they increase the complexity of managerial work. As environmental challenges move progressively faster, they increase the likelihood of strategic surprises. So, strategic thinkers use scenarios to capture the nonlinearity of turbulent environments. Examples are Hax and Majluf [38] and, more clearly so, Porter [61] and Raynor [64]. They consider scenarios instrumental both in defining uncertainty and in anticipating environmental trends.

Huss and Honton [41] see scenarios emerge as a distinct field of study, a hybrid of a few disciplines. They identify multiple scenarios methods that fall into three major categories:

1. Intuitive logics [78,79], now practiced by *SRI International*,
2. Trend-impact analysis, practiced by the *Futures Group* and
3. Cross-impact analysis, practiced by the *Center for Futures Research* using INTERAX (Interactive Cross-Impact Simulation) and by Battelle using BASICS (BAttelle Scenario Inputs to Corporate Strategies).

Similarly, after joining Ozbekhan to advocate reference scenarios, Ackoff [2] distinguishes between:

1. Reference projections as piecemeal extrapolations of past trends and
2. The overall reference scenario that results from putting them together.

Based on Acar's [1] work under Ackoff, Georgantzas and Acar [32] explore these distinctions with a practical managerial technology: *comprehensive situation mapping* (CSM). CSM is simple enough for MBA students to master in their capstone Business Policy course. With the help of *Vensim® PLE* [18], CSM computes scenarios toward achieving a well-structured process of managing ill-structured strategic situations. In their introduction to SD, Georgantzas and Acar (see Chap. 10 in [32]) draw from the banquet talk that Jay Wright Forrester, Germeshausen Professor Emeritus, MIT, gave at the 1989 *International Conference of the System Dynamics Society*, in Germany, at the University of Stuttgart:

After attending the Engineering College, University of Nebraska, which included control dynamics at its core, Forrester went to MIT. There he worked for Gordon S. Brown, a pioneer in feedback control systems. During World War II, Brown and Forrester worked on servomechanisms for the control of radar antennas and gun mounts. This was research toward an extremely practical end, during which Forrester run literally from mathematical theory to the battlefield, aboard the US carrier *Lexington*.

After the war, Forrester worked on an analog aircraft flight simulator that could do little more than solve its own internal idiosyncrasies. So, Forrester invented *random-access magnetic storage* or *core memory*. His invention went into the heart of *Whirlwind*, a digital computer used for experimental development of military combat systems that eventually became the *s*emi*a*utomatic *g*round *e*nvironment (SAGE) air defense system for North America.

Alfred P. Sloan, the man who built *General Motors*, founded the *Sloan School of Management* in 1952. Forrester joined the school in 1956. Having spent fifteen years in the science and engineering side of MIT, he took the challenge of exploring what engineering could do for management.

One day, he found himself among students from *General Electric*. Their household appliance plants in Kentucky puzzled them: they would work with three or four shifts for some time and then, a few years later, with half the people laid off. Even if business cycles would explain fluctuating demand, that did not seem to be the entire reason. *GE*'s managers felt something was wrong.

After talking with them about hiring, firing and inventory policies, Forrester did some simulation on a paper pad. He started with columns for inventories, employees and customer orders. Given these metrics and *GE*'s policies, he could tell how many people would be hired or fired a week later. Each decision gave new conditions for employment, inventories and production. It became clear that wholly determined internally, the system had potential for oscillatory dynamics. Even with constant incoming orders, the policies caused employment instability. That longform simulation of *GE*'s inventory and workforce system marked the beginning of system dynamics [23,24,25,26].

SdP with SD Use and Roadmap

Scenarios mostly help forecast alternative futures but, as firms abandon traditional forecasting methods for interactive planning systems, line managers in diverse business areas adopt scenario-driven planning with system dynamics. Realizing that a tradeoffs-free strategy design requires insight about a firm's environment, both business and sociopolitical, to provide intelligence at *all* strategy levels, firms use SdP with SD to design *corporate, business* and *process* or *functional* strategies. SdP with SD is not a panacea and requires discipline, but has been successful in many settings. Its transdisciplinary nature helps multiple applications, namely capital budgeting, career planning, civil litigation [31], competitive analysis, crisis management, decision support systems (DSS), macroeconomic analysis, marketing, portfolio management and product development [65]. SdP with SD is a quest for managers who wish to be leaders, not just conciliators. They recognize that *logical incrementalism*, a piecemeal approach, is inadequate when the environment and their strategy change together.

Top management might see both divisional, i. e., business, and process or functional strategies as ways of implementing corporate strategy. But *active subsidiaries* [43,44] provide both strategic ideas and results to their parent enterprise. Drawing too stiff a line between the corporate office and its divisions might be

> "an unhealthy side effect of our collective obsession with generating returns. The frameworks for developing competitive strategy that have emerged over the last thirty years have given us unparalleled insight into how companies can succeed. And competitive strategy remains enormously important, but it should be the preserve of divisional management… corporate strategy should be focused on the management of strategic uncertainty" (see p. 11 in [64]).

Roadmap It is material to disconnect scenarios from unproductive guesswork and to anchor them to sound practices for strategy design. This guided tour through the fascinating but possibly intimidating jungle of scenario definitions shows what the future might hold for SdP with SD. Extensive literature, examples, practical guidelines and two real-life cases show how computed scenarios help manage uncertainty, that necessary disciple of our open market system. Unlike extrapolation techniques, SdP with SD encourages managers to think broadly about the future.

The above sections clarify the required context and provide a glossary. Conceptual confusion leads to language games at best and to operational confusion at worst [15]. SdP with SD helps firms avert both types of confusion. Instead of shifting their focus away from actuality and rationality, managers improve their insight about fundamental assumptions underlying changes in strategy. The mind-set of SdP with SD makes it specific enough to give practical guidance to those managing in the real world, both now and in the future.

The sections below look at *three* SdP with SD facets linked to strategy design and implementation. The *first* facet involves the business environment, the forces behind its texture and future's requisite uncertainty (Sect. "Environmental Turbulence and Future Uncertainty"). The *second* entails unearthing unstated assumptions about changes in the environment and in strategy, and about their potential combined effects on performance. The SdP with SD framework (Sect. "SdP with SD: The Modeling Process ≡ Strategic Situation Formulation") builds on existing scenario methods. Its integrative view delineates processes that enhance institutional learning, bolster productivity and improve performance through strategic flexibility. It shows why interest in computed scenarios is growing.

The *third* facet entails *computing* the combined or mixed effects on performance of changes both in the environment and in strategy. Even in mature economies, no matter how and how frequently said, decision makers often forget how the same action yields different results as the environment changes. The result is often disastrous. Conversely, the tight coupling between computed scenarios and strategic results can create new knowledge. Linking a mixed environmental and decision scenario in a one-to-one correspondence to a strategic result suits the normative inclination of strategic management, placing rationalistic inquiry at par with purely descriptive approaches in strategy research.

The unified treatment of SdP with SD and the strategy-making process grants a practical bonus, accounting for the entry's peculiar nature. It is not only a conceptual or idea contribution, but also an application-oriented entry. Sections "Case 1: Cyprus' Environment and Hotel Profitability" and "Case 2: A Japanese Chemicals Keiretsu (JCK) present two real-life cases of scenario-driven planning with system dynamics. Written with both the concrete and the abstract thinker in mind, the two cases show how firms and organizations build scenarios with a modest investment. SdP with SD provides an effective management technology that serves well those who adopt it. It saves them both time and energy.

Improvements in causal mapping [19,20], and SD modeling and analysis [50,57] contribute to the SdP with SD trend (Sect. "Future Directions"). Behavioral decision theory and cognitive science also help translate the knowledge of managers into SD models. The emphasis remains on small, transparent models of strategic situations and on dialogue between the managers' mental models and the computed scenarios [53].

All prognosticators are bloody fools
—Winston Churchill

Environmental Turbulence and Future Uncertainty

Environmental Turbulence

Abundant frameworks describe the business environment, but the one by Emery and Trist [22], which Duncan [17] abridged, has been guiding many a strategic thinker. It shows four business environments, each more complex and troublesome for the firm than the preceding one (Fig. 1a).

1. *Placid* or *independent-static environment*: infrequent changes are independent and randomly distributed,

i. e., IID. Surprises are rare, but no new major opportunities to exploit either (*cell* 1, Fig. 1a).

2. *Placid-clustered* or *complex-static environment*: patterned changes make forecasting crucial. Comparable to the economist's idea of imperfect competition, this environment lets firms develop distinctive competencies to fit limited opportunities that lead to growth and bureaucracy (*cell* 2, Fig. 1a).
3. *Disturbed-reactive* or *independent-dynamic environment*: firms might influence patterned changes. Comparable to oligopoly in economics, this environment makes changes difficult to predict, so firms increase their operational flexibility through decentralization (*cell* 3, Fig. 1a).
4. *Turbulent field* or *complex-dynamic environment*: most frequent, changes are also complex, i. e., interdependent, originating both from autonomous shifts in the environment and from interdependence among firms and conglomerates. Social values accepted by members guide strategic response (*cell* 4, Fig. 1a).

Ansoff and McDonnell [7] extend the dichotomous environmental uncertainty perceptions by breaking turbulent environments (*cell* 4, Fig. 1a) into *discontinuous* and *surprising*. This is a step in the right direction, but not as helpful as a causal model specific to the system structure of a firm's strategic situation. Assuredly, 2 × 2 typologies help clarify exposition and are most frequent in the organization theory and strategy literatures. The mystical significance of duality affected even Leibniz, who associated one with God and zero with nothingness in the binary system. The generic solutions that dichotomies provide leave out the specifics that decision makers need. No matter what business they are in (Fig. 1b), managers cannot wait until a better theory comes along; they must act now.

It is worth noting that people often confuse the term 'complex' with 'complicated'. Etymology shows that *complicated* uses the Latin ending *-plic*: *to fold*, but *complex* contains the Greek root *πλέξ-* '*plēx-*': *to weave*. A complicated structure is thereby folded, with hidden facets stuffed into a small space (Fig. 1c). But a complex structure has interwoven parts with mutual interdependencies that cause dynamic complexity [46]. Remember: complex is the opposite of independent or untwined (Fig. 1a) and complicated is the opposite of simple (Fig. 1c).

Daft and Weick's [12] vista on firm *intrusiveness* and *environmental equivocality* is pertinent here. They see many events and trends in the environment as being inherently unclear. Managers discuss such events and trends, and form mental models and visions expressed in a fuzzy language and label system [80]. Within an *enactment* process, equivocality relates to managerial assumptions underlying the *analyzability* of the environment. A firm's *intrusiveness* determines how *active* or *passive* the firm is about environmental scanning. In this context, as the global environment gets turbulent, active firms and their subsidiaries construct SdP with SD models and compute scenarios to improve performance.

Managers of active firms combine knowledge acquisition with interpretations about the environment and their strategic situation. They reduce equivocality by assessing alternative futures through computed scenarios. In frequent meetings and debates, some by videoconferencing, managers use the dialectical inquiry process for *s*trategic *a*ssumption *s*urfacing and *t*esting (SAST), a vital strategic loop. Often ignored, the SAST loop gives active firms a strategic compass [47].

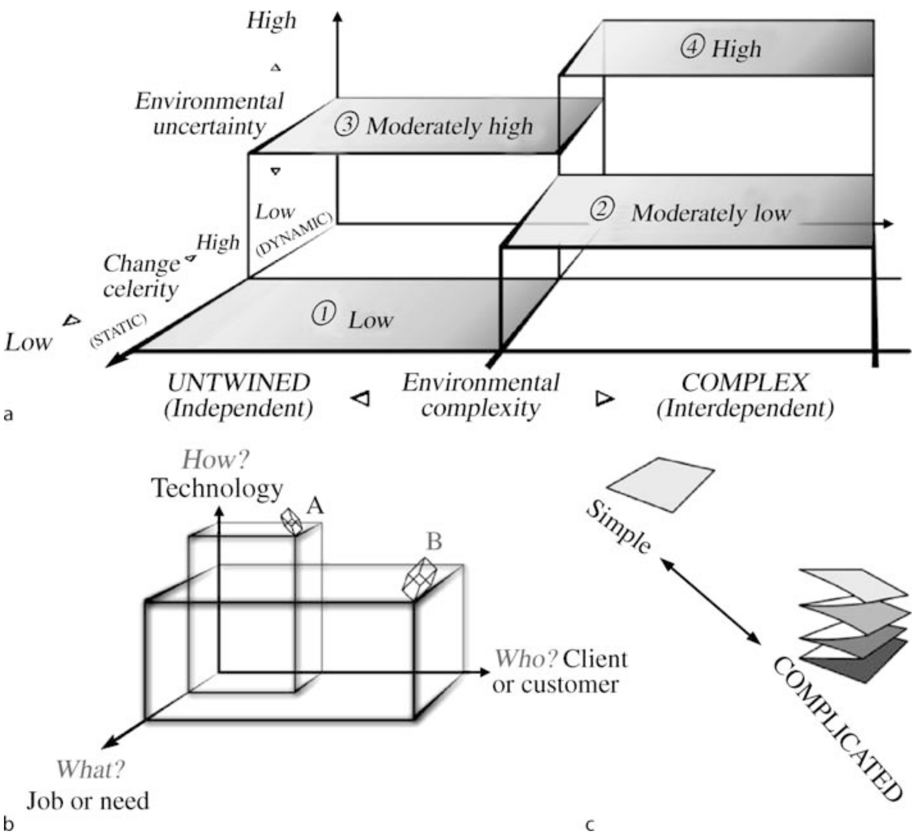
Conversely, passive firms do not actively seek knowledge but reduce equivocality through rules, procedures and regular reports: reams of laser-printed paper with little or no pertinent information. Managers in passive firms use the media to interpret environmental events and trends. They obtain insight from personal contacts with significant others in their environment. Data are personal and informal, obtained as the opportunity arises.

Future Uncertainty

"If we were omnipotent", says Ackoff, then we could get "perfectly accurate forecasts" (see p. 60 in [2]). Thank God the future is unpredictable and we must yet create it. If it were not, then life would have been so boring! Here are some facts about straight forecasting:

1. Forecasts are seldom perfect, in fact, they are always wrong, so a useful forecasting model is one that minimizes error.
2. Forecasts always assume underlying stability in systems.
3. Product family and aggregated forecasts are always more accurate than single product forecasts, so the large numbers law applies.
4. In the short-term, managers can forecast but cannot act because time is too short; in the long term, they can act but cannot forecast.

To offset conundrum #4, SdP with SD juxtaposes the decomposition of performance dynamics into the growth and decline archetypes caused by *balancing* (–) and *reinforcing* (+) recursive causal-link chains or *feedback loops* [33,50]. A thermostat is a typical example of a goal-seeking feedback loop that causes either balancing growth



Scenario-Driven Planning with System Dynamics, Figure 1
a Environmental complexity and change celerity dimensions that cause perceived environmental uncertainty (adapted from [32]). b Scenario-driven planning with system dynamics helps with strategy-design fundamentals, such as, for example, defining a business along the requisite client-job-technology three-dimensional grid. c The simple-complicated dimension must *not* be confused with the environmental complexity dimension (adapted from [46])

or decline. The gap between desired and room temperature causes action, which alters temperature with a time lag or delay. Temperature changes in turn close the gap between desired and room temperature.

Conversely, a typical loop that feeds on itself to cause either exponential growth or decline is that of an arms race. One side increases its arms. The other sides increase theirs. The first side then reacts by increasing its arms, and so on. Price wars between stores, promotional competition, shouting matches, one-upmanship and the wildcard interest rates of the late 1970s are good examples too. Escalation might persist until the system explodes or outside intervention occurs or one side quits, surrenders or goes out of business. In the case of wildcard interest rates, outside intervention by a regulatory agency can bring an end to irrationally escalating rates.

We've never been here before
—Peter Senge

SdP with SD: The Modeling Process ≡ Strategic Situation Formulation

The strategic management process (SMP, Fig. 2) starts with environmental scanning, in order to gauge environmental trends, opportunities and threats. Examples include increasing rivalry among existing competitors and Porter's [62] emphasis on the bargaining power of buyers and suppliers as well as on the threats of new entrants and substitutes. Even if some firms reduce environmental scanning to industry analysis in practice, changes in the environment beyond an industry's boundaries can determine what happens within the industry and its entry, exit and inertia barriers. Internal capability analysis comes next. It examines a firm's past actions and internal policy levers that can both propel and limit future actions. The integrative perspective of the SdP with SD framework on Fig. 2 delineates processes that enhance institutional learning, bolster productivity and improve performance through strategic flexibility.

Strategy design begins by identifying variables pertinent to a firm's strategic situation, along with their interrelated causal links. Changes in these variables can have profound effects on performance. Some of the variables belong to a firm's external environment. Examples are emerging new markets, processes and products, government regulations and international interest and currency rates. Changes either in these or their interrelated causal links determine a firm's performance through time.

It is a manager's job to understand the causal links underlying a strategic situation. SdP with SD helps anticipate the effects of future changes triggered in the external environment. Other variables are within a firm's control. Pulling or pushing on these internal levers also affects performance. To evaluate a change in strategy, one must look at potential results along with changes in the environment, matching resource capabilities, stakeholder purposes, and organizational goals and objectives (Fig. 2).

Most variables interact. Often, the entire set of possible outcomes is obscure, difficult to imagine. But if managers oversimplify, then they end up ignoring the combined effects of chain reactions. Even well-intended rationality often leads to oversimplification, which causes cognitive biases (CBs) that mislead decision makers [21,70,72]. Conversely, computing mixed environmental and decision scenarios that link internal and external metrics can reveal unwarranted simplification.

SdP with SD integrates business intelligence with strategy design, not as a narrow specialty, but as an admission of limitations and environmental complexity. It also uses multiperspective dialectics, crucial for strategic assumption surfacing and testing (SAST). Crucial because the language and labels managers use to coordinate strategic real options are imprecise and fuzzy. Fuzzy language is not only adequate *initially* for managing interdependence-induced uncertainty but required [80]. Decision makers rely on it to overcome psychological barriers and Schwenk's [70] groups of CBs.

The best-case scenario for a passive firm is to activate modeling on Fig. 2, sometimes unknowingly. When its managers boot up, for example, electronic spreadsheets that contain inside-out causal models, with assumptions hidden deeply within many a formula. At bootup, only the numbers show. So passive-firm managers use electronic spreadsheets to laser-print matrices with comforting numbers. They

> "twiddle a few numbers and diligently sucker themselves into thinking that they're forecasting the future" [69].

And that is only when rapid changes in the environment force them to stop playing *blame the stakeholder*. They stop fighting the last war for a while, artfully name the situation a crisis, roll up their sleeves, and chat about and argue, but quickly agree on some arbitrary interpretation of the situation to generate strategic face-saving options. Miller and Friesen (see pp. 225–227 in [48]) show how for futile firms, rapid environmental changes lead to crisis-oriented decisions. Conversely, successful firms look far into the future as they counter environmental dynamism through strategy design with real options. Together, their options and interpretation of the environment, through the consensus that SdP with SD facilitates, enable a shared logic to emerge: a shared mental model that filters hidden spreadsheet patterns and heroic assumptions clean and clear.

Managers of active firms enter the SdP with SD loop of Fig. 2 both consciously and conscientiously. They activate strategic intelligence via computed scenarios and the SAST loop. Instead of twiddling spreadsheet numbers, *pro*active firm managers twiddle model assumptions. They stake, through SD model diagrams, their intuition about how they perceive the nature and structure of a strategic situation. Computed scenarios quantitatively assess their perceived implications. Having quantified the implications of shared visions and claims about the structure of the strategic situation, managers of active firms are likely to reduce uncertainty and equivocality. Now they can manage strategic interdependence. Because articulated perception is the starting point of all scenarios, computed scenarios give active firms a fair chance at becoming fast strategic learners.

The design of action or implementation tactics requires detailing how, when and where a strategy goes into action. In addition to assuming the form of *pure communication* (III: 1 and 2, Fig. 2) or *pure action* (III: 3 and 4, Fig. 2), in a pragmatic sense, tactics can be either cooperative or competitive and defensive or offensive. Market location tactics, for example, can be either offensive, trying to rob market share from established competitors, or defensive, preventing competitors from stealing one's market share. An offensive tactic takes the form of frontal assault, flanking maneuver, encirclement, bypass attack or guerilla warfare. A defensive tactic might entail raising structural barriers, increasing expected retaliation or lowering the inducement for future attack. Conversely, cooperative tactics try to gain mutual advantage by working with rather than against others. Cooperative tactics take the form of alliances, joint ventures, licensing agreements, mutual service consortia and value-chain partnerships, the co-location of which often creates industrial districts [29].

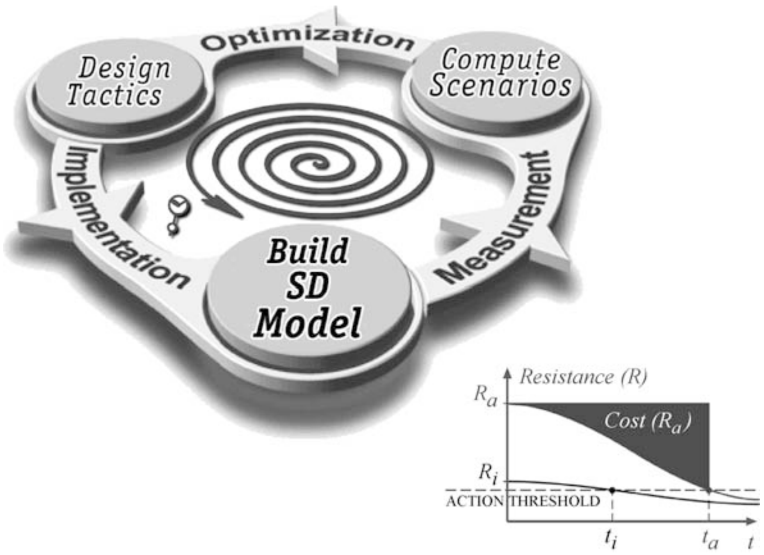
Scenario-Driven Planning with System Dynamics, Figure 2
Cones of resolution show how scenario-driven planning with system dynamics enhances the strategy design component of the strategic management process (SMP; adapted from [32])

The usual copycat strategy retort shows linear thinking at best and clumsy *benchmarking*, also known as shadow marketing, at worst. Its proponents assume performance can improve *incrementally*, with disconnected tactics alone, when strategy design is of primary concern. Piecemeal tactics can undermine strategy, but they are secondary. It might be possible to improve performance through efficient tactics, but is best to design strategies that expel counterproductive tactics. Counterproductive tactics examples are coercive moves that increase rivalry, without a real payoff, either direct or indirect, for the industry incumbent who initiates them. It is atypical of an industry or market leader to initiate such moves.

In strategy, superb action demands superior design. According to the design school, which Ansoff, Channon, McMillan, Porter, Thomas and others lead, logical incrementalism may help implementation, but becomes just another prescription for failure when the environment shifts. Through its judicious use of corporate resources, SdP with SD makes the tactics required for action clear. Also, it reveals their proper coalignment through time, so a firm can build strategic flexibility and save time!

The Modeling Process ≡ Strategic Situation Formulation

SdP with SD (Fig. 2) begins by modeling a business or 'social process' than a business or 'social system'. It is more productive to identify a *social process* first and then seek its causes than to slice a chunk of the real world and ask what dynamics it might generate. Distinguishing between a *social system* and a social process is roughly equivalent to distinguishing between a system's underlying causal structure and its dynamics. Randers (see p. 120 in [63]) defines a social system as a set of cause and effect relations. Its structure is a causal diagram or map of a real-world chunk. A social process is a behavior pattern of events evolving through time. The simulation results of SdP with SD models show such chains of events as they might occur in the real world. An example of a social system (structure) is the set of rules and practices that a firm might enact when dealing with changes in demand, along with the communication channels used for transmitting information and decisions. A corresponding social process (dynamics) might be the stop-and-go pattern of capital in-



Scenario-Driven Planning with System Dynamics, Figure 3
The recursive nature of the modeling process that scenario-driven planning with system dynamics entails a creates a sustainable, ever-expanding vortex of insight and wisdom, needed in strategic real-options valuation, and b saves both time and money as it renders negligible the cost of resistance (*R*) to change

vestment caused by a conservative bias in a firm's culture.

In his model of a new, fast-growing product line, for example, Forrester [24] incorporates such a facet of corporate culture. Causing sales to stagnate, considerable back orders had to accumulate to justify expansion because the firm's president insisted on personally controlling all capital expenditures.

People often jump into describing system structure, perhaps because of its tangible nature as opposed to the elusive character of dynamics or social process fragments. Also, modelers present model structure first and then behavior. Ultimately, the goal in modeling a strategic situation is to link system structure and behavior. Yet, in the early stages of modeling is best to start with system dynamics and then seek underlying causes. Indeed, SD is particularly keen in understanding system performance, "not structure per se" (see p. 331 in [56]), in lieu of SD's core tenet that structure causes performance.

The modeling process itself is recursive in nature. The path from real-world events, trends and negligible externalities to an effective formal model usually resembles an expanding spiral (Fig. 3a). A useful model requires conceptualization; also focusing the modeling effort by establishing both the time horizon and the perspective from which to frame a decision situation. Typically, strategy-design models require a long-term horizon, over which computed scenarios assess the likely effects of changes both in strategy and in the environment.

Computer simulation is what makes SdP with SD models most useful. Qualitative cause and effect diagrams are too vague, tricky to simulate mentally. Produced through knowledge elicitation, their complexity vastly exceeds the human capacity to see their implications. Casting a chosen perspective into a formal SdP with SD model entails postulating a detailed structure; a diagramming description precise enough to propagate images of alternative futures, i. e., computed scenarios, "though not necessarily accurate" (see p. 118 in [63]). But the modeling process must never downplay the managers' mental database and its knowledge content. Useful models always draw on that mental database [24].

Following Morecroft [53], SdP with SD adopters might strive to replace the notion of modeling an objectively singular world *out there*, with the much softer approach of building formal models to improve managers' mental models. The expanding spiral of Fig. 3a shows that the insight required for decisive action increases as the quantity of information decreases, by orders of magnitude. The required quantification of the relations among variables pertinent to a strategic situation changes the character of the information content as one moves from mental to written to numerical data. Perceptibly, a few data remain, but much more pertinent to the nature and structure of the situation. Thanks to computed scenarios, clarity rules in the end. And, if the modeling process stays *i*nteractive (i), as opposed to *a*ntagonistic (a), then clarity means low resistance to change ($R_i < R_a$, Fig. 3b), which helps reach

Case 1: Cyprus' Environment and Hotel Profitability

Cyprus' Hotel Association wished to test how Cyprus' year 2010 official tourism strategy might affect tourist arrivals, hotel bed capacity and profitability, and the island's environment [30]. Computed with a system dynamics simulation model, four tourism growth scenarios show what might happen to Cyprus' tourism over the next 40 years, along with its potential effects on the sustainability of Cyprus' environment and hotel profitability. Following is a partial description of the system dynamics model that precedes its dynamics.

Model Description (Case 1)

The SD model highlights member interactions along Cyprus' hotel value chain. The model incorporates a generic value-chain management structure that allows modeling customer-supplier value chains in business as well as in physical, biological and other social systems. Although the structure is generic, its situation specific parameters faithfully reproduce the dynamic behavior patterns seen in Cyprus' hotel value-chain processes, business rules and resources.

Cyprus' Environment, Population and Tourism Model Sectors Within Cyprus' environment and population sector (Fig. 4a), the carbon dioxide (CO_2) pollution stock is the accumulation of Cyprus' anthropogenic emissions less the Mediterranean Sea region's self clean-up rate. The clean-up rate that drains Cyprus' CO_2 pollution depends on the level of anthropogenic pollution itself as well as on the average clean-up time and its standard deviation (sd). Emissions that feed CO_2 pollution depend on Cyprus' population and tourism and on emissions per person [9].

In SD models, rectangles represent stocks, i. e., level or state variables that accumulate through time, e. g., the Tourism stock on Fig. 4b. The double-line, pipe-and-valve-like icons that fill and drain the stocks, often emanating from cloud-like sources and ebbing into cloud-like sinks, represent material flows that cause the stocks to change. The arrive rate of Fig. 4b, for example, shows tourists who flow into the tourism stock per month. Single-line arrows represent information flows, while plain text or circular icons depict auxiliary constant or converter variables, i. e., behavioral relations or decision points that convert information into decisions. Changes in the tourism stock, for example, depend on annual tourism, adjusted by tourism seasonality. Both the diagram on Fig. 4a and Table 1 are reproduced from the actual simulation model, first built on the glass of a computer screen using the diagramming interface of *iThink*® [67], and then specifying simple algebraic equations and parameter values. Built-in functions help quantify policy parameters and variables pertinent to Cyprus' tourism situation.

There is a one-to-one correspondence between the model diagram on Fig. 4a and its equations (Table 1). Like the diagram, the equations are the actual output from *iThink*® too. The equations corresponding to Fig. 8b are archived in [30]. Together, Cyprus' population, local tourism and monthly tourism determine the population and tourism sum (Eq. 1.11, Table 1). According to CYSTAT [11], both *Cyprus' Tourism Organization* and its government attach great importance to local tourism. A study on domestic tourism conducted in 1995 revealed that about 46 percent of Cypriots take long holidays. Of these, 61 percent take long holidays exclusively in Cyprus and eight percent in Cyprus and abroad, while 31 percent chose to travel abroad only. These are precisely the percentages in the model (Eq. 1.10, Table 1).

On Fig. 4a, the world land and population data, minus Cyprus' land, population and tourism co-determine the world EF (environmental footprint, Eq. 1.14, Table 1). Compared to Cyprus' smooth EF, i. e., the smooth ratio of the island's free land divided by its total population and tourism, the world EF gives a dynamic measure of Cyprus' relative attractiveness to the rest of the world. The EF ratio (Eq. 1.6, Table 1), i. e., the ratio of Cyprus' smooth EF (Eq. 1.13, Table 1) divided by the world EF (Eq. 1.14, Table 1), assumes that the higher this ratio is, the more attractive the island is to potential tourists, and vice versa. The EF ratio, which depends on Cyprus' total population and tourism, feeds back to the island's annual tourism via the inflow of foreign visitors who come to visit Cyprus every year (Fig. 4b).

The logistic or Verhulst growth model, after François Verhulst who published it in 1838 [66], helps explain Cyprus' actual annual tourism, a quantity that cannot grow forever (Fig. 4b). Every system that initially grows exponentially eventually approaches the carrying capacity of its environment, whether it is food supply for moose, the number of people susceptible to infection or the potential market for a good or a service. As an 'autopoietic' system approaches its limits to growth, it goes through a non-linear transition from a region where positive feedback dominates to a negative feedback dominated regime. S-shaped growth often results: a smooth transition from exponential growth to equilibrium.

The logistic model conforms to the requirements for S-shaped growth and the ecological idea of carrying capacity. The population it models typically grows in a fixed environment, such as Cyprus' foreign annual tourism has done since 1960 up to 2000. Initially dominated by positive feedback, Cyprus' annual tourism might soon reach the island's carrying capacity, with a nonlinear shift to dominance by negative feedback. While accounting for Cyprus' tourism lost to the summer of 1974 Turkish invasion, officially a very long 'military intervention', further depleting annual tourism is the outflow of Cyprus' visitors (not shown here) who might go as the island's free area reaches its Carrying Capacity, estimated at seventy times the number of Cyprus' visitors in 1960 [30].

Cyprus' Hotel Association listed Cyprus tourism seasonality as one of its major concerns. At the time of this investigation, CYSTAT [11] had compiled monthly tourism data for only 30 months. These were used for computing Cyprus' tourism seasonality (Fig. 4b). Incorporating both the foreign annual tourism and the monthly tourism stocks in the model allows both looking at the big picture of annual tourism growth and assessing the potential long-term effects of tourism seasonality on the sustainability of Cyprus' environment and hotel EBITDA, i. e., *e*arnings *b*efore *i*nterest, *t*axes, *d*epreciation and *a*mortization. The publicly available actual annual tourism data allow testing the model's usefulness, i. e., how faithfully it reproduces actual data between 1960 and 2000 [30].

Cyprus' foreign visitors and local tourists arrive at the island's hotels and resorts according to Cyprus' tourism seasonality, thereby feeding Cyprus' monthly tourism stock. About 11.3 days later, according to CYSTAT's [11] estimated average stay days, both foreign visitors and local tourists depart, thereby depleting the monthly tourism stock. By letting tourism growth = 0 and Cyprus' tourism seasonality continue repeating its established pattern, the model computes a zero-growth or *base-run* scenario. Subsequently, however, tourism growth values other than zero initiate different scenarios.

Cyprus' Tourism Growth Scenarios (Case 1)

What can Cyprus' hoteliers expect to see in terms of bottom-line dynamics? According to the four tourism-growth scenarios computed on Fig. 5, seasonal variations notwithstanding, the higher Cyprus' tourism growth is, the lower hotel EBITDA (smooth hE) is, in the short term. In the long term, however, higher tourism growth yields higher profitability in constant year 2000 prices.

Scenario-Driven Planning with System Dynamics, Table 1
Cyprus' environment and population (and local tourism) model sector (Fig. 4a) equations, with variable, constant parameter and unit definitions

Level or state variables **(stocks)**	***Eq.*** #
$CO_2Pollution(t) = CO_2Pollution(t - dt) + (emissions - clean\ up) * dt$	(1.1)

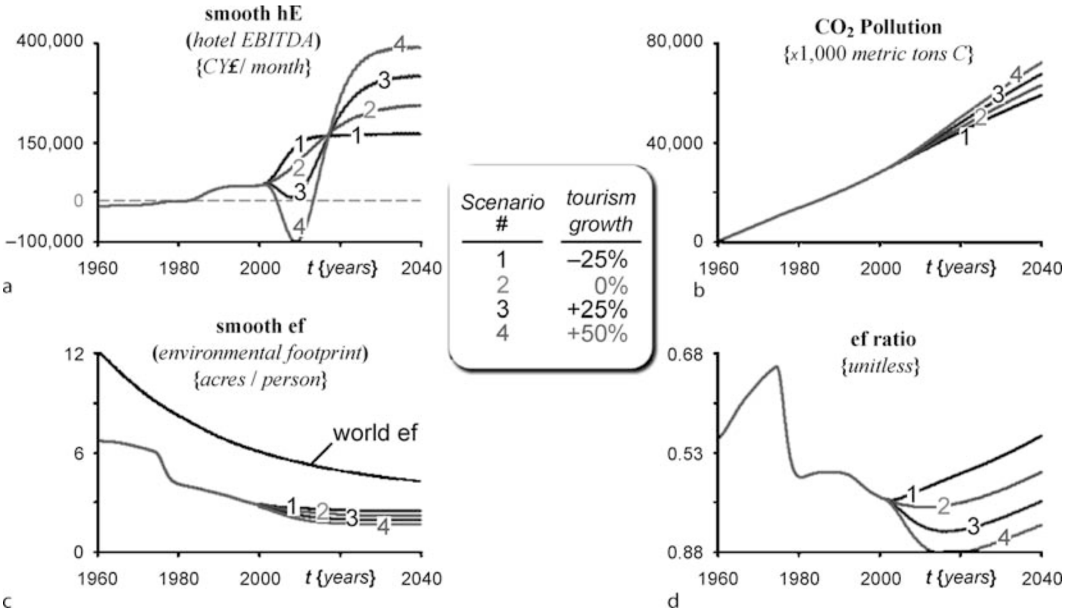
World population = GRAPH(time/12) (Divided by 12 since these are annual data; unit: persons) (0.00, 3e+09), (1.00, 3.1e+09), (2.00, 3.1e+09), (3.00, 3.2e+09), (4.00, 3.3e+09), (5.00, 3.3e+09), (6.00, 3.4e+09), (7.00, 3.5e+09), (8.00, 3.6e+09), (9.00, 3.6e+09), (10.0, 3.7e+09), (11.0, 3.8e+09), (12.0, 3.9e+09), (13.0, 3.9e+09), (14.0, 4e+09), (15.0, 4.1e+09), (16.0, 4.2e+09), (17.0, 4.2e+09), (18.0, 4.3e+09), (19.0, 4.4e+09), (20.0, 4.5e+09), (21.0, 4.5e+09), (22.0, 4.6e+09), (23.0, 4.7e+09), (24.0, 4.8e+09), (25.0, 4.9e+09), (26.0, 4.9e+09), (27.0, 5e+09), (28.0, 5.1e+09), (29.0, 5.2e+09), (30.0, 5.3e+09), (31.0, 5.4e+09), (32.0, 5.4e+09), (33.0, 5.5e+09), (34.0, 5.6e+09), (35.0, 5.7e+09), (36.0, 5.8e+09), (37.0, 5.8e+09), (38.0, 5.9e+09), (39.0, 6e+09), (40.0, 6.1e+09), (41.0, 6.2e+09), (42.0, 6.2e+09), (43.0, 6.3e+09), (44.0, 6.4e+09), (45.0, 6.5e+09), (46.0, 6.5e+09), (47.0, 6.6e+09), (48.0, 6.7e+09), (49.0, 6.8e+09), (50.0, 6.8e+09), (51.0, 6.9e+09), (52.0, 7e+09), (53.0, 7e+09), (54.0, 7.1e+09), (55.0, 7.2e+09), (56.0, 7.2e+09), (57.0, 7.3e+09), (58.0, 7.4e+09), (59.0, 7.5e+09), (60.0, 7.5e+09), (61.0, 7.6e+09), (62.0, 7.6e+09), (63.0, 7.7e+09), (64.0, 7.8e+09), (65.0, 7.8e+09), (66.0, 7.9e+09), (67.0, 8e+09), (68.0, 8e+09), (69.0, 8.1e+09), (70.0, 8.1e+09), (71.0, 8.2e+09), (72.0, 8.3e+09), (73.0, 8.3e+09), (74.0, 8.4e+09), (75.0, 8.4e+09), (76.0, 8.5e+09), (77.0, 8.5e+09), (78.0, 8.6e+09), (79.0, 8.6e+09), (80.0, 8.7e+09)	(1.17)

High tourism growth implies accommodating overbooked hotel reservations for tourists who actually show up. Free cruises erode Cyprus' hotel EBITDA. The alternative is, however, angry tourists going off in hotel lobbies. Tourists have gotten angry at hotels before, but hotels have made the problem worse in recent years worldwide [16]. They have tightened check-in rules, doubled their renovations and increased the rate of overbooking by about 30 percent. The results can be explosive if one adds the record flight delays that travelers endure. Anyhow, free cruises to nearby Egypt and Israel sound much better than simply training employ-



Scenario-Driven Planning with System Dynamics, Figure 5

Four computed scenarios show how tourism growth might affect Cyprus' hotel EBITDA (smooth hE) and the island's environment, with carbon-dioxide (CO_2) pollution (adapted from and extending [30])

ees to handle unhappy guests that scream in hotel lobbies.

Eventually, as Cyprus' bed capacity increases and thereby catches up with tourism demand, there will be less overbooking and a few free cruises to erode Cyprus' hotel EBITDA. Given enough time for an initial bed capacity disequilibrium adjustment, in the long term, high tourism growth increases both hotel EBITDA (Fig. 5a) and cash [30].

In addition to their profound consequences for its hotel value-chain participants, Cyprus' tourism growth might also determine the fate of the island's environment. Depending on the island's population and emissions per person, high tourism growth implies high anthropogenic emissions feeding Cyprus' CO_2 Pollution. Anthropogenic CO_2 emissions attributed to the upward and downward movements of recurring tourist arrivals create much more stress and strain for the island's natural environment than a consistent stream of tourism with low seasonality would. High tourism growth lowers Cyprus' environmental footprint (EF). The summer 1974 Turkish *military intervention* has had a drastic negative effect on Cyprus' relative attractiveness because it reduced the island's free land by 41 percent.

Although qualitatively similar to the world's average EF after the invasion, Cyprus' environmental footprint is lower than the world's average EF (Fig. 5c), rendering the island's free area relatively less attractive as more foreign tourists visit. Manifested in the EF ratio (Fig. 5d), Cyprus becomes relatively less attractive as more visitors choose to vacation on the island's free area.

Qualitatively, Cyprus' CO_2 pollution scenarios (Fig. 5b) look exactly like the A2 scenario family of harmonized anthropogenic CO_2 emissions, which the *Intergovernmental Panel on Climate Change* (IPCC) computed to access the risks of human-induced climate change [54]. Like in the rest of the world, unless drastic changes in policy or technology alter the emissions per person ratio in the next 40 years, CO_2 pollution is expected to grow proportionally with Cyprus' tourism, degrading the island's environment.

Case 2: A Japanese Chemicals Keiretsu (JCK)

Home of NASA's *Johnson Space Center*, the Clear Lake region in Texas boasts strong high technology, biotechnology and specialty chemicals firms. Among them is JCK, whose recent investment helps the Clear Lake region continue its stalwart role in Houston's regional economic expansion [40].

An active member of a famous Japanese giant conglomerate, JCK's history begun in the late 1800s. Despite its long history, however, it has not been easy for JCK to evade the feedback loop that drives Japanese firms to manufacture outside Japan. Since the 1950s, with Japan still recovering from WWII, the better Japanese companies performed, the better their national currency did. But the better Japan's currency did, the harder it became for its firms to export. The higher the yen, the more expensive and, therefore, less competitive Japan's exports become. This simple loop explains JCK's manufacturing lineage from Japan to USA [34].

But the transition process behind this lineage is not that simple. JCK's use of SdP with SD reveals a lot about its strategy design and implementation tactics. The model below shows a tiny fragment of JCK's gigantic effort to reperceive itself. The firm wants to see its keiretsu transform into an agile, virtual enterprise network (VEN) of active agents that collaborate to achieve its transnational business goals. Although still flying low under the media's collective radar screen, VENs receive increased attention by strategic managers [29].

Sterman (see Chap. 17 and 18 in [75]) presents a generic value-chain management structure that can unearth what VENs are about. By becoming a VEN, JCK is poised to bring the necessary people and production processes together to form *autopoietic*, i. e., self-organizing, customer-centric value chains in the specialty chemicals industry. JCK decided to build its own plant in USA because the net present value (NPV) of the anticipated combined cash flow resulting from a merger with other specialty chemicals manufacturers in USA would have been less then the sum of the NPVs of the projected cash flows of the firms acting independently. Moreover, JCK's own technology transfer cost is so low that the internalization cost associated with a merger would far exceed supplier charges plus market transaction costs. To remain competitive [62], JCK will not integrate the activity but offshoot it as a branch of its VEN-becoming keiretsu. The plant will be fully operational in January 2008. In order to maximize the combined *n*et *p*resent *v*alue of *e*arnings *b*efore *i*nterest, *t*axes, *d*epreciation and *a*mortization, i. e., NPV(EBITDA), of its new USA plant and the existing one in Asia, JCK wishes to improve its USA sales revenue before production starts in USA.

JCK's pre-production marketing tactics aim at building a sales force to increase sales in USA. Until the completion of the new plant (Dec. 2007), JCK will keep importing chemicals from its plant in Asia. Once production starts in USA (Jan. 2008), then the flow of goods from Asia to USA stops, the plant in USA supplies the USA market and the flow of goods from USA to Asia begins.

Strategic scenarios are not new to the chemical industry [82]. SdP with SD helps this specialty chemicals producer integrate its business intelligence efforts with strategy design in anticipation of environmental change. Modeling JCK's strategic situation requires a comprehensive inquiry into the environmental causalities and equivocalities that dictate its actions. Computed strategic and tactical scenarios probe the combined consequences of environmental trends, changes in JCK's own strategy, as well as the moves of its current and future competitors. The section below describes briefly how JCK plans to implement its transnational strategy of balanced marketing and production. This takes the form of a system dynamics simulation model, which precedes the interpretation of its computed scenarios.

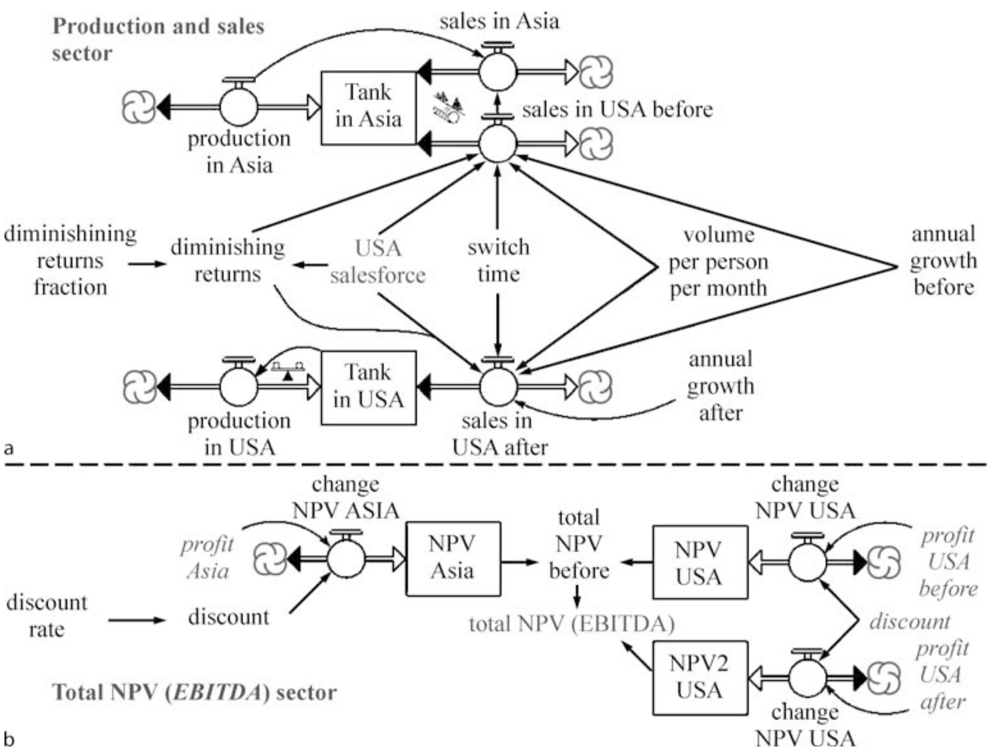
Model Description (Case 2)

The entire model has multiple sectors, four of which compute financial accounting data. Figure 6a shows the production and sales, and Fig. 6b the total NPV(EBITDA) model sectors. The corresponding algebra is in [34]. While JCK is building its USA factory, its factory in Asia makes and sells all specialty chemicals the USA market cannot yet absorb. This is what the *feed-forward* link from the production in Asia flow to the sales in Asia rate shows. The surplus demand JCK faces in Asia for its fine chemicals accounts for this rather unorthodox model structure. The surplus demand in Asia is the model's enabling *safety valve*, i. e., a major strategic assumption that renders tactical implementation feasible.

With the plant in Asia producing at full capacity before the switch, sales in the USA both depletes the tank in Asian stock and reduces sales in Asia. USA sales depend on JCK's USA sales force. But the size of this decision variable is just one determinant of sales in USA.

Sales productivity depends on many parameters, such as the annual growth before the switch rate of specialty chemicals in USA, the average expected volume a salesperson can sell per month as well as on the diminishing returns that sales people experience after the successful calls they initially make on their industrial customers. B2B or business to business, i. e., industrial marketing, can sometimes be as tough as B2C or business to customer, i. e., selling retail.

Time $t = 30$ months corresponds to January 2008, when the switch time converter cuts off the supply of JCK's chemicals from its plant in Asia. Ready by December 2007, the factory in the USA can supply the entire customer base its USA sales force will have been building for 30 months. As production in the USA begins, the sales in the USA before flow stops draining the tank in Asia and sales in Asia resume to match JCK's surplus demand there. Acting both as a production flow and as a continuous-review



Scenario-Driven Planning with System Dynamics, Figure 6
JCK's a production and sales, and b total NPV(EBITDA) model sectors (adapted from [34]; NPV = net present value, and EBITDA = earnings before interest, taxes, depreciation and amortization)

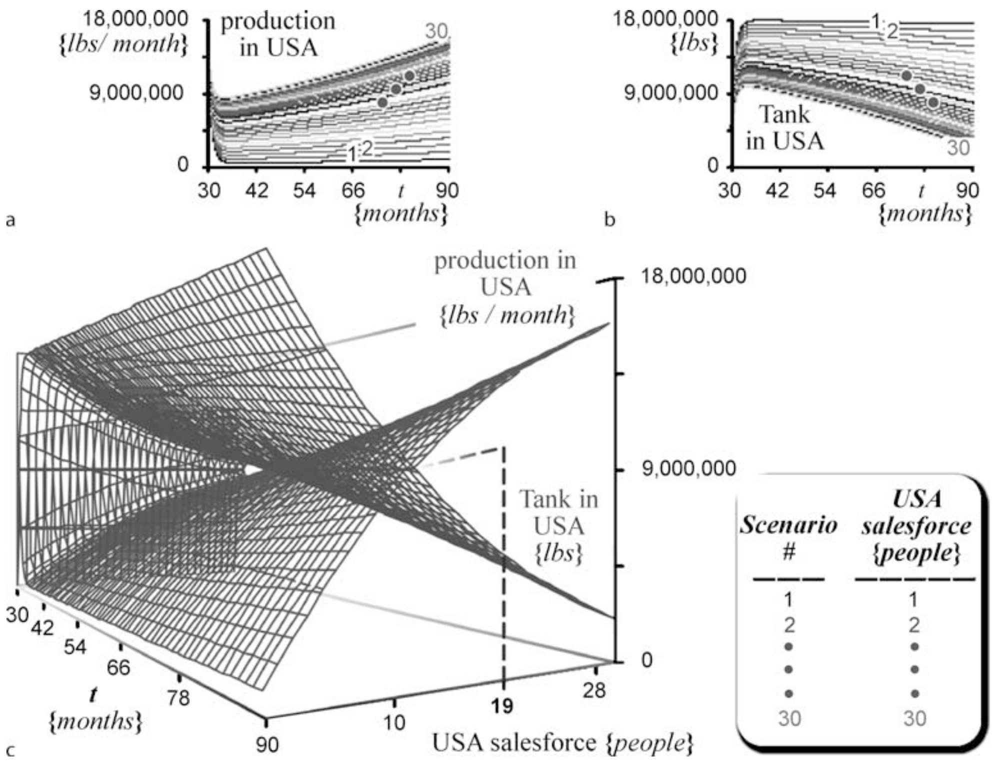
inventory order point, after January 2008, production in USA feeds the tank in USA stock of the rudimentary value-chain management structure on Fig. 6a.

Value chains entail stock and flow structures for the acquisition, storage and conversion of inputs into outputs, and the decision rules that govern the flows. The jet ski value chain includes, for example, hulls and bows that travel down monorail assembly paths. At each stage in the process, a stock of parts buffers production. This includes the inventory of fiberglass laminate between hull and bow acquisition and usage, the inventory of hulls and bows for the jet ski lower and upper structures, and the inventory of jet skis between dealer acquisition and sales. The decision rules governing the flows entail policies for ordering fiberglass laminate from suppliers, scheduling the spraying of preformed molds with layers of fiberglass laminate before assembly, shipping new jet skis to dealers and customer demand.

A typical firm's or VEN's value chain consists of cascades of supply chains, which often extend beyond a firm's boundaries. Effective value chain models must incorporate different agents and firms, including suppliers, the firm, distribution channels and customers. Scenario-driven planning with system dynamics is well suited for value chain modeling and policy design because value chains involve multiple stock and flow chains, with time lags or delays, and the decision rules governing the flows create multiple feedback loops among VEN members or value- and supply-chain partners (see Chap. 17 and 18 in [75]).

Back to JCK, its tank in the USA feeds information about its level back to production in the USA. Acting first as a decision point, production in the USA compares the tank in the USA level to the tank's capacity. If the tank is not full, then production in the USA places an order to itself and, once the USA factory has the requisite capacity, production in the USA refills the tank in the USA, but only until sales in the USA after the switch drains the tank. Then the cycle begins all over again.

Meanwhile, the profit in Asia, profit in the USA before and profit in the USA after sectors [34] perform all the financial accounting necessary to keep track of the transactions that take place in the value chain production and sales sector (Fig. 6a). As each scenario runs, the profit in Asia, the USA before and the USA after sectors feed the corresponding change in net present value (NPV) flows of



Scenario-Driven Planning with System Dynamics, Figure 7
Thirty computed scenarios show JCK's dual, smooth-switch and profitable purpose in production (adapted from [34])

the model's total NPV(EBITDA) sector (Fig. 6b). By adjusting each profit sector's EBITDA according to the discount rate, the change in NPV flows compute the total NPV(EBITDA) both in Asia and in the USA, both before and after JCK's January 2008 supply switch.

JCK's Computed Scenarios (Case 2)

Recall that the SdP with SD modeling-process spiral enabled our modeling team to crystallize JCK's strategic situation into the cyclical pattern that Fig. 3a shows. Although heavily disguised, the JCK measurement data and econometric sales functions let the system dynamics model compute scenarios to answer that razor-sharp optimization question the JCK executives asked:

> What size a USA sales force must we build in order to get a smooth switch in both sales and production in January 2008, and also to maximize the combined NPV(EBITDA) at our two plants in Asia and USA from now through 2012?

Treating the USA sales force policy parameter in the 'Sensi Specs…' menu item of *iThink*® allowed computing a set of 30 strategic scenarios. The 30 scenarios correspond to JCK's hiring from one to 30 sales people, respectively, to sell specialty chemicals to manufacturing firms in the USA, both before and after the January 2008 switch. Figures 7 and 8 show the 30 computed scenarios.

Figure 7c shows the response surfaces the production in USA rate and tank in the USA stock form after January 2008, in response to the 30 computed scenarios. The computed scenario that corresponds to JCK's building a USA sales force of 19 people achieves a smooth balance between sales in Asia and in the USA. Under this scenario, after January 2008, on the line where the two surfaces cross each other, not only the number of pounds of chemicals made and sold in Asia equals the number of pounds of chemicals made and sold in the USA, but as Fig. 7c shows, production in the USA also equals the tank in USA stock. So hiring 19 sales people now meets JCK's smooth switch in sales and production objective. But how?

How does producing and selling in the USA at rates equal to the corresponding rates in Asia constitute a fair response to JCK's smooth switch objective? The JCK executives seemed to accept this at face value. But our team had to clearly explain the dynamics of JCK's rudimentary USA value chain (Fig. 6a), in order to unearth what the USA member of this transnational VEN-becoming keiretsu might be up to.

It looks simple, but the value chain of the production and sales sector on Fig. 6a can show the same amplification symptoms that much more elaborate value chains show when they fall pray to bullwhip effects. Locally rational policies that create smooth and stable adjustment of individual business units can, through their interaction with other functions and firms, cause oscillation and instability. Figure 8a shows the profound consequences of JCK's switch for its value chain in the USA. Because of the sudden switch in January 2008, the computed scenarios cause 30 sudden step changes. Both variables' adjustment rates increase, but the tank in the USA stock's amplification remains almost constant below 50 percent. As customer demand steps up, so do both metrics' new equilibrium points, but in direct proportion to the step increase in customer demand in the USA.

The 30 computed scenarios confirm Sterman's argument that, while the magnitude of amplification depends on stock adjustment times and delivery lags, its existence does not. No matter how drastically customers and firms downstream in a value chain change an orders' magnitude, they cannot affect supply chain amplification. Value chain managers must never blame customers and downstream firms or their forecasts for bullwhip effects. The production in USA amplification is almost double the tank in USA for a small USA sales force, suggesting that JCK's USA factory faces much larger changes in demand than its sales people do. Although temporary, during its disequilibrium adjustment, the tank in the USA consistently overshoots the new equilibrium points that it seeks after the switch (Fig. 7b), an inevitable consequence of stock and flow structure. Customers are innocent, but JCK's value chain structure is not:

First, the tank in the USA stock adjustment process creates significant amplification of the production in the USA rate. Though the tank in the USA relative amplification is 36.18 percent under the USA sales force = 1 scenario, for example, the relative amplification of production in the USA (Fig. 8a) increases by a maximum of more than 90 percent (the peak production in the USA rate, after t = 30 months, divided by the minimum production in the USA rate $= 11,766,430.01/1,026,107.64 = 91.28$ percent). The *amplification ratio*, i. e., the ratio of maximum change in output to maximum change in input, therefore is $91.28\%/36.18\% = 2.52$. A one-percent increase in demand for JCK's chemicals causes a 2.52 percent surge in demand at JCK's USA plant. While the amplification ratio magnitude depends on the stock adjustment times and delivery lags, its existence does not (see p. 673 in [75]).

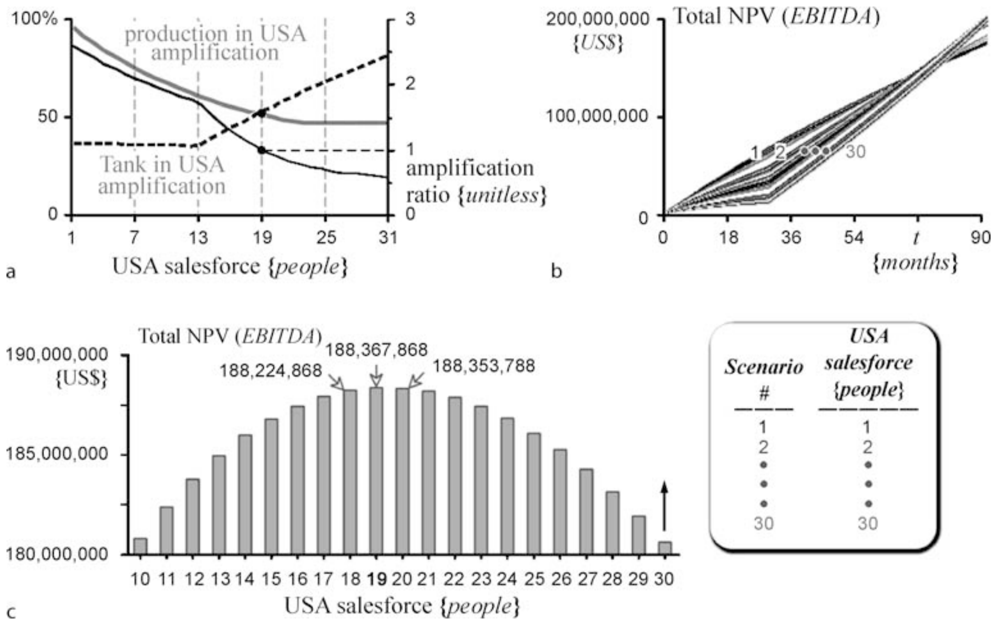
Second, amplification is temporary. In the long run, a one-percent increase in sales in the USA after leads to a one-percent increase in production in the USA. After two-adjustment times, i. e., two months, production in the USA gradually drops (Fig. 7a). During the disequilibrium adjustment, however, production in the USA overshoots its new equilibrium, an inevitable consequence of the stock and flow structure of customer-supplier value chains, no matter how tiny or simple they are. The only way the tank in the USA stock can increase is for its inflow production in the USA rate (order rate) to exceed its outflow rate sales in the USA after (Fig. 6a). Within a VEN's or keiretsu's customer-supplier value chain, supply agents face much larger changes in demand than finished-goods inventory, and the surge in demand is temporary.

The computed scenarios show that as the USA sales force increases, the production in the USA's rate of amplification declines because its new long-term equilibrium point is closer to its initial jump in January 2008. Conversely, as the tank in the USA stock's long-term equilibrium point remains consistently high because of the larger USA sales force, its relative amplification begins to rise. Since the two variables' relative amplification moves in opposite directions, eventually, they meet. What a coincidence! They meet above the USA sales force = 19 people. Now, is this not a much better interpretation of the word 'smooth' in fair response to JCK's smooth-switch performance purpose? The answer to JCK is now pertinent to its balancing its value chain in USA. With a USA sales force = 19, JCK's value chain components show equal relative amplification to sudden changes in demand, attaining nothing less than a magnificent amplification ratio = 1. Now that is smooth!

But what of profitability? JCK's polite executives said: "maximize… combined… NPV". In the time domain (Fig. 8b), total NPV(EBITDA) creates intricate dynamics that obscures the USA sales force effect. But the phase plot on Fig. 8c clearly shows a concave down behavior along the USA sales force: USA sales force = 19 maximizes the two plants' combined total NPV(EBITDA).

Future Directions

The above cases show how scenario-driven planning with system dynamics helps control performance by enabling organizational learning and the management of uncertainty. The strategic intelligence system that SdP with SD provides rests on the idea of a collective inquiry, which translates the environmental 'macrocosm' and a firm's



Scenario-Driven Planning with System Dynamics, Figure 8
Thirty computed scenarios show how hiring a sales force of 19 people in the USA might maximize JCK's NPV(EBITDA), and thereby fulfill its dual, smooth-switch and profitable purpose (adapted from [34])

'microcosm' into a shared causal map with computed scenarios. Informed discussion then takes place. Seeing SdP with SD as an inquiry system might help the outcomes of the situation formulation-solution-implementation sequence, each stage built on successive learning.

Strategic situations are complex and uncertain. Because planning is directed toward the future, predictions of changes in the environment are indispensable components of it. Conventional forecasting by itself provides no cohesive way of understanding the effect of changes that might occur in the future. Conversely, SdP with SD and its computed scenarios provide strategic intelligence and a link from traditional forecasting to modern interactive planning systems. In today's quest for managers who are more leaders than conciliators, the strategists' or executives' interest in scenarios must be welcomed. A clearer delineation of SdP with SD might make it a very rich field of application and research.

The SdP with SD inquiry system on Fig. 2 includes several contributions. *First*, by translating the environmental *macrocosm* and the firm *microcosm* into a common context for conceptualization, the requisites of theory building can be addressed. Planning analysts no longer have to operate piecemeal. A theory and a dominant logic typically emerge from shared perceptions about a firm, its environment and stakeholder purposes through model construction.

Second, the outputs of the strategic management process activities build on each other as successive layers. The SAST loop on Fig. 2 follows the counterclockwise direction of multiperspective dialectics [47]. This process allows adjustment of individual and organizational theories and logic, leading to an evolutionary interpretation of the real system that strategic decisions target.

Third, the inquiry system of Fig. 2 enables flexible support for all phases of strategy design. Problem finding or forming, or situation formulation receives equal attention as problem solving.

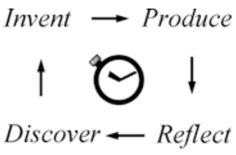
SdP with SD helps open up the black box of decision makers' mental models, so they can specify the ideas and rules they apply. That in turn helps enrich their language and label system, organizational capability and knowledge, and strategic decision processing system. Computed scenarios bring about transformation rules not previously thought of as well as new variables and interaction paths.

As an entity, each decision maker has a local scope and deals only with specific variables and access paths to other entities. But success factors are not etched in stone. Often, we only observe a representative state of each entity, namely, locally meaningful variables and parts of a scenario. This representativeness changes dynamically in the process of computing scenarios. Beyond the purely technical advantages of computed scenarios, planning becomes interactive, and language and label systems render themselves more adequate, effective and precise. Their associated organizational capability develops even more. In addition, the minor and major assumptions in decision makers' mental models surface as computed scenarios specify the conditions under which performance changes.

A line of great immediate concern requires researchers and practitioners alike to explore the modeling process behind SdP with SD. For the sake of realism, to make negotiated perceptions of reality explicit, we need representations where strategic real options and self-interest projections mold the way in which managers incorporate their observations and interpretations into strategy models. This is an unavoidable, most challenging path to tread, if we want to build a dialectical debate into the strategy design process.

Do we really want to? Yes because:

1. The traditional hierarchical organization dogma has been planning, managing and controlling, whereas the new reality of the learning organization incorporates vision, values and mental models. It entails training managers and teams in the IPRD learning cycle conceived by Dewey [14] (cf. Senge and Sterman [71]):



2. In the strategic management process (SMP) evolution, planning is evolving too, from objective-driven to budget-driven to strategy-driven to scenario-driven planning with system dynamics (SdP with SD, see pp. 271–272 in [32]).
3. The inquiry system that mediates the restructuring of organizational *theory in use* [68] determines the quality of organizational learning.

By looking into the dynamics of strategy design and the resulting performance of firms, the SdP with SD framework on Fig. 2 might let managers, planners and business researchers see the tremendous potential of computed strategic scenarios. They might choose to build intelligence systems around SdP with SD to create insight for strategy design. They will be building real knowledge in the process, while developing capability for institutional learning. Both Pascale [59] and de Geus [13] see the capability to speed up institutional learning as a truly sustainable competitive advantage.

Article Outline

Glossary

Bayesian analysis A model estimation technique that accounts for incomplete knowledge. Bayes' theorem is a mathematical formulation of how an a priori estimate of the probability of an event can be updated, if a new information becomes available.

Critical earthquake concept The occurrence of large earthquakes may be described in terms of statistical physics and thermodynamics. In this view, an earthquake can be interpreted as a critical phase transition in a system with many degrees of freedom. The preparatory process is characterized by acceleration of the seismic moment release and growth of the spatial correlation length as in the percolation model. This interpretation of earthquake occurrence is referred to as the critical earthquake process.

Earthquake forecast/prediction The forecast or prediction of an earthquake is a statement about time, hypocenter location, magnitude, and probability of occurrence of an individual future event within reasonable error ranges.

Fault model A fault model calculates the evolution of slip, stress, and related quantities on a fault segment or a fault region. The range of fault models varies from conceptual models of cellular automaton or slider-block type to detailed models for particular faults.

Probability A quantitative measure of the likelihood for an outcome of a random process. In the case of repeating a random experiment a large number of times (e. g. flipping a coin), the probability is the relative frequency of a possible outcome (e. g. head). A different view of probability is used in the → Bayesian analysis.

Seismic hazard The probability that a given magnitude (or peak ground acceleration) is exceeded in a seismic source zone within a pre-defined time interval, e. g. 50 years, is denoted as the seismic hazard.

Self-organized criticality
Self-organized criticality (SOC) as introduced by Bak [2] is the ability of a system to organize itself in

the vicinity of a critical point independently of values of physical parameters of the system and initial conditions. Self-organized critical systems are characterized by various power law distributions. Examples include models of sandpiles and forest-fires.

Definition of the Subject

The most fundamental question in earthquake science is whether earthquake prediction is possible. Related issues include the following: Can a prediction of earthquakes solely based on the emergence of seismicity patterns be reliable? In other words, is there a single or several "magic" parameters, which become anomalous prior to a large earthquake? Are pure observational methods without specific physical understanding, like the pattern recognition approach of Keilis–Borok and co-workers [41], sufficient? Taking into account that earthquakes are monitored continuously only for about 100 years and the best available data sets ("earthquake catalogs") cover only a few decades, it seems questionable to forecast earthquakes solely on the basis of observed seismicity patterns. This is because large earthquakes have recurrence periods of decades to centuries; consequently, data sets for most regions include less than ten large events making a reliable statistical testing questionable.

In the studies discussed here, the goal is not to forecast individual earthquakes. Instead, we aim at developing a combined approach based on numerical modeling and data analysis in order to understand seismicity and the emergence of patterns in the occurrence of earthquakes. The discussion and interpretation of seismcity in terms of statistical physics leads to the concept of "critical states", i. e. states in the seismic cycle with an increased probability for abrupt changes involving large earthquakes. A more general goal of this work is to provide perspectives for the understanding of the relevant mechanisms and to give outlines for developments related to time-dependent seismic hazard.

Introduction

Several empirical relationships for the occurrence of seismicity are well-known. The most common one is probably the Gutenberg–Richter law [30] for the relation between frequency and magnitude of earthquakes in a large seismically active region,

$$\log N = a - bM\,, \tag{1}$$

where N is the frequency of earthquakes with magnitude equal to or greater than M; a is a measure of the overall seismicity level in the region and the b value determines the relation between large and small earthquakes. The Gutenberg–Richter law provides an important constraint for the design of physical models and serves as a key ingredient for seismic hazard estimations. Statistical relations for the temporal occurrence of large events are less well known, because the corresponding data records are too short.

Several additional problems exist in the understanding and interpretation of observed seismicity patterns. First, it is important to decide whether an observed pattern has a physical origin or is an artifact, arising for example from inhomogeneous reporting or from man-made seismicity like quarry blasts or explosions [69]. Second, the non-artificial events have to be analyzed with respect to their underlying mechanisms. This leads to an inverse problem with a non-unique solution, which can be illustrated for the most pronounced observed temporal pattern associated with aftershocks. It is empirically known that the earthquake rate $\dot{N}$ after a large event at time t_{M} follows the Omori–Utsu law [49,67]

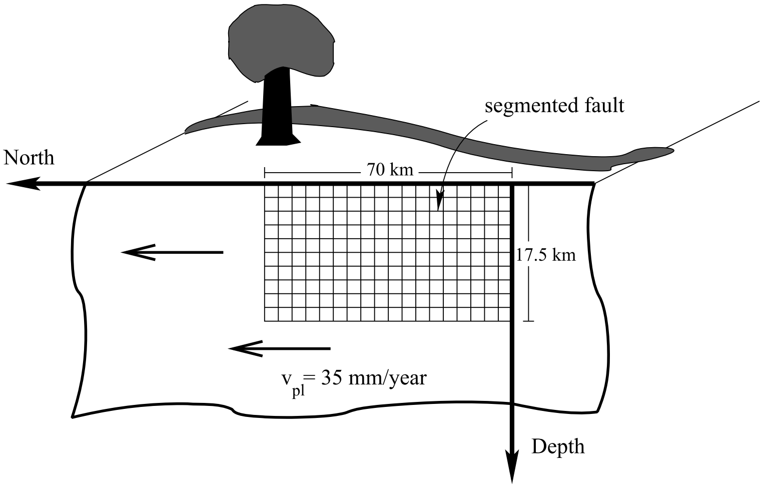
$$\dot{N} = \frac{K}{(c + t - t_{\mathrm{M}})^p}\,, \tag{2}$$

where t is the time, K and c are constants, and the Omori exponent p is close to unity. In particular, aftershocks are an almost universal phenomenon; that is, they are observed nearly after each mainshock. The underlying mechanisms leading to aftershocks are, however, unknown. Various physical models have been designed to explain aftershock occurrence following Eq. (2). These models include viscoelasticity [32], pore fluid flow [46], damage rheology [9,57], and rate-state friction [24]. The question which mechanism or combination of mechanisms is relevant in a given fault zone remains open. Detailed comparisons of observed and modeled seismicity with respect to the aftershock rate, the duration of aftershock sequences, the dependence on the mainshock size, and other features are necessary to address this problem. Additionally, results from lab experiments on rupture dynamics and satellite observations of deformation provide important information for the design of such models.

Apart from aftershock activity, other seismicity patterns are occasionally associated with observations, including foreshocks [39], seismic quiescence [34,72,78], and accelerating moment release [17,38]. These patterns have been documented in several cases before large earthquakes. They occur, however, far less frequently than aftershocks. For example, foreshocks are known to preceed only 20–30% of large earthquakes [71]. Therefore, their predictive power is questionable. Moreover, it is not clear whether these patterns can be attributed to physical processes or to random fluctuations in the highly sparse and noisy earthquake catalogs. This problem can be addressed by using fault models which simulate long and complete earthquake sequences over thousands of years. If the models capture the main features of the underlying physics, the occurrence of seismicity patterns can be studied with reasonable statistics. The main ingredients of such models are the geometry of a fault region, empirically known constitutive laws, spatial heterogeneities, and stress and displacement functions following dislocation theory [20,47]. In order to allow for detailed studies of the relations between the imposed mechanisms and the observed seismicity functions, it is important that the number of adjustable parameters is limited.

It is emphasized that these models do not aim to reproduce an observed earthquake catalog in detail. Instead, the main goal is to address questions like: Why is the Parkfield segment of the San Andreas fault characterized by relatively regular occurrence of earthquakes with magnitude $M \approx 6$, while on the San Jacinto fault in California the properties of earthquake occurrence are more irregular? Basic models for seismicity are mainly based on one or more solid blocks, which are driven by a plate over a sliding surface. The plate and the blocks are connected with springs. This model can generate stick-slip events considered to represent earthquakes. The slider-block models can produce a wide range of complexity, beginning with a single block model leading to periodic occurrence of events of uniform size, and progressing to an array of connected blocks [18] leading to complex sequences of events with variable size. In order to reduce the computational effort cellular automata are commonly used [42,48]. Mathematically, these models include maps instead of differential equations; physically, this corresponds to instantaneously occurring slip events, neglecting inertia effects. The main ingredients of slider-block and cellular automaton models are (1) external driving (plate motion), and (2) sudden local change of system parameters (stress), when a critical value (material strength) is reached, followed by an avalanche of block slips (stress drop and coseismic stress transfer during an earthquake). While the first process lasts for years to several hundred years, the second occurs on a time scale of a few seconds. The simplest model including these features has been formulated by Reid [52] and is known as *Reid's elastic rebound theory*; in terms of slider-block models, this corresponds to a single block model with constant plate velocity. Accounting for spatial heterogeneity and fault segmentation, many interacting blocks, or fault segments, have to be considered. This leads to a spatiotemporal stress field instead of a single stress value. In general, the material strength will also become space-dependent. Such a model framework can be treated with the methodology of statistical physics similar to the Ising model or percolation models [43]. In this context, large earthquakes are associated with second-order phase transitions [2,59,64]. The view of earthquakes as phase transitions in a system with many degrees of freedom and an underlying critical point, is hereinafter referred to as the "critical point concept". The period before such a phase transition is expected to be characterized by a preparation process including development of power laws and growing spatial correlation length [14]. However, depending on the parameters of a model, different situations are conceivable: the system trajectory can enter the critical state and the critical point frequently ("supercritical") or it may never becomes critical ("subcritical"). A case of special interest is the class of models [2] showing *self-organized criticality* (SOC), which have their origin in a simple cellular automaton model for a sandpile [3]. In this case the system drives itself permanently to the vicinity of the critical point with almost scale-free characteristics. Consequently, each small event can grow into a large earthquake with some probability [28].

Long simulations of earthquake activity can be used to calculate statistical features like the recurrence time distribution of large earthquakes and the frequency-size distribution with high precision. Despite the scaling behavior (Eq. (1)) in the earthquake magnitudes for small and intermediate earthquakes, which is observed for many sets of model parameters, clear deviations become visible for large magnitudes. Such deviations are known from real catalogs, but their statistical significance is not clear in all cases. The model simulations suggest that deviations from scaling for strong earthquakes can be attributed to physical properties. One important property is the spatial disorder of brittle parameters of the fault. The presence of strong heterogeneities suppresses system-wide events with some probability, whereas such events can evolve more easily on smooth faults. The degree of quenched (time-independent) spatial heterogeneity turns out to be a key parameter for statistical and dynamical properties of seismicity [5,12,80]. This includes the temporal regularity of mainshock occurrence, various properties of the stress and displacement fields, and a spontaneous mode-switching between different dynamical regimes without changing parameters. The degree of heterogeneity can act as a tuning parameter that allows for a continuous change of the model dynamics between the end-member cases of supercritical and subcritical behavior. Such a dependence, which is observed also for other parameters, can be visual-



Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 1
Sketch of the fault model framework

ized in phase diagrams similar to the phase diagram for the different aggregate states of water [22,79,80]. For increasing complexity of a model, the number of axes of the phase diagram, representing the relevant model parameters, will increase. The above mentioned question of distinguishing different faults like the Parkfield segment and the San Jacinto fault can be rephrased as the problem of assigning the faults to different regions in such a diagram. An important step in this direction is the physical modeling of observed seismicity patterns, including universal patterns like aftershocks (Eq. (2)), common fluctuations like foreshocks and the acceleration of seismic energy release before large earthquakes. The latter phenomenon which sometimes occurs over large regions including more than one fault, can be interpreted in terms of the approach towards a critical point. This view is supported by an observational study of the growth of the spatial correlation length which is a different aspect of the same underlying physics [73,75,76,77].

The establishment of relationships between model parameters and observational features may be used to tune the model towards a specific fault zone, and use the tuned fault model for practical applications of seismic hazard estimations. Toward this end the recurrence time distribution of large earthquakes is needed. Since observational data records are often short and noisy, the use of Bayesian probability theory is helpful for the estimation of uncertain model parameters, and the incorporation of various types of observational data in seismic hazard estimations. The Parkfield segment, as one of the best monitored seismically-active regions, serves as an excellent natural laboratory for such a case study. A discussed example illustrates how partially known parameters like the stress drop and the seismic hazard can be estimated by combining numerical models and observational data [74].

In Section “Modeling Seismicity in Real Fault Regions”, the physical fault model used for the discussed studies is described. Results from numerical simulations are presented in Sect. “Results”. A summary is given in Sect. “Summary and Conclusions”.

Modeling Seismicity in Real Fault Regions

Numerous frameworks have been used to simulate seismicity (see e. g. [6,9,10,18,32,37,48] and references therein). These include slider-block models, cellular automata, “inherently discrete” fault models where the discreteness is an inherent feature of the imposed physics, and continuum models. In this section we illustrate how a fault model (Fig. 1) can be adjusted in order to simulate seismicity of a real fault region, e. g. the Parkfield segment of the San Andreas fault in California.

Fault Geometry and Model Framework

A first constraint for a specific model is to represent the geometry of the fault segment. As shown in Fig. 2, the region of Parkfield is characterized by a distribution of fault segments, which have generally the same orientation. It is therefore reasonable to map these segments in the model on a plane intersecting the surface at a straight line from SE to NW. The dimensions of the fault segment for modeling (Fig. 1) are chosen to be 70 km in length and 17.5 km in depth. As discussed in [10], this geometry corresponds approximately to the San Andreas fault near Parkfield. The entire fault is an infinite half-plane, but the brittle processes are calculated on the above rectangular section referred to below as the computational grid. The computational grid is discretized to 128 × 32 cells of uniform size, where stress and slip are calculated. The size of the cells is not related here to observations; rather it depends on the magnitude range under consideration and the computational effort. The failure of a single cell defines the lowest magnitude. A higher resolution of the grid with same overall dimensions increases the magnitude range, because the magnitude is calculated from the slip of all cells during an earthquake. Following Ben–Zion and Rice [10], the material surrounding the fault is assumed to be a homogeneous elastic half space, which is characterized by elastic parameters and a related Green's function:

1. The elastic properties are expressed by the Lamé constants λ and μ, which connect stress and strain in Hooke's law. For many rocks, these constants are almost equal; therefore we use $\lambda = \mu$ with μ being the rigidity. An elastic solid with this property is called a *Poisson solid*. Because the strain is dimensionless, μ has the same dimension as the stress. In the present study, we use $\mu = 30\,\text{GPa}$.
2. The (static) Green's function $G(\vec{y}_1, \vec{y}_2)$ defines the static response of the half space at a position $\vec{y}_1$ to a displacement at $\vec{y}_2$, which may arise from (coseismic) slip or (aseismic) creep motion. Due to the discretization of the fault plane into computational cells, we use the Green's function for static dislocations on rectangular fault patches of width dx and height dz, which is given in [20] and [47]. The main difference between this Green's function and the nearest-neighbor interaction of most slider-block models and cellular automata is the infinite-range interaction following a decay according to $1/r^3$, where r is the distance between source cell and receiver point.

Interseismic Processes

The motion of the tectonic plates, indicated in Fig. 2, is responsible for the build-up of stress in the fault zone. Geodetic measurements of surface displacements provide estimates of the velocity of the plates. For the San Andreas fault, a value of $v_{\text{pl}} = 35\,\text{mm/year}$ as a long-term average [55] is widely accepted and is adopted for the model. The displacement du in the regions surrounding the grid during a time period Δt is simply $\mathrm{d}u = v_{\text{pl}} \cdot \Delta t$. While the average slip rate $\dot{u}$ is independent of the location of a cell, the stress rate $\dot{\tau}$ depends on space. The assumption that the computational grid is embedded in a half-plane which undergoes constant creep, implies that cells at the boundaries of the grid experience higher load than cells in the center of the grid. The Green's function $G(i, j; k, l)$ defines the interaction of points (i, j) and (k, l) in the medium. In particular, the stress response at a position (i, j) to a static change of the displacement field d$u(k, l)$ is given by

$$\mathrm{d}\tau(i, j) = - \sum_{(k,l)\in \text{half space}} G(i, j;\, k, l) \cdot \mathrm{d}u(k, l)\,, \qquad (3)$$

where the minus sign stems from the fact that forward (right-lateral) slip of regions around a locked fault segment is equivalent to back (left-lateral) slip of the locked fault segment. Taking into account that

$$\sum_{(k,l)\in \text{half space}} G(i, j;\, k, l) = 0\,, \qquad (4)$$

Eq. (3) can be written as

$$\tau(i, j;\, t) = - \sum_{(k,l)\in \text{half space}} G(i, j;\, k, l)\cdot[u(k, l;\, t) - v_{\text{pl}} t]\,, \qquad (5)$$

where $u(k, l;\, t)$ is the total displacement at position (k, l) and time t since the start of the simulation. Because the surrounding regions sustain stable sliding, $u(k, l;\, t) = v_{\text{pl}} t$ for $(k, l) \notin$ grid, the slip deficit outside the fault region vanishes and it is sufficient to perform the summation on the computational grid:

$$\tau(i, j;\, t) = \sum_{(k,l)\in \text{grid}} G(i, j;\, k, l)\cdot[v_{\text{pl}} t - u(k, l;\, t)]\,. \qquad (6)$$

Equation (6) can be decomposed to a part for the tectonic loading and a residual part for slip on the computational grid. The tectonic loading follows the formula

$$\tau_{\text{load}}(i, j;\, t) = \gamma(i, j) \cdot t \qquad (7)$$

with a space-dependent but time-independent loading rate

$$\gamma(i, j) = v_{\text{pl}} \cdot \sum_{(k,l)\in \text{grid}} G(i, j;\, k, l)\,. \qquad (8)$$

The build-up of stress may be reduced by aseismic creep motion, which is implemented by a local constitutive law corresponding to lab-based dislocation creep [5]:

$$\dot{u}_{\text{creep}}(i, j;\, t) = c(i, j) \cdot \tau^3(i, j;\, t) \qquad (9)$$

with space dependent but time-independent creep coefficients $c(i, j)$.

Friction and Coseismic Stress Transfer; Quasidynamic Approach

It is widely accepted that earthquakes on large faults are due to frictional processes on pre-existing structures. The friction is therefore an important empirical ingredient of a fault model [56]. Numerous laboratory experiments have been carried out to characterize frictional behavior of different materials (see e. g. [19]). An important finding is that the friction coefficient defined as the ratio of shear stress τ_{shear} and compressional normal stress τ_{normal}, $\mu_{\text{f}} = \tau_{\text{shear}}/\tau_{\text{normal}}$ at the initiation of slip is approximately constant for many materials; the value of μ_{f} lies between 0.6 and 0.85. This observation, known as *Byerlee's law*, is related to the Coulomb failure criterion [16] for the Coulomb stress *CS*,

$$CS = \tau_{\text{shear}} - \mu_{\text{f}}\tau_{\text{normal}} \,. \tag{10}$$

The Coulomb stress depends on a plane where shear stress and normal stress are calculated. Neglecting cohesion, the Coulomb criterion for brittle failure is

$$CS \geq \tau_0 \,, \tag{11}$$

which for $CS = 0$ is Byerlee's law.

The North-American plate and the Pacific plate move in opposite directions along the fault plane having strike-slip motion. The absence of normal and thrust faulting reduces the problem to a one-dimensional motion: all parts of the fault move along the fault direction. The stress state of the fault is fully determined by the shear stress τ_{xy} in the coordinates given in Fig. 2b. Slip is initiated if τ_{xy} exceeds $\mu_{\text{f}}\tau_{yy}$. This quantity, which is called the static strength τ_{s} is constant in time if μ_{f} is assumed to be constant. Note that the normal stress on a planar fault in a homogeneous solid does not change [1]. The shear stress τ_{xy} will be denoted simply by τ. In this notation, the failure criterion Eq. (11) reduces to

$$\tau \geq \tau_{\text{s}} \,. \tag{12}$$

When a cell (k, l) fails, the stress drops in this cell to the arrest stress τ_{a}:

$$\tau(k, l) \rightarrow \tau_{\text{a}} \,, \tag{13}$$

where the value τ_{a} maybe space-dependent. The stress change produces a corresponding slip

$$\text{d}u(k, l) = \frac{\tau(k, l) - \tau_{\text{a}}}{G(k, l\,;\, k, l)} \tag{14}$$

with the self-stiffness $G(k, l\,;\, k, l)$ of cell (k, l).

The observational effect of dynamic weakening includes also a strength drop from the static strength to a lower dynamic strength:

$$\tau_{\text{s}} \rightarrow \tau_{\text{d}} \,. \tag{15}$$

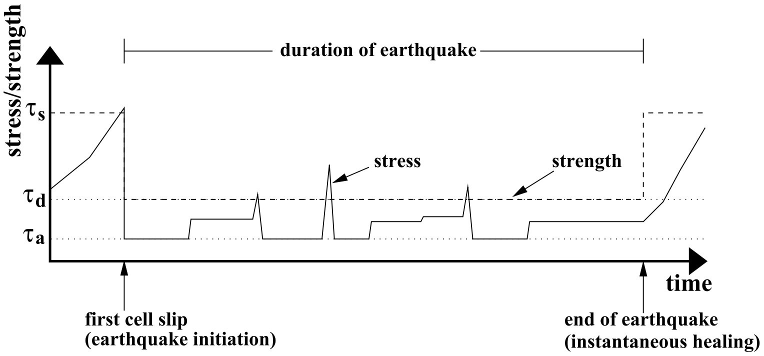
In particular, slipping material becomes weaker during rupture and recovers to the static level at the end of the rupture. This approximation of the strength evolution is known as static-kinetic friction.

The values τ_{s}, τ_{d}, and τ_{a} are connected by the dynamic overshoot coefficient D:

$$D = \frac{\tau_{\text{s}} - \tau_{\text{a}}}{\tau_{\text{s}} - \tau_{\text{d}}} \,, \tag{16}$$

or alternatively by the dynamic weakening coefficient ε:

$$\varepsilon = 1 - \frac{\tau_{\text{d}}}{\tau_{\text{s}}} \,. \tag{17}$$



Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 3
Pictorial evolution of stress (*solid line*) and strength (*dashed line*) of a hypocenter cell in the quasidynamic approach

Following [10] we use in most simulations $D = 1.25$.

The redistribution of the stress release $\Delta\tau(k,l) = \tau(k,l) - \tau_a$ from cell (k,l) to a point (i,j) at time t is

$$\mathrm{d}\tau(i,j;t) = G(i,j;k,l) \cdot \delta\left(t - \frac{r(i,j;k,l)}{v_s}\right) \cdot \frac{\Delta\tau(k,l)}{G(k,l;k,l)}, \tag{18}$$

where $\delta(x)$ denotes the δ-function, which is 1 for $x = 0$ and 0 else; v_s is the shear-wave velocity, and $r(i,j;k,l)$ is the distance between source cell (k,l) and receiver position (i,j). That is, regions far from the slipping cell receive their stress portion later than regions close to the slipping cell. The value of v_s is assumed to be constant. Each "stress transfer event" associated with Eq. (18) gives a transfer of a stress $\mathrm{d}\tau$ from a source cell (k,l) to a receiver cell (i,j) at time t. This time-dependent stress transfer is called the *quasidynamic* approach in contrast to the *quasistatic* approach used in most similar models.

The evolution of stress and strength in a failing cell is shown schematically in Fig. 3. When the slip is initiated, both the stress and the strength drop. Due to coseismic stress transfer during the event, the cell may slip several times before the earthquake is terminated and instantaneous healing takes place in all cells. The piecewise constant failure envelope (dashed line) indicates static-kinetic friction. A model version with gradual healing was employed by [79]. A review of analytical results associated with the basic model in the context of a large universality class is given in ▶ Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of.

We note that the Green's function leads to an infinite interaction range. Using open boundary conditions with respect to the computational grid, the stress release from a slipping cell is not conserved on the grid, but on the infinite half plane.

Data

The model produces two types of data, earthquake catalogs and histories of stress and displacement fields. As demonstrated below, all parameters of the model have physical dimensions and can therefore be compared directly with real data, where they are available. This is in contrast to most of the slider-block and cellular automaton models.

Earthquake catalogs include values of the earthquake time, hypocenter, and size. The time of an earthquake is the time of the first slip; the hypocenter is determined by the position of the corresponding cell along strike and depth. The size of an event can be described by different measures: The rupture area A is the total area, which slipped during an earthquake. The potency

$$P = \int u(A)\mathrm{d}A \tag{19}$$

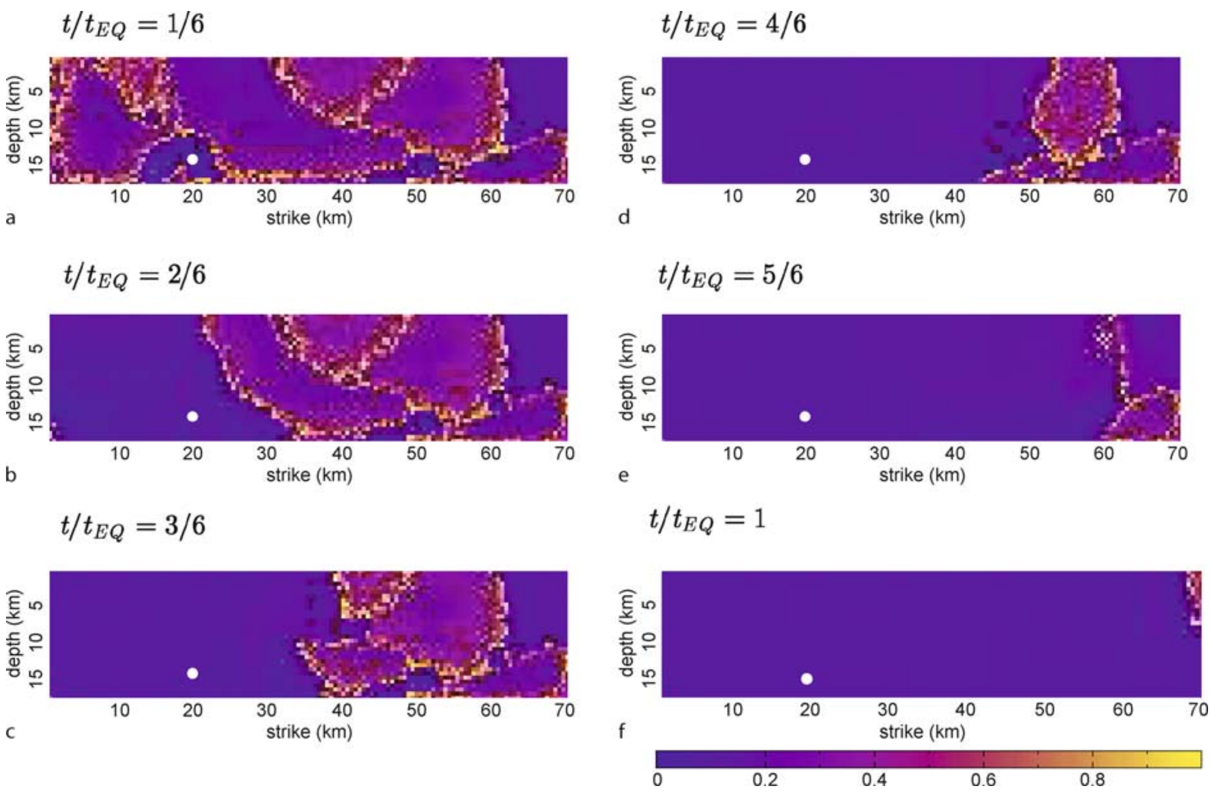
measures [7] the total slip during the event and is related to the seismic moment m_0 by the rigidity: $m_0 = \mu P$. The (moment) magnitude M can be calculated from the potency [10] using

$$M = (2/3)\log_{10}(P) + 3.6\,, \tag{20}$$

where P is given in $\mathrm{cm} \cdot \mathrm{km}^2$.

Results

Numerous simulations of the model described in the previous section have been performed. Firstly, simulations have been examined with respect to the spatiotemporal propagation of stress during single earthquakes ("rupture histories"). Then, long deformation histories have been



Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 4

Snapshots of rupture evolution for a system-wide event on a smooth fault without creep motion. *t* denotes the time after the rupture initiation (given in units of the total earthquake duration t_{EQ}). The white circle is the hypocenter of the event. The figure shows the dimensionless stress state $\hat{\tau} = \frac{\tau - \tau_a}{\tau_s - \tau_a}$ of the cells. a $t/t_{\mathrm{EQ}} = 1/6$; b $t/t_{\mathrm{EQ}} = 2/6$; c $t/t_{\mathrm{EQ}} = 3/6$; d $t/t_{\mathrm{EQ}} = 4/6$; e $t/t_{\mathrm{EQ}} = 5/6$; f $t/t_{\mathrm{EQ}} = 1$

simulated in order to search in a large fraction of the parameter space for relationships between input parameters and observed seismicity features. In this section, a selection of key results is presented and discussed in relation to critical states of seismicity.

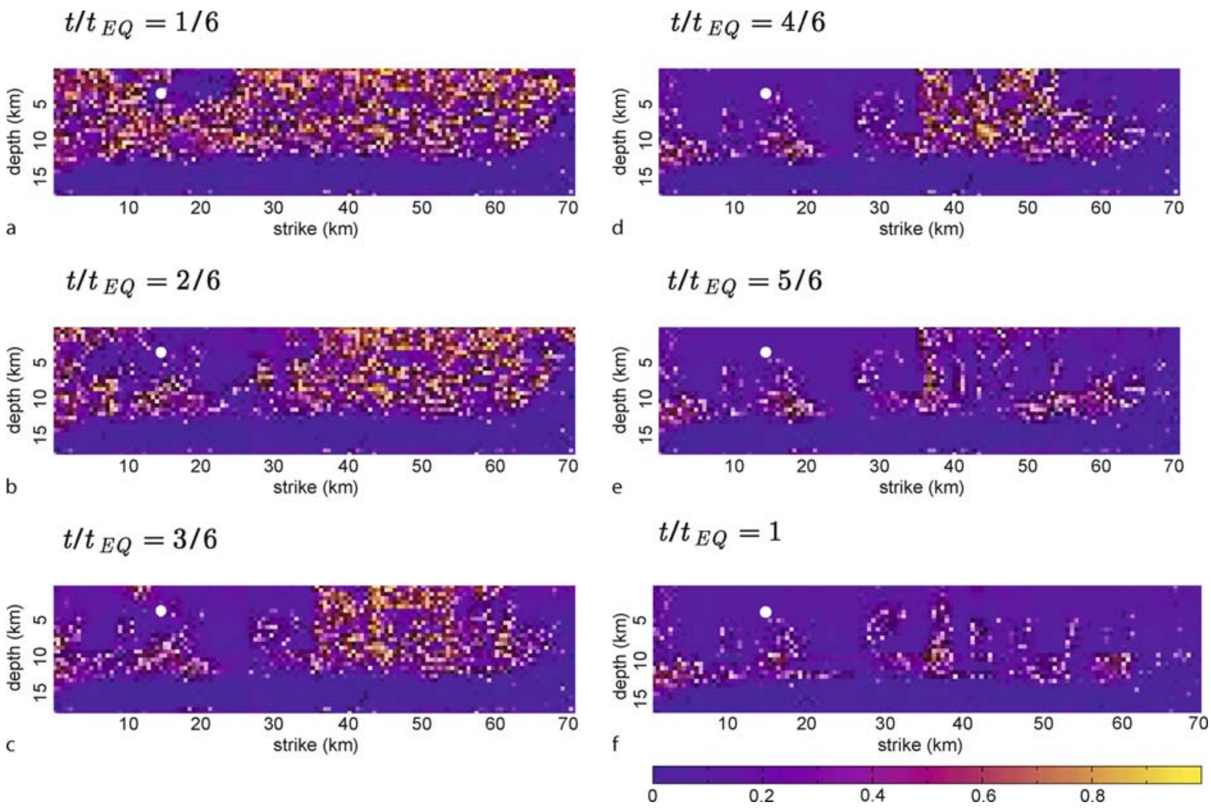
Rupture Histories

We compare qualitatively rupture histories of large earthquakes for three end-member cases in parameter space:

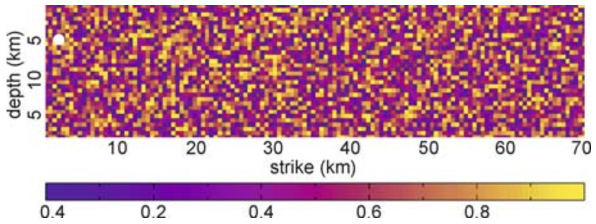
(1) a smooth fault,
(2) a rough fault, and
(3) a fault without dynamic weakening ($\tau_d = \tau_s$ or $D \to \infty$ in Eq. (16)).

Following [5], we vary the degree of quenched spatial disorder for a particular realization by introducing barriers of high stress drop $\tau_s - \tau_a$ in an environment of low stress drop.

The observation that smooth faults show a more regular earthquake occurrence than rough faults, can be explained by the ability of the stress field to synchronize on certain fault patches. On a disordered fault, this type of synchronization is unlikely. Figure 4a shows the stress field (normalized between 0 and 1) immediately before a large earthquake on a smooth fault. The most striking feature is the emergence of clearly defined patches with highly loaded boundaries. During rupture evolution, these patches rupture almost in series until the fault is nearly unloaded (see Fig. 4b–f). A different situation is shown in Fig. 5, corresponding to a rough fault with creep coefficients $c(i, j)$ (Eq. (9)) that increase with depth leading to a brittle-ductile transition zone as in [5] and [80]. Here the stress field in the brittle regime is irregular without obvious pattern formation. Similar behavior is found in a case where dynamic weakening is switched off ($D \to \infty$); in other words, the material heals instantaneously. Figure 6 shows the stress field in this case. In analytical studies, it has been shown that this corresponds exactly to a critical point in a phase diagram spanned by the stress dissipation and dynamic weakening [22,27]. Observational results indicate [68] that irregular slip histories and power



Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 5
Same as Fig. 4 for a strongly disordered fault with a brittle-ductile transition at about 15 km depth. a $t/t_{\text{EQ}} = 1/6$; b $t/t_{\text{EQ}} = 2/6$; c $t/t_{\text{EQ}} = 3/6$; d $t/t_{\text{EQ}} = 4/6$; e $t/t_{\text{EQ}} = 5/6$; f $t/t_{\text{EQ}} = 1$



Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 6
Same as Fig. 4a for a fault without dynamic weakening ($\tau_d = \tau_s$) corresponding to a dynamic overshoot coefficient $D \to \infty$ (Eq. (16))

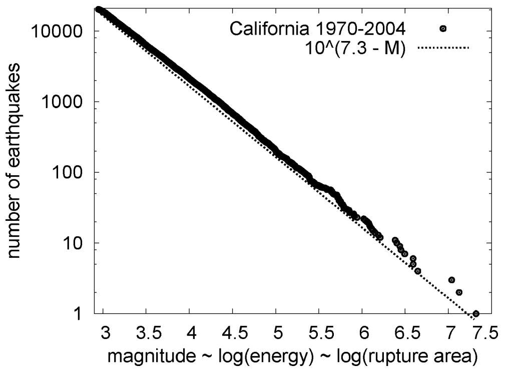
law frequency-size distributions are associated with geometrically disordered fault structures, while characteristic earthquake statistics and overall regular ruptures are found on mature fault with large total displacements.

Although the stress field shows a complex evolution during a simulation, the presence or absence of characteristic length scales indicating the relation to a critical point is easily detected. From an observational point of view, the stress field is not accessible. The evolution of the displacement field may be estimated, e. g. from seismic and geodetic data using slip inversion techniques. Because of the high uncertainties in the calculated slip histories, a quantitative comparison of the simulated data with "natural" data is questionable. However, general features of the quasidynamic ruptures are quite realistic, e. g. the irregular patterns in Fig. 5 resemble the rupture of the Chi–Chi (Taiwan) earthquake on September 21, 1999 ($M_w = 7.6$) [58].

Later we will show that the frequency-size distribution of earthquakes can serve to some extent as a proxy for the degree of disorder of the stress field. Ben-Zion et al. [12] discuss additional seismicity functions that may be used as surrogate variables for the stress.

Frequency–Size Distributions

The frequency-size (FS) distribution is one of the most important characteristics of observed seismicity. For world-



Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 7

Frequency-size distribution for California from 1970 to 2004; the dashed line denotes a power law fit to the data

wide seismicity, this distribution is given by the Gutenberg–Richter law (Eq. (1)). Figure 7 shows the FS distribution of California seismicity from 1970 to 2004. Here we use the non-cumulative version of Eq. (1), where N is the number of earthquakes with magnitude between M and $M + \mathrm{d}M$ with a magnitude bin $\mathrm{d}M = 0.1$.

For individual fault zones the FS distribution can deviate from Eq. (1), especially for high magnitudes. Examples are given in Fig. 8, which shows the FS distribution of the Parkfield segment (Fig. 8a) and for the San Jacinto fault (Fig. 8b) in California for a time span of 45 years. The distribution of the Parkfield segment consists of two parts: A scaling regime for $2.2 \leq M \leq 4.5$ and a "bump" for $4.5 < M \leq 6.0$. For the San Jacinto fault, the scaling range is observed for almost all events ($2.2 \leq M \leq 5.0$). The decrease for $M \approx 2$ in both plots is probably due to catalog incompleteness.

The FS distribution as shown in Fig. 8a is called the characteristic earthquake distribution, because of the increased probability for the occurrence of large ("characteristic") events compared to the prediction of the Gutenberg–Richter relation. The latter is an exponential distribution for the earthquake frequency as a function of magnitude, or a power law distribution for the earthquake frequency as a function of potency (Eqs. (19), (20)), moment, energy, or rupture area, over a broad range of magnitudes [66]. The Gutenberg–Richter relation is "scale-free" because a power law distribution indicates the absence of a characteristic scale of the earthquake size [64]. In terms of critical point processes, the absence of a characteristic length scale indicates that the system is close to the critical point. In this state, earthquakes of all magnitudes can occur, or each small rupture can grow into a large one. Therefore, the frequency-size distribution can serve as a proxy for the current state of a system in relation to a critical point.

The FS distribution in a model can be tuned by varying the mean stress $\langle\tau\rangle$ on the fault, where $\langle\rangle$ denotes the spatial average. This can be achieved, for instance, by varying brittle properties, e. g. in terms of the dynamic overshoot coefficient D (Eq. (16)), or by introducing dissipation [31,79]. Figure 9 shows FS distributions for two different values of $D : D = 5/4$ (Fig. 9a) and a higher value $D = 5/3$ (Fig. 9b). While Fig. 9a follows a characteristic earthquake behavior similar to the Parkfield case (Fig. 8a), Fig. 9b resembles the shape of the FS distribution of the San Jacinto fault (Fig. 8b).

As an outcome, three cases can be distinguished by means of a critical mean stress τ_{crit}:

1. subcritical fault ($\langle\tau\rangle < \tau_{\text{crit}}$): the mean stress on the fault is too small to produce large events. The system is always far from the critical point. The FS distribution is a truncated Gutenberg–Richter law.
2. supercritical fault ($\langle\tau\rangle > \tau_{\text{crit}}$): the mean stress is high and produces frequently large events. After a large earthquake (critical point), the stress level is low (system is far from the critical point) and recovers slowly (approaches the critical point). The FS distribution is a characteristic earthquake distribution.
3. critical fault ($\langle\tau\rangle \approx \tau_{\text{crit}}$): the system is always close to the critical point with scale-free characteristics. The FS distribution is a Gutenberg–Richter law with a scaling range over all magnitudes.

If the FS distribution is plotted as a function of the model parameters, the result can be visualized by a phase diagram [22,31,79,80]. An example is provided in Fig. 10, which shows schematically the phase diagram spanned by the degree of quenched spatial disorder and $1 - \varepsilon$ with the dynamic weakening coefficient ε (Eq. (17)). The phase diagram summarizes results from various studies, which demonstrate that the degree of spatial disorder of the stress drop acts as a tuning parameter for the FS distribution [5,36,80].

If the model is in the transition regime between Gutenberg–Richter statistics and characteristic earthquake behavior, the ability of the stress field to synchronize on parts of the fault can have additional impact on the dynamics of seismicity: for a model with small cells and high stress fluctuations along the cell boundaries arising from a high degree of spatial disorder, the system can undergo a spontaneous transition from an ordered state and characteristic behavior to a disordered state following Gutenberg–Richter statistics. Due to the high fluctuations in the

stress field, there is some probability that a certain number of cells synchronize by chance, leading to an ordered behavior for some seismic cycles, until the order is destroyed, again resulting from stress fluctuations. This type of mode-switching behavior has been observed earlier in a mean-field model and a damage rheology model [11,22]. Figure 11a gives a corresponding earthquake sequence with spontaneous mode-switching behavior. Figure 11b shows a sequence calculated with a higher grid resolution (128 × 50 cells). The tendency to mode-switching is less pronounced, but still visible. In [79] it is shown that the emergence of such mode-switching depends both on the spatial range of interaction (given as the decay of the Green's function) and the discretization of the computational grid. In the less realistic model of [22], where the stress redistribution is governed by a constant (space-independent) Green's function, analytical expressions for persistence times have been calculated [27]. In [11] some evidence for mode-switching behavior in long seismic

records based on paleoseismic and geologic data from the Dead Sea fault and other regions are discussed. However, the relevance of mode-switching to natural seismicity remains unclear due to the general lack of very long data records.

Aftershocks and Foreshocks

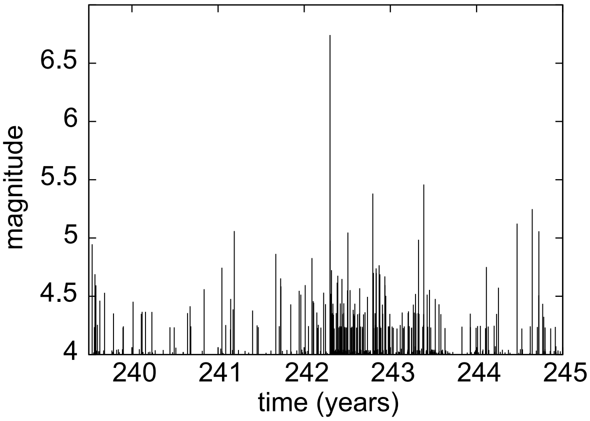
The most pronounced temporal pattern in observed seismicity is the emergence of strongly clustered aftershock activity following a large earthquake. Apart from the Omori–Utsu law (Eq. (2)), it is widely accepted that aftershocks are characterized by the following properties:

1. The aftershock rate scales with the mainshock size [51].
2. Aftershocks occur predominantly around the edges of the ruptured fault segments [66].
3. Båth's law [4]: The magnitude of the largest aftershock is usually about one unit smaller than the mainshock magnitude.

Deviations from the Omori–Utsu law, especially for rough faults, are discussed in [45]. While aftershocks are observed after almost all large earthquakes, foreshocks occur less frequent [71]. As a consequence, much less is known about the properties of these events. Kagan and Knopoff [40] and Jones and Molnar [39] propose a power law increase of activity according to an "inverse" Omori–Utsu law.

Figure 12a shows an example for the aftershock sequence following the *M*7.3 Landers earthquake in California on June 28, 1992. An earthquake of similar size generated by the model is given in Fig. 12b. The absence of aftershocks in the simulation is clearly visible. The reason for the lack of aftershocks is the unloading of the fault resulting from the mainshock: When a large fraction of the fault has ruptured, the stress in this region will be close to the arrest stress after the event. Consequently, the seismicity rate will be almost zero until the stress field has recovered to a moderate level.

Discussions for likely mechanisms of aftershocks are given in [9] and [81]. A common feature is the presence of rapid postseismic stress which generates aftershock activity. In [32], for instance, postseismic stress has been attributed to a viscoelastic relaxation process following the mainshock. In the work discussed here, continuous creep displacement following Eq. (9) is assumed. Additionally, the computational grid is divided by aseismic barriers from the free surface to depth into several seismically active fault segments. As shown in [81], this modification results in a concentration of stress in the aseismic regions during rupture and, subsequently in a release of stress after the event according to the coupled creep process. This stress release triggers aftershock sequences obeying the Omori–Utsu law (Eq. (2)). A typical aftershock sequence after a $M6.8$ event is shown in Fig. 13. In agreement with Båth's law, the strongest aftershock has the magnitude $M = 5.5$ in this sequence. The sequence shows also the effect of secondary aftershocks, namely aftershocks of aftershocks [61]. The stacked earthquake rate as a function of the time after the mainshock is given in Fig. 14. In this case, where the barriers are characterized by creep coefficients higher by a factor of 10^5 than in the other patches, a realistic Omori exponent of $p = 1$ is found.



Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 13
Earthquakes before and after a mainshock with $M = 6.8$ in the modified model

Aftershock sequences like in Fig. 13 emerge after all large events in the extended model. In contrast, there is generally no clear foreshock signal visible in single sequences. However, stacking many sequences together unveils a slight increase of the earthquakes rate prior to a mainshock supporting the observation of accelerating foreshock activity. An explanation of these events can be given in the following way: Between two mainshocks the stress field organizes itself towards a critical state, where the next large earthquake can occur. This critical state is characterized by a disordered stress field and the absence of a typical length scale, where earthquakes of all sizes can occur [12]. The mainshock may occur immediately or after some small to moderate events. The latter case can be considered as a single earthquake, which is interrupted in the beginning. This phenomenon of delayed rupture propagation has also provided a successful explanation of foreshocks and aftershocks in a cellular automaton model [33,35].

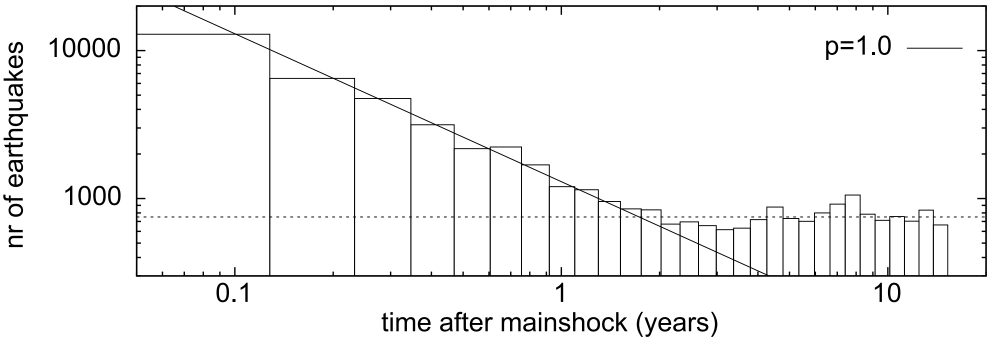
The hypothesis that foreshocks occur in the critical point and belong, in principle, to the mainshock, can be verified by means of the findings from Subsect. "Frequency–Size Distributions". In particular, the frequency-size distribution in the critical point (or close to the critical point) is expected to show scale-free statistics. If an overall smooth fault model following characteristic earthquake statistics is studied over a long time period, the approach of the critical point should be seen in terms of a change of the frequency-size distribution towards Gutenberg–Richter behavior [12]. This change of frequency-size statistics is indeed observed in the model (Fig. 15) and supports the validity of the critical point concept [82].

Accelerating Moment Release

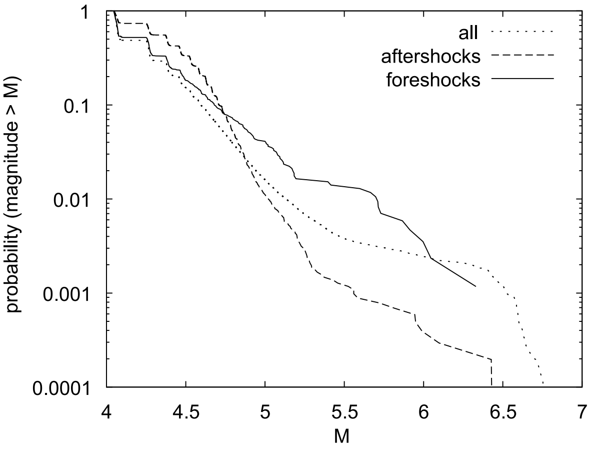
In the previous section, it has been argued that large earthquakes are associated with a critical point and the preparation process is characterized by increasing disorder of the stress field and increasing tendency for scale-free characteristics in the frequency-size distribution. Further support for critical point dynamics has been provided by the observational finding of [17] that the cumulative Benioff strain $\Sigma\Omega(t)$ follows a power law time-to-failure relation prior to the $M7.1$ Loma Prieta earthquake on October 17, 1989:

$$\Sigma\Omega(t) = \sum_{i=1}^{N(t)} \sqrt{E_i} = A - B(t_\mathrm{f} - t)^m \qquad (21)$$

Here, E_i is the energy release of earthquake i, $N(t)$ is the number of earthquakes before time t; t_f is the failure time



Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 14
Earthquake rate as a function of time for the model with seismic and aseismic regions. The calculation is based on a simulation with 200,000 earthquakes covering about 5000 years; the earthquake rates are averaged over about 300 mainshocks. A fit of the Omori–Utsu law (Eq. (2)) with $p = 1$ is denoted as a solid line. The dashed line gives the estimated background level of seismicity



Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 15

Mean potency release (Eq. (19)) as a function of the stress level. The stress level is normalized to the maximum (max) and minimum (min) observed stress

and A, B, and $m > 0$ are constants. Similar studies for numerous seismically active regions followed (see [8,77] and references therein).

The time-to-failure relation Eq. (21) has been explained by [54] and [60] from the viewpoint of renormalization theory and by [8] and [65] in terms of damage rheology. Similar to the findings about foreshocks, the time-to-failure pattern is not universal. Therefore, a stacking procedure is adopted in order to obtain robust results on the validity of Eq. (21) in the model. This is not straightforward, since the interval of accelerating moment release is not known a priori and the duration of a whole seismic cycle, as an upper limit, is not constant. To normalize the time interval for the stacking, the potency release (Eq. (19)) is computed as a function of the (normalized) stress level (Fig. 16). Taking into account that the stress level increases almost linearly during a large fraction of the seismic cycle, the stress level axis in Fig. 16 can effectively be replaced by the time axis leading to a power law dependence of the potency release on time. The best fit is provided with an exponent $s = -1.5$. Transforming the potency release to the cumulative Benioff strain (Eq. (21)), results in an exponent $m = 0.25$ in Eq. (21). This finding is based on a simulation over 5000 years; the exponent is in good agreement with the theoretical work [53], that derives $m = 0.25$ for a spinodal model, and the analytical result of $m = 0.3$ in the damage mechanics model [8]. An observational study of California seismicity finds m between 0.1 and 0.55 [15].

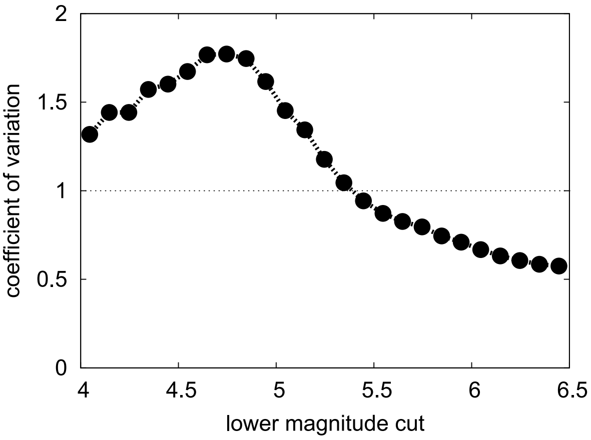
The normalized interevent time distribution of the model simulations (black dots) compared with the result of [21] and the distribution of earthquakes in California (ANSS catalog of $M \geq 3$ earthquakes occurred between 1970 and 2004 within 29° and 43° latitude and −113° and −123° longitude)



Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 18
The temporal earthquake occurrence quantified by the coefficient of variation as a function of the lower magnitude cutoff. Values larger than 1 indicate clustering, whereas lower values point to quasiperiodic behavior

Interevent Times

In recent studies it has been shown that the distribution of interevent times can be described by a universal law. In particular, the distributions from different tectonic environments, different spatial scales (from worldwide to local seismicity) and different magnitude ranges collapse if the time Δt is rescaled with the rate R_{xy} of seismic occurrence in a region denoted by (x, y) [21]. Such rescaling leads to

$$D_{xy}(\Delta t) = R_{xy} \cdot f(R_{xy}\Delta t) , \tag{22}$$

where D_{xy} is the probability density for the interevent time Δt, and f can be expressed by a generalized gamma distribution

$$f(\theta) = C\frac{1}{\theta^{\gamma-1}} \exp\left(-\frac{\theta^{\delta}}{B}\right) . \tag{23}$$

The parameters C, γ, δ, and B have been determined by a fit to several observational catalogs [21].

In Fig. 17 we compare $D_{xy}(\Delta t)$ from Eq. (22) with two earthquake catalogs: (1) The ANSS catalog of California (catalog ranges are given in the caption), and (2) the model catalog. Due to the universality of Eq. (22) with respect to different spatial scales, the comparison of the model simulating a single fault of 70 km length with a region of hundreds of kilometers including several faults in California does not require coarse graining the ANSS catalog. In the region where the interevent times are calculated, we find a remarkable agreement of the three curves. For small values of Δt, Eq. (22) deviates from the California data; for high values the model has a slightly better correspondence with the observational data than Eq. (22). Thus the results generally support the recent findings of [21].

The degree of temporal clustering of earthquakes can be estimated by the coefficient of variation CV of the interevent time distribution.

$$CV = \sigma/\mu , \tag{24}$$

where σ is the standard deviation and μ the mean value of the interevent time distribution. Values of $CV > 1$ denote clustered activity, while $CV < 1$ represents quasiperiodic occurrence of events. The case $CV = 1$ corresponds to a random Poisson process. The studies of [5] and [80] have found that the clustering properties of the large events depend on the degree of quenched spatial disorder of the fault. Figure 18 shows that CV as a function of the lower magnitude cutoff has a characteristic shape. The values of CV are higher than 1 (clustered) for small and intermediate earthquakes ($M \leq 5.4$) and smaller than 1 (quasiperiodic) for larger earthquakes. This corresponds to the case of a low degree of disorder in [80], because the brittle cells which participate in an earthquake have no significant spatial disorder. We note that this behavior resembles the seismicity on the Parkfield segment of the San Andreas fault, which is characterized by a quasiperiodic occurrence of mainshocks. Based on the analysis of 37 earthquake sequences, an estimation of $CV \approx 0.5$ has been found for multiple tectonic environments [26].

A different behavior is observed on the San Jacinto fault in California, where the largest events occur less regularly and have overall smaller magnitudes. As discussed in [5] and [80], this can be modeled by imposing higher degrees of disorder leading to a broader range of spatial size scales, e. g. by using a higher number of near-vertical barriers. While barriers provide a simple and physically motivated way to tune the degree of disorder, other types of heterogeneities may work as well, as long as they are able to produce strong enough fluctuations of the stress field. As an example, we mention fractal distributions of the stress drop, which can be tuned easily by changing the fractal dimension [63,80].

Recurrence Times of Large Earthquakes

While interevent times are waiting times between successive earthquakes in a given catalog, recurrence times are defined as waiting times between two successive *large* events, typically in the magnitude range $6 \leq M \leq 9$, depending on the region. For example, on the Parkfield segment of the San Andreas fault seven $\sim M6$ earthquakes occurred between 1857 and 2004 with recurrence times $T_1 = 24$ years, $T_2 = 20$ years, $T_3 = 21$ years, $T_4 = 12$ years, $T_5 = 32$ years, and $T_6 = 38$ years.

The distribution of recurrence times of large earthquakes is crucial for the calculation of seismic hazard. Due to a lack of observational data, this distribution is unknown for real fault systems. Commonly used distributions are based on extreme value statistics and on models for catastrophic failure. These include the lognormal distribution [50], the Brownian passage time distribution [44], and the Gumbel distribution [29]. All distributions are characterized by a maximum for a certain recurrence time followed by an asymptotic decay. The Brownian passage time distribution and the lognormal distribution have been used by the Working Group on California Earthquake Probabilities [70], e. g. for calculating earthquake probabilities in the San Francisco Bay area.

Figure 19a shows the probability density function (pdf) of the recurrence times of earthquakes with magnitude $M > 6.2$ in a realization of the numerical model for the Parkfield region [74]. Since we focus on long time-scales, we use here a minimal model without aseismic creep and strong spatial heterogeneities. This model leads to characteristic earthquake statistics and quasiperiodic occurrence of large events, and can therefore serve as a model framework for large earthquakes on the Parkfield segment. However, quantities which are only poorly known from empirical data, e. g. the stress drop, have to be chosen in order to perform a numerical simulation. Starting with an imposed uniform a priori distribution $P(\Delta\tau)$ of stress drops between a lower bound $\Delta\tau_{\min}$ and an upper bound $\Delta\tau_{\max}$, an a posteriori distribution $P(\Delta\tau|T_1,\ldots,T_N)$ can be estimated using observational recurrence times $T_1,\ldots,T_N$ from Parkfield and Bayes' theorem [13],

$$P(\Delta\tau|T_1,\ldots,T_N) = \frac{P(T_1,\ldots,T_N|\Delta\tau)P(\Delta\tau)}{\sum\limits_{s=\Delta\tau_{\min}}^{\Delta\tau_{\max}} P(T_1,\ldots,T_N|s)P(s)}\,, \tag{25}$$

with the likelihood function

$$P(T_1,\ldots,T_N|\Delta\tau) = \prod_{i=1}^{N} f(T_i|\Delta\tau)\,. \tag{26}$$

The function $f(T_i|\Delta\tau)$ denotes the pdf of recurrence times simulated with a model stress drop $\Delta\tau$. To get an analytic expression of this function, it is fitted by a Gamma distribution $f(t) = \beta^{-1}(\Gamma(\gamma))^{-1}(\frac{t-\mu}{\beta})^{\gamma-1}\exp(-\frac{t-\mu}{\beta})$ with the location parameter μ, the shape parameter $\gamma \equiv 2.0$ and the scale parameter β (with $x \geq \mu\,;\ \gamma,\beta > 0$). For an example see Fig. 19a. In [74] it is shown that the mean value μ_t and the standard deviation σ_t of the fits in this model are related to the average stress drop of a large earthquake $\Delta\tau$ by the simple empirical relations

$$\begin{aligned} \mu_t(\Delta\tau) &= 9.7\cdot\Delta\tau \\ \sigma_t(\Delta\tau) &= 1.8\cdot\Delta\tau^2 - 6.8\cdot\Delta\tau + 11.7 \end{aligned} \tag{27}$$

with $\mu_t\,,\sigma_t$ in years and $\Delta\tau$ in MPa. Using this approximation in combination with six observational recurrence times from $\sim M6$ earthquakes on the Parkfield segment, we find the a posteriori distribution of stress drops shown in Fig. 19b. The position where this distribution reaches the maximum, $\Delta\tau = (3.04 \pm 0.27)$ MPa, is the most representative value of the stress drop of $\sim M6$ Parkfield events.

The cumulative probability density function (cdf) of recurrence times based on Eq. (26) and the observational data can now be calculated by

$$C(t) = \int_0^t \int_{\Delta\tau_{\min}}^{\Delta\tau_{\max}} f(t'|\Delta\tau)P(\Delta\tau|T_1,\ldots,T_N)\mathrm{d}\Delta\tau\,\mathrm{d}t'\,. \tag{28}$$

The hazard function

$$H(\Delta t|t_0) = \frac{C(t_0+\Delta t) - C(t_0)}{1 - C(t_0)} \tag{29}$$

is the conditional probability that the next large earthquake occurs in the interval $[t_0\,;\ t_0+\Delta t]$ given the time t_0 since the last large event. Results for two choices of observational data (corresponding to two different observa-

tional periods) in comparison to the Parkfield cdf are given in Fig. 20a. The hazard function for three fixed values of t_0 and varying Δt is given in Fig 20b.

This approach enables us to calculate the most likely occurrence time of the next (post 2004) Parkfield earthquake by picking the maximum of the (non-cumulative) recurrence time distribution (inner integral in Eq. (28)) after taking all Parkfield earthquakes (1857–2004) into account. Based on the analysis done so far, we may forecast the next $\sim M6$ Parkfield earthquake to occur in May 2027. The error associated with one standard deviation of the pdf is 7.7 years. We note, however, that the probability for the occurrence of a $\sim M6$ earthquake between May 2026 and May 2028 is only about 14%.

Summary and Conclusions

The present review deals with the analysis, the understanding and the interpretation of seismicity patterns with a special focus on the critical point concept for large earthquakes. Both physical modeling and data analysis are discussed. This study aims at practical applications to model data from real fault zones. A point of particular interest is the detection of phenomena prior to large earthquakes and their relevance for a possible prediction of these events. Despite numerous reports on anomalous precursory seismicity changes [62], there is no precursor in sight which obeys a degree of universality that would make it practically useful. It is, therefore, important to study less frequent precursory phenomena by means of long model simulations.

Toward this goal, we discuss a numerical model which is on one hand reasonably physical, and on the other hand simple enough that it allows to obtain some analytical results and perform long simulations. The basic version of the model consists of a segmented two-dimensional strike-slip fault in a three-dimensional elastic half space and is inherently discrete because of the abrupt transition from static to kinetic friction [10]. This paper and ► Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of summarize a large body of analytical and numerical results associated with the model.

The results of the simulations indicate an overall good agreement of the synthetic seismicity with natural earthquake activity, with respect to frequency-size distributions and various features of earthquake sequences. The degree of spatial heterogeneity on the fault, which is implemented by means of space-dependent rheological properties, has important effects on the resulting catalogs. Smooth faults are associated with the characteristic earthquake statistics, regular occurrence of mainshocks and overall smooth stress fields. On the other hand, rough faults generate scale-free Gutenberg–Richter statistics, irregular mainshock occurrence, and overall rough stress fields. A closer look at the disorder of the stress field shows, however, that even on a smooth fault a gradual roughening takes place when the next large earthquake is approached [12,82]. This is reflected in the frequency-size distribution which evolves towards the Gutenberg–Richter law and other changes of seismicity. The results can be used to establish relations between the proximity of a state on a fault to a critical point, the (unobservable) stress field, and the (observable) seismicity functions. Furthermore, it is demonstrated that the concept of "self-organized criticality" can be folded back to criticality associated with tuning parameters [12,31]. We note that phase diagrams with different dynamic regimes as functions of tuning parameters, in addition to criticality, provide a general and rich description of seismicity. Accelerating seismic release, growing spatial correlation length, changes of frequency-size statistics and evolution of other seismicity parameters may be used to track the approach to criticality [73,75,76,77].

Future Directions

We have demonstrated that numerical fault models are valuable for understanding the underlying mechanisms of observed seismicity patterns, as well as for practical estimates of future seismic hazard. The latter requires model realizations that are tuned to a specific fault zone by assimilating available observational results and their uncertainties. In a case study, the seismic hazard in the Parkfield region has been estimated by combining such a tuned model with few observational data. The use of Bayesian analysis allows us to construct a flexible hazard model for this region which can, in general, incorporate statistical and non-statistical data (e. g. from paleoseismology and geodesy) to improve and update the estimations of the seismic hazard. This approach is particularly promising for less-well monitored regions, and especially for low-seismicity regions like those in central Europe.

Modification of the stress transfer calculations to account for a statistical preference of earthquake propagation direction on a given fault section, e. g. [6,25], can improve the estimates of seismic hazard associated with large faults. It is also possible to extend the discussed framework to other geohazards with even smaller amount of observational data, e. g. the occurrence of landslides. Since the fault model deals with coupled physical processes leading to interacting earthquakes, a challenging future direction will be the design of a more general model for interacting geohazards including earthquakes on different faults as well as landslides triggered by earthquakes, and perhaps tsunamis initiated by (submarine) earthquakes or landslides.

Glossary

Chaos Chaos occurs in dynamical systems with two ingredients: (i) nonlinear recurrent re-injection of the dynamics into a finite domain in phase space and (ii) exponential sensitivity of the trajectories in phase space to initial conditions.

Continuous phase transitions If there is a finite discontinuity in the first derivative of the thermodynamic potential, then the phase transition is termed first-order. During such a transition, a system either absorbs or releases a fixed amount of latent heat (e. g. the freezing/melting of water/ice). If the first derivative is continuous but higher derivatives are discontinuous or infinite, then the phase transition is called continuous, of the second kind, or critical. Examples include the critical point of the liquid–gas transition, the Curie point of the ferromagnetic transition, or the superfluid transition [127,235].

Critical exponents Near the critical point, various thermodynamic quantities diverge as power laws with associated critical exponents. In equilibrium systems, there are scaling relations that connect some of the critical exponents of different thermodynamic quantities [32,127,203,216,235].

Critical phenomena Phenomena observed in systems that undergo a continuous phase transition. They are characterized by scale invariance: the statistical properties of a system at one scale are related to those at another scale only through the ratio of the two scales and not through any one of the two scales individually. The scale invariance is a result of fluctuations and correlations at all scales, which prevents the system from being separable in the large scale limit at the critical point [32,203,235].

Declustering In studies of seismicity, declustering traditionally refers to the deterministic identification of fore-, main- and aftershocks in sequences (or clusters) of earthquakes clustered in time and space. Recent, more sophisticated techniques, e. g. stochastic declustering, assign to earthquakes probabilities of being triggered or spontaneous.

Dynamical scaling and exponents Non-equilibrium critical phase transitions are also characterized by scale invariance, scaling functions and critical exponents. Furthermore, some evidence supports the claim that universality classes also exist for non-equilibrium phase transitions (e. g. the directed percolation and the Manna universality class in sandpile models), although a complete classification of classes is lacking and may in fact not exist at all. Much interest has recently focused on directed percolation, which, as the most common universality class of absorbing state phase transitions, is expected to occur in many physical, chemical and biological systems [85,135,203].

Finite size scaling If a thermodynamic or other quantity is investigated at the critical point under a change of the system size, the scaling behavior of the quantity with respect to the system size is known as finite size scaling [32]. The quantity may refer to a thermodynamic quantity such as the free energy or it may refer to an entire probability distribution function. At criticality, the sole length scale in a finite system is the upper cut-off s_c, which diverges in the thermodynamic limit $L \to \infty$. Assuming a lower cut-off $s_0 \ll s_c, s$, a finite size scaling ansatz for the distribution $P(s; s_c)$ of the observable variable s, which depends on the upper cut-off s_c is then given by:

$$P(s; s_c) = a s^{-\tau} G(s/s_c) \quad \text{for} \quad s, s_c \gg s_0 \,, \tag{1}$$

where the parameter a is a non-universal metric factor, τ is a universal (critical) exponent, and G is a universal scaling function that decays sufficiently fast for $s \gg s_c$ [32,36]. Pruessner [163] provides a simple yet instructive and concise introduction to scaling theory and how to find associated exponents. System-specific corrections appear to sub-leading order.

Fractal A deterministic or stochastic mathematical object that is defined by its exact or statistical self-similarity at all scales. Informally, it often refers to a rough or fragmented geometrical shape which can be subdivided into parts which look approximately the same as the original shape. A fractal is too irregular to be described by Euclidean geometry and has a fractal dimension that is larger than its topological dimension but less than the dimension of the space it occupies.

Mean-Field An effective or average interaction field designed to approximately replace the interactions from many bodies by one effective interaction which is constant in time and space, neglecting fluctuations.

Mechanisms for power laws Power laws may be the hallmark of critical phenomena, but there are a host of other mechanisms that can lead to power laws (see Chapter 14 of [203] for a list of power law mechanisms as well as [37,143]). Observations of scale invariant statistics therefore do not necessarily imply SOC, of course. Power laws express the existence of a symmetry (scale invariance) and there are many mechanisms by which a symmetry can be obtained or restored.

Non-equilibrium phase transitions In contrast to systems at equilibrium, non-equilibrium phase transitions involve dynamics, energy input and dissipation. Detailed balance is violated and no known equivalent of the partition function exists, from which all thermodynamic quantities of interest derive in equilibrium. Examples of non-equilibrium phase transitions include absorbing state phase transitions, reaction-diffusion models, and morphological transitions of growing surfaces [85,135].

Phase transitions In (equilibrium) statistical mechanics, a phase transition occurs when there is a singularity in the free energy or one of its derivatives. Examples include the freezing of water, the transition from ferromagnetic to paramagnetic behavior in magnets, and the transition from a normal conductor to a superconductor [127,235].

Renormalization group theory A mathematical theory built on the idea that the critical point can be mapped onto a fixed point of a suitably chosen transformation on the system's Hamiltonian. It provides a foundation for understanding scaling and universality and provides tools for calculating exponents and scaling functions. Renormalization group theory provides the basis for our understanding of critical phenomena [32,216,235]. It has been extended to non-Hamiltonian systems and provides a general framework for constructing theories of the macro-world from the microscopic description.

Self-organized criticality (SOC) Despite two decades of research since its inception by [13] and the ambitious claim by [11] that, as a mechanism for the ubiquitous power laws in Nature, SOC was "How Nature Works", a commonly accepted definition along with necessary and sufficient conditions for SOC is still lacking [93,163,203]. A less rigorous definition may be the following: Self-organized criticality refers to a non-equilibrium, critical and marginally stable steady-state, which is attained spontaneously and without (explicit) tuning of parameters. It is characterized by power law event distributions and fractal geometry (in some cases) and may be expected in slowly driven, interaction-dominated threshold systems [93]. Some authors additionally require that temporal and/or spatial correlations decay algebraically (e. g. [84], but see [163]). Definitions in the literature range from broad (simply the absence of characteristic length scales in non-equilibrium systems) to narrow (the criticality is due to an underlying continuous phase transition with all of its expected properties) (see, e. g., [162] for evidence that precipitation is an instance of the latter definition of SOC in which a non-linear feedback of the order parameter on the control parameter turns a critical phase transition into a self-organized one attracting the dynamics [198]).

Spinodal decomposition In contrast to the slow process of phase separation via nucleation and slow growth of a new phase in a material inside the metasstable region near a first-order phase transition, spinodal decomposition is a non-equilibrium, rapid and critical-like dynamical process of phase separation that occurs quickly and throughout the material. It needs to be induced by rapidly quenching the material to reach a sub-area (sometimes a line) of the unstable region of the phase diagram which is characterized by a negative derivative of the free energy.

Statistical physics is the set of concepts and mathematical techniques allowing one to derive the large-scale laws of a physical system from the specification of the relevant microscopic elements and of their interactions.

Turbulence In fluid mechanics, turbulence refers to a regime in which the dynamics of the flow involves many interacting degrees of freedom, and is very complex with intermittent velocity bursts leading to anomalous scaling laws describing the energy transfer from injection at large scales to dissipation at small scales.

Universality In systems with little or no frozen disorder, equilibrium continuous phase transitions fall into a small set of universality classes that are characterized by the same critical exponents and by certain scaling functions that become identical near the critical point. The class depends only on the dimension of the space and the dimension of the order parameter. For instance, the critical point of the liquid–gas transition falls into the same universality class as the 3D Ising model. Even some phase transitions occurring in high-energy physics are expected to belong to the Ising class. Universality justifies the development and study of extremely simplified models (caricatures) of Nature, since the behavior of the system at the critical point can nevertheless be captured (in some cases exactly). However, non-universal features remain even at the critical point but are less important, e. g. amplitudes of fluctuations or system-specific corrections to scaling that appear at sub-leading order [32,216,235,239].

Definition of the Subject

A fundamental challenge in many scientific disciplines concerns upscaling, that is, of determining the regularities and laws of evolution at some large scale from those known at a lower scale: biology (from molecules to cells, from cells to organs); neurobiology (from neurons to brain function), psychology (from brain to emotions, from evolution to understanding), ecology (from species to the global web of ecological interactions), condensed matter physics (from atoms and molecules to organized phases such as solid, liquid, gas, and intermediate structures), social sciences (from individual humans to social groups and to society), economics (from producers and consumers to the whole economy), finance (from investors to the global financial markets), Internet (from e-pages to the world wide web 2.0), semantics (from letters and words to sentences and meaning), and so on. Earthquake physics is no exception, with the challenge of understanding the transition from the laboratory scale (or even the microscopic and atomic scale) to the scale of fault networks and large earthquakes.

Statistical physics has had a remarkably successful track record in addressing the upscaling problem in physics. While the macroscopic laws of thermodynamics have been established in the 19th century, their microscopic underpinning were elaborated in the early 20th century by Boltzmann and followers, building the magnificent edifice of statistical physics. Statistical physics can be defined as the set of concepts and mathematical techniques allowing one to derive the large-scale laws of a physical system from the specification of the relevant microscopic elements and of their interactions. Dealing with huge ensembles of elements (atoms, molecules) of the order of the Avogadro number ($\simeq 6 \cdot 10^{23}$), statistical physics uses the mathematical tools of probability theory combined with other relevant fields of physics to calculate the macroscopic properties of large populations.

One of the greatest achievement of statistical physics was the development of the renormalization group analysis, to construct a theory of interacting fields and of critical phase transitions. The renormalization group is a perfect example of how statistical physics addresses the micro-macro upscaling problem. It decomposes a problem of finding the macroscopic behavior of a large number of interacting parts into a succession of simpler problems with a decreasing number of interacting parts, whose effective properties vary with the scale of observation. The renormalization group thus follows the proverb "divide to conquer" by organizing the description of a system scale-by-scale. It is particularly adapted to critical phenomena and to systems close to being scale-invariant. The renormalization group translates into mathematical language the concept that the overall behavior of a system is the aggregation of an ensemble of arbitrarily defined sub-systems, with each sub-system defined by the aggregation of sub-subsystems, and so on [203].

It is important to stress that up to now the term "statistical" has different meanings in statistical physics and in statistical seismology, a field that has developed as a marriage between probability theory, statistics and the part of seismology concerned with empirical patterns of earthquake occurrences [225] (but not with physics). Statistical seismology uses stochastic models of seismicity, which are already effective large-scale representation of the dynamical organization. In contrast, a statistical physics approach to earthquake strives to derive these statistical models or other descriptions from the knowledge of the microscopic laws of friction, damage, rupture, rock-water interactions, mechano-chemistry and so on, at the microscopic scales [200,201]. In other words, what is often missing in statistical seismology is the physics to underpin the stochastic model on physically-based laws, e. g. rate-and-state friction [55].

The previously mentioned successes of statistical physics promote the hope that a similar program can be developed for other fields, including seismology. The successes have been more limited, due to the much more complex interplay between mechanisms, interactions and scales found in these out-of-equilibrium systems. This short essay provides a subjective entry to understand some of the different attempts, underlining the few successes, the problems and open questions. Rather than providing an exhaustive review, we mention what we believe to be important topics and have especially included recent work.

Introduction

Much of the recent interest of the statistical physics community has focused on applying scaling techniques, which are common tools in the study of critical phenomena, to the statistics of inter-event recurrence times or waiting times [14,40,41,42,43,44,46,48,134]. However, the debate over the relevance of critical phenomena to earthquakes stretches back as far as 30 years [7,11,12,47,61,84,93,104,106,109,114,147,151,178,192,193,194,202,203,207,223], ► Jerky Motion in

Slowly Driven Magnetic and Earthquake Fault Systems, Physics of and ► Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space. The current debate on recurrence statistics is thus the latest tack in an evolving string of arguments with a long history. As discussed below, many of the claims made in the recent articles on recurrence statistics have either been challenged, refuted or explained by previously known facts about earthquake statistics [132,133,145,176,177,230]. As will be discussed below, this debate in the literature is important because of the potential consequences for understanding earthquakes, but it needs to be pursued with rigorous scientific arguments accessible to both the seismological and the statistical physics communities.

The debate would almost certainly benefit significantly from testing hypotheses with simulations to establish null hypotheses and benchmarks: seismicity patterns are sufficiently stochastic and earthquake catalogs contain a sufficient amount of observational uncertainties so as to make inference difficult. It is often not straightforward to predict the signal of well-known statistical features such as clustering in new data analysis techniques. Therefore, testing the purported claims by realistic simulations of earthquake catalogs can provide a strong benchmark against which the claims can be evaluated. This view and the corresponding criticism of many studies has been put forward and defended for a long time by Kagan [111].

Such a model-dependent approach may be at odds with the philosophy of a so-called "model-free" analysis, which the community of statistical physicists claim to take in their analysis. For instance, network theory-based approaches, space-time window-based finite size scaling, box-covering methods and other techniques used in the study of critical and fractal phenomena are said to be "model-free" because no assumptions about seismicity are supposedly made at the outset. By using model-free analysis techniques, the often uncertain and sometimes clearly wrong assumptions of flawed models and resulting biased results are meant to be circumvented.

However, as is almost always the case in statistical hypothesis testing, the less assumptions are made about the test, the less powerful the test statistic. More importantly, seismicity is sufficiently stochastic so that well-known features may appear as novel in new analysis methods. Furthermore, to convince the seismological community of new data analysis techniques, the methods need to be tested on established knowledge and show the improvement over traditional methods. These types of initial tests are rarely performed by the statistical physics community.

In the next Sect. "Concepts and Calculational Tools", we present a summary of some of the concepts and calculational tools that have been developed in attempts to apply statistical physics approaches to seismology. Then, Sect. "Competing Mechanisms and Models" summarizes the leading theoretical physical models of the space-time organization of earthquakes. Section "Empirical Studies of Seismicity Inspired by Statistical Physics" presents a general discussion and several examples of the new metrics proposed by statistical physicists, underlining their strengths and weaknesses. Section "Future Directions" briefly outlines expected developments.

Concepts and Calculational Tools

Renormalization, Scaling and the Role of Small Earthquakes in Models of Triggered Seismicity

A common theme in many of the empirical relations in seismology (and in those employed in seismicity models) is the lack of a dominating scale. Many natural phenomena can be approached by the traditional reductionist approach to isolate a process at a particular scale. For example, the waves of an ocean can be described quite accurately by a theory that entirely ignores the fact that the liquid is made out of individual molecules. Indeed, the success of most practical theories in physics depends on isolating a scale [234], although since this recognition, much progress has been made in developing a holistic approach for processes that do not fall into this class. Given current observational evidence, earthquakes seem to belong to the set of processes characterized by a lack of one dominating length scale: fluctuations of many or perhaps a wide continuum of sizes seem to be important and are in no way diminished – even when one is interested solely in large-scale descriptions [206].

The traditional reductionist approach in seismology, which, for instance, attempted to separate large (main) shocks from small (fore- or after-) shocks, is slowly giving way to the holistic approach, in which all earthquakes are created equal and seismicity is characterized by fluctuations of all sizes. This gradual shift is supported, on a conceptual and qualitative level, by the vision of critical phenomena. A particularly strong model of the interactions between earthquakes has emerged in the concept of triggering, which places all earthquakes on the same footing: each earthquake can trigger its own events, which in turn can trigger their own events, and so on, according to the same probability distributions, and the resulting seismicity can be viewed as the superposed cascades of triggered earthquakes that cluster in space and time [77,117,149,150].

From this point of view, it is natural that small earthquakes are important to the overall spatio-temporal patterns of seismicity. Indeed, the scaling of aftershock productivity with mainshock magnitude suggests that small earthquakes are cumulatively as important for the triggered seismicity budget as rarer but larger events [60,76,82]. The importance of small earthquakes has also been documented in, e. g., [73,138,141].

But earthquake catalogs do not contain information (by definition) about the smallest, unobserved events, which we know to exist from acoustic emission experiments and earthquakes recorded in mines. To guarantee a finite seismicity budget, Sornette and Werner argued [209] for the existence of a smallest triggering earthquake, akin to a "ultra-violet cut-off" in quantum field theory, below which earthquakes do not trigger other events. Introducing a formalism which distinguishes between the detection threshold and the smallest triggering earthquake, Sornette and Werner placed constraints on its size by using a simplified version of the popular Epidemic-Type Aftershock Sequence (ETAS) Model [149], a powerful model of triggered seismicity based on empirical statistics, and by using observed aftershock sequences. Sornette and Werner [210] also considered the branching structure of one complete cascade of triggered events, deriving an apparent branching ratio and the apparent number of untriggered events, which are observed when only the structure above the detection threshold is known. As a result of our inability to observe the entire branching structure, inferred clustering parameters are significantly biased and difficult to interpret in geophysical terms. Second, separating triggered from untriggered events, commonly known as declustering, also strongly depends on the threshold, so that it cannot even in theory constitute a physically sound method.

Sornette and Werner [210] also found that a simplified, averaged version of the ETAS model can be renormalized onto itself, with effective clustering parameters, under a change of the threshold. Saichev and Sornette [175] confirmed these results for the stochastic number statistics of the model using a rigorous approach in terms of generating probability functions, but also showed that the temporal statistics could not be renormalized. Furthermore, it can be shown (see Chapter 4 of [229]) that the conditional intensity function of the ETAS model, the mathematical object which uniquely defines the model, cannot be renormalized onto itself under a change of magnitude threshold. It is not a fixed-point of the renormalization process operating via magnitude coarse-graining. The functional form of the model must change under a change in the detection threshold [175]. In other words, if earthquakes occur according to an ETAS model above some cut-off m_0, then earthquakes above m_d cannot be described by the ETAS model in a mathematically exact way. Although in practice, the ETAS model provides an excellent fit.

The issue of how to deal with small earthquakes is thus reminiscent of the decades of efforts that have been invested in physics to deal with the famous ultra-violet cut-off problem, eventually solved by the so-called "renormalization" theory of Feynmann, Schwinger and Tomonaga. In the 1960s and 1970s, this method of renormalization was extended into the "renormalization group" (in fact a semi-group in the strict mathematical sense) for the theory of critical phenomena (see glossary), which we also mention in Sect. "Competing Mechanisms and Models". It is fair to say that there has been limited success in developing a multi-scale description of the physics of earthquakes and, in particular, in addressing the upscaling problem and the impact of the many small earthquakes.

One tantalizing approach, not yet really understood in terms of all its consequences and predictions, is the variant of the ETAS model proposed by Vere-Jones [224], which has the remarkable property of being bi-scale invariant under a transformation involving time and magnitudes. One of the modifications brought in by [224] is to assume that the distribution of the daughter magnitudes is dependent on the mother magnitude m_i through a modification of the Gutenberg–Richter distribution of triggered earthquake magnitudes by a term of the form $\exp(-\delta|m - m_i|)$, where $\delta > 0$ quantifies the distance to the standard Gutenberg–Richter distribution. Remarkably, Saichev and Sornette [174], who studied the Vere-Jones model, found that, due to the superposition of the many magnitude distributions of each earthquake in the cascades of triggered events, the resulting distribution of magnitudes over a stationary catalog is a pure Gutenberg–Richter law. Thus, there might be hidden characteristic scales in the physics of triggering that are not revealed by the standard observable one-point statistical distributions. Simulation and parameter estimation algorithms for the Vere-Jones model are not yet available. If and when these algorithms become available, the study of this bi-scale invariant branching model may be a strong alternative to the ETAS model, as this model is exactly scale invariant with neither ultra-violet nor infra-red cut-offs.

Nevertheless, being empirically based, these stochastic point process models lack a genuine microscopic physical foundation. The underlying physics is not explicitly addressed and only captured effectively by empirical statistics, even at the smallest scales. The physical processes and their renormalization are missing in this approach.

Universality

Universality, as defined in the glossary, justifies the development and study of extremely simplified models (caricatures) of Nature, since the behavior of a studied system at the critical point can nevertheless be captured by toy models (in some cases exactly). For instance, the liquid–gas transition, the ferromagnetic to paramagnetic transition, and the behavior of binary alloys, all apparently different systems, can be described successfully by an extremely simplified picture of Nature (the Ising model) because of universality. The hope that a similar principle holds for earthquakes (and other non-equilbrium systems) underpins many of the models and tools inspired by statistical physics that have been applied to seismicity, to bring about the "much coveted revolution beyond reductionism" [17,67].

Speaking loosely, the appearance of power laws in many toy models is often interpreted as a kind of universal behavior. The strict interpretation of universality classes, however, requires that critical exponents along with scaling functions are identical for different systems. It is interesting to note that slight changes in the sand-pile model already induce new universality classes, so that even within a group of toy models, the promise of universality is not, strictly, fulfilled [13,98,136].

A lively debate in seismology concerns the universality of, on one hand, the frequency-size distribution of earthquake magnitudes (e. g. [47,61,91,108,111,232]), and, on the other hand, the universality of the exponent of the Gutenberg–Richter distribution (e. g. [25,184,212,233]). A spatio-temporally varying critical exponent is not traditionally part of the standard critical phenomena repertoire, although analytical and numerical results based on a simple earthquake model on a fault showed a possible spontaneous switching between Gutenberg–Richter and characteristic earthquake behavior associated with a non-equilibrium phase transition [24,47,61], ► Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of and ► Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space. Another possible mechanism for the coexistence of and intermittent shifts between different regimes (Gutenberg–Richter scaling and characteristic earthquakes) stems from the competition between several interacting faults which give rise to long intervals of activity in some regions followed by similarly long intervals of quiescence [129,213,214]. Both careful empirical investigations of seismicity parameters and theoretical progress on heterogeneous, spatially extended critical phenomena may help elucidate the controversy.

Intermittent Periodicity and Chaos

As part of the conquest of chaos theory in the 70s and 80s [58,139], its concepts and methods were invariably also applied to seismicity. Huang and Turcotte [87,88] modeled the interaction between two faults by two sliding blocks that are driven by a plate through springs, coupled to one another via another spring and endowed with a velocity-weakening friction law. The dynamical evolution of the blocks showed chaotic behavior and period-doubling (the Feigenbaum route to chaos [58]). Huang and Turcotte [87,88] suggested that the interaction of the Parkfield segment with the southern San Andreas fault may be governed by the kind of chaotic behavior they observed in their model: the lighter block slipped quasi-periodically for several times until both slipped together. Their study explained that apparent quasi-periodicity of earthquakes on fault segments may be a result of chaotic interactions between many fault segments, thereby providing a warning that the extrapolations of quasi-periodic models are not to be trusted (e. g. [15,75] and references therein). However, it is doubtful that models with just a few degrees of freedom can go a long way towards providing deeper physical insights, or predictive tools. One needs to turn to models with a large number of degrees of freedom, for which turbulence appears as the leading paradigm of complexity.

Turbulence

A drastically different approach has been favored by Yan Kagan [104,106,109,114], who described seismicity as the "turbulence of solids" – attesting to the far greater problems in earthquake seismology than the theory of critical phenomena promises to solve. While renormalization group methods and scaling theory have contributed immensely to the study of turbulence [63], the problem of turbulence involves significant additional complications. First, loosely speaking, renormalization group theory helps predict global behavior by coarse-graining over degrees of freedom, which is essentially a bottom–up approach. In turbulence, the enstrophy acts bottom–up, but the energy cascades top down. Secondly, there is a significant spatial and topological aspect to turbulence, for instance involving topological defects, such as filament structures, which are crucial to the dynamical evolution of the system. The existence of the two cascades (top–down and bottom–up) as well as the influence of the dissipation scale all the way within the so-called inertial range makes turbulence the most important problem still unsolved in classical Physics. The importance of addressing the issue of the interplay between the top–down and bottom–up cascades in earthquake toy models has been outlined by [65,66,236,237].

The analogous problem for seismicity lies in the complex fault network, which constrains seismicity through its weak structures but also grows and evolves because of earthquakes redistributing stresses and rupturing fresh surfaces. The statistical description of this tensorial and dynamical problem is only at its beginning [64,99,100,101,102,103,107,116,118,119,142,213]. But it is likely to be a key aspect to the dynamical evolution of faults and seismicity. New physics and approaches are required to tackle the tensorial nature of the stress and strain fields and the complex topological structures of defects, from dislocations to joints and faults, as well as the many different physical processes operating from the atomic scale to the macro-scale [200,201].

Self-Organized Criticality

Self-organized criticality (SOC) refers to the spontaneous organization of a system driven from outside into a globally dynamical statistical stationary state, which is characterized by self-similar distributions of event sizes and sometimes fractal geometrical properties. SOC applies to the class of phenomena occurring in driven out-of-equilibrium systems made of many interactive components, which possess the following fundamental properties: 1) a highly non-linear behavior, 2) a very slow driving rate, 3) a globally stationary regime, characterized by stationary statistical properties, and 4) power-law distributions of event sizes and fractal geometrical properties. The crust obeys these four conditions, as first suggested by [12,193], who proposed to understand the spatio-temporal complexity of earthquakes in this perspective.

The appeal of placing the study of earthquakes in the framework of critical phenomena may be summarized as follows. Power law distributions can be understood as a result of an underlying continuous phase transition into which the crust has organized itself [197,211]. Applying the methods of renormalization group theory may help calculate exponents and scaling functions and rationalize the spatio-temporal organization of seismicity along with its highly correlated structures. For instance, Sornette and Virieux [208] provided a theoretical framework which links the scaling laws exhibited by earthquakes at short times and plate tectonic deformations at large times. Perhaps earthquakes fall into a universality class which can be solved exactly and/or investigated in toy models. Moreover, studying the detailed and highly complicated microphysics involved in earthquakes may not lead to insights about the spatio-temporal organization, because, as a critical phenomenon, the traditional approach of separating length scales to describe systems is inadequate. On the other hand, as mentioned above, there is the possibility of a hierarchy of physical processes and scales which are inter-related [156,157], for which the simplifying approach in terms of critical phenomena is likely to be insufficient.

As another reason for the importance of the topic, interesting consequences for the predictability of earthquakes might be derived, for instance by mapping earthquakes to a genuine critical point (the accelerating moment release hypothesis, e. g. [202,207]) or by mapping earthquakes to SOC (e. g. [70,147]). The latter mapping had led some to argue that earthquakes are inherently unpredictable. In the sandpile paradigm [13], there is little difference between small and large avalanches, and this led similarly to the concept that “large earthquakes are small earthquakes that did not stop,” hence their supposed lack of predictability. More than ten years after this contentious proposal, a majority of researchers, including most of the authors of this “impossibility claim,” recognize that there is some degree of predictability [83,97]. Actually, the clarifications came from investigators of SOC, who recognized that the long-term organization of sandpiles [51,52] and of toy models of earthquakes and fault networks [142,213,214] is characterized by long-range spatial and temporal correlations. Thus, large events may indeed be preceded by subtle long-range organizational structures, an idea at the basis of the accelerating moment release hypothesis. This idea is also underlying the pattern recognition method introduced by Gelfand et al. [69] and developed extensively by V. Keilis-Borok and his collaborators for earthquake predictions [122]. In addition, Huang et al. [89] showed that avalanche dynamics occurring within hierarchical geometric structures are characterized by significant precursory activity before large events; this provides a clear proof of the possible coexistence between critical-like precursors of large events and a long-term self-organized critical dynamical state.

In summary, self-organized criticality provides a general conceptual framework to articulate the search for a physical understanding of the large-scale and long-time statistical properties of the seismogenic process and of the predictability of earthquakes. Beyond this, it is of little help as many different mechanisms have been documented at the origin of SOC (see, e. g., chapter 15 in [203]). SOC is not a theory, it does not provide any specific calculation tools; it is a concept offering a broad classification of the kinds of dynamics that certain systems, including the Earth crust, seem to spontaneously select.

Competing Mechanisms and Models

It should be noted at this point that the statistical physics approach to earthquake science is not limited to SOC. Over the years, several groups have proposed to apply the concepts and tools of statistical physics to understanding the multiscale dynamics of earthquake and fault systems. Various mechanisms drawn conceptually from statistical mechanics but not necessary even limited to critical (phase transition) phenomena have been proposed and are being pursued. Such approaches include the concept of the critical point earthquake related to accelerated moment release, network theory, percolation and fiber models as models for fracture, and many more, some of which can be found in [84,203,220,221].

In this section, we outline some of the major model classes which underpin distinct views on what are the dominating mechanisms to understand earthquakes and their space-time organization.

Roots of Complexity in Seismicity: Dynamics or Heterogeneity?

The 1990s were characterized by vigorous discussions at the frontier between seismology and statistical physics aimed at understanding the origin of the observed complexity of the spatio-temporal patterns of earthquakes. The debate was centered on the question of whether space-time complexity can occur on a single homogeneous fault, solely as a result of the nonlinear dynamics [23,38,39,128,186,187,188,189], associated with the slip and velocity dependent friction law validated empirically in particular by [53,54,55,56]. Or, is the presence of quenched heterogeneity necessary [21,22,126,168]?

The rediscovery of the multi-slider-block-spring model of [31,33] led to a flurry of investigations by physicists [34,128,170], finding an enticing entry to this difficult field, in the hope of capturing the main empirical statistical properties of seismicity. It is now understood that complexity in the stress field, in co-seismic slips and in sequences of earthquakes can emerge purely from the nonlinear laws. However, heterogeneity is probably the most important factor dominating the multi-scale complex nature of earthquakes and faulting [156,157,181,182]. It is also known to control the appearance of self-organized critical behavior in a class of models relevant to the crust [191,214].

Critical Earthquakes

This section gives a brief history of the "critical earthquake" concept.

We trace the ancestor of the critical earthquake concept to Vere-Jones [223], who used a branching model to illustrate that rupture can proceed through a cascade of damage events. Allègre et al. [7] proposed what is in essence a percolation model of damage/rupture describing the state of the crust before an earthquake. They formulated the model using the language of real-space renormalization group, in order to emphasize the multi-scale nature of the underlying physics, and the incipient rupture as the approach to a critical percolation point. Their approach is actually a reformulation in the language of earthquakes of the real-space renormalization group approach to percolation developed by [165]. Chelidze [35] independently developed similar ideas. In the same spirit, Smalley et al. [192] proposed a renormalization group treatment of a multi-slider-block-spring model. Sornette and Sornette [194] took seriously the concept put forward by [7] and proposed to test it empirically by searching for the predicted critical precursors. Voight [227,228] was probably the first author to introduce the idea of a time-to-failure analysis quantified by a second order nonlinear ordinary differential equation. For certain values of the parameters, the solution of [227,228]'s time-to-failure equation takes the form of a finite time singularity (see [180] for a review and [204] for a mechanism based on the ETAS model). He proposed and did use it later to predict volcanic eruptions. The concept that earthquakes are somehow associated with critical phenomena was also underlying the research efforts of a part of the Russian school [120,222].

The empirical seed for the critical earthquake concept were the repeated observations that large earthquakes are sometimes preceded by an increase in the number of intermediate size events [29,59,92,96,121,123,131,144,164,217]. The relation between these intermediate events and the subsequent main event took a long time to be recognized because the precursory events occur over such a large area. Sykes and Jaumé [217] proposed a specific law $\sim \exp[t/\tau]$ quantifying the acceleration of seismicity prior to large earthquakes. Bufe and Varnes [30] proposed that the finite-time singularity law

$$\epsilon_{\text{Benioff}} \sim 1/(t_c - t)^m \qquad (2)$$

is a better empirical model than the exponential law. In (2), $\epsilon_{\text{Benioff}}$ is the cumulative Benioff strain, t_c is critical time of the occurrence of the target earthquake and m is a positive exponent. The fit with this law of the empirical Benioff strain calculated by summing the contribution of earthquakes in a given space-time window is supposed to provide the time t_c of the earthquake and thus constitutes a prediction. This expression (2) was justified by a mechanical model of material damage. It is important to understand that the law (2) can emerge as a consequence of a variety of mechanisms, as reviewed by [180].

One of these mechanisms has been coined the "critical earthquake" concept, first formulated by Sornette and Sammis [207], who proposed to reinterpret the formula (2) proposed by [30] and previous related works by generalizing them within the statistical physics framework. This concept views a large earthquake as a genuine critical point. Using the insight of critical points in rupture phenomena, Sornette and Sammis [207] proposed to enrich Eq. (2), now interpreted as a kind of diverging susceptibility in the sense of critical phenomena, by considering complex exponents (i. e. log-periodic corrections to scaling). These structures accommodate the possible presence of a hierarchy of characteristic scales, coexisting with power laws expressing the scale invariance associated with a critical phenomenon [199]. This was followed by several extensions [89,94,95,178]. Sornette [202] reviewed the concept of critical "ruptures" and earthquakes with application to prediction. Ike and Sornette [90] presented a simple dynamical mechanism to obtain finite-time singularities (in rupture in particular) decorated by complex exponents (log-periodicity). Bowman et al. [28, 153,154,242,243] proposed empirical tests of the critical earthquake concept. The early tests of [28] have been criticized by [74], while [226] commented on the lack of a formal statistical basis of the accelerating moment release model. This stresses the need for rigorous tests in the spirit of [166,167]. The debate is wide open, especially in view of the recent developments to improve the determination of the relevant spatio-temporal domain that should be used to perform the analyzes [26,27,124,130] (see [62] for a review).

Spinodal Decomposition

Klein, Rundle and their collaborators have suggested a mean-field approach to the multi-slider-block-spring model justified by the long-range nature of the elastic interactions between faults. This has led them to propose that the fluctuations of the strain and stress field associated with earthquakes are technically those occurring close to a spinodal line of an underlying first-order phase transition (see [125,169,172] and references therein). This conceptual view has inspired them to develop the "Pattern Informatics" technique, an empirical seismicity forecasting method based on the idea that changes in the seismicity rate are proxies for changes in the underlying stress [86, 218].

The fluctuations associated with a spinodal line are very similar to those observed in critical phenomena. It is thus very difficult if not impossible in principle to falsify this hypothesis against the critical earthquake hypothesis, since both are expected to present similar if not identical signatures. Perhaps, the appeal of the spinodal decomposition proposal has to be found at the theoretical level, from the fact that first-order phase transitions are more generic and robust than critical phenomena, for systems where heterogeneity and quenched randomness are not too large.

Dynamics, Stress Interaction and Thermal Fluctuation Effects

Fisher et al. [24], Dahmen et al. [47], Ben-Zion et al. [61] and co-workers (see the reviews by ▶ Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of and ▶ Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space) have introduced a mean-field model (resulting from a uniform long-range Green function) of a single fault, whose dynamical organization is controlled by two control parameters, ϵ which measures the dynamic stress weakening and c which is the deviation from stress conservation (due for instance to coupling with ductile layers). The point ($\epsilon = 0$; $c = 0$) is critical in the sense of a phase transition in statistical physics, with its associated scale invariant fluctuations described by power laws. Dynamic stress strengthening ($\epsilon < 0$) leads to truncated Gutenberg–Richter power laws. Dynamic stress weakening ($\epsilon > 0$) is either associated with a truncated Gutenberg–Richter power law for $c > 0$ or with characteristic earthquakes decorating a truncated power law for $c < 0$. The coexistence of a characteristic earthquake regime with a power-law regime is particularly interesting as it suggests that they are not exclusive properties but may characterize the same underlying physics under slightly different conditions. This could provide a step towards explaining the variety of empirical observations in seismology [5,110,185, 232].

Sornette et al. [214] have obtained similar conclusions using a quasi-static model in which faults grow and self-organize into optimal structures by repeated earthquakes. Depending on the value of dynamical stress drop (controlling the coupling strength between elements) relative to the amplitude of the frozen heterogeneity of the stress thresholds controlling the earthquake nucleation on each fault segment, a characteristic earthquake regime with a truncated power law is found for small heterogeneity or large stress drop while the power law SOC regime is recovered by large heterogeneity or small stress drop. The two approaches of [24,47,61] and ► Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of on the one hand and of [214] on the other hand can be reconciled conceptually by noting that the dynamic stress weakening of ► Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of controls the dynamical generated stress heterogeneity while the lack of stress conservation c controls the coupling strength. Fundamentally, the relevant control parameter is the degree of coupling between fault elements seen as threshold oscillators of relaxation versus the variance of the disorder in their spontaneous large earthquake recurrence times. Generically, power law statistics are expected to co-exist with synchronized behavior in a general phase diagram in the heterogeneity-coupling strength plane [152,214].

Let us finally mention a promising but challenging theoretical approach, which has the ambition to bridge the small-scale physics controlled by thermal nucleation of rupture to the large-scale organization of earthquakes and faults [155,205]. Partial success has been obtained with a remarkable prediction on the ("multifractal") dependence of the Omori law exponent of aftershocks on the magnitude of the mainshock, verified by careful empirical analyzes on earthquakes in California, Japan and worldwide [158].

Empirical Studies of Seismicity Inspired by Statistical Physics

> *"False facts are highly injurious to the progress of science, for they often endure long; but false views, if supported by some evidence, do little harm, for everyone takes a salutary pleasure in proving their falseness."*
>
> Charles Darwin, in The Origin of Man, Chap. 6.

Early Successes and Subsequent Challenges

A significant benefit of the statistical physics approach to seismology has been the introduction of novel techniques to analyze the available empirical data sets, with the goal of obtaining new insights into the spatio-temporal organization of seismicity and of revealing novel regularities and laws that may guide the theoretical analysis.

A prominent forerunner is the application of the concept of fractals introduced by Mandelbrot [137] and of the measures of fractal dimensions to describe complex sets of earthquake epicenters, hypocenters and fault patterns. The use of fractals has constituted an epistemologic breakthrough in many fields, and not only in seismology. Indeed, before Mandelbrot, when dealing with most complex systems, one used to say: "this is too complicated for a quantitative analysis" and only qualitative descriptions were offered. After Mandelbrot, one could hear: "this is a fractal, with a fractal dimension equal to xxx!" By providing a new geometrical way of thinking about complex systems associated with novel metrics, Mandelbrot and his fractals have extended considerably the reach of quantitative science to many complex systems in all fields.

However, while there have been some attempts to use fractal dimensions as guidelines to infer the underlying organization processes, as for instance in [195,196], most of the initial reports have lost their early appeal [18,19,183,219] since the complexity of seismicity and faulting is much too great to be captured by scaling laws embodying solely a simple scale invariance symmetry. Among others, multifractal and adapted wavelet tools are needed to quantify this complexity, see for instance [68,146,156,157,159]. It should also be noted that few studies of the fractal dimensions of seismicity address the significant issues of errors, biases and incomplete records in earthquake catalogs – a notable exception being [115].

Since the beginning of the 21st century, a renewal of interest and efforts have burgeoned as groups of statistical physicists, interested in earthquakes as a potential instance of self-organized criticality (SOC), have claimed "novel", "universal" and "robust" scaling laws from their analysis of the spatio-temporal organization of seismicity. The authors purport to have discovered universal and hitherto unknown features of earthquakes that give new insights into the dynamics of earthquakes and add to the evidence that earthquakes are self-organized critical. We now discuss a few of these recent studies to illustrate the existence of potential problems in the "statistical physics" approach. In a nutshell, we show that perhaps most of these "novel scaling laws" can be explained entirely by already known statistical seismicity laws. This claim has been defended by other experts of statistical seismology, the most vocal being perhaps Yan Kagan at UCLA [111].

The flurry of interest from physicists comes from their fascination with the self-similar properties exhibited by seismicity (e. g. the Gutenberg–Richter power law of earthquake seismic moments, the Omori–Utsu law of the decay of aftershock rates after large earthquakes, the fractal and multifractal space-time organization of earthquakes and faults, etc.), together with the development of novel concepts and techniques that may provide new insights. But, and this is our main criticism based on several detailed examples discussed below, many of the new approaches and results do not stand close scrutiny. This failure is rooted in two short-comings: (i) the lack of testing of new methods on synthetic catalogs generated by benchmark models which are based on well-known statistical laws of seismicity, and (ii) the failure to consider earthquake catalog bias, incompleteness and errors. The latter may cause catalog artifacts to appear as genuine characteristics of earthquakes. Testing the results on a variety of catalogs and considering the influence of various catalog errors can help minimize their influence. The former short-coming often leads to the following scenario: authors fail to realize that a simpler null hypothesis could not be rejected, namely that their "discovery" could actually be explained by just a combination of basic statistical laws known to seismologists for decades.

The well-established laws of statistical seismicity that authors should consider before claiming for novelty include the following:

1. The Gutenberg–Richter law for the distribution of earthquake magnitudes with a b-value close to 1 (corresponding to an exponent $\simeq 2/3$ for the probability density function of seismic moments),
2. The Omori–Utsu law for the decay of the rate of aftershocks following a mainshock,
3. The inverse Omori law for foreshocks,
4. The fact that aftershocks also trigger their own aftershocks and so on, and that aftershocks do not seem to exhibit any distinguishable physical properties,
5. The fact that the distribution of distances between mainshocks and aftershocks has a power law tail,
6. The fertility law (the fact that earthquakes of magnitude M trigger of the order of 10^{aM} aftershocks with $a\sim \leq b \simeq 1$,
7. The fractal distribution of faults which are concentration centers for earthquakes.

This above non-exhaustive list selects "laws" which are arguably non-redundant, in the sense that it is likely not possible to derive one of these laws from the others (a possible exception is the inverse Omori law for foreshock, which can be derived from the direct Omori law for aftershocks in the context of the ETAS model [78,81]). Some experts would argue that we should add to this list other claimed regularities, such as "Båth's law" (see e. g. [190] for a recent discussion emphasizing the importance of this law), that states that the differences in magnitudes between mainshocks and their largest aftershocks are approximately constant, independent of the magnitudes of mainshocks [20]. However, Helmstetter and Sornette [79] and Saichev and Sornette [173] have shown that Bath's law can be accurately recovered in ETAS-type models combining the first, second, fourth, and sixth laws stated above, with the assumption that any earthquake can trigger subsequent earthquakes.

Entropy Method for the Distribution of Time Intervals Between Mainshocks

Mega et al. [140] used the "diffusion entropy" method to argue for a power-law distribution of time intervals between a large earthquake (the mainshock of a seismic sequence or cluster) and the next one. Helmstetter and Sornette [80] showed that all the "new" discoveries reported by [140] (including the supposedly new scaling) can be explained solely by Omori's law for intra-cluster times, without correlation between clusters, thus debunking the claim for novelty.

Scaling of the PDF of Waiting Times

Bak et al. [14] analyzed the scaling of the probability density function of waiting times between successive earthquakes in southern California as a function of "box size" or small regions in which subsequent earthquakes are considered. They found an approximate collapse of the pdfs for different seismic moment thresholds S and box sizes L which suggested the following scaling ansatz for the waiting times T:

$$T^{\alpha} P_{S,L}(T) = f(TS^{-b}L^{d_f}) \,, \tag{3}$$

where $b = 1$ is the Gutenberg–Richter exponent, $d_f \simeq 1.2$ was claimed to be a spatial fractal dimension of seismicity (see [146] and [115] for more in-depth studies), $\alpha = 1$ was identified as the exponent in the Omori law and $f(\cdot)$ is a scaling function which was proposed to be roughly constant up to a constant ("kink") beyond which it quickly decays. The scaling (3) was claimed to be a unified law for earthquakes that revealed a novel feature in the spatio-temporal organization of seismicity in that the Gutenberg–Richter, the Omori law and the spatial distribution of earthquakes were unified into a single picture that made no distinction between fore-, main- and aftershocks. The scaling relations and critical exponents were claimed to be contained in the scaling ansatz. Corral [40,41,42,43] and others broadened the analysis to other regions of the world. Corral [41] proposed a slightly different scaling ansatz for a modified data analysis.

Early criticism came from Lindman et al. [132], who noted that synthetic data generated using a non-homogeneous Poisson process derived from Omori's law was able to reproduce some of the results of [14], indicating a rather trivial origin of the unified scaling law. Molchan [145] showed that, if at least two regions in the data set are independent, then, if a scaling relation were to hold exactly, this scaling function could only be exponential. All other functions could only result in approximate data collapses.

Proponents of the unified scaling law, e. g. [44], argued that indeed all regions were correlated, as expected in systems near a critical point so that the assumption of independence between different regions should not hold. But Molchan [145] also showed that a simple Poisson cluster model (Poissonian mainshocks that trigger Omori-type aftershock sequences) could reproduce the short and long time limits of the observed statistics, indicating that the Omori law, the Gutenberg–Richter relationship and simple clustering were the sole ingredients necessary for the observed short and long time limit, and no spatial correlation was needed.

Saichev and Sornette [176,177] extended Molchan's arguments to show that the approximate data collapse of the waiting times could be explained completely by the Epidemic-Type Aftershock Sequence (ETAS) model of [149]. This provided further evidence that the apparent data collapse was only approximate. Remarkably, the theoretical predictions of the ETAS model seem to fit the observed data better than the phenomenological scaling function proposed by [41] to fit the data. Saichev and Sornette [176,177] thus showed that a benchmark model of seismicity was able to reproduce the apparent unified scaling law and that therefore the distribution of interevent times did not reveal new information beyond what was already known via statistical laws: The combination of the Gutenberg–Richter law, the Omori law, and the concept of clustering suffice to explain the apparent "universal" scaling of the waiting times.

Sornette et al. [215] developed an efficient numerical scheme to solve accurately the set of nonlinear integral equations derived previously in [177] and found a dramatic lack of power for the distribution of inter-event times to distinguish between quite different sets of parameters, casting doubt on the usefulness of this statistics for the specific purpose of identifying the clustering parameter (e. g. [72]).

Scaling of the PDF of Distances Between Subsequent Earthquakes

Davidson and Paczuski [49] claimed evidence contradicting the theory of aftershock zone scaling in favor of scale-free statistics. Aftershock zone scaling refers to the scaling of the mainshock rupture length, along which most aftershocks occur, with the mainshock magnitude [112]. Davidson and Paczuski [49] suggested that the probability density function of spatial distances between successive earthquakes obeys finite size scaling with a novel dynamical scaling exponent, suggesting that the mainshock rupture length scale has no impact on the spatial distribution of aftershocks and that earthquakes are self-organized critical.

Werner and Sonette [230] debunked this claim by showing that (i) the purported power law scaling function is not universal as it breaks down in other regions of the world; (ii) the results obtained by [49] for southern California depend crucially on a single earthquake (the June 28, 1992, M7.3 Landers earthquake): without Landers and its aftershocks, the power law disappears; (iii) a model of clustered seismicity, with aftershock zone scaling explicitly built in, is able reproduce the apparent power law, indicating that an apparent lack of scales in the data does not necessarily contradict aftershock zone scaling and the existence of scales associated with mainshock rupture length scales.

The Network Approach

The recent boom in the statistical mechanics of network analysis has recently extended to applications well beyond physics (for reviews, see [6,16,57,148]). Earthquake seismology is no exception [1,2,3,4,8,9,10,160,161]. The resulting impact has been limited so far for several reasons.

A major concern is the assumption that earthquake catalogs as downloaded from the web are data sets fit for immediate analysis. References [82,113,229] and [231] present modern and complementary assessments of the many issues of incompleteness spoiling even the best catalogs. In particular, we should stress that magnitude determinations are surprisingly inaccurate, leading to large errors in seismic rate estimates [231]. Furthermore, there is no such thing as a complete catalog above a so-called magnitude of completeness, due to the fact that a non-negligible fraction of earthquakes are missed in the aftermath of previous earthquakes [82,113]. One should be concerned that analyses in terms of network metrics could be particularly sensitive to these defects. Nevertheless, Abe and Suzuki [1,2,3,4] applied metrics of network analysis to "raw" catalogs which included events well below the estimated magnitude of completeness. As a result of neglecting to use a (reasonably) homogeneous and trustworthy data set, the results of their analysis may be severely biased, because the reliability of the inferred network structure is probably more sensitive than other metrics to the correct spatio-temporal ordering of the earthquake catalog. No serious study has yet been performed to quantify the usually serious impact of quality issues on the metrics used in network analysis. As a consequence, it is also not clear how to interpret the "success" of [160,161] in reproducing the "features" of Abe and Suzuki's analysis on the synthetic seismicity generated by a spring-block model.

In addition, at best limited attempts have been made to interpret the results of the new network metrics using well-known, established facts in seismology. Many of the claimed novel features are probably very well understood – they are mostly related to scale-invariance and clustering of seismicity, facts documented for decades. The authors should always strive to show that the new metrics that they propose give results that cannot be explained by the standard laws in statistical seismology. Toward this end, there are well-defined benchmark models that incorporate these laws and that can generate synthetic catalogs on which the new metrics can be tested and compared.

A few exceptions are worth mentioning. Motivated by the long-standing and unresolved debate over "aftershock" identification, Baiesi and Paczuski [9,10] and Baiesi [8] provided a new metric for the correlations between earthquakes based on the space-time-magnitude nearest-neighbor distance between earthquakes. The authors compared their results with known statistical laws in seismology and with the predictions of the ETAS model, actually confirming both. While no new law has been unearthed here, such efforts are valuable to validate known laws and continue to test the possible limits. Zaliapin et al. [238] extended their study and investigated the theoretical properties of the metric and its ability to decluster catalogs (i. e., separate mainshocks from aftershocks). They concluded that aftershocks defined from this metric seem to be different from the rest of earthquakes. It will be interesting to see head-to-head comparisons with current state-of-the-art probabilistic declustering techniques that are based on empirical statistical laws and likelihood estimation [105, 240,241].

Future Directions

The study of the statistical physics of earthquakes remains wide-open with many significant discoveries to be made. The promise of a holistic approach – one that emphasizes the interactions between earthquakes and faults – is to be able to neglect some of the exceedingly complicated micro-physics when attempting to understand the large scale patterns of seismicity. The marriage between this conceptual approach, based on the successes of statistical physics, and seismology thus remains a highly important domain of research. In particular, statistical seismology needs to evolve into a genuine physically-based statistical physics of earthquakes.

The question of renormalizability of models of earthquake occurrence and the role of small earthquakes in the organization of seismicity is likely to remain an important topic. It connects with the problem of foreshocks and the predictability of large events from small ones and therefore has real and immediate practical applications as well as physical implications.

More detailed and rigorous empirical studies of the frequency-size statistics of earthquake seismic moments and how they relate to seismo-tectonic conditions are needed in order to help settle the controversy over the power-law versus the characteristic event regime, and the role of regime-switching and universality.

Spatially extended, dynamically evolving fault networks and their role in the generation of earthquakes are mostly ignored in the statistical physics approach to seismicity. Akin to the filaments in turbulence, these may provide key insights into the spatio-temporal organization of earthquakes. Novel methods combining information from seismology to faulting will be required (e. g., [71,159,195, 196,197]) to build a real understanding of the self-organization of the chicken-and-egg structures that earthquakes-faults constitute. Furthermore, a true physical approach requires understanding the spatio-temporal evolution of stresses, their role in earthquake nucleation via thermally activated processes, in the rupture propagation and in the physics of arrest, both involved in the generation of complex stress fields.

The important debate regarding statistical physics approaches to seismicity would benefit significantly from two points. Firstly, earthquake catalogs contain data uncertainties, biases and subtle incompleteness issues. Investigating their influence on the results of data analyses inspired by statistical physics increases the relevance of the results. Secondly, the authors should make links with the literature on statistical seismology which deals with similar questions. It is their task to show that the new metrics that they propose give results that cannot be explained by the standard laws in statistical seismology. For this, there are well-defined benchmark models that incorporate these laws and that can generate synthetic catalogs on which the new metrics can be tested.

Article Outline

Glossary

Numerical methods Processes in nature are often described by partial differential equations. Finding solutions to those equations is at the heart of many studies aiming at the explanation of observed data. Simulations of realistic physical processes requires generally the use of numerical methods – a special branch of applied mathematics – that approximate the partial differential equations and allows solving them on computers. Examples are the finite-difference, finite-element, or finite-volume methods.

Spectral elements The spectral element method is an extension of the finite element method that makes use of specific basis functions describing the solutions inside each element. These basis functions (e. g., Chebyshev or Legendre polynomials) allow the interpolation of functions exactly at certain collocation points. This is often termed spectral accuracy.

Discontinuous Galerkin method The discontinuous Galerkin method is a flavor of the finite-element method that allows discontinuous behavior of the spatial or temporal fields at the element boundaries. The discontinuities – that might be small in the case of continuous physical fields such as seismic waves – then define so-called Riemann problems that can be handled using the concepts from finite-volume techniques. Therefore, the approximate solution is updated via numerical fluxes across the element boundaries.

Parallel algorithms All modern supercomputers make use of parallel architectures. This means that a large number of processors are performing (different) tasks on different data at the same time. Numerical algorithms need to be adapted to these hardware architectures by using specific programming paradigms (e. g., the message passing interface MPI). The computational efficiency of such algorithms strongly depends on the specific parallel nature of the problem to be solved, and the requirement for inter-processor communication.

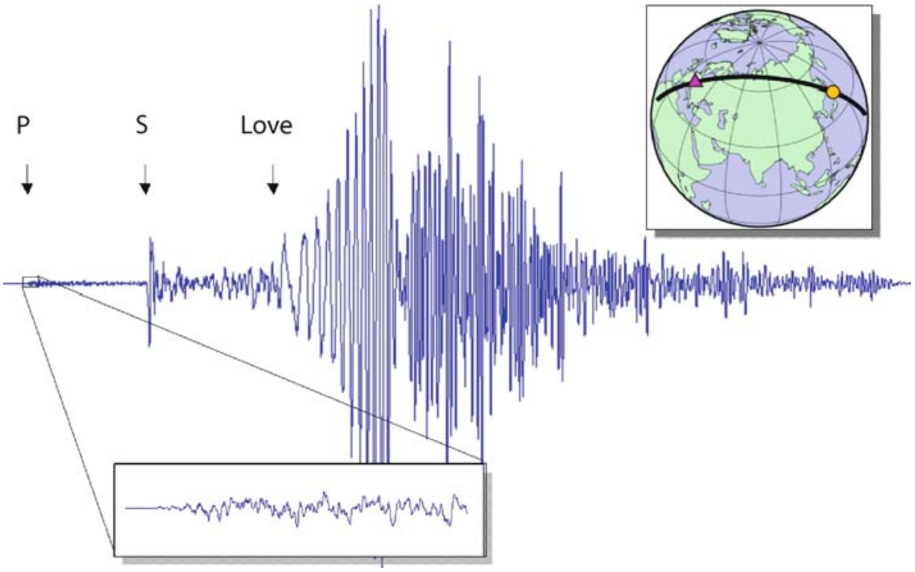
Grid generation Most numerical methods are based on the calculation of the solutions at a large set of points (grids) that are either static or depend on time (adaptive grids). These grids often need to be adapted to the specific geometrical properties of the objects to be modeled (volcano, reservoir, globe). Grids may be designed to follow domain boundaries and internal surfaces. Before specific numerical solvers are employed the grid points are usually connected to form triangles or rectangles in 2D or hexahedra or tetrahedra in 3D.

Definition of the Subject

Seismology is the science that aims at understanding the Earth's interior and its seismic sources from measurements of vibrations of the solid Earth. The resulting images of the physical properties of internal structures and the spatio-temporal behavior of earthquake rupture processes are prerequisites to understanding the dynamic evolution of our planet and the physics of earthquakes. One of the key ingredients to obtain these images is the calculation of synthetic (or theoretical) seismograms for given earthquake sources and internal structures. These synthetic seismograms can then be compared quantitatively with observations and acceptable models be searched for using the theory of inverse problems. The methodologies to calculate synthetic seismograms have evolved dramatically over the past decades in parallel with the evolution of computational resources and the ever increasing volumes of permanent seismic observations in global and regional seismic networks, volcano monitoring networks, and experimental campaigns. Today it is a tremendous challenge to extract an optimal amount of information from seismograms. The imaging process is still primarily carried out using ray theory or extensions thereof not fully taking into account the complex scattering processes that are occurring in nature.

To model seismic observations in their full complexity we need to be able to simulate wave propagation through 3D structures with constitutive relations that account for anisotropic elasticity, attenuation, porous media as well as complex internal interfaces such as layer boundaries or fault systems. This implies that numerical methods have to be employed that solve the underlying partial differential equations on computational grids. The high-frequency oscillatory nature of seismic wave fields makes this an expensive endeavor as far as computational resources are concerned. As seismic waves are propagating hundreds of wavelengths through scattering media, the required accuracy of the numerical approximations has to be of the highest possible order. Despite the fact that the physics of wave propagation is well understood, only recently computational algorithms are becoming available that allow us to accurately simulate wave propagation on many scales such as reservoirs, volcanoes, sedimentary basins, continents, and whole planets.

In addition to the imaging problem for subsurface structure and earthquake sources, the possibilities for 3D wave simulations have opened a new route to forecasting strong ground motions following large earthquakes in seismically active regions. In the absence of any hope to deterministically predict earthquakes, the calculation



Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 1
Transverse velocity seismogram of the M8.3 Tokachi-Oki earthquake near Hokkaido observed at station WET in Germany with a broadband seismometer. The total seismogram length is one hour. Arrival times of body wave phases (P, S) and the onset of transversely polarized surface (Love) waves are indicated

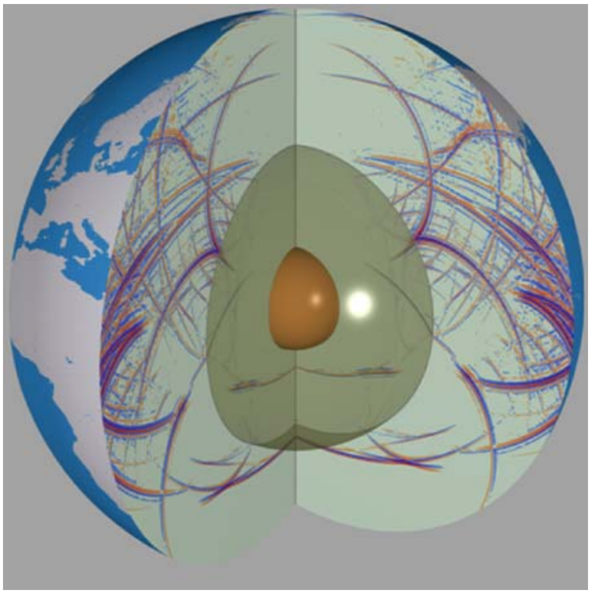
of earthquake scenarios in regions with sufficiently well known crustal structures and fault locations will play an important role in mitigating damage particularly due to potentially amplifying local velocity structures. However, to be able to employ the advanced 3D simulation technology in an efficient way, and to make use of the fast advance of supercomputing infrastructure, a paradigm shift in the concept of wave simulation software is necessary: The Earth science community has to build soft infrastructures that enable massive use of those simulation tools on the available high-performance computing infrastructure.

In this paper we want to present the state of the art of computational wave propagation and point to necessary developments in the coming years, particularly in connection with finding efficient ways to generate computational grids for models with complex topography, faults, and the combined simulation of soil and structures.

Introduction

We first illustrate the evolution of methodologies to calculate and model aspects of seismic observations for the case of global wave propagation. Seismology can look back at almost 50 years of systematic observations of earthquake induced teleseismic ground motions with the standardized global seismic and regional networks. The digital revolution in the past decades has altered the recording culture such that now seismometers are recording ground motions permanently rather than in trigger-mode, observations are becoming available in near-real time, and – because of the required sampling rates – the daily amount of observations automatically sent to the data centers is gigantic. If we take a qualitative look at a seismic observation (Fig. 1) we can illustrate what it takes to model either part or the whole information contained in such physical measurements.

In Fig. 1 a seismogram observed using a broadband seismometer (station WET in Germany) is shown. Globally observed seismograms following large earthquakes contain frequencies up to 1 Hz (P-wave motions) down to periods of around one hour (eigenmodes of the Earth) in which case modeling is carried out in the frequency domain. Seismograms of the kind shown in Fig. 1 contain many types of information. For large earthquakes the first part of the seismogram (inlet) contains valuable information on the spatio-temporal evolution of the earthquake rupture on a finite-size fault. A model of the fault slip history is a prerequisite to model the complete wave form of seismograms as the whole seismogram is affected by it unless severe low-pass filtering is applied. Information on the global seismic velocity structure is contained in the arrival times of numerous body-wave phases (here only P- and S-wave arrivals are indicated) and in the dispersive behavior of the surface waves (here the onset of the low-frequency Love waves is indicated). Further information is contained in the characteristics of the coda to body wave phases in-



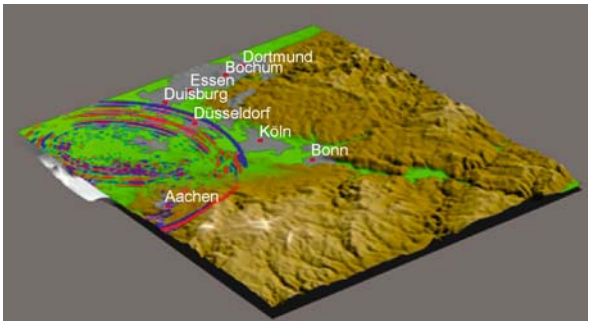
Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 2
Snapshot of wave propagation inside the Earth approx. 25 minutes after an earthquake occurs at the top part of the model. The radial component of motion is shown (blue and red denote positive and negative velocity, resp.). The simulation was carried out using an axi-symmetric approximation to the wave equation [55,58] and high-order finite-differences. Motion is allowed in the radial and horizontal directions. This corresponds to the P-SV case in 2D cartesian calculations. Therefore the wavefield contains both P- and S-waves and phase conversions

dicative of scattering in various parts of the Earth (see [62] for an account of modern observational seismology).

Adding a temporal and spatial scale to the above qualitative discussion reveals some important insight what it takes to simulate wave propagation on a planetary scale using grid-based numerical methods. Given the maximum frequency of around 1 Hz (P-waves) and 0.2 Hz (S-waves) the minimum wavelength in the Earth is expected to be O(km), requiring O(100 m) type grid spacing at least in the crustal part of the Earth leading to O(10^{12}) necessary grid points (or volume elements) for accurate numerical simulations. This would lead to memory requirements O(100 TByte) that are today possible on some of the world's largest supercomputers. The message here is that despite the rapid evolution of computational power, the complete modeling of teleseismic observations using approaches such as spectral elements (e. g., [63,64]) requiring tremendous numbers of calculations to constrain structure and sources will remain a grand challenge for some time to come. However, in many cases it is not necessary or not even desirable to simulate or model the whole seismogram, i. e. the complete observed frequency band. If we lower the cutoff frequency to 0.1 Hz (period 10 s), the required memory drops down to O(100 GByte). Such calculations can be done today on PC-clusters that can be inexpensively assembled and run on an institutional level (e. g., [8]). In addition, it means that the massive use of such forward simulations for imaging purposes and phenomenological investigations of wavefield effects is around the corner. This does not only apply to wave propagation or imaging on a planetary scale but in the same way to problems in volcanology, regional seismology, and exploration geophysics.

An illustration of global wave simulations using the finite difference method (e. g., [14,54,55,58,109,110,114]) is shown in Fig. 2 (more details on the methodologies are given in Sect. "The Evolution of Numerical Methods and Grids"). The snapshot of the radial component of motion at a time when the direct P-wave has almost crossed the Earth reveals the tremendous complexity the wave field exhibits even in the case of a spherically symmetric Earth model (PREM, [37]). The wavefield with a dominant period of ca. 15 seconds also highlights the short wavelengths that need to be propagated over very large distances. This is the special requirement for computational wave propagation that is quite different in other fields of computational Earth Sciences. While the theory of linear elastic wave propagation is well understood and most numerical methods have been applied to it in various forms, the accuracy requirements are so high that – particularly when models with complex geometrical features need to be modeled – there are still open questions as to what works best. One of the main goals of this paper is to highlight the need to focus on the grid generation process for various types of computational grid cells (e. g., rectangular, triangular in 2D, and hexahedral and tetrahedral in 3D) and the interface to appropriate highly accurate solvers for wave propagation problems.

As mentioned above computational modeling of strong ground motions following large earthquakes (see Fig. 3 for an illustration) is expected to play an increasingly important role in producing realistic estimates of shaking hazard. There are several problems that are currently unsolved: (1) to achieve frequencies that are interesting for earthquake engineers in connection with structural damage the near surface velocity structure needs to be known and frequencies beyond 5 Hz need to be calculated. In most cases this structure is not well known (on top of the uncertainties of the lower basin structures) and the required frequencies demand extremely large computational models. (2) In addition to structural uncertain-



Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 3
Snapshot (horizontal component) for a simulation of the M5.9 Roermond earthquake in the Cologne Basin in 1992 [38]. The 3D sedimentary basin (maximum depth 2 km) leads to strong amplification and prolongation of the shaking duration that correlates well with basin depth. Systematic calculations may help mitigating earthquake induced damage

ties, there are strong dependencies on the particular earthquake rupture process that influence the observed ground motions. This suggests that many 3D calculations should be carried out for any characteristic earthquake of interest, to account for such variations (e. g., Wang et al. 2006). (3) The large velocity variations (e. g., 300 m/s up to 8 km/s) require locally varying grid densities which is difficult to achieve with some of the classical numerical methods in use (e. g. finite differences). Some of the potential routes are developed below.

In summary, computational simulation of 3D wave propagation will be more and more a central tool for seismology with application in imaging problems, earthquake rupture problems, questions of shaking hazard, volcano seismology and planetary seismology. In the following we briefly review the history of the application of numerical methods to wave propagation problems and the evolution of computational grids. The increasing complexity of models in terms of geometrical features and range of physical properties imposes the use of novel methodologies that go far beyond the initial approximations based on finite differences.

The Evolution of Numerical Methods and Grids

In this section we give a brief history of the application of numerical methods to the problem of seismic wave propagation. Such a review can not be complete, certainly gives a limited perspective, and only some key references are given. One of the points we would like to highlight is the evolution of the computational grids that are being employed for wave propagation problems and the consequences on the numerical methods of choice now and in the future.

Why do we need numerical approximations to elastic wave propagation problems at all? It is remarkable what we learned about the Earth without them! In the first decades in seismology, modeling of seismic observations was restricted to the calculation of ray-theoretical travel times in spherically symmetric Earth models (e. g., [13,16]). With the advent of computing machines these approaches could be extended to 2D and 3D media leading to ray-theoretical tomography and the images of the Earth's interior that we know today (e. g., [115]). The analytical solution of wave propagation in spherical coordinates naturally leads to spherical harmonics and the possible quasi-analytical solution of wave propagation problems in spherically symmetric media using normal modes. As this methodology leads to complete waveforms the term "waveform inversion" was coined for fitting the waveforms of surface waves by correcting the phase differences for surface waves at particular frequencies (e. g., [118]). This allowed the recovery of seismic velocity models particularly of crust and upper mantle (surface wave tomography). A similar approach in Cartesian layered geometry led to complete solutions of the wave equation in cylindrical coordinates through the summation of Bessel functions, the reflectivity method [46]. This method was later extended to spherical media through the Earth-flattening transformation [85]. Recently, ray-theory was extended allowing the incorporation of finite-frequency effects (e. g., [84]). The impact on the imaging process is still being debated.

Most of these methods are still today extremely valuable in providing first estimates of 2D or 3D effects and are important for the use in standard seismic processing due to their computational efficiency. Nevertheless, with the tremendous improvements of the quality of seismic observations we strive today to extract much more information on Earth's structure and sources from recorded waveforms. As waveforms are in most places strongly affected by 3D structural variations the application of numerical methods that solve "directly" the partial differential equations descriptive of wave propagation becomes mandatory. This necessity was recognized early on and the developments of numerical wave propagation began in the sixties of the 20th century.

Numerical Methods Applied to Wave Propagation Problems

The finite-difference technique was the first numerical method to be intensively applied to the wave propagation problem (e. g., [1,6,61,77,82,83,88,89,116,117]). The partial differentials in the wave equation are replaced by finite differences leading to an extrapolation scheme in time that can either be implicit or explicit. The analysis of such simple numerical schemes led to concepts that are central to basically all numerical solutions of wave propagation problems. First, the discretization in space and time introduces a scale into the problem with the consequence that the numerical scheme becomes dispersive. This numerical dispersion – for the originally non-dispersive problem of purely elastic wave propagation – has the consequence that for long propagation distances wave pulses are no longer stable but disperse. The consequence is, that in any simulation one has to ascertain that enough grid points per wavelength are employed so that numerical dispersion is reduced sufficiently. Finding numerical schemes that minimize these effects has been at the heart of any new methodology ever since. Second, the so-called CFL criterion [24] that follows from the same theoretical analysis of the numerical scheme basically relates a "grid velocity" – the ratio between the space and time increments dx and dt, respectively – to the largest physical velocity c in the model. In order to have a stable calculation, this ratio has to be smaller than a constant ε that depends on the specific scheme and the space dimension

$$c\frac{\mathrm{d}t}{\mathrm{d}x} \leq \varepsilon\,. \tag{1}$$

This simple relationship has important consequences: When the grid spacing dx must be small, because of model areas with low seismic velocities, then the time step dt has to be made smaller accordingly leading to an overall increase in the number of time steps and thus overall computational requirements. In addition, the early implementations where based on regular rectangular grids, implying that large parts of the model where carrying out unnecessary calculations. As shown below local time-stepping and local accuracy are important ingredients in efficient modern algorithms.

The fairly inaccurate low order spatial finite-difference schemes were later extended to high-order operators [26,48,49,50,51,56,76,103]. Nevertheless, the required number of grid points per wavelength was still large, particularly for long propagation distances. This has led to the introduction of pseudo-spectral schemes, "pseudo" because only the calculations of the derivatives where done in the spectral domain, but the wave equation was still solved in the space-time domain with a time-extrapolation scheme based on finite differences [10,45,47,67]). The advantage of the calculation of derivatives in the spectral domain is at hand: The Fourier theorem tells us that by multiplying the spectrum with ik, i being the imaginary unit and k the wavenumber, we obtain an *exact* derivative (exact to numerical precision) on a regular set of grid points. This sounds attractive. However, there are always two sides to the coin. The calculation requires FFTs to be carried out extensively and the original "local" scheme becomes a "global" scheme. This implies that the derivative at a particular point in the computational grid becomes dependent on any other point in the grid. This turns out to be computationally inefficient, in particular on parallel hardware. In addition, the Fourier approximations imply periodicity which makes the implementation of boundary conditions (like the free surface, or absorbing boundary conditions) difficult.

By replacing the basis functions (Fourier series) in the classical pseudo-spectral method with Chebyshev polynomials that are defined in a limited domain (−1,1) the problem with the implementation of boundary problems found an elegant solution (e. g., [66,107,108]). However, through the irregular spacing of the Chebyshev collocation points (grid densification at the domain boundaries, see section below) new problems arose with the consequence that this approach was not much further pursued except in combination with a multi-domain approach in which the field variables exchange their values at the domain boundaries (e. g., [108]).

So far, the numerical solutions described are all based on the *strong* form of the wave equation. The finite-element method is another main scheme that found immediate applications to wave propagation problems (e. g., [79]). Finite element schemes are based on solving the *weak* form of the wave equation. This implies that the space- and time-dependent fields are replaced by weighted sums of basis (also called trial) functions defined inside elements. The main advantage of finite element schemes is that elements can have arbitrary shape (e. g., triangular, trapezoidal, hexahedral, tetrahedral, etc.). Depending on the polynomial order chosen inside the elements the spatial accuracy can be as desired. The time-extrapolation schemes are usually based on standard finite differences. There are several reasons why finite-element schemes were less widely used in the field of wave propagation. First, in the process a large system matrix needs to be assembled and must be inverted. Matrix inversion in principle requires global communication and is therefore not optimal on parallel hardware. Second, in comparison with the finite-element method, finite- difference schemes are more easily coded and implemented due to their algorithmic simplicity.

A tremendous step forward was the introduction of basis functions inside the elements that have spectral accuracy, e. g., Chebyshev or Legendre polynomials [11,15,39,40,65,86,90,98]. The so-called spectral element scheme became particularly attractive with the discovery that – by using Legendre polynomials – the matrices that required inversion became diagonal [65]. This implies that the scheme does no longer need global communication, it is a local scheme in which extrapolation to the next time step can be naturally parallelized. With the extension of this scheme to spherical grids using the cubed-sphere discretization [63,64] this scheme is today the method of choice on many scales unless highly complex models need to be initiated.

Most numerical schemes for wave propagation problems were based on regular, regular stretched, or hexahedral grids. The numerical solution to unstructured grids had much less attention, despite the fact that highly complex models with large structural heterogeneities seem to be more readily described with unstructured point clouds. Attempts were made to apply finite volume schemes to this problem [31], and other concepts (like natural neighbor coordinates [7] to find numerical operators that are applicable on unstructured grids [72,73,78]). These approaches were unfortunately not accurate enough to be relevant for 3D problems. Recently, a new flavor of numerical method found application to wave propagation on triangular or tetrahedral grids. This combination of a discontinuous Galerkin method with ideas from finite volume schemes [33,70] allows for the first time arbitrary accuracy in space and time on unstructured grids. While the numerical solution on tetrahedral grids remains computationally slower, there is a tremendous advantage in generating computational grids for complex Earth models. Details on this novel scheme are given below.

Before presenting two schemes (spectral elements and the discontinuous Galerkin method) and some applications in more detail we want to review the evolution of grids used in wave propagation problems.

Grids for Wave Propagation Problems

The history of grid types used for problems in computational wave propagation is tightly linked to the evolution of numerical algorithms and available computational resources. The latter in the sense that – as motivated in the introduction – even today realistic simulations of wave propagation are still computationally expensive. This implies that it is not sufficient to apply stable and simple numerical schemes and just use enough grid points per wavelength and/or extremely fine grids for geometrically complex models. Optimal mathematical algorithms that minimize the computational effort are still sought for as the recent developments show that are outlined in the following sections.

In Fig. 4 a number of different computational grids in two space dimensions is illustrated. The simple-most equally-spaced regular finite-difference grid is only of practical use in situations without strong material discontinuities. With the introduction of the pseudospectral method based on Chebyshev polynomials grids as shown in Fig. 4a grids appeared that are denser near the domain boundaries and coarse in the interior. While this enabled a much more efficient implementation of boundary conditions the ratio between the size of the largest to the smallest cell depends on the overall number of grid points per dimension and can be very large. This leads to very small time steps, that can in some way be compensated by grid stretching [9] but overall the problem remains. An elegant way of allowing grids to be of more practical shape is by stretching the grids using analytical functions (Fig. 4c, this basically corresponds to a coordinate transformation, e. g., [50,107]). By doing this either smooth surface topography or smoothly varying internal interfaces can be followed by the grid allowing a more efficient simulation of geometrical features compared to a blocky representation on standard finite difference grids.

The problem of global wave propagation using spherical coordinates (here in the two-dimensional, axi-symmetric approximation) nicely illustrates the necessity to have spatially varying grid density (e. g., [42,43,53,59,89,109]). The grid shown in Fig. 4b demonstrates that in spherical coordinates a regular discretization leads to grid distances that get smaller and smaller towards the center of the Earth. This is in contrast to what is required to efficiently model the Earth's velocity structure: Velocities are small near the surface (requiring high grid density) and increase towards the center of the Earth (requiring low grid density). One way of adjusting is by re-gridding the mesh every now and then, in this case doubling the grid spacing appropriately. This is possible, yet it requires interpolation at the domain boundaries that slightly degrades the accuracy of the scheme.

The problems with grid density and complex surfaces cry for the use of so-called unstructured grids. Let us define an unstructured grid as an initial set of points (a point cloud), each point characterized by its spatial coordinates. We wish to solve our partial differential equations on this point set. It is clear that – with appropriate grid generation software – it is fairly easy to generate such grids that obey exactly any given geometrical constraints be it in connection with surfaces or velocity mod-

See text for details and references

els (i. e., varying grid density). It is important to note that such point clouds cannot be represented by 2D or 3D matrices as is the case for regular or regular stretched grid types. This has important consequences for the parallelization of numerical schemes. The first step after defining a point set is to use concepts from computational geometry to handle the previously unconnected points. This is done through the idea of Voronoi cells, that uniquely define triangles and their neighbors (Delauney triangulation). In Fig. 4d an example is shown for a triangular grid that follows an internal interface [72]. For finite-difference type operators on triangular grids a grid-staggering makes sense. Therefore, velocities would be defined in the center of triangles and stresses at the triangle vertices. Voronoi cells (Fig. 4e) can be used as volumetric elements for finite volume schemes [31,73]. For finite-element schemes triangular elements (Fig. 4f, e. g., [70]) with appropriate triangular shape functions are quite standard but have not found wide applications in seismology.

If the grid spacing of a regular finite-difference grid scheme in 3D would have to be halved this would result in an overall increase of computation time by a factor of 8 (a factor 2 per space dimension and another factor 2 because of the necessary halving of the time step). This simply means that the accuracy of a specific numerical scheme and the saving in memory or computation time is much more relevant in three dimensions. The evolution of grids in three dimensions is illustrated with examples in Fig. 5. A geometrical feature that needs to be modeled correctly particularly in volcanic environments is the free surface. With standard regular-spaced finite-difference schemes only a stair-step representation of the surface is possible (Fig. 5a, e. g., [87,92]). While the specific numerical implementation is stable and converges to the correct solution a tremendous number of grid points is necessary to achieve high accuracy.

Chebyshev grids and regular grids were applied to the problem of wave propagation in spherical sections (Fig. 5b, e. g., [52,57]). The advantage of solving the problem in spherical coordinates is the natural orthogonal coordinate system that facilitates the implementation of boundary conditions. However, due to the nature of spherical coordinates the physical domain should be close to the equator and geographical models have to be rotated accordingly. A highly successful concept for wave propagation in spherical media was possible through the adoption of the cubed-sphere approach in combination with spectral-elements (Fig. 5c, [63,64]). The cubed-sphere discretization is based on hexahedral grids. Towards the center of the Earth the grid spacing is altered to keep the number of elements per wavelength approximately constant.

See text for details and references

Computational grids for wave propagation based on tetrahedra (Fig. 5d,e) are only recently being used for seismic wave propagation in combination with appropriate numerical algorithms such as finite volumes [34] or discontinuous Galerkin (e. g., [70]). The main advantage is that the grid generation process is greatly facilitated when using tetrahedra compared to hexahedra. Generating point clouds that follow internal velocity structures and connecting them to tetrahedra are straight forward and efficient mathematical computations. However, as described in more detail below, tetrahedral grids require more involved computations and are thus less efficient than hexahedral grids. Complex hexahedral grids – even for combined modeling of structure and soil (Fig. 5f) are possible but – at least at present – require a large amount of manual interaction during the grid generation process. It is likely that the combination of both grid types (tetrahedral in complex regions, hexahedral in less complex regions) will play an important role in future developments.

In the following we would like to present two of the most competitive schemes presently under development, (1) the spectral element method and (2) the discontinuous Galerkin approach combined with finite-volume flux schemes. The aim is to particularly illustrate the role of the grid generation process and the pros and cons of the specific methodologies.

3D Wave Propagation on Hexahedral Grids: Soil-Structure Interactions

We briefly present the spectral element method (SEM) based on Lagrange polynomials, focusing only on its main features and on its implementation for the solution of the elasto-dynamic equations. The SEM can be regarded as a generalization of the finite element method (FEM) based on the use of high order piecewise polynomial functions. The crucial aspect of the method is the capability of providing an arbitrary increase in spatial accuracy simply enhancing the algebraic degree of these functions (the spectral degree SD). On practical ground, this operation is completely transparent to the users, who limit themselves to choosing the spectral degree at runtime, leaving to the computational code the task of building up suitable quadrature points for integration and new degrees of freedom. Obviously, the increasing spectral degree implies raising the required computational effort.

On the other hand, one can also play on the grid refinement to improve the accuracy of the numerical solution, thus following the standard finite element approach. Spectral elements are therefore a so-called "$h-p$" method, where "h" refers to the grid size and "p" to the degree of polynomials. Referring to Faccioli et al. [40], Komatitsch and Vilotte [65], Chaljub et al. [15] for further details, we briefly remind in the sequel the key features of the spectral element method adopted. We start from the wave equation for the displacement $\boldsymbol{u}$:

$$\rho \frac{\partial \boldsymbol{u}^2}{\partial t^2} = \operatorname{div} \sigma_{ij}(\boldsymbol{u}) + f\,, \quad i,j = 1 \ldots \mathrm{d}(\mathrm{d} = 2,3) \quad (2)$$

where t is the time, $\rho = \rho(x)$ the material density, $f = f(x,t)$ a known body force distribution and σ_{ij} the stress tensor. Introducing Hooke's law:

$$\sigma_{ij}(\boldsymbol{u}) = \lambda \operatorname{div} \boldsymbol{u} \delta_{ij} + 2\mu \varepsilon_{ij}(\boldsymbol{u})\,, \quad (3)$$

where

$$\varepsilon_{ij}(\boldsymbol{u}) = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \quad (4)$$

is the strain tensor, λ and μ are the Lamé coefficients, and δ_{ij} is the Kronecker symbol, i. e. $\delta_{ij} = 1$ if $i = j$ and $\delta_{ij} = 0$, otherwise.

As in the FEM approach, the dynamic equilibrium problem for the medium can be stated in the weak, or variational form, through the principle of virtual work [121] and through a suitable discretization procedure that depends on the numerical approach adopted, can be written as an ordinary differential equations system with respect to time:

$$[M]\,\ddot{\boldsymbol{U}}(t) + [K]\,\boldsymbol{U}(t) = \boldsymbol{F}(t) + \boldsymbol{T}(t) \quad (5)$$

with matrices $[M]$ and $[K]$, respectively the mass and stiffness matrices, and vectors $\boldsymbol{F}$ and $\boldsymbol{T}$ representing the contributions of external forces and traction conditions, respectively. In our SE approach, $\boldsymbol{U}$ denotes the displacement vector at the Gauss–Lobatto–Legendre (GLL) nodes, that correspond to the zeroes of the first derivatives of Legendre polynomial of degree N. The advancement of the numerical solution in time is provided by the explicit 2nd order leap-frog scheme. This scheme is conditionally stable and must satisfy the well known and already mentioned Courant–Friedrichs–Levy (CFL) condition. The key features of the SE discretization are described in the following.

Like in the FEM standard technique, the computational domain may be split into quadrilaterals in 2D or hexahedra in 3D, both the local distribution of grid points within the single element and the global mesh of all the grid points in the domain must be assigned. Many of these grid points are shared amongst several spectral elements. Each spectral element is obtained by a mapping of a master element through a suitable transformation and all computations are performed on the master element. Research is in progress regarding the introduction of triangular spectral elements [80]. The nodes within the element where displacements and spatial derivatives are computed, on which volume integrals are evaluated, are not necessarily equally spaced (similar to the Chebyshev approach in pseudospectral methods mentioned above). The interpolation of the solution within the element is done by Lagrange polynomials of suitable degree. The integration in space is done through Gauss–Lobatto–Legendre quadrature formula.

Thanks to this numerical strategy, the exponential accuracy of the method is ensured and the computational effort minimized, since the mass matrix results to be diagonal. The spectral element (SE) approach developed by Faccioli et al. [40] has been recently implemented in the computational code GeoELSE (GeoELasticity by Spectral Elements) [93,102,120] for 2D/3D wave propagation analysis. The most recent version of the code includes: (i) the capability of dealing with fully unstructured computational domains, (ii) the parallel architecture, and (iii) visco-plastic constitutive behavior [30]. The mesh can be created through an external software (e. g., CUBIT [25]) and the mesh partitioning is handled by METIS [81].

Hexahedral Grids

As already mentioned in the SEM here presented the computational domain is decomposed into a family of non overlapping quadrilaterals in 2D or hexahedra in 3D. The grid discretization should be suitable to accurately propagate up to certain frequencies. Obviously, owing to the strong difference of the mechanical properties between soft-soil and stiff-soil (or building construction material) and to the different geometrical details as well, the grid refinement needed in the various parts of the model varies substantially. Therefore, a highly unstructured mesh is needed to minimize the number of elements. While 3D unstructured tetrahedral meshes can be achieved quite easily with commercial or non commercial software, the creation of a 3D non structured hexahedra mesh is still recognized as a challenging problem. In the following paragraph we provide state of the art results concerning the mesh creation.

Grid Generation

Hexahedral grids have more severe restrictions in meshing efficiently. This is basically related to the intrinsic difficulty that arises from the mapping of the computational domain with this particular element. As a consequence automatic procedures have difficulty capturing specific boundaries, create poor quality elements, the assigned size is difficult to be preserved and the generation process is usually much slower compared to the tetrahedral mesh generation algo-

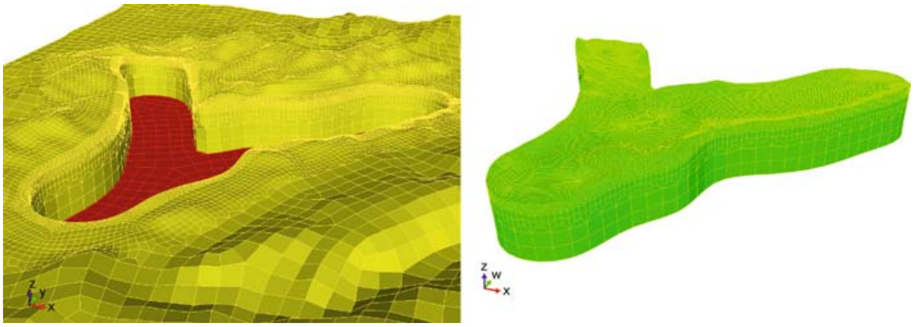
3D numerical model used for the simulations of ESG06 "Grenoble Benchmark". "Honoring" technique: The computational domain is subdivided into small chunks and each one is meshed starting from the alluvial basin down to the bedrock. For simplicity only the spectral elements are shown without GLL nodes



Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 7
3D numerical model used for the simulations of ESG06 "Grenoble Benchmark". "Not Honoring" technique: The computational domain is meshed with a coarse mesh and then refined twice approximately in the area where the alluvial basin is located

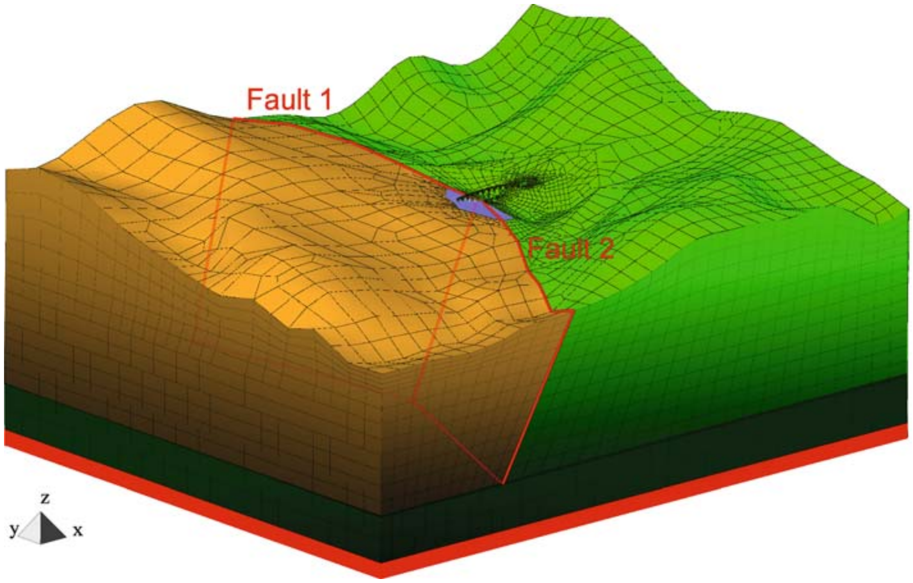
rithms. On the other hand the advantages of hexahedral meshes are usually related to the lower computational cost of the wave propagation solutions with respect to the one based on triangular meshes or hexahedral structured grids (like in the finite difference method).

Nevertheless certain problems can be addressed reasonably well with specific solutions. A quite typical case in earthquake seismology is the study of the alluvial basin response under seismic excitation. In handling this problem, a first strategy is to try to "honor" the interface between the sediment (soft soil) and the bedrock (stiff soil). The two materials are divided by a physical interface and the jump in the mechanical properties is strictly preserved. The major drawback of this approach is that usually it requires strong skills from the user to build-up the mesh and a significant amount of working time (Fig. 6). Given that the "honoring approach" is not always feasible in a reasonable time (or with a reasonable effort) a second strategy is worth to be mentioned: The so called "not honoring" procedure. In this second case the mesh is refined in proximity of the area where the soft deposit are localized but the elements do not respect the interface. On a practical ground the mechanical properties are assigned node by node and the sharp jump is smoothed through the Lagrange interpolation polynomial and substituted with smeared interfaces (Fig. 7). At the present time it is still strongly under debate if it is worth to honor or not the physical interfaces.

Finally, we highlight the fact that meshing software (e. g., CUBIT [25]) is available that seems to be extremely promising and potentially very powerful for the creation of geophysical and seismic engineering unstructured hexahedral meshes. Further very interesting mesh generation procedures based on hexahedral are under investigation [99].

Scale Problem with Structure and Soil

In engineering practice one of the most common approaches to design buildings under seismic load is the im-

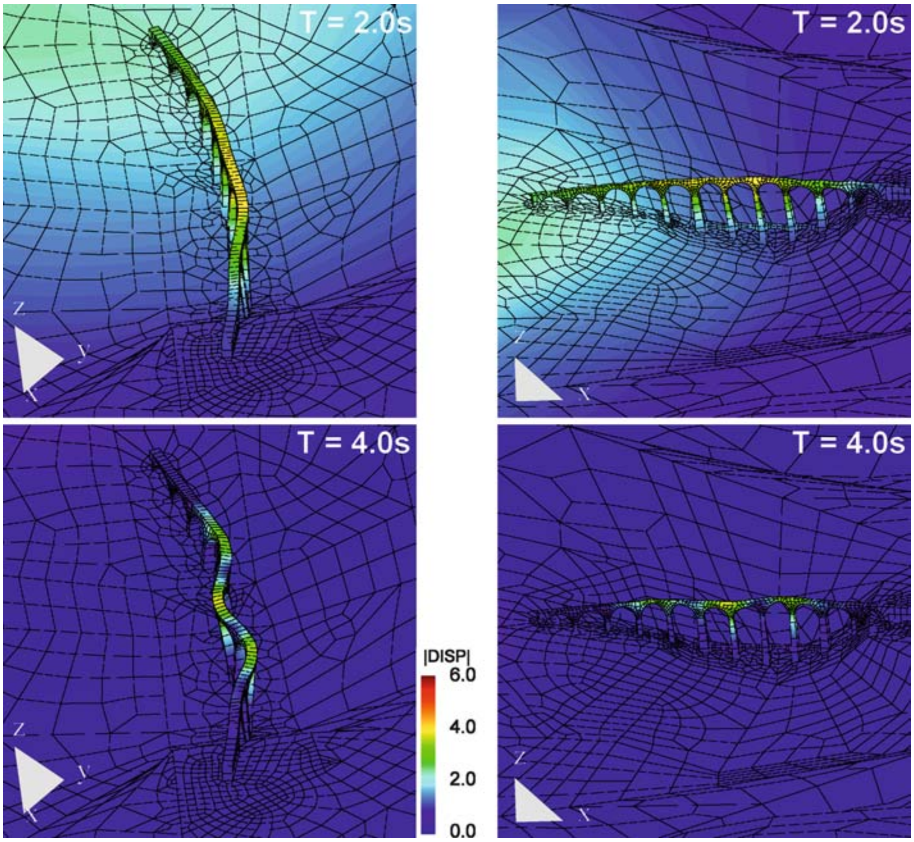


Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 8
3D model of Acquasanta bridge and the surrounding geological configuration. The investigated area is 2 km in length, 1.75 km in width and 0.86 km in depth. The model was designed to propagate waves up to 5 Hz with a SD = 3 (Order 4) and has 38,569 hexahedral elements and 1,075,276 grid points. The contact between calcareous schists (*brown color*) and serpentine rocks (*green color*) is modeled with two sub-vertical faults (*red-line*). *Cyan color* represents the alluvial and weathered deposits

position of an acceleration time history to the structure, basically acting like an external load. An excellent example of this technique can be found in recent publications (e. g., [68,69]) and in the study of the so-called "urban-seismology", recently presented by Fernandez-Ares et al., [44]. In this case the goal is to understand how the presence of an entire city can modify the incident wave-field. Due to the size of the simulation and the number of buildings, the latter are modeled as single degrees of freedom oscillators. The interaction between soil and structure is preserved but the buildings are simplified. For important structure (e. g.: Historical buildings, world heritage buildings, hospitals, schools, theaters, railway and highways) it is worth to provide an ad-hoc analysis capable to take into account the full complexity of the phenomena.

Here we present an example of a fully coupled modeling (Fig. 8): A railway bridge and its geotechnical-topographical surroundings. The Acquasanta bridge on the Genoa-Ovada railway, North Italy, is located in the Genoa district and represents a typical structure the ancestor of which can be traced back to the Roman "Pont du Gard". This structural type did not change significantly along the centuries, thanks to the excellent design achieved no less than 1900 years ago. The Acquasanta bridge structure is remarkable both for the site features and the local geological and geomorphological conditions. The foundations of several of the piers rest on weak rock; moreover, some instability problems have been detected in the past on the valley slope towards Ovada.

Several simulations have been performed with GeoELSE, in order to evaluate the influence of seismic site effects on the dynamic response of the Acquasanta bridge. A fully coupled 3D soil-structure model was designed: The grid is characterized by a "subvertical fault" between calcareous schists and serpentine rocks. This is in accordance with available data, even if further investigations in future should identify more in detail the tectonic structure of the area. The geometry of weathered materials overlaying the calcareous schists on the Ovada side has been assumed according to available information. The dimension of hexahedral elements ranges some tens of centimeters to about 1000 m. With such a model, the problem can be handled in its 3D complexity and we can examine the following aspects that are usually analyzed under restrictive and simplified assumptions: (i) soil-structure interaction, (ii) topographic amplification, (iii) soft soil amplification (caused by the superficial alluvium deposit shown in cyan), (iv) subvertical fault (red line) between the schists, on the Ovada side, and serpentine rock, on the Genoa side. For excitation a shear plane wave (x-direction) was used (Ricker wavelet, fmax = 3 Hz, $t0 = 1.0\,s$. and amplitude = 1 mm) propagating vertically from the bottom (red elements in Fig. 8).



Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 9
Snapshots of the modulus of the displacement vector and the magnified deformed shape of the bridge (in mm)

In Fig. 9 we present some snapshots of the modulus of the displacement vector and the magnified deformed shape of the bridge. It is worth to note that at $T = 2$ s the motion of the bridge is almost in-plane (direction x), while at $T = 4$ s is clearly evident how the coupling between the in-plane and out-plane (y-direction) motion starts to be important.

The study of the soil-structure interaction problem could be easily enhanced (i) improving the input excitation of the model here presented and (ii) taking into account complex constitutive behavior both from the soil and the structure side. The former is already available in GeoELSE thanks to the recent implementation [41,93] of the domain reduction method (DRM), a methodology that divides the original problem into two simpler ones [4,119], to overcome the problem of multiple physical scales that is created by a seismic source located some kilometers away from the structure with typical element size of the order of meters and located over a relatively small area (less than 1 km^2) on soft deposit. The latter still needs to be improved because of the lack of a complete tool capable to handle in 3D non linear soil behavior, non-linear structural behavior and the presence of the water, that play a crucial role in the failure of buildings. Partial response to this problem can be found in the recent work of Bonilla et al. [5] and in the visco-plastic rheology recently introduced in GeoELSE [30].

3D Wave Propagation on Tetrahedral Grids: Application to Volcanology

As indicated above, the simulation of a complete, highly accurate wave field in realistic media with complex geometry is still a great challenge. Therefore, in the last years a new, highly flexible and powerful simulation method has been developed that combines the Discontinuous Galerkin (DG) Method with a time integration method using Arbitrary high order DERivatives (ADER) of the approximation polynomials. The unique property of this numerical scheme is, that it achieves arbitrarily high approximation order for the solution of the governing seismic wave equation in space and time on structured and unstructured meshes in two and three space dimensions.

Originally, this new ADER-DG approach [32,35] was introduced for general linear hyperbolic equation systems with constant coefficients or for linear systems with variable coefficients in conservative form. Then, the extension to non-conservative systems with variable coefficients and source terms and its particular application to the simulation of seismic waves on unstructured triangular meshes in two space dimensions was presented [70]. And finally, the further extension of this approach to three-dimensional tetrahedral meshes has been achieved [33]. Furthermore, the accurate treatment of viscoelastic attenuation, anisotropy and poroelasticity has been included to handle more complex rheologies [28,29,71]. The governing system of the three-dimensional seismic wave equations is hereby formulated in velocity-stress and leads to the hyperbolic system of the form

$$\frac{\partial \boldsymbol{Q}_p}{\partial t} + A_{pq}\frac{\partial \boldsymbol{Q}_q}{\partial \xi} + B_{pq}\frac{\partial \boldsymbol{Q}_q}{\partial \eta} + C_{pq}\frac{\partial \boldsymbol{Q}_q}{\partial \zeta} = S_p \,, \qquad (6)$$

where the vector $\boldsymbol{Q}$ of unknowns contains the six stress and the three velocity components and S is the source term. The Jacobian matrices A, B and C include the material values as explained in detail in [33,70].

The ADER-DG Method: Basic Concepts

The ADER-DG method is based on the combination of the ADER time integration approach [113], originally developed in the finite volume (FV) framework [96,97,111] and the Discontinuous Galerkin finite element method [18,19,20,21,22,23,91]. As described in detail in [33] in the ADER-DG approach the solution is approximated inside each tetrahedron by a linear combination of space-dependent polynomial basis functions and time-dependent degrees of freedom as expressed through

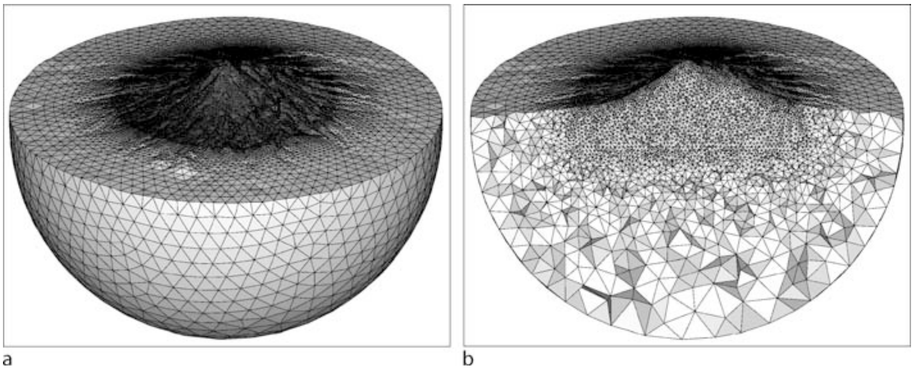
$$(\boldsymbol{Q}_h)_p(\xi,\eta,\zeta,t) = \hat{\boldsymbol{Q}}_{pl}(t)\boldsymbol{\Phi}_l(\xi,\eta,\zeta) \,, \qquad (7)$$

where the basis functions Φ_l form an orthogonal basis and are defined on the canonical reference tetrahedron. The unknown solution inside each element is then approximated by a polynomial, whose coefficients – the degrees of freedom $\hat{\boldsymbol{Q}}_{pl}$ – are advanced in time. Hereby, the solution can be discontinuous across the element interfaces, which allows the incorporation of the well-established ideas of numerical flux functions from the finite volume framework [75,112]. To define a suitable flux over the element surfaces, so-called Generalized Riemann Problems (GRP) are solved at the element interfaces. The GRP solution provides simultaneously a numerical flux function as well as a time-integration method. The main idea is a Taylor expansion in time in which all time derivatives are replaced by space derivatives using the so-called Cauchy–Kovalewski procedure which makes recursive use of the governing differential Eq. (6). The numerical solution of Eq. (6) can thus be advanced by one time step without intermediate stages as typical e. g. for classical Runge–Kutta time stepping schemes. Due to the ADER time integration technique the same approximation order in space and time is achieved automatically. Furthermore, the projection of the elements in physical space onto a canonical reference element allows for an efficient implementation, as many computations of three-dimensional integrals can be carried out analytically beforehand. Based on a numerical convergence analysis this new scheme provides arbitrary high order accuracy on unstructured meshes. Moreover, due to the choice of the basis functions in Eq. (7) for the piecewise polynomial approximation [23], the ADER-DG method shows even spectral convergence.

Grid Generation: Unstructured Triangulations and Tetrahedralization

Both tetrahedral and hexahedral elements are effectively used to discretize three-dimensional computational domains and model wave propagation with finite element type methods. Tetrahedra can be the right choice because of the robustness when meshing any general shape. Hexahedra can be the element of choice due to their ability to provide more efficiency and accuracy in the computational process. Furthermore, techniques for automatic mesh generation, gradual mesh refinement and coarsening are generally much more robust for tetrahedral meshes in comparison to hexahedral meshes. Straightforward tetrahedral refinement schemes, based on longest-edge division, as well as the extension to adaptive refinement or coarsening procedures of a refined mesh exist [3,12]. In addition, parallel strategies for refinement and coarsening of tetrahedral meshes have been developed [27].

Less attention has been given to the modification of hexahedral meshes. Methods using iterative octrees have been proposed [74,95], but these methods often result in nonconformal elements that cannot be accommodated by some solvers. Lately also conformal refinement and coarsening strategies for hexahedral meshes have been proposed [2]. Other techniques insert non-hexahedral elements that result in hybrid meshes that need special solvers that can handle different mesh topologies. Commonly, the geometrical problems in geosciences arise through rough surface topography, as shown for the Mer-



Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 10
Tetrahedral mesh for the model of the volcano Merapi. The zone of interest, such as the free surface topography and the volcano's interior are discretized by a fine mesh, whereas the spatial mesh is gradually coarsened towards the model boundaries

api volcano in Fig. 10, and internal material boundaries of complex shape that lead to wedges and overturned or discontinuous surfaces due to folding and faulting. However, once the geometry of the problem is defined by the help of modern computer aided design (CAD) software, the meshing process using tetrahedral elements is automatic and stable. After the mesh generation process, the mesh vertices, the connectivity matrix and particular information about boundary surfaces are typically imported to a solver.

The computational possibilities and algorithmic flexibility of a particular solver using the ADER-DG approach for tetrahedral meshes are presented in the following.

Local Accuracy: *p*-Adaptation

In many large scale applications the computational domain is much larger than the particular zone of interest. Often such an enlarged domain is chosen to avoid effects from the boundaries that can pollute the seismic wave field with possible, spurious reflections. Therefore, a greater number of elements has to be used to discretize the domain describing the entire model. However, in most cases the high order accuracy is only required in a restricted area of the computational domain and it is desirable to choose the accuracy that locally varies in space. This means, that it must be possible to vary the degree *p* of the approximation polynomials locally from one element to the other [36]. As the ADER-DG method uses a hierarchical order of the basis functions to construct the approximation polynomials, the corresponding polynomial coefficients, i. e. the degrees of freedom, for a lower order polynomial are always a subset of those of a higher-order one. Therefore, the computation of fluxes between elements of different approximation orders can be carried out by using only the necessary part of the flux matrices.

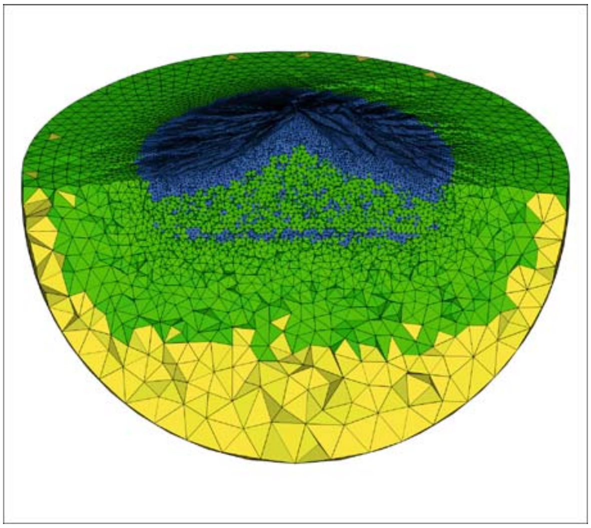
Furthermore, the direct coupling of the time and space accuracy via the ADER approach automatically leads to a local adaptation also in time accuracy, which often is referred to as p_t-adaptivity. In general, the distribution of the degree *p* might be connected to the mesh size *h*, i. e. the radius of the inscribed sphere of a tetrahedral element. In particular, the local degree *p* can be coupled to the mesh size *h* via the relations

$$p = p_{\min} + (p_{\max} - p_{\min}) \left(\frac{h - h_{\min}}{h_{\max} - h_{\min}} \right)^r , \qquad (8)$$

$$p = p_{\max} - (p_{\max} - p_{\min}) \left(\frac{h - h_{\min}}{h_{\max} - h_{\min}} \right)^r , \qquad (9)$$

where the choice of the power *r* determines the shape of the *p*-distribution. Note, that depending on the choice of the first term and the sign the degree *p* can increase as in Eq. (8) or decrease as in Eq. (9) with increasing *h*, starting from a minimum degree $p_{\min}$ up to a maximum degree $p_{\max}$. This provides additional flexibility for the distribution of *p* inside the computational domain. An example of a *p*-distribution for the volcano Merapi is given in Fig. 11.

Here the idea is to resolve the slowly propagating surface waves with high accuracy, whereas the waves propagating towards the absorbing model boundaries pass through a zone of low spatial resolution. This approach leads to numerical damping due to an amplitude decay that reduces possible boundary reflections. Furthermore, the computational cost is reduced significantly due to the strongly reduced number of total degrees of freedom in the model.



Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 11

The local degree p of the approximation polynomial depends on the insphere radius of each tetrahedral element and is given in color code. Close to the surface topography an approximation polynomial of degree $p = 5$ (*blue*) is used, whereas in depth the degree is reduced to $p = 4$ (*green*) and $p = 3$ (*yellow*)

Local Time Stepping: Δt-Adaptation

Geometrically complex computational domains or spatial resolution requirements often lead to meshes with small or even degenerate elements. Therefore, the time step for explicit numerical schemes is restricted by the ratio of the size h of the smallest element and the corresponding maximum wave speed in this element. For global time stepping schemes all elements are updated with this extremely restrictive time step length leading to a large amount of iterations. With the ADER-DG approach, time accurate local time stepping can be used, such that each element is updated by its own, optimal time step [36]. Local time-stepping was used in combination with the finite-difference method [42,106].

An element can be updated to the next time level if its actual time level and its local time step Δt fulfill the following condition with respect to all neighboring tetrahedra n:

$$t + \Delta t \leq \min(t_n + \Delta t_n) \, . \qquad (10)$$

Figure 12 is visualizing the evolution of four elements (I, II, III and IV) in time using the suggested local time stepping scheme. A loop cycles over all elements and checks for each element, if condition (10) is fulfilled. At the initial state all elements are at the same time level, however, element II and IV fulfill condition (10) and therefore can be updated. In the next cycle, these elements are already advanced in time (grey shaded) in cycle 1. Now elements I and IV fulfill condition (10) and can be updated to their next local time level in cycle 2. This procedure continues and it is obvious, that the small element IV has to be updated more frequently than the others. A synchronization to a common global time level is only necessary, when data output at a particular time level is required as shown in Fig. 12.

Information exchange between elements across interfaces appears when numerical fluxes are calculated. These fluxes depend on the length of the local time interval over which a flux is integrated and the corresponding element is evolved in time. Therefore, when the update criterion (10) is fulfilled for an element, the flux between the element itself and its neighbor n has to be computed over the local time interval:

$$\tau n = [\max(t, tn) \, , \quad \min(t + \Delta t, tn + \Delta tn)] \, . \qquad (11)$$

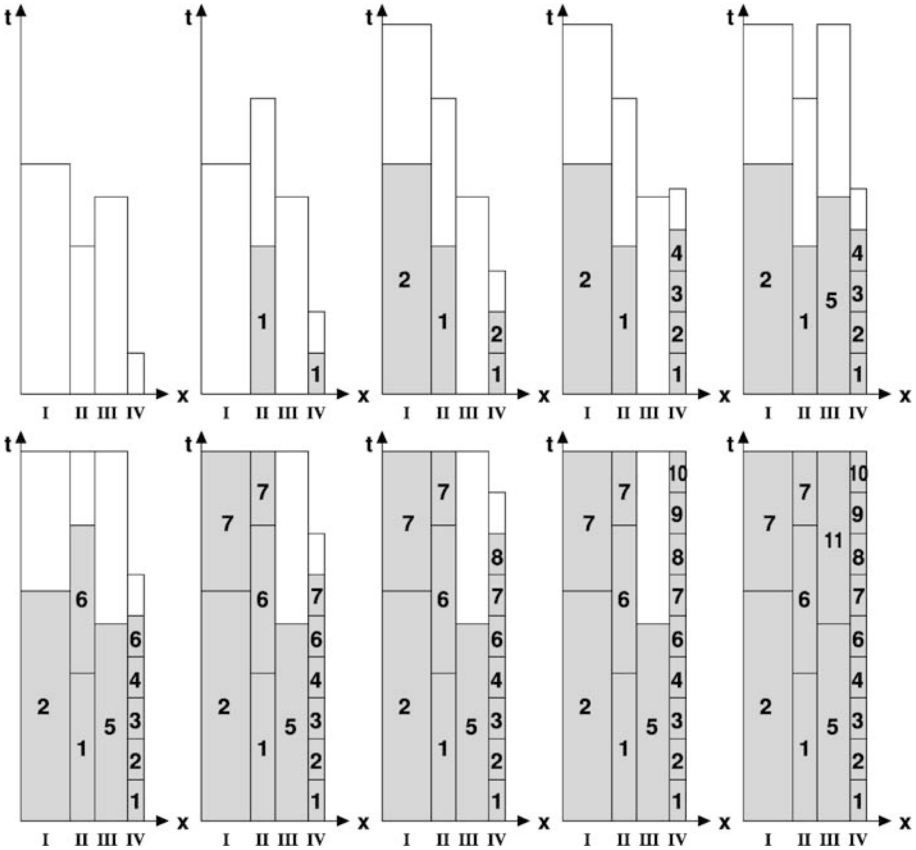
As example, the element III fulfills the update criterion (10) in cycle 5 (see Fig. 12). Therefore, when computing the fluxes only the remaining part of the flux given by the intervals in Eq. (11) has to be calculated. The other flux contribution was already computed by the neighbors II and IV during their previous local updates. These flux contributions have been accumulated and were stored into a memory variable and therefore just have to be added.

Note that e. g. element IV reaches the output time after 10 cycles and 9 local updates, which for a global time stepping scheme would require $9 \times 4 = 36$ updates for the all four elements. With the proposed local time stepping scheme only 16 updates are necessary to reach the same output time with all elements as indicated by the final number of grey shaded space time elements in Fig. 12.

Comparing these numbers leads to a speedup factor of 2.25. For strongly heterogeneous models and local time step lengths this factor can become even more pronounced. However, due to the asynchronous update of elements that might be spatially very close to each other the mesh partitioning for parallel computations becomes an important and difficult issue. Achieving a satisfying load balancing is a non-trivial task and still poses some unresolved problems as explained in the following.

Mesh Partitioning and Load Balancing

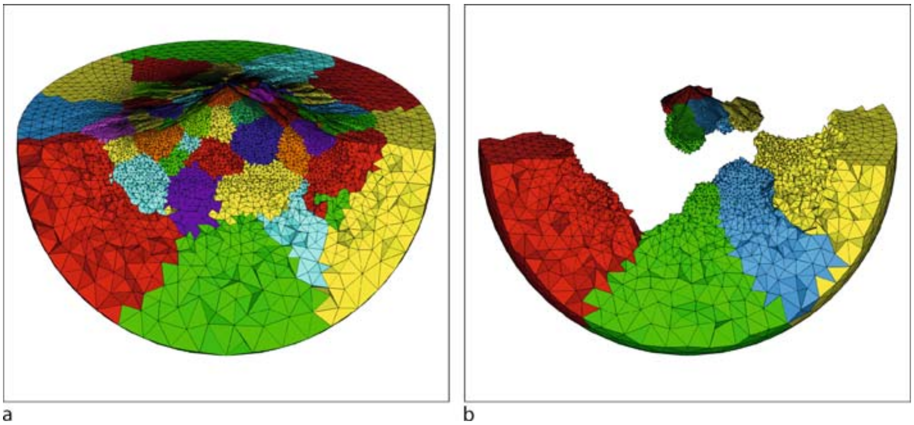
For large scale applications it is essential to design a parallel code that can be run on massively parallel supercomputing facilities. Therefore, the load balancing is an important issue to use the available computational resources efficiently. For global time stepping schemes with-



Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 12
Visualization of the local time stepping scheme. The actual local time level *t* is at the top of the *gray shaded* area with numbers indicating the cycle, in which the update was done. *Dotted lines* indicate the local time step length Δ*t* with which an element is updated

out p-adaptation standard mesh partitioning as done e. g. by METIS [60] is sufficient to get satisfying load balancing. The unstructured tetrahedral mesh is partitioned into subdomains that contain an equal or at least very similar number of elements as shown in Fig. 13. Therefore, each processor has to carry out a similar amount of calculations. However, if p-adaptation is applied, the partitioning is more sophisticated as one subdomain might have many elements of high order polynomials whereas another might have the same number of elements but with lower order polynomials. Therefore, the parallel efficiency is restricted by the processor with the highest work load. However, this problem can usually be solved by weighted partitioning algorithms, e. g. METIS.

In the case of local time stepping, mesh partitioning is becoming a much more difficult task. One solution is to divide the computational domain into a number of zones, that usually contain a geometrical body or a geological zone that typically is meshed individually with a particular mesh spacing h and contains a dominant polynomial order. Then each of these zones is partitioned separately into subdomains of approximately equal numbers of elements. Then each processor receives a subdomain of each zone, which requires a similar amount of computational work as shown in Fig. 13. In particular, the equal distribution of tetraheda with different sizes is essential in combination with the local time stepping technique. Only if each processor receives subdomains with a similar amount of small and large elements, the work load is balanced. The large elements have to be updated less frequently than the smaller elements and therefore are computationally cheaper. Note, that the separately partitioned and afterwards merged zones lead to non-connected subdomains for each processor (see Fig. 13). This increases the number of element surfaces between subdomains of different processors and therefore increases the communication required. However, communication is typically low as the degrees of freedom have to be exchanged only once per



Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 13
Standard partitioning of the computational domain (*left*) and an example of 4 subdomains grouped together for more efficient local time stepping

time step and only for tetrahedra that have an interface at the boundary between subdomains. Therefore, the improvements due to the new load balancing approach are dominant and outweigh the increase in communication.

However, care has to be taken as the distribution of the polynomial degree *p* or the seismic velocity structure might influence the efficiency of this grouped partitioning technique. A profound and thorough mesh partitioning method is still a pending task as the combination of local time stepping and *p*-adaptivity requires a new weighting strategy of the computational cost for each tetrahedral element considering also the asynchronous element update. The automatic partitioning of unstructured meshes with such heterogeneous properties together with the constraint of keeping the subdomains as compact as possible to avoid further increase of communication is still subject to future work.

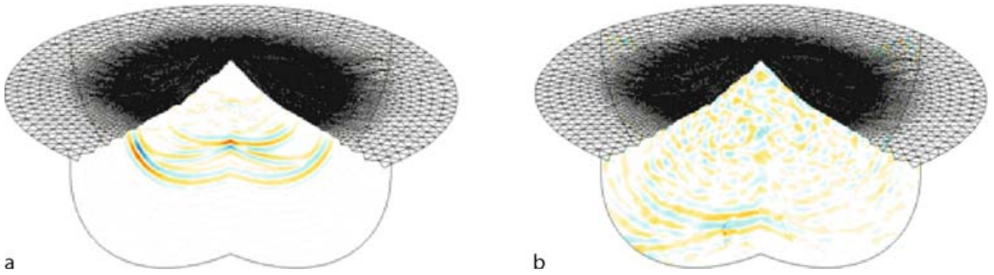
In Fig. 13 an example of a grouped partition of the tetrahedral mesh is shown for 4 processors. Two non-connected subdomains indicated by the same color are assigned to each processor including small – and therefore computationally expensive – tetrahedra that are updated frequently due to their small time step, and much larger elements that typically are cheap due to their large time step. This way, the work load often is balanced sufficiently well over the different processors.

Relevance of High Performance Computing: Application to Merapi Volcano

In recent years the development of the ADER-DG algorithm including the high order numerical approximation in space and time, the mesh generation, mesh adaptation, parameterization, and data visualization created the basis of an efficient and highly accurate seismic simulation tool. Realistic large scale applications and their specific requirements will further guide these developments. On the other hand, the study and incorporation of geophysical processes that govern seismic wave propagation insures, that the simulation technology matches the needs and addresses latest challenges in modern computational seismology. Hereby, the accurate modeling of different source mechanisms as well as the correct treatment of realistic material properties like anelasticity, viscoplasticity, porosity and highly heterogeneous, scattering media will play an important role.

However, only the combination of this state-of-the-art simulation technology with the most powerful supercomputing facilities actually available can provide excellent conditions to achieve scientific progress for realistic, large scale applications. This combination of modern technologies will substantially contribute to resolve current problems, not only in numerical seismology, but will also influence other disciplines. The phenomenon of acoustic, elastic or seismic wave propagation is encountered in many different fields. Beginning with the classical geophysical sciences seismology, oceanography, and volcanology such waves also appear in environmental geophysics, atmospheric physics, fluid dynamics, exploration geophysics, aerospace engineering or even medicine.

With the rapid development of modern computer technology and the development of new highly accurate simulation algorithms computer modeling just started to herald a new era in many applied sciences. The 3D wave propagation simulations in realistic media require a substantial amount of computation time even on large par-



Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 14
Snapshots of the seismic wave field after an explosive event close to the summit of Merapi volcano. The free surface topography introduces strong scattering of the waves making it extremely difficult to invert for the seismic source mechanism or the exact source location

allel computers. Extremely powerful national supercomputers already allow us to run simulations with unrivaled accuracy and resolution. However, using the extremely high accuracy and flexibility of new simulation methods on such massively parallel machines the professional support of experts in supercomputing is absolutely essential. Only professional porting, specific CPU-time and storage optimizations of current software with respect to continuously changing compilers, operating systems, hardware architectures or simply personnel, will ensure the lifetime of new simulation technologies accompanied by ongoing improvements and further developments. Additionally, the expertise and support in the visualization of scientific results using technologies of Virtual Reality for full 3D models not only enhances the value of simulation results but will support data interpretation and awake great interest in the new technology within a wide research community.

As an example, volcano monitoring plays an increasingly important role in hazard estimation in many densely populated areas in the world. Highly accurate computer modeling today is a key issue to understand the processes and driving forces that can lead to dome building, eruptions or pyroclastic flows. However, data of seismic observations at volcanoes are often very difficult to interpret. Inverting for the source mechanism, i. e. seismic moment tensor inversion, or just locating an exact source position is often impossible due to the strongly scattered wave field caused by an extremely heterogeneous material distribution inside the volcano. Furthermore, the rough topography alone can affect the wave field by its strongly scattering properties as shown in Fig. 14.

Therefore, it is fundamental to understand the effects of topography and scattering media and there influence on the seismic wave field. A systematic study of a large number of scenarios computed by highly accurate simulation methods to provide reliable synthetic data sets is necessary to test the capabilities of currently used inversion tools. Slight changes in parameters like the source position, the source mechanism or the elastic and geometric properties of the medium can then reveal the limits of such tools and provide more precise bounds of their applicability in volcano seismology.

Finally, the implementation of the ADER-DG method is still much more expensive than other state-of-the-art implementations of existing methods. However, a fair comparison between accuracy and computational cost is still a pending task. The main reason for the CPU-time difference is the much larger number of tetrahedral elements than hexahedra that have to be used to cover the same volume. Furthermore, due to the choice of the basis functions, the flux computations are expensive, as the matrix-matrix multiplications involved are not sparse.

However, the ADER-DG method is currently implemented on hexahedral meshes to make fair comparisons possible. Preliminary tests show, that the change of mesh topology from tetrahera to hexahedra significantly reduces the computational cost. However, final results are subject to future investigations.

Discussion and Future Directions

As indicated in the introduction and highlighted in the previous sections, computational tools for wave propagation problems are getting increasingly sophisticated to meet the needs of current scientific problems. We are far away from simple finite-difference time schemes that are solving problems on regular grids on serial computers in which case the particular programming approach did not affect dramatically the overall performance. Today, competitive algorithms are results of years of partly highly professional coding. Implementations on high-performance computing hardware requires in-depth knowledge of parallel algorithms, profiling, and many technical aspects of modern computations. To make complex scientific software available to other researchers requires implementation and testing on many different (parallel) platforms. This may involve parallelization using different programming paradigms (e. g., the combination of OpenMP and MPI on nodes of shared memory machines), and interoperability on heterogeneous computational GRIDs.

This has dramatic consequences particularly for young researchers in the Earth Sciences who want to use advanced computational tools to model observations. While in the early days a finite-difference type algorithm could be understood, coded, implemented and tested in a few weeks, this is no longer possible. In addition, standard curricula do not offer training in computational methods allowing them to efficiently write and test codes. This suggests that at least for some, well-defined computational problems verified and professionally engineered scientific software solutions should be provided to the community and also professionally extended and maintained in close collaboration with scientists. In seismology we are in a quite fortunate situation. In contrast to many other fields of physical sciences, our constitutive relations (e. g., stress-strain) are fairly well understood, and – as indicated in this paper – numerical solutions for 3D problems and their implementation on parallel hardware are well advanced. Another argument for stable tested "community"-codes for wave propagation is the fact that advancement in many scientific problems (e. g., imaging the Earth's interior, quantifying earthquake-induced shaking hazard) relies on zillions of forward modeling runs with only slight variations of the internal velocity models.

As far as technical developments are concerned, the efficient initialization of complex 3D models on computational grids is still a great challenge. Realistic models may be composed of complex topography, families of overlapping fault surfaces, discontinuous interfaces, and varying rheologies (e. g., elastic, anisotropic, viscoelastic, viscoplastic, porous). This may require the combination of tetrahedral and hexahedral grid in models with strongly varying degree of complexity. Ideally, standards for Earth models (and synthetic data) formats should be established by the communities that allow easy exchange and multiple use of models with different simulation tools (e. g., wave propagation, deformation, earthquake rupture). In addition, the rapid developments towards PetaFlop computing opens new questions about the scalability and efficient parallelization of current and future algorithms.

As the forward problem of wave propagation is at the core of the seismic imaging problem for both source and Earth's structure, in the near future we will see the incorporation of 3D simulation technology into the imaging process. Provided that the background seismic velocity models are fairly well known (e. g., reservoirs, global Earth, sedimentary basins), adjoint methods provide a powerful analytical tool to (1) relate model deficiencies to misfit in observations and (2) quantify the sensitivities to specific aspects of the observations (e. g., [100,104,105]). As the core of the adjoint calculations is the seismic forward problem, the challenge is the actual application to real data and the appropriate parametrizations of the model and the data that optimize the data fitting process.

In summary, while we look back at (and forward to) exciting developments in computational seismology, a paradigm shift in the conception of one of the central tools of seismology – the calculation of 3D synthetic seismograms – is necessary. To extract a maximum amount of information from our high-quality observations scientists should have access to high-quality simulation tools. It is time to accept that "*software is infrastructure*" and provide the means to professionally develop and maintain community codes and model libraries at least for basic Earth science problems and specific focus regions. Developments are one the way along those lines in the SPICE project (Seismic Wave Propagation and Imaging in Complex Media, a European Network [101]), the Southern California Earthquake Center (SCEC [94]) and the CIG Project (Computational infrastructure in geodynamics [17]).

Acknowledgments

We would like to acknowledge partial support towards this research from: The European Human Resources and Mobility Program (SPICE-Network), the German Research Foundation (Emmy Noether-Programme), the Bavarian Government (KOHNWIHR, graduate college THESIS, BaCaTec), and MunichRe. We would also like to thank J. Tromp supporting MS's visit to CalTech. We also thank two anonymous reviewers for constructive comments on the manuscript.

Article Outline

Glossary

Attenuation factor Q^{-1} A measure of attenuation characteristics of a medium caused by intrinsic absorption and scattering loss. The former means the transfer of vibration energy into heat and the latter means the transfer of vibration energy from the direct wave to coda waves caused by scattering due to medium heterogeneity.

Coda waves Wave trains that follow the arrival of the direct S-wave phase are called S-coda waves or simply coda waves. Coda waves are interpreted as a superposition of S waves scattered by distributed heterogeneities. Wave trains between direct P and S wave arrivals are called P-coda waves.

Coda attenuation factor Q_C^{-1} This parameter characterizes the amplitude decay of S coda of a local earthquake with the lapse time increasing based on the S-to-S single scattering. The coda duration shortens for a larger coda attenuation factor.

Envelope broadening The source duration time of a microearthquake is short; however, the apparent duration time of the S-wave seismogram increases with the travel distance increasing because of diffraction and scattering by medium heterogeneities. This phenomenon is called envelope broadening.

Radiative transfer theory A phenomenological theory that describes scattering process of wave energy in a scattering medium on the basis of causality, geometrical spreading and the energy conservation. It neglects the interference of waves but focuses on the intensity only. This theory admits various types of scattering patterns. It is often applied to model the energy propagation of high-frequency seismic-waves in heterogeneous Earth media.

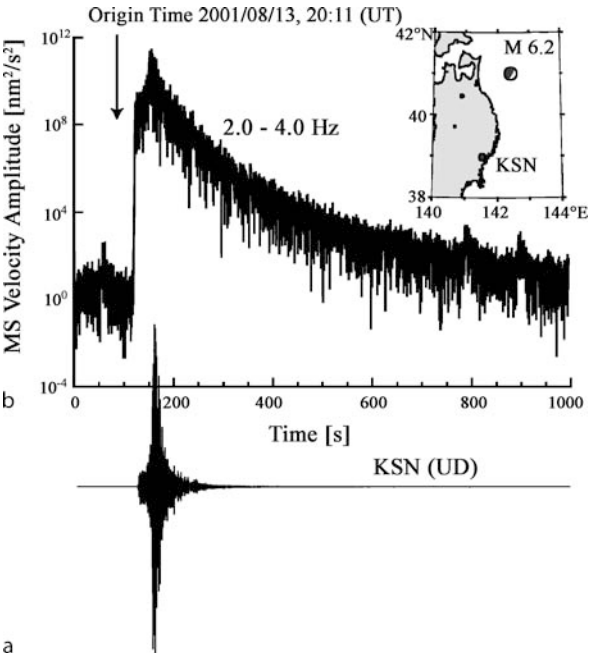
Random media A mathematical model for media whose parameters are described by random functions of space coordinates. The stochastic properties of the ensemble of random media are characterized by their autocorrelation function or the power spectral density function.

Scattering coefficient g A measure of the scattering power in a unit solid angle at a certain direction by a unit volume of heterogeneous media for the incidence of unit energy flux density. The average of g over the solid angle gives the total scattering coefficient g_0, of which the reciprocal gives the mean free path. This quantity characterizes the coda excitation and the scattering loss in the heterogeneous media.

Definition of the Subject

The structure of the solid Earth was extensively studied by using seismic waves such as travel time analysis based on Snell's law, dispersion analysis of surface waves, and spectral analysis of free oscillation, where the notion of a horizontally stratified structure or a spherical shell structure prevailed among the geophysical community. This means the acceptance of the dominance of gravity in geodynamic process. Velocity tomography revealed that the solid Earth structure is three-dimensionally inhomogeneous with various ranges of scales; however, the resolution of velocity tomography is much coarser than the wavelength of seismic waves. In 1970s, the existence of distributed inhomogeneities having the order of the wavelength of seismic waves was recognized from the observation of coda waves of local earthquakes, which are long-lasting wave trains following the direct S-wave arrival in high-frequency seismograms. Here, we use "high-frequency" for frequency higher than about 1 Hz. The long duration time of coda waves can be interpreted as a direct evidence of wide-angle scattering caused by distributed small-scale heterogeneities since the source duration time is generally very short. S-wave seismograms of microearthquakes show broadened envelopes with travel distance increasing. This envelope broadening phenomenon is also an evidence of scattering around the forward direction due to random velocity inhomogeneities.

Since then, focusing on the frequency dependence of seismogram envelopes, geophysicists have extensively studied the scattering process of high-frequency seismic waves in relation to the spectral structure of velocity inhomogeneities, where the statistical characterization of the medium inhomogeneity is inevitable. The radiative transfer theory and the stochastic Markov approximation have been developed as mathematical tools for the analyzes of seismogram envelopes. The strength of scattering and/or the spectral structure of random inhomogeneity have been measured in various regions of the solid Earth. The scattering approach is found to be also useful for detecting temporal changes in the crustal medium associated with earthquake occurrences. Thus, scattering of high-frequency seismic waves in the heterogeneous Earth medium is important for understanding the physical structure and the geodynamic process reflecting the evolution of the solid Earth.



Seismic Waves in Heterogeneous Earth, Scattering of, Figure 1
a Seismogram of a local earthquake of M 6.2 in northeastern Honshu, Japan recorded by F-net, NIED. b Bandpass-filtered MS envelope (Courtesy of T. Maeda)

Introduction

Coda Waves

The high-frequency seismogram of a local earthquake has a long tail after the direct S-coda arrival. The tail portion of seismogram is called “S-coda waves” or simply “coda”. As an example, Fig. 1a and b show the raw seismogram and the band-pass filtered mean square (MS) trace of an earthquake of magnitude (M) 6.1, respectively. We note that the mean square wave envelope, which is the running mean of the squared trace with characteristic time of a few times the center period, is proportional to the time trace of the wave energy density. The coda wave oscillation lasts more than several hundreds of seconds. The duration of coda waves measured from the P-wave onset until when the coda amplitude decreases to the microseism’s level has been used as a quick measure of the earthquake magnitude from a single station observation since the 1960s. Having a motivation to extract the source spectrum of a large earthquake from clipped seismograms, Aki [1] first studied the characteristics of coda waves as scattered waves. Coda envelopes of a local earthquake have a smoothly decaying common curve with lapse time increasing irrespective of epicentral distances and the source radiation pattern. Aki and Chouet [4] interpreted coda waves as single back-scattered S-waves due to heterogeneities randomly distributed in the lithosphere. Their model based on the radar equation for the same location of a source and a receiver can be written as follows.

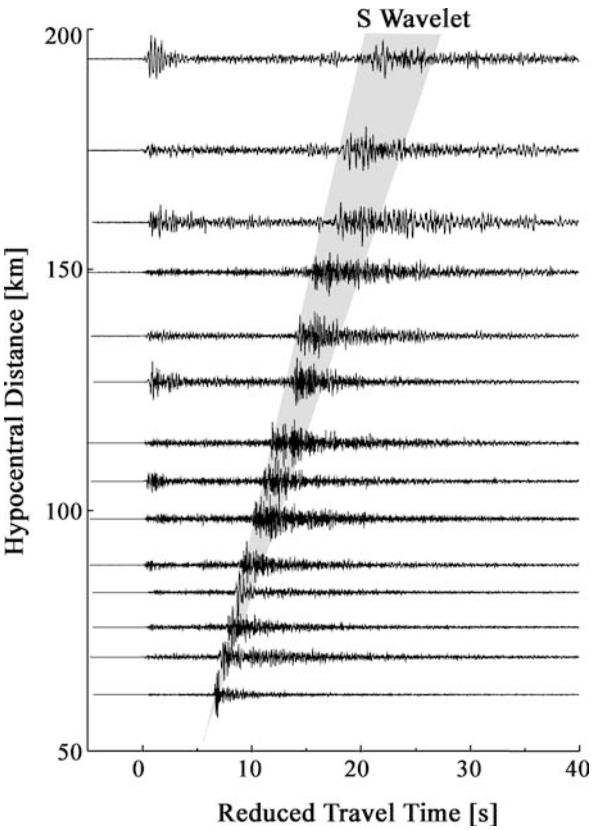
Point-like isotropic scatterers characterized by total scattering cross-section σ_0 are randomly and homogeneously distributed with number density n in a 3-D medium with background wave velocity V_0. The scattering power per unit volume is characterized by the total scattering coefficient $g_0 = n\sigma_0$, of which the reciprocal gives the mean free path. When the total wave energy W is impulsively radiated from a point source at time $t = 0$, the wave energy density of singly back-scattered waves at the source location is written as

$$E^{\mathrm{SB}}(t) \approx \frac{W g_0}{2\pi V_0^2 t^2} \mathrm{e}^{-Q_{\mathrm{C}}^{-1} 2\pi f t} \tag{1}$$

since the interference of scattered waves can be neglected because of the random distribution of scatterers. The inverse square of lapse time means geometrical spreading in a 3-D space. Here, an exponential damping term with coda attenuation factor Q_{C}^{-1} is introduced to represent phenomenological attenuation effect. This simple formula has been widely used for measurements of g_0 and Q_{C}^{-1} for S-waves in the world since the 1980s. Reported g_0-values are of the order of 0.01 km^{-1} for 1–30 Hz and Q_C^{-1} values are about 10^{-2} at 1 Hz and decrease to about 10^{-3} at 20 Hz in the lithosphere [74].

Envelope Broadening of S-Seismogram

There is another evidence of scattering due to random inhomogeneity in high-frequency seismograms. Observed S-seismograms of a microearthquake have broadened envelopes around their peaks after the direct arrivals. As shown by an example in Fig. 2, the apparent duration time of the S-seismogram just after the direct S-arrival increases with increasing travel distance. It is more than ten seconds at distances larger than 100 km, where the source duration time is less than one second for an earthquake of M 4.0. Sato [70] called this phenomenon observed in an island arc as "envelope broadening", and Atkinson [6] reported similar phenomenon in a continent. For P-waves of teleseismic events, broadening of the vertical component envelope [35] and the excitation in the transverse component amplitude [52] have been used as a measure of lithospheric heterogeneity. These phenomena can be interpreted by multiple scattering within a narrow angle around the global ray direction due to random velocity inhomogeneities. When the wavelength is much shorter than the characteristic scale of the random velocity inhomogeneity, the scattering process of waves can be represented by successive ray bending processes, where scattering angles are statistically controlled by the spectrum of random velocity inhomogeneity. At a given distance from the source, a small number of rays with large scattering angles arrive long after the direct ray.



Seismic Waves in Heterogeneous Earth, Scattering of, Figure 2
Envelope broadening shown in horizontal component seismograms of a microearthquake with M 4.0 in Japan recorded by Hi-net, NIED, where the abscissa is reduced travel time with move-out velocity 7 km/s (Courtesy of T. Takahashi)

Radiative Transfer Theory for a Scattering Medium

Radiative Transfer Integral Equation for the Isotropic Scattering Process

Disregarding wave interference and focusing on wave power, the radiative transfer theory [8] treats the propagation of wave energy in a scattering medium. Wu [85] first introduced the radiative transfer theory for the stationary state in the synthesis of seismogram envelopes. The non-stationary multiple isotropic scattering process in 1-D was solved by Hemmer [24] and that in 2-D was solved by Shang and Gao [77]. Later, Zeng et al. [92] formulated the time-dependent multiple isotropic scattering process in 3-D as an extension of the single backscattering model [4] as follows.

In a 3-D scattering medium characterized by background velocity V_0 and total scattering coefficient g_0, when the total wave energy W is impulsively radiated isotropically from a source at the origin, the multiple isotropic scattering process is written by the following integral equation for energy density:

$$E(\mathbf{x},t) = WG_E(\mathbf{x},t) + g_0 V_0 \cdot \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} G_E\left(\mathbf{x}-\mathbf{x}', t-t'\right) E\left(\mathbf{x}', t'\right) \mathrm{d}\mathbf{x}'\mathrm{d}t' , \tag{2}$$

where the convolution integral in the second term means the propagation of energy from the last scattering point $\mathbf{x}'$ to a receiver at $\mathbf{x}$. The first term is the ballistic term that means the direct propagation of energy from the source with scattering loss, $G_E(\mathbf{x},t) = \delta(t - r/V_0)\exp(-g_0 V_0 t)/(4\pi V_0 r^2)$, where $r = |\mathbf{x}|$. The solution is written as [92]

$$
\begin{aligned}
E(\mathbf{x}, t) = {} & W G_{\mathrm{E}}(\mathbf{x}, t) + \frac{W g_0 \mathrm{e}^{-g_0 V_0 t}}{4\pi r^2}\frac{r}{V_0 t} \\
& \cdot \ln\left[\frac{V_0 t + r}{V_0 t - r}\right] H\left(t - \frac{r}{V_0}\right) \\
& + W g_0^2 V_0^2 \frac{1}{(2\pi)^2} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mathrm{d}\omega \mathrm{d}k \, \mathrm{e}^{-i\omega t - ikr} \\
& \cdot \frac{ik}{2\pi r}\frac{\bar{\bar{G}}_{\mathrm{E}}(-k, -i\omega)^3}{1 - g_0 V_0 \bar{\bar{G}}_{\mathrm{E}}(-k, -i\omega)} ,
\end{aligned}
\tag{3}
$$

where $\bar{\bar{G}}_{\mathrm{E}}(k, s) = (1/k V_0)\tan^{-1} k V_0/\left(s + g_0 V_0\right)$ is the Fourier–Laplace transform of G_{E} with respect to coordinate and time, respectively. The second term represents the single scattering process (see Sato [67]), which has a logarithmic divergence at the direct arrival $t = r/V_0$ and decreases according to the inverse square of lapse time at long lapse times as $W g_0/\left(2\pi V_0^2 t^2\right)$. The third term representing multiple scattering converges to a diffusion solution with lapse time increasing as

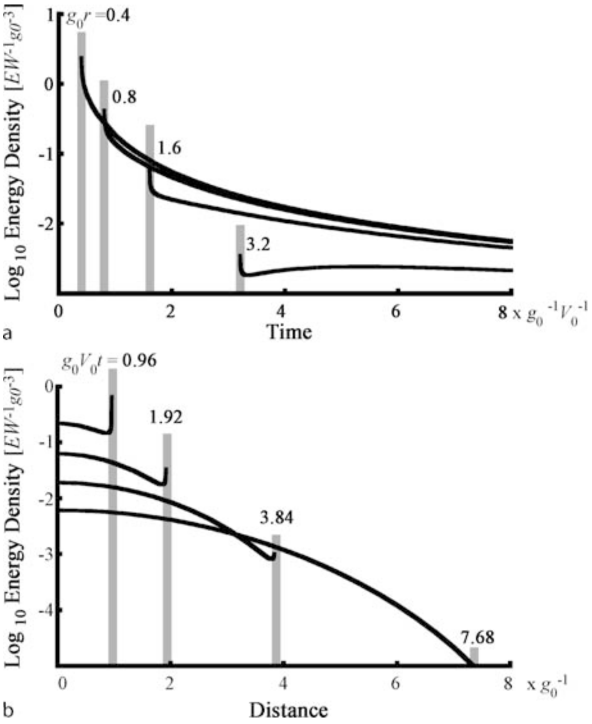
$$
E^{\mathrm{Dif.}}(\mathbf{x}, t) = W\left(\frac{3 g_0}{4\pi V_0 t}\right)^{3/2} \mathrm{e}^{-\frac{3 g_0 r^2}{4 V_0 t}} H(t) ,
\tag{4}
$$

where the factor $V_0/\left(3 g_0\right)$ is the diffusivity. Later, Paaschens [54] proposed an approximation as

$$
\begin{aligned}
E^{\mathrm{Paa.}}(\mathbf{x}, t) \approx {} & W G_{\mathrm{E}}(\mathbf{x}, t) + \frac{W \mathrm{e}^{-g_0 V_0 t}}{\left(4\pi V_0 t/\left(3 g_0\right)\right)^{3/2}} \\
& \cdot \left(1 - \frac{r^2}{V_0^2 t^2}\right)^{\frac{1}{8}} M\left(g_0 V_0 t\left(1 - \frac{r^2}{V_0^2 t^2}\right)^{\frac{3}{4}}\right) \\
& \cdot H\left(t - \frac{r}{V_0}\right) ,
\end{aligned}
\tag{5}
$$

where $M(x) \approx \mathrm{e}^x \sqrt{1 + 2.026/x}$. The error of this approximation is of the order of 2% outside the ballistic peak and its tail for $g_0 V_0 t < 6$ and $2 < g_0 r < 4$.

Figure 3 shows spatiotemporal variations in energy density in a scattering medium theoretically predicted by the approximation solution (5) for instantaneous spherical source radiation at the origin. Scattered energy density is shown by a black curve, where the ballistic term is shown by a vertical gray line. At a small distance from the source compared with the mean free path $1/g_0$, the energy density decreases rapidly after the direct arrival as predicted by the single scattering term; however, the decay rate becomes smaller due to multiple scattering according to the power of lapse time $t^{-3/2}$ at long lapse times. At a long distance, for example at $r = 3.2/g_0$, the energy density has an additional diffusion peak. The spatial distribution of scattered energy density is uniform around the source at a short lapse time compared with the mean free time $1/g_0 V_0$; however, it converges to a Gaussian curve at a long lapse time as theoretically predicted by the diffusion solution (4), for example at $t = 7.48/g_0 V_0$. There is no violation of causality since no signal exists beyond the ballistic peak. The smooth spatial distribution of scattered energy density around the source location gives the physical basis of the coda normalization method for measurements of S-wave attenuation and site amplification factors (e. g. [3,56,89]).



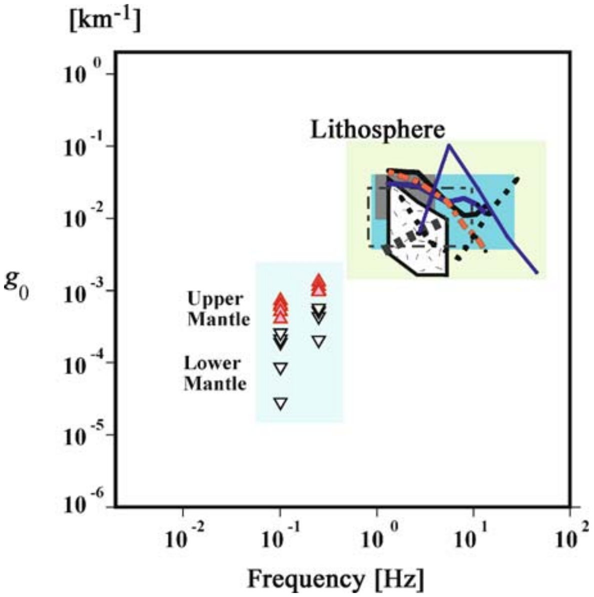
Seismic Waves in Heterogeneous Earth, Scattering of, Figure 3
a Temporal change and b spatial variation of energy density in an isotropic-scattering medium for a point source radiation. Each *black curve* shows the scattering contribution predicted by the Paaschens approximation and each *vertical gray line* shows a ballistic term

Gusev and Abubakirov [21] and Hoshiba [27] numerically solved the radiative transfer equation for the isotropic scattering process by using the Monte Carlo method. Yoshimoto [88] numerically simulated envelopes in scattering media of which the background velocity decreases with depth. He found the concentration of scattered energy near the surface because of seismic ray bending.

Nonisotropic radiation from a source can be easily introduced in the radiative transfer equation. Sato et al. [75] analytically solved the case of double couple source radiation: the energy density theoretically predicted faithfully reflects the source radiation pattern near the direct arrival; however, the azimuthal dependence diminishes with increasing lapse time. It qualitatively agrees with the observed radiation pattern independence of coda amplitudes at long lapse times. Their solution has been used in the envelope inversion of strong motion records for the spatial distribution of high-frequency wave energy radiation from an earthquake fault (e. g. [47]).

Measurements of Total Scattering Coefficient and Attenuation

For the practical application of the radiative transfer theory to observed seismograms, it is necessary to introduce intrinsic absorption Q_{Int}^{-1} by multiplying an exponential temporal decay factor $\exp[-Q_{\mathrm{Int}}^{-1} 2\pi f t]$ to the resultant energy density. By using the solution (3) of the radiative transfer theory for the isotropic scattering model, total scattering coefficient g_0 and intrinsic absorption factor $Q_{\mathrm{Int.}}^{-1}$ of the S-wave have been measured. Reported g_0 values in the lithosphere are of the order of $10^{-2}\,\mathrm{km}^{-1}$ for frequencies from 1 to 30 Hz as plotted in Fig. 4.



Seismic Waves in Heterogeneous Earth, Scattering of, Figure 4
Total scattering coefficient of S-waves in the Earth. Measurements in the mantle [40] are added to lithospheric inhomogeneity [74]

From the observed lapse time dependence of Q_{C}^{-1}, Gusev [20] quantitatively explained the decrease of g_0 with depth. Lee et al. [40] analyzed coda envelopes of regional earthquakes before and after the ScS arrival around 900s in lapse time from the origin time based on the numerically simulated envelopes for the PREM model, which is characterized by depth-dependent background velocity and total attenuation for S-waves. They reported lower g_0 values in 4s and 10s period bands in the upper and lower mantle compared with those in the lithosphere as illustrated in Fig. 4.

Hoshiba et al. [28] and Fehler et al. [10] developed a method to measure simultaneously g_0 and Q_{Int}^{-1} values for the S-wave from the whole S-envelope analysis based on the synthetic envelope derived from the radiative transfer theory. Their multiple lapse-time window analysis method has been widely used in the world. Estimated scattering loss $g_0 V_0/\omega$ decreases with frequency; however, intrinsic absorption Q_{Int}^{-1} is rather insensitive to frequency. Estimated seismic albedo $B \equiv g_0 V_0 / \left(\omega Q_{\mathrm{Int}}^{-1} + g_0 V_0\right)$, the ratio of scattering loss to the total attenuation, of S-waves in the lithosphere widely distribute from 0.2 to 0.8 for 1–6 Hz, but they are limited between 0.2 and 0.5 for 6–20 Hz.

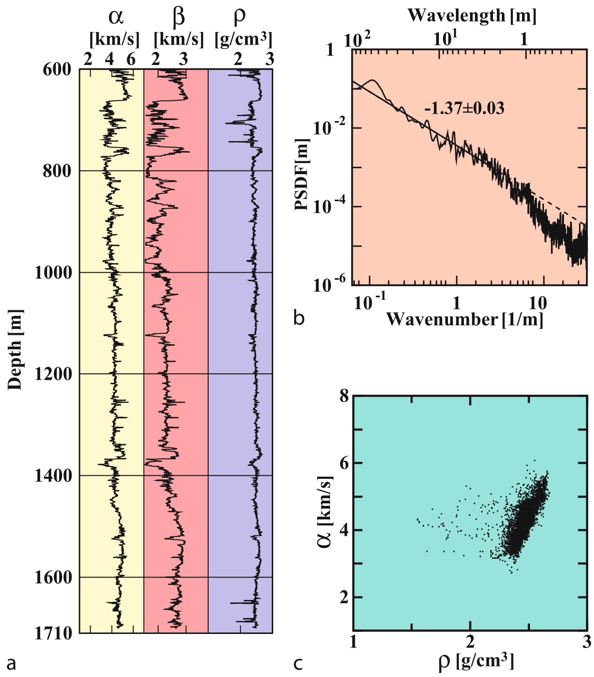
Total scattering cross-section and number density of scatterers appear jointly as the total scattering coefficient in theoretical models; however, Matsumoto [44] proposed a method to separate them from the temporal variation of the semblance coefficient of coda waves recorded by a seismic array. Analyzing data obtained in the aftershock area of the 2000 western Tottori earthquake, Japan, he estimated $n = 0.03\,\mathrm{km}^{-3}$ and $g_0 = 0.001\,\mathrm{km}^{-1}$ at 20 Hz.

It should be noted that lunar seismograms have coda durations exceeding one hour. Applying the diffusion model for the explanation of spindle-like envelopes of lunar-quakes, Dainty and Toksöz [9] estimated g_0 to be as large as 0.05–0.5 km^{-1} at 0.45 Hz.

Wave Envelopes in Random Media and Statistical Characterization

Statistical Characterization of Random Media

As revealed from tomography analyses (e. g. [93]), velocity structure is three-dimensionally inhomogeneous especially in the lithosphere. Well log data show typical samples of the shallow crust. Figure 5a shows well log data of P- and S-wave velocities and mass density obtained in Kyushu, Japan [80], where wave velocities and mass density are measured in a borehole by using ultrasonic waves and gamma rays, respectively. These well log data clearly show random fluctuation with short wavelengths.



Seismic Waves in Heterogeneous Earth, Scattering of, Figure 5

a Well log data at the YT-2 site, Kyushu, Japan. b Power spectral density function of the fractional fluctuation of P-wave velocity log. c Scattergram of P-wave velocity and mass density. Reproduced from [80]

As a natural consequence, we imagine random inhomogeneities widely distributed in the solid Earth medium.

By using computer power, wave propagation in random media has been numerically studied extensively. Using finite difference simulations of waves in random media, Frankel and Clayton [14] first examined the relation between coda excitation and scattering loss and the spectrum of random inhomogeneity. On the basis of numerical simulations, Frankel and Wennerberg [15] proposed the energy flux model that has a uniform distribution of scattered energy behind the direct waves for the analysis of high-frequency seismogram envelopes. Using a boundary integral method for the simulation of waves in a medium containing many cavities, Yomogida and Benites [87] examined a relation between coda attenuation and the distribution of cavities.

There is an alternative approach to treat statistically randomly inhomogeneous media. The wave-velocity is written as $V(\mathbf{x}) = V_0\{1 + \xi(\mathbf{x})\}$, where V_0 is the average velocity and fractional fluctuation $\xi(\mathbf{x})$ is a homogeneous and isotropic random function of space coordinate $\mathbf{x}$. We imagine an ensemble of random media $\{\xi\}$, which is statistically characterized by the autocorrelation function (ACF) $R(\mathbf{x}) \equiv \left\langle \xi\left(\mathbf{x}+\mathbf{x}'\right)\xi\left(\mathbf{x}'\right)\right\rangle$, where angular brackets mean the ensemble average. The MS fractional fluctuation $\varepsilon^2 \equiv R(0)$ and the correlation distance a are key parameters. The Fourier transform of ACF gives the power spectral density function (PSDF) P. The PSDF of the P-wave velocity fractional fluctuation of well log data shows a power-law characteristic at large wavenumbers as illustrated in Fig. 5b. P-wave velocity and mass density show a good correlation as shown in Fig. 5c. The statistical view is useful for representing geological data, too (e. g. [18,26]).

Scattering Coefficient Based on the Born Approximation

When the medium inhomogeneity is small $|\xi| \ll 1$, scalar wave ϕ is governed by the following wave equation:

$$\left(\Delta - \frac{1}{V_0^2}\partial_t^2\right)\phi + \frac{2}{V_0^2}\xi(\mathbf{x})\partial_t^2\phi = 0\,. \tag{6}$$

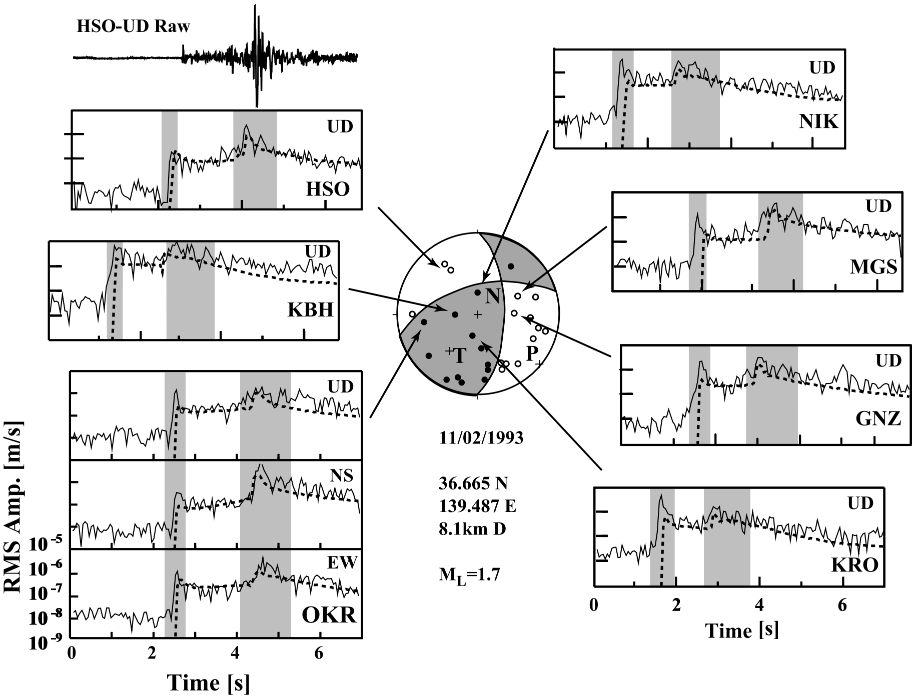
Velocity inhomogeneity is supposed to localize in a volume around the origin, of which the dimension is chosen to be much larger than a. For the incidence of a plane wave of unit amplitude at angular frequency ω as $e^{i(k_0\mathbf{e_z}\mathbf{x}-\omega t)}$, where $\mathbf{e_z}$ is the unit vector to the z direction, we calculate the spherically outgoing scattered waves due to a localized inhomogeneity by using the Born approximation as $\phi^1(\mathbf{x}, t) = -k_0^2 e^{i(k_0 r-\omega t)}\tilde{\xi}\left(k_0\mathbf{e_r} - k_0\mathbf{e_z}\right)/(2\pi r)$, where the tilde means the Fourier transform with respect to coordinates in 3-D space and $\mathbf{e_r}$ is a radial unit vector (e. g. [74]). According to Aki and Chouet [4], the scattering coefficient defined as the scattering power in a unit solid angle at certain direction by a unit volume of random inhomogeneous media for the incidence of unit energy flux density is statistically written by using its PSDF as

$$g(\psi;\omega) = \frac{k_0^4}{\pi}P\left(k_0\mathbf{e_r} - k_0\mathbf{e}_3\right) = \frac{k_0^4}{\pi}P\left(2k_0\sin\frac{\psi}{2}\right)\,, \tag{7}$$

where ψ is the scattering angle measured from the z direction. This functional form means anisotropic scattering depending on frequency. In general, scattering near around the forward direction becomes larger with increasing wavenumber in random media.

Radiative Transfer Theory with Scattering Coefficients Calculated by the Born Approximation

Extending the above formulation to vector wave propagation in random elastic media, we can define scattering coefficients for different scattering modes as PP, PS, SP,



Seismic Waves in Heterogeneous Earth, Scattering of, Figure 6
RMS envelopes of a microearthquake in the shallow crust, Nikko in northern Kanto, Japan. *Fine curves* and *broken curves* are observed and best-fit synthesized envelopes, respectively, where *shades* show time windows used for the estimation of the source radiation energy. The trace on the *top left* shows a raw seismogram. Reproduced from [90]

and SS. For the case of random elastic media characterized by an exponential ACF with $\varepsilon = 10\%$ and $a = 2$ km, Sato [68] synthesized three-component seismogram envelopes of a microearthquake of M 3 as a superposition of polarized scattered waves' power at a finite distance from a point shear dislocation source. That is the single scattering approximation of the radiative transfer theory with scattering coefficients calculated by the Born approximation. The SS scattering mode dominates in S coda, and pseudo P and S waves are produced even at a receiver on the null direction of the source radiation. By using a von Kármán-type ACF for describing random elastic media, Sato [71] estimated parameters $\kappa = 0.35, \varepsilon = 8.4\%$ and $a = 2.1$ km from observed frequency dependence of S-wave attenuation and g_0, where the parameter κ controls the role-off of PSDF at large wavenumbers. Extending the above vector wave envelope synthesis to include mode conversions at the free surface, Yoshimoto et al. [90] analyzed three-component seismogram envelopes of microearthquakes in the shallow crust in Nikko, northern Kanto, Japan. A raw seismogram is shown at the top-left of Fig. 6 as an example. Fine curves in Fig. 6 are logarithmic plots of observed root mean square (RMS) envelopes in the 2–16 Hz band. Broken curves are best-fit theoretical envelopes for random elastic media characterized by an exponential ACF with $\varepsilon = 5.7\%$ and $a = 400$ m. We find that the fitness is good not only for S coda but also for P coda.

Wave theory in random media predicts that the scattering coefficient has a large lobe in the forward direction in higher frequencies. Gusev and Abubakirov [22] used the Monte Carlo method to simulate envelopes for the multiple nonisotropic scattering process. There have been mathematical developments to derive the radiative transfer equation for multiple nonisotropic scattering from the stochastic averaging of the wave equation in random media (e. g. [13,29,41,64]). Przybilla et al. [58] showed an excellent coincidence of vector envelopes calculated from finite difference simulation in 2-D random elastic media and those synthesized by the radiative transfer theory with scattering amplitudes derived from the Born approximation and the wandering effect of travel time.

Interference of Scattered Waves

The interference effect is neglected in conventional studies of wave scattering in random media; however, it becomes important for a specific case even in random media. When randomness is strong enough to produce multiple scattering, coda wave intensity at a receiver near a source is enhanced compared to the prediction of conventional radiative transfer theory. Margerin et al. [42] showed that a spot of backscattering enhancement stabilizes in a sphere of radius half a wavelength centered at the source after a transient regime. The enhancement persists in time and should be observable as long as a coda is measurable. From field experiment of seismic waves in a shallow volcanic structure Larose et al. [39] reported the existence of weak localization, where the size of enhancement spot was one wavelength and the estimated mean-free path was 200 m for seismic waves around 20 Hz.

Envelope Broadening of a High-Frequency Seismogram

Markov Approximation for Parabolic Wave Equation

For the study of light propagation through the upper atmosphere and/or acoustic sound propagation through internal waves in oceans, various stochastic methods have been developed in the fields of physics. One of the most attractive methods for explaining the wave envelope around the direct arrival is the Markov approximation for the parabolic wave equation, which is an extension of the phase screen method or the split step Fourier method (e. g. [29,63]). This method is found to be applicable to seismogram envelopes. We imagine an elastic medium composed of a homogeneous half space $z < 0$ and an inhomogeneous half space $z > 0$, where the inhomogeneity is supposed to be small ($\varepsilon^2 \ll 1$) and the randomness is statistically homogeneous and isotropic. When the wavelength is smaller than the correlation distance a, we may neglect conversion scattering between P and S waves. Then, we can describe the principal characteristics of vector wave propagation by using potentials. For the incidence of plane P-wavelet to the z direction from the homogeneous zone, scalar potential is written as a superposition of harmonic waves of angular frequency ω as $\phi = \int_{-\infty}^{\infty} (2\pi i k_0)^{-1}\, U(\mathbf{x}_\perp, z, \omega)\, \mathrm{e}^{i k_0 z - i\omega t}\, \mathrm{d}\omega$ for $z > 0$, where $\mathbf{x}_\perp = (x, y)$ on the transverse plane. Neglecting the second derivative with respect to z, we have the parabolic-type equation for U as

$$2 i k_0 \partial_z U + \left(\partial_x^2 + \partial_y^2\right) U - 2 k_0^2 \xi(\mathbf{x})\, U = 0\,. \tag{8}$$

We define the two-frequency mutual coherence function (TFMCF) of field U between two different locations on the transverse plane at a distance z and different angular frequencies at ω' and ω'' as $\Gamma_2(\mathbf{x}_{\perp\mathrm{c}}, \mathbf{x}_{\perp\mathrm{d}}, z, \omega_\mathrm{c}, \omega_\mathrm{d}) \equiv \langle U(\mathbf{x}'_\perp, z, \omega') U(\mathbf{x}''_\perp, z, \omega'')^* \rangle$, where ω_c and ω_d are center-of-mass and difference angular frequencies, respectively. In the case of quasi-monochromatic waves $|\omega_\mathrm{d}| \ll |\omega_\mathrm{c}|$, using causality and neglecting back scattering, we derive the master equation for TFMCF. This derivation is called the Markov approximation. For the ith component, the intensity is defined as the ensemble average of the square of displacement $\langle \partial_i \phi\, \partial_i \phi^* \rangle = 1/(2\pi) \int_{-\infty}^{\infty} \widehat{I}_i^{\mathrm{P}}\, \mathrm{d}\omega_\mathrm{c}$. The integrand is the intensity spectral density (ISD) $\widehat{I}_i^{\mathrm{P}}$, which means the time trace of MS amplitude in a band having the central angular frequency ω_c.

Vector Envelopes for a Gaussian ACF

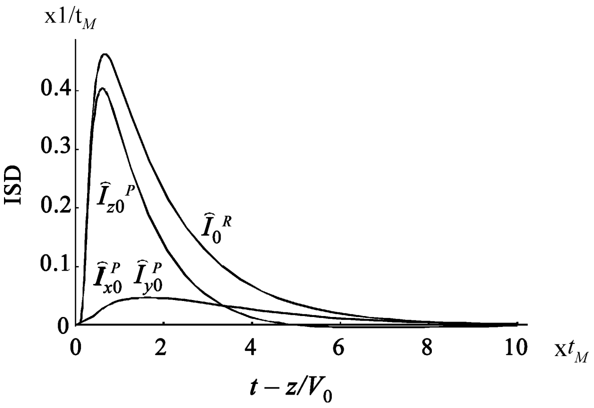
The case of a Gaussian ACF $R(\mathbf{x}) = \mathrm{Exp}\left(-r^2/a^2\right)$ is mathematically tractable. For the initial condition $\widehat{I}_x^{\mathrm{P}} = \widehat{I}_y^{\mathrm{P}} = 0$ and $\widehat{I}_z^{\mathrm{P}} = \delta(t - z/V_0)$ at $z = 0$, ISDs are analytically written as [72]

$$\begin{aligned} \widehat{I}_{x0}^{\mathrm{P}}(z, t, \omega_\mathrm{c}) &= \widehat{I}_{y0}^{\mathrm{P}}(z, t, \omega_\mathrm{c}) \\ &= 2(V_0/z)(t - z/V_0) \cdot \widehat{I}_0^{\mathrm{R}}(z, t, \omega_\mathrm{c}) \\ \widehat{I}_{z0}^{\mathrm{P}}(z, t, \omega_\mathrm{c}) &= [1 - 4(V_0/z)(t - z/V_0)] \\ &\quad \cdot \widehat{I}_0^{\mathrm{R}}(z, t, \omega_\mathrm{c})\ , \end{aligned} \tag{9}$$

where subscript “0” means ISD without the wandering effect. The reference ISD is a solution for scalar waves for the initial condition $\Gamma_2(\mathbf{x}_\perp, z = 0) = 1$ [82]:

$$\begin{aligned} \widehat{I}_0^{\mathrm{R}}(z, t, \omega_\mathrm{c}) &= \frac{1}{t_\mathrm{M}} \frac{\pi}{8} \vartheta_1{}' \left(0, \mathrm{e}^{-\frac{\pi^2}{4} \frac{(t - z/V_0)}{t_\mathrm{M}}}\right) \\ &\quad \cdot H\left(t - \frac{z}{V_0}\right)\ , \end{aligned} \tag{10}$$

where $t_M = \sqrt{\pi}\varepsilon^2 z^2/(2V_0 a)$ is the characteristic time and function ϑ_1' is the derivative of the elliptic theta function of the first kind. Function $\widehat{I}_0^{\mathrm{R}}$ shows a broadened envelope having a delayed peak and a smoothly decaying tail as illustrated by a chained curve in Fig. 7, where solid and broken curves show three-component ISDs $\widehat{I}_{0z}^{\mathrm{P}}$ and $\widehat{I}_{x0}^{\mathrm{P}} (= \widehat{I}_{y0}^{\mathrm{P}})$, respectively, for $V_0 t_\mathrm{M}/z = 0.05$ as an example. All the three component envelopes have broadened traces; however, the peak height of the transverse component is smaller than that of the longitudinal component and the peak delay of the transverse component is larger than that of the longitudinal component. When $\varepsilon^2 z/a \ll 1$, the peak height of $\widehat{I}_{z0}^{\mathrm{P}}$ approximately decays according to the square of travel distance and the peak ratio of the trans-



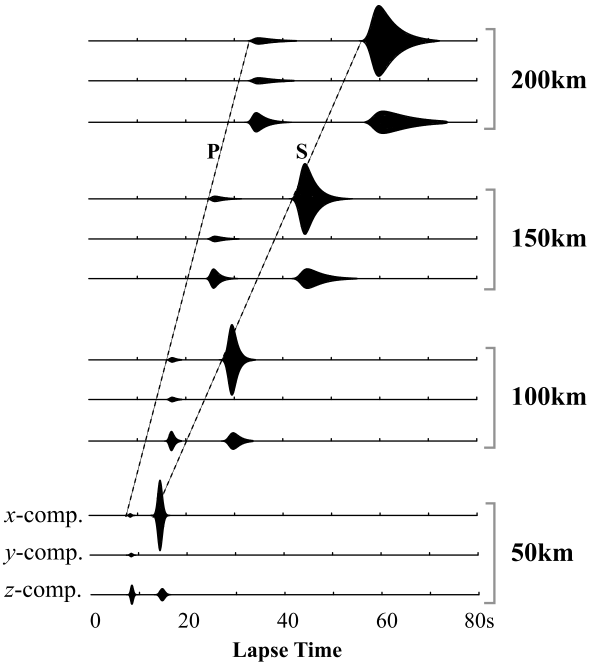
Seismic Waves in Heterogeneous Earth, Scattering of, Figure 7
Chained curve shows the reference ISD without the wandering effect in 3-D random elastic media characterized by a Gaussian ACF for the incidence of a plane P-wavelet. *Solid* and *broken curves* show three-component ISDs without the wandering effect for $V_0 t_M/z = 0.05$. Reproduced from [72]

verse component to longitudinal component is proportional to $\varepsilon^2 z/a$. ISDs $\widehat{I}_x^{\,\mathrm{P}}$, $\widehat{I}_y^{\,\mathrm{P}}$, and $\widehat{I}_z^{\,\mathrm{P}}$ can be calculated by using the convolution of (9) with the travel-time wandering effect $\exp\left[-(V_0 t - z_0)^2/2\sqrt{\pi}\varepsilon^2 az\right] V_0/\sqrt{2\pi\sqrt{\pi}\varepsilon^2 az}$ in time domain. For 2-D cases, the validity of the Markov approximation was numerically confirmed by a comparison with the finite difference simulations [11,36].

The above synthesis can be simply extended to S wave envelopes. Extension from plane wave incidence to impulsive radiation from a point source is also possible [73]. Figure 8 shows simulated three-component RMS envelopes along the z axis for a point source radiation, where random media are characterized by average P and S wave velocities, 6 km/s and 3.46 km/s, respectively, and a Gaussian ACF with $\varepsilon = 5\%$ and $a = 5$ km. We assume that P-wavelet radiation is isotropic and S-wavelet radiation is axially symmetric around the y axis with polarization to the x axis, where the ratio of S to P-wave source energy is chosen to be 23.3. Envelope broadening is common to both P and S waves in the syntheses. Excitation of the transverse component for P-waves and that of the radial component for S-waves are prominent. The appearance of scattered S-waves having long duration in synthesized envelopes at large travel distances qualitatively well explains observed characteristics shown in Fig. 2.

Randomness in the Lithosphere

Applying the envelope broadening model to S-wave seismograms recorded in Kanto, Japan, Sato [70] estimated the ratio $\varepsilon^2/a \approx 10^{-3}\,\mathrm{km}^{-1}$ with the assumption of a Gaussian ACF and S-wave attenuation $Q^{-1} = 0.014 f^{-1}$.



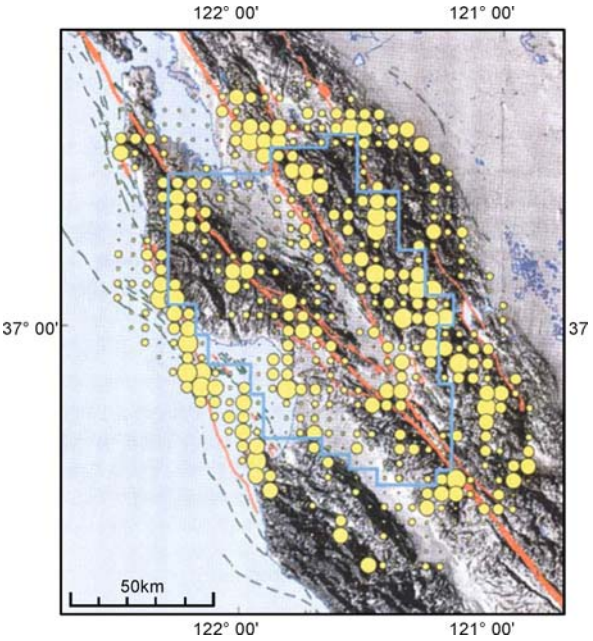
Seismic Waves in Heterogeneous Earth, Scattering of, Figure 8
Synthesized vector envelopes in random media characterized by a Gaussian ACF for radiation of P wavelet and S wavelet with a polarization to the *x*-axis from a point source. Reproduced from [73]

Saito et al. [66] studied the case of a von Kármán-type random media having a power-law spectrum at large wavenumbers, which are more appropriate for the real Earth inhomogeneity. The resultant envelope shows frequency dependence, which is controlled by the roll-off of the PSDF. Analyzing the hypocentral-distance dependence and frequency dependence of S-wave seismogram envelopes in northern Honshu, Japan for 2–32 Hz, Saito et al. [66] estimated parameters of von Kármán-type ACF as $\kappa = 0.6$ and $\varepsilon^{2.2}/a \approx 10^{-3.6}\,\mathrm{km}^{-1}$ with $Q^{-1} = 0.009 f^{-1}$. It means the PSDF decreases as wavenumber to the power of −4.2. Petukhin and Gusev [55] averaged S-wave seismogram envelopes of small earthquakes recorded in Kamchatka and compared the shapes with those numerically calculated for various types of random media. They concluded that random media whose PSDF decreases as the wavenumber to the power of −3.5 to −4 are appropriate.

Spatial Variation of Scattering Characteristics

Scattering Coefficient and Active Faults

Precisely examining coda envelopes of local earthquakes against lapse time measured from the origin time, we find



Seismic Waves in Heterogeneous Earth, Scattering of, Figure 9
Distribution of relative scattering coefficient at a depth of 0–5 km in central California revealed from the coda envelope inversion. *Circles* with larger diameter indicate stronger scattering and *solid lines* represent active faults. Reproduced with permission from [49]

temporal fluctuations around the smoothly decaying master curve. We may interpret that swellings and dips around the master curve are caused by stronger and weaker scatterers, respectively, distributed in the subsurface. By using a single isotropic scattering model, Nishigami [48] proposed an inversion scheme from coda envelopes of local earthquakes recorded at multiple stations for estimating the spatial variation of the scattering coefficient. Applying this inversion scheme to coda records obtained in central California, Nishigami [49] mapped the distribution of relative scattering coefficient in the shallow crust as in Fig. 9. A good correlation is found between sub-parallel active faults and relatively stronger scattering zones marked by larger circles, where some large circles are caused by topographic roughness. He also suggested that segment boundaries of the San Andreas Fault are characterized by relatively stronger scattering.

Stacking forward scattered energy in the coda of teleseismic P waves observed by a local seismographic network, Revenaugh [59] proposed a Kirchhoff coda migration method, which puts a focus on small-angle scattering from the forward direction. He made a map of *P*-wave scatterers in the upper mantle beneath southern California. Between depths of 50 km and 200 km, the southern flank of the slab subducting beneath the Transverse Ranges was marked by strong scattering. Using the same method, Revenaugh [60,61] estimated geographic variation of the statistical significance of scattering potential in the upper crust in California, where the scattering potential is a measure of the likelihood that scattering strength locally exceeds the regional mean. In the region surrounding the 1992 Landers earthquake of M 7.3, he found a noticeable tendency for aftershocks to cluster in regions of strong scattering potential.

There were more precise mappings of scattering coefficient. Slant-stacking records of 12 explosions in the Awaji island, Japan registered by a dense seismic array for a 6–10 Hz band, Matsumoto et al. [45] mapped the spatial distribution of PP single scatterers. The resultant distribution of scatterers shows higher strengths beneath the initiation point of the mainshock rupture and in the southwestern part of the fault plane of the 1995 Kobe earthquake (M 7.2). Analyzing precisely aftershock records of the 2000 western Tottori earthquake (M 7.3), Japan registered by a dense seismic network, Asano and Hasegawa [5] found strong scattering along and around the fault zone of 20 km in length.

Coda Attenuation and Deformation Zone

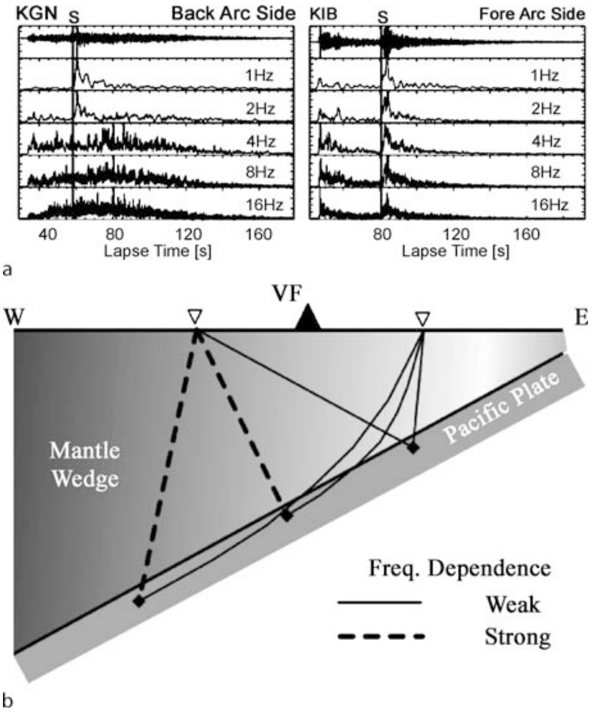
Regional variation of coda attenuation Q_c^{-1} has been measured from the decay gradient of coda amplitude envelopes of small earthquakes in various areas in the world. Jin and Aki [31] made a map of Q_c^{-1} at 1 Hz in China. They reported that Q_c^{-1} is as large as 0.01 in Tibet at the active continental collision. They found that large historical earthquakes took place in large Q_c^{-1} regions. Jin and Aki [33] made precise analysis of Q_c^{-1} for 1–32 Hz in Japan. They found significant spatial variation up to a factor of 3 for the lower frequency bands, as well as its strong frequency dependence. They found conspicuous large Q_c^{-1} for 1–4 Hz in a narrow belt from Niigata towards the south-west to the Biwa lake along the Japan Sea coast, which coincides with a high-deformation rate zone revealed from the GPS observation. For frequency bands 4–16 Hz (2–4 Hz in Kyushu), large Q_c^{-1} areas agree with volcanic and geothermal areas.

Attenuation and Volcanoes

Yoshimoto et al. [91] studied the spatial variation of MS amplitude of *S*-coda at a fixed lapse time across the volcanic front in northeastern Honshu, Japan: *S*-coda energy is uniformly distributed in the fore-arc side, whereas an exponential decrease with horizontal offset to the west from the volcanic front was found in the back-arc side. The decay rate increases with increasing frequency. They interpreted this variation by a diffusion–absorption model, where the intrinsic absorption factor of S-wave $Q_{\mathrm{Int}}^{-1} = 0.02$ at a frequency of 10 Hz beneath the back-arc side, which is about twice as large as those reported for the fore-arc side.

Scattering and Volcanoes

Medium heterogeneity is strong beneath volcanoes. Applying the diffusion model to seismogram envelopes beneath Merapi volcanoes, Friedrich and Wegler [16] estimated the total scattering coefficient as large as 5 km^{-1} as shown in Fig. 4. Nishimura et al. [50] applied an envelope inversion method based on the isotropic scattering model for PP and PS scattering to artificial explosion records obtained in Jemez volcanic field, New Mexico. They found that the mid-crust under most of the region is fairly transparent but that the lower crust is heterogeneous. The strongest scattering occurs at shallow depths beneath the center of the caldera, where the medium is highly heterogeneous.



Seismic Waves in Heterogeneous Earth, Scattering of, Figure 10
a Seismogram envelopes observed in the back-arc side and fore-arc side in Kanto-Tokai, Japan and b a schematic illustration of seismic rays. Reproduced from [53]

Obara and Sato [53] analyzed S-wave envelopes of microearthquakes in Kanto-Tokai, Japan, where the Pacific plate is subducting from east to west, to examine regional differences in their envelope broadening. As shown by examples in Fig. 10a, envelope broadening is typically stronger for higher frequencies in records at stations on the back-arc side of the volcanic front but weaker and frequency independent in records on the fore-arc side. These regional differences in the envelope broadening mean that PSDF of velocity inhomogeneity is rich in short-wavelength components in the mantle wedge on the back-arc side and poor on the fore-arc side as schematically illustrated in Fig. 10b. Takahashi et al. [83] precisely examined how the peak delay from the S-wave onset depends on the ray path in northern Japan. They found that peak delays observed in the back-arc side of the volcanic front are larger for rays which propagate beneath Quaternary volcanoes (see Fig. 11b and d); however, peak delays for rays which propagate between Quaternary volcanoes are as short as those observed in the fore-arc side (see Fig. 11a, c, and e). Large peak delay suggests strong scattering due to medium inhomogeneity. That is, the structure beneath Quaternary volcanoes is not only characterized by low velocity and large intrinsic absorption revealed from tomography studies but also by strong inhomogeneity.

Nonisotropic Random Medium Oceanic Slab

If random media are statistically nonisotropic, scattering contribution depends on the propagation direction. Saito [65] studied the envelope broadening in nonisotropic random media based on the Markov approximation. His simulations show that the envelope of scalar wavelet propagating in parallel to the longer correlation direction has longer duration compared to that with the shorter correlation direction. The effective envelope broadening in the elongated direction shows the wave trap phenomenon of nonisotropic random media.

An intensity anomaly is observed on the eastern seaboard of northern Japan for deep earthquakes. The waveform records in the region of high intensity show a low-frequency ($f < 0.25$ Hz) onset for both P and S waves, followed by large-amplitude high-frequency ($f > 2$ Hz) later arrivals with long coda. A simple subduction zone model comprising a high-velocity plate with low attenuation cannot explain quantitatively these observed facts. Furumura and Kennett [17] proposed a scattering slab model that the nonisotropic random structure in the Pacific plate works as a wave-guide for high-frequency seismic waves. Their preferred random medium is characterized by a von Kármán-type ACF with elongated cor-

relation distance of about 10 km parallel to the plate margin and much shorter correlation length of about 0.5 km in thickness and ε of about 2%. They clearly demonstrated the scattering waveguide effects and frequency selectivity for seismic waves traveling through the Pacific plate by using 3-D numerical simulations.

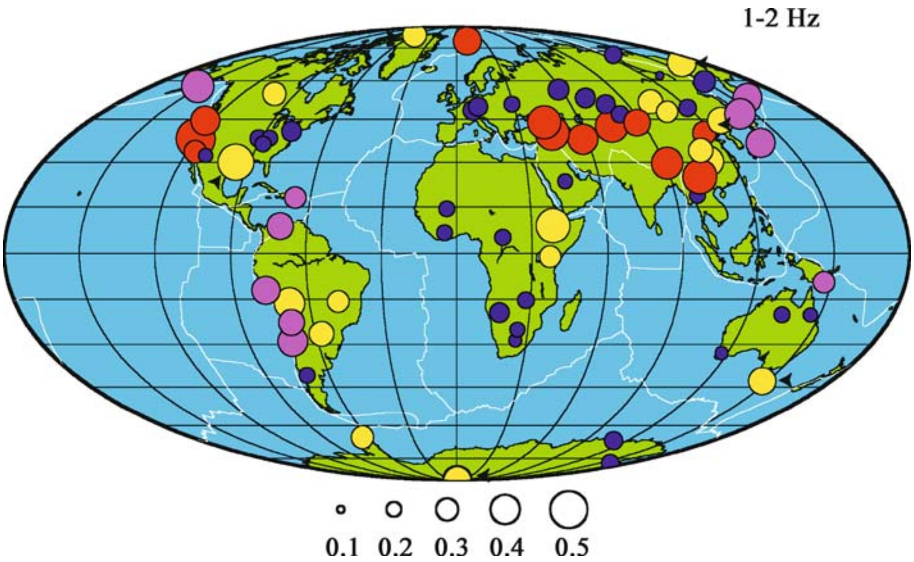
Lateral Variation of Lithospheric Heterogeneity

Korn [34] developed the energy flux model [15] appropriate for the wave front of teleseismic P and P-coda waves propagating through a scattering layer. During the propagation the primary wave loses energy due to scattering and intrinsic absorption, then the scattered energy appears as coda energy behind the wave front. From the analysis of vertical component trace envelopes observed in the world, Korn [35] found strong scattering at island arcs and smaller scattering on stable continental areas like Australia. Nishimura et al. [52] analyzed the energy partition of teleseismic P and P-coda into the transverse component to evaluate the lithospheric heterogeneity in the western Pacific region. They showed the presence of strong heterogeneity in and around the tectonically active regions. Kubanza et al. [37] systematically characterized the medium heterogeneity of the lithosphere by analyzing the partition of P-wave energy into the transverse component for 0.5–4 Hz. They found significant regional differences as shown in Fig. 12. The energy partition to the transverse component is small at stations on stable continents while the partition is large at stations in tectonically active regions such as island arcs or collision zones.

Random Inhomogeneity in the Lithosphere and Mantle

Records of earthquakes registered by arrays of seismographs are useful for the statistical measurement of the Earth inhomogeneity. Aki [2] first analyzed teleseismic P-waves centered on about 0.6 Hz registered by a seismic array in Montana for the quantification of the lithospheric inhomogeneity. Measuring transverse correlation functions of teleseismic P-waves arriving from near vertical incidence, he found a positive correlation between log-amplitude and phase fluctuations as theoretically predicted for a Gaussian ACF. From plots of the ratio of RMS log-amplitude to RMS phase fluctuations against the correlation between log-amplitude and phase fluctuations, he estimated the thickness of the inhomogeneous lithosphere to be 60 km, $a = 10$ km, and $\varepsilon = 4\%$. Flatté and Wu [12] measured the transverse correlation of log-amplitude and phase fluctuations of teleseismic P-wave beams with 2 Hz center frequency recorded at NORSAR. They also introduced the new concept of angular correlation functions, which are based on measurements of two rays with different incident angles. They proposed a model for lithospheric and asthenospheric inhomogeneities that consists of two overlapping layers: the upper layer extending from the surface to about the 200 km depth has a white PSDF, however, the lower layer extending from 15 to 250 km has poor amplitude in the short wavelength spectrum. There are more small-scale inhomogeneities near the surface compared with the deeper portions.

The radiative transfer theory with scattering coefficients calculated from the Born approximation was also used for the study of mantle inhomogeneity. Analyzing stacked P and P coda envelopes of teleseismic (>10°) events at 1 Hz, Shearer and Earle [79] concluded that most scattering occurs in the lithosphere and upper mantle, but that some lower mantle scattering is likely required. They estimated ε to be 3–4% and $a = 4$ km in the upper mantle and 0.5% and 8 km in the lower mantle. Analyzing envelopes of precursors to PKP, Margerin and Nolet [43] found that inhomogeneity can not be restricted to the D″ layer and a small inhomogeneity spread over the whole



Seismic Waves in Heterogeneous Earth, Scattering of, Figure 12
Plots of the square root of the relative partition of wave energy into the transverse component (1–2 Hz) by a diameter of the circle revealed from the teleseismic P-waves. Reproduced from [37]

lower mantle. They proposed a von Kármán ACF of $\kappa = 0$ for random media, which has a power law PSDF rich in short wavelengths compared with an exponential ACF. They mentioned that ε of 0.1–0.2% in the whole lower mantle is enough to explain the observation even though correlation distance is irresolvable because of the limited range of observations.

Imaging of Subsurface Heterogeneity

There have been developments in deterministic imaging of medium inhomogeneity from the analysis of array records of P-coda waves. When the structures of interest are characterized by laterally variable stratification, the receiver-function technique [38] is useful since it is based on the deconvolution of the horizontal component trace in the radial direction by the vertical component trace for measuring the Ps conversion depth. On the other hand, scattering from localized volume inhomogeneity is most readily treated by using the Born approximation. Analyzing array records of teleseismic P coda in central Oregon by using the Born approximation for both forward scattered waves and backscattered free-surface reflected waves, Rondenay et al. [62] successfully imaged the precise structure of the Cascadia subduction zone, which is consistent with the consequences of prograde metamorphic reactions occurring within the oceanic crust. Analyzing array records of P coda waves of regional earthquakes at Izu-Oshima volcano, which erupted in 1986, Mikada et al. [46] deterministically imaged PP and PS scatterers on the basis of diffraction tomography. They interpreted a cloud of scatterers centered at about 10 km depth beneath the volcano crater as a primary magma reservoir and smaller and shallower patches of high scattering strength with sub-magma reservoirs.

Temporal Change in the Earth Medium Structure

There were reports on the temporal changes in the Earth medium structure revealed from the analyses of scattered waves. One is coda amplitude envelope analysis, which gives information about the change in intrinsic absorption and scattering strength of the crustal heterogeneity. Another is coda phase interferometry, which offers information about the change in background velocity.

Change in Coda Characteristics

Monitoring coda envelopes of local earthquakes, Gusev and Lemzikov [23] reported temporal change in Q_c^{-1} before and after the 1971 Ust-Kamchatsk earthquake (M 7.8), and Jin and Aki [30] reported temporal change in Q_c^{-1} associated with the 1976 Tangshan earthquake (M 7.8) in China. Their observation attracted the interest of geophysicists to the temporal variation of coda characteristics because of a potential for monitoring the stress accumulation process preceding an earthquake occurrence. Analyzing high-frequency seismograms recorded at Riverside, California for 55 years, Jin and Aki [32] found a temporal variability in Q_c^{-1} at about 1.6 Hz having a positive correlation with the seismic b-value calculated for $M > 3$ earthquakes within a 180 km radius. The seismic b-value is a measure of the ratio between the numbers of small to large earthquakes; smaller b-values mean that there are relatively fewer small earthquakes compared to the number of larger ones. They interpreted these changes in Q_c^{-1} and the b-value by creep fractures in the ductile part of the lithosphere. Hiramatsu [25] precisely examined the temporal variation in Q_c^{-1} and b-value for 10 years before and after the 1995 Hyogo-ken Nanbu earthquake (M 7.2) in Japan. At frequencies between 1.5 and 4.0 Hz the temporal variation in Q_c^{-1} increased after the mainshock occurrence, where the variation in b-value was opposite.

Sato [69] analyzed the relation between coda duration time and earthquake magnitude of small earthquakes before and after an M 6.8 earthquake in central Japan. He found that coda durations were anomalously longer than usual for 16 months before the earthquake occurrence. From 24-year observation of coda at 0.5 Hz in Kamchatka Gusev [19] reported prominent anomalies in coda level residual from the mean coda excitation level at 100s lapse time associated with two M 8 earthquakes and a volcanic eruption.

Sawazaki et al. [76] measured the temporal variation of the spectral ratio of coda waves registered on the ground surface to that at the bottom of a borehole of 100 m depth in Japan, which experienced strong ground motion of several hundred gals. They reported a sudden drop of the site amplification factor caused by earthquake strong motion and gradual recovery for a few years approaching to the original ratio. They suggested crack formation and ground water movement for explaining the site factor weakening observed.

Coda Interferometry

Pairs of earthquakes with almost identical focal mechanisms are called earthquake doublets. The cross-correlation function of earthquake doublet records allow us to detect differences in the background velocity of the Earth medium that took place in between the pair of earthquakes. Applying the phase spectral analysis to coda wave records of earthquake doublets before and after the 1979 Coyote earthquake of M 5.9 in California, Poupinet et al. [57] found that the coda wave arrivals for some stations are progressively delayed for the second earthquake in the doublet. They interpreted systematic variation along the coda as a decrease of background S-wave velocity by 0.2% in an oblong region 5–10 km in radius at the south end of the aftershock zone. Applying the phase spectral analysis to records of repeated artificial explosions, Nishimura et al. [51] found that the average seismic velocity of the crust in the frequency range of 3–6 Hz decreased by about 1% around the focal region of an M 6.1 earthquake at Iwate volcano in northeastern Honshu, Japan in 1998. They interpreted this velocity drop by the dilatation caused by the M 6.1 earthquake with stress sensitivity of the velocity change $(\delta V/V)/\delta\sigma$ of the order of 0.1 MPa^{-1}. From the set of successive artificial explosion experiments, they observed gradual recovery of the seismic velocity towards its original value over the next four years. While interferometry detected a change in velocity of the order of 1%, it was unidentifiable from travel time analysis of first arrivals. Using coda waves is superior to direct waves since coda waves volumetrically sample the Earth medium.

Snieder et al. [81] demonstrated detection of the nonlinear dependence of the seismic velocity in granite on temperature and the associated acoustic emissions from the interference measurement of coda waves in rock samples as a laboratory experiment. They named this method "coda interferometry" and proposed to use it for detecting the presence of temporal changes in the medium, or in diagnostic mode. There is an idea to retrieve the Green function from the stacked cross-correlation function (CCF) of multiple scattered waves or microseisms at a pair of stations on condition that the propagation directions of those waves are randomly isotropic. Stacking CCFs of coda waves at several pairs of stations for regional earthquakes in Mexico, Campillo and Paul [7] estimated the surface wave velocity between each station pair from the peak delay. The idea was extended for monitoring the temporal change in the crustal structure. Wegler and Sens-Schönfelder [84] computed the ACF of microseisms recorded at a site in the vicinity of the source region of the 2004 Mid-Niigata earthquake (M 6.6) in Japan for three months. They detected a sudden decrease of relative seismic velocity in the crust of 0.6% at the occurrence of the earthquake from the temporal variation of stacked ACFs.

Future Directions

In addition to classic parameterization as a layered structure with sharp edges and smooth velocity perturbation, we introduced new approaches using scattered waves that reflect solid Earth heterogeneity. For high-frequency seismograms of earthquakes, envelope characteristics such as the excitation level and the decay gradient of coda envelopes and the envelope broadening of the direct wavelet are useful for the study of small-scale inhomogeneities. The lithospheric inhomogeneity is phenomenologically well characterized by the scattering coefficient and coda attenuation factor as a function of frequency. Furthermore, the power spectral density function of random velocity inhomogeneity is estimated from the frequency dependence of high-frequency seismogram envelopes of local earthquakes or the array analysis of teleseismic waves. The radiative transfer theory with scattering coefficients calculated from the Born approximation and the Markov approximation for the parabolic wave equation are useful mathematical tools for the analyses.

Scattering characteristics are found to vary spatially reflecting seismotectonic settings. It will be necessary for us to make a classification of seismogram-envelope patterns in various regions in the world under different tectonic conditions. It is interesting to model how such a variation of medium inhomogeneity was created through the geodynamic process. Compared to the lithospheric inhomogeneity, there were insufficient numbers of studies on the mantle inhomogeneity. It will be necessary to map the distribution of inhomogeneities deep in the mantle, which is useful for the study of the evolution of the planet Earth.

For mathematical simplicity; however, most approaches assume homogeneity and isotropy of randomness and a constant background velocity, which are somewhat different from reality. It will be necessary to mathematically develop the envelope synthesis in inhomogeneous media that are a superposition of small-scale random inhomogeneities and a gradually varying background velocity. As revealed from the ray path dependence of S-wave envelope broadening, randomness varies from place to place. It is also necessary to develop the envelope synthesis for random media having spatially varying statistical parameters. In addition, it is important to examine how conversion scattering between P and S waves contributes to form spindle-like envelopes in highly scattering media as shown in high-frequency seismograms observed in volcanoes and on the Moon.

For further understanding, there are monographs that treat the discussed subjects as follows: Sato and Fehler [74] review seismological observation and mathematical models; Shapiro and Hubral [78] put special focus on wave propagation through stratified random media; Goff and Holliger [18] summarize the crustal heterogeneity; Wu and Maupin [86] compile recent developments in mathematical modeling of wave propagation in inhomogeneous media; Chandrasekhar [8] is a classic text for radiative transfer theory; Ishimaru [29] and Rytov et al. [63] offer advanced mathematical tools for the study of wave propagation in random media.

Definition of the Subject

The concept of self-assembly is today highly popular and frequently used to describe a wide range of phenomena. It is also a concept that has a possibility to change the way we produce various types of materials [1]. Self-assembly can broadly speaking be defined as a process with the following features [2], where: (i) it involves pre-existing components, i. e. the components are not formed by the reaction itself. (ii) the process should be reversible to some extent. (iii) it can be controlled by design.

The supramolecular chemistry approach, pioneered by Jean-Marie Lehn [3], where molecular recognition is used to assemble supramolecular materials is clearly an important starting point for much of this work. The pre-existing components are usually molecules, amphiphilic species, or oligomeric or polymeric species. However, self-assembly can also be observed on larger length scales involving e. g. nanoparticles (superlattices) and larger colloidal particles (colloidal crystals). The final self-assembled material should display certain features that can be related to the building blocks in addition to the novel features that are created by the self-assembled material itself. Reversibility is a key feature since self-assembly processes commonly scan a rich energy landscape with many metastable states. This is commonly regulated by the balance between the attractive and repulsive interactions between the self-assembling components, involving e. g. van der Waals, electrostatic, hydrophobic, hydrogen bonding and entropic forces (molecules and mesoscale objects), and magnetic, capillary, and gravity forces (meso- or macroscale objects).

The degree of versatility, simplicity and flexibility of the various self-assembly methods and the ability to introduce specific functions with a high degree of spatial accuracy are important features for self-assembled materials to move beyond academic beauty and be interesting for applications. The preparation of self-assembled coatings can be traced back to the seminal work by Irving Langmuir and Katherine Blodgett prior to the Second World War. The development of a theory for adsorption on surfaces by Langmuir together with the design of a technique that both could measure the pressure-area isotherms of monolayers of amphiphilic molecules assembled at the air-liquid interface, and also be used to transfer these monolayers onto different substrates was a very important discovery that has had a profound effect on future work on self-assembled layers. The observation by Nuzzo and coworkers [4] that alkanethiolates can self-assemble on gold surfaces and result in well-ordered films sparked a large research interest in these so called self-assembled monolayers (SAMs). The relatively non-local nature of the thiol bond to the gold surface allows the much weaker, attractive interaction *between* the amphiphilic chains in the monolayer to control the film structure. The SAMs are a beautiful example of self-assembly as a crucial process in the formation of a dense monolayer.

Self-organization of nanoparticles into two- and three-dimensional superlattices has attracted much interest since the early work on iron oxide "super crystals" [5]. Indeed, understanding and optimizing the structures, at all length scales, of nanocrystal superlattices is an important step towards controlled design of novel nanostructured materials and devices. This work did not really gain momentum until methods to achieve shape and size control with a high fidelity was established in the end of 1980s by e. g. Brus, Steigerwald et al. [6] and Moerup, Thölen and Koch [5] mentioned above. The ability to assemble different nanocrystals with size-tunable optical, electronic and magnetic properties into well-defined structures opens up the possibility to study and develop new materials with tailored couplings between the constituent units [7,8]. Layer-by-layer (LbL) self-assembly of charged polymers has evolved as probably the most versatile technique to create multifunctional coatings on a wide range of substrates [9]. These are but a limited set of examples of self-assembly processes to produce novel materials that has been demonstrated in the last decades [10,11,12,13, 14,15,16,17,18,19,20]. While the examples of self-assembly are plentiful, the attempts to model the self-assembly processes and systems is still in its infancy. This review attempts to be a guide and introduction to the field of computer modeling of self-assembly.

Introduction

Computer modelling of structural properties and dynamical processes in matter is based on physical and mathematical models. Ideally, we would prefer to use first-principles methods of quantum mechanics with no other input than atomic nuclei and the electrons spontaneously forming atoms, molecules and more complicated systems through local intermolecular interactions. Unfortunately this is possible only for systems of very modest sizes using rather drastic approximations and simplifications. We can always blame the computers for not been powerful enough but the truth is that the "first-principles" models would grow too complicated and out of hands very rapidly. We therefore use different physical models to describe matter at different length and time scales together with an increasing amount of empirical data as input to the models.

Atomistic computer simulations such as the classical Molecular Dynamics (MD) are currently run for molecular systems consisting of the order of 10^5 atoms, corresponding typically to a system size (length scale) of 5–10 nm. These simulations are typically extended to 10–100 ns (time scale). This may be enough for simulations of isotropic liquids of simple molecules, whereas for many complex systems, the requirements for the length and time scales are much more extensive. To extend the simulations to cover longer scales requires either simplifications of used models or choosing more suitable modelling technique [21]. In the first strategy the resolution of the model is reduced by removing certain degrees of freedom of the studied system which are not important or can be considered as fluctuations while keeping those degrees of freedom which are operational on the longer scales. This is

Self-assembled Materials, Table 1
Time and length scales covered by modelling methods reviewed in this article

Scale	Typical length	Typical time
sub-atomic	< 0.1 nm	~ 1 fs
atomic	0.1–1 nm	1 fs–1 ns
meso	1 nm–1 μm	1 ns–1 ms
macro	1 μm–	1 ms–

generally called coarse-graining of the model leading to a much fewer interaction sites thereby speeding up the calculations. An alternative approach is to use a hybrid by keeping an accurate description for a selected area of importance and the environment is merely made to a fluctuating medium with more or less specific interactions. These techniques may include combining quantum and classical mechanics [22] or classical mechanics and hydrodynamic/continuum models.

In Table 1 there is a somewhat artificial division of matter on scales from sub-atomic (with nuclei and electrons) to macroscopic. There are modelling and simulation methods designed separately to these scales. Going from one scale to the next in the table requires either coarse-graining or fine-graining of the used model by building a bridge between two techniques. This means taking as much vital information as possible to the next level. Coarse-graining is obviously easier than fine-graining as the latter requires re-activating non-existing degrees of freedom from an under-defined system. Multiscale modelling is currently a hot topic and in a rapid development with the purpose to bridge several scales in a more systematic way.

The aim of this chapter is to describe a box of tools containing some selected modelling methods to study self-assembly. The tools should together cover the scales in the table in Table 1. We will give a short description of each of them together with some examples of applications. At the end of the chapter we show examples of how to combine several techniques to extend length and time scales in modelling. We will work from the "bottom-up" by starting with first-principles calculations on electrons and nuclei. Classical Molecular Dynamics (MD) and Monte Carlo (MC) are mainly used in atomistic simulations with empirically parameterized potential functions. Meso-scale simulations of aggregates and soft particles use coarse-grained models. We will discuss methods equally applicable on both short and long scales such as the kinetic Monte Carlo (kMC) and Phase Field (PF) modelling. All these techniques so far are examples of off-lattice modelling methods. We then discuss two lattice methods with some further development towards more off-lattice character, namely Random Sequential Adsorption (RSA) and Cellular Automata (CA). Finally we will discuss multiscale modeling before the paper ends with a discussion on future directions.

First-Principles Calculations and Simulations

Down in the bottom of the world of atoms and molecules, quantum mechanics should be used to treat the moving nuclei and electrons building up the matter. The electronic structure in atoms and molecules and molecules gives the first level of properties to all matter around us. Theoretical calculations utilize the so-called Born–Oppenheimer (BO) approximations which keeps the much heavier nuclei in fixed positions while the electrons adapt themselves pair wise in binding and non-binding molecular orbitals (MO), constructed as linear combinations of atomic orbitals (LCAO) using suitable basis sets (normally Gaussian functions or plane waves). Computational quantum chemistry is largely based on solving the Schrödinger equations interactively within the self-consistence field (SCF) theory until suitable convergence criteria are reached. The previously commonly used Hartree–Fock (HF) method was made computationally convenient in matrix form by Roothaan [23] in early 50s and allowed accurate calculations for larger and larger molecules at the same time as computers were made more and more powerful [24]. As there is no exact solution to many-body problems ($N > 2$) all modelling methods use approximations to reduce the problem to independent particle or pair problem [25]. Within the HF approximation the full N-electron problem is reduced to an independent N single-electrons moving in a mean-field of the other electrons. By increasing the size of the basis set a so called HF limit can be reached where the electron-electron repulsions are treated uncorrelated. As the electron correlation effects are very important for many molecular properties a number of post-HF schemes have been developed, for example Møller–Plesset (MPn ($n = 2, 4, \ldots$)), configuration interaction (CI) or coupled cluster (CC) [25].

The most affordable quantum chemistry methods are the semi-empirical MO methods [26,27,28]. Among the most popular are those based on the neglect of diatomic differential overlap (NDDO) approximation, such as Austin Model 1 (AM1) [29], Parametric Model 3 (PM3) [30,31] and modified NDO (MNDO) [32]. All these schemes start from HF-Roothaan equations [25] introducing the frozen-core approximation and using only the valence AOs. Some electron-electron integrals are simply neglected, some calculated approximately and some are replaced by empirical parameters. These methods are very fast compared to *ab initio* methods but give often unreliable results; the errors tend to be unsystematic and therefore both relative energies and conformational energies become less reliable when calculated using semi-empirical schemes. Also hydrogen bonds are not accurately described. These shortcomings are found to be largely due to an unbalanced treatment of core-electron and electron-electron interactions. Orthogonalization corrections have been worked out to improve the NDDO schemes [33,34] but have given only a slight improvement. This unbalance is corrected in the recently published Extended NDDO scheme [35] where the old NDDO is expressed as zeroth order term. However, it still remains to be parameterized and packaged to a new semi-empirical scheme, which is a major undertaking.

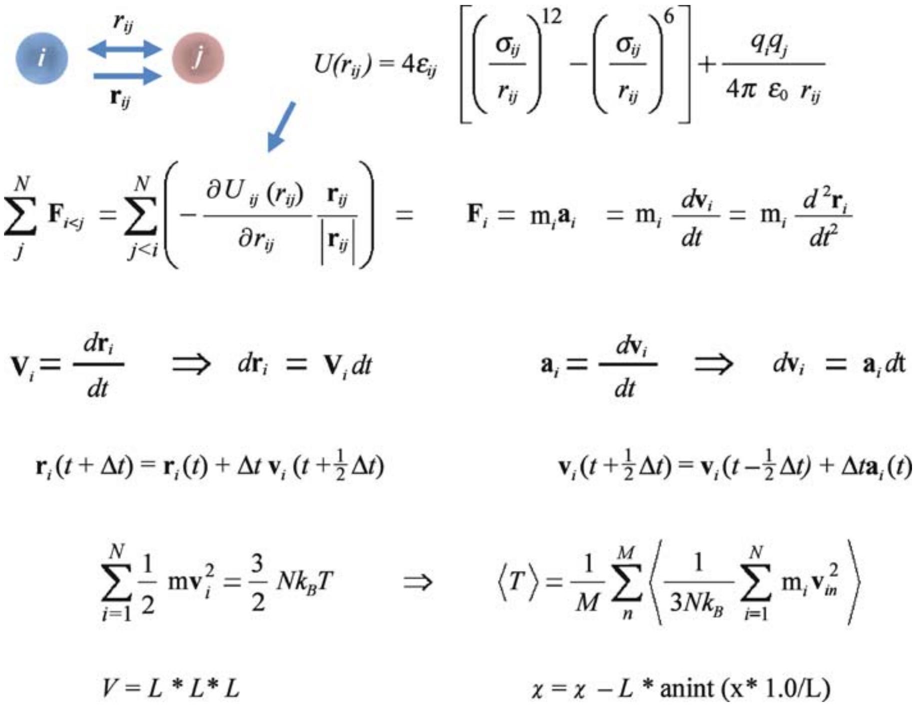
In both materials science and chemistry, the density functional theory (DFT) has recently gained the position as the most popular method [25]. It is basically as fast as the HF method but can incorporate a large part of the electron correlation effects. In DFT the energy is given as a functional of the electron density $\rho(\mathbf{r})$. The contributions to total energy come from the kinetic energy of the electrons, nuclear-electron attraction, electron-electron Coulombic repulsion and finally from combined exchange and correlation energy. The most difficult problem in DFT is to derive the exchange-correlation (XC) term. In materials science for solids and metals the so called local density approximation (LDA) is used as it is suitable in cases of slowly fluctuating electron densities [25]. LDA is not a good choice for chemical problems and so called gradient corrected methods like the generalized gradient approximation (GGA) are used where the XC term is not just functional of the electron density but also derivatives of the density with respect of the coordinates (x, y, z) [25]. The most popular XC functionals are currently those by Lee, Yang and Parr (LYP) [36] and by Perdew and Wang (PW91) [37]. In chemical applications the hybrid methods where the HF exchange energy is mixed the corresponding DFT term have gained popularity. Becke's three parameter hybrid [38] with the LYP functional, the so called B3LYP, is frequently used. Current DFT methods are based on formulation proposed by Kohn and Sham (KS) [39,40] by constructing the total electron density from a KS orbital. This gives conceptually similar equations as in HF method. Car and Parrinello (CP) presented a DFT based Molecular Dynamics method using plane-wave basis functions [41] which is the most popular *ab initio* simulation tool both in chemistry and materials science.

Recently a robust approximate DFT method is introduced where the electron-electron interactions in the total energy density functional in DFT are expanded with respect to a reference density and keeping the first order correction and neglecting the higher order corrections. This is called Harris–Foulkes functional [42,43] and is stable with respect to the used reference density as a small change in the reference density introduces an error only to second order term. Computational schemes based on Harris–Foulkes functionals are normally called *ab initio* tight-binding density functional theory (AB-TBDFT) methods, and were first introduced by Sankey et al. [44]. A highly efficient AB-TBDFT method is recently presented by Tu and Laaksonen [45,46] applicable on simulations of large systems. Various methods to incorporate quantum mechanics into molecular dynamics simulations are reviewed in [22].

First principles electronic structure calculations and simulations have a firm position in materials science. First-principles MD simulations to materials properties are reviewed in [47]. In the following a few examples are chosen from literature. Materials simulations using VASP gives a quantum perspective to materials science according to [48] using pseudo potentials (PP) and a plane wave basis set based on a finite-temperature local-density approximation. Density functional theory meeting statistical physics [49]: from the atomistic to the mesoscopic properties of alloys by combining DFT calculations with the so-called Cluster Expansion (CE) methods and Monte-Carlo (MC) simulations is reported. Determination of solid-state nanostructure from *ab initio* structure calculations of nano-structured materials using diffraction data in combination with distance geometry methods is explained in [50]. Tools, results and perspectives of quantum software interfaced with crystal structure databases are given [51]. Density-functional theory electronic structure calculations of static and elastic properties and *ab initio* molecular dynamics simulations for poly-atomic systems made possible in package reported in [52] and first-principles computation of material properties using the ABINIT software package in [53]. A primer to efficient tight-binding molecular dynamics is given by Colombo [54]. CONQUEST code for large-scale *ab initio* calculations in materials science is presented in [55]. Prediction of materials properties by *ab initio* computer simulations is reported [56].

Atomistic Molecular Dynamic Simulations

Molecular Dynamics (MD) [57,58,59,60,61,62,63,64,65] is, in its simplest formulation, numerical integrations of Newton's second law (acceleration $(\mathbf{a}(t))$ of a particle is equal to the force $(\mathbf{F}(t))$ acting on a particle divided by the mass $(\mathbf{m})$ of the particle) applied on a collection of inter-



$$U(r_{ij}) = 4\varepsilon_{ij}\left[\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}}\right)^{6}\right] + \frac{q_i q_j}{4\pi\ \varepsilon_0\ r_{ij}}$$

$$\sum_j^N \mathbf{F}_{i<j} = \sum_{j<i}^N \left(- \frac{\partial U_{ij}(r_{ij})}{\partial r_{ij}} \frac{\mathbf{r}_{ij}}{|\mathbf{r}_{ij}|} \right) = \mathbf{F}_i = \mathrm{m}_i \mathbf{a}_i = \mathrm{m}_i \frac{d\mathbf{v}_i}{dt} = \mathrm{m}_i \frac{d^2\mathbf{r}_i}{dt^2}$$

$$\mathbf{v}_i = \frac{d\mathbf{r}_i}{dt} \Rightarrow d\mathbf{r}_i = \mathbf{v}_i dt \qquad \mathbf{a}_i = \frac{d\mathbf{v}_i}{dt} \Rightarrow d\mathbf{v}_i = \mathbf{a}_i dt$$

$$\mathbf{r}_i(t+\Delta t) = \mathbf{r}_i(t) + \Delta t\, \mathbf{v}_i\,(t + \tfrac{1}{2}\Delta t) \qquad \mathbf{v}_i(t+\tfrac{1}{2}\Delta t) = \mathbf{v}_i(t - \tfrac{1}{2}\Delta t) + \Delta t\mathbf{a}_i(t)$$

$$\sum_{i=1}^N \frac{1}{2}\,\mathrm{m}\mathbf{v}_i^2 = \frac{3}{2}\,Nk_BT \quad \Rightarrow \quad \langle T \rangle = \frac{1}{M}\sum_n^M \left\langle \frac{1}{3Nk_B} \sum_{i=1}^N \mathrm{m}_i \mathbf{v}_{in}^2 \right\rangle$$

$$V = L * L * L \qquad \chi = \chi - L * \text{anint } (\text{x}* 1.0/\text{L})$$

Self-assembled Materials, Figure 1
Molecular Dynamics simulations in a nutshell

acting particles. Integrating the acceleration of each particle gives the velocity ($\mathbf{v}(t)$) and a subsequent integration of the velocity gives the actual position ($\mathbf{r}(t)$) of the particle. Thereby the trajectory of the particle can be determined. The forces momentarily acting on the particles (masses) are calculated as negative spatial derivatives of the potential functions $U(\mathbf{r})$ (force fields) describing the attractive and repulsive interactions between the particles (including the internal degrees of freedom): $\mathbf{F} = -\nabla U(\mathbf{r})$. Normally only the pairwise intermolecular interactions are included as an approximation in classical MD simulations of liquids and solutions. The number of particles (N) in current simulations is from thousands to hundreds of thousands and is a compromise set by the available computing power. Particles are inserted into a cell (box) with a volume V. The shape of the cell is preferably chosen to have translational symmetry so that replicas of the cell make a pseudo-infinite periodic system where particles are synchronously able to leave and enter the cells according to periodic boundary conditions (PBC). This keeps the particle density constant. So called minimum image convention connected to the PBC is applied to avoid artificial condensation effects (for more details see Table 1 and the text in connection to the figure). In Newtonian dynamics the energy (E) is expected to be conserved at equilibrium conditions and the simulation corresponds to a microcanonical (NVE) ensemble. By using suitable Hamiltonians containing thermostats canonical (NVT) ensembles can be constructed and with corresponding barostats isobaric (NPT) ensembles. Several other ensembles can be constructed for MD simulations as well.

Historically, Alder and Wainwright introduced the method of Molecular Dynamics 50 years ago by simulating a system of hard spheres [66,67] observing a phase transition, while Rahman [68] carried out the first simulation for a liquid system using argon atoms in 1964 giving fairly accurate diffusion coefficient. Verlet was able to obtain thermodynamic state functions noble gases [69]. A very important pioneering work for molecular systems was that of Rahman and Stillinger for liquid water in 1974 obtaining radial distribution functions in close agreement with experiments [70], which also started a real boom in computer simulations. MD simulation is a powerful method to study structural, thermodynamic and dynamical properties in gases, liquids and solids. Using MD the motion of molecules can be followed to gain a better understanding of chemical reactions, fluid flow, phase transformations, droplet formation, and other physical phenomena. MD is a statistical mechanical method (both equilibrium and non-equilibrium).

Figure 1 gives all the information needed to write a simple computer program to run MD simulations of N

charged particles in a cubic volume V. *First row*: Pairwise interaction potential consisting of Lennard–Jones (van der Waals) and Coulombic terms. Particle sizes are determined by the σ parameter and strength of the van der Waals attractions is given by ε. Particle charges are given by q in the Coulombic term and pairwise distances are given by r_{ij} (scalar) and the $\mathbf{r}_{ij}$ (vector). *Second row*: Forces acting on each particle are obtained as the negative spatial derivative of the potential function given in first row and are equal to particles mass times its acceleration (Newton's II law). *Third row*: By integrating the fluctuating time-dependent acceleration gives particle's velocity and a subsequent integration of the velocity gives the momentary position of the particle. *Fourth row*: Example of a numerical finite difference algorithm called the "Verlet leap-frog" to carry out the integration. Δt is the time step and is normally of order of a few femto seconds depending of the particle masses and the density of the system. Observe that the velocities in the Verlet leap-frog scheme are obtained as half time steps to increase the accuracy and stability of the algorithm. *Fifth row*: Example of how compute the average temperature from simulation data using the kinetic energy and the equipartition principle (each translational degree of freedom contributes 1/2 kT to the kinetic energy). M is the total number of time steps in the simulation. Other average quantities, for example the total energy (potential+kinetic energy) is calculated similarly. *Sixth row*: For a cubic simulation cell of a volume V (containing the N particles) the side length is L. Periodic boundary conditions (PBC) are easily applied on the positions (to keep the particles inside the cell) by the simple formula where the anint is a function which truncates the floating point number keeping only the integer digit. Example here is given for the x-components and should be done same way for y- and z-components. PBCs are applied on the distances as well according to the minimum distance convention to avoid artificial condensation effects during the simulations. Large scale simulations are carried out using parallel computers with a large number of processors. This requires computer software adapted to parallel architectures [71,72]. A large number of simulation packages are available from the authors developing them. Most of them are publicly available while some (most often those who are made particularly user-friendly by graphical interfaces) require a license to be purchased.

MD is an example of N-particle simulation techniques, a wide-spread method found virtually in all areas dealing with interacting dynamical particles from solvated electrons to protein-lipid interactions and from orientations of liquid crystals to formation of galaxies [58,59,60,61,62,63,64,65]. It is also the main simulation method in materials science from metals to zeolites and from polymers to colloids.

Self-assembled thiol monolayers on Au(111) made hydrophilic with polar end groups are studied with STM and MD simulations [73] to examine the role of the formation of hydrogen bonds between the molecules in the layer and with polar co-adsorbates (water and solvent). MD have been performed [74] to investigate the two-dimensional structure of organosilane self-assembled monolayers (SAMs). Unlike alkanethiol SAMs, the arrangement of molecules in organosilane SAMs is not crystalline. Simulations performed for structures with different bonding networks in the polysiloxane layer shows that the ratio of hydrogen bonds has a profound effect on conformations and strain energies. Water density profile close to spherical and planar hydrophobic objects is studied [75] using MD simulations. A substantial increase of the depletion layer thickness was found with the temperature. High electrostatic surface potential presumably plays an important role in the presence of charged solutes possibly promoting adsorption into the interfacial layer. MD investigations [76] of the morphology and structure of monolayer and multilayer of chiral molecule N-stearoy-L-glutamic acid (C-18-L-Glu) self-assembled on a mica surface show that hydrogen-bonding effects are the major driving forces in the layer formation proposing a multilayered model for the self-assembling. Static and dynamic properties of 2:1 layered silicates ion exchanged with alkyl-ammonium surfactants are studied using MD simulations [77] providing the structure and dynamics of the intercalated surfactant in agreement with experiments. Structure and properties of self-assembled monolayers (SAMs) of a bi-stable[2]rotaxane on Au(111) surfaces as a function of surface coverage are reported based on atomistic molecular dynamics (MD) studies with a force field optimized from DFT calculations with several experiments validating the predictions [78]. To develop strategies to self-assembly of nanostructured materials MD simulations for telechelic molecules composed of two polyhedral oligomeric silsesquioxane cages connected by one hydrocarbon backbone dissolved in liquid normal hexane were carried out [79]. MD simulations of nanoparticle self-assembly at a liquid-liquid interface are carried out showing in situ formation of clusters and migration of both single particles and clusters from the water phase to the trichloroethylene phase [80].

Among similar modelling works related to self-assembly could be mentioned recent advances of classical density functional theory with emphasis on applications to quantitative modeling of the phase and interfacial behavior of condensed fluids and soft materials, including colloids, polymer solutions, nanocomposites, liquid crystals, and biological systems are summarized [81]. Molecular mechanical methods are used to calculate strain distribution in self-assembled interfacial misfit dislocation arrays in highly mismatched III–V semiconductor materials in good agreement with experimental data using cross section high-resolution transmission electron micrograph images and also with other theoretical values [82]. Molecular self-assembly at equilibrium is studied using a family of simple directional and short-range van der Waals potentials giving rise to the self-assembly of linear polymeric, random surface, tubular, and hollow icosahedral structures. Dipolar potential with its continuous rotational symmetry about the dipolar axis contributes to chain formation, while higher multipoles lead to the self-assembly of open sheet, nanotube, and hollow icosahedral geometries [83]. To further understand the mechanism behind Layer-by Layer assembly processes requires even theoretical work, including thermodynamics calculations and molecular dynamics simulation as many kinds of physicochemical molecular interactions, including hydrogen bonding, charge transfer interactions, and stereocomplex formation are involved [84].

Monte Carlo Simulations

With modern computers the Monte Carlo technique has evolved from a classical numerical algorithm to solve multi-dimensional definite integrals based on statistical sampling to a very powerful simulation technique to study a large variety of complex systems with interacting particles [59]. The name “Monte Carlo”, given by Stanislaw Ulam [85], refers to the capitol of Monaco at Mediterranean, famous for its casinos and roulette tables. The corresponding “roulette” in the MC method is the random number generator supplying a sequence of numbers normally between 0 and 1 from a uniform random distribution (rand[0, 1]). MC methods can be used, for example, to compute equilibrium properties of classical many-particle systems. MC was in fact among the first applications run in the first computers in early 50s. The first liquid simulation using MC was carried out by Metropolis and coworkers [86]. As molecular computer simulation methods MC and MD are very similar until the particles start to move. The simulated systems in both MC and MD are built in the same way by inserting the N particles in a simulation cell of volume V, applying the periodic boundary conditions and choosing a force field to describe the interactions between the particles and the cut-off distances for short and long-range interactions. Ewald summation can be employed if found necessary. By fixing the temperature T we can perform the MC simulation in a canonical (NVT) ensemble which is also the simplest choice in molecular MC simulations. Recall that the NVE (microcanonical) ensemble is the natural choice in the case of Newtonian MD simulations. While the MD simulation method is completely deterministic in the sense that the particles always follow exactly same trajectories if same input is given, the Monte Carlo (MC) method is stochastic and the particles are moved as a random walk. How the particles are moved depends on the studied systems. In the case of small and rigid molecules (as a liquid) the molecules (center-of-mass) is translated (displaced) in x, y and z direction of a small distance one molecule at a time rotating it slightly around its principal axes. For larger and flexible molecules the individual atoms are slightly moved and in addition different types of specific movements are performed mimicking somehow the real motion of the molecule. For example MC simulations of polymers are undergoing residual “flips”, “rotations”, “crankshaft”, “slithering snake” moves and “end-bridging” plus many more. Probably the simplest MC technique to simulate interacting particles at a desired temperature is Metropolis Monte Carlo [86].

The mother of all Monte Carlo methods is the Markovian master equation:

$$\begin{aligned}&\frac{\mathrm{d}P(\vec{r}_i,t)}{\mathrm{d}t}\\&\quad=\sum_{\vec{r}_j} W(\vec{r}_j,\vec{r}_i)P(\vec{r}_j,t)-\sum_{\vec{r}_j} W(\vec{r}_i,\vec{r}_j)P(\vec{r}_i,t)\end{aligned} \tag{1}$$

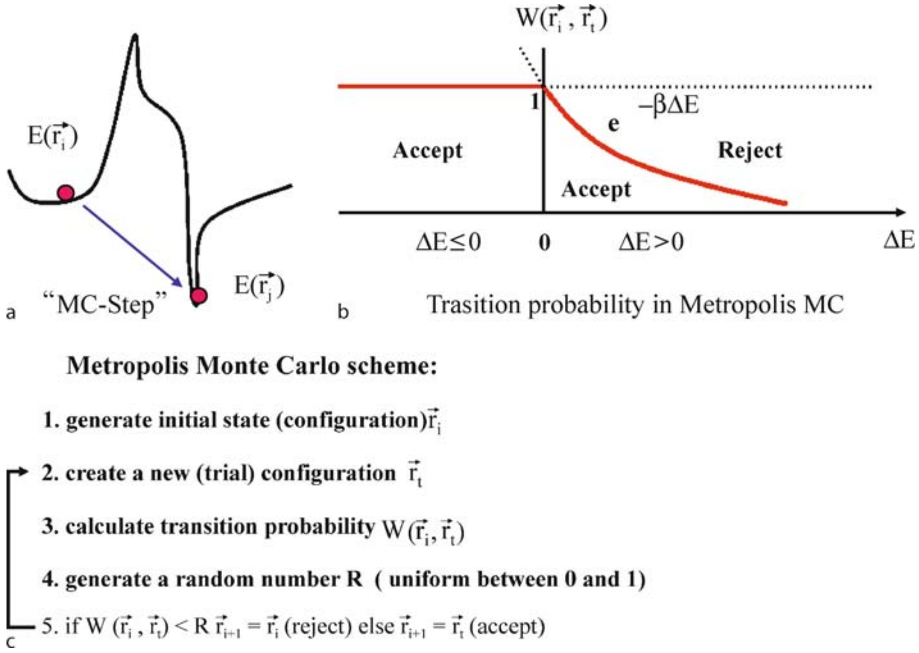
where $P(\vec{r},t)$ is the probability that the system is in state $\vec{r}$ at time t (time-dependent distribution of states/configurations) and $W(\vec{r}_i,\vec{r}_j)$ is the transition probability/rate per unit time for the system to undergo a transition from i-state to j-state. All MC techniques can be seen as methods for solving the master equation. At steady state (stationary or equilibrium):

$$\begin{aligned}&\frac{\mathrm{d}P(\vec{r}_i,t)}{\mathrm{d}t}=0;\quad t\to\infty\wedge P(\vec{r}_i,t)\to P(\vec{r}_i)\\&\quad\Rightarrow\sum_{\vec{r}_j} W(\vec{r}_i,\vec{r}_j)P(\vec{r}_i)=\sum_{\vec{r}_j} W(\vec{r}_j,\vec{r}_i)P(\vec{r}_j)\,.\end{aligned} \tag{2}$$

The detailed balance (microscopic reversibility) is valid. The canonical contribution is:

$$\sum_{\vec{r}_j} W(\vec{r}_i,\vec{r}_j)\mathrm{e}^{-\frac{E(\vec{r}_i)}{k_\mathrm{B}T}}=\sum_{\vec{r}_j} W(\vec{r}_j,\vec{r}_i)\mathrm{e}^{-\frac{E(\vec{r}_j)}{k_\mathrm{B}T}} \tag{3}$$

$$W(\vec{r}_i,\vec{r}_t)=\min\left(1,\mathrm{e}^{-\frac{E(\vec{r}_t)-E(\vec{r}_i)}{k_\mathrm{B}T}}\right)\,. \tag{4}$$



Metropolis Monte Carlo scheme:

1. generate initial state (configuration) $\vec{r}_i$
2. create a new (trial) configuration $\vec{r}_t$
3. calculate transition probability $W(\vec{r}_i, \vec{r}_t)$
4. generate a random number R (uniform between 0 and 1)
5. if $W(\vec{r}_i, \vec{r}_t) < R$ $\vec{r}_{i+1} = \vec{r}_i$ (reject) else $\vec{r}_{i+1} = \vec{r}_t$ (accept)

Self-assembled Materials, Figure 2

a Schematic illustration of a Monte Carlo move. b Transition probability *W* in Metropolis Monte Carlo. c Computational scheme for Metropolis Monte Carlo

However, it is not possible to calculate W from this equation. MC methods therefore use different functional forms for W. Transition probabilities in thermodynamical MC (like Metropolis) do not need to have *any* relationship to the dynamics (energy barriers) of the system. To assign real time to MC steps (Fig. 2a) is not possible. Conventional MC methods are only applied to sample systems in (or close to) thermal equilibrium. Functional form of transition probability in Metropolis MC:

In standard Metropolis MC the looping should not be done until accepted. All moves with probability W larger than 1 are accepted (the energy goes down) while if W is less or equal to 1 the move is accepted if the random number is less than the Boltzmann factor in Eq. (4) (see also Figs. 2). A rule of thumb is to choose the size of the displacements in such a way that the acceptance/rejection ration is close to 1/2 which might be considered as the upper limit while the lower limit is roughly 1/3 [87]. Several particles should not be moved simultaneously in Metropolis MC. There is no direct correspondence between a Monte Carlo step and real time but it is possible to use experimental information of for example diffusion to calibrate the MC simulations to obtain a rough estimate of real time.

Some examples of MC works in connection to self-assembly are for example the MC (both multi-scale NVT and grand canonical) simulations carried out to investigate nano patterns an self-assembly of surfactants inside SWCNT systems [88] and Monte Carlo simulations of gold nanocrystals and (111) slabs covered with alkyl thiols are carried out with and without explicit solvent (n-hexane) at $T = 300\,\mathrm{K}$. Inclusion of explicit solvent is found important in [89]. Self-organization and chain-forming of large ensembles of nanoparticles is studied by combining DLVO theory and MC simulations [90]. The growth of linear agglomerates is kinetically controlled by a high activation barrier from all of the directions except one at end of the chain. Adsorption of different model amphiphiles in apolar and polar solvents is investigated using MC simulations with a coarse grained model. As coating agents the surfactants with a single hydrocarbon tail or two branches are found to protect better the particle surfaces than amphiphiles with three or more branches [91]. Lattice Monte Carlo simulation is used to investigate the equilibrium between free surfactant molecules in aqueous solution and those adsorbed layers on structured solid. The solid surfaces are composed of hydrophilic and hydrophobic surface regions [92]. Lattice MC simulation of self-assembled ordered hybrid materials is reported and a comparison of structural characterization of the different phases using aggregate size distribution, density profiles, and radial distribution functions [192]. MC simulations are used to study self-assembly of symmetric diblock copolymers in confined state resulting novel self-assembled strip, circle, core-multishell, and multi-barrel layer structures [94]. Self-assembly and adsorption on hydrophobic surfaces are studied by MC methods in [95,96,97,98].

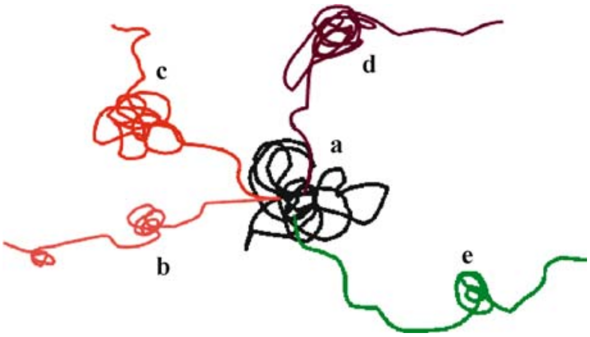
Kinetic Monte Carlo Simulations

Ideally we would like to have a general computer simulation method operational on atomistic level of matter which we can used for both short and long length and time scales. We wish to use it to simulate general dynamical processes with many different types of transitions between various states the system populates during its evolution towards a more permanent equilibrium state. The method of molecular dynamics (MD) is often the first choice. Using MD we model our system by applying realistic physical conditions. We also have correct real time in our simulation procedure. However, the time step Δt in atomistic MD simulation to numerically solve the equations of motion has to be chosen according to the frequency ($\omega_{\max}$) of the fastest dynamical event in the molecular system this being in practice $\Delta t \ll (\omega_{\max})^{-1}$. This makes atomistic MD simulations very inefficient if the events of interest occur beyond nanosecond time scales. Unfortunately a vast amount of motional modes and dynamical events take place beyond the capability of MD simulations even with the fastest computers around.

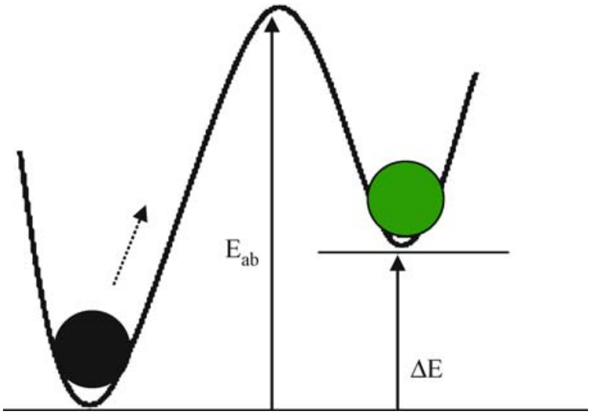
We can use Monte Carlo (MC), such as the common Metropolis method discussed above. We can build the molecular system similarly as in MD and impose the desired conditions onto it. We start simulations and pick up the particles randomly and one at a time moving them in small displacements based on the Boltzmann probability. Again, we realize that as the size of the system increases together with the number of motional degrees of freedom our simulation starts to take too long time. Besides, as mentioned in the previous chapter, we do not even know how to add the time into a Metropolis simulation as different events have different characteristic times for their dynamical behavior. MC as we perform it is normally only for sampling ensembles.

We now consider using a method called the kinetic Monte Carlo (kMC). Using kMC dynamical processes can be simulated with real time incorporated and all possible time scales can be covered easily. This sounds simply too good to be true so what is the “catch” here? Before going into details of kMC method (in fact there are many variants of it) we try to trace its origin by going back almost four decades ago and to computer simulations of vapor deposition on two-dimensional lattices [99] and crystal growth with surface diffusion [100]. These two works carry much of the basic underlying idea behind several kMC schemes developed later. The paper by Bortz, Kalos and Lebowitz (BKL) presents elegantly the theory and algorithms for a method finding immediately a strong position among physicists [101]. The BKL scheme is the solid framework in many kMC programs used today. In almost parallel and from purely chemical point of view Gillespie presented his stochastic simulation method for coupled chemical reactions [102] with the starting point being that on atomistic level the time evolution of chemical systems such as chemical reactions can be seen as both discrete and stochastic rather than continuous and deterministic as the text book kinetic equations are presented for us. Although the BKL method and the Gillespie method appear to have been developed in separate communities they both lead to same family of kMC methods [103]. The name kinetic Monte Carlo appears first as late as in 1992 [104].

Kinetic Monte Carlo is also based on solving the Markovian master Eq. (1) discussed in the previous Chap-



Self-assembled Materials, Figure 3
Accessible stationary states (b–d) from state a



Self-assembled Materials, Figure 4
Transition from state a to state b

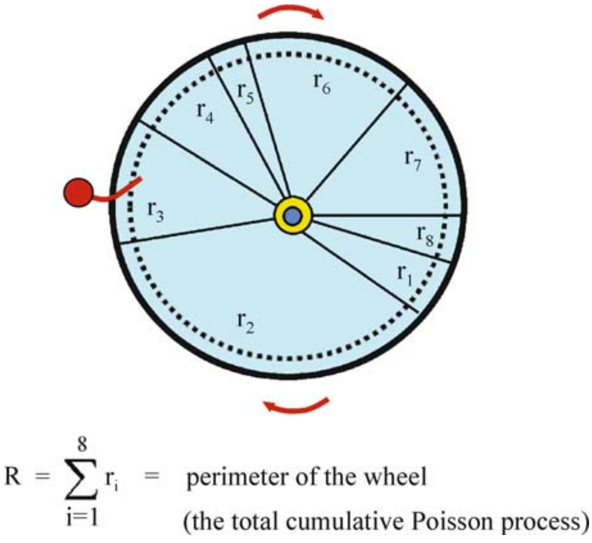
ter. In kMC we assume that the system is in a (stationary) state and that a number of other states are accessible from the current state (Fig. 4). A new state is randomly chosen among the neighboring states and a transition is made to this new state. The real time spent in the state before transition is added to the time development and can be seen as the time step in kMC. The time spent in a state (Fig. 4) is related to the transition rate:

$$r_{ab} = \upsilon \mathrm{e}^{-\frac{E_{ab}}{k_{\mathrm{B}}T}} \tag{5}$$

– where υ is the "attempt frequency". The time step is then calculated as:

$$\Delta t = -\frac{\ln(\mathrm{rand}[0,1])}{\sum\limits_{i=b,c,d,\dots} r_{ai}} \tag{6}$$

kMC requires that the simulated events are Poisson processes. There should also be a dynamic hierarchy among the processes. The real time increments (time steps) should be able to be calculated based on Eqs. (5)–(6). In practice the detailed balance (Eq. (2)) is not strictly required as the systems can be far from equilibrium. If the transition probabilities are: (i) independent on previous history, (ii) the same at all times and (iii) a uniform function of time, the the transitions are Poisson processes. A kMC transition should not have any effect on any other transition. Also the time when the next transition will occur should be independent from the occasion of the previous transition. To illustrate kMC we may consider a "wheel of fortune" (Fig. 5) where the sectors correspond to individual Poisson processes (events) and are not necessarily evenly divided. The perimeter of the wheel is the cumulative process (also a Poisson process). The corresponding dynamical hierarchy in Fig. 5 is as:



r6
r5
r4
r7
r3
r8
r1
r2
$R = \sum_{i=1}^{8} r_i$ = perimeter of the wheel
(the total cumulative Poisson process)

Self-assembled Materials, Figure 5
The Poisson "wheel of fortune" to illustrate the kMC

$$[0 \leqslant r_5/r_{\max} \leqslant r_8/r_{\max} \leqslant r_1/r_{\max} \leqslant \cdots \leqslant r_{\max}/r_{\max} \leqslant 1] \,.$$

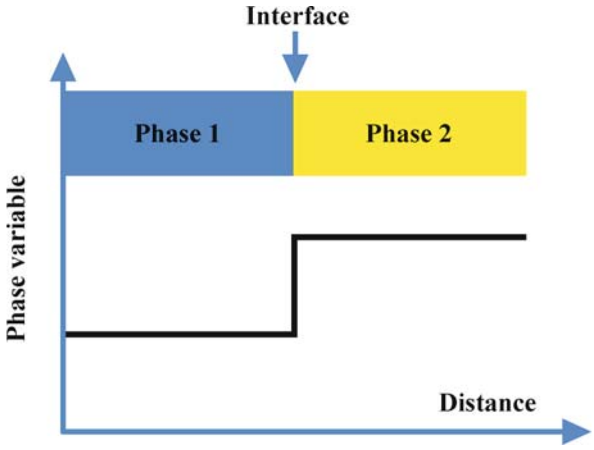
The whole spectrum of rates exists and the fastest rate (r_2 in Fig. 5) gives the highest probability. Note, the Metropolis MC does not fullfill dynamic hierarchy as all $\Delta E \leqslant 0$ transitions are given probability 1. After a kMC time step we are in a new state and we have a new "wheel" like the one in Fig. 5 but possibly with a different number of sectors corresponding to the new states with a finite probability to make transitions to. A new ensemble of processes is obtained after each transition. This also means that the time step in kMC changes continuously from one step to another. There are no restrictions how short or long the time step is: it can be for example a few femtoseconds or several hours. It simply follows the evolution of the system during the simulation. Time steps can be shorter in the beginning of simulation due to (initially) fast moving objects. Also, slow moving objects may break to smaller ones moving faster. Kinetic MC sounds like the optimal simulation method which can cover all possible time and length scales. The "catch" here is that the *user* has to supply both the states and the transition rates to the new states after each time steps. The kMC is not a self-going scheme in the same way as the other simulation methods are. This of course limits its use currently. Transitions rates can be obtained for example from quantum chemical calculations, MD simulations, transition state theory and experiments. As all the information of the system and rates is available the method has many attractive features: No thermodynamical equilibration is needed and no simulation of "dead dynamics" like in MD (event/step is always guaranteed). kMC is suitable for "driven systems" (irradiation, high pressure, etc.). kMC has been used in studies surface diffusion, crystal growth, molecular beam epitaxy growth, defect mobility, vacancy diffusion, reactions of surfaces, diffusion in zeolites, clustering dynamics, nucleic acid hybridization, protein folding, etc. The number of new application areas is growing rapidly. kMC can be easily incorporated in multiscale simulations schemes.

Kinetic MC is used to determine the critical layer thickness for misfit dislocations using deposition flux, temperature and a pairwise interaction potential between the particles as parameters [105]. Kinetic MC simulations are used to study the deposition rate dependence of nanopattern formation on periodically strained surfaces. The optimum nanopattern quality depends on surface strain field, temperature and deposition rate and the amount of material deposited [106]. Self-assembly of the elementary building blocks of nanophase materials are studied using both a kinetic mean-field model and a mesoscopic approach in which self-assembly is viewed as an encounter-controlled process on a discrete lattice [107]. A 3D kMC model with a Green's function-based long-range strain energy contribution and with an up-down ratio for atoms to jump out of the plane of the surface is developed to simulate the growth of self-assembled quantum dot islands [108].

Phase-Field Modeling

Classical (macroscopic) theories & models assume sharp interfaces (infinitely thin with a specific surface tension) between phases and thermodynamical variables such as T, P, concentration, etc. are used independently in each phase obeying the phenomenological rules (schematically shown in Fig. 6). Phase diagrams are common tools in chemistry text books and traditionally the compositional and structural evolution of the phase regions have been treated mathematically using distinct interfaces with suitable boundary conditions at the interfaces. The idea of a *sharp* interface is old going back to early 19th century and Young, Laplace and Gauss. Gibbs later presented the interface as a dividing surface so that the properties were distinctly different on both sides of the interface (Fig. 7). Subtraction of the upper curve (real system) from the idealized system below gives the corresponding excess quantity (here concentration) and sharp mathematical surface line. The Gibbs dividing surface has zero volume but non-zero excess quantities.

Also the idea of a *diffuse* continuous interface (Fig. 8) goes back to 19th century when it was thought that gas and liquid states were simply distant points of the same condition of matter and it was possible to move from one phase to another along a continuous path. This picture was established both experimentally by Andrews and theoretically by Thompson and van der Waals [109]. Compared to singularly sharp interface model there are many benefits with using a diffuse inteface with a finite interface volume. All field variables and corresponding equations can be defined simultaneously for the whole system. Diffuse interface allows modelling of various types of physical variables, systems and effects in a flexible and efficient way. Diffuse inteface exists on atomic scale as the surface layers are rough on atomic scale rather than mono-molecular. The density profile at the interface becomes larger than the atomic length scale due to the roughness.



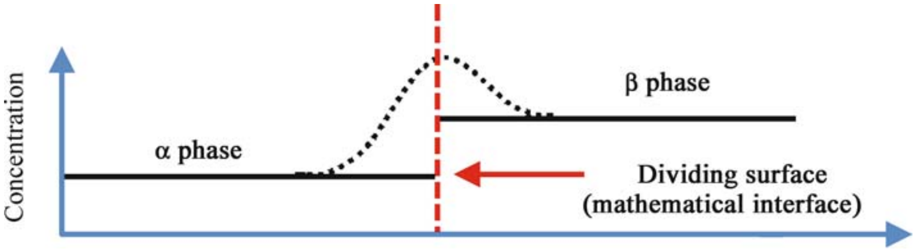
Self-assembled Materials, Figure 6
Sharp limit between two phases

Phase field modelling gathers all categories of diffuse interface models to describe a wide variety of materials phenomena (for excellent reviews, see [110,111,112,113, 114,115,116,117]). It can describe easily a large number of phenomena from nucleation to solute trapping as different physical effects can be easily included [115]. It is based on two assumptions: (i) There exists a continuous phase field variable $\phi(x, t)$ which characterizes the phases and interfaces of the system at any point point in space and time. In bulk phases it is given a constant value. (ii) The total (Helmholtz) free energy, $F[\phi, \ldots]$ can be given as a functional of the phase field variable ϕ together with any other thermodynamical variable, for example temperature, concentration etc. Even other variables can be introduced depending on the studied system. A general form of F is given as [113]:

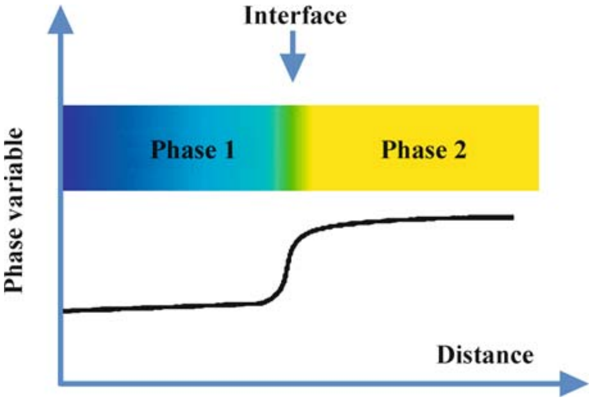
$$F = \int \Big[f(c_1, c_2, \ldots, c_n, \eta_1, \eta_2, \ldots, \eta_p) + \sum_{i=1}^{n} \alpha_i (\nabla c_i)^2 + \sum_{i=1}^{3} \sum_{j=1}^{3} \sum_{k=1}^{p} \beta_{ij} \nabla_i \eta_k \nabla_j \eta_k \Big] \mathrm{d}^3 r + \iint G(r - r') \mathrm{d}^3 r \mathrm{d}^3 r' \tag{7}$$

c denotes *conserved* variables (satisfying local conservation conditions)
η denotes *non-conserved* variables.
f is local free-energy density,
α and β are coefficients for energy gradients.

The first integral in Eq. (7) contains the local short-range interactions to the free energy, while the second integral represents the non-local long-range interactions, such as, elastic, electrostatic, polar, etc. Various phase-field models differ in their ways to treat all these contributions



Self-assembled Materials, Figure 7
Gibbs dividing surface



Self-assembled Materials, Figure 8
Diffuse continuous interface between two phases

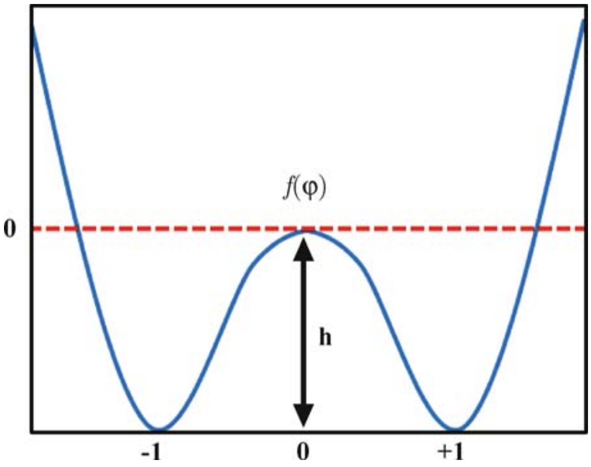
to the total free energy functional. The local free energy f is the most important term in the phase field models:

$$f = f(c_1, c_2, \ldots, c_n, \eta_1, \eta_2, \ldots, \eta_p)\,.$$

A large variety of these functions have been proposed. In many phase-field models (like for solidification) simple double-well potential functions are used for local free density like the one given in Eq. (8) and in Fig. 9:

$$f(\varphi) = 4h\left(-\tfrac{1}{2}\varphi^2 + \tfrac{1}{4}\varphi^4\right)\,. \tag{8}$$

The variable ϕ in Eq. (8) is normally called order parameter. It varies smoothly from one phase to another, distributing interfacial forces and other interactions over the interface region [8]. We can often use it in a simple double-well potential for a case where the values $\phi = -1$ and $+1$ represent liquid and solid state, respectively, h is the barrier height between the two states. We may also have the phase field $\phi = -1$ and $+1$ representing two different heterogenous mixtures during an isostructural (spinodal) decomposition while 0 is a single homogeneous phase and h is the driving force for the transformation. Other types of



Self-assembled Materials, Figure 9
Simple double-well free energy density function

similar simple local free energy density functions can also be found in literature.

Some other forms of local free energy profiles are for example the "double-obstacle" potential:

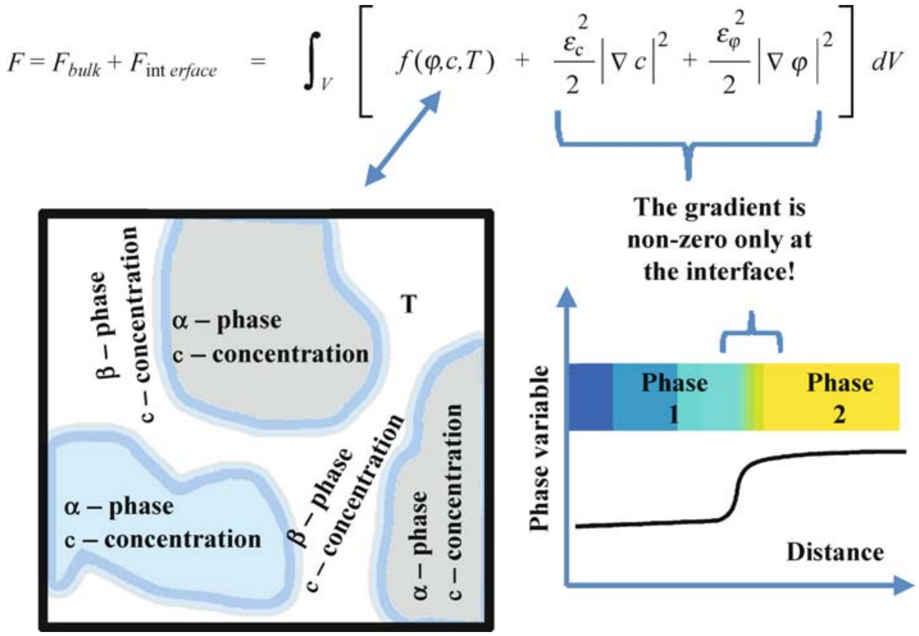
$$f(\varphi) = h(1-\varphi^2) + I(\varphi)$$
$$I(\varphi) = \begin{cases} \infty & \text{if } |\varphi| > 1 \\ 0 & \text{if } |\varphi| \leqslant 1\,. \end{cases} \tag{9}$$

Or a "crystalline" potential having infinite number of minima:

$$f(\varphi) = h\sin(\pi\varphi)\,. \tag{10}$$

Often additional phase field parameters like temperature are needed, T = temperature, T_m melting point and α is a positive constant:

$$f(\varphi, T) = 4h\left(-\tfrac{1}{2}\varphi^2 + \tfrac{1}{4}\varphi^4\right) + \frac{15\alpha}{8}\left(\varphi - \tfrac{2}{3}\varphi^2 + \tfrac{1}{5}\varphi^4\right)(T - T_\mathrm{m})\,. \tag{11}$$



Self-assembled Materials, Figure 10
Two main contributions to free energy: bulk and interface

Often coupling of phase field variables are needed – like in the following function to describe the spatial distribution for grain growth (for grains with different orientations):

$$f(\varphi_1, \varphi_2, \dots) = 4h\left(-\tfrac{1}{2}\sum_i \varphi_i^2 + \tfrac{1}{4}\sum_i \varphi_i^4\right) + \alpha \sum_i \sum_{j>i} \varphi_i^2 \varphi_j^2 \,. \qquad (12)$$

When $\alpha > 2h$ (in Eq. (12)), infinite number of of minima are located at $(1, 0, \dots)$, $(0, 1, \dots)$, $(-1, 0, \dots)$, etc., representing possible orientations of grains in a polycrystal. Functions in Eqs. (9)–(12) are discussed in [113] where several other types local free density functions are found. In general there are a large number of free energy functions like those above, all designed for specific applications and studies of phenomena. For many studies like solid-state transformations the energy functions are made of well-defined physical order parameters and use required symmetry operations of the studied high temperature phases. In general, the interfacial energies should be seen as anisotropic due to the crystalline feature of solid phase [113]. Multiple order parameter models have been proposed using both thermodynamical and geometrical formulations [114].

There are two main contributions to the total free energy; bulk and interface as illustrated in the example in Fig. 10.

Consider the isothermal process from the example in Fig. 10 with a decreasing total free energy F. At equilibrium, if the gradient coefficients are constants, the variational derivatives of F satisfy following equations [114]:

$$\frac{\delta F}{\delta \varphi} = \frac{\delta f}{\delta \varphi} - \varepsilon_\varphi^2 \nabla^2 \varphi = 0 \qquad (13)$$

$$\frac{\delta F}{\delta c} = \frac{\delta f}{\delta c} - \varepsilon_c^2 \nabla^2 c = \text{constant} \,. \qquad (14)$$

The Eq. (13) is for non-conservative variables while Eq. (14) is for conservative variables. Equation (14) is constant as the amount of solute is constant in the volume (concentration is one of the conserved quantities).

Time evolution of the phase field is assumed to be proportional to variation of the total free energy functional with respect to the order parameter ϕ [110]: $\partial\varphi/\partial t \;\propto\; L(\delta F/\delta\varphi)$. Where L = partial differential operator $(L(0) = 0)$. The phase field equations are given:

Cahn–Hillard equation [118,119]:

$$\frac{\partial c}{\partial t} = \nabla M \nabla \frac{\delta F}{\delta c} = \nabla M \nabla \left(\frac{\delta f}{\delta c} - \varepsilon_c^2 \nabla^2 c\right) \qquad (15)$$

– for conserved variables such as: concentration, molar fraction, mass, etc.

Allen–Cahn equation [120,121]:

$$\frac{\partial \eta}{\partial t} = -L\frac{\delta F}{\delta \eta} = -L\left(\frac{\delta f}{\delta \eta} - \varepsilon_\eta^2 \nabla^2 \eta\right) \qquad (16)$$

– for non-conserved variables such as: order parameters, phase fields, etc. This equation is also known as the time-dependent Ginzburg–Landau equation.

The evaluation of the phase field variables can be obtained by solving the kinetic Eqs. (15) and (16) above. Finite difference methods with explicit time-stepping are normally used by constructing a uniform grid. Discussion of numerical methods and stability of the computational schemes are given in [122].

The areas of applications of phase field simulations are increasing rapidly. Solidification and solid-state transformations are examples of the use phase field modelling as well as coarsening, grain growth and dislocation dynamics. A list of several applications can be found in Table 1 of [113].

A further development of phase field theory, called phase-field crystal (PFC) method, was present by Elder and Grant [123] for elastic and plastic deformations, free surfaces and multiple crystal orientations.

Continuous phase field model by Lu and Suo have been found applicable on self-assembly and monolayer growth on surfaces describing all required components: the phase separation, phase coarsening and phase refining processes [112]. Lu and Salac [124] have developed a phase field model to simulate pattern formation due to electric dipole interactions among adsorbate molecules revealing a unique self-assembly behavior. Wang [125] has developed a diffuse interface field approach (DIFA) which is capable to explicitly describe short- and long-range interactions and treat arbitrarily shaped particle packing processes and other related applications.

Molecular dynamics simulations can be combined with phase field modelling. Two basic approaches have been used where MD simulations carried out at the interface region are connected the phase field simulations using finite element methods [126,127] or where (moving region) MD simulations are carried out at the interface region to supply parameters, such as the strain response, kinetic coefficient (velocity vs. under-cooling behavior) and diffusivity, to the phase field model [128]. As the microstructure in many phase-field models is assumed to be coherently uniform, which is, in many cases incorrect, atomistic MD simulations may be of help in supplying anisotropic information about structure and dynamics of interface regions. A very interesting theoretical model for binary crystal nucleation was developed by Gránásy and coworkers [129,130,131,132,133,134,135,136,137,138,139], and incorporated into simulations and applied on Lennard–Jones and ice-water systems [129,130,131], polymeric dendrites [132,134,136], hydrate formation by Gránásy, Kvamme and coworkers [133,135,137,138] and heterogeneous crystal nucleation [139]. Davidchack and Laird [140,141] have used MD simulations with hard spheres to study interfacial planes between crystal and fluid-like domains.

Plapp and Karma have proposed a robust hybrid multi-scale scheme applicable in one, two and three dimensions by combining diffusion Monte Carlo (similar to the one used to solve Schrödinger equation) and phase-field models to perform simulations of dendrictic solidification. The method is applicable for other applications than solidification [142]. General critical discussion of microstructure modelling is given in [143] highlighting phase field and cellular automata methods. More examples of multi-scale methods will be given below in a dedicated chapter.

Random Sequential Adsorption

Random sequential adsorption (RSA) is a family of models for a variety of phenomena in chemistry, physics, biology, ecology, sociology and in many other fields as it is a general and highly interesting mathematical and physical packing problem [144]. It is applicable on all kinds of moving particles from atoms to motor vehicles arriving randomly as a Poisson process selecting a free space based on a distribution of sites or slots. Particles become bound if they find a vacant place (with no overlap with other particles already occupying the actual space), or they leave the system in case of no luck (possibly to try again). The process continues for a certain period of time until the distribution of sites becomes saturated (complete packing) following the random packing scheme, or if no more particles are arriving although there may still be sites available. For excellent reviews see [145,146,147,148,149]. Colloids and Surfaces A, vol. 165 is a special issue containing several articles of RSA. The one-dimensional RSA model is known as the "car parking" problem as it can be seen as an illustrative and familiar analog. Imagine a long street with apartment houses where people and families live. During the day (office hours) there is plenty of space to park but in the evening the parking spots become quickly occupied (adsorption). In the next morning cars one after another are driven away (desorption). The solution of this 1D RSA problem would give us an answer of how many drivers on average (driving similar cars) can park at random positions along a street of a certain length? This can be solved analytically if the cars are equally long and the parking slots are discrete. For continuous space along the street the exact solution was given by a Hungarian mathematician Alfréd Rényi [150]. Higher dimensional problems are complicated and approximate solutions are given

based on series expansion, or as a sequential Markovian process solved using Monte Carlo simulations although the detailed balance does not apply for irreversible processes.

The two dimensional RSA is an important and reliable model for molecules adsorbing on a surface reversible or binding irreversibly (with covalent bonds) to specific sites on the surface. Molecules can typically be monomers, dimers (occupying two neighboring sites which are vacant). Polymers can be adsorbed if they find successive empty slots on the surface. Various rules can be imposed on gas molecules approaching already occupied site. The interactions can be both specific and non-specific depending on the studied systems. Orchestration of van der Waals, electrostatic, hydrophilic/phobic interactions as well as hydrogen bonds covalent and ionic bonds leads to adsorption of molecules onto surfaces (consisting of atoms and molecules). Collective sequential adsorption (CSA) is a further generalization of RSA taking into account the local environment around the adsorption site [146]. Even large biomolecular systems (e. g. proteins, DNA, colloids, cells) can be coarse-grained and treated with RSA methods. RSA have been used even for translocation of biopolymers through pores [151] and nuclesomes on a stretched single strand DNA [152]. Generalized RSA methods can used to simulate multilayer buildup in a self-assembled layer-by-layer (LbL) process [153]. Good agreement was obtained between the simulations and experiment for colloids and poly-electrolytes suggesting that the method could be extended to polymers and proteins. Kinetics, jamming limit and structural phase behavior of polydisperse tethered nanoparticles are studied by Gray et al. [154]. Dynamics of self-assembled polyelectrolyte multilayers on glass substrates have been studied by Breit and coworkers [155]. The kinetics could be quantitatively understood using a RSA model for the buildup of a film consisting of polyelectrolyte disks with polydisperse sizes. RSA types of methods in modelling of self-assembled monolayers of charged colloidal particles are reviewed in [156]. Erban and Chapman have presented a diffusion driven random sequential adsorption simulation model operating in real physical time containing features for both reaction kinetics between the molecules and the surface and geometrical constraints of the molecular surface. It is illustrated by an assembly of reactive polymers on a virus surface [157]. Pre-patterning is used as a tool in RSA-based lattice Monte Carlo simulations to improve the self-assembly in nano and micro-scale structure engineering by Cadilhe et al. [158]. RSA model is applied for gelatin self-assembly in binary mixture of water and ethanol [159]. Short-time and long-time kinetics in colloidal adsorption to a monolayer are studied by combining RSA model and Brownian dynamics by Gray and Bonnegaze [160] in the case of self-assembly to meso-structures.

Cellular Automata

The Cellular Automaton (CA) concept was created by John von Neuman and Stanislaw Ulam more than a half century ago to originally solve problems in evolutionary biology [161]. CAs are discrete dynamical systems where space and time variables and all properties have finite discrete values. CAs start from simple identical (or nearly identical) individual systems interacting locally but evolve to complex systems following simple rules in a synchronous manner. CAs are similar to Petri nets [162] in providing a less mathematical way to differential equations and calculus. Other similar automata are the Turing systems, presented by Alan Turing in 1952 [163] showing how a simple mathematical model can describe spontaneously spreading of reacting chemical specie giving stationary concentration patterns. Turing patterns can also be found as stripes on zebras and spots on cheetahs and elsewhere in nature. Maybe the most widely known application of CAs is the tic-tac-toe like "Game of Life" by John Conway from 1970, a very simple model simulating birth and death of cells in a square lattice interacting according to a set of Boolean conditions. It was easily adapted from paper sheets to computer screen. Dynamic Cellular Automata (DCA) by Wishart and coworkers [164] is a simulation approach allowing a Brownian type of stochastic motion of individual molecules. DCA is more flexible as it allows several cells/molecules to move in a single step. Lattice gas automata are another common use of CA which together with the Boltzmann equation and kinetic theory has led to development of Lattice Boltzmann simulations [165], a powerful method to do fluid dynamics and to solve the Navier–Stokes equations in a from-bottom-up way. The obvious drawback in the current CA methods is that the objects do not have realistic features.

The quantum-dot cellular automata (QCA) approach is proposed as an alternative to molecular electronics. Theoretical behavior of QCA (arrays of Coulomb- coupled quantum-dot cells) is studied in [166] and the state of each QCA cell is determined by its interaction with neighboring cells through the Coulomb interaction and demonstrated experimentally [167] and the field was reviewed [168,169, 170]. A single-molecule implementation of a QCA cell is presented combined with *ab initio* electronic structure calculations [171] using simple prototype molecular systems with a molecule in which charge is localized on specific sites and can tunnel between those sites while the role of the dots is played by redox sites, with tunneling paths provided by bridging ligands. Possibilities to coarse-grain cellular automata, emergence, and the predictability of complex systems are studied by Israeli and Goldenfeld [172]. As molecular self-assembly is driven by local, short-range forces and therefore the dynamics is solely based on local interactions and as atomistic simulations of self-assembly become quickly complicated, a cellular automata based simulation, in which data structures, representing different molecular entities such as water and hydrophilic and hydrophobic monomers, share locally propagated force information on a hexagonal, two-dimensional lattice is proposed, with the purpose of this level of description to gain insight about entropy-driven processes in molecular many-particle systems [173].

Nilsson and Rasmussen present a lattice gas technique for simulating molecular self-assembly of amphiphilic polymers in aqueous environments, where water molecules, hydrocarbons tail-groups and amphiphilic head-groups are explicitly represented on a three dimensional discrete lattice [174]. A Cellular Automata Model of Diffusion in Aqueous Systems show that lipophilic solutes diffuse faster than do polar solutes (in agreement with experiments) [175]. Cellular automaton and MC simulations for the case of CO oxidation on a catalytic surface with simultaneous adsorption, reaction, and diffusion, including the Eley–Rideal step in the reaction mechanism is presented [176]. As properties of diffusing species in microporous materials are strongly influenced by the confining framework, providing the energy landscape for the transport process. Because of the simple topology and the cellular nature of the cages of a zeolite Demontis et al. [177] suggest that it is appropriate to apply to the study of the problem of diffusion in tight confinement a time-space discrete model such as a lattice-gas cellular automaton.

Multi-Scale Modeling

Molecules are moving in a world where "nanometer" could be used as a standard length unit and "femtosecond" is a convenient time unit. For us humans "meter" and "second" are the familiar units to which we all can relate our daily activities. In measuring the time from the big bang and distances between galaxies, both meter and second turn out immediately not to be very convenient to use. Obviously phenomena occur at different length and time scales. Connecting time and length scales has rapidly become a very vital area in from-bottom-up strategies. It will certainly still take quite some time for multi-scale modelling of matter to mature. Below we give examples of both concurrent and hierarchical approaches to multiscale modelling, the two main approaches.

"Concurrent" multiscale modelling can be accomplished by making geometric network of grid points describing the system at a detailed level successively coarser while losing more and more details. For example a crystal could be described with atoms or molecules in crystal sites connected together in 3D net. By applying a scheme with successive coarsening of connecting grid points approaching a continuum description can be coupled to the atomistic scheme by finite element methods [178]. A specific hand-shake region is created between the both scales. This is used to model cracks and fractures both at atomistic and macroscopic scale.

"Hierarchical" multiscale modelling can be performed by successively reducing the degrees of freedom which are not needed in the next less accurate description of the studied system. This makes the modelling faster and allows longer length and time scales to be covered. A powerful method called the Inverse Monte Carlo (IMC) was presented by us [179] where the "Inverse Problem" was solved completely to obtain interaction potentials (force fields) from radial distribution functions (RDF). The IMC constructs effective potentials consistent with the original RDFs. It can be used for example by starting from *ab initio* MD simulations and construct atomistic interaction potentials to be used in classical all-atom simulations. In all-atom simulations IMC can construct coarse-grained potentials for example by grouping together functional groups in large molecular systems and eliminate the solvent by incorporating it into the coarse-grained potentials. These coarse-grained potentials reproduce the RDFs in the all-atom simulations carried out with explicit solvent. This scheme can be used even beyond this kind of meso-scale description. There are other related methods presented [180,181].

Innovative computational schemes for multiscale modelling are reported continuously based on varying strategies. Examples below are given of studies (i) to couple first-principles simulations and other quantum schemes (ii) to use results from atomistic simulations to carry out subsequent coarse-graining (iii) to connect atomistic schemes with continuum models (iv) to apply kinetic Monte Carlo and other kinetic schemes subsequent to particle simulations, as well as (v) other combinations of various methods discussed earlier in this article are listed below, including a beautiful text-book example (vi) of multi-scale modelling of human hair.

(i) Transparent interface is created between classical molecular dynamics and first-principles molecular dynamics combining first-principles Born–Oppenheimer local spin density molecular dynamics (BO-LSD-MD) with classical molecular dynamics in [182]. Effective quantum mechanical classical mechanical (QM/CM) partitioning method for multiscale modeling is proposed in [183]. Quantum mechanics at the core of multi-scale simulations with neglect of diatomic differential overlap theory (used in common semi-empirical schemes such as AM1, PM3 and MNDO) is considered in [184]. Potential parameterization based on extended model systems where the force data is calculated from QM methods on a limited range of applications is shown to be essential for a consistent and ultimately, predictive embedding approach to concurrent multi-scale materials simulation in [185].

(ii) Automatic coarse-graining of polymers by deriving effective potentials for multi-atom units or super-atoms from atomistic simulations is reported in [186]. Hierarchical multi-scale modelling of plasticity of submicron thin metal films allowing modelling of thicker films a discrete dislocation model of "diffusional creep" is presented in [187]. Materials modeling platform bridging the molecular characteristics of polymers with macroscopic properties is given in [188]. Linkage between atomistic and meso-scale coarse-grained simulation based on model where the force acting on the CG particles is divided into the mean force (calculated from constrained MD simulations), friction force and random force is discussed in [189,190]. Combined atomistic and meso-scale simulation of grain growth in nanocrystalline thin films with input materials parameters obtained by MD simulation in [191]. Fuzzy clustering approach to hierarchical MD simulation of multiscale materials phenomena by combining a hierarchy of sub-dynamics: (i) rigid-body cluster dynamics for global conformational changes; (ii) implicit integration of Newton's equations for the coalescence of the clusters; and (iii) normal-mode analysis of fast atomic oscillations is used to facilitate the seamless integration of the multiple levels of abstraction in [192]. A multi-scale simulation of tungsten film delamination from silicon substrate where MD simulations of a single crystal *W* block under tension are used to calibrate a new decohesion model to investigate the effect of specimen size and loading rate on the material properties in [193].

(iii) Coupling of atomistic and continuum models in computational materials science using finite element methods is studied in [194] and finite-element method multi-scale atomistic-continuum modelling of crack propagation in a two-dimensional macroscopic plate by coupling the crack dynamics at the macro scales and nano-scales via an intermediate meso-scale continuum is carried out with molecular dynamics simulation driving the crack tip forward in [195].

(iv) Molecular simulations in zeolitic process design using configurational-biased Monte Carlo simulations combined with transition rate theories kinetic Monte Carlo and molecular dynamics simulations [196].

Multi-scale modeling of hydrogen isotope diffusion in graphite is carried out where molecular dynamics calculations resolve the microscopic length scale and deliver reliable input data for kinetic Monte Carlo calculations (jump frequencies, migration energies, jump step-sizes) from meso-scale up to the macroscopic system length [197]. An MD study of the carbon-catalyst interaction energy for multi-scale modelling of single wall carbon nano-tube growth is presented [198]. A multi-scale approach to radiation-induced segregation at various grain boundaries based on a new rate equation model and MD simulations is reported in [199]. Multi-Scale Computational Framework by integrating a Computational Fluid Dynamics software, a Kinetic Monte Carlo solver and an MD simulator for the self-assembly of atoms into molecular structures is presented in [200]. A novel polycrystalline thin film growth simulator with an atomic level one-dimensional kinetic lattice Monte Carlo model and a real time feature scale two-dimensional facet nucleation and growth model is demonstrated in [201]. A multi-scale atomistic study of the interstitials agglomeration in crystals using a hierarchy of atomistic approaches: the tight-binding molecular dynamics, molecular dynamics based on environment dependent inter-atomic potentials and a lattice kinetic Monte Carlo (LKMC) I reported in [202]. Computer simulations, spanning across different time and length scales, are used to study thin film growth morphology in organic self-assembled monolayers using thiophenes on gold. *Ab initio* calculations created a catalog of the energetics in vacuum and interactions in three orthogonal orientations to a Au (111) surface in [203]. This information was supplied as the input for kMC simulations of dimer and trimer representations of small organic molecules to describe both sub-monolayer and multilayer growth. Finally, MD studies were used to understand the packing structures of stable polymorphs of thiophene SAMs.

(v) Studies of behavior and structure of charged surfaces on different length scales is carried out using a different computational schemes yielding different levels of description of charged surfaces. (a) Coarse grained MC simulations of idealized surfaces incorporate large-length-scale fluctuation and correlation effects in the counter-ion cloud at a charged surface. (b) Brownian dynamics simulations of more realistic and structured surfaces give modified counter-ion distributions, also allowing estimations of mobility of counter-ions at charged surfaces. (c) All-atomistic MD simulations reproduce water structuring effects at surfaces such as hydration and hydrophobic de-wetting. (d) *Ab initio* calculations finally give the effective interactions between oppositely charged groups in vacuum and in solution in [204]. Multiscale simulations using generalized interpolation material point method and Structured Adaptive Mesh Refinement Application Infrastructure parallel processing as a multiple length scale tool from nanometer to millimeter is presented in [205]. To simulate the agglomeration carbonaceous nanoparticle assembly was studied using a multiscale coarse-graining by starting with an atomistic ensemble of 10 000 nanoparticles (or effectively 2 million total carbon atoms). The coarse-graining was accomplished applying a force-matching procedure. The results show rich and varied clustering behaviors for different particle morphologies [206]. A multiscale coarse-graining to derive coarse-grained models is applied to C60 and to carbonaceous nano-particles produced in combustion environments. The coarse-graining of the inter-particle force field is accomplished applying a force-matching procedure from all-atom MD simulations reproduce accurately the structural properties of the nano-particle systems [207].

(vi) A very impressive multiscale modelling approach to the mechanics of human hair fibres is given by Akkermans in [208] providing a very concrete example of multiscale modelling work-flows at their best where mesoscale models are constructed from atomistic simulations and where meso-scale simulation methods are used as input to finite-element calculations.

There are several excellent reviews discussing a great variety of invented multi-scale modelling schemes in materials science listed below and well worth of consulting. Simulation methods including broad areas of quantum mechanics, molecular dynamics and multiple-scale approaches, based on coupling the atomistic and continuum models are discussed in [209] and continuum/quasi-continuum approaches, the kinetic Monte Carlo technique and accelerated molecular dynamics simulation are gathered in [210]. Recent advances in bridging scale between quantum mechanical and continuum coupling are briefly described in [211] and multiscale hybrid simulation methods for material systems based on tight-binding DFT, MD and continuum models for deformation and diffusion on surfaces are reviewed in [212]. A seamless coupling of quantum to statistical to continuum mechanics involving models for unifying finite elements, molecular dynamics and semi-empirical tight-binding and coarse-grained Molecular Dynamics as an effective model in solid state is explained in [213]. Current trends from atomistic simulation towards multiscale modelling of materials based on quantum mechanical, especially density functional theory for electronic properties linked to atomic/molecular dynamics and kinetic Monte Carlo simulations where coarse graining leads to lattice gas and cellular automata, and also to continuum equations solved by finite-element and finite-difference techniques are discussed in [214]. Vvedensky presents a comprehensive outlook and an excellent review of current multiscale modelling methods for nanostructures across a vast range of length and time scales clearly stating that a complete understanding of the behavior of materials thereby requires theoretical and computational tools that span from the atomic-scale detail of first-principles methods to the more coarse-grained description provided by continuum equations with the ultimate aim to systematically couple the scales from the atomistic to the continuum level in [215].

Multi-scale mechanics of nano-composites including an interface to better understand the phenomenological changes across multiple length and time scales are reviewed in [216] and current multi-scale modeling and simulation of nano-structured materials in [217]. Modelling the nano-scale phenomena in condensed matter physics via computer-based numerical simulations focusing on the adhesive and indentation properties of the solid surfaces in nano-contacts, the nucleation and growth of nanophase metallic and semi-conducting atomic and molecular films on supporting substrates, and the nano- and multiscale crack propagation properties of metallic lattices are discussed in [218]. Heterogeneous multiscale methods, applicable on complex fluids, micro-fluidics, solids, interface problems, stochastic problems, and statistically self-similar problems are reviewed in [219] and the emerging role of multiscale modeling in nano- and micro-mechanics of materials in [220].

Hierarchical modeling of amorphous polymers where a broad spectra of length and time scales governing the behavior of these materials is based on the use of connectivity-altering Monte Carlo algorithms for rapid equilibration of atomistic models of long-chain polymer systems, calculation of their conformational, packing and volumetric properties, and assessment of their entanglement structure, and self-consistent field calculations of morphology development in complex systems containing block copolymers, coupled with rubber elasticity theory for the prediction of the stress-strain behavior of these systems are discussed in [221]. Linking various length scales via materials informatics is reviewed in [222]. Recent progress in the simulations of liquid crystals across a range of length and time scales is reviewed in [223] with three material properties of liquid crystals (the archetypal self-assembled materials in Nature) are discussed in detail: elastic constants, rotational viscosity and helical twisting powers. Computer simulations of surfactant solutions are reviewed by Shelley & Shelley discussing the importance of connecting the inherently disparate length scales treating the systems using a single coherent multiscale simulation [224]. In an excellent review dealing with self-assembly from nano-scale to micro-scale colloids, issues like the effect of the shape and composition on assembly and the role of these factors in the self-organization of particles into ordered assemblies, scale dependent effects on assembly related to interparticle forces, vitrification and gelation and also building block design rules from computer simulations using anisotropic interactions are discussed in [225]. Karakasisis and Charitidis give an excellent review of methods in multiscale computational materials science how to connect electronic structure calculations with classical atomistic simulation using molecular dynamics or Monte Carlo methods at the nano/micro scale and further with kinetic Monte Carlo for larger system/time scales and finite elements for very large scales, presenting both hierarchical and hybrid strategies in [226]. A multiscale modelling scheme is reviewed, starting the initial nucleation processes using MD simulation and inputing the data into a cellular automaton (CA)-based model of the microstructure formation at the micro-scale, as well as to the macroscopic heat flow equation in [227]. Thermodynamics of self-assembly of surfactants in solution through simulations is now being expanded to include phenomena in the fluid dynamic regime a smooth link from MD to mesoscopic and macroscopic length and time scales. Recent trends in this area along with new results based on classical approaches are reviewed in [228].

Future Directions

Self-assembly is a process of pivotal importance that should be very attractive to study using modelling and simulations. The intermolecular interactions that drives the process can be directly introduced into common forms of the interaction potentials and force-fields. Many self-assembly processes can indeed also be rationalized and understood both molecularly and macroscopically by means of thermodynamics.

Self-assembly is typically a relatively slow process that proceeds through several metastable states. The extended time-scale and structure evolution that usually extends of several length scales requires a combination of approaches. The rapid expansion of multi scale modeling approaches show much promise but it is still a long way to go before the fine details of self assembly processes with durations of hours up to weeks can be captured accurately. In principle the kinetic Monte Carlo method could cover arbitrary long time scales but it requires detailed knowledge about the system, its states and barriers between them.

Another great challenge in modern computational molecular science is the transition from a descriptive to a predictive level of molecular modeling. Despite several examples of successful predictions of molecular properties *in silico*, current molecular modeling remains largely on a descriptive stage: simulations are used to describe already known experimental phenomena, in order to give a better understanding, for testing the theories describing experiment, or for correct interpretation of the experimental data. Ability of simulations to predict, to discover something new is still rather limited. While some properties are predicted, others are not, successful investigations are published while failures are not, etc., so it is still difficult to rely on simulation results and experimental verification of simulation is therefore always needed. One of the reasons to a limited predictability of molecular models is that the currently used force fields were developed originally at the early stages of molecular modeling in the 80s with rather limited computing resources at hands and later only refined in a few occasions. In the case of meso-scale modeling on a coarse-grained level, even a functional form of the interaction potential is not known and therefore many *ad hoc* models are used. In order to substantially improve reliability and predictability of molecular simulations, a new generation of force fields would be necessary, which have to be derived in a more consecutive manner with more emphasis on the fundamental *ab-initio* approaches. To replace experiment with a computer experiment surely lies far in the future. However, if modelling can point the right direction to an experimentalist, much guesswork, effort and resources can be saved.

Article Outline

Glossary

Self organization A property of open and complex systems that achieve their order spontaneously, that is, by means of "self-organization".

City A form of settlement that first emerged in the Near East (the core being Mesopotamia) some 5500 years ago. Since its first appearance in Mesopotamia it has diffused in space and time. With colonialism the Western–European form of city has diffused to the entire world, suppressing on the way other forms of cities (e. g. in South America, East Asia, etc.). In the last few decades the city has become the most dominant form of settlement: for the first time in human history more than half of world population lives in cities.

Urbanism The term refers to the totality of life in cities: the interrelations between the social structure, culture, economy, politics, architecture, physical morphology, … associated with life in cities. The first appearance of cities is thus termed *the urban revolution*. Most students of urbanism would agree that 21st century society is undergoing a major urban transformation; some describe it as a new urban revolution.

Planning Planning is, on the one hand, a basic cognitive capability of humans while on the other, a profession and research domain termed interchangeably *city planning*, *urban and regional planning* or *environmental planning*. City planners work and act in the context of planning law and administration the aim of which is to regulate and control life in cities.

SIRN (synergetic inter-representation network) An approach to cognitive mapping and urban dynamics suggesting that cities emerge, maintain their order and change again as a consequence of an on-going interaction between cognitive maps that are constructed in the mind/brain of humans as internal representations and the city as a collective external representation. This on-going interaction gives rise to a network some of whose elements are in the mind/brain, while others in the world.

Information compression, inflation and adaptation A view suggesting that Shannon's notion of information is a property of closed systems and that in complex, self-organizing systems one has to take into consideration the role of *semantic information*. Due to semantic information, the process of self-organization often entails *information compression*; in some cases it entails *information inflation*. The suggestion is that information compression and inflation are two facets of the process of *information adaptation*.

Definition of the Subject

Self-organization is a central property of open and complex systems. While the concept had already appeared in the 1940s, its modern use was pioneered in the 1960s by people such as Haken [50,51] with his theory of *synergetics*, Prigogine with his notion of *dissipative structures* [87,109,110] and others (see review in Chap. 3.1 [95]). Such systems are typically in "a far from equilibrium condition" and exhibit phenomena of chaos, fractal structure and the like. For a long time, the term "self-organization" was used also as an umbrella name for these theories; nowadays it is common to refer to these theories as *complexity theories*.

The notions of self-organization and complexity originated in the sciences, specifically in physics, as a property of natural systems. However, as we shall see below, from the start they were associated with the city – at the beginning the city was used as a metaphor to convey the notion of "self-organization" [87] and at a later stage it was studied as a genuine self-organization system in its own sake [5].

Most theories and methodologies of complexity developed in the last three decades have been applied also to the study of cities with the result that we now have a rich body of research on *fractal cities* [20], *self-organization and the city* [95], *cities and complexity* [16], cellular automata and agent base urban simulation models [22], studies on cities from the perspective of Bak's self-organized criticality [20], studies on cities as networks [16] and much more. This growing body while enriching our understanding of cities and providing sophisticated tools to city planning, also exposes problems that will become the challenges for the next generation of studies on complexity, self-organization and the city.

Introduction

The title "Self-Organization and the City" enfolds *two notions* – 'Self-organization' and 'City', *a thesis* suggesting that cities are complex self-organizing systems, and an *inconsistency* – the view of cities as complex systems that achieve their order spontaneously contradicts the traditional view of cities as symbols of organized order and planning. From the title thus follow four questions: what is self-organization? What is a city? In what sense are cities self-organizing systems? What is the meaning of planning in a self-organizing system? In an *Encyclopedia of Complexity and System Sciences* such as this, there is no need to introduce the term self-organization beyond what has been said about it above; we are thus left with three introductory tasks, namely, to clarify the notion "City", elaborate the thesis that cities are self-organizing systems, and, solve the contradiction between self-organization and planning in the realm of cities.

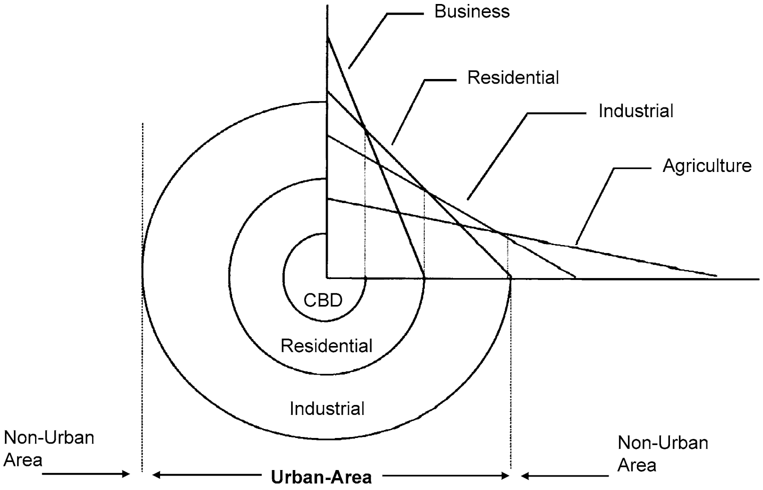
What is a City?

There are two ways to answer this question: first, by looking at explicit attempts to define a city. Second, by exposing the way the different theories of cities explicitly describe, or implicitly perceive, a city.

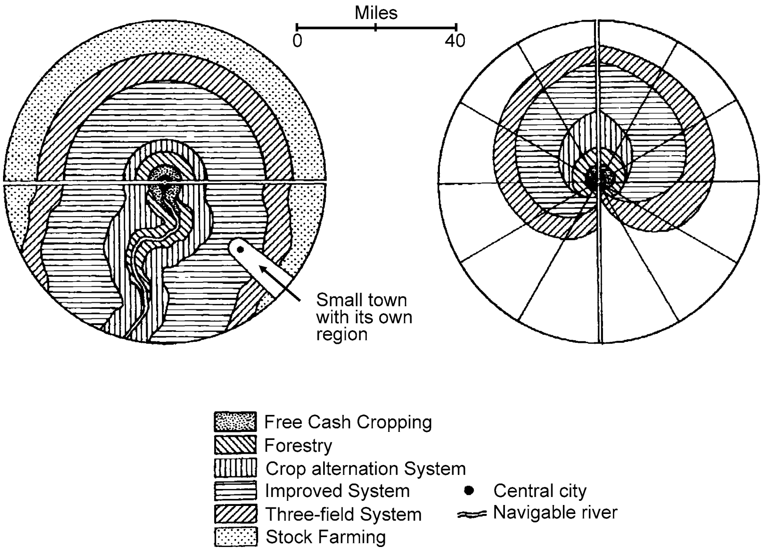
Explicit Attempts to Define a City The history of the many attempts to define "a city" is rather confusing: Whenever a definition was proposed, it was always possible to falsify it (in Popper's [90] sense) by putting forward cities that do not comply with the definition. The main reason for the failure to define cities is that the various attempts to do so were always made with reference to what in cognitive science [115] is called *classical categories*. That is, groups composed of entities sharing some necessary and sufficient conditions that define them as a category and distinguish them from other categories. Students of urbanism have implicitly treated cities as classical categories, and yet, cities are not classical categories – they form a category due to what Wittgenstein [136] has termed *family resemblance*. As a consequence, attempts to define them in terms of a classical category ended up with a failure [95].

A family resemblance category becomes a category not when its elements share some common denominators, but when they form a *network* of partial links and similarities. Further research and experiments have found that many family resemblance categories have a *core-periphery* structure, in the sense that some instances of the category are more *prototypical* of the category than others and they thus form its center while the rest of the instances form the category's periphery [74,78,115].

The city is a good example of a family resemblance category with a core periphery structure. On the one hand, there are no common elements between the "first" cities of some 5,500 years ago and the cities of today except for the name. On the other hand, the first cities had space-time links and similarities with subsequent cities, which in turn had common elements with subsequent cities, and so on until the global cities of today. The result of this process is that cities form a huge space-time family resemblance network extending in time and space from the ancient cities of 5,500 years ago to the cities of today. In this network, one can identify space-time moments during which certain cities became more characteristic or proto-



Self-Organization and the City, Figure 1
Thünen's type land-use system as transformed into an urban land-use system by location theory. Businesses are prepared to pay high rent at the center of the city, but are reluctant to "live" far from it. Their spatial demand curves (or rbc – rent bid curves) are thus the highest and steepest. Industrialists, in this exposition, are exactly the opposite and residents are in between: they cannot afford to pay the high prices at the center, but are prepared to live far from it, and so on. Each land use thus occupies a ring were it can pay (bid for) the highest rent. Note that the principle of marginal utility which is implicit in Thünen's landscape, here appears explicitly as the central economic principle



Self-Organization and the City, Figure 2
The diagrams of Thünen's *Isolated State*: *Left, upper part of the diagram* "This shows the Isolated State in the shape it must take from the assumptions made in Section One...". *Left, lower part* "Here we see the Isolated State crossed by a navigable river. Here the ring of crop alternation become very much larger, stretching along the river ... The effect of constructing a highway is similar, ... " (Par. 385). *Right* "The diagram illustrates the effect of the Town grain price on the extension of the cultivated plain" (Par. 386). Source: [129]

typical of the category than others. Such cities have temporarily captured the center of the category city, pushing to the periphery the rest of the instances, only to be replaced in subsequent space-time moments by other prototypical cities, other centers and other peripheries. How does this huge network evolve in time and space? The answer is: "by means of self-organization" [95].

Images of Cities This section discusses images of cities that are implicit or explicit in several of the urban theories.

(Source: Figs. 2, 4, 6 in [36])

Only theories that facilitate subsequent discussion will be discussed.

The Economic City The city is portrayed as a center-periphery structure with several rings that come into being by an economic competition between land uses that differ in their spatial demand function (Fig. 1). The land uses with the highest and steepest *spatial demand curves* or *rent bid curves* [8,69] capture the central ring – the most accessible area of the city – thus forming the CBD (central business district); the rest of the land uses occupy the peripheral rings. The origin of this city image is von Thünen's [129] *Isolated State* (Fig. 2): Originally formulated as a theory of agricultural land uses it became the founding theory of all location theories including urban land use theories.

The City as a Central Place The city is perceived as a central place that mediates between the city's complementary region and other cities that form a hierarchical network of central places (Fig. 3). The origin of this view is Christaller's [36] *central place theory* that perceived the city as a central place for tertiary activities (a market place, transportation node and administrative center). Losch's [81] central place theory was more ambitious and complicated and portrayed the city as a central place for all production, consumption, transportation and political activities (Fig. 4).

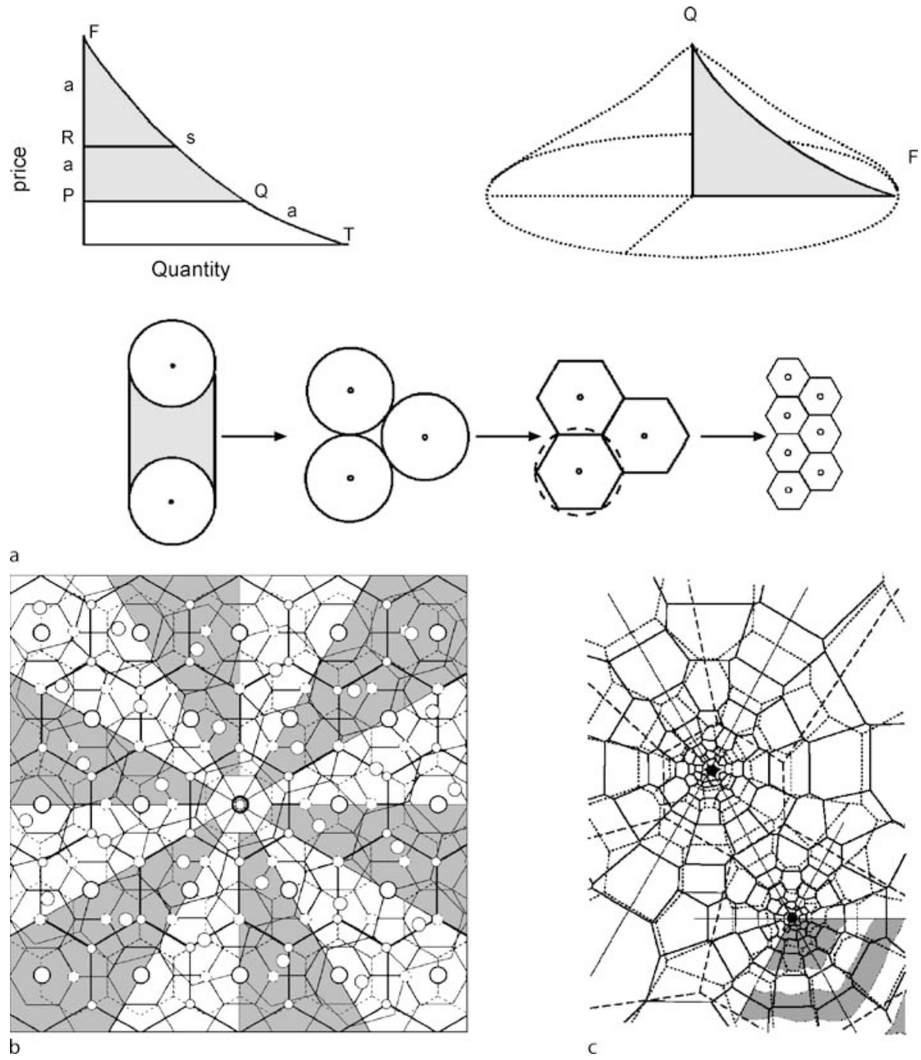
The City as a Node in a System of Cities The city here "looses" its autonomy in the sense that it is perceived as a node in a system of cities – no attention is paid to the city's role or function; the focus of interest is on the system as a whole. This view is due to Auerbach [10] who already at the turn of the 20th century showed that the rank-size distribution of cities obeys the power law. In a famous work from 1949 Zipf showed that this rank-size distribution typifies not only cities (Fig. 5), but a whole range of phenomena [138]. Zipf's work provided a source of inspiration to a long list of subsequent studies on systems of cities [111].

The Ecological City As in the economic city, here too, the city is portrayed as a center-periphery ring structure. However, here the city's structure emerges out of a competition between cultural and socio-economic groups in a way similar to competition between species in natural ecology. The various studies in this domain are termed *urban ecology*; their source of inspiration is the Chicago school of social ecology. Several urban landscapes were suggested the most dominant one is Burgess' [30,31,32] ring structure (Fig. 6).

The City as a Representation of Society The city is here perceived as a spatial representation of society as a whole. This image of the city emerged in the early 1970s as a consequence of a paradigm shift the study of cities underwent – from liberal social and economic theories to more radical ones with Marxism being the most dominant view. Two Marxist interpretations of the city can give the flavor of this approach. The first is Castells' [33] view according to which the city is a spatial representation of the structure of society as perceived by structuralist-Marxist theory (Fig. 7). The second is Harvey's view according to which the city's landscape emerges, as a logical consequence, out of internal contradictions inherent in the capitalist *mode of production* that according to this view, dominates world society of the 20th and 21st centuries. Namely, between forces of spatial agglomeration and processes of spatial dispersion. As illustrated in Fig. 8, this tension can be resolved only by *the urbanization of capital* [47,63].

The City as a Socio-cultural Force The city is here perceived as a force that is shaping the life of the people living in it. In urban societies it implies that the city is in fact shaping society. This view is due to the study of Wirth's [135] *Urbanism as a way of life* and also of Park's study *The City* [88]. In 1970 Lefebvre has published a monograph *La Révolution Urbaine* suggesting from a Marxist point of view that society is reaching a stage of being completely urban so that urbanism is replacing industrialism as the major force of society [79].

The Postmodern City The city of 21st century is described as the postmodern city [95]: Untamed, shrew, capricious, ever-changing; actually it is not a city but a text written by millions of unknown writers, unaware that they are writers, read by millions of readers, each reading his or her own personal and subjective story in this ever-changing chaotic text, thus changing and recreating and further complicating it. Today's urbanism is a big theater at the center of whose stage we see a kaleidoscope of shapes, forms, high-tech science-fiction structures, cultures and sub-cultures, Italians, Chinese, Japanese, Jews, Indians, Gays, Lesbians. Yapese; nothing is stable, nothing



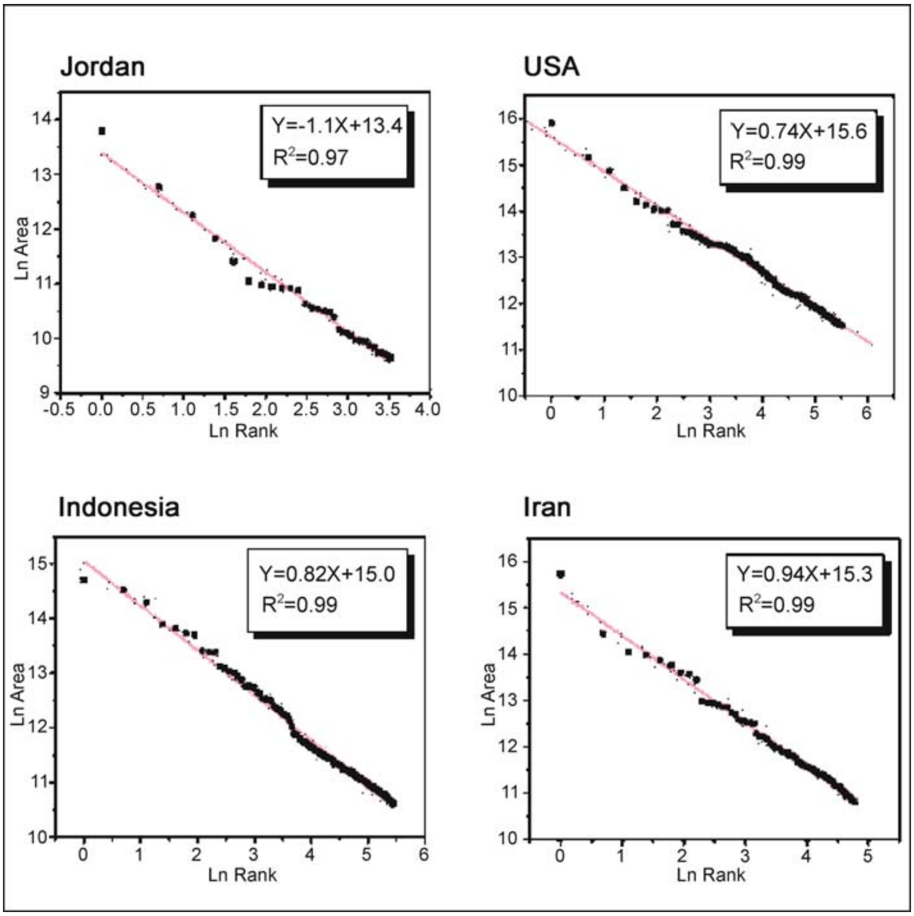
Self-Organization and the City, Figure 4
a The derivation of Lösch's system of central places. *Top* The derivation of a *spatial demand cone* with its market area (*right*) out of an "ordinary" demand curve (*left*). *Bottom* Development of market areas from the large circle to the final small hexagon. Source: Figs. 20–23 in [81]. b Lösch's derived system of central places with their market areas, divided into "city-poor", "city-rich" sectors. Source: Fig. 28 in [81]. c A Lösch system of central places modified by Isard [69] so as to be consistent with the resulting population distribution

is true nor matter for more than a second, not the Marxist urban categories, nor any other grand theory or truth; all must go, must move, clear the way to the new next whatever it is.

The Self-organizing City Strangely enough, an image of the city similar to the postmodern one is emerging out of complexity studies of cities. This is a seemingly similarity, however; a closer look reveals, first, that theories of complexity made a direct and explicit link to the views of cities as central places, to the studies on systems of cities and to the ecological views on the city. Second, that the notion of self-organizing city has several important resemblances with modern social theory oriented urban studies that perceive the city as the representation of society.

In What Sense Are Cities Self-organized Systems?

Self-organization is a property of systems that are open and complex. No one plan such systems, no one fully controls them and yet they have order, rules, organization and all these emerge spontaneously by means of self orga-



Self-Organization and the City, Figure 5

nization. A nice example of self-organization is provided by human languages (Chinese, Hebrew, English …). Each such language is an open system; each is a complex system; each is a system that emerged out of synergetic interaction between a huge number of people (the "parts" of such systems); no one has ever fully controlled languages; no one has fully planned a language; and yet each of the human languages has order, rules, organization and all these emerged spontaneously by means of self organization.

Similarly to human languages, each city is an artifact; each is an open system; each is a complex system; each city is a system that emerged out of interaction between a huge number of people; no one fully controls it; and yet it has order, rules, organization and all these spontaneously by means of self organization.

But cities are not languages. For one thing, their products are stand-alone objects such as buildings, roads, bridges, etc. that exist and survive independently of their producers. The products of languages are humans' voices and gestures that have no existence independent of their producers. Cities, in this respect, are akin to writing and texts – the external, stand-alone, representations of languages. The appearance of cities, some 5,500 years ago, hand in hand with writing, is, to my mind, not accidental.

A second difference concerns planning: There are no language planners and the attempt to "plan" the international language of Esperanto ended in failure. But there are many city planners – much more than appreciated in conventional planning theory. This is so because planning is a basic human property with the implication that each agent operating in the city (person, family, company) is a planner on a certain level. In certain cases, because of the nonlinearities that typify the complexity of cities, the planned action of a single individual might influence the city more than that of the official planners and their plans. Urban dynamics can thus be seen as an on-going interaction between planners and their plans when none of them

can fully determine the final form and structure of the city. They are all *participants* in a big city-planning game (see Part III in [95]).

The Inconsistency Between Self-Organization and Planning

All theories of cities were associated with city planning. The basic idea is that the city is an artifact and as such a product of humans' intentions and needs. Planning is needed in order to implement human needs and intentions in a rational way. The notion of complexity suggests that the city is a product of self-organization; if this is so, who needs city planning? The answer to this inconsistency has already been given above: the plans produced by city planners, like those produced by "ordinary" urban agents, are *participants* in a big city-planning game.

Complexity Theories of Cities – an Overview

The discussion in this section proceeds under the titles of eight "cities" that are related to general theories or specific methodologies. It starts with 'dissipative cities' to indicate that Prigogine's was the first complexity theory applied to the study of cities

Dissipative Cities

In their introduction to *Self-Organization in Nonequilibrium Systems* Nicolis and Prigogine [87] use the example of a city as a metaphor to convey to their fellow physicists what they mean by "self-organization."

> "An appropriate illustration would be a town that can only survive as long as it is a center for inflow of food, fuel … and sends out products and wastes."

Peter Allen [5] – Prigogine's student – showed that towns and cities are not just metaphors, but genuine self-organizing systems. He did so by reformulating *central place theory* (above Sect. "Images of Cities") in terms of Prigogine's theory. (Note the resemblance between the hexagonal landscapes of *central place theory* and the hexagonal Bénard cells – one of the canonical experiments of the paradigm of self-organization).

Allen and co-workers' have developed a sequence of several models which elaborated their theoretical treatment of hierarchical landscapes of central places, first with respect to systems of cities in a given region and later at the intra-urban scale in connection with a single city. At a later stage they have also applied their models to real case studies of Brussels and the Belgian provinces [121], see also [109].

A typical model of Allan's starts with an infrastructure of localities in a region, each with its residents and jobs. The actors are individuals who migrate in order to get employment, and employers who offer or take away

jobs depending on the market's situation. The migration/interaction between localities and the introduction and extraction of economic activities (i. e. employment opportunities), create for each locality a kind of local "carrying capacity" and for the system as a whole nonlinearities and feedback loops which link population growth and manufacturing activities. An example for a simulated scenario produced by the model is Fig. 9. It starts (Fig. 9a) with a hypothetical region characterized by a rectangular lattice of homogeneous localities. Then, the mere play of chance factors, such as the place and time where different enterprises and migrations start, produce symmetry breakings which entail an uneven distribution of population, employment and so on (Figs. 9b–d). The result is an evolutionary process by which new urban centers emerge, grow, and form the whole of the regional system of central places; as the system evolves, some old localities grow, others decline or even disappear, thus constructing the specific history of this region.

Allen and co-workers' approach exposes the similarity and difference between the "old" static approaches of Christaller and Lösch, and the new treatment by means of self-organization. In both, economic activities and interactions give rise to cities as central places. However, while in the old formulations the landscape reflects an equilibrium state which is the optimized sum of the properties of the various economic forces, the new landscape reflects a far-from-equilibrium situation in which the spatial hierarchical order among the central places is obtained, maintained and then transformed, by means of interplay between interaction, fluctuations and dissipation.

Synergetic Cities

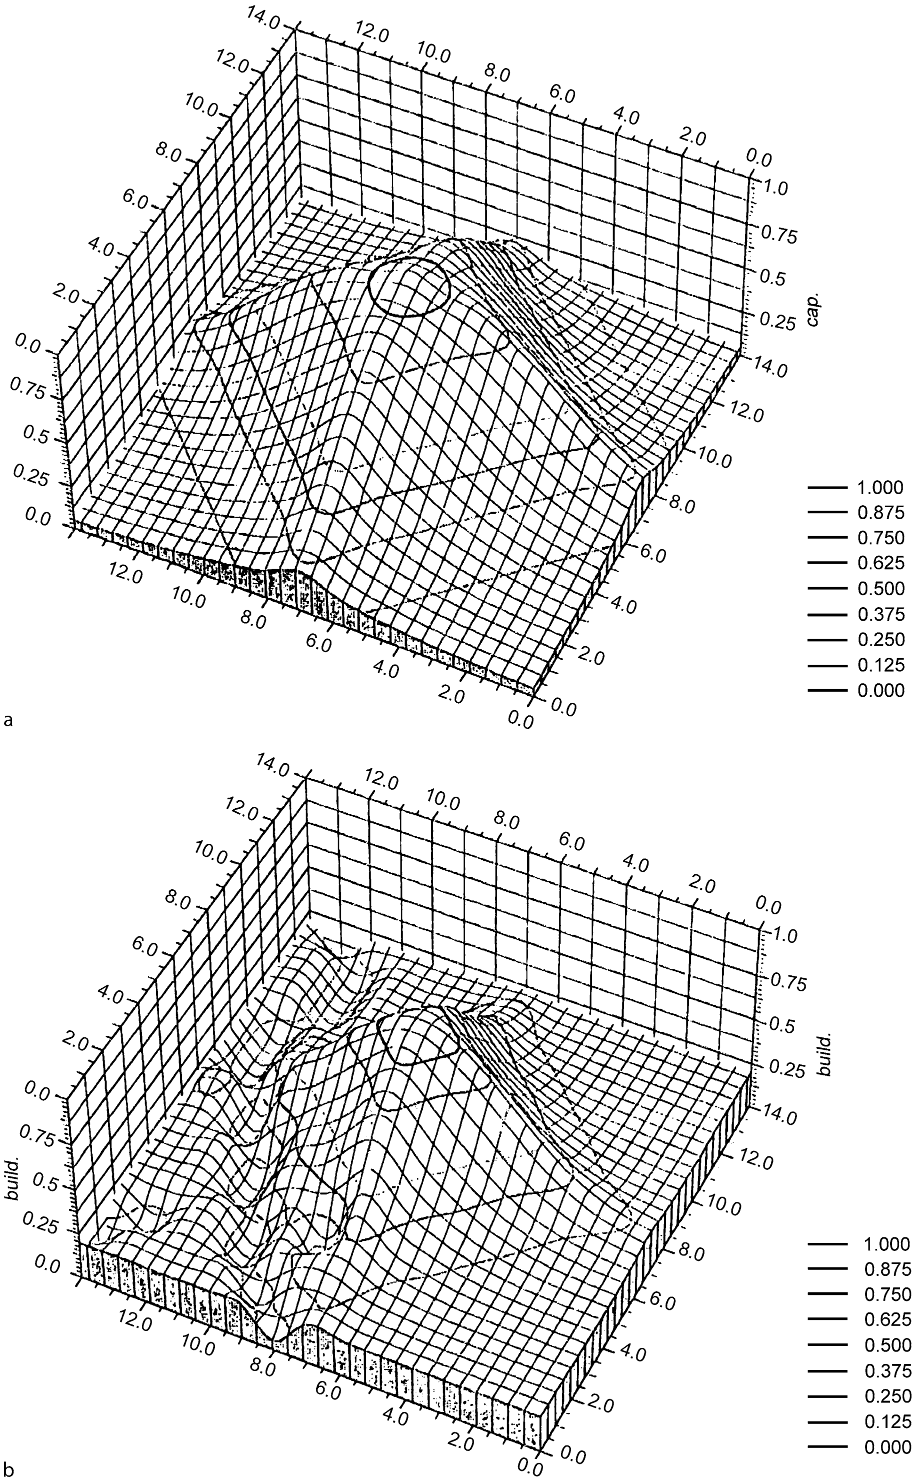
Two main approaches of synergetics have been applied to the study of cities. The first is the master-equation approach that is characteristic of Weidlich and co-workers studies in sociology, economics and urban dynamics [131,132,133,134]. For many years this was the main synergetic approach to cities, and most applications thus far have been within this conceptual frame [48,112,119]. The second, the pattern recognition approach, typifies the synergetics' treatment of pattern formation, cognition, pattern recognition and brain activities, as developed in the last three decades by Haken and co-workers [56]. Since the 1990s this approach has been applied to the study of cities as self-organizing systems [58,95].

Slow Cities and Fast Regions One way to look at Haken's synergetics and its slaving principle is in terms of interplay between slow and fast processes:

> If in a system of nonlinear equations of motion for many variables these variables can be separated into slow ones and fast ones, a few of the slow variables … are predestined to become "order parameters" dominating the dynamics of the whole system on the macro-scale [134].

This perspective stands at the basis of Weidlich's and co-workers studies on sociodynamics and cities [131,132, 133,134]. According to this perspective, fast and slow processes are easily identifiable in processes of settlement and urbanism. The fast ones typify the local microlevel of building sites, streets, subways, etc., whereas the slow processes typify the macrolevel of whole regions which are often described as systems of cities. The relations between the slow and the fast processes are described by the slaving principle: on the one hand, the regional system

> serves as the environment and the boundary condition under which each local urban microstructure evolves. On the other hand, the … regional macrostructure is … the global resultant of many local structures [134].



Self-Organization and the City, Figure 10

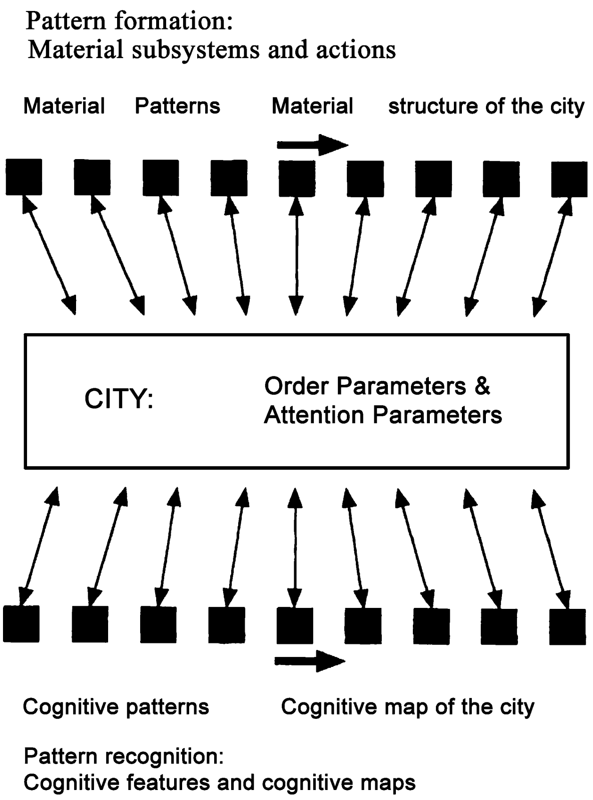
Building and development under population pressure [134]. ***Top*****: on a uniform urban plain.** ***Bottom:*** **on an urban plain with disturbances**

This circular causality between the local and the global, allows one to study global regional systems by assuming that local processes adapt to the slow regional ones, and to study local urban processes by treating the regional context as given, and of course to study the complex interplay between the local and the global. In all three cases Weidlich has recently prescribed a four stages approach: stage 1 concerns the configuration space of the variables; stage 2, measures the utility of each configuration; stage 3, defines transition rates between configurations which are in fact utility differences; stage 4 derives stochastic or quasi-deterministic evolution equations for the system under consideration. The central evolution equation is the master equation which defines the probability that the configuration under examination is realized at a certain time.

The above theoretical procedure has been used to study the role of population pressure in "fast and slow processes in the evolution of urban and regional settlement structures". Figure 10 brings some results from these studies, in which the city capacity for building and development is related to population pressure. Figure 10a shows the evolving city capacity when the urban plain is uniform, and Fig. 10b, when it is disturbed in one of its sites.

Pattern Formation and Pattern Recognition in the City

The paradigm of pattern recognition was derived by an analogy to the material process of pattern formation [54]. Haken and Portugali suggested that the synergetic pattern recognition paradigm is specifically attractive for the study of cities [58]. The latter can be perceived as self-organizing systems which are both physical and cognitive: individuals' cognitive maps determine their location and actions in the city, and thus the physical structure of the city and the latter simultaneously affects individuals' cognitive maps of the city. In their preliminary mathematical model Haken and Portugali construct the city as a hilly landscape which is evolving, changing and moving as a consequence of the movement and actions of individuals (firms etc.). The latter give rise to the order parameters which compete and enslave the individual parts of the system and thus determine the structure of the city. The new feature of this exposition is that the order parameters enslave and thus determine two patterns (Fig. 11): one is the material pattern of the city, and the other is the cognitive pattern of the city – its cognitive map(s).



Self-Organization and the City, Figure 11
The city as self-organizing systems which is at the same time both physical and cognitive. Its emerging order- and attention-parameters enslave the city's cognitive and material patterns. Source: [95]

Chaotic Cities

Self-organization is often regarded as a theory about *Order out of Chaos* [110] and yet, with a few exceptions [39,95] chaotic behavior is rarely studied in cities. Most complexity studies of cities perceive cities as ordered structures which the theory of complexity explains just how their order state was created. According to Batty (see p. 29 in [16]) this is "because the required growth rates [for chaotic behavior to appear in cities] are far too large". My view is that this is due, firstly, to the tendency of most students of complexity to focus on the short-term dynamics of Western cities from which perspective cities are indeed structurally stable. However, when the focus of interest turns to the long-term rural urban migration process in a country such as China, or to the archaeological record of the rise and fall of urban cultures [95,105], chaos suddenly appears. Looking at this *longue durée* [26] of cities, their evolution exhibits a very distinct and routinized path: a long period of "steady state", followed by a short period of strong fluctuations or chaos, from which the system re-emerges to a new level of steady state and structural stability, and so on (Fig. 12). As can be seen, the urban system moves from one structurally stable state to another, via bifurca-

Source: [93,95]

tions, when every evolutionary move is a transition from a microscopic chaotic state to an ordered, macro, steady state.

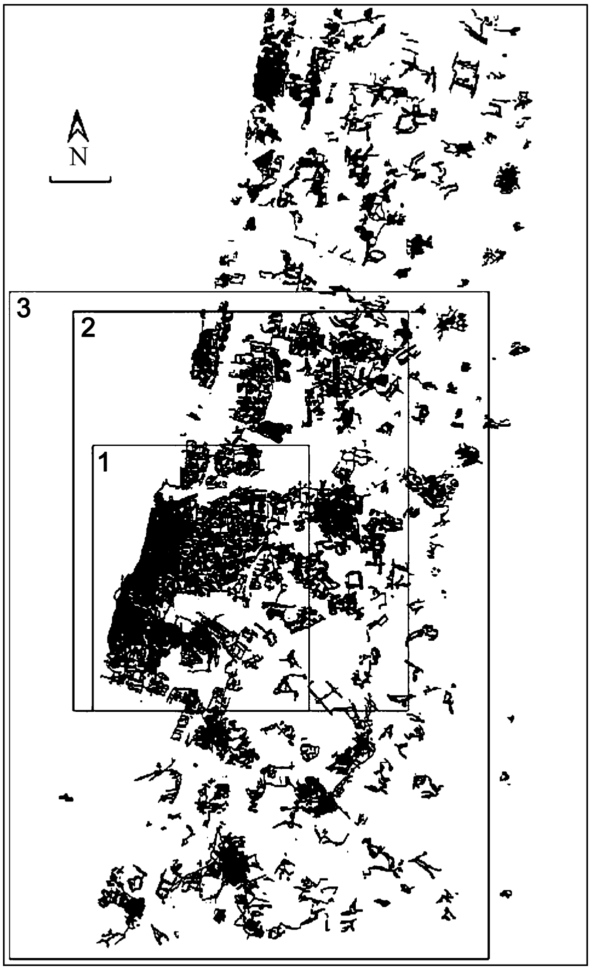
Secondly, this is due to the fact that phenomena of chaos and their role in cities during their short-term structurally stable periods have not as yet been fully studied. In a preliminary attempt to do so it has been found that often, when the city as a whole evolves stably, a few local unstable chaotic areas are found captive within the otherwise stable city. This phenomenon has been termed *the captivity principle* with the suggestion that it might play a supplementary role to Haken's slaving principle (see Chap. 5.8 in [95], [61]), namely, that these local islands of instability are needed in order to maintain the overall global stability of the city. Figure 15 below provides a hypothetical example simulated by means of cellular automata.

The play between chaos and order might show up also in the daily routines of cities. The movement of cars on the roads, or of pedestrians on pavements, are characterized by shifts between instable and stable motions and might thus be candidates for this kind of interpretation.

Fractal Cities

Mandelbrot's theory of fractals is based on the notions of *self similarity* and the *fractal dimension*, and, on the idea that a rather simple iterative process might produce highly complex geometrical shapes. Using these principles, several scholars have demonstrated, first, that the complex geometries of urban form, growth and evolution, on intra-urban and inter-urban regional scales, can be generated by means of a simple iterative process with a few and simple rules. Second, that many urban structures are self-similar and have fractal structure. The most comprehensive study in this domain is Batty and Longley's [19] *Fractal Cities*, to which one can add studies on urban structure, on the fractal structure of transportation networks [23], on the question "when and where is a city fractal?" [24] and more (For updated survey of studies see [16]). Figure 13 illustrates the evolving fractal structure of the Tel-Aviv metropolitan area from 1935 onwards.

Another important insight implied by fractal cities studies is that a city, or a system of cities, in a steady state

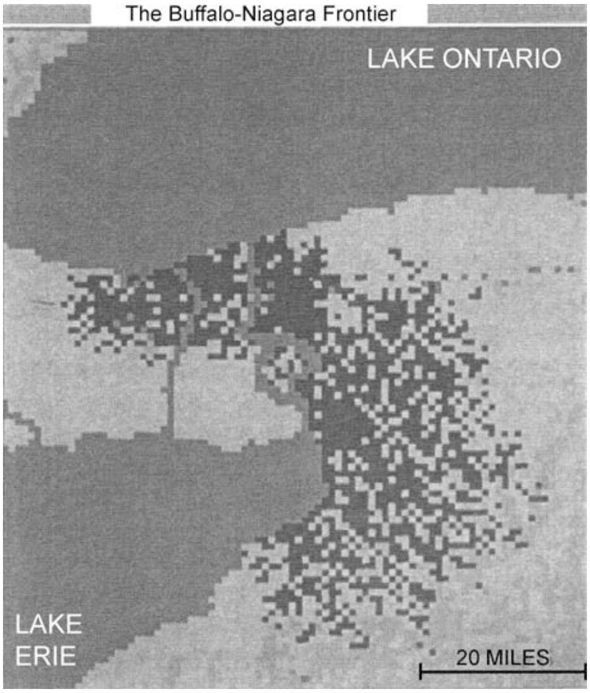


Self-Organization and the City, Figure 13
The evolving fractal structure of the Tel-Aviv metropolitan area from 1935 onwards: The central parts 1 and 2 were fractal during the entire period, while their fractal dimension increased with time. The entire metropolitan area became fractal only after 1985. In 1991 the fractal dimension of the Tel Aviv metropolitan area was found to be 1.667 with error of 0.037. Source: [23]

does not mean equilibrium and stability, as is the case of Christaller's and Lösch's central place theories, for example, but rather a rich and complex evolution and change according to a given ordering principle.

Cellular Automata Cities

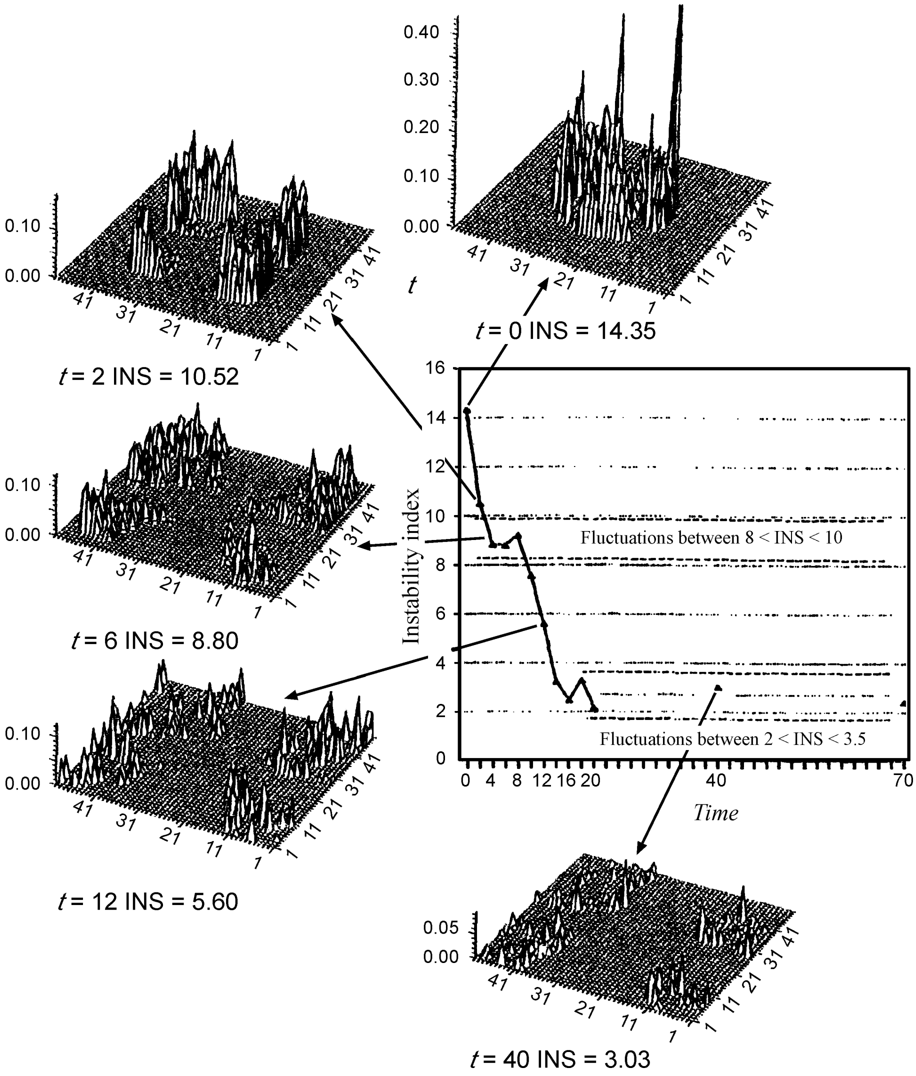
The attraction of CA (cellular automata) models to the study of cities is almost self-evident. Real cities are built of discrete spatial units such as houses, lots, city-blocks and the like. CA models are also built of discrete spatial units – the cells. In real cities the properties of local spatial units (e. g. land value) are determined, to a large extent, in relation to their immediate neighbors; so are the properties of the cells in CA models. These resemblances, together with the mathematical simplicity of CA models, make them natural tools to simulate urban processes. In the last few years CA urban simulation models are among the most popular approach to simulate the dynamic of cities [16,22,95].



Self-Organization and the City, Figure 14
Cellular automata simulation of the Buffalo–Niagra frontier. Source: [17]

One can divide the various models of CA cities into implicit and explicit self-organized CA cities. The first group refers to studies the aim of which is to use the simulation capabilities of the CA city in order to best-fit a certain simulated pattern to an existing one [16]. Figure 14 is an example. The general motivation here is to explain an existing or historical pattern, or alternatively to predict a future one for the purpose of planning. The fact that the model has properties of self-organization, just adds more realism and sophistication to the simulation.

The second group concerns explicit self-organized CA cities. Here the central motivation is to use the model as means to investigate the self-organization properties inherent in cities and urbanism. For example, how micro decisions and behavior of individuals and firms, taken at the local scale, are related to the global behavior and structure of the city. Such models are essentially heuristic and they regard the simulated CA city as essentially a learning device (Fig. 15).



Self-Organization and the City, Figure 15

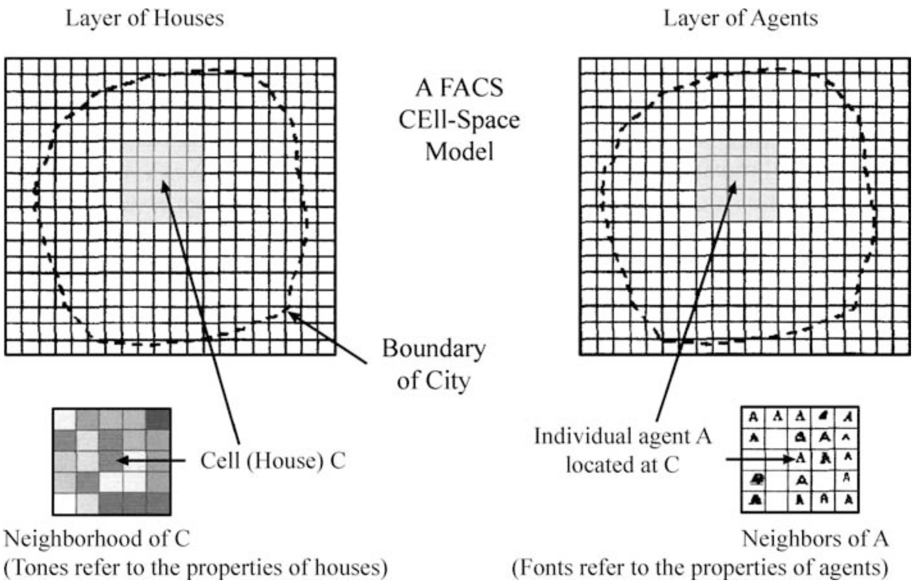
Time evolution of consecutive stages of SIS (stability-instability surface) in the development of a city with 33% neutral Greens when the rest of the Greens and all the Blues are segregatives. Source: [95]

Because of their iterative structure, CA models can be used as convenient tools to generate fractal structures [16,17] and the insight they add to our understanding of cities is similar: an iterative process guided by a few simple rules, can generate complex structures such as cities [16].

AB and FACS Cities

CA is an efficient tool to model the relations between infrastructure objects of the city. Unlike infrastructure object, urban agents have aims and plans, can learn and move in the city, and see and know beyond their nearest neighbors. *Agent base* (AB) models that are built to imitate such cognitive entities were applied to the city dynamic too. An important source of inspiration here was Schelling's model that demonstrated how local and simple behavior of urban agents can give rise to complex residential segregation in cities – even when their tendency for segregation is minimal [122]. Subsequent agent base studies have supported Schelling's finding [16] and added that a small minority of agents with a tendency for segregation is sufficient to turn the whole city into a segregative structure [95].

Free agents on a cellular space (FACS) models combine CA and AB models [95]. A typical such model is built as a superposition of a CA layer simulating the relationship



Self-Organization and the City, Figure 16
A typical FACS model is constructed of two-layers: a population layer of human agents describing the migratory and interaction activities of individuals (*right*), superimposed on a CA infrastructure describing the urban landscape (*left*). Source: [95]

between the city's infrastructure objects (buildings, roads …) and AB layer that simulates the activities of the urban agents (Fig. 16). At each model iteration new agent(s) come to the city with a certain intention in mind – say to find a house to live in. The agent then examines the available empty cells/buildings, ranks them according to its set of preferences and picks the best one. Once the agent located itself in a certain cell, the CA dynamics starts: The properties of each cell are determined by reference to the properties of its neighbors; and if the cell is occupied by a certain agent, by some mix between the properties of the agent and its neighbors. Figure 17 presents typical results.

Sandpile Cities

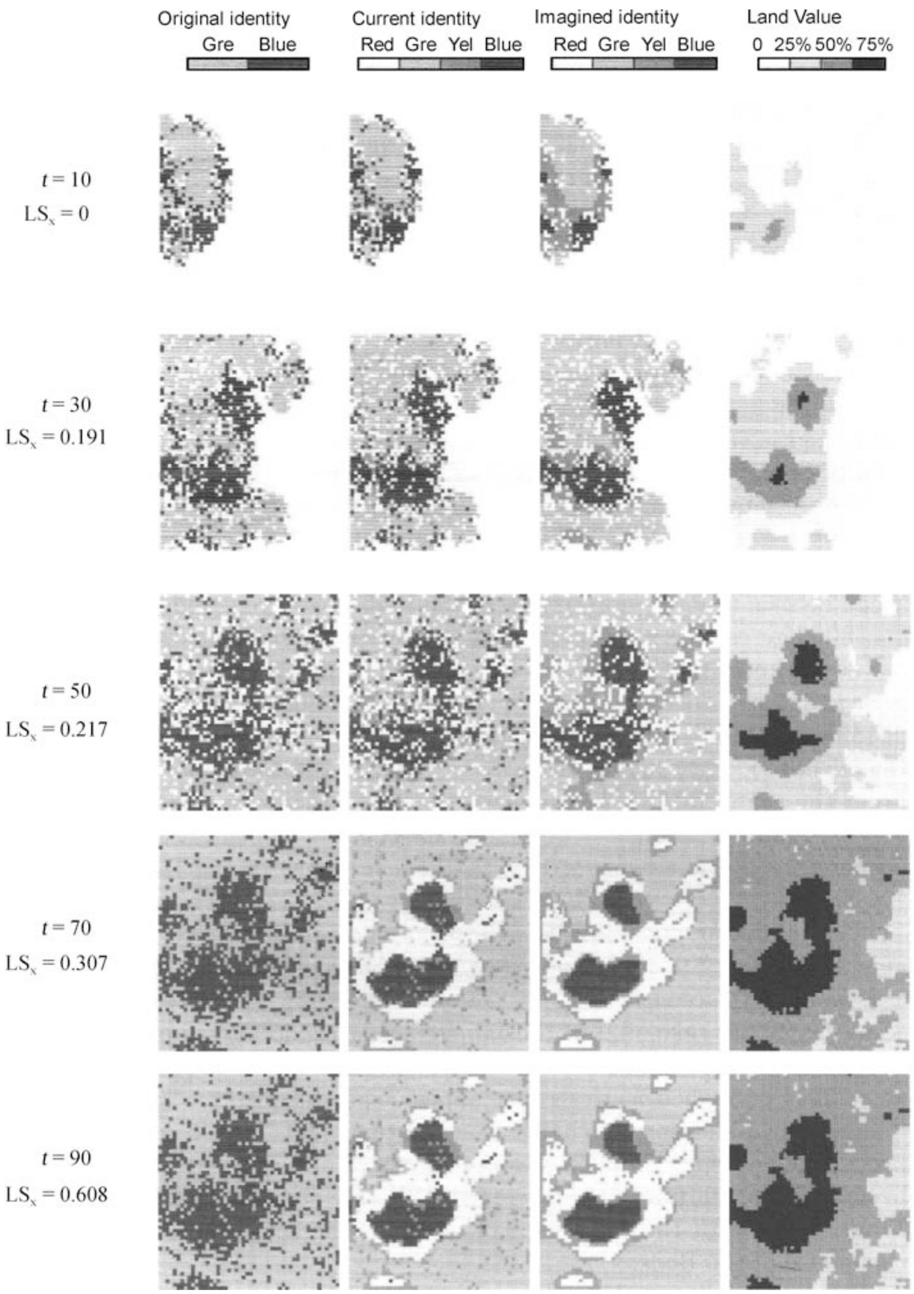
The sandpile, the canonical example of *self-organized criticality* [11,12,16,20], has two incongruous features: the system is unstable in many of its local locations; nevertheless its global state is absolutely robust: The local configurations of the sand change all the time because of the avalanches, while the statistical properties, such as the size distribution of the avalanches, remain essentially the same. Similarly to the sandpiles, cities appear volatile and fast moving at their local scales while at their global scale they appear absolutely robust [16,20]. For example, the size-distribution of many cities and systems of cities remains essentially the same under circumstances such as ongoing population growth (Above Sect. "Image of Cities").

Compared to the "grand" synergetic and dissipative cities, the sandpile city is a kind of a zooming-in to the internal dynamics of self-organized cities in their steady state periods – when they are controlled by what in synergetics is called order parameters. Sandpile cities show how complex and rich is the internal dynamics of a city in steady state (Fig. 18).

Small World Cities

The notion *network* is implicit in all theories of complexity. Recently, Watts and Strogatz [130] showed that complex networks have 'small world' characteristics [84] and Barabasi and Albert [14] demonstrated that complex networks are scale free thus following the *power law* that according to Barabasi [13] is a mark of self organization.

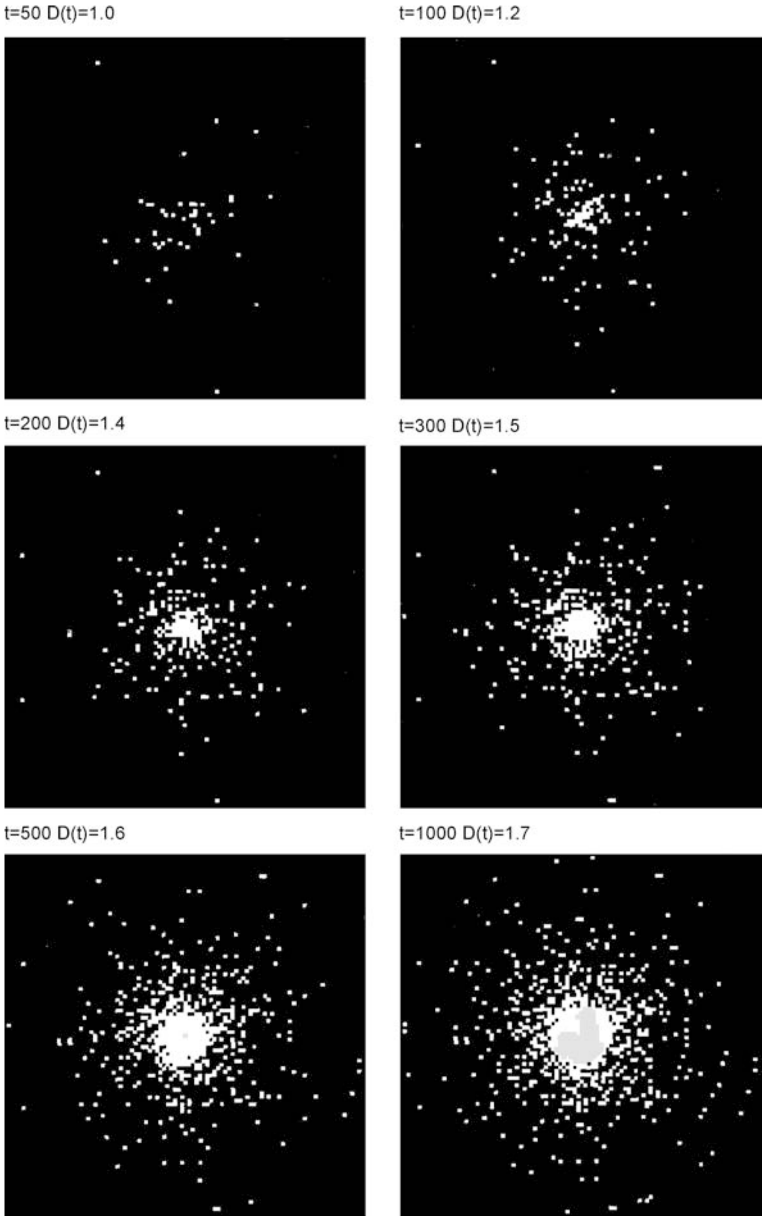
The link to cities as complex systems was just natural: The view of systems of cities as networks characterized by the power law was indicated above. Single cities too were described as networks. Thus Alexander's classic "a city is not a tree" [1] demonstrated that cities are typified not by a simple *tree network*, but by a complex *semi-lattice network* (Fig. 19). Alexander's view was recently reformulated in terms of the new science of networks [117,118]. Another example is Hillier's *space syntax* that analyzes the morphology of urban spaces in terms of networks [65,66]. Space syntax exposes the way society



Self-Organization and the City, Figure 17
Several snapshots from an evolving FACS city. Source: [95]

determines the urban morphology and the way the letter feeds back and re-shapes society. The link between space syntax and network analysis has already produced several useful results [38,41,67,89,114].

In the domain of transportation one can mention studies that characterize roads' traffic dynamics in terms scale-free networks (Fig. 20) [68,72], the same was found for the transit system in Beijing [137], pedestrian movement [73] and for the canal networks of Venice [25]. Andersson et al. [9] showed that the market dynamics generates land values that can be represented as a growing scale-free network. Finally, Batty [16] has suggested viewing cities and their dynamics from the combined perspectives of networks, fractals, self-organized criticality and AB.



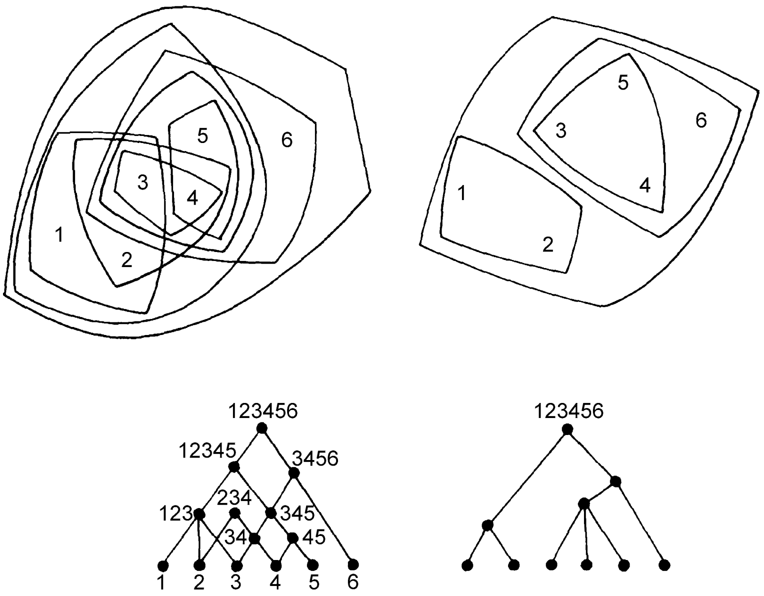
Self-Organization and the City, Figure 18
Self-organized criticality: "Simulation of a hypothetical urban growth pattern in its critical level". Source: [16]

Self-Organization and the City

Self-Organization and the City is an ongoing project that explores the city as a complex system from two interrelated perspectives: Haken's (1983) synergetic theory of complex systems, in particular from the perspective of the pattern recognition paradigm [50,51,55] and IRN – inter-representation nets [94]. The link between the two is termed SIRN – synergetic inter-representation nets.

SIRN – Synergetic Inter-representation Networks

IRN commences with a distinction between cognitively *simple tasks* that can be performed by working memory (e.g. $2 \times 3 = 6$) and *complicated tasks* (e.g. $257 \times 389 = 99\,973$) that are the result of the "magic number seven" that constraints our ability to process information in working memory [85]. One way to overcome this limitation is by means of IRN: We first externalize the task



Self-Organization and the City, Figure 19
A tree network (*right*) versus a semi-latice network (*left*). Source: [1]

(write it down on a paper); then we solve part of it internally ($9 \times 7 = 63$); externalize it again and so on in a sequence until the task is completed.

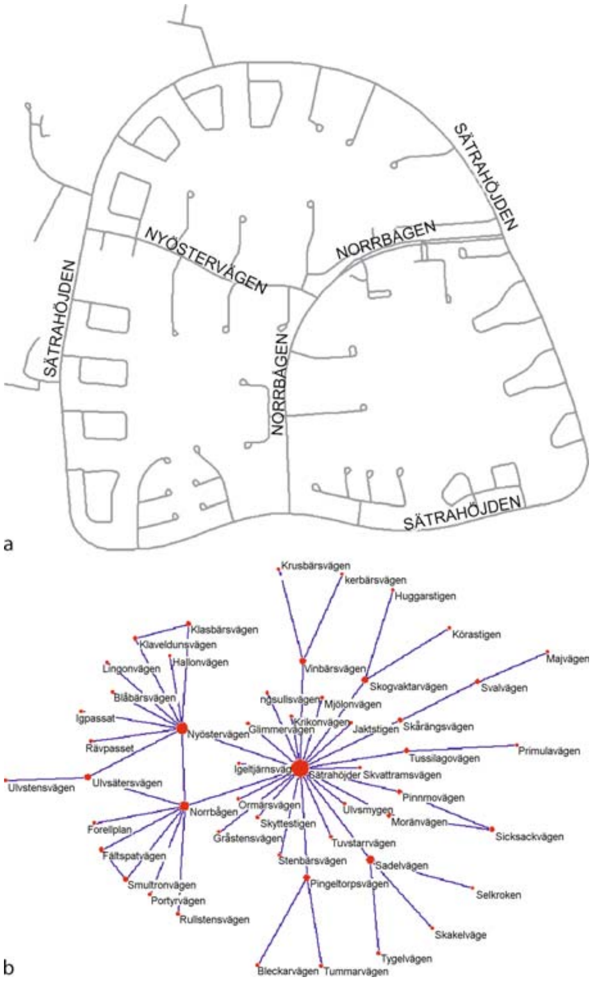
Complex tasks refer to creative cognitive tasks, when a person writes, paints, designs etc. Such a task often starts with a vague idea in mind that the person then externalizes by writing it down or painting … Here too the process proceeds by interplay between internal and external representations, but with one important addition – it involves emerging properties. It is here were synergetics gets in and the process becomes SIRN. More specifically, the process might start with a preliminary internal idea (or external cue that entails internal idea), that the person then externalizes and so on. After a few internal-external iterations an order parameter (in the sense of synergetics) emerges and enslaves subsequent iterations.

The development of the notion of SIRN was inspired by Bartlett's serial reproduction scenarios in his study *Remembering* [15]. A typical such scenario starts when a test person is shown a text or a figure and is asked to reproduce it out of memory (Fig. 21). The result is offered to a second person that is asked to do the same and so on. As shown by Bartlett, at the beginning the reproductions change from person to person, however, at certain stage they stabilize and become a *scheme*. Stadler and co-workers [126] demonstrated that the scenarios proceed as synergetic self-organized process. The focus of interest in the above studies was on the way schemata are created. Haken and Portugali have used the Bartlett scenarios as illustration of the play between internal and external representations [59,94].

It is important to emphasis, first, that external representations are media that enable communication between persons and the emergence of collective SIRNs – e. g. a brain storm. Second, that internal and external representations are *generative* – once produced, they generate new ideas and properties not seen before in previous representations.

The Basic SIRN Model Haken and Portugali [59] have cast the SIRN process into the formalism of synergetics. They started with Haken's [54] 'synergetic computer' (Fig. 22, *Top*), composed as it is of an input layer with model neurons representing the initially given input activity; a middle layer representing the order parameters, and an output layer with neurons representing the final activity of each neuron. The first step is to look at this network from the side, as indicated by the arrow. The result is shown in Fig. 22, *bottom, left*. Adding to the latter external inputs and outputs, we arrive at our basic SIRN model (Fig. 22, *bottom, right*) that has two kinds of inputs, internal and external and two kinds of outputs, again internal and external. The middle node symbolizes the order parameters that emerge out of the interaction between internal and external representations.

The basic SIRN model can be seen as symbolizing a self-organizing active agent that is subject to two flows of information: internal and external (Fig. 23). The first



Self-Organization and the City, Figure 20

A small street network (a) and its connectivity graph (b). Every node in b is labeled by the corresponding street name, and the size of nodes shows the degree of connectivity of individual streets. Source: [73]

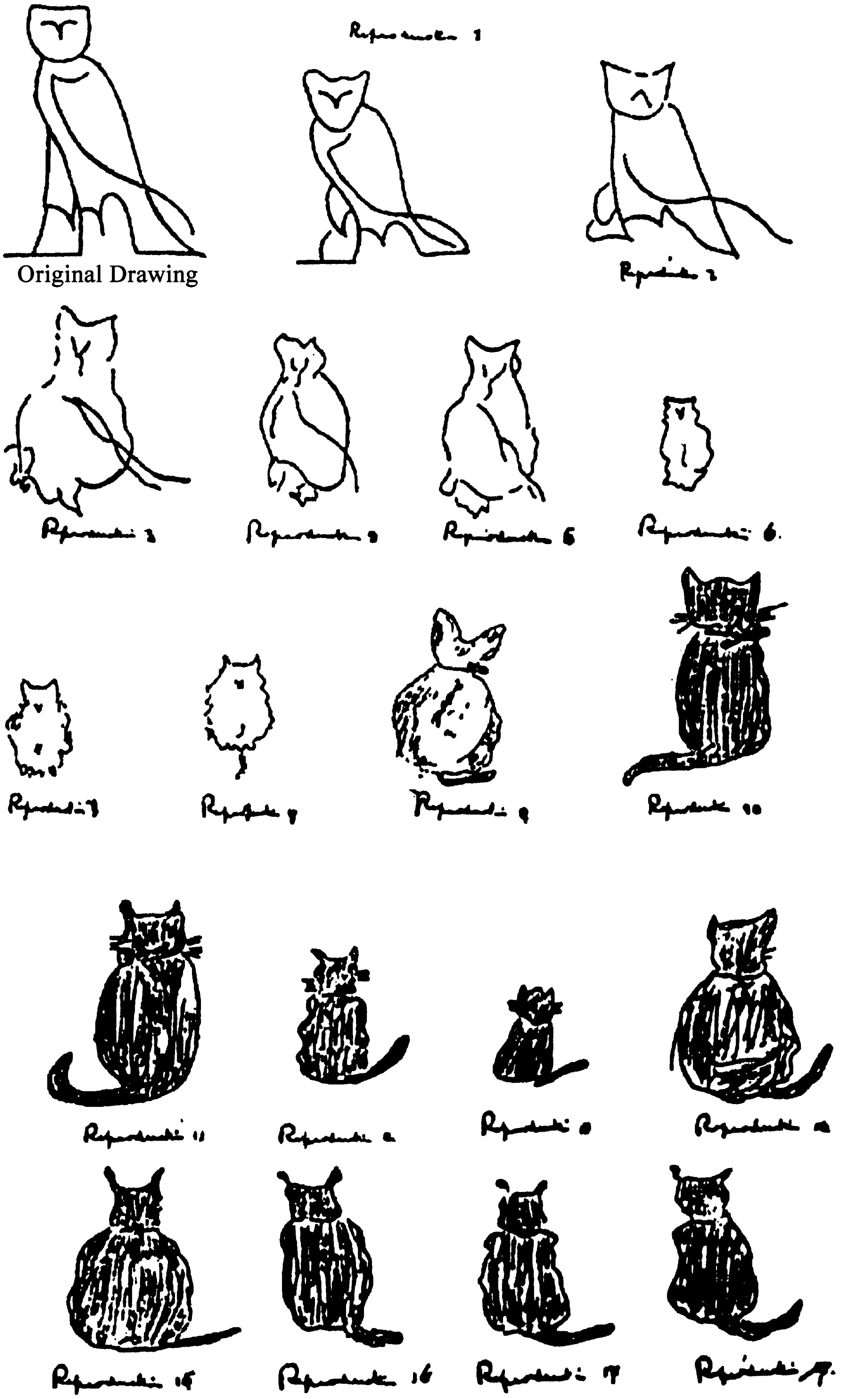
is coming from the mind/brain, in the form of ideas, fantasies, dreams, thoughts, and the like, while the second from the 'world' – via the senses, the agent's body and/or artifacts. The interaction between these two flows gives rise to an order parameter that governs the agent's action and behavior, as well as the feedback information flow to the agent's mind. 'Action or behavior' may refer to a single individual executing exploratory behavior, reproducing texts or drawing, as well as to several individuals collectively reproducing a large-scale artifact such as a city. In an analogous fashion, the 'feedback information flow' refers to the formation of internal representations, such as images or learned patterns. The order parameters are determined by a competition in line with the synergetics' pattern recognition paradigm noted above. Note that all the above steps (and below), can and have been, performed by a computer so that the approach is entirely operational.

In order to apply the basic SIRN model to specific case studies, Haken and Portugali [59] reformulated it in terms of three prototype sub-models: the *intrapersonal*, the *interpersonal collective*, and the *interpersonal with a common reservoir* sub-models (Fig. 24). The first refers to a solitary agent, the second to a sequential dynamics of several agents whereas the third to a simultaneous interaction. The third sub-model is, in fact, a theory of urban dynamic. The intrapersonal is typical to the way of an artist, for instance, develops her/his work (Fig. 25), whereas the interpersonal to the Bartlett scenario that provided a source of inspiration to IRN (above, Fig. 21).

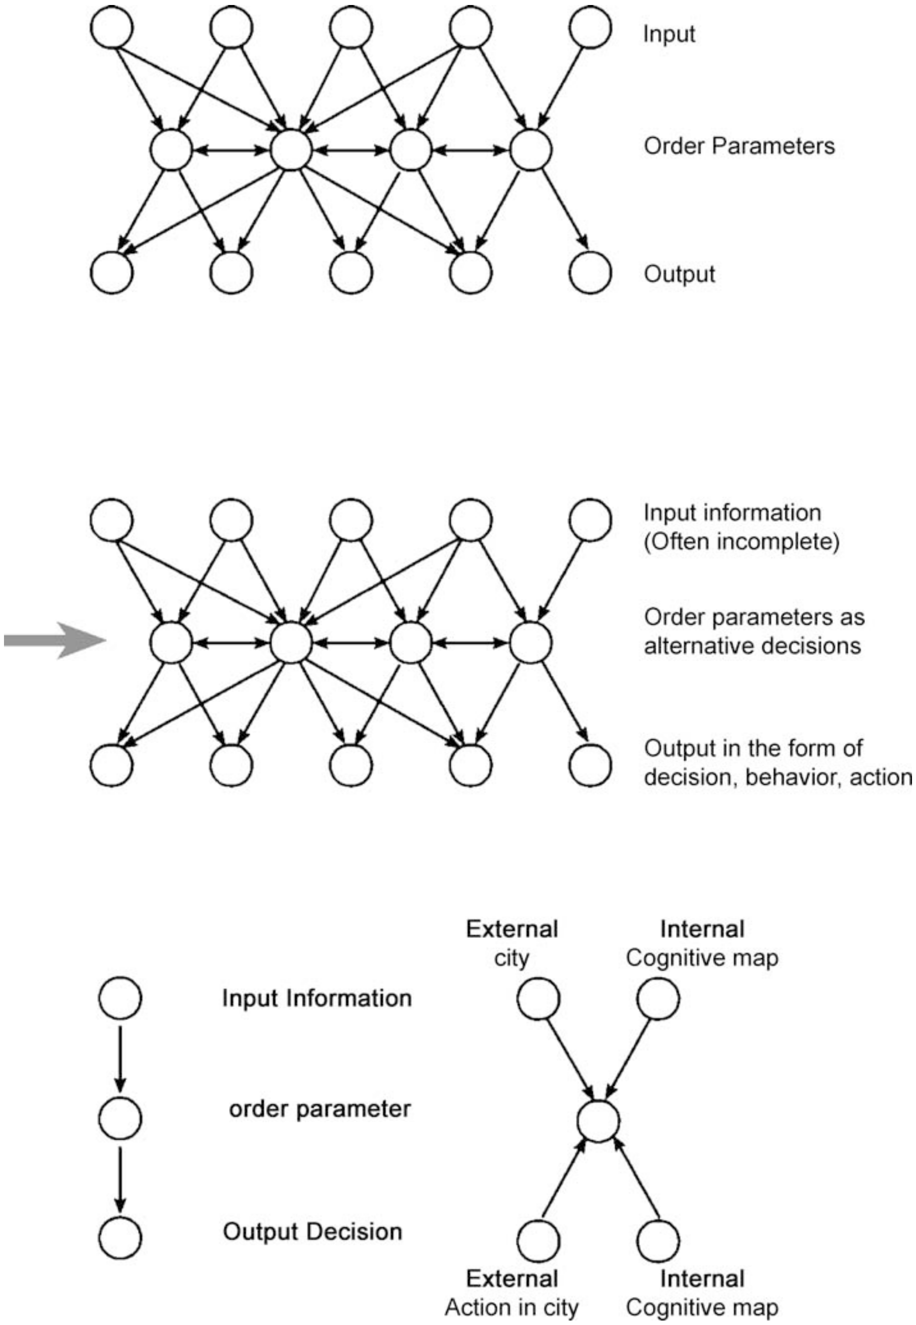
In the first two sub-models the process depends fully on the biological memories of individuals. In the third sub-model the process depends partly on biological memories, as before, but partly also on externalized non-biological memory that we term a *common reservoir*. This common reservoir of external, artificial and non-biological memory, might take the form of texts, Internet, buildings or whole cities.

Figures 24 (*bottom*) and 26 illustrate graphically this public-collective SIRN sub-model. Each individual agent is subject to internal input constructed by the mind/brain, and external input which is the legible information coming from the common reservoir, that is, the city. The interaction between these two forms of input gives rise to a competition between alternative decision rules that ends up when one or a few decision rules "wins". The winning rule(s) is/are the order parameter(s) that enslave(s) the system. The emerging order parameter governs an external output, which in the case of a city is the agent's behavior and action in the city, and an internal output, which is an information feedback loop back to the agent's mind/brain.

Both the previous sub-model and the present one involve a two-scale self-organization process: an individual-local scale referring to each individual agent as a self-organizing system, and a collective-global scale, referring to the whole city as a self-organizing system. The individual agents by their action and behavior determine the city, which by means of its emerging order parameter(s) enslaves the minds of the individual agents. In the language of synergetics this process is termed *circular causality*. In terms of social theory it is close to notions of socio-spatial *reproduction* and *structuration*. Recent applications show that the common reservoir might be a non-biological externalized memory such as a city[95,96,97,98], a planning



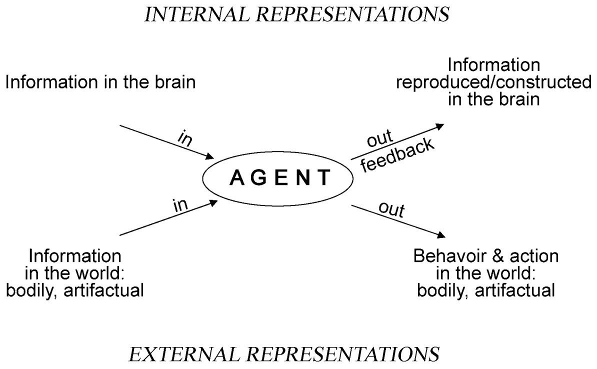
Self-Organization and the City, Figure 21
A Bartlett's scenario of serial reproduction: an Egyptian 'Mulak' (owl) transformed into a cat (see pp. 180–181 of [15])



Self-Organization and the City, Figure 22
The derivation of the SIRN model. See text

textual report or an urban planning policy emerging out of a discourse among the members of a planning team [105]. Note that as in the previous model, here too, due to circular causality, as the process evolves the subjective cognitive maps of the individual agents are becoming more similar to each other and an inter-subjective, collective cognitive map emerges. Both private–subjective cognitive maps and public-collective ones are thus *constructions*.

The City Game A simple and effective way to illustrate the SIRN view on the dynamics of cities is by means of a set of experiments termed *city games* [94]. A city game



INTERNAL REPRESENTATIONS
Information in the brain
Information reproduced/constructed in the brain

out
feedback
AGENT
in
out
Information in the world: bodily, artifactual
Behavoir & action in the world: bodily, artifactual
EXTERNAL REPRESENTATIONS

Self-Organization and the City, Figure 23
The SIRN model symbolizes a self-organizing agent that is subject to two forms of information: internal and external, and is actively constructing two forms of information, again internal and external. Graphically, Fig. 23 corresponds to Fig. 22 (*bottom, right*) turned 180° on its NW-SE axis

can be described as a group dynamics that involves some 40 to 70 participants. Their aim is to build a city on a floor, representing the site for a new city. Each player is given a 1:100 mock-up of a building and in his/her turn is asked to locate it in the virtual city on the floor, in what s/he considers as the best location for that building. In a typical game (Fig. 27a and Fig. 27b), the players observe the city as it develops, and in the process also learn the spontaneously emerging order on the ground. It is typical in such games that, after a few initial iterations, an observable urban order emerges. The participants internalize this emerging order and tend to locate their buildings in line with it. As can be seen, the main features of such a game are the main ingredients of SIRN, namely, a sequential interplay between internal and external representations, the emergence of a collective complex city as an artifact and a typical synergetic process of self-organization. Needless to say that the city game is not a 1:1 description of reality, but an illustration of the dynamics of cities as *dual* self-organizing systems.

Cognition and the City

SIRN is at once a theory of cognition, cognitive mapping and urban dynamics. This emphasis on cognition is a direct consequence of complexity theory; a major achievement of complexity theory was to show how local behavior and interaction between urban agents give rise to the global structure of the city. The agent is thus the main and most important actor. Given this, one would assume that practitioners of complexity theory and urban simulation models will have an elaborated theory of agents' perception, behavior, decision making and action; especially so, in light of the fact that a whole body of research on agents' behavior was readily available. I'm referring to studies on spatial cognition, spatial behavior and cognitive mapping that were developed on the interface between cognitive science and urban studies [45,77,92,98,99,103]. And yet, with few exceptions such as SIRN, this body of theoretical and empirical studies is largely overlooked by students of complexity theory of cities. Researchers in this field tend to follow economists by assuming that individuals behave in space as simple "economic persons". The result is that the rather *simple* behavior of agents in the models contradicts the *complex* behavior revealed by studies on cognitive mapping and spatial behavior.

In *The Sciences of the Artificial* Simon [124] suggested that the observed complex behavior of human agents, guided as it is by aims, plans, intentions, needs, policies and so on, misleads us as it is only an external appearance of innately simple behaving entities: Similarly to simple animals, we humans as

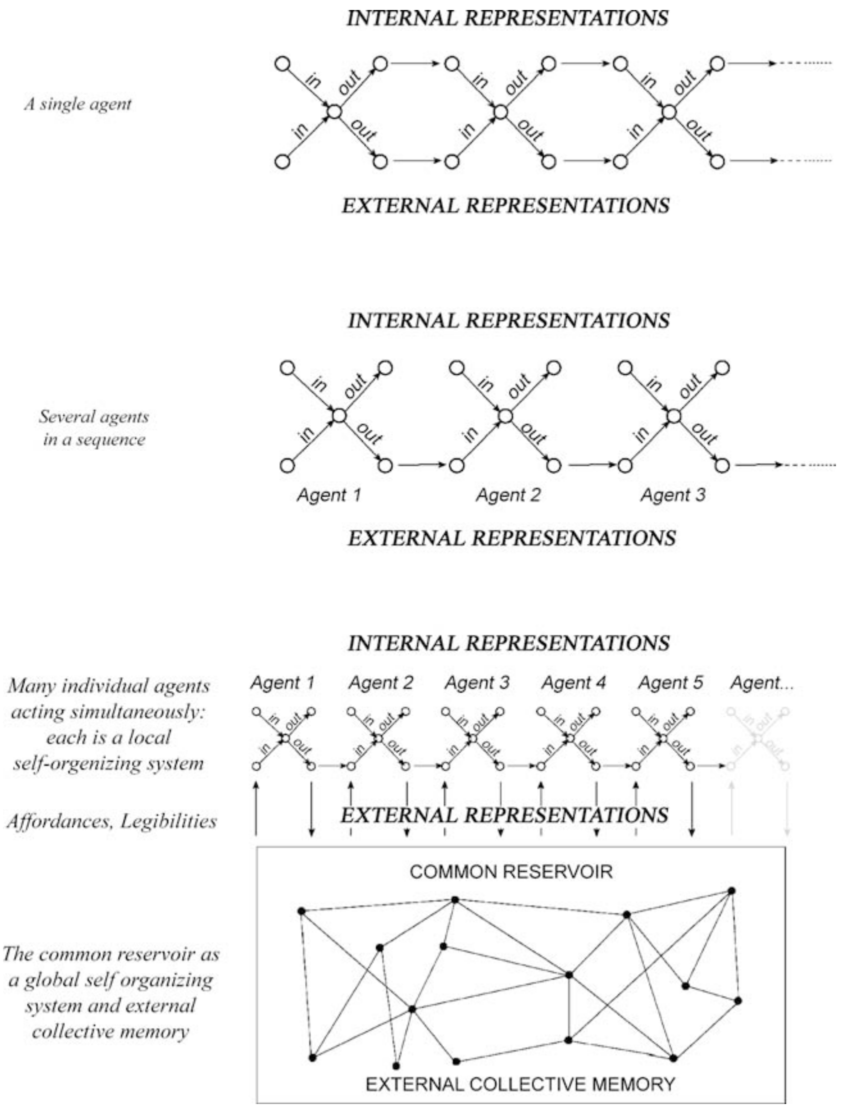
> "behaving systems, are quite simple. The apparent complexity of our behavior over time is largely a reflection of the complexity of the environment in which we find ourselves" (ibid. 53).

Most AB/CA urban simulation models are built in line with Simon's logic. They typically start with local interactions between agents having a few simple aim(s) "in mind". This interaction gives rise to an urban system, which from iteration to iteration becomes increasingly complex. Complexity is thus understood as a property of the whole global system, but not of its individual parts.

The efficiency of the *simple cause→complex effect* model is apparent. But there is a catch here: Several empirical studies, of animals' and humans' exploratory behavior, for example, falsify Simon's view [96,97,98]. Furthermore, the property of the city as a *dual* self-organizing system implies that the initial conditions of such complex systems are relatively large numbers of interacting parts, each of which is itself a complex system exhibiting complex behavior. Can there then be a science of cities that is not based on Simon's model? The answer is yes! To see how we shall look at the relations between self organization and information.

Information Compression, Inflation, Adaptation

Complexity is a property of systems that exchange matter and *information* with their environment and that their huge number of parts forms networks characterized by complex feedback and feedforward loops that allow intensive flow of *information* inside the system.

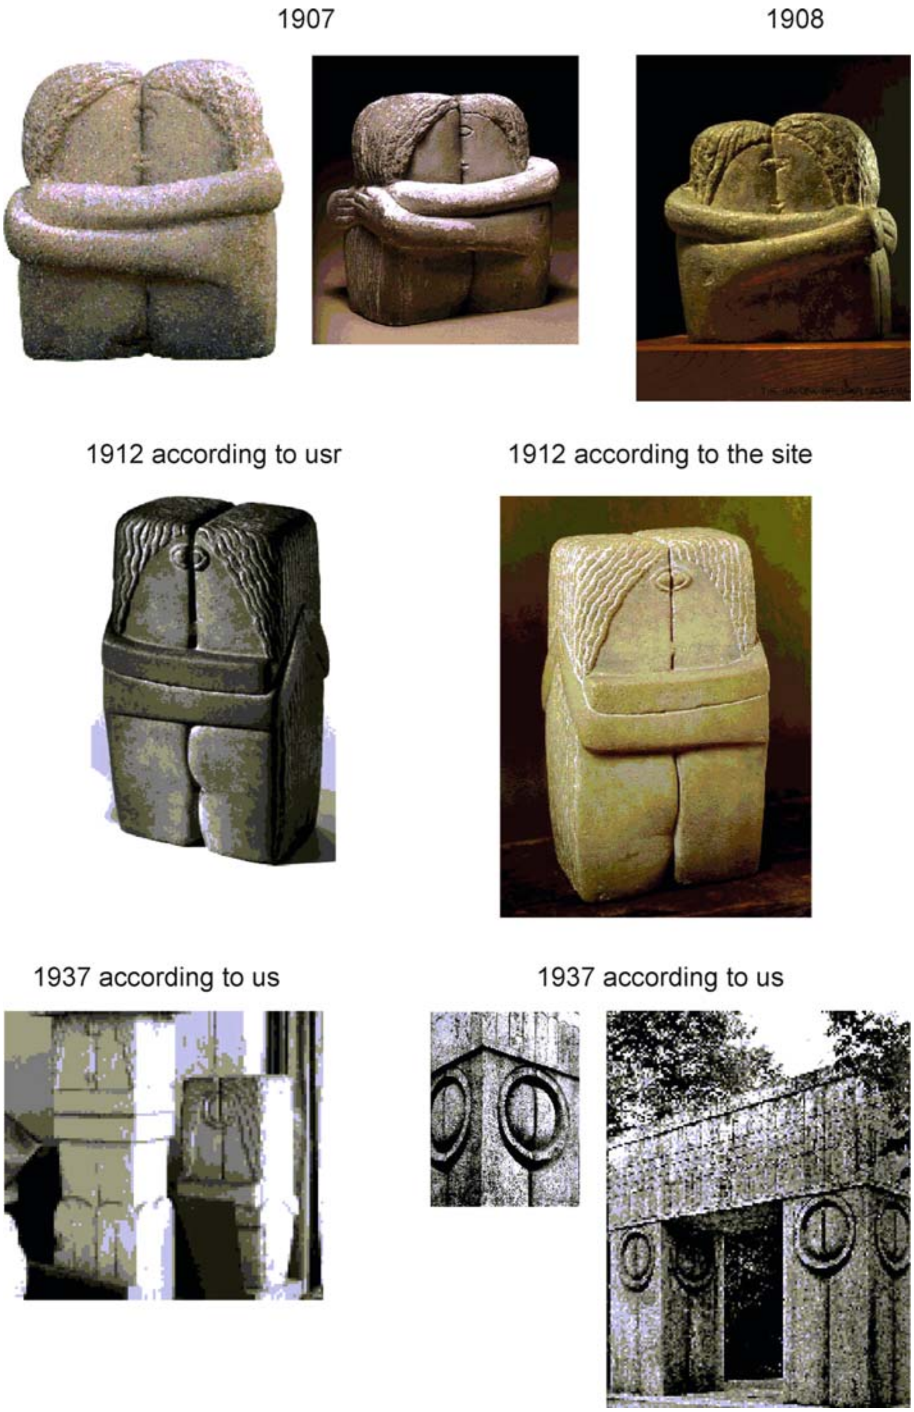


Self-Organization and the City, Figure 24

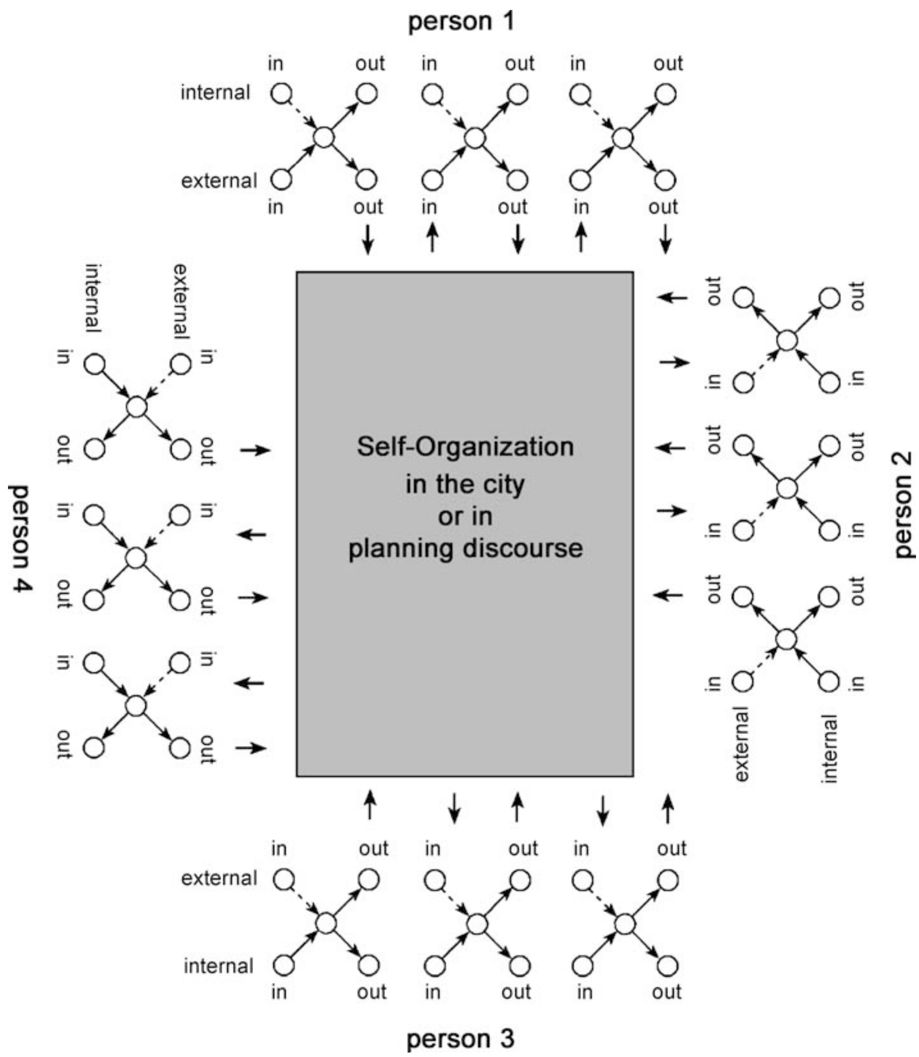
***Top:* The intrapersonal SIRN submodel of a single person. *Middle:* The interpersonal submodel: serial reproduction of several persons. *Bottom:* The interpersonal with a common reservoir submodel. Note that in the intrapersonal submodel information is transmitted via external and internal outputs, in the interpersonal via external output only (action and behavior), while in the third submodel information and interaction between the agents are mediated by the common reservoir (e. g. a text, a city, Internet, etc.). Source: [96]**

The notion *Information* is associated with Shannon's theory of information [123] that has played a seminal role in the development of system thinking. In Shannon's theory the notion of information is a pure quantity (usually measured by *bits*) devoid of any meaning. Such a concept of information makes sense only in closed systems where the number of possible states the system can take is finite and a-priori known; hence the link between information and the notion of Entropy, which is a property of closed systems. For example, the information conveyed by throwing a die is 2.5 bits, that is, the logarithm to the base of 2 of the six possible states the system can take. But the complex systems we are dealing with are by definition *open*. So what is the meaning of information in complex systems?

In *Information and Self-Organization* Haken [52] suggested that complex systems 'self-organize', that is, 'interpret', the information that comes from the environment. In other words, the meaning assigned to the message depends on the receiver (the receiving system) and not just on the message itself as in Shannon's theory. Haken (see



Self-Organization and the City, Figure 25
'The Kiss' by Brancusi: from a figurative kiss in 1907, to the geometrical 'Gate of the Kiss' in 1937: An intrapersonal SIRN process in sculpturing

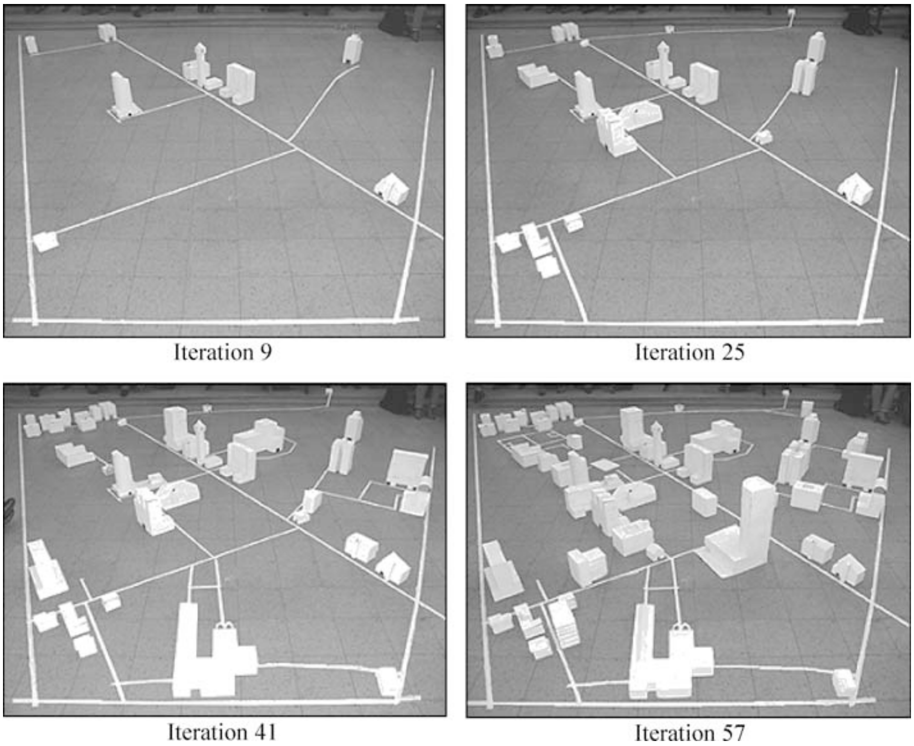


Self-Organization and the City, Figure 26

Another conceptualization of the public-collective SIRN sub-model. Each individual agent is subject to internal input – a cognitive map constructed by the mind/brain and external input –the legible information coming from the common reservoir, that is, the city of a planning team. The interaction between these two forms of input gives rise to a competition between alternative decision rules that ends up when one or a few decision rules "wins". The winning rule(s) is/are the order parameter(s) that enslave(s) the system. The emerging order parameter governs an external output, which in the case of a city is the agent's behavior and action in the city, and an internal output, which is an information feedback loop back to the agent's mind/brain

p. 15 in [53]) has consequently suggested two forms of information: *semantic information* which is information *with* meaning, versus *Shannonian information* which is "information with meaning exorcised". Haken further emphasizes that the process of self-organization implies "an enormous compression of information" (see pp. 25, 35, 151 in [52]).

Haken and Portugali [60] have studied information in the context of the city. They show that different elements of the city transmit different quantities of Shannonian information that can be practically measured by means of information *bits*, for example (Fig. 28). They further show that cognitive processes such as pattern recognition and categorization entail an enormous information compression thus affecting the quantity of the Shannonian information conveyed by the city (ibid) and that information compression is just one facet of the process – the other facet is *information inflation* [62]: In certain urban situations categorization might entail information compression while in others information inflation (Fig. 29). Infor-



Iteration 9

Iteration 25

Iteration 41

Iteration 57

Self-Organization and the City, Figure 27a
Four snapshots from a typical city game (at iterations 1, 15, 35, 57)

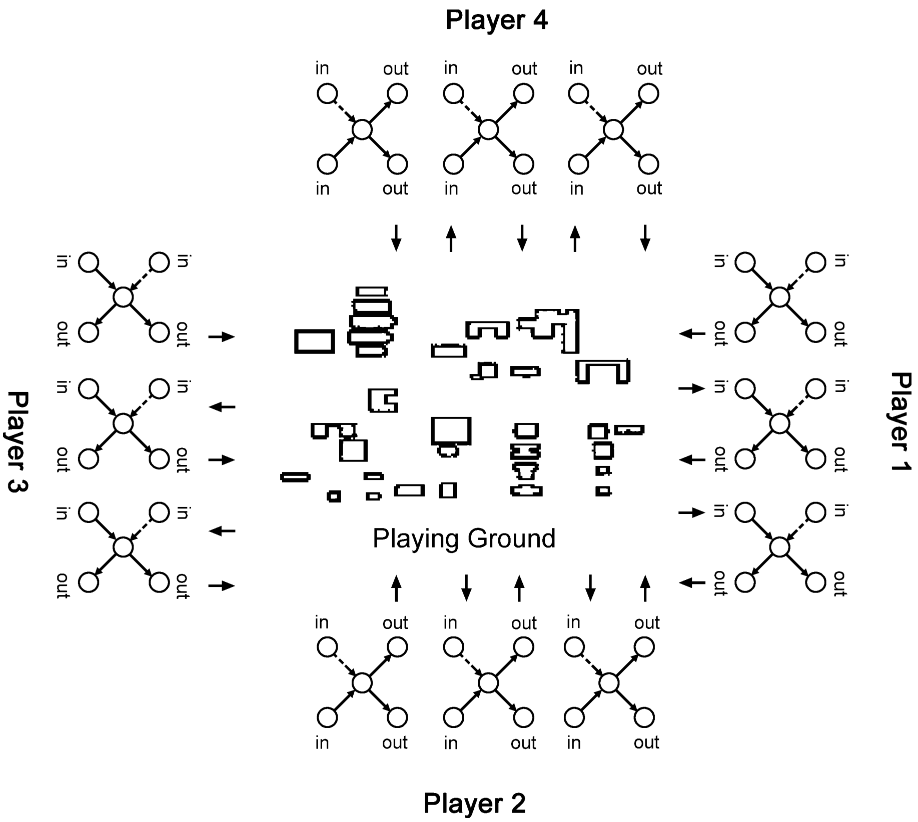
mation inflation and compression are thus two aspects of the process of *information adaptation* by which individuals and collectivities shape the city in a way that is adapted to the inhabitants' cognitive capabilities.

The notion information adaptation has far reaching implications to the above discussion about the scientific method and the science of cities: Self-organization as information compression implies a *complex* → *simple* model and thus an alternative Simon's *simple* → *complex* model. The process of information inflation, on the other hand, is in line with Simons' model. These two models are thus two facets of a single process of information adaptation that in some cases requires inflations while in others compression. Complexity theory shows that whatever are the opening conditions (complex or simple) a scientific approach is possible.

CogCity A central property of complex systems is the process of *circular causality* that typifies also the dynamics of cities: Thus in the SIRN model the interaction between the local/micro urban agents gives rise to the global structure of the city, which then feeds back and prescribes the behavior, interaction and action of the agents, and so on. Guided by Simon's *simple* → *complex* model, standard urban simulation models have become excellent tools to simulate the first part of this loop – the way local interactions give rise to a global structure – but they fail to describe the second, feedback part of the loop. CogCity (cognitive city) is a model that attempts to simulate the dynamic of cities as a process of circular causality [98].

CogCity is essentially a FACS model (above Sect. "AB and FACS cities") with several additions that make it an explicit SIRN, cognitive, urban simulation model. It differs from standard AB/CA urban simulation models in that the latter are essentially bottom-up in their structure (Fig. 30, *left*). CogCity, per contra, is characterized by an on-going interaction between top-down and bottom-up. Figure. 30, *right* describes a typical scenario: It starts top-down when an agent arrives to the city with a global cognitive map in mind; compares it to the global structure of the city and selects a local sub-area. Now starts the bottom-up process: the agent selects the empty cells in that local area; evaluates the appropriateness of the cells and their nearest neighbors in light of its needs and then takes a decision and action. In parallel, the properties of every cell are determined according to its relations to its nearest neighbors and so on.

In a regular AB/CA simulation the process ends here: the global outcome is recorded and mapped as the output



Self-Organization and the City, Figure 27b
A conceptualization of the city game

of this specific iteration and the model is ready for a new iteration. In a SIRN-CogCity model the process continues and feeds back to the global structure of the city that allows the top-down process in the next iteration: Firstly, the state of the various central places is determined. Secondly, peripheries are determined around central places. Thirdly, areas are defined or redefined. Fourthly, subareas are redefined. Fifthly, given areas and subareas, the global state of the city as a whole and its rank-size structure, is defined. The latter changes redefine the local membership state of each cell in the various infrastructure objects and become the externally represented input for a new agent in the next iteration, and so on in circular causality (Figs. 31, 32).

Planning

The link between self-organization and cities is contradictory. Firstly, since cities were always regarded as symbols of planned action – walls, roads, castles, fortresses, indicated a central authority that is capable of planning. Secondly, since planning as means to achieve a controlled order diametrically opposes self-organization as the spontaneous emergence of order. This is a seemingly contradiction, however, since cities are *dual* self-organizing systems with the implication that every urban agent is a planner at a certain scale. This view is supported by psychology and cognitive science that consider planning as one of the basic cognitive capabilities of humans [86].

Cognitive planning, that is, the ability to think, decide and act ahead, must be based on information about the future which by definition is partial and insufficient – a situation that according to Haken typifies also the process of pattern recognition as conceptualize by synergetics. Based on this analogy Haken [57] described decision situation in the context of planning as in Fig. 33.

This decision situation raises the question of 'How do people complement the unknown data?' According to Haken and Portugali, as in pattern recognition tasks here too, the unknown data is being supplied by means of associative memory [57,95], conceptual cognitive maps [98,99] and decision heuristics [95,127,128]. Table 1 specified several decision heuristics and their interpretation in the context of cities.

Self-Organization and the City, Table 1

Seven heuristics and their interpretation in the context of cities. For sources see [95]

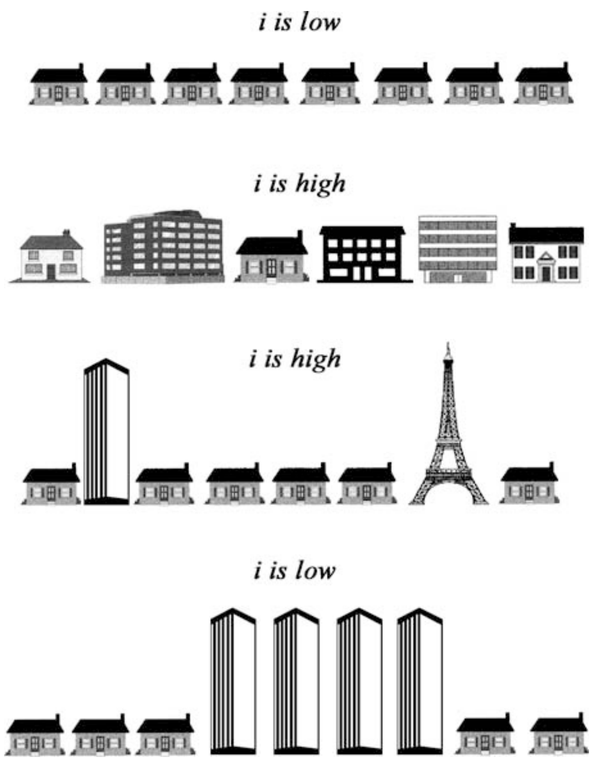
Heuristic	Description	Urban interpretation
Similarity	The similarity of two items is expressed as a function of their common and distinctive features.	The recognition of fundamental rules of urban composition, such as a grid layout, built form, or urban fabric, is performed through similarity.
Representativeness	The probability that an object or event belongs to a particular class is judged by the degree to which the description is representative of a stereotype.	Urban categories are identified on the basis of architectural stereotypes, such as church, skyscraper, boulevard, tower, park, arch, etc.
Availability	The probability of an event, or frequency of a class, is assessed by the ease with which instances or occurrences can be brought to mind, or recalled.	Availability would make universal symbols (such as Macdonald's signs, Stop signs, etc.) more easily identified and recalled.
Decision frame	The frame that a decision maker formulates of the problem (gain versus loss, etc.) is influenced by norms, habits, and personal characteristics of the decision maker.	Urban frames for decisions (congested versus free, public versus privet, etc.) depend on the cultural code of each agent (e. g. a tourist, a taxi driver, a policeman, etc.).
Anchoring	The tendency of people to make estimates by starting from an initial base value that is adjusted to yield the final answer.	City's internal representations can contain certain categories such as style, urban violence, town size, etc., which can be 'fired on' early in the process of cognition; once switched on, it stays on and is only eventually reprocessed.
Synergetic I: Collective effects	When facing complex decision situations people tend to rely on what other people are doing or saying.	Drivers, pedestrians, intra- and inter-urban immigrants, tend to 'follow the stream'. That is: to take decisions in line with what others are doing.
Synergetics II: Attention parameters effect	When facing complex decision situations people often employ several heuristics in a sequence. First, the attention parameter calls into use a heuristic. Then, when exhausted, another attention parameter heuristic emerges and so on.	Intra- and inter-urban immigrants, for example, often start with a given location decision heuristic (say synergetic I); if it doesn't work, they switch to an alternative heuristic and so on.

Haken and Portugali [95] have further suggested that complex processes of decision making in the context of city planning evolve according to their SIRN model. This suggestion was further elaborated by Portugali and Alfasi [105] who demonstrated empirically how this SIRN process practically takes place in the reality of *planning discourse* as it evolved among members of a planning team engaged in formulating urban policies concerning the development of the city of Beer Sheva, Israel (Fig. 34).

As a basic cognitive capability planning is intimately associated with the fact that humans are social creatures – people tend to plan together (e. g. families, friends, firms etc). Some planning decisions are thus made solitarily while others collectively. Planning is also a profession that is closely linked to the central authorities of society (municipal, regional, national governments etc.). We thus have three forms of planning – *solitary*, *collective* and *professional*.

The notion that cities are complex self-organizing systems thus implies a novel view on planning the essence of which is, first, that all three forms of planning (solitary, collective and professional) participate in the dynamic of cities. Second, that due to non-linearities that typify cities as complex systems, the act of a single solitary planner might affect the evolution of a city more than the planning act of a professional planning team. (For an example see [101]). Does that mean that due to self-organization there is no need for city planning? Not at all! – It means that we have to adopt a new perception of *plans as participants* in the overall urban dynamics. It also means that we have to adopt a new perception of urban dynamics as a complex interaction between many plans at different scales, or more specifically, between solitary, collective and professional, planning agents, each with its specific plan.

Can there be an administrative planning process that is built in line with the above? The answer suggested by Portugali and Alfasi is positive [105]: In a sequence of studies they have portrayed the principles of such self-planned city [95] and the way it can be applied to the reality of city planning law and structure of Israel [2]. Similarly to current planning systems it is a 3-layers system: the legislative, the judiciary and the executive. It differs in the following: First, its planning law refers to the qualitative relations between the various city objects (Fig. 35) and not to land use plans that assume to determine top-down the urban landscape. Second, it suggests a novel planning judicature



Self-Organization and the City, Figure 28
Different configurations and categorizations of buildings convey different quantities of Shannonian information. When all building are similar, information (*i*) is low. When they are different, *i is high* but difficult to memorize. When landmarks are added *i is high*, provided that they are located apart from each other; otherwise, *i is low*. Source: [60]

composed of spatially distributed "planning courts" conducted by professionals who have specialized in both law and planning. Their aim is to evaluate, accept or reject the plans proposed by all planning agents – solitary, collective or professional. Third, it suggests a separation of authorities that doesn't exist today in standard planning administrations. Fourth, it suggests a process of hermeneutic planning that enables phase transition and adaptation to new situations. Figure 36 describes the structure and operation of this self-organized planning system.

Prediction, Planning, Self-Organization and Cities

The first principle of the above planning system is that its planning laws refer to qualitative relations between the various city objects and not to land use plans. The reason is that land use plans are commonly based on predictions. This is problematic since prediction in the context of complex systems such as cities is associated with four fundamental properties. First, the nonlinearities that typify cities imply that one cannot establish predictive cause-effect relationships between some of the variables. Second, many of the triggers for change in complex systems have the nature of unpredictable mutations [4]; not because of lack of data, but because of their very nature. Third, unlike closed systems, in complex systems, the observer, with his/her predictions, is part of the system – a point made by Jantsch [71] more than two decades ago and largely ignored since then. In such a situation, predictions are essentially feed-forward loops, affecting the system and its future evolution with implications that include self-fulfilling and self-falsifying or self-defeating predictions [101].

From the above follows a dilemma: complex systems are in essence unpredictable and yet, the current practice of planning as well as planning administration and law are based on the ability to predict. In a recent paper (ibid) it was shown that this situation leads to planning paradoxes that are the result of phenomena of self-fulfilling and self-falsifying predictions. It was further shown that these phenomena are the result of the *feed-forward* and *feedback loops* that are typical of complex systems in general and of cities and regions in particular. The existence of such loops is one of the properties that make systems complex. Such loops are responsible to the situation by which a prediction or a plan, once produced, becomes a *participant* in the system's dynamic.

Another way to look at this issue is from the point of view of the distinction between Shannonian and semantic information (above, Sect "Information Compression, Inflation, Adaptation"): Predictions and plans are essentially kinds of information transmission. One can thus speak of Shannonian prediction and semantic prediction. In the first, the outcome of the prediction is independent of the receiver(s) while in the second it depends on the meaning attached to it by a receiver or receivers. A weather forecast is a good example for both: it has no effect on the climatic system, but it might affect the urban system – following the prediction people might behave in different ways that might entail phenomena of self-falsifying and self-fulfilling predictions as described above.

Planning theory has not as yet internalized the implications of complexity theory to city planning. For example, in the planning and decision support systems (PSS, DSS) that are currently discussed and built by proponents of the complexity paradigm, urban simulation models are assumed to function as sophisticated prediction devises [28,29,43]. The result is a discrepancy that to my mind characterizes the domain of urban and regional planning: On the one hand, planning theory, as well as the structure of planning law, practice and administration, are all based on the (usually implicit) assumption that

Self-Organization and the City, Figure 29
If all buildings in the city are different from each other, categorization entails information compression; if they are similar – information inflation

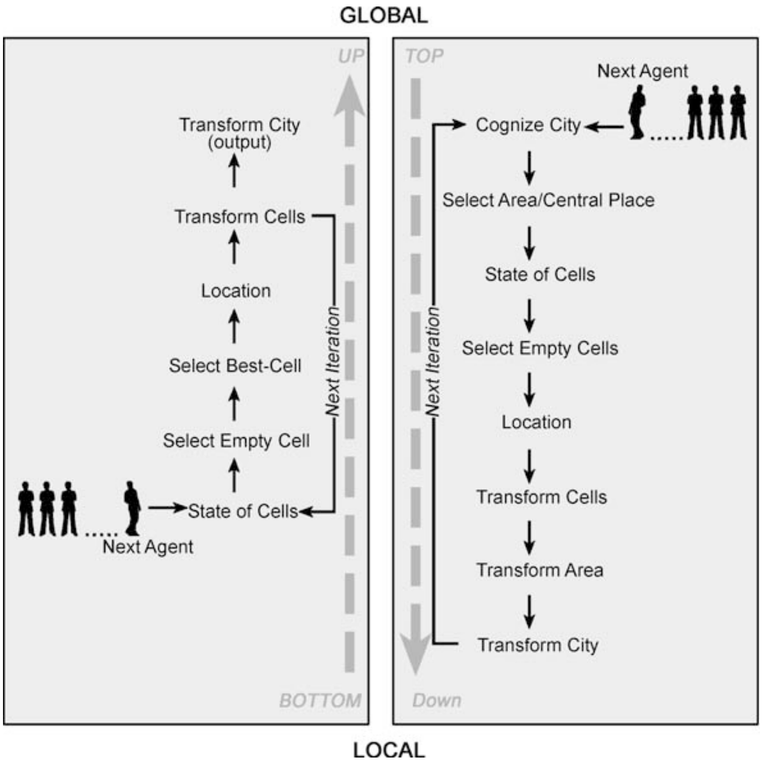
cities are essentially predictable entities; that given sufficient data, information and models, their future behavior is in essence predictable. On the other hand, current urban theory suggests that cities are complex, self-organizing and non-linear systems and that as a consequence their future behavior is in essence not predictable; even if sufficient information and data is collected and available [95].

Urbanism

In Sect. "Explicit Attempts to Define a City" we've defined the category "city" in terms of a family resemblance according to which a settlement becomes a "city" not by having some necessary and sufficient properties, but by being a member in a network of cities that has center, periphery etc. This view is in line with cognitive science's approach to concepts and categories. In the latter it is common also to distinguish between *basic level* categories and *super-ordinate* categories [116]. A 'chair', for instance, is a basic level category whereas 'furniture' a super-ordinate. The suggestion here is that a *city* is a basic level category whereas *urbanism* is a super-ordinate one, referring to the totality of cities ranging from their physical structure, architecture, economics, politics, social and cultural composition, and so on. The term 'urban revolution' (coined by Childe, [35]) thus implies a major transformation in society with the basic level category 'city' at its center.

Most complexity studies of cities have traditionally focused on specific aspects of cities – land-use, morphology, transportation, social segregation etc. – but not on the totality of city life which is what urbanism is all about. Why? Because they evolved mainly out of regional sciences' attempt to develop a scientific approach to cities and the consequent tendency to choose research issues that can be analyzed by reference to 'real world' data. The study of urbanism was thus left to the "soft" social theory approaches to cities[33,34,63,64].

This is rather unfortunate because 21st century world society is undergoing a major transformation with urbanism at its center: Massive rural-urban migration and demographic processes entailed a situation by which cities such as Mexico City, Bombay (Mumbai) and Sao Paolo grew from 8.8 million, 6.2 million and 8.3 million respectively in 1970 to over 20 million, over 16 million and again over 18 million today; for the first time in human history, the number of people living in cities is crossing 50% of the world's population and the process is still on. In the last



Self-Organization and the City, Figure 30
A cognitive (*right*) vs non-cognitive (*left*) AB/CA urban simulation model. Source: [98]

few decades we've witnessed the emergence of *world cities*, or *global cities*, that form the centers for the globalization process.

These quantitative processes are associated with several qualitative processes: a process of privatization that leads to the decline of the welfare nation-state; the emergence of a civil society that takes over many of the past duties and functions of the nationalist welfare state; the crucial problems of many (post)modern counties are no longer classical national problems (e. g. national self-determination, national boundaries etc.), but rather the problems of cities. The events of September 11 and the ensuing wars in Afganistan and the Middle East are tragic indications to the *urbanization of war*. Finally, the process of globalization is making some world cities more dominant than the states within which they exist thus repressing the nation states.

All the above indicates the more fundamental change: According to Lefebvre [79], its essence is that urbanism is replacing industrialization as the dominant force in society. My view is that the essence of this change is that urbanism is challenging nationalism as the order parameter of modern society [101].

Complexity and Urbanism Complexity studies of cities, with their focus on the short-term dynamics of cities and of national systems of cities are indeed highly advanced in terms of mathematical formalism and data analysis but rather anachronistic in terms of the issues studied; as such they have so far said very little on the dramatic urban phenomena of 21st century. Can they say more about the issue of urbanism? The answer is yes! And for several reasons: To my mind the "deeper messages" of complexity theories is that they have discovered properties in matter hitherto assigned to life, art and society [91]. It is not surprising therefore that complexity theories, particularly synergetics, bear many similarities to social theory and philosophy and, as a consequence, several of the notions that originated in the study of complex systems can be related to similar notions that originated in the domain of social theory [100]:

- Both are essentially systemic and even holistic.
- Both tend to conceptualize 'development' and 'evolution' in terms of abrupt changes rather then a smooth progression. In social theory the common terms for an abrupt change is (social/political/cultural) 'revolution',

while in the language of complexity 'bifurcations' and 'phase transitions' (that reminds one of Gould's and Eldredge's, [46] *punctuated equilibrium*).

- Synergetics' notion of 'order parameter' is similar to social theory's notion of 'mode of production'.
- Synergetics' notions of 'enslavement' and 'circular causality' are close to social theory's notions of 'social reproduction' and 'socio-spatial reproduction' [44,80].
- Complexity's view of systems in 'a far from equilibrium condition' comes close to postmodernism's recent emphasis on viewing reality as ever changing and transforming; hence the general popularity of notions such as 'chaos' and 'butterfly effect'.

Several writers have already responded to these similarities from the perspective of the sciences, philosophy, media/cultural critics and modern and postmodern social theory [37,75,76,100,113]. A preliminary attempt has also been made to employ synergetics as a complexity theory of urbanism [95,101]. That is, to interpret the current changes in cities and urbanism in terms of synergetics along the following scenario: the combined force of rapid population growth, urban expansion and technological change throughout the 20th century acted as a control parameter. Toward the end of the 20th century and at the beginning of the 21st, we are witnessing a bifurcation and phase transition followed by a competition between the newly emerging *urban order parameter* and the old nationalist one. My personal view is that what we see emerging today out of this competition is not the replacement of nationalism as an order parameter by urbanism as an order parameter, but the *urbanization of nationalism*.

Future Directions

Looking in retrospect at more than two and a half decades of complexity theory studies of cities, one can now appreciate some of its major achievements: First, the link between cities and complexity theory gave urban studies a strong theoretical basis it never had before. The fact that complexity theory was applied to a large number of domains gave urban studies a wide context and many sources of inspiration. The fact that complexity theory comes with a rich and strong mathematical formalism gave urban studies a sound methodological background. The attempt

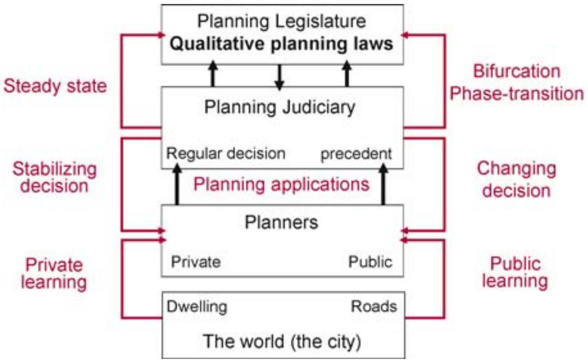
Self-Organization and the City, Figure 35

Proposition for a new planning structure for a self-planned city: The interrelations between urban elements provide the basis for planning law. A singular urban element might be a building, a linear one might be a road, while an example for a spatial urban element is a park



Self-Organization and the City, Figure 36

Proposition for a new planning structure for a self-planned city: The system is built of private planners (the inhabitants of the city) and professional planners. Each of them might submit a plan to the planning judiciary. In the latter the "planning judge" takes decisions according to the planning law as determined by the planning legislature. Unlike the current structure, there is a clear separation of authorities

to transform the study of cities into a science of cities is today closer than ever.

Complexity theory has given us a new insight to our understanding of the dynamics of cities. According to Batty [16] the most important contribution is that complexity studies of cities have verified the intuitive views of Jean Jacobs [70] and Alexander [1], namely, that the complex entity "city", with its variety of different land-uses, socio-spatially and culturally segregated communities, transportation networks and all the rest, is an outcome of "bottom-up" processes: The local interaction between agents at local scale, conducted by very few and simple rules gives rise the complexity we term 'city'.

At the same time, however, it must be admitted that the potential contribution of complexity theories to urbanism, planning and urban design has yet to be realized. The complexity approach has indeed given the bottom-up views on the nature of cities a strong mathematical formalism that can be quantified by real data. But this focus on the local, the bottom-up and the quantifiable was not without price: Cities and urbanism of the 21st century are in the midst of a dramatic transformation, new forms of cities are emerging – world cities, global cities, megacities, and yet the vast majority of complexity studies still focus on the old traditional quantitative urban questions, leaving the qualitative grand urban issues to the "non-scientific" social theory oriented urban studies. Can complexity theories of cities contribute? The answer suggested above is yes! SIRN is one approach in this direction and the field is ripe for others.

The same applies to planning. In the literature on planning theory it is common to make a distinction between *planning theory* versus *theory in planning* [40]. That is, between a theories about how to plan and theories about urban and regional dynamics that planners can use during the planning process. Examining complexity theories of cities from this perspective we see that they are very innovative with respect to theory in planning, but very conservative when it comes to theory of planning: The vast majority of studies simply ignore the implications of complexity to urban, regional and environmental planning.

Why do we need a complexity theory of planning? The answer is twofold: First, standard planning theory was developed in the 1950s and 1960s hand in hand with what we consider today as anachronistic urban theory: Both are based on the (usually implicit) assumption that cities are in essence simple, mechanistic systems that given sufficient data and advanced technologies, their future behavior is predictable and hence controllable. As we've seen above, complexity theories tell us a different story: Cities are complex self-organized systems that are in essence unpredictable and controllable; even if sufficient data and the most advanced technologies are at hand. From here follow a whole set of new and interesting questions: what is the role of planning in a complex system? Are all parts and components of the system unpredictable? In the above we've suggested some preliminary answers – but new ones must still come.

Finally it is important to mention the issue of extreme events in cities. The rapid processes of urbanization cities underwent in the last few decades and the 'urbanization of war' made cities rather vulnerable areas in cases of extreme events. The question of how cities and their inhabitants behave and respond to extreme events, is a pressing social issue that already started to capture the attention of students of complexity theory of cities and urbanism.

Article Outline

Definition of the Subject

Clinical psychology is a sub-discipline of psychology engaged in the description, classification, explanation, and treatment of mental disorders. The primary focus is on psychological methods, models, and topics such as behavior, cognition, emotion, and social interaction with substantial overlap with related areas in psychiatry, psychosomatics, or behavioral medicine. Yet, the main stream in clinical psychology views the etiology of mental disorders, their time courses and susceptibility to psychological treatment still through the magnification glass of linear input-output philosophy of human functions. Owing to this paradigm, linear combinations of variables (as inner conflicts, irrational cognitions, or stressors) trigger the development of psychiatric diseases or disorders in genetically predisposed individuals. Therefore, linear multivariate regression models are assumed be able to predict the probability of falling ill or suffering from disorders. As an important field in clinical psychology, psychotherapy research defines randomized controlled trials as the golden standard of outcome research. Here, patients randomly assigned to different treatment modalities are being compared with respect to the outcome of different tests. In this regard, the input (treatment) is thought to determine the outcome (treatment effects).

Contrary, or rather, supplementing this line of research is the scientific paradigm of self-organization, i. e. the functioning of complex nonlinear systems with circular causality at its center. Gestalt psychology, traditionally concerned with patterns ("Gestalts") in perception, human behavior and interaction (e. g., those prevalent in group dynamics, Lewin [25]) focuses on such self-organization processes. Gestalt psychologists like Wolfgang Köhler (e. g. [28]), Wolfgang Metzger, Max Wertheimer, Kurt Lewin and others can be seen as direct predecessors of modern complexity researchers in psychology [67]. Another root of this development is Jean Piaget's equilibration theory of action-cognition patterns (schemata) describing assimilation-accommodation-cycles of these schemata [49]. During these processes, input from the inner and outer environment assumes the role of disturbing stimulation of individual system dynamics. A third important line of thinking in circular causality comes from anthropological medicine. The "Gestaltkreis" integrates feedback loops between sensorial and actional systems on the one side, and individual and environmental systems on the other side (ecosystemic approach) [84].

Introduction

During the past decades in clinical psychology, it was particularly the transdisciplinary approach of *synergetics* [16] which inspired a specific nonlinear and complexity research on cognition [17,79]), social interaction [41,77], etiology and dynamics of mental diseases (e. g., [57,78]), and psychotherapy (for an overview see Haken and Schiepek [21]). Synergetics describes, measures, and explains the autonomous processes of pattern formation and pattern transitions in complex nonlinear systems. Founded on Haken's fundamental discovery that these processes do not depend of the matter of the systems they occur in, synergetics became one of the most important inspirations to many scientific fields and topics. Especially, Haken early transferred synergetics to brain research (e. g., [3]), since the brain is an outstanding example of a complex, self-organizing system. Today, it is widely accepted that the brain and a serial computer not only differ profoundly, but there is almost nothing they share: No wonder in light of the more than 10^{11} nonlinear interconnected neurons forming a dynamic mega-network of neural networks with essential features like arrays of emerging and submerging synchronizations, its flexibility and ever changing pattern formation, working at the edge of chaos, or realizing combined (activating and inhibiting) feedback mechanisms following the principles set forth by synergetics which describes the laws of self-organizing systems [18,19].

Taking a closer look at most of the phenomena clinical psychology is concerned with it becomes obvious that they appear to be of dynamic nature. Human development processes, human change and learning processes, the dynamics and prognosis of mental disorders, problems manifesting in social systems like couples, families, teams, or the question of how psychotherapy works: Self-organization is a ubiquitous entity.

Dynamic Diseases

Mental disorders are characterized by specific dynamic patterns, mirroring "endogenous" and common features of a disorder (like the repetitive phases of unipolar major depression or the bipolar phases of bipolar disorders, oscillating between mania and depression), as well as the effects of an individual life-style including individual coping and treatment efforts. Mental disorders can be conceived as highly structured and coherent states which enslave and thus impair the individual's mental and social functioning. Following the "enslaving principle", emerging order parameters reduce the degrees of freedom in the behavior of the single parts of a system. There is phenomenal evidence that this is the case in many mental disorders. Obsessive-compulsive disorder patients coerced to repeat unwished thoughts or rituals are just but one most impressive example. On the brain level, such pathological states correspond with abnormal synchronization in specific neural networks impairing brain functions. In obsessive-compulsive disorders, cortico-striato-thalamo-cortical feedback-loops are thought to be at the center of the dysfunctional network [55,59], while abnormal synchronization in highly similar neural populations is the source of Parkinsonian resting tremor [34,43].

At times, transitions between different pathological states or between states of health and disease are linear and balanced, at other times they are discontinuous and abrupt, such as in nonlinear phase transitions accompanied by critical fluctuations described by synergetics to occur in physical systems. Such transitions have been reported for unipolar or bipolar cyclic depression (e. g., [1]), and also for schizophrenia [68]. The usefulness of the concept of attractors in psychopathology is best reflected by the final common pathway of different disorders with similar phenomenology and syndromal patterns. Different initial conditions and different qualities and degrees of stressors and vulnerability factors may result in similar pathological end-states on the one hand. But on the other hand, small fluctuations within the intrapsychic or environmental conditions or small differences of some boundary or threshold conditions may result quite different disorders or may decide between health and disease (for a dynamical simulation of major depression see Schaub and Schiepek [56]). The encouraging message synergetics delivers is that while the structure of a generic system may stay unchanged, small changes in control parameters, threshold conditions, and internal or external fluctuations are able to trigger dramatic changes in the behavior of the system. As a consequence, therapy exerting changes of these parameters is thus able to trigger return of the system to a healthy state.

For illustrative purposes we present results of a computer simulation of different chronic courses of schizophrenia [57]. A qualitative network model of five macroscopic variables was transformed into a set of nonlinear difference equations, with each equation describing and determining the change rate of each variable from t to $t+1$. The empirical references of the simulation model were empirical studies of the chronic course of schizophrenic patterns, mostly mixed psychotic episodes, healthy functioning, and chronic states. For example, Ciompi and Müller [12] report on eight different patterns in the long-term evolution of schizophrenia, most of them reproduced by our model. These patterns result from various combinations of slow vs. acute onset, acute episodes vs. progressive deterioration, and remission vs. chronic end-state.

Variables taken into account were chosen from reviews in psychiatric and psychological schizophrenia research (e. g., [6,7,11]). Selected were (1) degree of cognitive disorders, (2) emotional and interpersonal stress, (3) withdrawal and social isolation, (4) degree of expressed (negative) emotions in the social environment of the patient, and (5) positive symptoms like delusions and hallucinations. The parameters mediating the nonlinear interplay of these macroscopic variables or order parameters were (a) diffuseness of affective-cognitive schemata as a central long-term vulnerability of mental functioning, (b) dopamine and serotonin metabolism, (c) social deficits and lack of competencies, (d) genetic risk for schizophrenia, and (e) some parameters mediating mixed feedback processes, especially the negative feedback responsible for antipsychotic damping effects of the pathology. Results of the simulation runs are indicated in Fig. 1. The simulation reproduces most precisely (a) episodic patterns with prodromal symptoms and acute onset, (b) acute onset, but continuous evolution with chronic end-state, and (c) slow and smooth onset with chronic long-term course (see also [76]).

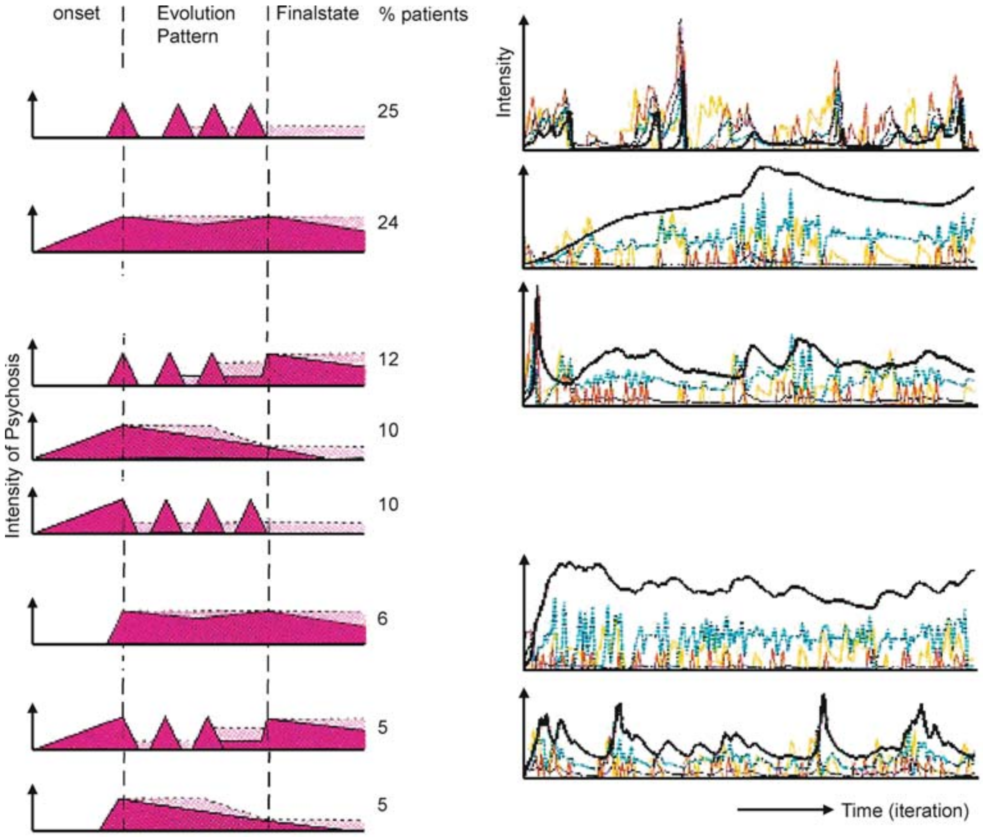
Other simulation models are effective on the microscopic level of neural networks. Kruse et al. [27] introduced a model focusing on the coupling dynamics between neurons processing brain correlates of social experiences. If unable to learn from cues delivered by the relevant environment, this system will fail to establish adaptive and coherent structures. When inducing fluctuations which promote re-learning and self-healing processes, the neural network causes incoherent and chaotic behavior. Most current models of schizophrenia take into account the neural circuits of relevant brain regions (cortical areas, basal ganglia like striatum and pallidum, thalamic areas, brain stem centers) and particularly the equilibria between different neurotransmitters and neuromodulators (e. g. [9]). The complicated local balances and their (non-) equilibria states are in the focus of the strongly evolving field of computational or systems neuroscience [15,44].

Not only central neuroscience has benefitted from concepts introduced by synergetics, however, but also physiology studying the effects of the autonomic nervous system (ANS) activities on peripheral systems, such as the cardiovascular, the respiratory, or the microcirculation system. Such activities are most prominent as the ANS engages in the mediation of emotions.

Self-Organized Synchronization Patterns in Peripheral Physiological Systems

For decades, the study of the ANS involvement in emotional arousal and its impact on the cardiovascular system has attracted clinical and scientific attention in psychology and psychophysiology (e. g. [65]). Ever since the seminal findings of W. B. Cannon [8] and H. Selye [63] on the general adaptation syndrome, colloquially condensed as stress, the clinical relevance of emotional responses became ultimately clear. This obvious clinical relevance is thwarted by the fact that direct observations of ANS activity in humans are restricted not only because of ethical constraints but also because of the fear to provoke what they strive to detect. Therefore, the study of the ANS in humans had to rely for a long time preferably on indirect measures, such as the power spectral density (PSD), a linear computation method. Based on the fast Fourier transform (FFT) which extracts periodic components in the frequency domain, the PSD was favored by many researchers due to its computational ease to analyze frequencies inherent in the two branches of the ANS, the parasympathetic (PNS) and the sympathetic nervous system (SNS). This allowed to divide the effects of the PNS and SNS activity on variations of the heart rate, the so-called heart rate variability (HRV), into three major variance components, the very low frequency (VLF) band below 0.04 Hz, the low frequency (LF) band between 0.04–0.15 Hz, and the high frequency (HF) band between 0.15–0.45 Hz. While the origin of both VLF and the HF bands is not debated, controversy reigns whether the origin of the LF band is attributable to SNS activity or whether it represents a mixture of SNS and PNS activity. Subsequently, some authors propose calculating the LF to HF ratio assumed to reflect the sympathovagal balance (for an overview see [73]). There has been growing discontent and criticism as to the validity of such drawer style classifications based on the consideration that the PSD, or FFT resp., as a linear routine is only able to detect linear properties, that are to some extent included in most physiological signals [23,86]. That, however, should restrict and limit its use since an increasing body of scientific evidence is demonstrating the obvious: In times of adaptation and rapid changes – a hallmark of life and its living systems – healthy ANS activity exhibits nonlinear dynamics necessary to mediate responses appropriate to those change processes. This is particularly the case for emoting as one of the most volatile change patterns.

However, this is not only true for discrete emotion transitions but also for a process crucial for the maintenance of health, namely psychophysical relaxation. Contrary to the rigid scheme depicted above, Perlitz and coworkers have introduced a relaxation model which takes into account adaptive, self-organizing characteristics of the central and peripheral subsystems involved in the psychophysical relaxation process. They scrutinized the physiological conditions and interactions observed with the emergence of a frequency at ca. 0.15 Hz, which in terms of the classical scheme is attributed to the transition between parasympathetic and sympathetic nervous activity. This frequency prevailed at different amplitudes in HRV, blood pressure and respiration, but foremost in the microcirculation of the forehead skin. Using several nonlinear methods, such as wavelet time frequency distribu-



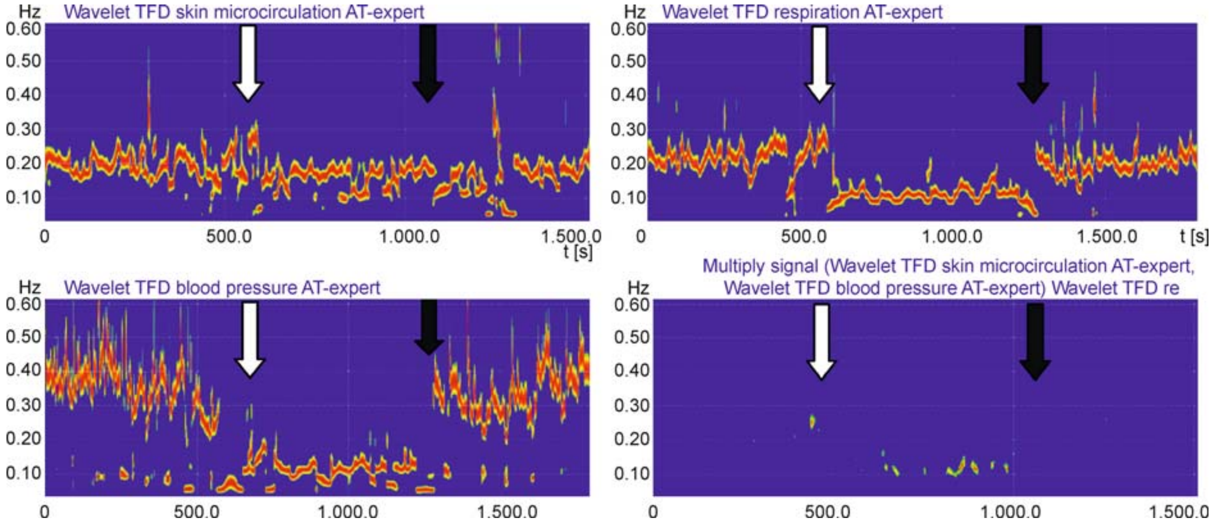
Self-Organization in Clinical Psychology, Figure 1
Different patterns of the long-term evolution of schizophrenia (empirical data from a study by Ciompi and Müller [12]) (*left*) were reproduced by simulations based on a set of five coupled nonlinear difference equations with different parameter values [57] (*right*)

tions (TFD) or post-event-scan (PES) analysis, this 0.15 Hz frequency band (range 0.12–0.18 Hz) emerged or erupted with amplified oscillations and periods of 6–7 s in all time series of subsystems under study. The emergence clearly depended on psychomotor drive reduction which can be either reduced by taking naive relaxation maneuvers (such as closing the eyes), or be enhanced using auto-suggestive means, such as autogenic training. Their zest to elaborate the origin of this frequency was supported by invasive observations with anesthetized dogs made by Lambertz and colleagues who had presented their findings earlier. They found a rhythm at a similar frequency which originated in reticular brainstem neurons of freely breathing dogs when administering narcotics to reduce drive. Followed by the emergence in those unspecific reticular neurons, this frequency also emerged in arterial blood pressure, HRV, and respiration [32,47,48]. This reticular rhythm, termed retR, was unaffected by changes in the frequency of respiration or arterial blood pressure which could both be presumed to exert distinct influences owing to linear models. Rather, in these experiments respiration and HRV were entrained to the 0.15 Hz band at 1:1, 2:1 and 1:2 integer number ratios which are, according to Bethe [5], an outflow of central-peripheral order–to–order transitions. With regard to parallels in frequency and dynamics observed in man and dog, Perlitz and coworkers suggested that also in humans the 0.15 Hz band most likely originates from reticular neurons of the lower brainstem network [46,47,48].

In summary, the findings presented in Fig. 2 underpin the theory of synergetics, since there is reason to regard the ca. 0.15 Hz frequency as an order parameter and the level of mental drive as control parameter. The ca. 0.15 Hz frequency is a prominent example of biological pattern formation lacking external or macroscopic control.

Nonlinear Dynamics in the Communication of Patient and Therapist

As mentioned above, psychotherapy is usually conceptualized as the application of psychological treatments to pa-



Self-Organization in Clinical Psychology, Figure 2

Wavelet time frequency distributions (TFD) of peripheral noninvasively obtained recordings of a female expert in autogenic training (AT, 56 yrs., healthy, non-smoker, 15 yrs practice AT). ***Top left*****: TFD of glabella skin microcirculation photoplethysmography;** ***top right*****: TFD of chest respiration related movements;** ***bottom left*****: TFD of peripheral systemic arterial blood pressure;** ***bottom right*****: So-called "joined TFD" of PPG-, respiration- and blood pressure-TFD, a novel method by Besting and colleagues (2005) (multiplying TFDs yielding only frequencies prominent at identical times and identical frequencies, www.Simplana.de) used to compute the intersection of TFD time series.** ***White arrows*** **mark the start of AT,** ***black arrows*** **mark the end of AT. In the TFD of PPG, the main frequency is at ca. 0.21 Hz prior to the onset of AT and is clearly stabilized at ca. 0.18 Hz with the start of AT, with signs of dissociation when terminating AT. The TFD of respiration supplies ample evidence of an order–order transition triggered by the practice of AT: The main frequency plummets from ca. 0.25 to 0.15 and 0.07 Hz to be maintained at ca. 0.12 Hz. With termination of AT, the main frequency skips back to frequencies shown beforehand. The TFD of systemic arterial blood pressure exhibits an intersection of approx. 90% during the AT section, but also few minor intersections before and after AT (data not shown); the joined TFD intersection shows merely few frequency "spots" at ca. 0.12 Hz during AT**

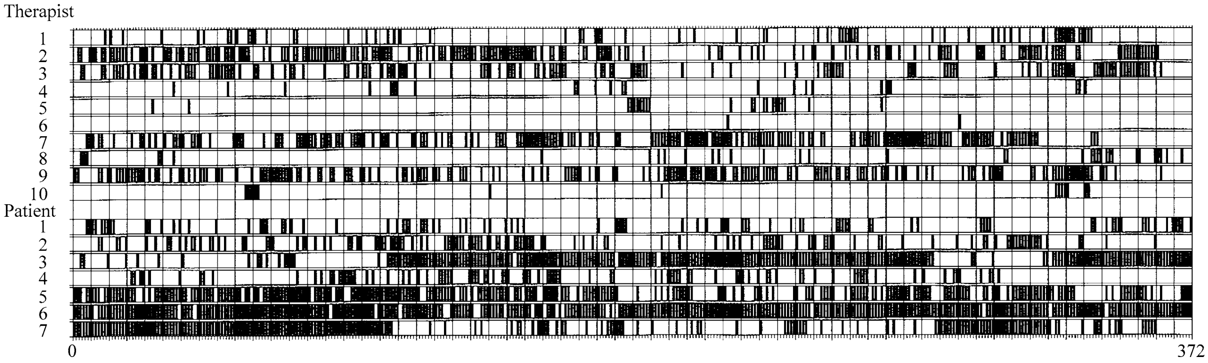
tients in order to change their problem states and diseases. However, as different research programs revealed during the last decades, psychological change processes show all important features of nonlinear systems – like deterministic chaos, nonstationary phase transitions, and nonlinear coupling between patient and therapist. Physiological synchronization appears to be realized at an interpersonal level (between therapist and patient) as well as between different phenomenological levels of the interpersonal system (speech qualities and psycho-physiological variables). In a study of Villmann et al. [83] heart rate, respiratory frequency, muscular tension, and skin conductivity were measured from both, therapist and patient, during 37 therapy sessions. Speech production was analyzed by the Mergenthaler model focusing on emotional feeling and cognitive referential activity/abstraction [38]. Physiological data were analyzed by an artificial neural network approach (growing self-organizing map), which uses a kernel smoothing for improved data density estimation. It was possible to generate an entropy model of psycho-physiological variability detecting emotionally instable phases during the therapy process. The entropy reflecting psycho-physiological and emotional variability was related to the dramatic value of speech analysis according to the cycle model of Mergenthaler.

Empirical evidence exists also for synchronized chaoto-chaotic phase transitions in the brains of therapist and patient during a therapeutic interview, measured by local largest Lyapunov exponents in the EEGs of both interaction partners [52].

Taking into account the importance of the therapeutic relationship for the treatment outcome the attention of a study realized by Schiepek and co-workers focused on the interactional process between therapist and patient [26,58]. The authors used the method of sequential plan analysis, which is a development of the hierarchical plan analysis proposed by Grawe and Caspar (e. g. [10]). Plans in this sense are verbally or non-verbally communicated intentions of self-presentation in a social situation. Patient's and therapist's interactional behavior was analyzed on the basis of video recordings. Two complete therapies (13 and 9 therapy sessions, resp.) were encoded with a sampling rate of 10 s (Fig. 3). The construction of an inclusive hierarchical plan-analysis leads to an

Self-Organization in Clinical Psychology, Table 1
Second-order plans and categories of self-presentations as identified by the hierarchical plan analysis of a complete 13-session psychotherapy. Encoding of therapist and patient. Plans and categories are used as ideographic observation categories for the sequential plan analysis

	Second-order plans	Categories of self-presentation
Therapist	1 show competence 2 encourage a trusting relationship 3 show understanding 4 motivate her	I encourage trust/create a secure atmosphere
	5 encourage her to reflect on her patterns of thinking 6 confront her with her avoidance and problem behavior	II confrontation/exposing to insecurity
	7 activate her 8 show her that she is responsible	III encourage self-responsibility of the patient
	9 guide her focus of attention 10 give her structure	IV activate structuring work
Patient	1 demonstrate strength and competence 2 make it clear that things are or have been difficult 3 be a good patient/create a good relationship to the therapist	I search for sympathy/appreciation/good relationship
	4 show that your suffering is strongly influenced by external causes 5 ask for help from the therapist	II externalization/demonstration of helplessness
	6 show interest and willingness in solving your problems 7 protect yourself from threatening changes	III problem-oriented work (self-relatedness vs. avoidance)

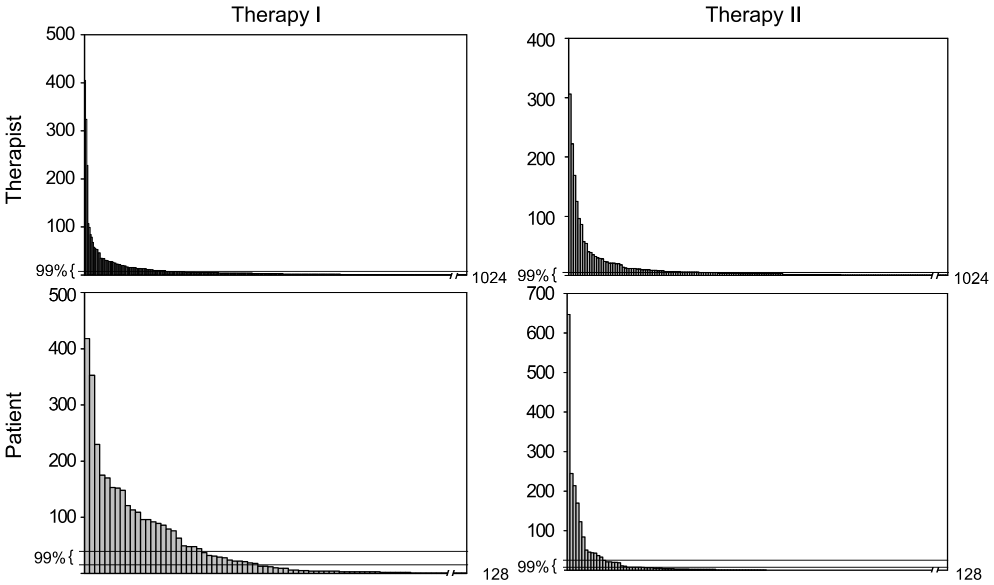


Self-Organization in Clinical Psychology, Figure 3
Nominal sequences of interactional plans of the therapist (*top*) and the patient (*bottom*) during a psychotherapy session. The sampling rate is 10 s. Different plans can be realized simultaneously. The pattern looks like a music score with the plans representing the different instruments of an orchestra. A sonification of the score of plans coded from a 13-session psychotherapy is recorded on a DVD added to the textbook of Haken and Schiepek [21]

ideographic categorical system for the observation of the client–therapist interaction (Table 1).

The first hints of order in the dynamics came from the distribution of simultaneous configurations (on-off-patterns) of plans in the scores. This distribution follows a power law ($1/f^a$) demonstrating a distinct structure order within the data (Fig. 4). Following Bak et al. [2], power law-distributions as demonstrated in Fig. 4 emerge from self-organized criticality within dynamic systems.

Further data analysis was based on the time series of the highest-level categories, the so-called categories of self-presentation (see Table 1). Since in the hierarchical system of the plan analysis the operators at the lowest observation level were quantified by intensity ratings, the plans and the self-presentation categories at the top level integrating the lower level categories were also quantified. The time series were analyzed by methods which are sensitive to the nonlinearity as well as the nonstationarity of the time series [21,26,58,70]. Nonlinearity was proofed by surrogate data tests [51] using random surrogates and FFT-based phase-randomized surrogates [69]. Whereas fractal dimensionalities of the empirical time series (based on



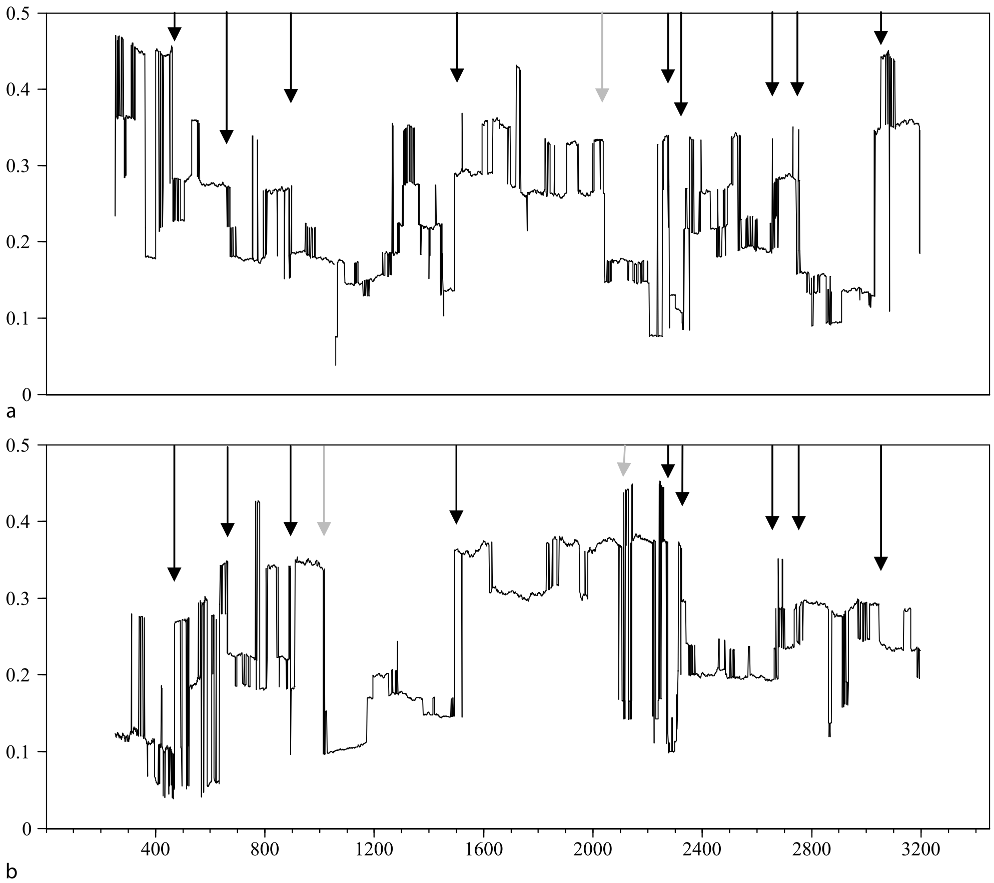
Self-Organization in Clinical Psychology, Figure 4

Empirical frequencies of constellations of interactional plans realized by therapists (10 plans) and patients (7 plans) within two psychotherapies (therapy I: 13 sessions, therapy II: 9 sessions). *X*-axis: Number of all possible configurations of plans (therapist: $2^{10} = 1024$, patient: $2^7 = 128$) ordered by the frequency of their realization. *Y*-axis: Frequencies of plan configurations. The distributions follow a power-law ($1/f^a$) distribution

the correlation dimension D2 as well as mean Pointwise D2 [66]) saturated at finite values (convergence to a fractal dimensionality of about 6), random and FFT-surrogates did not. The methods of PD2 [66] and of the local largest Lyapunov exponents (algorithm from Rosenstein et al. [53]) were used to identify phase-transition like discontinuities. Following the evolution of PD2 dimensionalities, both therapies realized nonstationarities, and both therapies showed periods of strongly synchronized (with correlations from 0.80 to 1.00) and anti-synchronized PD2-processes (with correlations from −0.80 to −1.00) between patient and therapist. Quite similar and even more pronounced dynamical jumps were to be seen in the development of the local largest Lyapunov exponents (Fig. 6), representing changes in the chaoticity of a time signal [26]. An important part of the discontinuities of the LLLE were exactly synchronized between patient and therapist. Obviously both persons create a dynamic self-organizing communication system, which allows for the individual change processes of the patient.

These results get support from nonlinear coupling measures between the time series of the interaction partners. Pointwise transinformation as well as pointwise coupling conditional divergence [33,80] were applied to the data, and both indicate changing and time-dependent coupling strengths between the time series of the interaction partners. There is no priority to the therapist's influence on the patient, which contradicts the classical idea that input from the therapist should determine the client's output. The other way round is also true and both constitute the circular causality of psychotherapeutic self-organization.

In other studies, sequential plan analysis was applied to the microdynamics of group interaction [21]. In a group of five persons a creativity and problem solving task was to be solved within 2,5 h (creation of ideas, rules, and physical handicraft realization of a prototype board game from different materials). Similar to the psychotherapy study the sampling rate was 10 s. The superordinate plans which could be identified for all five persons were (1) spontaneity and emotional engagement vs shyness, restricted behavior, and orientation to social norms, (2) engagement in the group interaction and in positive social climate, (3) task orientation. Length of time series was about 810 coding points (= intervals). D2 as well as mean PD2 estimates saturated at a fractal dimensionality of about 5 for all categories. The embedding of the time series was realized by two ways: (1) The phase space was constituted by the three dimensions of superordinated plans with five trajectories representing the five group members, or (2) the phase space was constituted by the five persons with three trajectories representing the time course of the three plans



Self-Organization in Clinical Psychology, Figure 5
Synchronized jumps in the dynamics of local largest Lyapunov exponents (*black arrows*). *Grey arrows* indicate not clearly synchronized changes. a Therapist, b Patient

Self-Organization in Clinical Psychology, Table 2
Factors (principal component analysis) of the Therapy Process Questionnaire (TPQ). Factor analysis was based on 94 therapy processes (mean stay = 66 days, daily ratings). Seven first-order factors (*right*) are related to three second-order factors (*left*). Numbers behind the first-order factors indicate factor loadings on second-order factors (for details see [21])

I(2) Change involvement	I Therapeutic progress/confidence in treatment effects/self-efficacy (.571) VI Intensity of therapeutic work/motivation to change (.596) V Opening of perspectives/personal innovations (.649)
II(2) Relationship/Social climate	III Quality of the therapeutic relationship/openness/confidence in the therapist (.705) II Ward atmosphere, social relationship to other inpatients (.692)
III(2) Emotionality	IV Dysphoric emotions/self-relatedness (.732) VII Impairment by symptoms and problems

(additional embedding dimensions result from time delay coordinates). In both cases PD2 results show an evolving pattern of quasi-attractors with changing complexity, and LLLEs (algorithm from Rosenstein et al. [53]) portray chaoto-chaotic phase transitions with clear-cut and interpersonally synchronized jumps – similar to the dyadic interaction of the psychotherapy study.

Self-Organization in Human Change Processes

A quite different approach to human change processes focuses on inpatient treatments at a hospital of psychosomatics. In a study by Schiepek and coworkers (results in [21]) 94 change processes were investigated, realized by 91 inpatients with different diagnoses (depression, anxiety disorders, posttraumatic stress disorders, eating disorders, somatoform disorders, and others). The time series data was produced by patients' self-ratings which were completed once a day in the evening. For this purpose a 53-item rating sheet was developed (*Therapy Process Questionnaire [TPQ]*, [21]) whose factor analysis resulted in a solution of seven factors defining the subscales of the questionnaire (Table 2). The ratings combined seven-step Likert scales and visual analogue scales especially for ratings of emotions. TPQ measurements reflect important aspects of the patient's experience of progress and goal attainment, emotional involvement, self-efficacy, therapeutic relationship, social relations with other inpatients, and the ward atmosphere.

The inclusive outcome criterion integrated the following measures: Inventory of Interpersonal Problems (IIP), Gießener Beschwerdebogen (GBB), Hospital Anxiety and Depression Scale (HADS), Questionnaire for Social Support (F-SOZU), a life-quality questionnaire (Münchener Lebensqualitäts-Dimensionenliste), a self-efficacy questionnaire (Fragebogen zur Generalisierten Kompetenzerwartung), the Sense-of-Coherence Questionnaire, and an interview-based assessment of personal resources. Additionally, therapists and patients scored the overall treatment effectiveness and treatment quality.

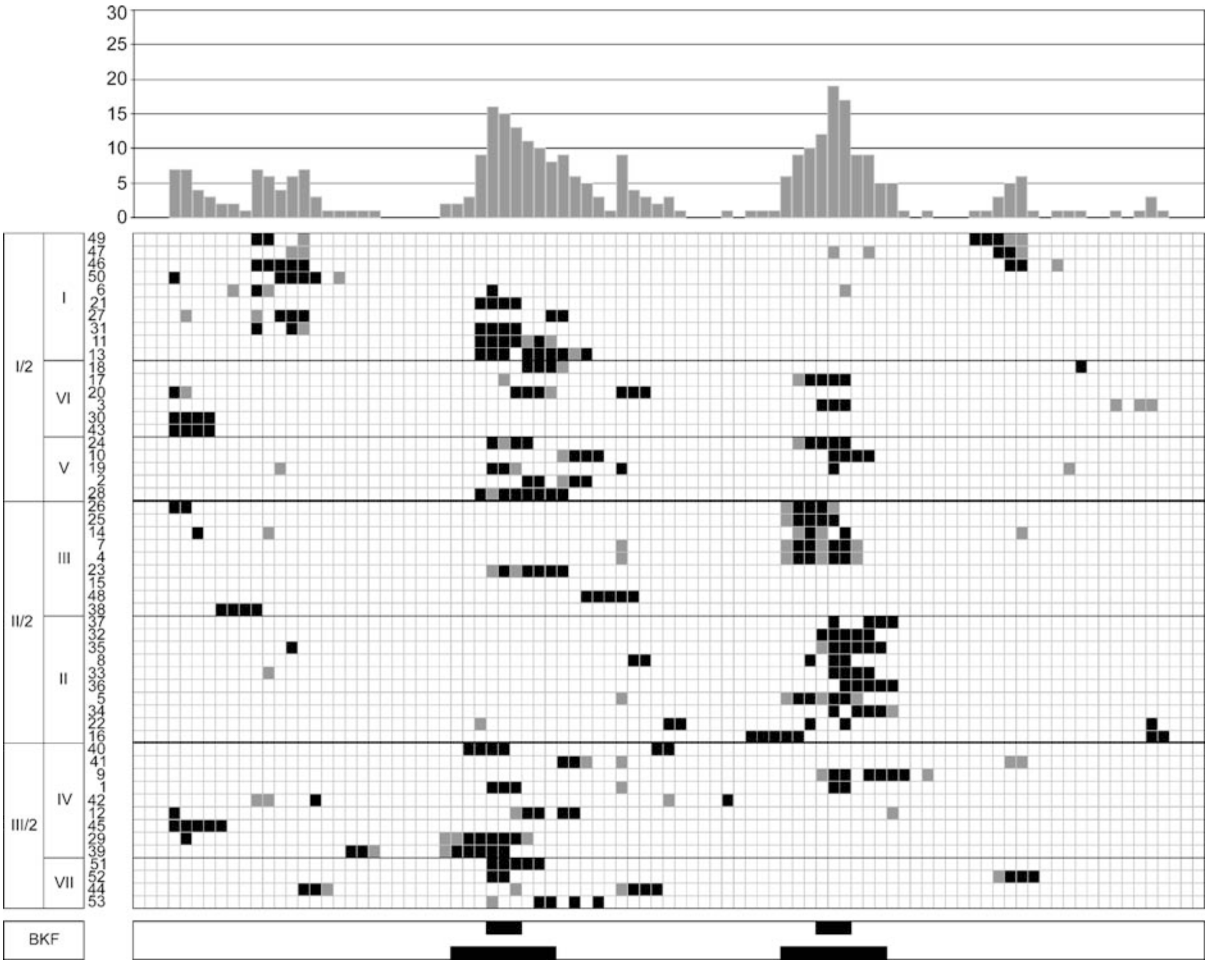
Results confirmed synergetic conceptualizations of how psychotherapy works and corroborated hypotheses drawn from this model. Here therapy is supposed to provide support for the patient's own self-organization processes, which should be characterized by cascades of order-to-order transitions accompanied by critical instabilities of the process. Pathological and restrictive order should be transformed into more flexible and adaptive patterns of behavior, and the synchronization of the different aspects of the patient's experience should undergo some transformations. Exactly this could be observed.

Significant correlations exist between the local maxima of critical fluctuations and the outcome of psychotherapy. The local maxima were defined by the difference between the mean dynamic complexity of the whole psychotherapy process and the maximum of the complexity which was observed during the process. Correlations were −0.455 (second-order factor I: "Change involvement" of the TPQ, $p = 0.002$), −0.431 (second-order factor 2: "Relationship/social climate", $p = 0.003$), and −0.572 (second-order factor 3: "Emotionality", $p = 0.000$) (compare Table 2). Negative correlations result from the fact that increased local maxima of dynamic complexity correspond to reduced problems, symptoms, and impairment.

The *dynamic complexity* combines a fluctuation index with a distribution index. The fluctuation index measures the frequency and amplitude of the change rates of a time series between the reversals of the development within a scanning window gliding over the whole time series. For analysis purpose a window width of seven measurement points (= days) was introduced. The distribution index measures the scattering of realized values within a given scanning window. The more scores are restricted to only narrow intervals of the available scale range, the smaller the distribution index becomes. The score of this index increases as the interval filled by the realized values grows. The algorithm solves the problem of value distribution independently of the scale resolution, the width of the scanning window, and of any combination of these parameters.

In order to answer the question if the observed intensities of dynamic complexity reach critical values, intra-item calibration procedures were used in order to define adequate thresholds fitting to the actual dynamics. The time series of dynamic complexity were standardized by z-transformations, providing significance thresholds of 5% or 1%. Applying this threshold method to all items of the TPQ reduces the quantitative complexity signals of each time series to a three-step signal (not significant, complexity exceeds a 5% threshold, complexity exceeds a 1% threshold). A synopsis of these qualitative signals referring to all items of the TPQ gives an impression of the localization of critical fluctuations during the whole process. Dynamic complexities seem to be synchronized over many items and factors of the TPQ, resulting in the structure of columns of grey (<5%) or black (<1%) dots. In a large part of the investigated therapies such column-like structures could be identified. In an item-by-time synopsis they indicate phases of intensified as well as synchronized fluctuations and entropies of quite different aspects of the process. Consequently, these item-by-time synopses are called *complexity resonance diagrams* (Fig. 6).

In order to confirm the structures found within the complexity-resonance-diagrams, surrogate tests were realized based on random as well as on FFT-based surrogates of the time series. The empirical patterns are impressively different from the surrogate-based patterns (all realized comparisons with $p = 0.000$). Further support for phase-transition like phenomena in the change processes came from recurrence plots representing similarities and dissimilarities of dynamic segments of a whole time series [13,80,85]. This method is based on the embedding of time series into a phase space constructed by time-delay coordinates, a method which is also crucial in the algorithms for the estimation of dimensional complexity or chaoticity (e. g., Kolmogorov–Sinai-Entropy, Lyapunov Exponents). Neighbors in the time-delay phase space rep-

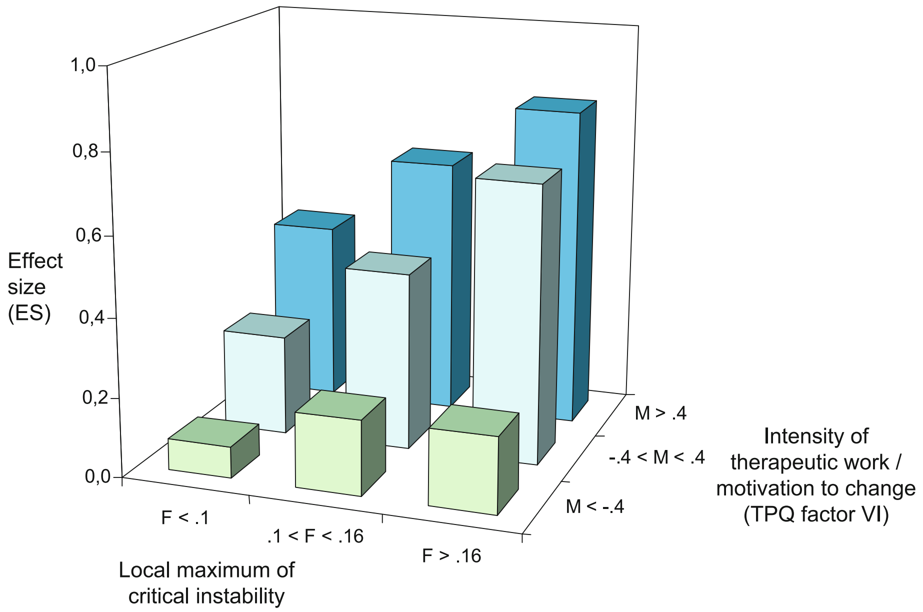


Self-Organization in Clinical Psychology, Figure 6

Complexity resonance diagram of a psychotherapy process. Such diagrams portray the threshold exceeding dynamic complexities of a process encoded by the 53 items of the Therapy Process Questionnaire (TPQ). *Gray dots*: 5% threshold of significance; *black dots*: 1% threshold of significance. *X*-axis: Days of hospital stay, *Y*-axis: Items of the TPQ arranged by the order of the factors as reported in Table 2. Window width for the calculation of dynamic complexities is 7. Column-like structures indicate phases of critical instabilities during the process

resent similar dynamic segments and are plotted by a dot in the recurrence plot. Dissimilarities are represented by empty columns in the recurrence plots, which in many cases exactly correspond to the columns of dots in the complexity-resonance diagrams. The overall correlation is -0.45, if small shifts (lags of $+$ or -3 measurement points at maximum) will be allowed. This means that periods of critical instability correspond to transient dynamics outside of the quasi-attractors established by the self-organizing system under consideration. These different ways to identify critical phase transitions are further validated by the time frequency distribution (TFD) of the time series. The TFD method uses wavelet spectra in order to scan the evolution of the frequency distributions within a signal [33,80]. It is a dynamic counterpart to the static fast Fourier transformation and allows for the identification of pronounced frequency amplitudes or changes in the frequency distributions. In the data set of the referred study these often appear exactly during the phase transitions which can be identified by other methods (see the synoptical representations of different time series analysis methods on the DVD in the textbook of Haken and Schiepek [21]).

An overall result of the study is shown in Fig. 7. It portrays the evidence that in order to bring forth change processes within self-organizing systems at least two conditions should be realized. The first condition: The degree of the control parameter energizing the system and push-



Self-Organization in Clinical Psychology, Figure 7
The effect size (ES) (mean ES of all outcome measures introduced in the study, see text) of inpatient psychotherapy is produced by an interaction between the local maximum of critical fluctuations and the intensity of the control parameter realized during the change process. The local maxima of fluctuations were defined by the difference between the mean dynamic complexity of the whole therapy process and the maximum of the complexity observed during the process. The diagram is based on the mean of the local maxima of all items. The control parameter was defined by the overall mean of the TPQ factor VI: Intensity of therapeutic work/motivation to change

ing it away from its actual equilibrium state should exceed a certain intensity level. With respect to psychotherapies this control parameter could be the patient's motivation to change including his engagement into the therapeutic work. Second condition: The degree of instability the system attains during its change process. This instability during emerging symmetries and symmetry breaking transitions is given by the local maximum of dynamic complexity during the hospital stay. The interaction of both conditions results in treatment effectiveness. A third important condition is not represented in Fig. 7: It is the experienced stability of the outer environment (context at the ward or therapeutic bond) or of the inner environment (as self-esteem, self-confidence, or activated resources). This context of stability is a prerequisite for a system to undergo critical instabilities.

The Concept of Self-Organization Promotes New Information Technologies in Clinical Psychology – The Synergetic Navigation System

Since self-organization and nonlinear dynamics seem to be ubiquitous in human change processes, it should be helpful to go beyond the diagnostics of steady states to an assessment of dynamics. Practitioners should get information on the therapy and its features *during* the ongoing process in order to use this information for an adequate placement of interventions and a control of the dynamics. "Controlling" self-organization processes in psychotherapies means the generation and co-creation (together with the patient) of adequate boundary conditions, the decision to do or to retain certain interventions, and to support the dynamics which the system is creating by itself. The patient takes an active and cooperative role in this understanding of data-based and co-creative change processes. Another important motivation for the development of real-time assessment comes from the evidence that most of the empirically identified specific and non-specific factors driving therapeutic change processes are connected with specific persons (the concrete therapist who meets a concrete patient in a concrete setting) and evolve by its nonlinear interactions in specific systems. These factors are (i) personal features of the patient like his motivation to change, his premorbid adaptation and degree of social functioning, personality integration, ego-strength, or comorbidities, (ii) personal and professional features of the therapist like his own personality integration, social and professional competencies, allegiance to his approach of

◀ Self-Organization in Clinical Psychology, Figure 8

Synopsis of a psychotherapy process as monitored by the Synergetic Navigation System. The time course of the inpatient treatment of a patient with eating disorders portrays a clear cut phase-transition associated with critical instabilities. *Top*: Recurrence plot of the item "Today I was successful to do steps towards my personal goals". *Dots* represent recurrent segments of the time series, empty spaces represent transitions. *Middle*: Complexity resonance diagram of all items of the TPQ. Different from Fig. 6, the intensities of the dynamic complexity of each item is transformed into colors. Items are arranged by the order of the first- and second-order factors of TPQ. *Bottom*: Mean of all inter-item correlations irrespective of the sign (absolute values). This is a measure of the overall synchronisation of the patient's experiences as represented by the items of the TPQ. The correlation structure is shown at four measurement points (days) of the psychotherapy process ($t = 4$, $t = 19$, $t = 33$, $t = 46$). Intensity of green represents positive correlations, intensities of red represents negative correlations

doing therapy, stress-resistance, and so on, and (iii) factors of the professional and social context (see the so-called generic model of psychotherapy [29,42]). In consequence, *evidence-based treatments* should be based on the evidence of concrete data mirroring the ongoing change process and on the professional decisions reflecting this insight.

Real-time monitoring actually uses internet-based presentations (including PDA or cell phone technology) of outcome and process questionnaires. Data are sent to a server, where they are stored and analyzed. Professionals and patients can inspect the results whenever they want. Experiences with real-time feedback to therapists (based on an outcome questionnaire the patient fills out during the therapy sessions in an ambulatory or outpatient context) are encouraging. Lambert and co-workers (e. g., [31]) were able to identify processes on the way of getting difficult or unsuccessful ("not on track" therapies, compared to more promising "on track" therapies), and helped therapists to correct these not-on-track dynamics by specific interventions. By this, threatening drop-outs could be avoided, bad results could be corrected, and on-track processes could be optimized and even shortened.

More sophisticated than the distinction between "on-track" and "not-on-track" courses is the feedback on self-organization features realized by a system based on synergetics [21]. The *Synergetic Navigation System* uses the therapy process questionnaire for daily ratings and applies methods from nonlinear time series analysis in order to identify important qualities of the change process. This are:

- Stability or instability of the dynamics as represented by the subscales (factors) of the TPQ (see Table 2), which is measured by the dynamic complexity
- Recurrence plots indicating transitions or repeating patterns
- Intensity of synchronization and time-dependent synchronization patterns between the items and the factors of the TPQ (realized by the cross-correlations of all items of the TPQ, calculated within a running window).

Figure 8 shows a synopsis of these analysis methods applied to a specific change process. Preceding the inspection of all analysis results the raw data series of the items and the time courses of the factors (z-transformed values) are available. Additionally patients can write an electronic diary after filling out the questionnaire. The diary entries can be presented within a gliding tip-tool running over the time series. By this, corresponding qualitative and quantitative information completes the picture.

The Self-Organizing Brain

The human brain is one of the most outstanding examples of a complex nonlinear system producing self-organized patterns of functioning. Since function corresponds to structure and vice versa, structural changes (changes of intersynaptic coupling strengths and network configurations, (re-)wiring patterns following the synchronized co-activity of neurons) can be explained by functional self-organization of neural populations. Perception, action and transition of action patterns, decision making, and cognitive, behavioral, as well as emotional learning are psychological functions following the principles of self-organization [21]. At a neural level they correspond to and are based on nonlinear brain dynamics. The emergence of order parameters and the occurrence of phase transitions can be described and measured on a psychological as well as on a neural level.

One of the phenomena modeled by synergetics is Gestalt perception – the construction of percepts and the switching of ambiguous visual patterns (e. g., Necker cube or stroboscopic alternative motion). These processes of Gestalt perception constitute the link between Gestalt psychology and actual mathematical modeling in synergetics [17]. The binding of different perceptual features or components to coherent structures or "qualia" seems to be due to synchronization processes of extended brain regions and converging integrative areas [64]. Pattern perception corresponds to pattern formation – as H. Haken puts it into pointed words. Tallon-Baudry et al. [71,72] measured enhanced gamma-band activity (30–50 Hz) in the EEG of the primary and secondary visual cortex while subjects identified a triangle within the offered stimulus material. This could be a fingerprint of corresponding neural synchronization processes. This activity occurred when subjects saw a real object (triangle) as well as a figural illusion of the object (Kanizsa triangle), but not if geometrical components could not be composed to a true Gestalt. The research group of Basar–Eroglu and Stadler [4] measured significant gamma-band activity in EEG during states of perceptual switching triggered by stroboscopic alternative motions. In summary: Perception of multistability is one of the multifold cognitive processes giving rise to 40 Hz enhancement in the cortex, and coherent oscillations reflect an important mechanism of feature linking in the visual cortex which corresponds to the emergence of a neural order parameter. Changing order parameter dynamics during different cognitive activities was shown by Schupp et al. [62]. Mental imagery of an object could be differentiated from its concrete perception. The dimensional complexity of prefrontal EEG was increased during sensory imagery compared to the real perception of the same object (compare [36]).

The well-known movement coordination paradigm modeled by Haken et al. [22] was used to demonstrate neural correlates of instability and symmetry breaking processes in the motor brain. The order parameter in this finger movement experiment is the relative phase of the index fingers of both hands. Metronome-pacing – with movement frequency as the control parameter – triggers the system from parallel (out-of-phase) to mirror (in-phase) movement. Meyer-Lindenberg et al. [39] showed that the emergence of patterns in open, nonequilibrium systems like the brain is governed by their stability in response to small disturbances. Transitions could be elicited by interference at the neural level. Functional neuroimaging (PET) identified premotor (PMA) and supplementary motor (SMA) cortices as having neural activity linked to the degree of behavioral instability, induced by increasing frequency of the finger movement. These regions then were transiently disturbed with graded transcranial magnetic stimulation (TMS), which caused sustained and macroscopic behavioral transitions from the less stable out-of-phase to the stable in-phase movement, whereas the stable pattern could not be affected. Moreover, the strength of the disturbance needed (a measure of neural stability) was linked to the degree of the control parameter (movement frequency) and thereby to the behavioral stability of the system.

Synergetic research in clinical psychology is now reaching the brain level. The aim of an actual fMRI-study [60] is the investigation of phase transitions of brain activity and related subjective experiences of patients during their psychotherapy process. Repeated fMRI scans are related to the degree of stability or instability of the ongoing dynamics (measured by the dynamic complexity of daily TPQ-ratings) as well as to the therapy outcome. Real-time monitoring by the *Synergetic Navigation System* allows for the identification of stable or unstable periods and by this for a decision on the appropriate moments of fMRI acquisitions. Three or four scans are realized during each of the psychotherapy processes of 15 patients. The study includes only patients with obsessive-compulsive disorder (OCD) of the washing/contamination fear subtype (DSM IV: 300.3), without any medication or comorbid psychiatric or somatic diagnoses. Patients are matched to healthy controls. (This research is a multi-center study of the Ludwig-Maximilians-University Munich, Institute of Psychology (Prof. Dr. Günter Schiepek, head of the project), and Clinic of Psychiatry (PD Dr. Oliver Pogarell, Dipl. Psych. Susanne Karch, Dr. Christoph Mulert), Hospital of Psychosomatic Medicine Windach/Ammersee and Day Treatment Centre Munich/Westend (Dr. Igor Tominschek, cand. Psych. Stephan Heinzel, Prof. Dr. Michael Zaudig), University Hospital Vienna/Astria, Clinic of Psychiatry (Prof. Dr. Martin Aigner, Prof. Dr. Gerhard Lenz, cand. med. Markus Dold, Dr. Annemarie Unger), MR Centre of Excellence, Medical University Vienna/Austria (Prof. Dr. Ewald Moser, Dr. Christian Windischberger).

OCD seems to be an appropriate model system for synergetic studies in clinical psychology, since the pathological order parameter is phenomenologically quite evident, the disease has an obvious and quite stable time course, and therapeutic phase transitions – if they do occur at all – are easy to be observed. OCD-specific functional neuroanatomy is partially known: Friedlander and Desrocher [14] report on an executive dysfunction model corresponding to the cortico-striato-thalamo-cortical feedback-loops involved in perseverations and compulsions, and on a modulatory control model involved in the pathological mechanisms of anxiety and distress provoking obsessions.

The visual stimulation paradigm of the study uses symptom provoking, disgust provoking, and neutral pictures. The disgust and the neutral pictures are taken from the International Affective Picture System, whereas the OCD-related pictures are photographed in the home setting of the patients, showing specific and individualized symptom provoking stimuli.

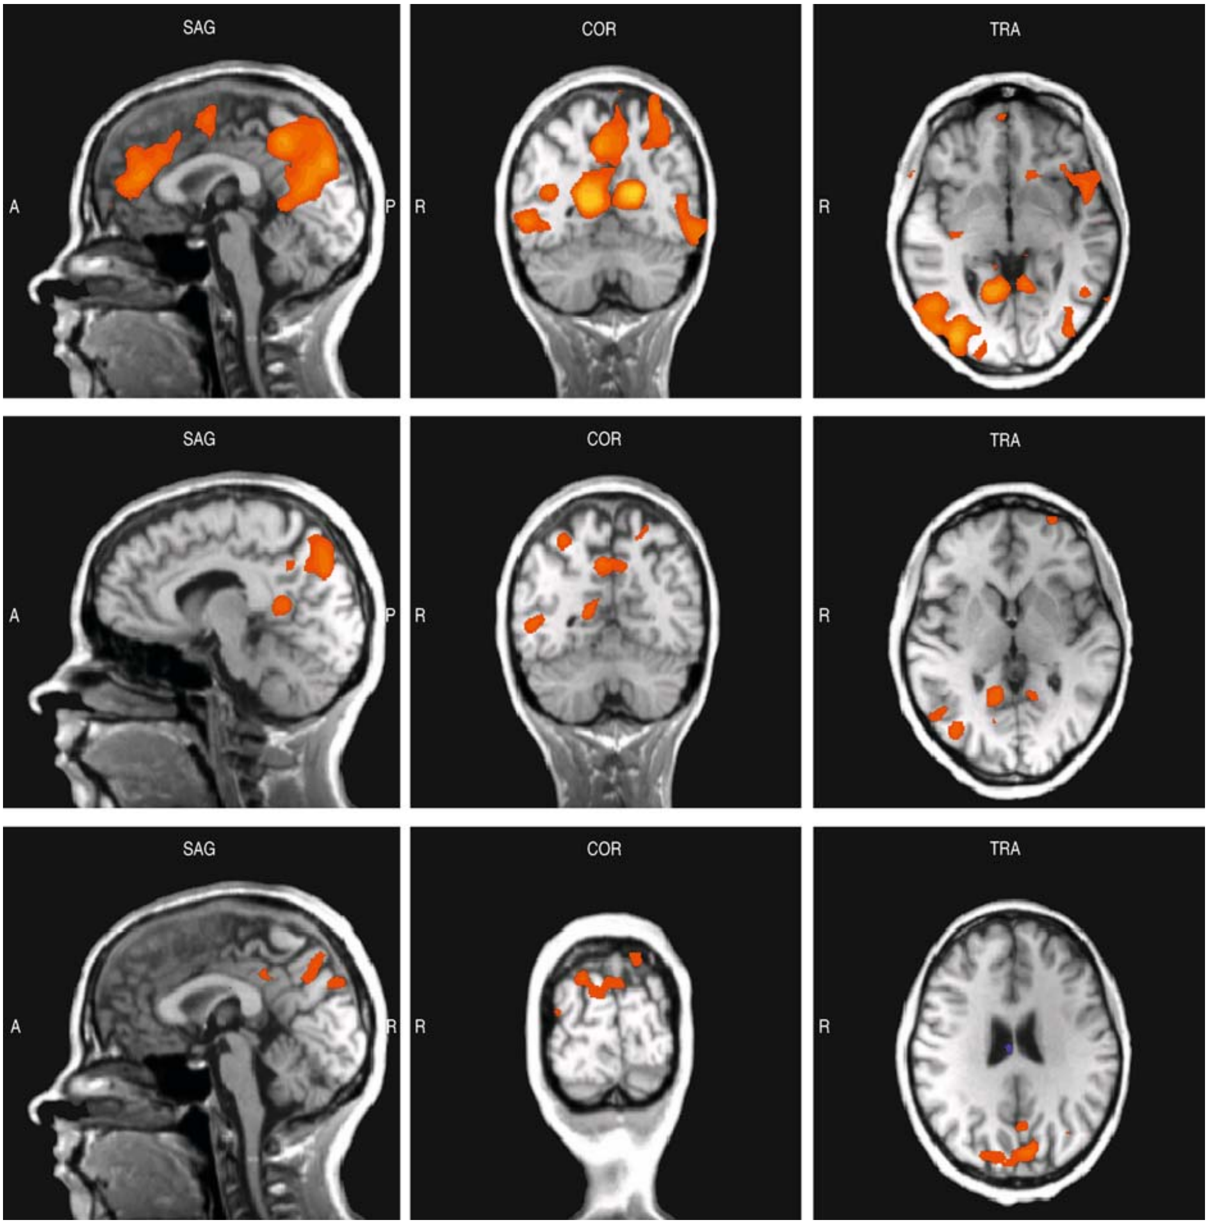
For illustrative purposes we report on the results of a single case. It is a female patient, whose fMRI scans were taken three times during the 59 days of their hospital stay at days 9, 30, and 57. The healthy control was also scanned three times at identical time intervals as the patient. The second acquisition was done after an intensive period of critical instability of the TPQ-based time series, but just before the flooding was started. (Flooding or response prevention is an essential therapy technique in the treatment of OCD, where patients are confronted with symptom provoking stimuli but abstain from performing compulsive rituals.) The instability of the patient's process was the precursor of an important personal decision to divorce from her husband. (It should be noted that the development of her OCD symptoms was in the context of a long-lasting marital conflict.) This decision was the essential phase transition of the therapy.

Indeed, the most pronounced changes in brain activity occurred from the first to the second fMRI scan, whereas BOLD response differences from the second to the third session were only slight. They perhaps represent the neural correlates of an important personal phase transition related to the resolution of a severe personal conflict. Because these changes occurred before the flooding procedure was started, this can be seen as indicator of an early rapid response in the therapy [29]. Additionally, marked alternations in brain activity were to be observed before or during symptom reduction took place (measured by the Y-BOCS), not afterwards.

Alternations in brain activity involved widespread areas, e. g. the medial frontal brain regions including anterior cingulate cortex, superior and middle frontal gyrus, inferior frontal and precentral gyrus, superior temporal gyrus, superior parietal lobe, cuneus, thalamus and caudate nucleus in both hemispheres, as well as the right fusiform gyrus (see Fig. 9 for a OCD to disgust contrast). Thalamic and basal ganglia activation is part of the dorsolateral-caudate-striatum-thalamus circuitry of OCD. Especially the caudate nucleus takes a role within the executive dysfunction model of compulsions, and its activity has been found to be reduced after treatment [40].

The function of the anterior cingulate cortex is interesting with regard to synergetics. The cingulate cortex comprises various functions like somatosensoric integration, mediation of affective and cognitive processes, control of attention, and processing of painful stimuli. Additionally, it plays an important role as conflict monitoring system: It is sensitive to ambiguous or conflicting information [81,82], is involved in decision making [24,54], and its activation is predictive to treatment outcome in depression (e. g. [37]). This is true especially for the dorsal (cognitive) structures of the ACC. It could be an indicator of symmetry states of brain functioning, which is characterized by two or more dynamic patterns or attractors in competition. In the present case, the ACC activation at the beginning of the therapy could be either part of the pathology or could be indicative for the critical instability of the cognitive-affective system of the patient, preparing her important decision. The second fMRI measure was conducted during a local minimum of critical fluctuations. If the impressive change in cingulate activation could be attributed to a changed critical symmetry state of the neural self-organization before vs. after the phase-transition or to changes in symptom severity cannot be decided within a single case study, but seems to be an interesting question to further research. Perhaps the fact that during the second fMRI measure the Y-BOCS score was nearly on the same level as during the first measure – only 14% reduction, compared to 50% reduction in dynamic complexity – could be a first argument in favor of the instability hypothesis.

The paradigm of self-organization is a very promising approach to clinical as well as other fields of psychology. Its interdisciplinary is due to the fact that the laws and principles of self-organization are true for neural, mental, and behavioral processes (and the corresponding data qualities). Interdisciplinary cooperation is underpinned by the unifying terminology as well as by the unifying formalism and modeling tools of synergetics. This opens new perspectives for basic and applied research, but also for the treatment of mental disorders. New developments in the real-time monitoring of human change processes based on synergetics and nonlinear science have been mentioned. Another field of encouraging developments is deep brain stimulation (DBS), which apply to neurological diseases as Parkinsonian or essential tremor, but also to psychiatric disorders as OCD or mayor depression [75]. The difference between new technologies (applying the mathematical instruments and concepts of synergetics as well as methods from stochastic phase resetting) and classical electrical deep brain stimulation is that normal DBS at high frequencies has a blocking effect on the stimulated target and mimics the effect of tissue lesioning. New technologies are demand-controlled, working with low stimulation frequencies, and avoid the suppression of neurons' firing. Its effect is a desynchronization of pathologically synchronized populations of neurons, using multi-site coordinated reset stimulation [74] or nonlinear delayed feedback stimulation [50]. Both methods counteract abnormal interactions and detune the macroscopic frequency of the collective oscillators – that is the abnormally established order parameters of neural synchronization. Thereby they restore the natural frequencies of the individual oscillatory units. Neurons get in the range of physiological functioning and can engage in changing and varying synchronization patterns. If altered synchronization patterns also change the coupling strength connecting synapses, a rewiring of neural nets could be reached. Changed function triggers the emergence of healthy at-



Self-Organization in Clinical Psychology, Figure 9

Brain activation patterns of a patient with OCD during psychotherapy. BOLD signals from a 1.5 Tesla fMRI scanner. *Top*: First scan (9th day of hospital stay; $x = 0$, $y = -55$, $z = -2$; p(uncor) <0.001). *Middle*: Second scan (30th day of hospital stay; $x = 8$, $y = -54$, $z = 5$; p(uncor) $<$ 0.001). *Bottom*: The third scan (57th day of hospital stay; $x = 0$, $y = -85$, $z = 26$; p(uncor) $<$ 0.001). Activations during the presentation of OCD-related pictures compared to activations during the presentation of neutral pictures (OCD > disgust)

tractors and by this changes the structure of neural networks. Perhaps in the future technologies of DBS or even non-invasive brain stimulation could be combined with psychotherapy and psychological navigation instruments developed to optimize self-organizing change processes.

Future Directions

The future developments of self-organization and complexity research in clinical psychology and psychotherapy will be interconnected to its acceptance in practice and training. Perhaps this sounds paradoxically, since in most other scientific fields the future depends on the investigations to basic research and to new technologies. Of course this holds also for synergetics and its applications to clinical psychology. However, it should be noted that complexity research and nonlinear dynamics are done since more than two decades in European academic psychology with poor impact to mainstream science. So, the future will depend on a greater number of new arriving and highly qualified students in this topic who do not avoid the touch with mathematics. Self-organization and complexity research including its mathematical backgrounds should become part of the training curricula in psychology and psychotherapy. Since the Synergetic Navigation System waits for its broad application in clinical and psychotherapeutic practice, a new decade of practice-based research can be started. But these developments depend on its acceptance by practitioners because of the competencies required for the widespread use of sophisticated methods. This integration of science with practice will open huge sources and new dimensions of data gathering on dynamic systems. An important database for outcome and time series data (including biomarkers) of human change processes is actually prepared.

Another stream of development is concerning the integration of psychological and biological/physiological data. Since human self-organization takes place on synchronized mental, social, and biological system levels, all of them should be taken into account in further research. One research paradigm was suggested in this chapter: The investigation of individual and social processes by the Synergetic Navigation System, and in parallel repeated brain scans using fMRI technology or other methods to get insight into brain dynamics (EEG, gene expression markers [25], immune or endocrine markers [61], or others). Two final remarks: First, future developments of synergetic-based minimal invasive DBS could be combined with psychotherapy and psychological interventions – as pharmacological and psychological treatments are combined nowadays. Second, the nonlinear networks underlying psychological as well as neural self-organization will not be understood without applying appropriate mathematical tools, giving raise to a new systemic psychology and neuroscience.

Article Outline

Glossary

Alfvén speed The Alfvén speed c_{A} is the propagation speed of Alfvén waves and is given by $c_{\text{A}} = B_0/(4\pi\rho)^{1/2}$, where $\mathbf{B}_0$ is mean magnetic field and ρ the plasma mass density. Alfvèn waves are transverse, incompressible magnetohydrodynamic waves that propagate along $\mathbf{B}_0$ and originate from the tension of magnetic field lines.

Elsässer variables Elsässer variables $\mathbf{z}^{\sigma}$ are defined by $\mathbf{z}^{\sigma} = \mathbf{v} + \sigma\mathbf{B}/(4\pi\rho)^{1/2}$, with $\sigma = \pm 1$, $\mathbf{v}$ the velocity field, $\mathbf{B}$ the magnetic field and ρ the plasma mass density. The equations of incompressible MHD are often written in terms of these variables in order to describe the propagation of Alfvén waves and the non-linear couplings occurring in MHD turbulence.

Magnetohydrodynamics Magnetohydrodynamics (abbreviated, MHD) represents a one-fluid mathematical model which describes plasma dynamics at low frequencies: The main dynamical variables are the velocity of the fluid and the magnetic field. The vector equations for these variables are the fluid momentum conservation and the induction Maxwell equation.

MHD turbulence MHD turbulence is that turbulence which develops inside plasmas at macroscopic level, when viscosity and resistivity are low. Apart from velocity fluctuations which are also present in ordinary fluids, it is characterized also by the presence of magnetic field fluctuations.

Reverse field pinch Reverse field pinch (abbreviated, RFP) are plasma fusion toroidal devices whose conception is based on the idea that non-linear interactions in plasmas spontaneously give rise to magnetic structures where the Laplace force is zero (force free structures).

Shell models Shell models of turbulence are dynamical systems consisting of a set of ordinary differential equations representing a simplified version of the Navier–Stokes or MHD equations in the wavevector space. These models provide the possibility to investigate turbulence at very high Reynolds number regimes at the cost of neglecting information about spatial structures.

Solar corona The solar corona is the region extending from the solar surface up to one million of kilometers in the space, which can be visible to the naked eye during the eclipses. It is constituted mainly by a hydrogen plasma (proton and electrons) at a temperature of about two million degrees. The corona is highly structured by the magnetic field generated at the sun surface.

Solar wind The solar wind is a stream of plasma mainly composed of protons and electrons (hydrogen plasma), which flows out of the sun, due to the fact that plasma pressure associated to the very high coronal temperature overcomes the sun gravity. The flow velocity ranges from 250 km/s in the equatorial plane to about 900 km/s in the polar regions. Solar wind represents an extremely efficient plasma laboratory where the turbulence associated with the supersonic flow can be studied using space experiment data.

Definition of the Subject

Plasma dynamics at low frequency, i. e. at frequencies lower then the ion cyclotron frequency, can be described using a one-fluid model usually called magnetohydrodynamics (MHD), where the main dynamical variables are represented by fluid velocity and magnetic field, which evolve non-linearly being coupled to each other. This description applies both to laboratory plasma devices (tokamaks, reverse field pinch etc.), devoted to realize controlled nuclear fusion, and to space and astrophysical plasmas (Solar corona, Solar wind). Very often, when viscosity and resistivity are sufficiently small, the plasma behavior is characterized by the presence of a developed turbulence. In the last 20 years huge progress in understanding the properties of such turbulence has been realized, both by the use of high resolution computer simulations and by analysis of space and laboratory data. One of the most fascinating results of these studies concerns the evidence of self organization processes which have been shown to be very effective inside this kind of turbulence. Other aspects of turbulence and dynamical complexity in space plasmas are considered in the review by Chang ► Space Plasmas, Dynamical Complexity in in this Encyclopedia.

Introduction

Dynamical systems, whose time evolution is described by non-linear equations, can often give rise to chaotic behavior, i. e. to a behavior characterized by a strong dependence on initial conditions, which, in all practical cases, does not allow to predict the final fate of such systems, or at least limits considerably the possibility to make predictions. Nevertheless, inside these systems, sometimes new complex, coherent structures, without any need of external intervention, can develop. This phenomenon is called self-organization.

Self-organization requires decreasing the entropy inside the coherent organized structures and exporting such entropy to the surroundings. For this reason the coherent structures can be called, following Prigogine, *dissipative structures*, in that their organization is always associated with an increased efficiency of dissipative processes around them.

MHD turbulence, as well as ordinary fluid turbulence, is characterized by a phenomenology, first described some centuries ago around the year 1500 by Leonardo da Vinci (Piumati 1894, fo. 74,v), where energy injected at large scales (injection range) is transferred by non-linear interactions (inertial range) towards smaller and smaller scales where it is finally dissipated (dissipative range). The physical phenomenon by which coherent organized structures are produced through an increased dissipation inside MHD turbulence has been evidenced both at large scale and at small scales. In the latter case it is usually called *intermittency*. We will discuss separately the two cases.

The occurrence of self organization at large scale seems to be directly related to the existence in MHD equations of some quadratic invariants (energy, magnetic helicity, cross helicity), which are conserved inside inviscid flows and are dissipated at very different rates in dissipative flows. Actually the existence of some long-living non-trivial states, towards which dissipative flows are attracted, has been evidenced for a long time. Moreover it has been suggested that these states could be derived from a variational principle, i. e. by minimizing an energy integral subject to some constraints on the other quadratic invariants. Woltjer [58] first explored the astrophysical implications of this possibility. The conjecture by Taylor [51] that an MHD system relaxes towards a state where the energy is minimum, subject to the constraint that magnetic helicity is conserved, allowed one to obtain a quite particular solution, usually called *Taylor's vortex*. This solution was extremely useful to explain the large scale behavior of reverse field pinch (RFP) devices [51]. The same conjecture has also been used to estimate the energy release in coronal structures [25,42] in connection to the problem of coronal heating.

The discovery in the solar wind of quite peculiar *Alfvénic fluctuations*, characterized by a high degree of correlation between velocity and magnetic field [3], which was interpreted by Dobrowolny et al. [20] as the result of a self organization of MHD turbulence, has suggested the formulation [10,38,53] of a different minimum principle: Alfvénic solutions can be obtained by minimizing the energy subject to the condition that cross-helicity is conserved.

In any case the energy minimization is dynamically realized through a *selective decay process*, i. e. a process during which some energy is dissipated into heat and the appearance of the coherent large scale structures is associated with redistribution of entropy to the surroundings.

The self organization processes discussed above, and related to the spontaneous creation of large scale coherent structures during the MHD turbulence dynamics, have their counterpart also at small scales. Actually, the nonlinear energy cascade process in fully developed MHD turbulence is characterized by the formation at the smallest dissipative scale of coherent structures. These structures are strictly related to the intermittency phenomenon; that is, to the breakdown of global self-similarity in the turbulent cascade, which represents a typical signature of nonlinear interactions.

In the following sections we first present the MHD equations (Sect. "MHD Equations and Quadratic Invariants") properties and discuss the characteristics of the self organized structures at large scales (Sect. "Self-Organization at Large Scales"). Then in Sect. "Self-Organization at Small Scales and Intermittent Structures in MHD Turbulence" we show that at small scales coherent dissipative structures are spontaneously formed in a physical process usually called *intermittency*. Finally in Sect. "Future Directions" we discuss the possible future developments and perspectives of such kind of studies.

MHD Equations and Quadratic Invariants

The equations describing the time evolution of an incompressible magnetofluid can be written

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v}\cdot\nabla)\mathbf{v} = -\frac{1}{\rho}\nabla p + (\nabla\times\mathbf{b})\times\mathbf{b} + \nu\nabla^2\mathbf{v}\,, \quad (1)$$

$$\frac{\partial \mathbf{b}}{\partial t} = \nabla\times(\mathbf{v}\times\mathbf{b}) + \mu\nabla^2\mathbf{b} \quad (2)$$

where $\mathbf{v}$ represents the fluid velocity and p the fluid pressure, $\mathbf{b} = \mathbf{B}/\sqrt{4\pi\rho}$ ($\mathbf{B}$ being the magnetic field and ρ the mass density), ν is the kinematic viscosity and $\mu = (c^2\eta)/(4\pi)$ the magnetic diffusivity (η being the fluid resistivity). The velocity and magnetic field must also satisfy the incompressibility conditions

$$\nabla\cdot\mathbf{v} = 0 \qquad \nabla\cdot\mathbf{b} = 0\,. \quad (3)$$

Quadratic Invariants

It can be easily shown that during their ideal time evolution, i. e. in absence of viscosity and resistivity, these equations conserve the following quadratic invariants: Total energy (kinetic + magnetic) per mass unit

$$E = \frac{1}{2}\int(\mathbf{v}^2 + \mathbf{b}^2)\mathrm{d}V \tag{4}$$

and cross helicity

$$H_\mathrm{c} = \int \mathbf{v}\cdot\mathbf{b}\mathrm{d}V\,. \tag{5}$$

Moreover Woltjer [58] showed that in the ideal 3D MHD, also magnetic helicity

$$H_\mathrm{m} = \int \mathbf{a}\cdot\mathbf{b}\mathrm{d}V \tag{6}$$

($\mathbf{a}$ being the magnetic vector potential defined through $\mathbf{b} = \nabla\times\mathbf{a}$) remains invariant during the evolution of any closed magnetic flux system. In 2D MHD on the contrary, the third conserved quantity is the square of the magnetic field vector potential [24]

$$A = \int \mathbf{a}^2\mathrm{d}V \tag{7}$$

In Eqs. (4), (5), (6) and (7) the integrals are extended to the whole volume of the magnetofluid.

Elsässer's Variables

In the following we will find it useful to rewrite these equations in terms of the Elsässer [21] variables $\mathbf{z}^\sigma$ defined by $\mathbf{z}^\sigma = \mathbf{v} + \sigma\mathbf{b}$ with $\sigma = \pm 1$. Using such variables the equations governing incompressible MHD are recast to the more compact form

$$\frac{\partial\mathbf{z}^\sigma}{\partial t} + (\mathbf{z}^{-\sigma}\cdot\nabla)\mathbf{z}^\sigma = -\frac{1}{\rho}\nabla\left(p + \frac{B^2}{8\pi}\right) + \nu^+\nabla^2\mathbf{z}^\sigma + \nu^-\nabla^2\mathbf{z}^{-\sigma} \tag{8}$$

with $\nu^\sigma = \nu + \sigma\mu$. Obviously also the fields $\mathbf{z}^\sigma$ must satisfy the incompressibility conditions

$$\nabla\cdot\mathbf{z}^\sigma = 0\,. \tag{9}$$

In terms of these variables, the conservation of total energy per mass unit and cross helicity can be written as the conservation of the two pseudo-energies

$$E^\sigma = \frac{1}{2}\int \mathbf{z}^{\sigma^2}\mathrm{d}V\,. \tag{10}$$

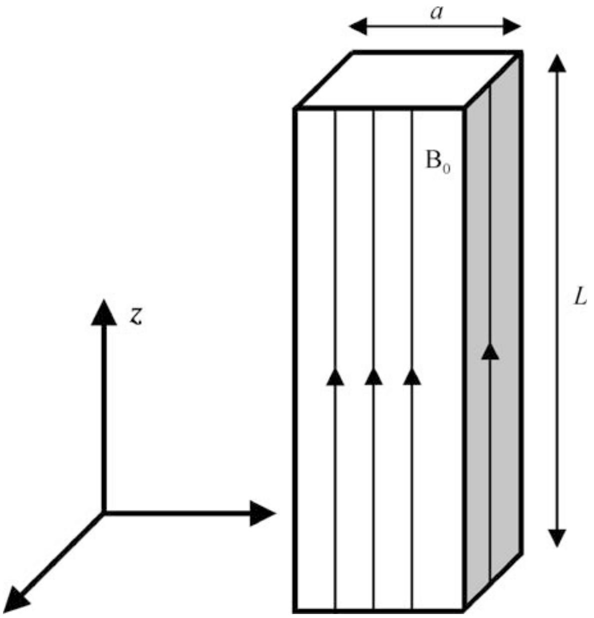
MHD equations display and infinite number of ideal non-quadratic invariants, but quadratic invariants (4), (5) and (6) (or in 2D (7)) play a key role. Actually, let us introduce the Fourier transform of the field $\mathbf{z}^\sigma$ in a cubic periodic box of size a

$$\mathbf{z}^\sigma(\mathbf{r}, t) = \sum_{\mathbf{k}} \mathbf{z}^\sigma(\mathbf{k}, t)\exp(i\mathbf{k}\cdot\mathbf{r})$$

where $\mathbf{k} = 2\pi\mathbf{m}/a$, and $\mathbf{m}$ is vector of integer numbers. In terms of these Fourier transforms (taking into account the incompressibility condition (9) and neglecting dissipative terms), MHD Equations (8) can be written

$$\frac{\partial z_i^\sigma(\mathbf{k}, t)}{\partial t} = \sum_{l,s=1}^{3}\sum_{\mathbf{p},\mathbf{q}} M_{i,l,s}(\mathbf{k}, \mathbf{p}, \mathbf{q}) z_l^\sigma(\mathbf{p}, t) z_s^{-\sigma}(\mathbf{q}, t)\delta_{\mathbf{k},\mathbf{p}+\mathbf{q}} \tag{11}$$

with $M_{i,l,s}(\mathbf{k}, \mathbf{p}, \mathbf{q}) = -i\left(\delta_{il} - \frac{k_i k_l}{k^2}\right)k_s$ and where $\delta_{\mathbf{k},\mathbf{p}+\mathbf{q}}$ is the usual Kronecker symbol. The peculiar form of these equations shows that non-linear terms are characterized by triad interactions among wave vectors $\mathbf{k}$, $\mathbf{p}$ and $\mathbf{q}$ such that $\mathbf{k} = \mathbf{p} + \mathbf{q}$. Quadratic invariants are also called *rugged* invariants, because they are conserved in any single interaction among a triad of wave vector and for this reason



Self-Organization in Magnetohydrodynamic Turbulence, Figure 1
Sketch of the reduced MHD configuration

they survive also when a Galerkin approximation is performed on MHD equations. In other words, even if the r. h. s. of (11) contains an infinite number of non-linear interactions, $E(t)$, $H_c(t)$ and $H_m(t)$ remain invariant also by retaining any finite number of interacting triads in Equation (11).

Reduced Magnetohydrodynamics

In some fusion plasma devices, or in the solar corona, the plasma β parameter (that is the ratio between the kinetic and magnetic pressure) is low $\beta \simeq 10^{-2}$, and MHD equations can be simplified into the so-called Reduced MHD [47,61]. This approximation is valid, for example, for a plasma column with a low aspect ratio $a/L \ll 1$ (a and L being respectively the width and the height of the plasma column), with a strong magnetic field $\mathbf{B}_0$ along the z-direction (Fig. 1).

In this case the plasma dynamical variables reduce to the velocity field $\mathbf{v}_\perp$ and the magnetic field $\mathbf{b}_\perp$ perpendicular to $\mathbf{B}_0$, so that starting from MHD Equs. (8), the following set of RMHD equations [61] is obtained:

$$\frac{\partial \mathbf{z}^\sigma}{\partial t} - \sigma c_A \frac{\partial \mathbf{z}^\sigma}{\partial z} + (\mathbf{z}^{-\sigma} \cdot \nabla_\perp)\mathbf{z}^\sigma = -\frac{1}{\rho}\nabla(p + \frac{B^2}{8\pi}) + \nu^+ \nabla_\perp^2 \mathbf{z}^\sigma + \nu^- \nabla_\perp^2 \mathbf{z}^{-\sigma} \quad (12)$$

$$\nabla_\perp \cdot \mathbf{z}^\sigma = 0 \quad (13)$$

where $\mathbf{z}^\sigma = \mathbf{v}_\perp + \sigma \mathbf{b}_\perp$ (with $\sigma = \pm 1$), $\nabla_\perp$ is the spatial gradient perpendicular to $\mathbf{B}_0$, $c_A = B_0/(4\pi\rho)^{1/2}$ is the Alfvén velocity associated with B_0.

Equation (12) shows that, in this approximation, non-linear interactions are retained only in the directions perpendicular to $\mathbf{B}_0$, while only propagation at the Alfvén speed takes place parallel to $\mathbf{B}_0$.

Let us now Fourier transform the fields with respect to the perpendicular variable $\mathbf{r}_\perp = (x, y)$, in a 2D periodic box of size a

$$\mathbf{v}_\perp(\mathbf{r}, z, t) = \sum_{\mathbf{k}} v(\mathbf{k}, z, t)\mathbf{e}(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{r}) \,, \quad (14)$$

$$\mathbf{b}_\perp(\mathbf{r}, z, t) = \sum_{\mathbf{k}} b(\mathbf{k}, z, t)\mathbf{e}(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{r}) \,, \quad (15)$$

where $\mathbf{k} = 2\pi\mathbf{m}/a$, ($\mathbf{m}$ is a couple of integers) and $\mathbf{e}(\mathbf{k})$ is a unit vector perpendicular to $\mathbf{k}$. After some algebra, it can be shown that in this approximation, for each value of z, the MHD equations reduce to [49]

$$\begin{aligned} \frac{\partial v(\mathbf{k})}{\partial t} &= c_A \frac{\partial b(\mathbf{k})}{\partial z} + \sum_{\mathbf{pq}} c(k, p, q)(p^2 - q^2) \\ &\quad \times \left[v(\mathbf{p})v(\mathbf{q}) - b(\mathbf{p})b(\mathbf{q})\right] \delta_{\mathbf{k},\mathbf{p}+\mathbf{q}} \\ \frac{\partial b(\mathbf{k})}{\partial t} &= c_A \frac{\partial v(\mathbf{k})}{\partial z} + \sum_{\mathbf{pq}} c(k, p, q)k^2 \\ &\quad \times \left[b(\mathbf{p})v(\mathbf{q}) - v(\mathbf{p})b(\mathbf{q})\right] \delta_{\mathbf{k},\mathbf{p}+\mathbf{q}} \end{aligned} \quad (16)$$

(for simplicity we omit the time and z dependence of the Fourier amplitudes) where

$$c(k, p, q) = \frac{p_x q_y - p_y q_x}{2kpq}$$

means that the sum is extended over all wave vectors $\mathbf{p}$ and $\mathbf{q}$ which satisfy the triad-interaction relation $\mathbf{k} = \mathbf{p} + \mathbf{q}$. Let us note that, if we chose a box of size $a = 2\pi$, each wave vector $\mathbf{k}$ turns out to be represented by a couple of integers.

Equations (16) have quadratic invariants namely the total energy

$$E(t) = \sum_{\mathbf{k}} [|v(\mathbf{k}, t)|^2 + |b(\mathbf{k}, t)|^2]$$

and the cross-helicity

$$H_c(t) = \sum_{\mathbf{k}} \mathrm{Re}[v(\mathbf{k}, t)b^*(\mathbf{k}, t)] \,.$$

When the background magnetic field is set to zero $B_0 = 0$, also the mean-square of the vector potential

$$A(t) = \sum_{\mathbf{k}} |b(\mathbf{k}, t)|^2/k^2$$

is conserved. On the contrary, when $B_0 \neq 0$, the last quantity is almost constant, with relative fluctuations of about $\Delta A/A \simeq 10^{-2}$ [49].

This means that 2D MHD has a much wider field of physical applications then those situations where no explicit dependence on the z components exists. Actually 2D MHD represents a good approximation for the low-beta and low aspect ratio plasmas as for example some laboratory devices (tokamaks, RFP, etc.) or some magnetic structures (loops) in the solar corona. In the next section we will take advantage of this result.

Self-Organization at Large Scales

Relaxation Processes in MHD

In MHD, the quadratic invariants (4, 5, 6) play a crucial role in the problem of predicting the final fate of solutions starting from quite general initial conditions. When studying the ideal relaxation, the quadratic invariants remain constant during time evolution, and the problem of predicting the final state reduces to calculating the ensemble–averaged equilibrium spectra of these invariants. Using a standard statistical approach it has been shown by Frisch et al. [23] that these spectra are determined by the ensemble-averaged initial values of invariants. Dissipative relaxation processes in MHD are much more complicated, since the values of the ideal invariants change during the evolution. It seems however that some long-living non-trivial states toward which dissipative flows are attracted exist, and that these states could be derived by minimizing an energy integral subject to some constraints.

Dissipative relaxations have been investigated in connection with measurements in laboratory plasmas, and observations in the solar wind turbulence. Taylor [51], inspired by laboratory plasma experiments, conjectured that an MHD system relaxes towards a state where the energy tends to a minimum, subject to the constraint that magnetic helicity is conserved. The relaxation can then be seen as a *selective decay* between the two invariants. From a mathematical point of view, the solution of the problem can be obtained through a variational principle

$$\delta\left\{\int(\mathbf{v}^2+\mathbf{b}^2)\mathrm{d}V-\lambda\int\mathbf{a}\cdot\mathbf{b}\mathrm{d}V\right\}=0\,,$$

where λ is a Lagrange multiplier. By imposing the conservation of magnetic helicity, we get the so-called force-free solution, characterized by $\mathbf{v}=0$ and

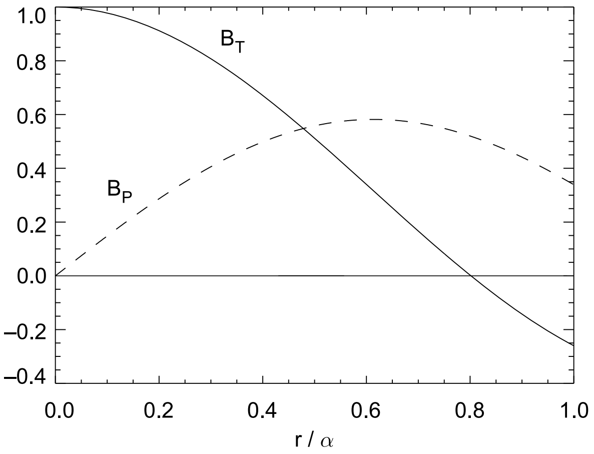
$$\nabla\times\mathbf{b}=\alpha\mathbf{b} \tag{17}$$

(α being a constant), i. e. a solution where the velocity field and the Laplace force are both null. This means that the kinetic energy decays to zero and the magnetic energy occupies the largest scale. Taylor's hypothesis allows one to circumvent in an elegant way the complex plasma relaxation dynamics (involving turbulence and reconnection).

When looking at (17) in cylindrical coordinates, the following solution can be obtained

$$B_T=B_0J_0(\alpha r)\quad B_P=B_0J_1(\alpha r) \tag{18}$$

where B_T and B_P are respectively the axial and poloidal components of the magnetic field (B_0 is a constant and J_0 and J_1 are Bessel functions). This solution, which can display a change in the sign of the magnetic field axial component (Fig. 2), was able to explain the puzzling phenomenon of field reversal spontaneously observed in some laboratory experiments, where no current necessary to produce such reversal was present in the initial state. This theory has also been the basis for the development of RFP devices (Fig. 3), toroidal devices which at a first order approximation can be considered periodic cylinders (Fig. 4). Applications to spheromak and other plasma fusion devices [4,52,59] have been considered more recently.



Self-Organization in Magnetohydrodynamic Turbulence, Figure 2
Axial (*solid line*) and poloidal (*dashed line*) components of magnetic field in a force free cylindrical plasma column as function of the radial coordinate normalized to α^{-1} ($B_0 = 1$)

Belcher and Davis [3] analyzing solar wind data discovered velocity and magnetic field fluctuations were extremely well-correlated (Fig. 5). Dobrowolny et al. [20] suggested that this correlation could be the result of a self organization of MHD turbulence and set up a phenomenological explanation for this self organization, based on the idea that between the two modes of propagation of *Alfvénic* fluctuations in solar wind only that initially dominating survives to the non-linear cascade process towards dissipative scales.

This kind of self organization can also be obtained through a variational principle. Let us impose that energy assumes a minimum value, constrained to the conservation of cross-helicity, we have then to write

$$\delta\left\{\int(\mathbf{v}^2+\mathbf{b}^2)\mathrm{d}V-\lambda\int\mathbf{v}\cdot\mathbf{b}\mathrm{d}V\right\}=0\,,$$

once again λ is a Lagrange multiplier. By imposing the conservation of cross helicity, we finally get the two solutions

$$\mathbf{v}=\sigma\mathbf{b} \tag{19}$$

with $\sigma=\pm1$. These solutions, which can also be written $\mathbf{z}^\sigma=0$ for either $\sigma=1$ or $\sigma=-1$ in terms of the Elsässer [21] variables, correspond to annihilating non-linear interactions in (1, 8). This phenomenon has been

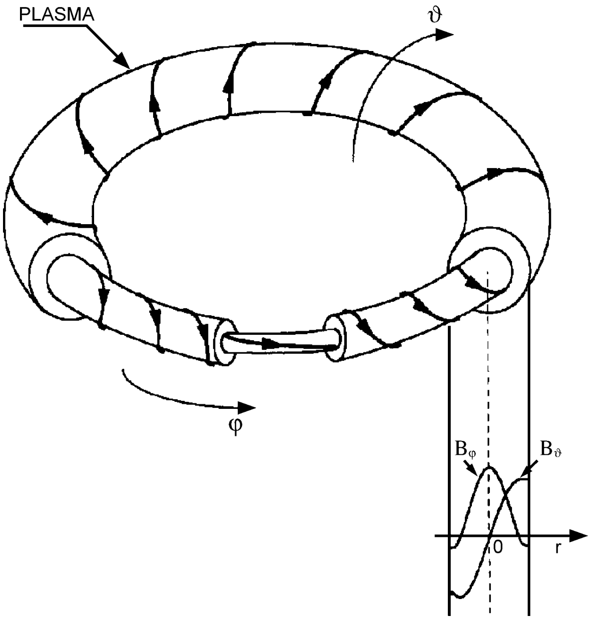
The RFX: A reverse field pinch plasma device in Padua (Italy) (Consorzio RFX is a research organization promoted by CNR, ENEA, Università di Padova, Acciaierie Venete S.p.A. and INFN, within the framework of the Euratom – ENEA Association)



Self-Organization in Magnetohydrodynamic Turbulence, Figure 4

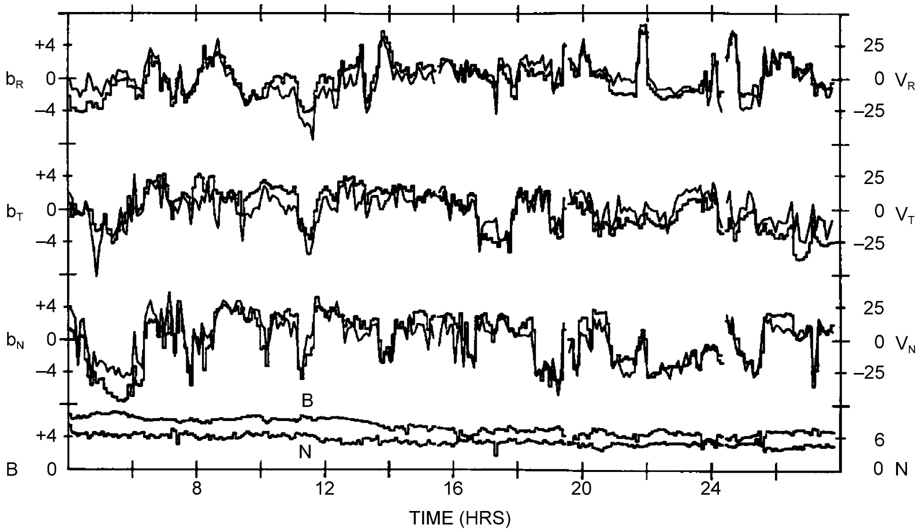
Typical profile of the magnetic field in an RFP device (reprinted from [48])

called *dynamical alignment* in that velocity and magnetic field tend to become aligned to each other.

It has been shown that also in numerical simulations of 2D and 3D MHD equations [17,38,39,46,53] there exists systematic behavior of turbulent flows. In particular, relaxation processes which bring the fluid toward those particular states like *Taylor solutions* or *Alfvénic solutions* have been found to emerge systematically from numerical simulations. In terms of ideal invariants, it has been shown that the Taylor's solution is obtained, when starting with almost zero cross helicity, while the *dynamical alignment* is found when the initial value of the cross helicity is substantially different from zero. In general when both effects are in competition, the situation is much more complicated. A systematic analysis of a wide number of 2D MHD simulations at different resolutions have been performed by Ting et al. [53]. Their results can be summarized by referring to the time behavior of the system projected on the plane (a, h), where $a = A/E$ and $h = 2H_c/E$. In fact, starting from whatever initial conditions, in that plane the system tends to approach the ellipse

$$\frac{1}{a} = 2\left(\frac{k_{\min}}{h}\right)^2 \left[1 \pm \sqrt{1-h^2}\right] , \qquad (20)$$

where $k_{\min}$ represents the minimum wave vector allowed in the simulations. Of course the points $(a, h) = (1/2, \pm 1)$ represents the *attractors* of dynamical alignment solutions, the point $(a, h) = (1, 0)$ represents the attractor of selective decay, and the point $(a, h) = (0, 0)$ represents the attractor when the system behaves like a fluid, with zero magnetic field. These extreme points can be recovered through the minimization of energy subject to the



Self-Organization in Magnetohydrodynamic Turbulence, Figure 5

Velocity (v_R, v_T, and v_N) and magnetic field (b_R, b_T, and b_N) fluctuations measured in solar wind in the RTN reference system (reprinted from [3]). The RTN system has the R unity vector along the radial direction, positive from the sun to the spacecraft, the T unity vector perpendicular to the plane formed by the rotation axis Ω of the sun and the radial direction, i. e., T = Ω × R, and the N component resulting from the vector product N = R × T. Particle density N and magnetic field intensity B are also shown in the lowest part of the plot. Units are 10^{-5} gauss for magnetic fields, km/s for velocities, and cm^{-3} for particle density

conservation of the other invariants. When the magnetic field is zero, the kinetic helicity is invariant and the point $(a, h) = (0, 0)$ can be recovered by allowing that the kinetic energy decays, subject to the constraint that the kinetic helicity remains constant. The entire curve, however, does not represent the locus of the extreme of anything over its entire range of definition.

A Minimal Triad-Interaction Model of Relaxation Processes in 2D MHD

As we have seen, 2D MHD plays a privileged role, in that it describes low-beta and low aspect ratio 3D plasmas. Here we briefly present how the basic non-chaotic triad-interaction works in 2D MHD, and how this represents a minimal basic model for relaxation processes. Choosing only three wave vectors, namely $\mathbf{k}_1 = (1, 1)$, $\mathbf{k}_2 = (2, -1)$, $\mathbf{k}_3 = (3, 0)$, we obtain a set of 12 ordinary differential equations [18] for the complex Fourier modes of both velocity $u_i(t) = u(\mathbf{k}_i, t)/2\sqrt{5}$ and magnetic field $b_i(t) = b(\mathbf{k}_i, t)/2\sqrt{5}$. The system can be further reduced through a projection of equations on a subset of the phase space, that is by considering only real fields. This can be seen by writing the fields in the form $u_j = |u_j| e^{i\alpha_j}$ and $b_j = |b_j| e^{i\beta_j}$, and by defining real fields through $V_j(t) = |u_j| \cos\alpha_j$ and $B_j(t) = |b_j| \cos\beta_j$ (subject to the conditions $\sin\alpha_j = 0$ and $\sin\beta_j = 0$). In this case we found a set of 6 ordinary differential equations for V_j and B_j, namely

$$\begin{aligned}
(\mathrm{d}/\mathrm{d}t + 2\nu)V_1 &= 4(V_3 V_2 - B_3 B_2)\\
(\mathrm{d}/\mathrm{d}t + 5\nu)V_2 &= -7(V_3 V_1 - B_3 B_1)\\
(\mathrm{d}/\mathrm{d}t + 9\nu)V_3 &= 3(V_1 V_2 - B_1 B_2)\\
(\mathrm{d}/\mathrm{d}t + 2\mu)B_1 &= 2(B_3 V_2 - V_3 B_2)\\
(\mathrm{d}/\mathrm{d}t + 5\mu)B_2 &= 5(V_3 B_1 - B_3 V_1)\\
(\mathrm{d}/\mathrm{d}t + 9\mu)B_3 &= 9(V_1 B_2 - B_1 V_2)\,.
\end{aligned}$$

For its simplicity the model represents the basic system to investigate the structure of nonlinear interactions in 2D MHD, and to study the role played by the rugged invariants during the dynamical evolution.

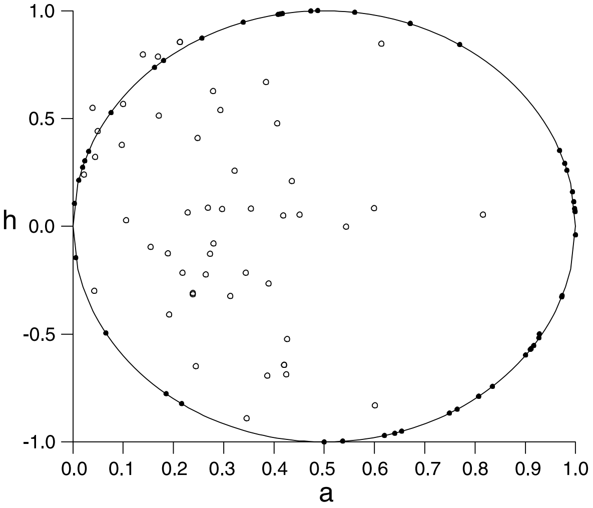
Let us introduce the phase space Ω, of dimension $\mathrm{Dim}[\Omega] = 6$, which can be built up by using as coordinates the Fourier amplitudes. A point $\Psi_i(t) \in \Omega$, defined as $\Psi_i(t) := \{[u_i(t), b_i(t)] \in \Omega\}$ represents the system at a certain time, and this point moves in Ω according to the flow $T_\tau[\Psi_i(t)] = \Psi_i(t + \tau)$ which represents the result of the equation of motion for the system. In absence of dissipative terms the phase space volume is conserved

$$H = \sum_i \frac{\partial}{\partial \Psi_i}\left(\frac{\mathrm{d}\Psi_i}{\mathrm{d}t}\right) = 0\,, \qquad (21)$$

where H represents the rate of change of volumes in phase space.

If we define the ideal flow T_τ^{id} as the flow T_τ obtained when $\nu = \mu = 0$, the phase space volume conservation can be expressed as $T_{\tau\to\infty}^{id}[\Psi_i(t)] = \Psi_i(t+\tau)$. In this case, for a given set of initial values $\Psi_i(0)$, the point moves on a hyper-surface $S \subset \Omega$ defined by the initial value of the invariants. In presence of dissipative terms the quadratic invariants decay, and the rate of change of the volume in the phase space is $H = -16(\nu + \mu) \leq 0$. The condition $H \leq 0$ implies that the dissipative flow pushes the system toward the trivial asymptotic state where all the amplitudes of the fields are zero $T_{\tau\to\infty}^{\text{diss}}[\phi(t)] = 0$.

The triad-interaction model is able to capture the dynamics of the quiescent states observed in MHD. We solved our system by starting from random initial conditions uniformly distributed $\Psi_i(0) \in [-1, 1]$. We used a fourth-order Runge–Kutta scheme, with a time step $\Delta t = 10^{-3}$ and $\nu = \mu = 0.01$. This value for the dissipative coefficients allows the nonlinear interactions to have sufficient time to set up the dynamical behavior. In Fig. 6 we report the curve ε along with two ensembles of points. The first ensemble (white circles) represents the set of points (a, h) obtained with some different initial conditions $\Psi_i(0)$ randomly chosen in the interval $[-1; 1]$. The second ensemble (black circles) represents the set of points (a, h) at time $t = 80$ (in unit of time steps), calculated from the set of fields $\Psi_i(t)$ which are obtained through the time evolution of the set $\Psi_i(0)$, that is $\Psi_i(t) = T_t^{\text{diss}}[\Psi_i(0)]$. As it can be seen that all the initial conditions lead to the final state which belongs to the ellipse ε.



Self-Organization in Magnetohydrodynamic Turbulence, Figure 6

Numerical simulations of the triad-interaction model reported in the plane (a, h). We show two sets of different solutions at two different times. *White circles* refer to a set of 45 initial values $\Psi_i(0)$, *black circles* represent the set of point at a given time $t = 80$ (in unit of time steps) obtained from the time evolution of the above initial values $\Psi_i(t = 80) = T_{t=80}^{\text{diss}}[\Psi_i(0)]$. The solutions represented on that plane are such that, after an initial transient, they fall on the ellipse represented as a *full line*

Since nonlinear interactions in the simple triad-interaction model have the same structure as in the 2D MHD equations, the model is able to capture relaxation properties. These properties are the fixed points and some invariant subspaces. The fixed points of the system can be classified as follows:

a) Two Alfvénic fixed points (say $A^\pm$) characterized by $u_i = \pm b_i$;
b) Three fluid fixed points $F(i)$ $(i = 1, 2, 3)$ where all variables but the velocity V_i are zero;
c) Three magnetic fixed points $M(i)$ $(i = 1, 2, 3)$ where all variables but the magnetic field B_i are zero.

A standard analysis of stability can be performed by linearizing the system around each fixed point. We find that $A^\pm$ are always stable, $M(1)$ is the only stable magnetic fixed point, while $F(1)$ and $F(3)$ are stable. The only stable magnetic fixed point $M(1)$ is such that the energy is localized on the minimum wave vector.

Apart from fixed points the system displays some other interesting properties. Looking at the equations, it can be easily shown that there exists some 3D subspaces of the 6D phase space which remain invariant under the ideal flow operator. Let us denote by I^α the αth invariant subspace, which is then characterized by the fact that if $\Psi_i(0) \in I^\alpha$ then $\Psi_i(t) = T_t^{id}[\Psi_i(0)] \in I^\alpha$ for each $t > 0$. In other words an ideal invariant subspace is a portion of the phase space where the system lies for all times. The most useful way to classify these structures is through the initial values the rugged invariants assume on them, since under the ideal flow they remain constant:

a) A fluid subspace F, characterized by $a = A/E = 0$ and $h = 2H_c/E = 0$. This can be recovered by imposing that the magnetic field is always zero, namely

$$\Psi_i[F] = (V_1, V_2, V_3, 0, 0, 0)$$

is the vector which describes this subspace.

b) Two Alfvénic subspaces $A^\pm$, characterized by $a = A/E = 0$ and $h = 2H_c/E = 1$, which can be recovered by imposing that $V_i = \pm B_i$ for each $i = 1, 2, 3$. These subspaces are also fixed points of the system.

c) Three magnetic subspaces H^A, H^B and H^C characterized by $a \neq 0$ and $h = 0$, i. e. a minimal value for the cross-helicity. These subspaces can be recovered by imposing that the cross-helicity is initially zero over all wave vectors, namely either $V_i = 0$ and $B_i \neq 0$ or vice versa; specifically,

$$\begin{aligned}\Psi_i[H^A] &= (0, 0, V_3, B_1, B_2, 0)\\ \Psi_i[H^B] &= (V_1, 0, 0, 0, B_2, B_3)\\ \Psi_i[H^C] &= (0, V_2, 0, B_1, 0, B_3)\,.\end{aligned}$$

The stability properties of each subspace can be investigated numerically [11]. Simulations start by putting the system on a given subspace, and by adding a small perturbation on the complementary manifold. The motion is not limited to the 3D subspace, and the problem of the stability of a particular I^α consists of determining if the perturbed solution remains close to I^α or goes away from it covering all the allowed 6D phase space. For each subspace we can define two pseudo-energies $E^{(\alpha)}_{\text{int}}(t)$ (built up with the fields which belong to the αth subspace) and $E^{(\alpha)}_{\text{ext}}(t)$ (built up with the fields which do not belong to the αth subspace). The external energy represents the distance $\|\Delta^{(\alpha)}[\Psi_i(t)]\|$ between the point $\Psi_i(t)$ and the αth invariant subspace. Since the total energy $E(t) = E^{(\alpha)}_{\text{ext}}(t) + E^{(\alpha)}_{\text{int}}(t)$ must remain constant under the ideal flow, two situations can arise, namely

1) During the time evolution both $E^{(\alpha)}_{\text{ext}}(t) \simeq E^{(\alpha)}_{\text{ext}}(0)$ and $E^{(\alpha)}_{\text{int}}(t) \simeq E^{(\alpha)}_{\text{int}}(0)$, which means that the solution remains trapped near the invariant subspace. In that case, the subspace is ideally stable.
2) During the time evolution energies become comparable $E^{(\alpha)}_{\text{ext}}(t) \simeq E^{(\alpha)}_{\text{int}}(t)$, which means that the solution is repelled from the invariant subspace. In that case the subspace is ideally unstable.

Numerical simulations show that the fluid subspace is always stable. As far as the magnetic subspaces are concerned, we find that H^A is always stable, while H^B and H^C are always unstable. More information about the behavior of the system near the invariant subspaces can be obtained by considering the characteristic of solutions when the dissipative coefficients are set different from zero. In that case, the energies decay in time, but the rate of decay is different, thus indicating a kind of selective dissipation. In particular, looking at the time evolution of their ratios $R^\alpha(t) = E^{(\alpha)}_{\text{ext}}(t)/E^{(\alpha)}_{\text{int}}(t)$, we find that it decays to zero for the ideally stable subspaces, while it settles to a constant value for the unstable subspaces. This means that ideally stable subspaces, namely the Alfvénic, fluid and magnetic H^A represent a kind of attractor for the system, while unstable subspaces, say H^B and H^C, repel solutions.

When we start numerical solutions near the stable subspaces, the system is attracted to the extreme points of the plane (a, h). When we start near the fluid attractor, the system reach the point $(a, h) = (0, 0)$, and when we start near one of the Alfvénic attractors the system is attracted to $(a, h) = (1/2, \pm 1)$. Finally, when we start near the stable magnetic subspace H^A the system is attracted to the extreme point $(a, h) = (1, 0)$. This last point represents a Taylor regime, say the magnetic field lies on the lowest allowed wave vector. On the contrary, when we start near the unstable magnetic attractors H^B or H^C, the system evolves in an erratic way towards any point (a, h) of the curve (20). Each point (a, h) is made by only one mode with wave vector $k_1 = k_{\text{min}} = \sqrt{2}$, so that if $\eta = V_1/B_1$ we have

$$\begin{aligned}a &= \frac{2}{\left(1+\eta^2\right) k^2_{\text{min}}}\\ h &= \frac{\eta}{1+\eta^2}\,.\end{aligned} \tag{22}$$

This last equation is nothing but the parametric equation of the curve (20).

The behavior we have just described can be recovered also when we start the numerical computation with general initial conditions. In that case, we can associate to each initial condition an invariant subspace according to the rule that the αth subspace is associated with the initial condition $\Psi_i(0)$ when the distance $\|\Delta^{(\alpha)}[\Psi_i(0)]\|$ is the minimum one over α. In other words, we associate an initial condition to the nearest subspace. Numerical simulations show that when the initial conditions are associated to the unstable subspaces H^B and H^C, the final point reached by the system will be any point (a, h) on the curve (20). When the initial conditions are associated with one of the stable subspaces, the final state will be one of the extreme points of the curve (20).

Self-Organization at Small Scales and Intermittent Structures in MHD Turbulence

The self organization processes discussed in the previous sections are related to the spontaneous creation of large scale coherent structures during the MHD turbulence dynamics. However, also at small scales the nonlinear energy cascade process in fully developed MHD turbulence is characterized by the presence of self organization and coherent structures. These structures are strictly related to the intermittency phenomenon, that is, the breakdown of global self-similarity in the turbulent cascade.

The turbulence theory proposed by Kolmogorov in 1941 [30] is based on the conjecture that, within the inertial range, the statistical properties of the fluid motions depend only on the mean energy transfer rate ε and on the scale ℓ, and that the nonlinear energy cascade occurring in this range is a self similar (fractal) process. According to this idea, the velocity field increments $\delta\boldsymbol{v}_\ell(\boldsymbol{r}) = \boldsymbol{v}(\boldsymbol{r}+\boldsymbol{\ell}) - \boldsymbol{v}(\boldsymbol{r})$ scale as $\delta v_\ell \sim \ell^{1/3}$. The self similarity of the turbulent cascade implies that the probability density function (PDF) of field increments $P(\delta v_\ell)$ should be invariant under the scale change

$$P(\delta v_\ell) = \ell^{-1/3} F\left(\frac{\delta v_\ell}{\ell^{1/3}}\right) , \qquad (23)$$

which means that PDFs of normalized velocity increments at different scales collapse onto the same curve. Another consequence of the global self similarity is that the structure functions $S_p(\ell) = \langle \delta v_\ell^p \rangle$, usually defined using the longitudinal field increments, that is, $\delta v_\ell(\boldsymbol{r}) = \left[\boldsymbol{v}(\boldsymbol{r}+\boldsymbol{\ell}) - \boldsymbol{v}(\boldsymbol{r})\right] \cdot \frac{\boldsymbol{\ell}}{\ell}$, should follow the scaling law $S_p(\ell) \sim \ell^{p/3}$.

When considering incompressible MHD turbulence, the scaling properties of the field increments $\delta\boldsymbol{z}^\sigma_\ell(\boldsymbol{r}) = \boldsymbol{z}^\sigma(\boldsymbol{r}+\boldsymbol{\ell}) - \boldsymbol{z}^\sigma(\boldsymbol{r})$, expressed here in terms of Elsässer variables $\boldsymbol{z}^\sigma = \boldsymbol{v} + \sigma\boldsymbol{B}/\sqrt{4\pi\rho}$ ($\boldsymbol{B}$ being the magnetic field and ρ the mass density) can be modified with respect to the fluid case by the so-called Alfvén effect, consisting of the fact that nonlinear interactions take place between eddies of different σ, which propagate in opposite directions at the Alfvén velocity along the large scale magnetic field reducing the efficiency of the non linear energy cascade [20,29,31].

In the fluid-like case a Kolmogorov-like scaling can be expected for the field increments, that is, $\delta z^\sigma_\ell \sim \ell^{1/3}$. On the other hand, when the Alfvén effect is at work the Kraichnan's scaling $\delta z^\sigma_\ell \sim \ell^{1/4}$ is recovered. However, in both cases the turbulent energy cascade is supposed to be a self similar process, resulting in a linear behavior of the structure function exponents, that is, $S_p(\ell) \sim \ell^{p/m}$, where $m = 3$ and $m = 4$ for the fluid-like and Alfvenic case respectively.

Several studies on the statistical properties of fields in fully developed turbulence have shown that the PDFs of field increments are not self similar, that is, their shape change with the scale ℓ. The PDFs at large scales are nearly Gaussian, while, as the scale decreases, the PDFs show sharper and sharper peaks and, correspondingly, higher and higher tails. As far as MHD turbulence is concerned, this behavior has been found both in the solar wind [36,50] and in laboratory plasmas [13]. This departure from self similarity has also been inferred from structure function analysis (see e. g. [8,12,13,35]) which have shown that for both velocity and magnetic field fluctuations the scaling exponents are nonlinear functions of p.

This behavior indicates thus that the turbulent, nonlinear energy cascade is not a fractal (self similar), but rather a multifractal process. In other words, small scale fluctuations much larger than their RMS are present in some spatial positions and the corresponding spatial fluctuations of the energy transfer rate $\varepsilon(\boldsymbol{r})$ play a primary role in the cascade process. These small scale fluctuations have been interpreted as the signature of localized coherent structures spontaneously produced by the nonlinear dynamics. The phenomenon described above is known as *intermittency* in fully developed turbulence.

Another important aspect of intermittency is the occurrence of impulsive bursts of energy dissipation which are observed in different systems characterized by the presence of MHD turbulence, e. g. the magnetic loops of the solar corona [1], and laboratory plasma devices such as reversed field pinches [5] and tokamaks [56]. This phenomenon is often referred to as *temporal intermittency*, to distinguish it from the *spatial intermittency* described above, as it consists in the observation of strong bursts of activity in the time series of a quantity which traces the energy dissipation in the system (e. g. radiation intensity). These bursts are separated from each other by intervals of low activity, denoted as laminar times or waiting times.

While temporal intermittency occurring in turbulent systems has been described, until the end of 90s, in the framework of theoretical paradigms other than turbulence (e. g. Self organized criticality [2]), the idea that spatially and temporal intermittency in fully developed turbulence are both due to the underlying nonlinear dynamics of the energy cascade, giving rise to small scale coherent structures, has now gained considerable standing. In the MHD turbulence context this picture has been supported by a number of results based on the analysis of solar wind and solar corona observations and laboratory plasma experimental data.

The intermittent, coherent events can be viewed as localized zones of fluid where phase correlations exist. These structures, which dominate the statistics of small scales, occur as isolated events. They continuously appear and disappear, apparently in a random fashion, at some locations in the fluid, and they carry most of the flow energy. Among the different techniques which can be used to identify such structures within a turbulent signal, a very effective one is based on the use of wavelet transforms [22]. The wavelet transform of a real square integrable signal $f(x)$ (where x is usually the time or a spatial coordinate) is defined as

$$W(x,r) = C_{\psi}^{-1/2} r^{-1/2} \int_{-\infty}^{\infty} \psi\left(\frac{x'-x}{r}\right) f(x')\mathrm{d}x' \,, \quad (24)$$

where r is a scale dilation, x is a position (time) translation, $\psi(x)$ is the so called mother wavelet function, and C_{ψ} is a normalization constant, which must satisfy the admissibility condition $\int_{-\infty}^{+\infty} |k|^{-1}|\hat{\psi}(k)|^2 \mathrm{d}k < \infty$ where $\hat{\psi}(k)$ is the Fourier transform of $\psi(x)$. The wavelet coefficients $W(x,r)$ give a decomposition of $f(x)$ at the scale r as a function of the position x. For each scale, it is possible to identify the position (or the time occurrence) of strong, intermittent events through a method proposed by Farge [22] based on the so-called Local Intermittency Measure (LIM) $l(x,r)$ defined as

$$l(x,r) = \frac{|W(x,r)|^2}{\langle |W(x,r)|^2 \rangle} \,. \quad (25)$$

The identification method of intermittent structures is based on the idea that large values of $l(x,r)$ represent a signature of large fluctuations with respect to the background level. The wavelet coefficients can thus be classified as "passive" if $l(x,r) < F$ or "intermittent" when $l(x,r) > F$, where F is a threshold which can be chosen by using different suitable criteria [9,41,54].

Another possible method to select intermittent bursts [6] consists of defining bursts as the time intervals during which the condition $f(x) \geq f_{\text{th}}$ is satisfied, where the threshold value f_{th} is calculated through the following iterative method. One starts by defining $f_{\text{th}} = \langle f(t) \rangle + a\sigma$ (a is an arbitrary positive number, usually 2 or 3), where the average and the standard deviation are computed from the whole time series. After excluding the values which exceed f_{th}, the average and the standard deviation are calculated again using the remaining part of the time series. This process is repeated until convergence of f_{th} is reached. This procedure allows one to remove strong events and to evaluate the threshold taking into account only the background contribution.

Once intermittent structures are identified, it becomes possible to study their typical profiles and some relevant statistical properties such as the distributions of event energy and of time intervals between successive bursts. Such investigations allow one to shed light on the physical mechanisms underlying the bursting process. We discuss now the properties of intermittent events observed in three different systems where MHD turbulence occurs, namely the solar wind, reversed field pinches devices, and magnetic loops of the solar corona. Related aspects of intermittency and multifractality are discussed in the review by Chang ▶ Space Plasmas, Dynamical Complexity in in this Encyclopedia.

Intermittent Structures in Solar Wind MHD Turbulence

Intermittent events in solar wind turbulence have been studied by Veltri and Mangeney [54] and Veltri et al. [55] by applying the LIM technique, with the Haar wavelet basis, to fluid velocity and magnetic field measurements performed during about 1 year in the space experiment ISEE. In this experiment only two components of the fluid velocity, namely, V_x and V_y, were measured, together with all the three components of the magnetic field. The reference frame used was the standard GSE frame and the sample was formed by data at a time resolution of $T = 1$ min, so that the sampling rate was $\Delta = V_{\text{sw}} T \sim 24.000$ km (V_{sw} is the average solar wind velocity).

The classification of wavelet coefficients allows for an identification and a study of the most intermittent events in solar wind turbulence, which occur in those positions where the amplitude of the wavelet coefficients displays the largest values compared to the average. These events, which occur on time scale of the order of few minutes, exhibit a small number of typical profiles, summarized as follows:

a) "Tangential discontinuities": These structures are almost incompressible, pressure balanced one dimensional current sheets. A minimum variance analysis performed on the magnetic field around the singularity shows (Fig. 7) that the component of the magnetic field which varies most changes sign, and this component is perpendicular to the average magnetic field (the magnetic field component along the third axis being almost zero). The magnetic field rotates then in a plane by an angle which is about 120°–130°. There is one more interesting property: When these structures occur during an Alfvénic period (velocity and magnetic field fluctuations highly correlated), the Alfvénic correlations go from 1 to zero during the traversal of the current sheet (Fig. 7, left panel), when, on the contrary, these structures occur during a period of almost no Alfvénic correlation, the correlation increases to about 1 at the current sheet location (Fig. 7, right panel).

b) "Compressive discontinuities": These structures can be either parallel shocks, mainly observed on the radial component of the velocity field, but clearly seen also on the magnetic field intensity, proton temperature and density (Fig. 8, left panel); or slow mode wavetrains, characterized by a value of $\beta \sim 0$, a constantpressure,

anticorrelated density and proton temperature fluctuations and with velocity fluctuations along the average magnetic field (Fig. 8, right panel).

Very interesting statistics can be studied on the time separation Δt (often denoted as *waiting time*) between the occurrence of two consecutive structures. Waiting times of solar wind intermittent structures are distributed according to a power law $P(\Delta t) \sim \Delta t^{-\gamma}$ extended over two decades at least, with an exponent $\gamma \simeq 2.18$ (Fig. 9) [14].

This property is very interesting, because it indicates that the energy cascade process is non-Poissonian. Waiting times occurring between isolated Poissonian events must be distributed according to an exponential function. The power law represents the asymptotic behavior of a Lévy function, which describes self-affine processes and is obtained from the central limit theorem by relaxing the hypothesis that the variance of variables is finite. The power law waiting time PDF is thus a clear evidence that long-range correlations (or in other words "memory") exist in the underlying cascade process.

Intermittent Structures in Laboratory MHD Turbulence

The properties of intermittent events in the magnetic turbulence observed at the edge of a toroidal plasma device in reversed field pinch configuration has been studied by Carbone et al. [14] through the analysis of magnetic field fluctuations in the Reversed Field Pinch experiment RFX [48]. Events have been identified by applying the LIM technique on radial and toroidal magnetic field time series. The magnetic field fluctuations for some of the most intermittent events are shown in Fig. 10 by using the minimum variance reference frame.

One of the two components displays a peak when the other component changes sign. This behavior suggests that the intermittent structures identified in the RFX magnetic field are tangential discontinuities similar to those found in the solar wind, although measurements of all the magnetic field components would be needed to confirm this interpretation.

Also in RFP magnetic turbulence, the waiting time PDF of intermittent structures shows a power law behavior $P(\Delta t) \sim \Delta t^{-\gamma}$ extended over two decades as in the case of solar wind MHD turbulence, with an exponent $\beta \simeq 1.5$ (Fig. 11) [14].

Intermittent Energy Release Events in the Solar Corona

Another manifestation of intermittency phenomena in systems where MHD turbulence is present is the occurrence of impulsive energy release events, the so-called solar flares, which take place in the magnetic loops of the solar corona. Energy is released mainly through accelerated particles and emission of electromagnetic radiation in a wide range of wavelengths, from radio to γ-rays, and can vary between 10^{24} and 10^{33} erg. The smallest events, namely those between 10^{24} and 10^{27}, are usually denoted as nanoflares and microflares.

Parker [43] conjectured that nanoflares are produced by the dissipation of small current sheets, associated with tangential discontinuities, forming as a consequence of the continuous shuffling and intermixing of field footpoints in the photospheric convection. In the Parker's picture, flares of all sizes result from the superposition of small dissipation events (nanoflares) which can trigger energy releases in the neighboring discontinuities, originating a fragmented energy release process which can produce both small and large-scale events, depending on the details of the magnetic configuration.

Starting from the idea that MHD turbulence is most probably a fundamental ingredient of coronal loop (Fig. 12) dynamics, it has been proposed [6] that nanoflares and flares can be identified with dissipation events of small-scale current sheets forming as a consequence of the nonlinear turbulent cascade which occurs inside coronal magnetic structures. The cascade would be driven by the energy input due to photospheric footpoint motions. In this framework, current sheets are coherent intermittent small scale structures of MHD turbulence. The energy injected at large scales by photospheric motions is transferred to small scales through the nonlinear cascade, which goes down to the dissipative scales. The intermittent nature of the energy release process is thus associated with the intermittency of energy dissipation in MHD turbulence.

This picture is supported by the statistical properties of solar flares inferred from the analysis of the associated radiation bursts. Nanoflares are detected as extreme ultraviolet (EUV) brightenings, while larger flares are observed through several types of emission (radio, microwaves, $H\alpha$, UV, X-rays) and most often studied analyzing Soft X-ray (SXR) and Hard X-ray (HXR) flare bursts. Probability distributions of the relevant quantities (peak flux, total energy, duration) characterizing the flare bursts have been found to be well represented by power laws $P(x) = Ax^{-\alpha}$ (see Fig. 13 for an example).

Using various SXR and HXR observations it has been found that, for energy and peak flux distributions, $\alpha \simeq 1.6$–2 (see e. g. [15,16,34]). For the EUV nanoflare brightenings the power law exponent is much more uncertain, $\alpha = 1.3$–2.8 (see e. g. [32,44]). The waiting time distribution (WTD) has been studied both for HXR and SXR bursts [6,45,57]. SXR observations acquired by the GOES

satellites have the advantage to provide a long sequence of bursts (from 1975 to today) with few gaps and allow, thus, to analyze the WTD with a much better statistical accuracy than HXR data. The WTD of GOES SXR flares has been shown to display a clear power law tail $P(\Delta t) \sim \Delta t^{-\gamma}$ in the range $5\,\mathrm{h} \lesssim \Delta t \lesssim 100\,\mathrm{h}$, with an exponent $\gamma \simeq 2.4$ (Fig. 14) [6].

The power law behavior of the solar flare WTD represents an indication of the existence of correlations between successive bursts [6,33]. These correlations can be related to the nonlinear dynamics of the MHD turbulent energy cascade which generates intermittent bursts of chaoticity at small scales.

From the theoretical point of view, describing in a proper way the intermittency of the turbulent energy

dissipation process is one of the basic ingredients for the study of intermittent events occurring in the solar corona, as well as in other astrophysical systems such as the solar wind and accretion disks. These astrophysical plasmas are characterized by huge Reynolds numbers. The number N_{df} of degrees of freedom, i.e the number of grid points necessary to resolve the entire inertial range of turbulence in a direct numerical simulation of Navier–Stokes or MHD equations, grows with the Reynolds number Re as $N_{\mathrm{df}} \sim \mathrm{Re}^{9/4}$. Therefore performing direct numerical simulations at Reynolds number regimes of interest for space plasmas is out of the present computational possibilities. The so called shell models, a class of dynamical deterministic models of turbulence in which N_{df} grows logarithmically with Re, can represent an extremely helpful tool for the modeling of such physical systems, as these models are able to simulate the turbulent cascade and the related intermittency of the energy dissipation process in Reynolds number regimes which are not far from the real ones (at least with respect to direct numerical simulations). The statistical properties of intermittent events in MHD turbulence can thus be effectively investigated through the use of shell models [6,14,15].

Shell models [7] are dynamical systems designed in order to represent in a simplified way the spectral Navier–Stokes or MHD equations for turbulence. They were originally proposed by Obukhov [40], Desnyansky and Novikov [19], and Gledzer [26] in hydrodynamic turbulence.

In order to build up the evolution equations for a shell model, the wavevector space is divided into a discrete number of shells of radius $k_n = \rho^n k_0$, with $\rho > 1$, $n = 1, 2, \ldots, N$. Each shell is assigned a scalar dynamic variable (real or complex) $v_n(t)$ which represents the averaged effect of velocity modes with wavenumber between k_n and k_{n+1}. $v_n(t)$ can also be regarded as the velocity increments $|v(x+\ell) - v(x)|$ on an eddy of scale $\ell \sim k_n^{-1}$. For MHD shell models, besides $v_n(t)$, another variable $b_n(t)$, representing magnetic field modes between k_n and k_{n+1} (or, alternatively, magnetic field increments $|b(x+\ell) - b(x)|$), is assigned to each shell. The nonlinear terms of the equations are quadratic combinations of the dynamic variables and are written under the assumption that the interactions among shells are local in k-space. This means that only nearest and, at most, next-nearest shells are introduced in the non-linear terms. The coupling coefficients are found by imposing conservation of the ideal invariants of Navier–Stokes or MHD equations.

The main advantage of shell models is that they can be studied through numerical simulations at very high Reynolds numbers. Moreover, they provide the possibility to obtain long time series with a fairly small computational effort, allowing thus a robust investigation of the statistical properties of intermittent events The weak point is that they are scalar models, that is, any information about spatial structures, such as vortices, sheets, and filaments, is lost.

Among the various shell models which have been proposed in the literature, we consider here the so called GOY (Gledzer–Ohkitani–Yamada) model, which has been used by several authors both in hydrodynamics and MHD. In the MHD context, the advantage of the GOY model with respect to previous shell models, where only the conservation of two quadratic invariants, i. e. total energy and cross helicity, can be imposed, is that it allows to conserve also magnetic helicity. The GOY model involves nearest and next-nearest interactions and was originally introduced in the framework of hydrodynamic turbulence by Gledzer [26], using real shell variables. The model was extended by Yamada and Ohkitani [60] to the case of complex variables. The MHD generalization of the GOY model has been considered by several authors (see [6,27,28] and references therein). The evolution equations for the dynamic variables $v_n(t)$ and $b_n(t)$ in the GOY shell model can be written as [6]

$$\begin{aligned}\frac{\mathrm{d}v_n}{\mathrm{d}t} = -\nu k_n^2 v_n + f_n + ik_n \Big\{ &(v_{n+1}v_{n+2} - b_{n+1}b_{n+2}) \\ &- \frac{1}{4}(v_{n-1}v_{n+1} - b_{n-1}b_{n+1}) \\ &- \frac{1}{8}(v_{n-2}v_{n-1} - b_{n-2}b_{n-1}) \Big\}^* , \quad (26)\end{aligned}$$

$$\begin{aligned}\frac{\mathrm{d}b_n}{\mathrm{d}t} = -\mu k_n^2 b_n + g_n + ik_n \frac{1}{6} \Big\{ &(v_{n+1}b_{n+2} - b_{n+1}v_{n+2}) \\ &+ (v_{n-1}b_{n+1} - b_{n-1}v_{n+1}) \\ &+ (v_{n-2}b_{n-1} - b_{n-2}v_{n-1}) \Big\}^* . \quad (27)\end{aligned}$$

f_n and g_n represent external forcing terms, usually acting on low wavenumber shells, while ν and μ appearing in the linear, dissipative terms, are the kinematic viscosity and the resistivity respectively, viscous and resistive terms provide a mechanism for energy dissipation at small scales. In turbulent space plasmas such as solar corona and solar wind dissipation mechanisms are different, involving kinetic plasma processes. Nevertheless, the properties of low frequency MHD turbulent cascade in the inertial range and of the related intermittency do not depend, in general, on the details of the dissipation mechanism, hence the use of viscous and resistive dissipation in the standard incompressible form does not represent a serious limitation in this context.

The GOY model described here has been designed to investigate 3D MHD turbulence. This means that it satisfies the conservation of the ideal 3D MHD quadratic invariants (4), (5) and (6). In terms of shell variables, the invariants read [27,28]

$$E = \frac{1}{2}\sum_{n=1}^{N}(|v_n|^2 + |b_n|^2) , \quad (28)$$

$$H_\mathrm{c} = \frac{1}{4}\sum_{n=1}^{N}\Re(v_n b_n^*) , \quad (29)$$

$$H_\mathrm{m} = \sum_{n=1}^{N}(-1)^n \frac{|b_n|^2}{k_n} . \quad (30)$$

The energy dissipation rate in the GOY MHD shell model can be defined as [6]

$$\varepsilon(t) = \nu \sum_{n=1}^{N} k_n^2 |v_n|^2 + \mu \sum_{n=1}^{N} k_n^2 |b_n|^2 . \quad (31)$$

A statistical analysis of intermittent events in the GOY MHD shell model shows that the PDFs of event energies, duration and waiting times display power law tails (Figs. 15 and 16) [6,14]. This behavior is consistent with the statistics of intermittent events observed in the solar wind, reversed field pinch devices and solar corona.

In closing this section, it can thus be remarked that the study of intermittent events in MHD turbulence, mainly based on wavelet transforms and PDFs of various event parameters, has provided a quite detailed picture of the coherent structures produced by the self-organization of the MHD turbulence cascade at small scales. The analysis of data from solar wind and RFP devices has demonstrated that the most intermittent structures in incompressible MHD are one dimensional current sheets associated with tangential discontinuities. The statistical analysis of intermittent events occurring in solar wind, laboratory plasma and magnetic structures of the solar corona has shown that these events are characterized by power law distributions of event energy and waiting times, which are naturally reproduced by MHD turbulence models. The power law behavior of the waiting time distribution indicates the

The *solid line* represents a power law with exponent $\beta = 2.13$. b Waiting time PDF for intermittent events identified in the time series of the energy dissipation rate ε (Eq. 31). The solid line represents a power law with exponent $\beta = 2.33$. In both cases, intermittent events were identified through the iterative procedure proposed in [6] and described in the text, using the threshold $\langle\cdot\rangle + 2\sigma$

presence of long range time correlations which can be attributed to the non-linear dynamics of the turbulent energy cascade.

Future Directions

In the previous sections we have discussed how coherent dissipative structures are spontaneously formed by non-linear interactions both in laboratory and in natural plasmas. A further understanding of these processes requires an increase in the performance of computers, which will allow one to simulate 3D MHD turbulence at Reynolds numbers larger than 10^3, which represents the actual limit. On the other hand, an improved effort in the analysis of solar wind space data and laboratory plasma devices measurements should also be necessary. An increased knowledge of these phenomena is crucial in order to try to control the transport processes in fusion plasmas and then to improve the plasma confinement, since the presence of coherent structures inside turbulence greatly affect the plasma diffusion process. Moreover a better comprehension of the self organization in MHD turbulence can greatly help in explaining some basic phenomena in solar corona (flares and coronal heating), which occur in a region where in situ observations cannot be performed.

Article Outline

Glossary

Abelian group A mathematical group wherein all the elements commute.

Avalanche A possibly large disturbance induced in a system by a small perturbation.

Cellular automaton This refers to the dynamics of a collection of cells each of which can be in a finite set of states. The evolution is discrete, with the state of a cell at the next time step being dependent only on its previous state and that of its neighbors.

Chaos The tendency of a system of a few degrees of freedom to exhibit highly erratic behavior characterized by an infinite range of time scales.

Self-organized criticality The tendency of certain discrete and dissipative dynamical systems to evolve to a state where changes occur over all possible length scales.

Definition of the Subject

Self-organized criticality is a concept invoked to explain the frequent occurrence of fractal structures and multiscale phenomena in nature. In contrast with the ideas of chaos, here simple common features appear in systems with many degrees of freedom. For modeling this phenomenon, cellular automata provide an elegant class of dynamical systems which are easily simulated numerically.

Introduction

Cellular automata provide a fascinating class of dynamical systems based on very simple rules of evolution yet capable of displaying highly complex behavior. These include simplified models for many phenomena seen in nature. Among other things, they provide insight into self-organized criticality, wherein dissipative systems naturally drive themselves to a critical state with important phenomena occurring over a wide range of length and time scales.

This article begins with an overview of self-organized criticality. This is followed by a discussion of a few examples of simple cellular automaton systems, some of which may exhibit critical behavior. Finally, some of the fascinating exact mathematical properties of the Bak–Tang–Wiesenfeld sandpile model [1] are discussed.

Self-Organized Criticality

Self-organized criticality refers to the tendency of many dynamical systems to naturally drive themselves to a state displaying fluctuations over a wide range of scales [1]. The concept is invoked as a possible "explanation" of the omnipresent multi-scale structures throughout the natural world, ranging from the fractal structure of mountains, to the power law spectra of earthquake sizes [2]. Recent applications include such diverse topics as punctuated evolution [3] and traffic flow [4]. The concept has even been invoked to explain the unpredictable nature of economic systems; i. e. why you can not beat the stock market [5].

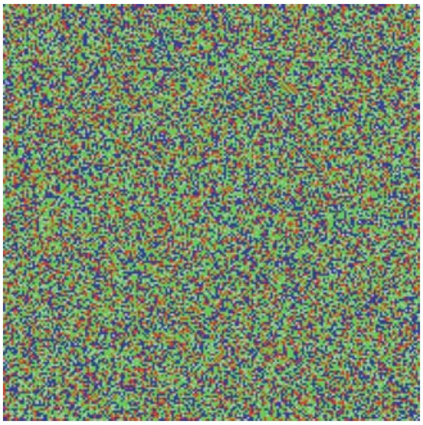
Self-organized criticality nicely compliments the concept of chaos. In the latter, dynamical systems with a few degrees of freedom, say as little as three, can display highly complex behavior, often generating beautiful fractal structures. With self-organized criticality, we start instead with systems of many degrees of freedom, and find a few general common features.

Another attractive feature of both self organized criticality and chaos is the ease with which computer models can be implemented and the elegance of the resulting graphics. Most of the figures in this chapter were produced using my publicly available set of programs "xtoys" [6]. Indeed, much of this presentation is based on my similar article in [7].

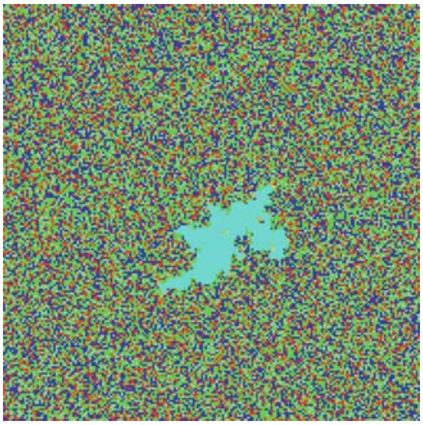
The paradigm for the phenomenon is the sandpile. On slowly adding grains of sand to an empty table, a pile will grow until its slope becomes critical and avalanches start spilling over the sides. If the slope becomes too large, a large catastrophic avalanche is likely, and the slope will reduce. If the slope is too small, then the sand will accumulate to make the pile steeper. Ultimately one should obtain avalanches of all sizes, with the prediction of the size for the next avalanche being impossible to determine without actually running the experiment.

The original Bak, Tang, Wiesenfeld paper [1] presented a particularly simple model to mimic the sandpile idea. For this, each site of a two dimensional lattice has a state represented by a positive integer z_i. This integer can be thought of as representing the amount of sand at that location, or in another sense it represents the slope of the sandpile at that point. Neither of these analogies is fully accurate, the model has aspects of each.

The dynamics follows by setting a threshold z_{T} above which any given z_i is unstable. Without loss of generality, I take this threshold to be $z_{\mathrm{T}} = 3$. Time now proceeds in discrete steps. In one such step each unstable site with $z_i \geq 4$ "tumbles" or "topples," dropping by four and adding one grain to each of its four nearest neighbors. This may produce other unstable sites, and thus an avalanche can ensue. This proceeds for further time steps until all sites are stable. Figure 1 shows a typical configuration on a 198 by 198 lattice after lots of random sand addition followed by relaxation. Figure 2 shows an avalanche proceeding on this lattice, and Fig. 3 shows the final avalanch region after the system reaches stability.

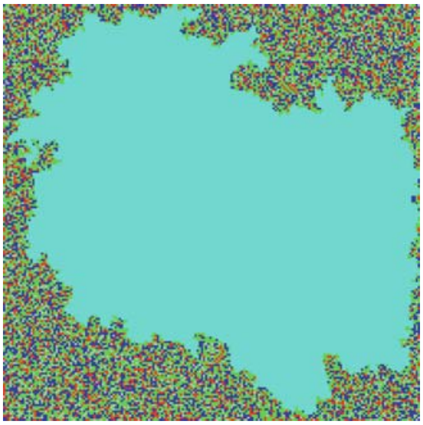


Self-organized Criticality and Cellular Automata, Figure 1
The sandpile model in the final stable state after adding lots of sand to random places. The lattice is 198 cells by 198 cells. The color code is *gray*, *red*, *blue*, and *green* for heights 0, 1, 2, and 3, respectively. Despite the lack of obvious patterns, subtle correlations are present; for example no two adjacent sites have height zero



Self-organized Criticality and Cellular Automata, Figure 2
An ongoing avalanche obtained by adding a small amount of sand to the configuration in Fig. 1. Stable sites which have tumbled during the avalanche are distinguished by being colored *light blue*. The still active sites are colored *yellowish brown*

A natural experiment consists of adding a grain of sand to a random site and measuring the number of topplings and the number of time steps for the resulting avalanche.



Self-organized Criticality and Cellular Automata, Figure 3
The final state after the avalanch in Fig. 2 has completed. The sites which tumbled during the avalanche are distinguished by being colored *light blue*. Note that the final avalanche region is simply connected. This is a general result proven later in the text

Repeating this many times to gain statistics, the distribution of avalanche sizes and lengths displays a power law behavior, with all sizes appearing. In [8] such experiments showed that the distribution of the number of tumbling events s in an avalanche empirically scales as

$$P(s) \sim s^{-1.07} \tag{1}$$

and the number of time steps τ for avalanches scales as

$$P(\tau) \sim \tau^{-1.14} \, . \tag{2}$$

This model has been extensively studied analytically. While as yet there is no exact calculation of these exponents, a lot is known. In particular, the critical ensemble is well characterized. I will return to these points later.

The extent to which laboratory experiments reproduce these phenomena is somewhat controversial. A study of avalanche dynamics [9] in rice piles showed power laws with long-grain rice, but more ambiguous results followed similar experiments with short-grain rice.

Cellular Automata

The sandpile model is a simple example of a system of cellular automata [10,11]. Each site or "cell" of our lattice follows a prescribed rule evolving in discrete time steps. At each step, the new value for a cell depends only on the current state of itself and its neighbors. These systems are fascinating in that deceptively simple rules can give rise to extremely complex behavior. Furthermore, slight changes in the rules can dramatically change their behavior.

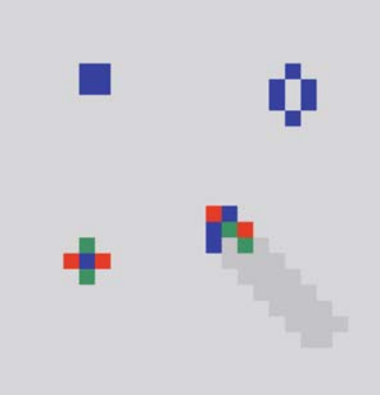
Even though the formulation of a cellular automaton may seem almost trivial, there are a huge number of possible rules. For example, suppose I consider two dimensional models where each cell can take only one of two possible states. These might be referred to as unset or set bits, or more figuratively as "dead" or "alive." Suppose furthermore that I restrict myself to rules where the evolution of a given cell to the next time step depends only on the current values of the cell and each of its eight neighbors. In this case there are $2^9 = 512$ possible arrangements for the cell and its neighbors. A general rule needs to specify the next state of the cell for each of these arrangements. This gives $2^{512} = 1.3 \times 10^{154}$ possible rules. Given that the universe is only of order 4×10^{17} seconds old, clearly only a vanishing fraction of these rules have a chance of being studied in any of our lifetimes.

A simple subset of rules called "totalistic" have the state of the updated cell only depend on the total number of living neighbors. With the eight cell neighborhood, there are nine possible values for this sum, and the new value for the cell requires specification of the new state for each of these as well as the current state of the cell. This gives $2^{18} = 262,144$ rules; still large, but not truly astronomical. If I restrict the rule to depending on the total of only the four nearest neighbors, I then have a modest $2^{10} = 1024$ cases to consider. Other than the sandpile model, most of the following will be restricted to such totalistic rules.

With a discrete set of states, cellular automata have the appealing feature of being easily implementable entirely by logical operations, the natural functions of computer circuitry. Also, the state of several cells can be stored and manipulated within a single computer word. Using such tricks, these models can often be implemented to run extremely fast, leading to hope that such models may supply simulation methods as good as or better than the conventional use of floating point fields on a discrete grid. With this motivation, considerable attention has been paid to cellular automata that may simulate fluid flow. Another advantage of this approach is the ability to work with arbitrary boundary conditions. These topics go beyond the scope of this article. A nice review can be found in [12].

Conway's Life

Perhaps the most famous cellular automaton model is Conway's "Game of Life" [13]. For this there exists a vast literature; so, I will only mention a couple of interesting features. The rule involves the eight cell neighborhood, and if a cell is initially "dead" it becomes alive if and only if it has exactly three live neighbors, or "parents". A living cell dies of loneliness if it has less than two live neighbors,



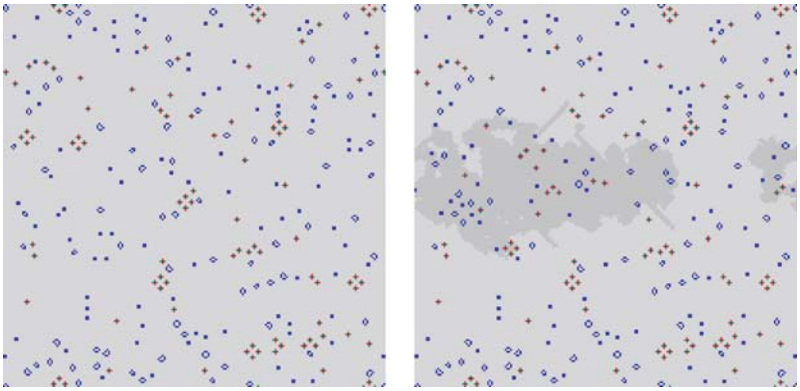
Self-organized Criticality and Cellular Automata, Figure 4
Some living configurations in life. The *top* two are stable patterns. The *lower left* shows a "blinker" or "traffic light" which oscillates with a period of two. On the *lower right* is a glider, which propagates diagonally through the lattice. *Blue* denotes a state that is and just was alive, *red* is newborn, and *green* represents just died. The track of the glider is *darkened* slightly over the remaining *gray background* to show its motion

and of overcrowding if it has more than three live neighbors. Only in the case of exactly two or three live neighbors does it survive.

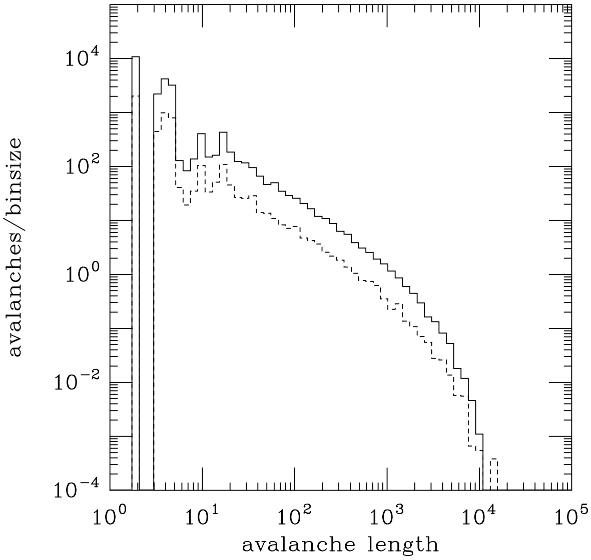
While simple to state, this model displays fascinating complexity. There are simple isolated sets of live cells that quietly survive, such as a block of four neighboring live cells forming a two by two square. Other configurations oscillate, such as three live cells in a row, which alternate between being vertically and horizontally oriented. A particularly amusing local configuration has five live cells; say starting with coordinates $\{(0,0),(0,1),(0,2),(1,2),(2,1)\}$. After four time steps this configuration returns to its original shape, but displaced by $(-1,1)$. On an otherwise empty board, this "glider" continues to propagate as a single entity. In an on-screen simulation, it appears much as a small insect crawling about. Some elementary configurations are shown in Fig. 4. A large collection of fascinating life configurations can be found in the Wikipedia [14].

Gliders allow information to be propagated over long distances, and it has been proven that with a complicated enough initial configuration, one can construct a computer out of live cells on a life board [13]. Special sub-configurations form the analog of electronic gates, which can control beams of gliders representing bits. Indeed, since life is capable of universal computation, one might imagine a life board programmed to simulate the game of life.

There is some limited evidence that the game of life also displays self-organized criticality [15,16]. One can repeatedly throw down gliders, which collide and create a background of static and oscillating clumps. While oscillators of arbitrarily long period are known to exist, those with period longer than two are extremely rare and almost never created from unorganized initialization. Once the system has settled into a loop, then another glider can be tossed on, giving a disturbance. An avalanche is defined to occur during the period until the system again goes into an oscillating state. Figure 5 shows the effect of such a disturbance. In Fig. 6 I show the distribution of such avalanches as measured on modest lattices. There is a hint of a power law superposed on additional structure from avalanches of only a few time steps, and a rounding at large times possibly due to finite size effects. The criticality of life remains controversial; [17] has looked unsuccessfully for a power



Self-organized Criticality and Cellular Automata, Figure 5
On the *left* is a configuration in life resulting from a random start and evolved until only stable and period two oscillators remain. On the *right* is the state after a small disturbance was introduced in the center and allowed to die out. Note the irregular shape of the disturbed region, which has been tinted a *darker gray*. The lattice here is 198 sites wide by 198 sites high, with periodic boundaries



Self-organized Criticality and Cellular Automata, Figure 6
The distribution of avalanches generated by adding gliders randomly to a system in the game of life consisting of stable and period two oscillators. An avalanche occupies the period until the system has relaxed again into such a periodic state. The *solid line* represents 25,000 avalanches on a 512 by 512 lattice, and the *dashed line* is for 6,000 avalanches on a 1024 by 1024 system. This figure is taken from [16]

law distribution of activity as one moves in from a source on the boundary. The relation between these two experiments is unclear.

Fredkin's Modulo-Two Rule

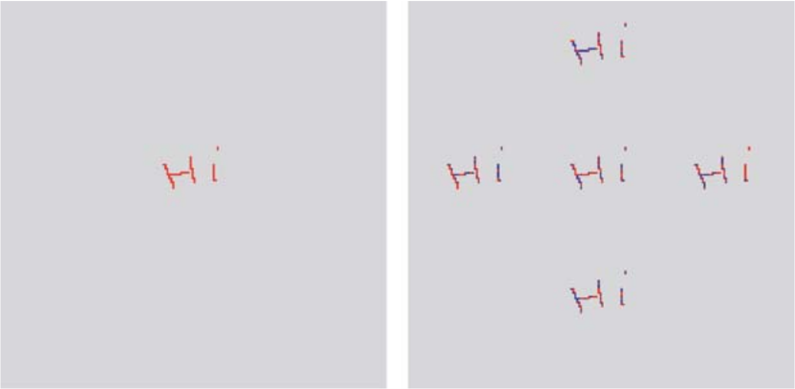
An extremely simple but highly amusing rule takes at each time step the "exclusive or" (XOR) operation between a site and its neighbors. This rule has the remarkable property of self replication [18]. Starting with any given initial pattern, after 2^n time steps copies of the original state occupy positions separated by 2^n spatial sites from the original in every direction as specified in the chosen neighborhood. In Fig. 7 I show an example of this with the four cell neighborhood.

In this rule, the pattern is generally rather complex just before returning to the replicated case, i. e. after $2^n - 1$ steps. Figure 8 shows the pattern obtained from a single set pixel after this rule has been applied for 63 time steps using the four nearest cells as the neighborhood. Note the fractal structure. In one more time step, all but five copies of the original set bit die.

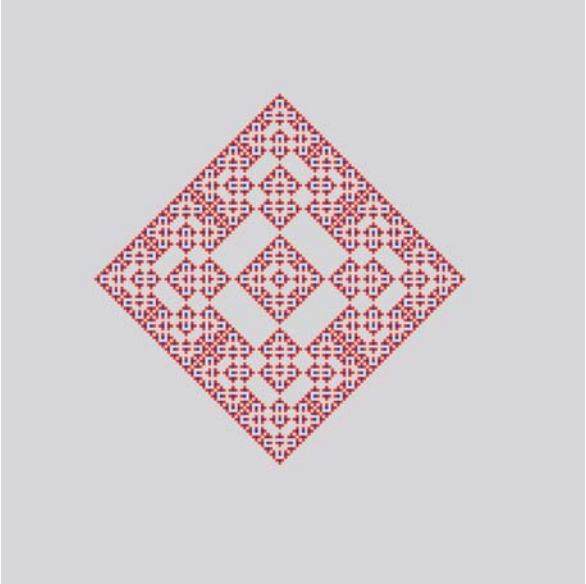
Unlike most cellular automaton rules, this gives a dynamics which in some sense is not really "complex". In most cases the simplest way to predict the evolution of a cellular automaton rule is to actually run it. Here, however, there is an easier way to predict what the final pattern will look like; it is always an XOR operation between several displaced copies of the configuration that appeared 2^n time steps in the past. Despite the lack of complexity, this rule shows rather dramatically that cellular automata are capable of "reproduction".

Reversible Rules

Reversibility is rather elusive among cellular automata. In the game of life, a single isolated cell immediately dies leaving no trace; thus it is impossible from the state at a given time to reconstruct what was there one time step back. A related difficult problem is to construct "garden of Eden" configurations which are impossible to arrive at from any previous state [19].



Self-organized Criticality and Cellular Automata, Figure 7
Starting from the initial configuration *on the left*, the modulo two rule is evolved for 64 steps using the four nearest neighbors. At a certain stage, five copies of the original image appear. The *blue pixels* indicate which sites were also alive one step before



Self-organized Criticality and Cellular Automata, Figure 8
The state after applying 63 steps of the modulo two rule using the four nearest neighbors to an initial state of a single set bit. After the next time step this fractal structure decays into only five remaining live cells

Fredkin pointed out an interesting class of reversible rules based on an analogy with molecular dynamics [11]. In the later one specifies both the position and the velocities of a set of particles and evolves the system under Newton's equations with some given inter-particle force law. Reversal can then be accomplished by merely changing the signs of all the velocities.

In a cellular automaton an analog of velocity requires the value of the cells at two successive time steps. Based on this, Fredkin presented a very simple scheme using the previous state to generate a wide class of reversible rules. He considered taking an arbitrary automaton rule at a given time, and then added an exclusive or (XOR) operation of the result with the state one step back in time. These combined operations could then be reversed by merely interchanging two successive time steps, the analogy of reversing the velocities.

To see this more mathematically, suppose the state at time i is s_i, and the underlying rule begins by taking some arbitrary function $f(s_i)$. Then the full rule takes for the next time step $s_{i+1} = f(s_i)$ XOR s_{i-1}. Here the exclusive or operation is taken site by site over the entire lattice. Elementary properties of the XOR operation then give $s_{i-1} = f(s_i)$ XOR s_{i+1}, which is the identical rule for the time reversed dynamics.

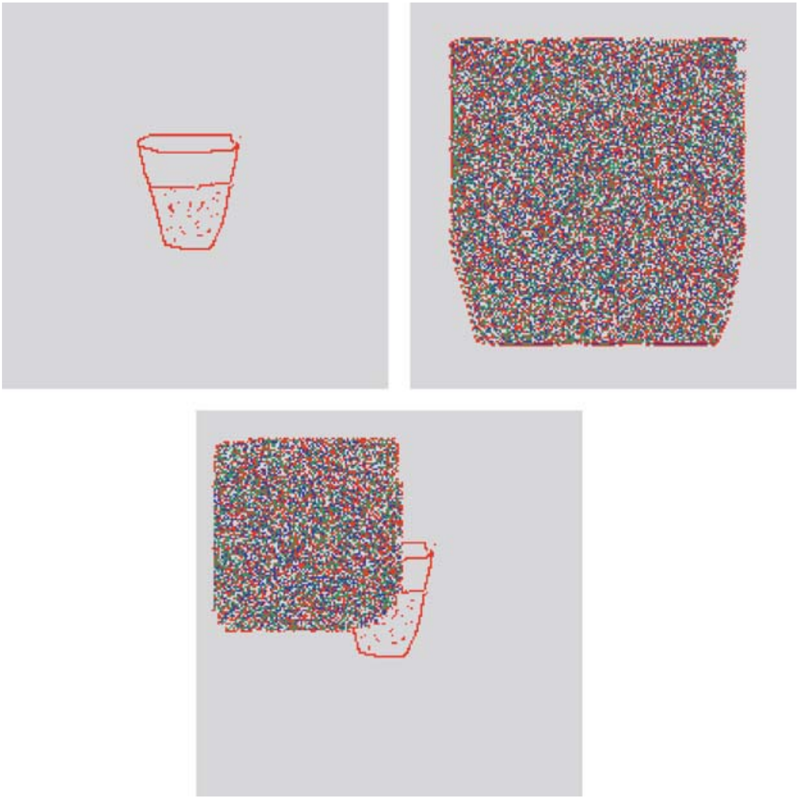
These rules provide a wonderful way to play with the concepts of entropy and reversibility. Indeed, an idealized universe of cellular automata enables experiments which would be impossible to carry out in the real world. In Fig. 9 I show the evolution of a simple image under such a rule. The experiment is a crude simulation of a beer glass shattering after being dropped on the floor. After a few steps it appears quite randomized. Reversal of the momenta of all relevant atoms in the beer glass would allow its reconstruction. In the model this is easily accomplished by swapping two time steps. After reversal, continuing with the same rule reconstructs the original image. At all stages the "information" contained in the system must be constant, even though the image may appear of drastically different complexity.

The reconstruction process is highly sensitive to the reversal being precise. The analog here is to the sensitivity to initial conditions in dynamical systems. In the bottom of Fig. 9c I try to reproduce the beer cup from its shards as in the above experiment, except that now at the time of reversal I modify the state of exactly one pixel. The reversal process recovers the original image only in regions outside the "light cone" for the modified pixel. As the disturbance can only propagate to neighbors in one time step, pixels outside n steps can not know of the change before an equal number of time steps. This use of an XOR operation to generate reversible complex mappings is an integral part of the Data Encryption Standard; see, for example, [20].

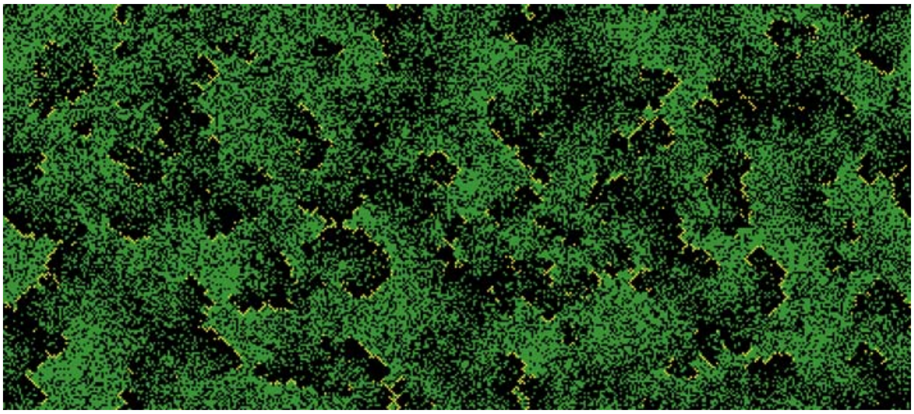
Forest Fires

An amusing model of forest fires has three possible states per cell, empty, a tree, or a fire. For the updating step, any empty site can have a tree born with a small probability. At the same time, any existing fire spreads to neighboring trees leaving its own cell empty. The rule here differs from those discussed previously in having a stochastic nature. As the system is made larger, the growth rate for the trees should decrease to just enough to keep the fires going.

If too many trees grow, one obtains a large fire reducing their density, while if there are too few trees, fires die out. On a finite system, one should light a fire somewhere to get the system started. On the other hand, as the system becomes larger, the growth rate for the trees can be reduced without the fire expiring. In a steady state the system has fire fronts continually passing through the system, as illustrated in Fig. 10. Perhaps there is a moral here that one should be careful about extinguishing all fires in the real world, for this may enhance the possibility for a catastrophic uncontrollable fire. It is not entirely clear whether this model is actually critical. What seems to happen on



Self-organized Criticality and Cellular Automata, Figure 9
The encryption of a glass of beer. The original rule uses the eight cell neighborhood with births on 1, 3, 5, and 7 neighbors and survivors on exactly 1 neighbors. The rule is modified at each step by XOR'ing the result with the history one time step back. Swapping two adjacent time steps will bring the glass back exactly. The first figure is the starting configuration, the second after 50 steps of evolution. At this point one bit in the *upper left hand quadrant* is flipped, and the dynamics is reversed. The glass is restored in all places beyond 50 steps from the flipped bit. Note the effect of a "speed of light" in the problem



Self-organized Criticality and Cellular Automata, Figure 10
A snapshot of the forest fire model on a 450 by 200 periodic lattice. Trees are continuously burning at a slow rate, while fires burn them down and spread to nearest neighbor trees. Here the four cell neighborhood is used

large systems is that stable spiral structures form and set up a steady rotation. For a review of this and several related models, see [21].

The Sandpile Revisited

Very little is known analytically about general cellular automata. However, in a series of papers, Deepak Dhar and co-workers have shown that the sandpile model has some rather remarkable mathematical properties [22,23,24,25]. In particular, the critical ensemble of the system has been well characterized in terms of an Abelian group. In the following I will generally follow the discussions given in [2,26].

Dhar introduced the useful toppling matrix $\Delta_{i,j}$ with integer elements representing the change in the height, z at site i resulting from a toppling at site j [22]. More precisely, under a toppling at site j, the height at any site i becomes $z_i - \Delta_{i,j}$. For the simple two dimensional sand model the toppling matrix is thus

$$\begin{array}{ll} \Delta_{i,j} = 4 & i = j \\ \Delta_{i,j} = -1 & i, j \text{ nearest neighbors} \\ \Delta_{i,j} = 0 & \text{otherwise.} \end{array} \tag{3}$$

For this discussion there is little special to the specific lattice geometry; indeed, the following results easily generalize to other lattices and dimensions. The analysis requires only that under a toppling of a single site i, that site has its slope decreased ($\Delta_{i,i} > 0$), the slope at any other site is either increased or unchanged ($\Delta_{i,j} \le 0$, $j \ne i$), the total amount of sand in the system does not increase ($\sum_j \Delta_{i,j} \ge 0$), and, finally, that each site be connected through toppling events to some location where sand can be lost, such as at a boundary.

For the specific case in Eq. (3), the sum of slopes over all sites is conserved whenever a site away from the lattice edge undergoes a toppling. Only at the lattice boundaries can sand be lost. Thus the details of this model depend crucially on the boundaries, which we take to be open. A toppling at an edge loses one grain of sand and at a corner loses two.

The actual value of the maximum stable height z_T is unimportant to the dynamics. This can be changed by simply adding constants to all the z_i. Thus, as in Sect. "Self-Organized Criticality", I consider $z_T = 3$. With this convention, if all z_i are initially non-negative they will remain so, and I thus restrict myself to states C belonging to that set. The states where all z_i are non-negative and less than 4 are called stable; a state that has any z_i larger than or equal to 4 is called unstable. One conceptually useful configuration is the minimally stable state C^* which has all the heights at the critical value z_T. By construction, any addition of sand to C^* will give an unstable state leading to a large avalanche.

I now formally define various operators acting on the states C. First, the "sand addition" operator α_i acting on any C yields the state $\alpha_i C$ where $z_i = z_i + 1$ and all other z are unchanged. Next, the toppling operator t_i transforms C into the state with heights z'_j where $z'_j = z_j - \Delta_{i,j}$. The operator U which updates the lattice one time step is now simply the product of t_i over all sites where the slope is unstable,

$$UC = \prod_i t_i^{p_i} C \tag{4}$$

where $p_i = 1$ if $z_i \ge 4$; 0 otherwise. Using U repeatedly gives the relaxation operator R. Applied to any state C this corresponds to repeating U until no more z_i change. Neither U nor R have any effect on stable states. Finally, I define the avalanche operators a_i describing the action of adding a grain of sand followed by relaxation

$$a_i C = R \alpha_i C\,. \tag{5}$$

At this point it is not entirely clear that the operator R exists; in particular, it might be that the updating procedure enters a non-trivial cycle consisting of a never ending avalanche. I now prove that this is impossible. First note that a toppling in the interior of the lattice does not change the total amount of sand. A toppling on the boundary, however, decreases this sum due to sand falling off the edge. Thus, during an avalanche the total sand in the system is a non-increasing quantity. No closed cycle can have toppling at the boundary since this will decrease the sum. Next, the sand on the boundary will monotonically increase if there is any toppling one site further in. This also can not happen in a cycle; thus, there can be no topplings one site away from the edges. By induction there can be no toppling arbitrary distances in from the boundary; thus, there can be no cycle, and the relaxation operator exists. Note that for a general geometry this argument requires that every site be eventually connected to an edge where sand can be lost.

With a system lacking edges, such as under periodic boundaries, no sand would be lost and thus cycles are expected and easily observed. These models might be called "Escher models" after the artist constructing drawings of water flowing perpetually downhill and yet circulating in the system. While little is known about the dynamics of this variation on the sandpile model, some studies have been done under the nomenclature of "chip-firing games" [27]. It has been argued [28] that this lossless sandpile model on an appropriate lattice is capable of universal computation.

I now introduce the concept of recursive states. This set, denoted $\mathcal{R}$, includes those stable states which can be reached from any stable state by some addition of sand followed by relaxation. This set is not empty because it contains at least the minimally stable state C^*. Indeed, that state can be obtained from any other by carefully adding just enough sand to each site to make each z_i equal to three. Thus, one might alternatively define $\mathcal{R}$ as the set of states which can be obtained from C^* by acting with some product of the operators a_i.

It is easily shown that there exist non-recursive, transient states; for instance, no recursive state can have two adjacent heights both being zero. If you try to tumble one site to zero height, then it drops a grain of sand on its neighbors. If you then tumble a neighbor to zero, it dumps a grain back on the original site. One can also show that the self-organized critical ensemble, reached under random addition of sand to the system, has equal probability for each state in the recursive set. This is a consequence of the Abelian nature of this system, as discussed below.

The crucial results of [22,23,24,25] are that the operators a_i acting on stable states commute, and they generate an Abelian group when restricted to recursive states. I begin by showing that the operators commute, that is $a_i a_j C = a_j a_i C$ for all C. First I express the a's in terms of toppling and adding operators

$$a_i a_j C = \left(\prod_{k=1}^{n_1} t_{l_k}\right) \alpha_i \left(\prod_{k=n_1+1}^{n} t_{l_k}\right) \alpha_j C \qquad (6)$$

where the specific number of topplings n_1 and n depend on i, j, and C. Acting on general states, the operators t and α all commute because they merely linearly add or subtract heights. Therefore I can shift α_i to the right in this expression:

$$a_i a_j C = \left(\prod_{k=1}^{n} t_{l_k}\right) \alpha_i \alpha_j C\,. \qquad (7)$$

Now I rearrange the product of topplings. In the nontrivial case that the α-operators render either i or j (or both) unstable, the product must contain toppling operators corresponding to those unstable sites. I shift those operators to the right. Those operators constitute by definition the update operator, U, so I can write

$$a_i a_j C = \left(\prod t_{l_k}\right) U \alpha_i \alpha_j C \qquad (8)$$

where the factors within the bracket are the remaining t's. Now, the update operator may leave some sites still unstable, and then the product must include further toppling operators; working on those sites, I can pull out another factor of the update operator. This procedure can be repeated until I have used all the toppling factors and the state is stable. Thus, I can identify the operator within the brackets in Eq. (8) as the relaxation operator R. But $\alpha_i \alpha_j C$ is the same state as $\alpha_j \alpha_i C$, so $a_i a_j C = a_j a_i C$.

A trivial consequence of this argument is that the total number of tumbling events occurring in the operations $a_i a_j C$ and $a_j a_i C$ are the same. Of course, if a particular site k tumbles it can be caused by either addition; the orders of the tumbling events may or may not be altered.

An intuitive argument that sand addition may be commutative uses an analogy with combining many digit numbers under long addition. The tumbling operation is much like carrying, except rather than transferring to the next digit, the overflow spreads to several neighbors. As addition is known to be Abelian, despite the confusing elementary-school rules, I might expect the sandpile addition rule also to be.

I now prove that the avalanche operators have unique inverses when restricted to recursive states; that is, there exists a unique operator a_i^{-1} such that $a_i(a_i^{-1}C) = C$ for all C in $\mathcal{R}$. This implies that the operators a_i acting on the recursive set generate an Abelian group. For any recursive state C I first find another recursive state such that a_i acting on it gives C, and I then show that this construction is unique.

I begin by adding a grain of sand at site i to the state C and then relax the system. This generates a new recursive state $a_i C$. Now since the state C is by assumption recursive, there is some way to add sand to regenerate C from any given state. In particular, there is some product P of addition operators a_j such that

$$C = P a_i C\,. \qquad (9)$$

But the a's commute, so I have

$$C = a_i P C \qquad (10)$$

and thus PC is a recursive state on which a_i gives C.

I must now show that this state is unique. Consider repeating the above process to find a series of states C_n satisfying

$$(a_i)^n C_n = C\,. \qquad (11)$$

Because on a finite system the total number of stable states is finite, the sequence of states C_n must eventually enter a loop. I can run backwards around this loop by adding back the sand repeatedly to the given site. As the original state C appears in resupplying the sand, C itself must itself belong to the loop. Calling the length of the loop m, I have $(a_i)^m C = C$. I now uniquely define $a_i^{-1} C = a_i^{m-1} C$.

I now have sufficient machinery to count the number of recursive states. As all such can be obtained by adding sand to C^*, I can write any state $C \in \mathcal{R}$ in the form

$$C = \left(\prod_i a_i^{n_i} \right) C^* \,. \tag{12}$$

Here the integers n_i represent the amount of sand to be added at the respective sites. However, in general there are several different ways to reach any given state. In particular, adding four grains of sand to any one site must force a toppling and is equivalent to adding a single grain to each of its neighbors. This can be expressed as the operator statement

$$a_i^4 = \prod_{j \in nn} a_j \tag{13}$$

where the product is over the nearest neighbors to site i. I can rewrite this equation by multiplying by the product of inverse avalanche operators on the nearest neighbors on both sides, thus obtaining for any site i

$$\prod_j a_j^{\Delta_{ij}} = E \tag{14}$$

where E is the identity operator. This allows me to shift the powers appearing in Eq. (12). Define N to be the number of sites in the system. If I label states by the vector $\mathbf{n} = (n_1, n_2, n_3, \dots, n_N)$ I see that two states are equivalent if the difference of these vectors is of the form $\sum_j \beta_j \Delta_{ij}$ where the coefficients β_j are integers. These are the only constraints; if two states can not be related by toppling they are independent. Thus any vector $\mathbf{n}$ can be translated repeatedly until it lies in an N-dimensional hyper-parallelepiped whose base edges are the vectors Δ_{ji}, $j = 1, \dots, N$. The vertices of this object have integer coordinates and its volume is the number of integer coordinate points inside it. This volume is just the absolute value of the determinant of Δ. Thus the number of recursive states equals the absolute value of the determinant of the toppling matrix Δ.

For large lattices this determinant can be found easily by Fourier transform. In particular, whereas there are $4N$ stable states, there are only

$$\exp\left(N \int_{(-\pi,-\pi)}^{(\pi,\pi)} \frac{\mathrm{d}^2 q}{(2\pi)^2} \ln(4 - 2q_x - 2q_y) \right) \simeq (3.2102\dots)^N \tag{15}$$

recursive states. Thus starting from an arbitrary state and adding sand, the system "self-organizes" into an exponentially small subset of states forming the attractor of the dynamics.

An Isomorphism

Following [26], I now look into the consequences of stacking sand piles on top of one another. Given stable configurations C and C' with configurations z_i and z'_i, I define the state $C \oplus C'$ to be that obtained by relaxing the configuration with heights $z_i + z'_i$. Clearly, if either C or C' is a recursive state, so is $C \oplus C'$.

Under the operation $\oplus$ the recursive states form an Abelian group isomorphic to the algebra generated by the a_i. First, the addition of a state C with heights z_i is equivalent to operating with a product of a_i raised to z_i, that is

$$B \oplus C = \left(\prod a_i^{z_i} \right) B \tag{16}$$

for any recursive state B. The operation $\oplus$ is associative and Abelian because the operators a_i are.

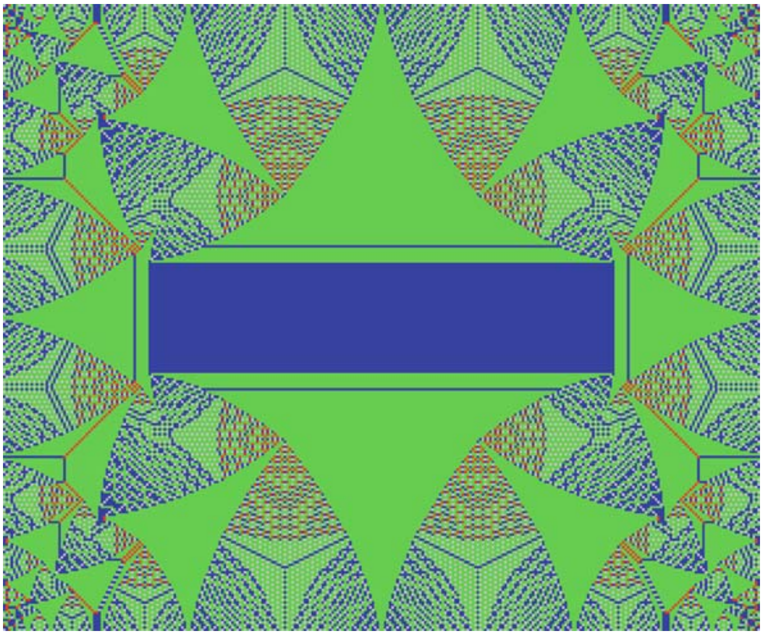
Since any element of a discrete group raised to the order of the group gives the identity, it follows that $a_i^{|\Delta|} = E$. This implies the simple formula $a_i^{-1} = a_i^{|\Delta|-1}$. The analog of this for the states is the existence of an inverse state, $-C$

$$-C = (|\Delta| - 1) \otimes C \,. \tag{17}$$

Here, $n \otimes C$ means adding n copies of C and relaxing. The state $-C$ has the property that for any state $B \oplus C \oplus (-C) = B$.

The state $I = C \oplus (-C)$ represents the identity and has the property $I \oplus B = B$ for every recursive state B. The state which is isomorphic to the operator a_i is simply $a_i I$. The identity state provides a simple way to check if a state, obtained for instance by a computer simulation, has reached the attractor, i. e. if a given state is a recursive state: A stable state is in $\mathcal{R}$ if and only if $C \oplus I = C$. The proof is simple. By construction, a recursive state has this property. On the other hand, since I is recursive, so is $C \oplus I$.

The identity state can be constructed by taking any recursive state, say C^* and repeatedly adding it to itself to use $|\Delta| \otimes C = I$. However, on any but the smallest lattices, $|\Delta|$ is a very large integer. A more economical scheme is to start with an empty table but use sandy boundary conditions which continually pour sand onto the table. Once it reaches a steady state, switch to open boundary condi-



Self-organized Criticality and Cellular Automata, Figure 11

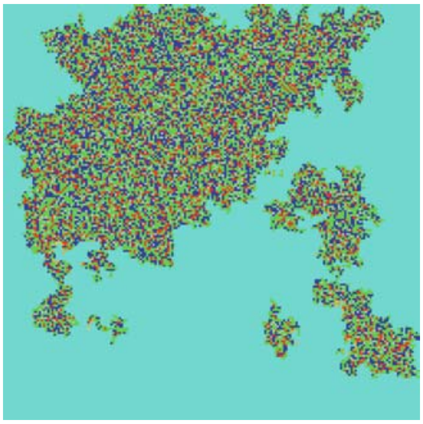
tions and let the sand run back off. This then relaxes to the desired identity. Figure 11 shows the identity state on a 302 by 250 lattice. Note the fractal structure, with features on many length scales.

Majumdar and Dhar [25] have constructed a simple "burning" algorithm to determine if a state belongs to the recursive set. For a given configuration, first add one particle to each of the edge sites and two particles to the corners. This again corresponds to imagining a large source of sand just outside the boundaries, which then tumbles one step onto the system. Then return to open boundaries and update according to the usual rules. If and only if the original state is recursive, this will generate an avalanche under which each site of the system tumbles exactly once. Also, the final state after the avalanche will be identical to the original. However, if the state is not recursive, some untumbled sites will remain. Figure 12 shows such a process underway on the configuration of Fig. 1. Here sites which have already burned are shown in cyan, while the remaining sites in the center have not yet tumbled. The small number of sites shown in orange are the still active sites, which eventually burn the entire remaining lattice.

The burning algorithm provides a simple way to prove that the avalanche regions are simply connected once one is in the critical state. In a burning process, any sub-lattice of the original will have all of its sites tumbled onto from outside. This is the condition for starting a burning on the sub-lattice. Thus, if a configuration is in the critical ensemble for the whole lattice, then any extracted piece of



Self-organized Criticality and Cellular Automata, Figure 12
The burning algorithm being applied to the state in Fig. 1. Burnt sites are *cyan*, burning sites are *orange*, and the remaining sites are colored as previously. This avalanche eventually tumbles every site exactly once

this configuration on a subset of the original lattice is also in the critical ensemble of the extracted part. Now suppose that one constructs an avalanche with any initial addition to a state from the critical ensemble. In any subregion enclosed by this avalanche, sand will fall from the tumbling sites on its outside. Since the sub-lattice is itself in its own critical ensemble, this must induce an avalanche which, by the burning algorithm, will tumble all enclosed sites. Thus any avalanche on a state from the critical ensemble cannot leave untumbled any sites in a region isolated from the boundary, i. e. an untumbled island. This result that avalanches must be simply connected does not follow for states outside the recursive set, as can be easily demonstrated by considering a sandpile with a hole of empty sites in the middle.

The burning algorithm has several amusing consequences. One is that any configuration with only height 2 or 3 present is in the critical ensemble as long as the lattice has corners. For example, with all height 2, the burning will start at the four corners of a rectangular lattice and steadily work its way to the center of the system. Another consequence is that in addition to the tumbling region from an avalanche being simply connected, so will the smaller region where the number of tumblings exceed any fixed number; i. e. the region of sites that tumble twice or more is also simply connected.

Future Directions

Simple models as implemented by cellular automata provide a rich area for the study of complex phenomena. Some systems can self organize with physics at many scales, while others provide fascinating demonstrations of thermodynamic laws. I have only touched on a few issues here, leaving out many related topics such as lattice gasses, driven interfaces in random media, growth processes, and evolution. As the ease of programming and the speed of modern computers continue to rush forward, so will the fascination with such models.

Acknowledgments

I am thankful for discussions with many people, but most particularly P. Bak, D. Dar, E. Fredkin, N. Margolis, M. Paczuski, T. Toffoli, F. Van Scoy, and G. Vichniac. Article Outline

Glossary

Attractor A special set of system states approached by a dynamical system after some time has passed when starting from a variety of initial states.

Autopoiesis The process by which systems maintain their identity and organization and regenerate their components in the course of their operation.

Competition and cooperation Types of interaction between two or more elements of a system. Competition refers to each element striving to maximize its use of a finite and/or non-renewable resource. Cooperation refers to the elements engaging in a mutually beneficial exchange.

Complexity Measure of number of elements and way of their interaction (structural c.); measure of variety of behavioral repertoire of a system (functional c.).

Constructive system A system whose later components are generated during the interaction of its earlier components.

Dynamics The quantitative development of a system's state variables over time.

Emergence The appearance of qualitatively new phenomena on higher levels of a hierarchical system.

Evolution A process of structural or qualitative change in some direction.

Instability Inability of a system to keep its state or structure.

Mode Macroscopic behavior of a system caused by the interaction of its microscopic parts via long-range correlations.

Non-equilibrium System state with inflow of matter, energy and/or information causing it to stay away from its most probable state under the hypothetical condition of isolation.

Phase transition A point at which the appearance or behavior, or qualitative nature of the steady state of a system changes suddenly.

Resilience Measure of a system's ability to remain within a domain of stability in response to fluctuations of the system by a perturbation, and the ability of the system to return to that stable domain having once left.

Self-organized criticality The ability of a system to evolve in such a way as to approach a critical point and then maintain itself at that point.

Definition of the Subject

Self-organization is a core concept of Systems Science. It refers to the ability of a class of systems (self-organizing systems (SOS)) to change their internal structure and/or their function in response to external circumstances. Elements of self-organizing systems are able to manipulate or organize other elements of the same system in a way that stabilizes either structure or function of the whole against external fluctuations. The process of self-organization is often achieved by growing the internal space-time complexity of a system and results in layered or hierarchical structures or behaviors. This process is understood not to be instructed from outside the system and is therefore called *self-organized*.

Modern ideas about self-organization start with the foundation of cybernetics in the 1940s. W. Ross Ashby, H. von Foerster and N. Wiener, among others, have contributed to an early understanding. Later, the concept was adopted in physics and nowadays pervades most of natural sciences. Many systems have been identified as possessing aspects of self-organization, though a clear definition is still lacking. As a result of this inaccuracy, the theory of self-organization is still in its infancy. While the concept has found applications in the social sciences and engineering as well, SOSs are an area of active research, with fundamental questions still being explored.

Introduction

Over the last decades a variety of features have been identified as typical for self-organizing systems. Not all of these features are present in all systems able to self-organize. Self-organizing systems are *dynamic*, often *non-determin-*

istic, *open*, exist *far from equilibrium* and sometimes employ *autocatalytic amplification of fluctuations*. Often, they are characterized by *multiple time-scales* of their internal and/or external interactions, they possess a *hierarchy of structural and/or functional levels* and they are able to *react* to external input *in a variety of ways*. Many self-organizing systems are *non-teleological*, i. e. they do not have a specific purpose except their own existence. As a consequence, *self-maintenance* is an important function of many self-organizing systems. Most of these systems are *complex* and use *redundancy* to achieve *resilience* against external pertubation tendencies.

Key aspects of self-organizing systems are:

- Growth of Complexity
- Emergence of new phenomena
- Positive and negative feedback loops of internal regulation.

The process of self-organization has been invoked to explain numerous phenomena in the natural sciences. From non-living systems like galaxies and stars down to nanoparticle aggregates, self-organizing systems have been observed. In the living world cells, organisms and ecosystems provide examples of systems classified as self-organizing. The concept has found applications in man-made systems like communication networks, societies, economies, and has been identified to be at work in the world of ideas in the development of world views, scientific beliefs and norm systems.

History of the Concept of Self-Organization

Early History

The concept of self-organization can be traced back to at least two sources: Western philosophy influenced heavily by Greek thinking; and eastern philosophy, centered around the process thinking of Bhuddism. The ideas derived from both sources resound with the modern way of thinking about self-organization although the word itself had never been used.

On wondering about the origin of the world, Greek atomists from Democritos of Abdera to Epicuros of Samos argued that world order arose from chance collisions of particles. First, the cosmos (from Greek *kosmos* = *the ordered*) did not exist but chaos instead (from Greek *chaos* = *the disordered*). In modern times chaos theory has taken up this topic again, with deep connections to ideas about self-organization and the origin of order in the universe.

In the Christian tradition, St Thomas Aquinas contributed through his interest in logical proofs for the existence of God. One of these proofs considered God to be the ultimate organizer or designer. The argument was that everything had to be organized and this called for an organizer. In turn, the organizer had to be organized and so on back to the original organizer: this was God. Since God is present without cause (otherwise he would have to be organized by another entity), he must have somehow organized himself.

The Bhuddist way of thinking, on the other hand, was fundamentally process-oriented. Things are considered not to be in static existence, but rather are thought to be generated and maintained by proper processes. The emphasis on processes is reminescent of self-organizing systems whose structure is determined by proper processes of internal and external interactions.

The First Use of the Term

Work on General Systems Theory (von Bertalanffy) [1] and Cybernetics (Wiener) [2] paved the way for the idea of self-organization.

The concept of a self-organizing system was introduced by Ashby in 1947 [3]. In the 1950s a self-organizing system was considered to be a system which changes its basic structure as a function of its experience and environment. The term was used by Farley and Clark in 1954 to describe learning and adaptation mechanisms [4]. Ashby [5], in 1960, redefined a self-organizing system to include the environment with the system proper. Von Foerster argued [6], also in 1960, that a self-organizing dynamical system possesses some stable structures (eigenvalues, attractor states) which he later termed eigenbehavior.

Further Developments

This notion was further developed by Haken [7] in 1977 who termed the global cooperation of elements of a dynamical system – resulting in it assuming an attractor state – *self-organization*. Both Haken and Kauffman (1993) [8] argued for a deep connection between self-organization and *selection*. Haken found that modes of collective behavior are competing against each other and considered this process to be Darwinian selection in the non-living world. Kauffman, on the other hand, emphasized the role of constraints on the direction of evolution (mostly of the living), caused by self-organization.

Already in the 1970s, however, ideas branched out into different directions. One branch of the development of the idea deepened the relation to studies of learning and adaptation (Conrad, Kohonen, [9,10]), another branch studied processes of self-organization in systems far from equilibrium (Prigogine, Haken) [11,12]. Chaos

Self-organizing Systems, Table 1
Examples of Self-Organizing Systems

System	Flow	Self -organizing entities	Emergence
Atmosphere	Solar energy	Gas molecules	Patterns of atmospheric circulation
Climate	Energy	Weather conditions (humidity, precipitation, temperature, ...)	Distribution patterns
Liquid between plates	Heat	Particle circulation	Movement patterns
Laser	Excitation energy	Phase of light waves	Phase-locked mode
Reaction vessel	Chemicals for BZ reaction	Chemical reactions	Patterns of reaction fronts
Neural networks	Information	Synapses	Connectivity patterns
Living cells	Nutrients	Metabolic reactions	Metabolic pathways/network patterns
Food webs	Organisms of different species	Species rank relation	Networks of species
Highway traffic	Vehicles	Distance of vehicles	Density waves of traffic
City	Goods, information	Human housing density	Settling patterns
Internet	Computer nodes	Connections between nodes	Network connection pattern
Web	Information posted in websites	Links between websites	Patterns of web communities

theory (Thom, Mandelbrot) [13,14] was the line of inquiry into nonlinear systems in mathematics, whereas autopoiesis and self-maintenance where at center stage in biology (Eigen, Rosen) [15,16] neurophysiology (von der Mahlsburg, Linsker [17,18]) and cognitive science (von Foerster, Maturana and Varela) [19,20].

In recent years, self-organizing systems have assumed center stage in the natural sciences [21,22], and the social sciences [23,24,25]. Engineering is beginning to see the usability of the concept [26] in connection with the approach of nano-scale applications and the growing complexity of human artefacts.

Examples of Natural Self-Organizing Systems

Classical examples of natural self-organizing systems are the formation of Benard convection cells in non-equilibrium thermodynamics, the generation of laser light in non-linear optics and the Belousov–Zhabotinsky reaction in chemistry. These are examples from the non-living world, and the complexity of resulting macroscopic space-time patterns is restricted.

Nearly unrestricted complexity through self-organization can be achieved in the living world. For instance, the interaction of species in foodwebs could be looked at from this point of view [22]. Here, we shall briefly look at the self-organization of the Earth's biosphere known as the Gaia hypothesis [27]. This hypothesis states that Earth's living and non-living components self-organize into a single entity called *Gaia*. Gaia can be understood as the whole of the biosphere, that is able to self-stabilize. The model states, in other words, that the biomass of Earth self-regulates to make conditions on the planet habitable for life. In this way, a sort of homeostasis would be sought by the self-organizing geophysical/physiological system of Earth.

In recent years, the Gaia hypothesis has found its place in Earth Systems Science as the realization that there is just one global ecosystem, containing the entirety of resources and all living organisms, all interacting with each other in multiple regulatory cycles. These ideas have been connected to the Darwinian theory of evolution via natural selection [28,29], providing a mechanism by which such a stable state can be assumed to have emerged.

Other examples of natural self-organizing systems can be found in Table 1.

Examples of Artificial Self-Organizing Systems

There are numerous examples of man-made systems or systems which involve man that exhibit self-organization phenomena. Among them are traffic patterns, self-organizing neural networks, celular phone networks or the development of web communities.

The example we shall briefly discuss is that of traffic flow patterns. Macroscopic patterns of traffic jams on highways have been observed and experimentally examined [30]. Their appearance is closely related to traffic density, the model of behavior for drivers and the traffic flow that this allows [31]. Traffic flow is an open system, and it develops waves of traffic jams (solitons) excited by the density of traffic. Transitions between different traffic flow patterns have been considered as phase transitions, typical products of self-organization in the non-living world.

A number of examples of self-organizing systems from different fields is given in Table 1, lower section.

Explanatory Concepts of Self-Organization

Despite half a century of inquiry, the theory of self-organizing systems is still in its infancy. There is no "standard model" of SOS, only various aspects emphasized by different researchers. Here we shall discuss the most important of these.

Non-Equilibrium Thermodynamics

Thermodynamics has been concerned with the notion of order and disorder in physical systems for more than a century. The theory of self-organization has to address fundamental issues of this field. The most important question in this regard is, how order can arise through self-organization.

Classical thermodynamics has focused on closed systems, i. e. systems isolated from external influence in the form of matter and energy flow. This allowed to understand the processes involved when a system evolves undisturbed. A key result of this inquiry is the second law of thermodynamics, originally formulated by Carnot and later refined by Clausius in the 19th century. It states that "any physical or chemical process under way in a system will always degrade the energy". Clausius introduced a quantitative measure of this irreversibility by defining entropy:

$$S \equiv \int \mathrm{d}Q/T \tag{1}$$

with Q the heat energy at a given temperature T. In any process of a closed system, entropy always rises

$$\frac{\mathrm{d}S}{\mathrm{d}t} \geq 0\,. \tag{2}$$

According to Eddington, 1928 [32] this universal increase in entropy "draws the arrow of time" in nature.

Boltzmann had reformulated entropy earlier in terms of the energy microstates of matter. In his notion, entropy is a measure of the number of different combinations of microstates in order to form a specific macrostate.

$$S = k_{\mathrm{B}} \ln(W) \tag{3}$$

with k_{B} Boltzmann's constant and W the thermodynamic probability of a macrostate. He argued that the macrostate with most microstates (with maximum entropy) would be most probable and would therefore develop in a closed system. This is the central tenet of equilibrium thermodynamics.

More interesting phenomena occur if the restrictions for isolation of a system are removed. Nicolis and Prigogine [11] have examined these systems of non-equilibrium thermodynamics which allow energy and matter to flow across their boundary. Under those conditions, total entropy can be split into two terms, one characterizing internal processes of the system, $\mathrm{d}_{\mathrm{i}}S$ and one characterizing entropy flux across the border $\mathrm{d}_{\mathrm{e}}S$. In a generalization of the second law of thermodynamics, Prigogine and Nicolis postulated the validity of the second law for the internal processes,

$$\frac{\mathrm{d}_{\mathrm{i}}S}{\mathrm{d}t} \geq 0 \tag{4}$$

but explicitly emphasized that nothing can be said about the sign of the entropy flux. Specifically, it could carry a negative sign and it could be larger in size than the internal entropy production. Since the total entropy is the sum of both parts, the sign of the total entropy change of an open system could be negative,

$$\frac{\mathrm{d}S}{\mathrm{d}t} = \frac{\mathrm{d}_{\mathrm{i}}S}{\mathrm{d}t} + \frac{\mathrm{d}_{\mathrm{e}}S}{\mathrm{d}t} < 0 \tag{5}$$

a situation impossible in equilibrium thermodynamics. Thus, increasing order of the system considered would be possible through export of entropy. Self-organization of a system, i. e. the increase of order, would not contradict the second law of thermodynamics. Specifically, the non-equilibrium status of the system could be considered a source of order.

Even in the distance from thermodynamic equilibrium, however, certain stable states will occur, the *stationary* states. These states assume the form of *dissipative structures* if the system is far enough from thermodynamic equilibrium and dominated by non-linear interactions. The preconditions for dissipative structures can be formulated as follows:

1. The system is open.
2. The inner dynamics is mainly non-linear.
3. There are cooperative microscopic processes.
4. A sufficient distance from equilibrium is assumed, e. g. through flows exceeding critical parameter values.
5. Appropriate fluctuations appear.

If those conditions are fullfilled, the classical thermodynamic branch of stationary solutions becomes unstable and dissipative structures become stable system solutions.

Synergetics

Prigogine's description of dissipative structures is formally limited to the neighborhood of equilibrium states. As

Haken pointed out, this is a severe restriction on its application and in particular precludes its formal application to living systems. Instead, Haken proposed *order parameters* and the *slaving principle* as key concepts for systems far from equilibrium. Let the time evolution of a continuous dynamical system is described by

$$\frac{\mathrm{d}\mathbf{q}}{\mathrm{d}t} = \mathbf{N}(\mathbf{q}, \alpha) + \mathbf{F}(t) \tag{6}$$

where $\mathbf{q}(t) = [q_1(t), q_2(t), \ldots, q_N(t)]$ is the system's state vector and $\mathbf{N}$ is the deterministic part of the system's interaction whereas $\mathbf{F}$ represent fluctuating forces, and α are the so-called control parameters. Then the stable and unstable parts of the solution can be separated by linear stability analysis, as can the time dependent and time independent parts. As a result, the solution can be written as

$$\mathbf{q}(t) = \mathbf{q}_0 + \sum_u \xi_u(t)\mathbf{v}_u + \sum_s \xi_s(t)\mathbf{v}_s \tag{7}$$

$\mathbf{v}_u, \mathbf{v}_s$ are the unstable and stable modes, respectively, and $\xi_u(t), \xi_s(t)$ are their amplitudes. These amplitudes obey the following equations

$$\frac{\mathrm{d}\xi_u}{\mathrm{d}t} = \lambda_u \xi_u + N_u(\xi_u, \xi_s) + \mathbf{F}_u(t) \tag{8}$$

$$\frac{\mathrm{d}\xi_s}{\mathrm{d}t} = \lambda_s \xi_s + N_s(\xi_u, \xi_s) + \mathbf{F}_s(t) \tag{9}$$

with λ_u, λ_s characterizing the linear part of the equations and function N summarizing the non-linear deterministic components. The slaving principle formulated by Haken now allows to eliminate the stable mode development by expressing them as a function of unstable modes

$$\xi_s(t) = f_s[\xi_u(t), t] \,. \tag{10}$$

Thus, the unstable modes (order parameters) enslave the stable modes and determine the development of the system's dynamics. This result is useful both to describe *phase transitions* and *pattern formation* in systems far from equilibrium.

Synergetic concepts have been applied in a variety of disciplines [33].

Chaos and Complexity

The treatment of *chaotic systems* has been derived from non-linear system theory. Chaotic systems are usually low-dimensional systems which are unpredictable, despite being deterministic. The phenomenon was originally discovered by the meteorologist E. Lorenz in 1963 [34], although H. Poincare in 1909 was aware of the possibility of certain systems to be sensitive to initial conditions [35]. The reason for the difficulty to predict their behavior stems from the fact that initially infinitesimal differences in trajectories can be amplified by non-linear interactions in the system. These instabilities, together with the lack of methods for solving even one-dimensional non-linear equations analytically, produce the difficulties for predictions. Modern theory of deterministic chaos came into being with the publication of a seminal article by May in 1976 [36].

Complex systems, on the other hand, have many degrees of freedom, mostly interacting in complicated ways, i. e. they are high-dimensional. All the more astonishing is the fact that our world is not totally chaotic in the sense that nothing can be predicted with any degree of certainty. It became apparent, that chaotic behavior is but one of the ways non-linear dynamical systems behave, with other modes being complex attractors of a different kind.

Complexity itself can be measured, notably there exist a number of complexity measures in computer science, but describing or measuring complexity is not enough to understand complex systems.

Self-Organized Criticality

For particular high-dimensional systems, Bak et al. [43] have suggested a dynamic system approach toward the formation of fractal structures, which are found to be widespread both in natural and artificial environments. Their canonical example was a pile of sand. They examined the size and frequency of avalanches under certain well-prepared conditions, notably that grains of sand would fall on the pile one by one. This is an open system with the forces of gravity and friction acting on the possibly small fluctuations that are caused by deviations in the hitting position of each grain of sand. They observed how the grains would increase the slope of the sand pile until more or less catastrophic avalanches developed.

Bak suggested the notion of *self-organized criticality* (SOC) as a key concept which states that large dissipative systems drive themselves to a critical state with a wide range of length and time scales. This idea provided a unifying framework for the large-scale behavior in systems with many degrees of freedom. It has been applied to a diverse set of phenomena, e. g. in economic dynamics and biological evolution. SOC serves as an explanation for many power-law distributions observed in natural, social and technical systems, like earthquakes, forest fires, evolutionary extinction events, and wars. As opposed to the widely studied low-dimensional chaotic systems, SOC systems have a large number of degrees of freedom, and still exhibit fractal structures as are found in the extended space-time systems in nature.

The Hypercycle

In a series of contributions since 1971, Eigen and Schuster have discussed particular chemical reaction systems responsible for the origin, self-organization and evolution of life [37,38,39,40]. By considering *autocatalytic sets* of reactions they arrived at the most simple form of organization, the *hypercycle*, which is able to explain certain aspects of the origin of life. They have considered a chemical reaction system composed of a variety of self-reproductive macromolecules and energy-rich monomers required to synthesize those macromolecules. The system is open and maintained in a non-equilibrium state by a continuous flux of energy-rich momomers. Under further assumptions they succeeded in deriving Darwinian selection processes at the molecular level. Eigen and Schuster have proposed rate equations to describe the system.

The simplest system realizing the above mentioned conditions can be described by the following rate equations

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = (A_i Q_i - D_i)x_i + \sum_{k \neq i} w_{ik} x_k + \Phi_i(\mathbf{x}) \qquad (11)$$

where i enumerates the individual self-reproducing units and x_i measures their respective concentrations. Metabolism is quantified by the formation and decomposition terms $A_i Q_i x_i$ and $D_i x_i$. The ability of the self-reproducing entities to mutate into each other is summarized by the quality factor for reproduction, Q_i, and the term $w_{ik} x_k$ which takes into account all catalytic productions of one sort using the other. A_i, D_i are rate constants for selfreproduction and decay respectively. The flow term Φ_i finally balances the production/destruction in this open system in order to achieve $\sum_k x_k = \text{const.}$

By introducing a new feature called excess production

$$E_i \equiv A_i - D_i \qquad (12)$$

and its weighted average

$$\bar{E}(t) = \sum_k E_k x_k / \sum_k x_k \qquad (13)$$

and symbolizing the "intrinsic selection value" of a sort i by

$$W_{ii} = A_i Q_i - D_i \qquad (14)$$

one arrives at reduced rate equations

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = (W_{ii} - \bar{E})x_i + \sum_{k \neq i} w_{ik} x_k \,. \qquad (15)$$

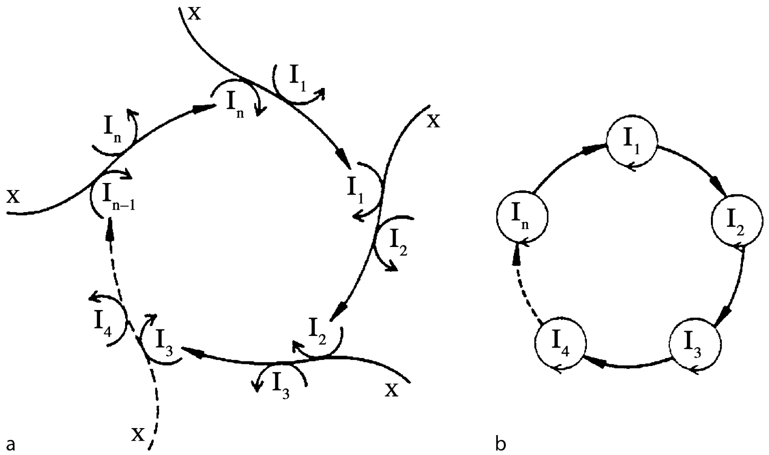
These equations can be solved under certain simplifying assumptions and notably yield the concept of a *quasi-species* and the following extremum principle: A quasi-species y_i is a transformed self-replicating entity with the feature that it can be considered as a cloud of sorts x_i whose average or consensus sequence it is. The extremum principle reads: Darwinian selection in the system of quasi-species will favor that quasi-species which possesses the largest eigen-value of the rate equation system above.

The Origin of Order

In the 1990s Kauffman [41] pointed out one of the weaknesses of Darwinian theory of evolution by natural selection: It cannot explain the '*origin* of species' but rather only their subsequent development. Kauffman instead emphasized the tendency of nature to constrain developments along certain paths, due to restrictions in the type of interaction and the constraints of limited resources available to evolution. In particular he held up the view that processes of spontaneous order formation conspire with the Darwinian selection process to create the diversity and richness of life on Earth.

Previously, Kauffman had formulated and extensively studied [42] the NK fitness landscapes formed by random networks of N Boolean logic elements with K inputs each. Kauffman observed the existence of cyclic attractor states whose emergence depended on the relation between N and K, and the absolute value of K. In the case of large K ($K \approx N$), the landscape is very rugged and behavior of the network appears stochastic. The state sequence is sensitive to minimal disturbances and to slight changes of the network. The attractor length is very large, $\approx N/2$, and there are many attractors. In the other extremal case, $K = 2$, the network is not very sensitive to disturbances. Changes of the network do not have strong and important consequences for the behavior of the system.

Kauffman proposed NK networks as a model of regulatory systems of living cells. He further developed the notion of a *canalizing function* that is a Boolean function in which at least one variable in at least one state can completely determine the output of the function. He proposed that canalizing functions are an essential part of regulatory genetic networks.



Self-organizing Systems, Figure 1
The Hypercycle (reproduced from [15])

Emergence and Top-Down Causation

The notion of *emergence* has been introduced in complex systems theory in order to explain the appearance of new qualitative features on the level of an entire system that could not be observed at the level of its components. Emergent behavior can be connected to the afore-mentioned complex attractors. It requires switching the level of description of behavior of a system, from local (component-centered) to global (system-centered), or at least to a meso-level (sub-system-centered). Emergent behavior happens when

a) the system shows qualitatively new behavior on a higher level of description which
b) could not have been easily predicted from the interactions of components at the lower level (obeys a non-linear relationship)
c) is the result of a self-organization process.

Emergence is strongly related to self-organization. It is often understood as a pattern formation process. While it essentially has to do with changing the perspective and looking at the system at a different level, it concerns itself with a change in behavior (e. g. the system is getting more organized, shows new coordinated modes of behavior). It has been further conjectured that there is top-down causation, i. e. the structures forming on the higher level of the system are able to affect the lower levels (system components) and influence them in a way that stabilizes the newly emergent behavior. Haken could show in the context of Synergetics that this phenomenon exists. *Top-down causation* is believed to be an important source of complexity, especially in living systems, because it stabilizes patterns.

Self-organization draws heavily from this source of qualitative innovation in complex systems.

Modeling Methods

A formal model is a simplified mathematical or algorithmic representation of a system. Often it has been simplified to the point of a carricature, and this has to be born in mind when making conclusions about the consequences of model predictions. No model can predict beyond the limits of its approximations.

Mean-Field Methods

One of the most important methods used to model complex systems is tied to the notion of dynamical systems. Dynamical systems are systems whose time development is accessible to a description by state changes. It entails the existence of a state space in which these changes can be traced and quantified.

Mean-field methods of description focus on average behavior. They abstract away from the local correlations between a system's elements and describe only long-range changes. For instance, the behavior of a planet could be described as a point on its trajectory around the star it circles. Detailed interactions of its atmosphere would not be part of that description.

Mean-field methods are formulated in the form of time-dependent differential or difference equations which can be solved under certain conditions and predict the behavior of a system in its state space.

Assuming that the state of a system can be subsumed in a vector of state variables **x** whose values are observable and depend on time, we can generally formulate an equation for continuous time development as:

$$\frac{\mathrm{d}\mathbf{x}}{\mathrm{d}t} = \mathbf{f}(\mathbf{x}) . \tag{16}$$

If time does not develop continuously, a discrete (iterative) equation can be used to describe system behavior:

$$\mathbf{x}_{t+1} = \mathbf{f}(\mathbf{x}_t) . \tag{17}$$

The notion is that the state of the system at time t, $\mathbf{x}(t)$ or $\mathbf{x}_t$, is everything that is of interest and can be known about the system. It turned out that with this extreme simplification many systems became treatable that would have otherwise resisted quantitative treatment. The non-linear nature of many of the state development equations, however, and the high-dimensionality of state space vectors often constitute prohibitive hurdles to exact or even approximate mathematical solution of these equations.

As a result, algorithmic approaches for modeling self-organizing systems have become more prevalent in recent years.

Agent-Based Models

A very general class of algorithmic systems is subsumed under the term agent-based models. In these systems, individual entities are modeled that interact with each other. Thus, the approximation of average behavior, and the interest for long-term behavior only is abandoned in favor of a microscopic description of the elements of a system and their interactions. The abstraction of features of a system is achieved through the assumption of rules of behavior of the agents, including their interaction behavior. Agent-based systems must be implemented as computational systems, and run on a computer to obtain results. Agents are assigned states, and transition rules between states, depending on interacting agents, and then these rules are executed in parallel over the set of agents under consideration.

Cellular Automata A particular subset of agent-based models is the class of cellular automata introduced by von Neumann [47] going back to lattice networks of Ulam. The agents of cellular automata are placed on a grid of cells and allowed to assume a finite number of states. Interactions are determined by state transition rules and the definition of a neighborhood, which determines the interactivity of the cellular automaton. Many variants of cellular automata exist, differing in the number of dimensions of the grid, the number of states, the sort and distribution of transition rules and the nature of the neighborhood.

A typical cellular automata model might, e. g. consist of digital cells (allowing only two states, "ON" and "OFF"), homogeneous and deterministic transition rules between states, a one-dimensional grid, and nearest-neighbor interactions. Cellular automata of this type have been thoroughly examined in [44,45] and show a surprising variety and richness in behavior.

In a cellular automaton like LIFE, for instance, one can observe how macroscopic and mesocopic structures appear through self-organization, that is, as a process determined solely by the local interaction of the CA's elements. some structures, e. g. spiral waves, are more resilient against perturbation than others, e. g. glider canons. A moving structure like a glider can be interpreted as an emergent phenomenon as it does not seem to be present on the microscopic scale (single CA cells do not move).

Graphs and Networks A more general class of automata can be formulated if the notion of cellular neighborhood is abandoned. Instead of a rigidly defined grid, a graph or network of automata connected through edges to other automata is introduced. Each node of the graph/network represents an automaton, with interactions allowed via edges.

The notion of a graph is, however, more general, and allows other agent-based systems to be simulated. For instance, the nodes of a graph might represent species of an ecosystem interacting with other species (connected by edges). Each species might be represented by a state counting the number of individuals of that species. Nodes might further hold information on particular features of individuals, and possibly their variants. Explicit simulations of such systems have been considered in the context of "Artificial Chemistries" [46].

In recent years, the structure and dynamics of networks has been a major focus of interest in the scientific community. Network science has become a converging point for different disciplines interested in modelling complex behavior.

Observables

Self-organizing phenomena rest on the appearance of particular sets of behaviors. If ever they are to be understood, a clear notion of observable quantities needs to be developed that allows a proper description of the behavior of such systems. At present, no such canonical set of observables exists, owing to the bewildering variety of systems that show signs of self-organization. However, one can discern a number of different measures and observables that might form the core of such a set [49].

Entropic and Information Theoretic Measures One class of observables can be considered entropic and information-theoretic measures. These measures have in common a statistical root, and seek to describe a self-organizing system in terms of the order (or disorder) that develops over time [48].

Stability Measures Another class of observables can be discussed as stability measures. In this class, systems are sought to be disturbed from their regular behavior in order to obtain a clearer idea of their resilience.

Scaling Measures A further class of observables can be attached to features of scaling. Both theoretical and experimental approaches can be used to vary the number of dimensions, number of equations/agents, number and complexity of interactions, etc, in these systems. Scaling behavior can then be observed for particular quantities and systems classified accordingly.

Patterns and Flows The defining observables of a self-organizing system are patterns. These refer to the collective behavior of the elements of a system, differentiating them from noise. If individual entities would not show such correlations in their behavior, self-organization could not be observed. Patterns can be described in a variety of ways, e. g. as multidimensional vectors, using spatial and temporal coordinates. If patterns change dynamically one can speak of flows.

The central tenet of self-organization is that systems exist whose pattern forming tendencies are determined by themselves, and not by an outside agency.

The Role of Self-Organization in Science, the Social Sciences and Engineering

Self-organization as a concept has assumed center stage in Science. With the advent of nonlinear systems and studies on complex systems in non-equilibrium situations, the explanatory power of self-organization now permeates every branch of scientific enquiry.

From structure formation at the level of super-galactic clusters, even starting from the development of the entire universe, down to microscopic particles and their interaction patterns, self-organizing phenomena have been postulated, theorized, observed and confirmed.

In particular the origin and evolution of life have been studied under the aspect of self-organization. Within Biology, the developmental process of organisms as well as their metabolisms, growth and learning have been identified as self-organizing processes.

In the humanities, the idea of self-organization has taken roots, although the paradigm is far from being fully recognized yet. Since the 1990s the origin and development of languages has been an object of study under the premise of self-organization. In social science the concept of self-organization has been studied since a number of years, due to the obvious fact that interaction between social actors generate a society. Even in psychology, self-organizing principles begin to appear.

Economy and Management Science have taken notice of the concept, and a growing number of enterprise concepts promote the idea of a form as a self-organizing entity.

Finally, Philosophy has embraced the concept of self-organization and connected it to earlier thoughts on the development of the scientific process and epistemology. Whitehead put forward his process philosophy, and Smuts, already in the 1920s, promoted the notion of holism which has strong connections to self-organization. Evolutionary epistemology was formulated as a response to traditional epistemology and emphasizes the aspect of natural selection affecting senses and cognitive abilities.

Engineering is beginning to grasp the ubiquity of self-organization in Nature. Specifically in the area of nanotechnology the concept is used extensively for the purpose of self-assembly of molecular entities. At nanoscales, it is very difficult to directly specify the structuring behavior of entities. As a result, self-organizing properties of matter are used to the advantage of the structural outcome.

Different kinds of infrastructure networks have been recognized as self-organizing, and Engineering begins to make use of the tendency of networked systems to self-organize.

In the area of adaptation, there exists a long tradition of making use of self-organization principles. The self-organizing feature map, introduced by Kohohen, has been a key step forward in the domain of unsupervised learning of artificial neural networks.

Open Issues and Future Directions

So far, there is no unique theory of self-organization. Over the course of many years different approaches have been used, but a coherent picture has not yet emerged.

An important open question in the area of the mathematical basis for self-organization is the formulation of a theory of *constructive (evolutionary) systems*, that is systems which, in the course of their development, generate new elements that subsequently interact with elements already created earlier.

Another question aims at the raison d'etre of *hierarchical systems*. Why do they form, how do they structure themselves, and what would be possible to apply from these principles in Engineering? Notably, how would one build self-organizing systems such that they do something useful? How could they be controlled?

In Science, the build-up of complexity remains a controversial issue. Is it true that evolution of the universe tends to increase complexity, or is there no tendency of complexity increase at all? What are the mechanisms by which Nature increases complexity, if any? How could we apply this knowledge in planning and managing complexity in the human world?

A wealth of questions remains, and it is anticipated that the 21st century will shed light on at least a few of them.

Article Outline

Glossary

Artificial life Artificial life refers to the study of artificial systems that exhibit lifelike properties, typically involving some form of self-replication and/or evolution. This is a very broad field of study and includes work involving computer simulations, cellular automata, chemistry, robotics, and synthetic biology.

Cellular automata A cellular automaton (CA) is a theoretical construct where a collection of cells are organized into regular grids or lattices. Many arrangements are possible, but typically one-dimensional CAs are composed of square cells arranged in a line, and two-dimensional CAs are composed of square cells arranged in a square grid. Each cell contains a finite state machine. The state of all cells in a CA are typically updated synchronously (at the same time) with each cell changing to a new state that is a function of its previous state and the previous states of its neighbors. The surrounding cells that affect a given cell's state transition are called the cell's neighborhood. CAs can simulate a wide variety of physical processes by designing an appropriate neighborhood and state transition function. CAs are most often studied by implementing them with computer simulations.

Finite state machine A finite state machine (FSM) is a conceptual computing machine with an input, output, and memory. At regular intervals in time the machine transitions (changes) to a new state, which is a function of the current state and the machine's current input. The output is a function of the input and the state. The function of the memory is to store the state information between each transition. FSMs are easily implemented with discrete digital electronic components, microcontrollers, or computer simulations. Implementations of FSMs are widely used to control industrial devices and consumer electronics.

Modular robot A modular robot is composed of distict "modules" which contain motors, mechanisms, electronics, and interconnections. Modules are typically designed so that they can easily be connected and disconnected from each other. In some modular robotic systems, many identical modules are assembled into larger robots. This allows the same set of modules to form robots optimized for different tasks. In other cases, the modules may be specialized for certain tasks, and when assembled they form a robot with additional functionality. Motivation for building modular robots includes increased versatility, ease of replacing damaged components, and potentially lower manufacturing costs.

Self-reconfigurable robot A self-replicating robotic system is a robotic device that exhibits some form of self-replication. This chapter is concerned primarily with directed robotic self-replication, in which a robotic device interprets some form of coded instructions in order to carry out the replication process. In nature deoxyribonucleic acid (DNA) typically encodes replication instructions. In the examples of robotic self-replication presented in this chapter, the instructions may be encoded in a computer program, an arrangement of modular components, or as a pattern of lines that guide the motion of a mobile robot.

Self-replication Self-replication is the process by which an entity creates a duplicate of itself. The most familiar example is the self-replication of living organisms, although other natural processes such as crystal growth can be classified as self-replication.

Universal constructor A universal constructor (UC) is a conceptual machine that reads instructions and executes them to construct an object. A key property of a UC is that it can construct any object which can be described to it via the instructions, including duplicates of itself. UCs have been demonstrated in computer simulations using cellular automata. Modern manufacturing tools, such as assembly robots and computer-controlled machine tools, are similar to UCs but practical limitations make these machines "somewhat less than universal" constructors. The ribosome, a complex molecule present in nearly all biological cells, performs a function very similar to that of a UC, assembling proteins according to instructions encoded in messenger ribonucleic acid (mRNA).

von Neumann universal constructor The mathematician John von Neumann proposed a cellular automata model of a universal constructor capable of self-replication. Many researchers have refined and improved von Neumann's original design since it was first presented in the 1950s. The original design used tens of thousands of cells in a two-dimensional CA with 29 states. The general structure of the model is a movable constructing arm controlled by instructions encoded in a long line of cells resembling a tape, conceptually similar to a computer-controlled robot arm.

Introduction

The concept of an artificial self-replicating system was introduced in the 1950s by John von Neumann [31]. Von Neumann introduced the theory of self-replicating automata and established a quantitative definition of self-replication. His early results on self-replicating machines have become useful in several diverse research areas such as: cellular automata, nanotechnology, macromolecular chemistry, and computing [8,23,26,27]. However, prior to the turn of the millennium, a fully autonomous self-replicating physical robot had never been implemented. In this chapter, a series of prototype designs from our laboratory and their physical implementation are described. We begin by discussing some motivation and history, then go on to describe a remote-controlled replicating robotic system and a semi-autonomous replicating robotic system. We then describe some fully autonomous self-replicating systems, and discuss how manufacturing work cells might be designed so as to reproduce.

Motivation

People have imagined for years a factory that could autonomously replicate itself for multiple generations, requiring neither people nor the monstrous machinery typically associated with a factory. Over recent decades, outer space has been mentioned as one potential application for such self-replicating robotic factories (see e. g., [3,10], and [7]). However, enormous technical barriers must be overcome before these systems can become feasible. The purpose of the current work is to take one small step toward realizing this goal.

In contrast to self-reconfigurable robotics [1,12,14,21,34], self-replication utilizes an original unit to actively assemble an exact copy of itself from passive components. This has the potential to result in exponential growth in the number of robots available to perform a job, thus drastically shortening the original unit's task time.

Descriptions of Self-Replication by Johns von Neumann

According to von Neumann there are four components required for a self-replicating machine: the builder, the controller, the copier, and the blueprint [31]. The process of self-reproduction begins with the controller commanding the builder to fabricate an exact mechanical system by following the blueprint. Then the controller instructs the copier to replicate the blueprint, input the new blueprint in the replica, and start the new machine. The process described in the previous paragraph was written as a mathematical model called the "Von Neumann Kinematic Beast" by Rolf Pfeifer et al. of the University of Zurich [24], which goes as follows:

1. Let A represent the builder. If a machine G is desired, one can build this machine with the blueprint, *Blue(G)*.

   $$A + \mathit{Blue}(G) \rightarrow G\,.$$

   Where '+' indicates that the machine is composed of the left and right components ($A + \mathit{Blue}(G)$) and '→' indicates construction.
2. Let B represent the copier. B would make a copy of the blue print, *Blue(G)*.

   $$B + \mathit{Blue}(G) {\rightarrow} \mathit{Blue}(G)\,.$$

3. Let C be the controller. With the combination of A and B, this would trigger them to follow in the correct order to generate a desired mechanical system G and the new blueprint *Blue(G)*, and then wrap them up together and split them from the original machine

   $$A + B + C + \mathit{Blue}(G) \rightarrow G + \mathit{Blue}(G)\,.$$

4. Let G be the machine $A + B + C$ then we get:

$$A{+}B{+}C{+}\mathit{Blue}(A{+}B{+}C) \rightarrow A{+}B{+}C{+}\mathit{Blue}(A{+}B{+}C).$$

Any system that observes this is a self-reproducing machine in Neumann's view. A short time after successfully presenting some of his theoretical work, von Neumann began working on the implementation of his theories. In the 1950's, with the help of Stanislaw Ulam, von Neumann invented the Cellular Automata concept (redrawn and shown in Fig. 1.)

Previous Efforts in Mechanical Self-Replicating System

Von Neumann [31] was the first to seriously study the idea of self-replicating machines from a theoretical perspective. In the late 1950's, Penrose performed the first recognized demonstration of a self-replicating mechanical system [22]. It consisted of passive elements that self-assembled under external agitation. This is similar in many ways to the modern work of Whitesides [32], only at a different length scale. Moore [19] was interested in von Neumann's concepts, but he commented that Neumann's Cellular Automata was only for demonstration, and that applications of self-replicating systems needed to be carried out. Moore described several conceptual designs of artificial living plants which could duplicate themselves not only from off-the-shelf artificial parts, but also from materials from nature. Jacobson [13] constructed a self-replicating machine using parts of toy trains. His replication was done on a round section of toy track.

In the 1980s, NASA established a series of studies on the topic of "Advanced Automation for Space Missions" [10]. These studies investigated the possibility of building a self-replicating factory on the moon. References [5,6,7,9,30] also outlined strategies for space utilization. Recently, research on robots that are capable of designing other machines with little help from humans has also been performed (see [17] and references therein). This uses rapid prototyping technologies.

Our Previous Replicating Prototypes

This section describes in chronological order the robotic prototypes capable of various levels of self-replication that have been designed and built in our laboratory. Our prototypes are constructed from modified LEGO Mindstorm kits with enhanced electrical connections because of their modularity, functionality and ease of use.

Demonstration I: Prototype 1

We built this robot as the first prototype to demonstrate that it is mechanically feasible for one simple robot to produce a copy of itself. This robot depends on external passive fixtures for self-replication. Figure 2 shows fixtures, the original prototype 1, and a set of the replica's subsystems. (Details of Prototype 1 can be found in [27].)

Demonstration II: Prototypes from the Spring 2002 Mechatronics Class at JHU.

From experience gained from Demonstration 1, we introduced the concept of self-replicating robots to students in a hands-on Mechatronics course (taught in the Department of Mechanical Engineering at the Johns Hopkins University) under the supervision of the last author, and TA'ed by the first author. We divided students in this course into eight groups to explore designs and implementations of the concept of self-replicating robotic systems. In order to focus on the mechanical issues involved in the design of the self-replicating systems, the robots

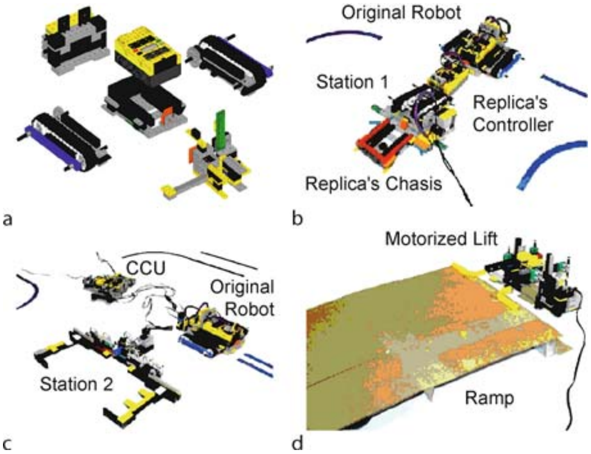
were remote-controlled rather than autonomous. (Details of Demonstration II can be found in [27], and [2].)

Demonstration III: A Semi-Autonomous Replicating System

This work builds upon previous results in remote-controlled robotic replication with a new feature that many subtasks in the replication process are now autonomously performed by the robot. The use of feedback sensors was implemented. The robot is unable to directly build



Self-replicating Robotic Systems, Figure 3
a An assembly view of the semi-autonomous robotic system, b Assembling station 1, c Assembling station 2, and d Assembly station 3

its replicas. Therefore, several work-cells (intermediate robots) are required to assist the original robot in the replicating process. Each work-cell works as a station in this factory-liked replicating system. Figures 3a, b, c, and d illustrate an assembly view of the original robot, stations 1, 2, and 3, respectively. Full details of the semi-replicating robot can be found in [27,28].

Design and Descriptions of an Autonomous Self-Replicating Robot

The robot and its replicas each consist of four subsystems: controller, left tread, right tread, and gripper/sensor subsystems. All subsystems are connected to others using magnets and shape constraints. Figure 4 shows an assembly view of the robot.

The controller subsystem is made up of a LEGO RCX programmable controller fit inside a chassis. The chassis's sides are used to connect to the left and right treads. Each side has a set of magnets, a set of shape-constraining blocks, and a set of electrical connections. The front end of the chassis is designed to attach with the gripper. The front end also has a set of magnets, a set of shape-constraining blocks, and a set of electrical connections, which transfer electrical signals and power from the controller to the gripper's motor and the navigating sensors installed on the gripper subsystem.

The magnets and the shape-constraining blocks are used in collaboration to aid aligning and interlocking subsystems. On each chassis side, the magnets are symmetrically placed in opposite polar directions to each other. This is to protect against incorrect positioning of the subsystems. The concept of using the magnets (with different polarizations) and shape-constraining blocks was influenced by the self-complementary molecules of Rebek [25]. Figure 5 illustrates the concepts of using the polar magnets and shape-constrained blocks to align and interlock subsystems. By design, it is very difficult for these connectors to misalign.

The left and right tread subsystems are designed to be identical to each other, with the purpose of reducing the system's design complexity. A tread subsystem hosts a rubber tread with a driving gear system, a 9 V LEGO DC motor, and a light-reflective pad which helps the original robot's navigation. One side of the tread has a set of magnets, a set of shape-constrained blocks, and a set of electrical connections, all of which correspond to the side of the controller subsystem. On the other side, the tread has a wedge which is fitted to the gripper. The wedge is used during the tread subsystem's transferring and assembling processes. Figure 6 shows how the original robot grasps

the tread subsystem, and Fig. 7 shows the connections located between the controller and tread subsystems.

The gripper/sensor subsystem is comprised of a 9 V LEGO DC motor, a set of rack and pinion gears used to drive the left/right fingers of the gripper, a set of magnets, a set of shape-constrained blocks, a set of electrical connections, and two light sensors (one is pointed downward, and the other is pointed forward).

The set of magnets, shape-constraining blocks, and electrical connections are attached to their corresponding part, on the front side of the controller subsystem. The left finger of the gripper is designed in a wedge shape to be fitted with the gripper in any identical robot. This wedge is used in the same manner as in the tread subsystems during assembling processes. Figure 8 shows how the original robot grasps the gripper/sensor subsystem, and Fig. 9 shows the connections located between gripper/sensor and controller subsystems. The two LEGO light sensors are employed in the robot's navigation system. The first light sensor (pointed downward) is used to detect the blue painted lines and silver acrylic spots on the experiment surface. The second light sensor (pointed forward) is used to detect objects (the subsystems of the replica) which the robot runs into.

The experimental area is a 2 m x 3 m area made of white colored paper with lines and spots painted in blue and silver acrylic colors. The original robot starts at the initial position, and the replica's subsystems are at their locations. Figure 10 shows the experimental area with locations of the replica's subsystems and the initial position of the original robot.

Controls and Programming of the Autonomous Self-Replicating Robot

The prototype robot is a fully autonomous system. Figure 11 shows the conceptual control architecture of the robot. The robot and its replicas, using the LEGO light sensor No. 1 (pointed downward), is capable of tracking the blue lines, and it can recognize the assembling spots, painted in a silver acrylic. The sensor detects and returns different analog values, corresponding to different colors. The robot tracks the painted lines to navigate between positions. Once the robot detects the assembling spot, the robot begins the assembling process. The LEGO light sensor No. 2 (pointed forward) returns an analog value once it detects a light-reflective pad attached to the tread and gripper/sensor subsystems. This notifies the robot to begin grasping the detected subsystem.

The grasping process consists of an aligning push toward the subsystem, and closing the gripper to grasp the subsystem. On the other hand, the assembly process consists of opening the gripper to release the subsystem, and an aligning push forward to snap the subsystem to the controller. Figure 12 shows the original robot grasping a subsystem, and moving toward an assembling spot, in silver acrylic, along the blue line.

The programming of the prototype is described here. The code is programmed on a PC and transferred through a LEGO infrared program-transferring tower. In the order in which events take place in the replication process, the programming is separated into seven stages: 1) replication process is activated, 2) line tracking and searching for a subsystem, 3) grasping the subsystem and changing to a new path which leads to the next step, 4) line tracking and searching for the assembly location, 5) assembling the subsystem to the controller and changing to a new path, 6) the new path leads to the next subsystem, 7) The final step loops back to steps 2 through 6 so the process repeats indefinitely. Figure 13 illustrates the programming flowchart of the self-replicating robot system.

The flowchart of the self-replication process

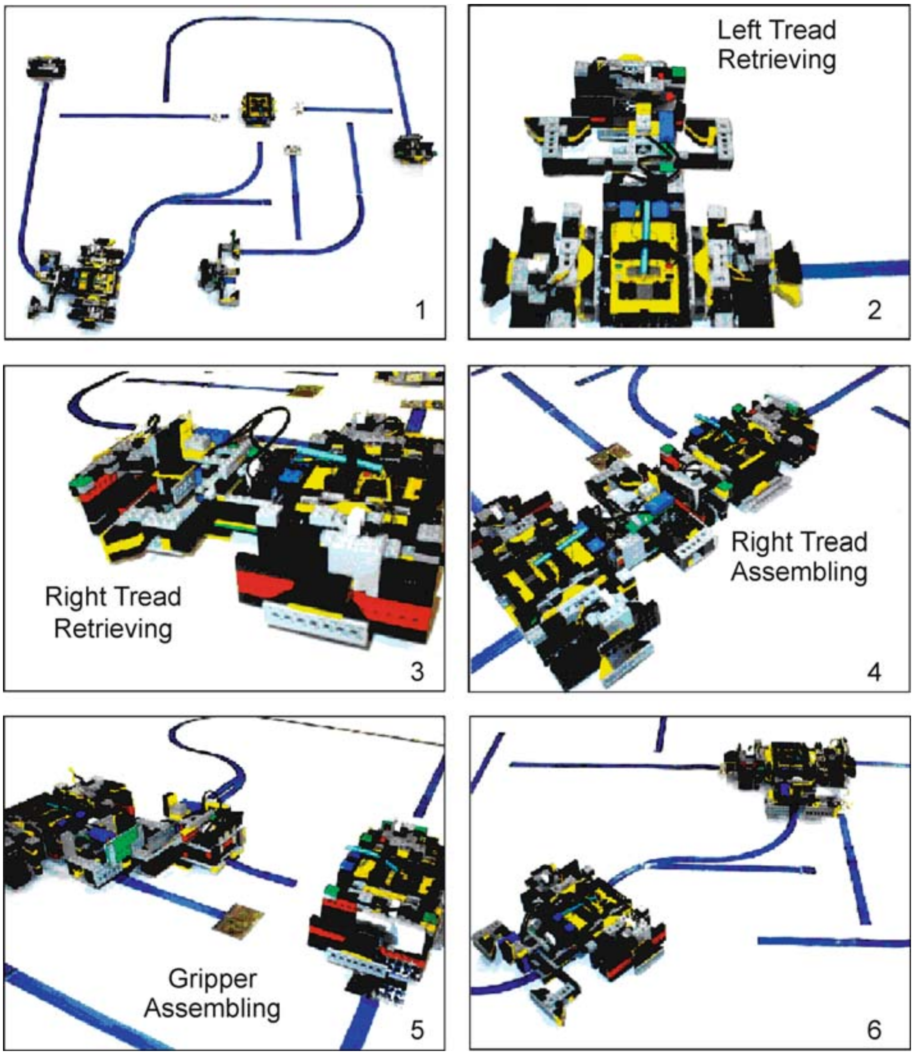
goes (Fig. 14 is a photographic representation of these step but they are not synchronous):

1. The original robot starts following the line from the starting point to the first subsystem using sensor No. 1.
2. Once light sensor No. 2 detects the first subsystem (right tread), the original robot begins the grasping process and grasps the right tread subsystem.
3. After the grippers are closed the original robot turns to the right until it detects a line.
4. The original robot follows the second line until it reaches the assembly location.
5. When light sensor No. 1 on the original robot detects the silver acrylic spot (the assembly location), the robot stops, and begins the attaching process.
6. The original robot opens the grippers, and gives a final push to secure the right tread subsystem to the controller subsystem.
7. The original robot then backs up and turns to the left until it detects a line value on sensor No. 1.
8. The original robot follows the line until it reaches the left tread subsystem.
9. Once light sensor No. 2 detects the second subsystem, the robot will stop, and begin the grasping process by closing its gripper around the left tread's wedge.
10. The original robot turns right until it detects the next line.
11. The original robot will follow the second line until it reaches the assembly location.
12. The original robot opens its gripper to release the left tread subsystem.
13. The original robot gives a final push on the left tread subsystem to help secure it.
14. The original robot then backs up and turns left until it detects the next line, using sensor No. 1.
15. The original robot follows the line to the final subsystem.
16. Once it reaches the gripper/sensor subsystem, it stops, and begins the grasping process.
17. The original robot closes its gripper, and turns right until it detects a line value with sensor No. 1.
18. The gripper/sensor subsystem is now transferred to the assembly location.
19. Once the original robot reaches the assembly location it stops, and opens the gripper.
20. The original robot backs up and turns left until sensor No. 1 is a line value.
21. The original robot then follows the line back to the starting point, and is ready to replicate again.
22. The completed replica self-activates (20 seconds after completion) and begins following the line to the starting point.
23. Once each robot reaches the starting point, it begins the replication procedure again.

The replication process takes two minutes and fifteen seconds per cycle. Although each subsystem is required to be placed in its starting location, errors in initial position and orientation are not very critical. We found slight errors during the grasping process in a few experiments caused by improper placement of the subsystems. Overall, the system is robust and very repeatable.

Our Approach to Self-Replicating Control Circuitry

Ideally, for a robotic system to be truly self-replicating, it would have to demonstrate the ability to assemble all of



Self-replicating Robotic Systems, Figure 14

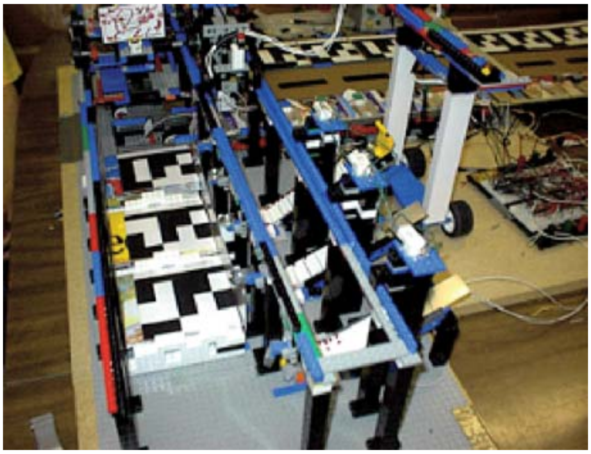
Self-replication process: 1) the original robot begins at the initial position with every part placed in their position. 2) The robot detects the right-tread subsystem. 3) The robot grasps the right-tread subsystem, and attaches it to the controller. 4) In the same manner, the robot performs the assembly of the left-tread subsystem. 5) After the robot grasps the gripper/sensor subsystem the robot transfers the subsystem to the next assembly step at the controller. 6) After being fully assembled, the replica is self-activated, and ready to replicate just like the original

its own subsystems from the most fundamental components. In the case of the robot controller, we consider the most fundamental components to be transistors, resistors, capacitors, etc., whereas microcontrollers are too complex to be considered as basic elements.

Our approach is to build a circuit capable of controlling an electro-mechanical system to re-build replicas of the control circuit from the most fundamental electronic components. In the von Neumann universal constructor paradigm, an associated instruction code is also required. In contrast it is possible to replicate a particular system by self-inspection without invoking von Neumann's universal constructor. We illustrate both concepts in hardware designed and constructed by students in a Mechatronics course taught at Johns Hopkins University in 2003. Two prototypes illustrate replication by self-inspection, and one demonstrates the universal constructor. In all three cases, pre-built electro-mechanical systems (called the SRI-builders) use the transistorized circuit as its controller. While in the von Neumann paradigm, the controller follows instructions that are explicitly encoded (and hence must reproduce the code for the overall system to be self-replicating), in the self-inspection paradigm, actions are taken implicitly as a result of observing the spatial layout of components in the original and feeding that information into the circuit itself. Clever electromechanical design ensures that observations obtained during self-inspection are translated directly into actions without requiring the interpretive step of consulting a long sequence of encoded construction commands.

A von Neumann Universal Constructor Prototype

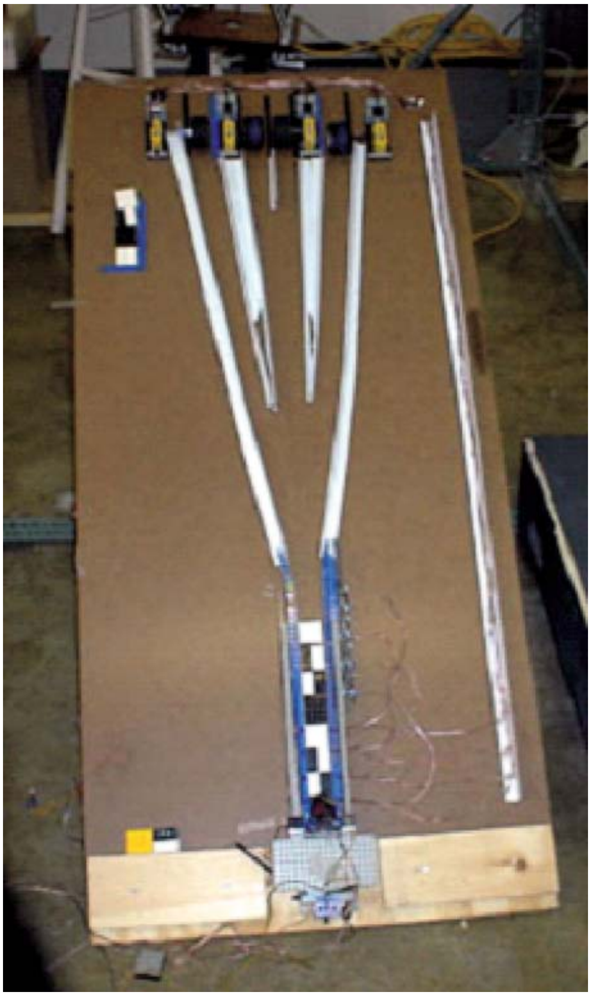
The prototype is a two-arm gantry-style robot with two degrees of freedom. The first degree of freedom moves along the whole system, includes the feeders and the assembly boards. The second degree of freedom moves vertically to pick and place codes and circuit pieces. A controller circuit is used to control motions of the robot. There are two boards being assembled at a certain amount of time. The first board is the replicated circuit, and the second is the replicated codes. The circuit is pre-wired before it is placed into the carrier. This is similar to a process of placing a chip into a circuit board. In the code part, each code consists of three lines of black and white strip representing 3 bits. A series of codes is set up on a code array where it is fed simultaneously to a reader array. The reader array is made of an array of photo-transistors and infrared LED emitters used to read black (0) and white (1) colors in each code. Infrared LED emitters are used instead of regular LED for reducing problem with ambient light distractions. Figure 15 shows the system in a side view. Once the acquisition part of the system reads the code, the assembly part of the system works by following the instruction code, replicating the code and circuit of that part.



Self-replicating Robotic Systems, Figure 15
Side view of the replicating system (von Neumann universal constructor prototype)

Non-Universal Self-Replication by Self-Inspection (Design 1)

This design is the first design of a non-universal self-replication by self-inspection. The self-replicating control circuit has the ability to identify the proper electronic components required, translate information about its own constituent parts obtained from self-inspection into mechanical tasks that create a replica, and transfer all functions to the replica. There is no list of instructions in the form of a code. Each electronic component has a black-and-white color code. Parts are loaded into feeders, and as a reading head traverses the control circuit, the information about which part of the control circuit is being observed is fed into the circuit itself. This actuates the solenoid in the ap-



Self-replicating Robotic Systems, Figure 16
Side view of the replicating system (non-universal self-replication by self-inspection – design 1. (See [11] for details))

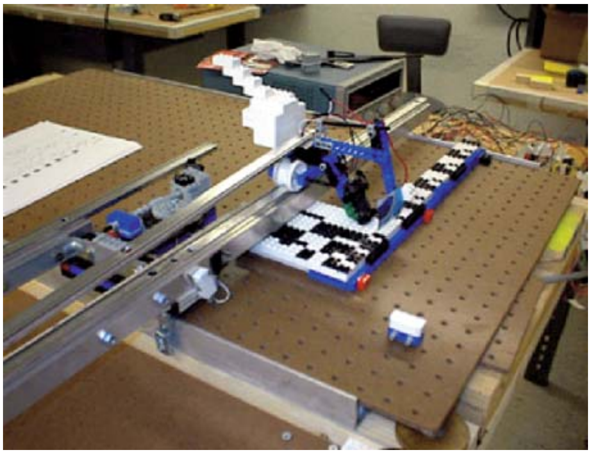
propriate feeder to release the parts needed to form the replica. Parts then slide down an incline and form an orderly array. The reading head continues to move and creates replicas until resources are completely utilized or its track ends. The design is scalable and the components are modular, allowing many different levels of intelligence to be replicated. This concept is one of many which we are investigating to enable self-replicating robots to perform complex behaviors. See Fig. 16.

Non-Universal Self-Replication by Self-Inspection (Design 2)

This robotic system is an X-Y table constructed from modified LEGO components. A photo-transistor sensor system is attached to the end-effector of the X-Y system in order to inspect the control circuit (the components of which are each assigned a unique black and white code). On the top of the X-Y system, a set of component feeders is installed. The circuit converts the signal from the sensor system to control the component feeders to release the correct component to the parts assembler. The parts assembler then arranges all the components to create a new replica of the control circuit. See Fig. 17.

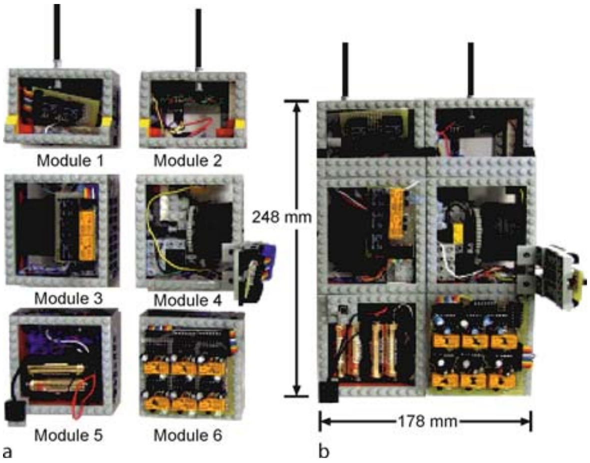
Merging the Self-Replicating Robot and Self-Replicating Circuit Concepts

In prior prototypes we considered two disjoint cases: (1) self-replicating robots constructed from modules where one module contained a computer; (2) a control circuit that commanded a mechanical device to assemble copies of the circuit. In this section we review very recent work with K. Lee and the JHU authors that merges these two concepts.



Self-replicating Robotic Systems, Figure 17
Side view of the replicating system (non-universal self-replication by self-inspection – design 2)

Basically, the autonomous self-replicating robot described previously in this paper functions as a finite-state machine in a highly structured environment. This same behavior can be implemented by a robot controlled by a simple circuit without using a microprocessor. Discrete electronics elements of this circuit such as transistors, resistors, etc., can be distributed over the modules from which the robot is constructed. This means that as the original robot assembles these modules to form a replica, the controller for the replica is assembled as the robot is. Prototypes are shown in Figs. 18 and 19.



Self-replicating Robotic Systems, Figure 18
A modular self-replicating robot controlled by a finite state circuit (see [15,16])

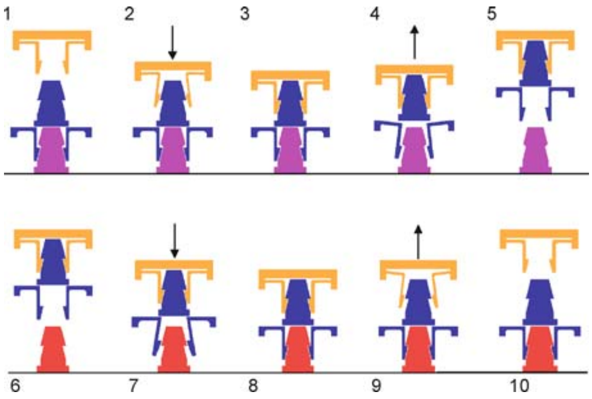
Towards a Universal Constructor

Whereas other prototypes of self-replicating robotic systems use relatively few subsystems as the initial parts, and connect these subsystems with magnets, the desire to create machines that can reproduce from a large number of basic parts requires thought about mechanical design, manufacturing, and assembly issues. Therefore, in this section the work of the second author in [20] is reviewed. In this work, a novel set of mechanical components that can be assembled into a wide variety of devices is presented. The components are specifically designed to be handled and assembled by devices made of the same type of components. A 3-axis Cartesian manipulator built with these components is presented. It is shown that in principle the manipulator can assemble duplicates of itself in addition to arbitrary devices when provided with properly oriented components and controlled by a human operator.

All components in the component set are variants of the "basic component". Figure 20 shows a cutaway view of two basic components. Each component consists of two parts: an upper "handle" and a lower "base". The base dimensions are 3.8 by 3.8 by 2.3 cm. The handle and base are individually cast from polyurethane resin in a silicone mold and then fixed together with epoxy adhesive. The base contains four compliant snap tangs that are complementary to the four tapered surfaces of the handle. Figure 21 shows how the snap tangs of the base grasp the undercut of the handle of another part. Additionally, the convex tapered surfaces of the base mate with concave tapered surfaces of the handle in order to provide rigidity with respect to shear and torsion between parts. Chamfers on the edges of the parts allow a certain amount of positioning error during assembly. The tangs and handle also contribute to error tolerance, since they are tapered such that two parts need not be exactly positioned before assembly. The slots cut in each side of the base allow the part to be assembled onto other parts that have reinforcing segments. The tangs are L-shaped, and the top part of each tang is exposed by a slot cut in each side of the handle.

The parts have a common handle, so they all can be manipulated by a single grasping tool. A part can be connected to another part by simply lowering it into place such that the tangs engage the handle of the other part (sliding components are slid sideways onto the handle of the other part). Depending on the grasping tool used, part connections can be reversible or irreversible. A section view of the steps in reversible assembly are shown in Fig. 21. The grasping tool (upper part) has thin tangs and a release mechanism. The process is initiated when the grasping tool is lowered onto the part to be disconnected. The release mechanism is engaged, depressing the tangs of the part to be disconnected. The upper part of the tangs deflect, disengaging the tangs of the middle part from the handle of the lower part (step 3). In step 4 the grasping tool and middle part are lifted from the lower part. To re-connect the part, the grasping tool and part are lowered onto the destination part (step 7). The grasping tool is removed simply by lifting it from the newly connected part. The snap tangs in the grasping tool are thinner than normal tangs, so they deflect first and disengage the grasping tangs from the handle on the newly connected part (step 9).



Self-replicating Robotic Systems, Figure 22
Steps in irreversible assembly process. The tool retrieves a part from a special storage site and attaches it to another component

Irreversible assembly is also possible, as shown in Fig. 22. In this case, the grasping tool has thin tangs like the reversible tool, but there is no release mechanism. Parts must be stored at a special "storage site" before assembly. The storage site (lower part in steps 1–5) is a normal part with reduced undercut on the handles. The amount of undercut on the storage site handles and the thickness of the tangs on the tool are carefully chosen so that the force required to disassemble two components is greatest between two normal parts, and least between a normal part and the storage site. This allows the grasping tool to pick a part from a storage site and connect it to another part with two simple up/down vertical movements. The irreversible assembly method, due to its simplicity, is used in the manipulator described below.

These basic components can be used to form a constructing machine capable of assembling a wide variety of devices, including duplicates of itself. By "capable" is meant kinematically capable - the machine can grasp, manipulate, and place all of the components required for constructing a duplicate of its "mechanical self". The machine's "mechanical self" includes the hardware required to manipulate mechanical components, but excludes the portion responsible for control. The machine lacks any type of sensor or onboard control, and so must be controlled either by a human operator or a sophisticated external controller. By "assemble" is meant the retrieval of components from a storage site and subsequent connection of them to an assembly or operating plane. Components must arrive at the storage site through action of another entity – namely a human operator.

A total of 16 different variations on the basic component were built. Most of these are used in the manipulator, and the remainder are useful for constructing other types of devices. Figure 23 shows a diagram of these parts. Figure 24 shows a CAD model of a constructing machine made from parts in the component set. It is essentially a 3-axis Cartesian manipulator. The base of the machine is a platform that slides along the x-axis, and is actuated by a DC motor. A motor-driven boom rides on top of the platform, and slides along the y-axis. The end-effector is mounted to a vertically-linear motor on the end of the boom. The reachable space of the end-effector is a rectangular volume of size 3 × 4 × 6 in units of component-widths. Note that the tool does not rotate. This requires

Large downward deflection of extended boom

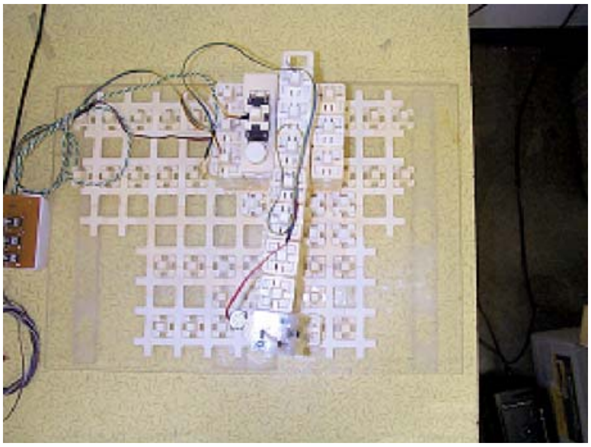
parts to be loaded at the storage site in their proper orientation. The constructor has a total of 45 components of eleven different types, not counting the operating plane. The details of the assembly process of this machine can be found in [20].

Figure 25 shows the experimental setup in its finished state. Both devices are operable. A human operator controls them through a switchbox that turns the various motors on or off. A topic that has been neglected so far is that of running wires to the motors. As seen from the figure, this is done rather haphazardly. This prototype had a number of problems that are worth mentioning which are helping us to design better systems.

The first problems that were encountered dealt with getting the constructor boom to move smoothly. When the boom is extended, it applies high forces to the parts that hold it to the platform. This results in more friction, and requires a higher torque from the motor. In these conditions the motor tended to separate from the platform, and the drive gear would lose contact with the racks on the boom. This problem was eventually "solved" by using a metal screw and adhesive between certain parts to hold them in place.

Most of the other problems occurred during assembly, and centered around the extended boom. Figure 26 shows the large downward deflection occurring in the extended boom. This made it difficult to align parts. A human operator could successfully place parts, using repeated effort and visual feedback, but a simple controller surely could not.

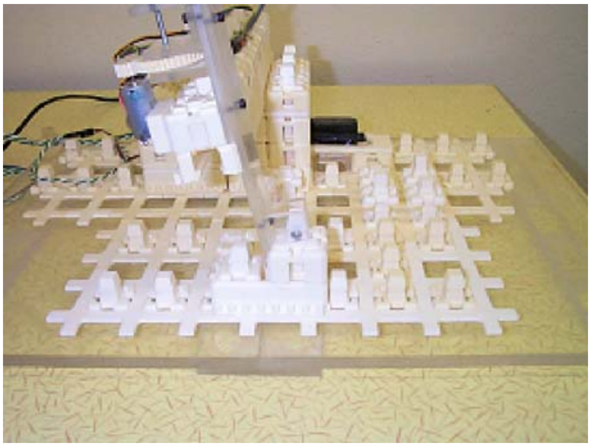
Deflection of the boom in the x-direction presented problems for sliding the far racks into place (Fig. 27). This would cause the sliding platform under the boom to jam. In addition to sideways deflection, the boom would also twist along the y-axis (Fig. 28). The constructor was able to place the near racks, but the far racks had to be placed by hand.



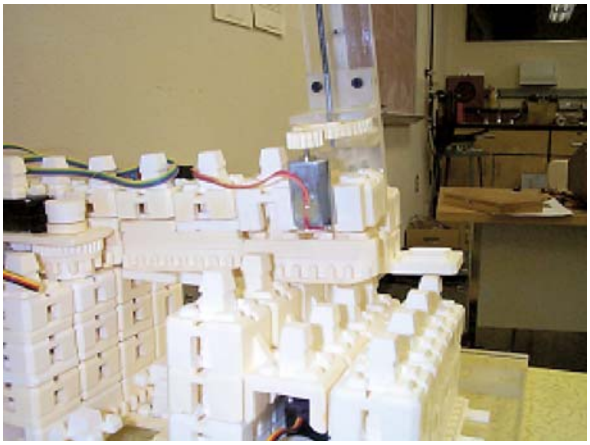
Self-replicating Robotic Systems, Figure 27
Sideways deflection of extended boom caused the sliding platform to jam

The torsion of the boom created problems in later assemblies steps as well. The twisting deflection of the boom would tend to misalign parts so that their snap-tangs would not engage with the parts below them. For this reason, the tool was mounted to the slide in a rotating bracket. This allowed the tool a small, passive amount of rotation about the y-axis. With this feature, the boom could still twist, but the parts would self-align and engage.

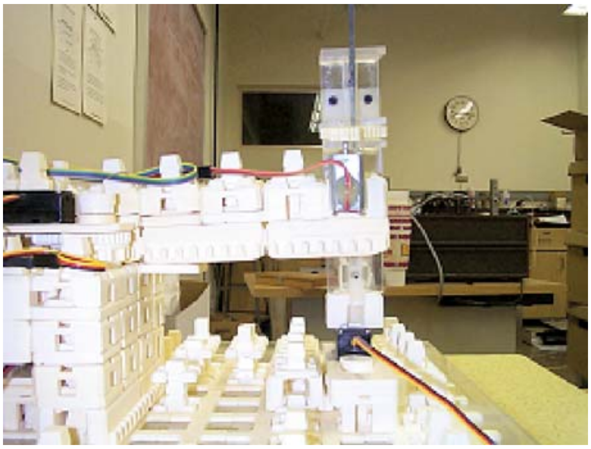
In many cases, the constructor could not develop the necessary force to assemble components. This was especially true when assembling components with multiple sets



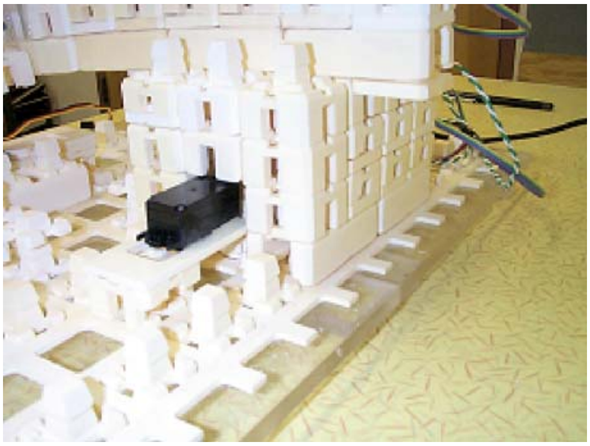
Self-replicating Robotic Systems, Figure 28
Torsion of boom



Self-replicating Robotic Systems, Figure 30
Separation of components within the boom



Self-replicating Robotic Systems, Figure 29
Upward deflection of boom



Self-replicating Robotic Systems, Figure 31
Separation of sliding platform and operating plane

of snap tangs, and in parts where the tangs were offset horizontally from the handle. Sometimes this occurred because the vertical linear actuator did not produce enough force, and sometimes it occurred because upward deflection of the boom caused the parts to misalign (Fig. 29). In a few cases, components in the boom would separate (Fig. 30). This only occurred when the boom was prevented from deflecting because it was engaged on the growing assembly.

The extended boom indirectly caused another problem. Recall that two of the handles in the tracks on the operating plane are modified as entry sites for racks. These sites do not help hold the platform to the plane. This, in combination with the high moment exerted on the platform by the extended boom, would cause the platform to separate from the plane and get stuck on adjacent, non-modified handles (Fig. 31).

Some aspects of the constructor worked well, such as the stage-by-stage assembly of the boom and the retrieval of parts from the storage site. The boom does not have to extend to reach the storage site, so deflections are not a problem and part retrieval was easy. The thickness of the tool tangs was found by trial and error – the tangs of a basic part were successively machined until the disassembly force fell within the correct range. Although no measurements were taken, the distribution of assembly and disassembly forces across various parts was fairly tight. The tool could lift all of the parts. Once parts were connected to an assembly, the tool could be separated from the connected parts in all cases.

In short, this initial concept of a desktop universal constructor provided us many valuable lessons about the importance of mechanical design, parts assembly and manufacturability issues that we are incorporating in future designs.

Discussion

Several self-replicating robot prototype have been constructed and tested. An autonomous prototype uses two light sensors in its navigation system to detect objects and also to track lines. Magnets and shape-constraining blocks are used to aid in aligning and interlocking the subsystems of the replica. As a result, the robot is capable of automatically assembling its replicas. All of the replicas are also capable of completing the same replicating process. The autonomous self-replicating system presented here has been recognized by authors of the book, "Kinematic Self-Replicating Machines" [25] that this prototype is the world's first fully functional autonomous self-replicating robot. Self-replicating circuits, as well as self-replicating robots whose controllers can be fully decomposed into basic parts have also been reviewed here.

Whereas von Neumann's architecture for self-replicating kinematic automata is the most widely known approach, it is not the only one. Self-reproduction by self-inspection in which a non-universal constructor "reads" an original device and "writes" a copy by executing a very small set of hardwired commands is an alternative. In our experience observing students attempting to build self-replicating devices, self-replication by self-inspection appears to be a more robust and less complicated alternative to the universal constructor.

Future Works

In previous sections we discussed a series of mechanical replicating prototypes in which programs are preloaded onto control computers which are then treated as one of several subsystems to be assembled. However, our ultimate goal is to develop a self-replicating robotic system capable of autonomously assembling its replicas from simple components using only electro-mechanical intelligence, i. e. a mechanical code, and transistor-based control circuits. This eliminates complicated electronic components, such as programmable micro-controllers, and makes the concept more appropriate for future space systems that can use in-situ resources for self-replication. The prototypes reviewed here are one step in this direction. Other related technologies are discussed in [33].

Acknowledgments

This work was made possible by support from the Royal Thai government, the Mellon Foundation, and the National Science Foundation under Grant ITS 0205466. The results and opinions expressed are solely those of the authors. We thank A. Cushing, Y. Kwon, K. Lee, M. Kutzer and all of the undergraduate students in the Mechatronics courses over the past five years who have designed several of the prototypes shown in this review. The work presented in Sect. "Towards a Universal Constructor" was performed at University of New Mexico with help from Professors G. Starr, H. Tran, and J. Wood.

Article Outline

Glossary

Cellular automaton A cellular automaton (CA) is a mathematical framework modeling an array of *cells* that interact locally with their neighbors. In this *cellular space*, each cell has a set of *neighbors*, cells have *values* or *states*, all the cells update their values simultaneously at discrete *time steps* or *iterations*, and the new state of a cell is determined by the current state of its neighbors (including itself) according to a local *function* or *rule*, identical for all cells. In the article, the term is extended to account for systems that introduce variations to the basic definition (for example, systems where cells do not update simultaneously or do not have the same set of rules in every cell).

Following the historical pattern, in the article the same term is also used to refer to an object or structure built within the cellular space, i. e., a set of cells in a particular, usually active, state (overlapping with the definition of *Configuration*).

Configuration A set of cells in a given state at a given time. Usually, but not always, the term refers to the state of all the cells in the entire space. The *initial configuration* is the state of the cells at time $t = 0$.

Self-replication The process whereby a cellular automaton configuration creates a copy of itself in the cellular space. Incidentally, you will note that in the article we use the terms self-replication and self-reproduction interchangeably. In reality, the two terms are not really synonyms: self-reproduction is more properly applied to the reproduction of organisms, while self-replication concerns the cellular level. The more correct term to use in most cases would probably be self-replication, but since von Neumann favored self-reproduction, we will ignore the distinction.

Self-reproduction See *Self-Replication*

Construction The process that occurs when one or more cells, initially in the inactive or *quiescent* state are assigned an active state (in the context of this article, by the self-replicating structure).

Definition of the Subject

Machine self-replication, besides inspiring numerous fictional books and movies, has long been considered a powerful paradigm to allow artifacts, for example, to survive in hostile environments (such as other planets) or to operate more efficiently by creating *populations* of machines working together to achieve a given task. Where the self-replication of *computing* machines is concerned, other motivations can also come into play, related to concepts such as fault tolerance and self-organization.

Cellular automata have traditionally been the framework of choice for the study of self-replicating computing machines, ever since they were used by John von Neumann, who pioneered the field in the 1950s. In this context, self-replication is seen as the process whereby a configuration in the cellular space is capable of creating a copy of itself in a different location.

As a mathematical framework, CA allow researchers to study the mechanisms required to achieve self-replication in a simplified environment, in view of eventually applying this process to real-world systems, either to electronics or, more generally, to computing systems.

Introduction

The self-replication of computing systems is an idea that dates back to the very origins of electronics. One of the pioneers of the field, John von Neumann, was among the first to investigate the possibility of creating machines capable of self-replication [1] with the purpose of achieving reliability through the redundant operation of "populations" of computing machines.

Throughout the more than 50 years since von Neumann's seminal work, research on this topic has gone through several transformations. While interest in applying self-replication to electronic systems waned because of technological hurdles, the field of Artificial Life, starting with the pioneering work of Chris Langton [14], began studying this process in the more general context of achieving life-like properties in artificial systems.

Throughout its long history, cellular automata (CA) have remained one of the environments of choice to study how self-replication can be applied to computing systems. In general, researchers in the domain (including von Neumann) have never regarded CA as the environment in which self-replication would be ultimately applied. Rather, CA have traditionally provided a useful platform to test the complexity of self-replication at an early stage, in view of eventually applying this process to real-world systems, either to electronics or, more generally, to computing systems.

Of course, the concept of self-replication has been applied to artificial systems in contexts other than computing. A classic example is the 1980 NASA study by Robert Freitas Jr. and Ralph Merkle [10] (recently expanded in a remarkable book [11]), where self-replication is used as a paradigm for efficiently exploring other planets. However, this kind of self-replication, applied to physical machines rather then computing systems, does not commonly make use of cellular automata and is beyond the scope of this article.

Following the historical progress of self-replication in cellular automata (derived in part from [40]), we will first examine in some detail von Neumann's seminal work (Sect. "Von Neumann's Universal Constructor"). Then, the use of self-replication as an Artificial Life paradigm will be discussed (Sect. "Self-Replication for Artificial Life") before dealing with some of the latest advances in the field in Sect. "Other Approaches to Self-Replication".

Von Neumann's Universal Constructor

Many of the existing approaches to the self-replication of computing systems are essentially derived from the work of John von Neumann [1], who pioneered this field of research in the 1950s.

Von Neumann, confronted with the lack of reliability of computing systems, turned to nature to find inspiration in the design of fault-tolerant computing machines. Let us remember that the computers von Neumann was familiar with were based on vacuum-tube technology, and that vacuum tubes were much more prone to failure than modern transistors. Moreover, since the writing and the execution of complex programs on such systems represented many hours (if not many days) of work, the failure of a system had important consequences in wasted time and effort.

In particular, Von Neumann investigated self-replication as a way to design and implement digital logic devices. Unfortunately, the state of the art in the fifties restricted von Neumann's investigations to a purely theoretical level, and the work of his successors mirrored this constraint.

Indeed, it is not until fairly recently that some of the technological problems associated with the implementation of such a process in silicon have been resolved with the introduction of new kinds of electronic devices (see Sect. "Other Approaches to Self-Replication").

In this section, we will analyze von Neumann's research on the subject of self-replicating computing machines, and in particular his universal constructor, a self-replicating cellular automaton [44].

Von Neumann's Self-Replicating Machines

Natural systems are among the most reliable complex systems known to man, and their reliability is a consequence not of any particular robustness of the individual cells (or organisms), but rather of their extreme redundancy. The basic natural mechanism which provides such reliability is *self-reproduction*, both at the cellular level (where the survival of a single organism is concerned) and at the organism level (where the survival of the species is concerned).

Thus von Neumann, drawing inspiration from natural systems, attempted to develop an approach to the realization of self-replicating computing machines (which he called *artificial automata*, as opposed to natural automata, that is, biological organisms). In order to achieve his goal, he imagined a series of five distinct models for self-reproduction ([44], pp. 91–99):

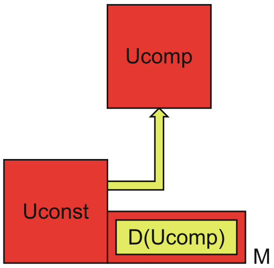
1. The *kinematic* model, introduced by von Neumann on the occasion of a series of five lectures given at the University of Illinois in December 1949, is the most general. It involves structural elements such as sensors, muscle-like components, joining and cutting tools, along with logic (switch) and memory elements. Concerning, as it does, physical as well as electronic components, its goal was to define the bases of self-replication, but was not designed to be implemented.
2. In order to find an approach to self-replication more amenable to a rigorous mathematical treatment, von Neumann, following the suggestion of the mathematician S. Ulam, developed a *cellular* model. This model, based on the use of cellular automata as a framework for study, was probably the closest to an actual realization. Even if it was never completed, it was further refined by von Neumann's successors and was the basis for most further research on self-replication.
3. The *excitation-threshold-fatigue* model was based on the cellular model, but each cell of the automaton was replaced by a neuron-like element. Von Neumann never defined the details of the neuron, but through a careful analysis of his work, we can deduce that it would have borne a fairly close relationship to today's simplest artificial neural networks, with the addition of some features which would have both increased the resemblance to biological neurons and introduced the possibility of self-replication.
4. For the *continuous* model, von Neumann planned to use differential equations to describe the process of self-reproduction. Again, we are not aware of the details of this model, but we can assume that von Neumann planned to define systems of differential equations to describe the excitation, threshold and fatigue properties of a neuron. At the implementation level, this would probably correspond to a transition from purely digital to analog circuits.
5. The *probabilistic* model is the least well-defined of all the models. We know that von Neumann intended to introduce a kind of automaton where the transitions between states were probabilistic rather than deterministic. Such an approach would allow the introduction of mechanisms such as mutation and thus of the phenomenon of evolution in artificial automata. Once again, we cannot be sure of how von Neumann would have realized such systems, but we can assume they would have exploited some of the same tools used today by genetic algorithms.

Of all these models, the only one von Neumann developed in some detail was the cellular model. Since it was the basis for the work of his successors, it deserves to be examined more closely.

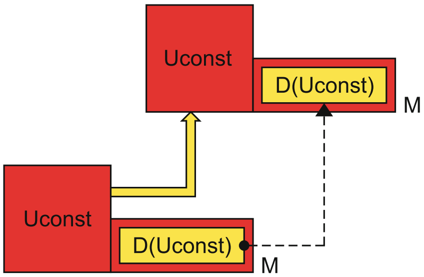
Von Neumann's Cellular Model

In von Neumann's work, self-reproduction is always presented as a special case of universal construction, that is, the capability of building any machine given its description (Fig. 1). This approach was maintained in the design of his cellular automaton, which is therefore much more than a self-replicating machine. The complexity of its purpose is reflected in the complexity of its structure, based on three separate components:

1. A *memory tape*, containing the description of the machine to be built, in the form of a one-dimensional string of elements. In the special case of self-reproduction, the memory contains a description of the universal constructor itself (Fig. 2). It is interesting to note that the memory of von Neumann's automaton bears a strong resemblance to the biological genome. This resemblance is even more remarkable when considering that the structure of the genome was not discovered until after the death of von Neumann.



Self-Replication and Cellular Automata, Figure 1
Von Neumann's universal constructor `Uconst` can build a specimen of any machine (e. g., a universal Turing machine `Ucomp`) given its description `D(Ucomp)`



Self-Replication and Cellular Automata, Figure 2
Given its own description `D(Uconst)`, von Neumann's universal constructor is capable of self-replication

2. The *constructor* itself, a very complex machine capable of reading the memory tape and interpreting its contents.
3. A *constructing arm*, directed by the constructor, used to build the offspring (i. e., the machine described in the memory tape). The arm moves across the space and sets the state of the elements of the offspring to the appropriate value.

The implementation as a cellular automaton is no less complex. Each element has 29 possible states, and thus, since the next state of an element depends on its current state and that of its four cardinal neighbors, $29^5 = 20,511,149$ transition rules are required to exhaustively define its behavior.

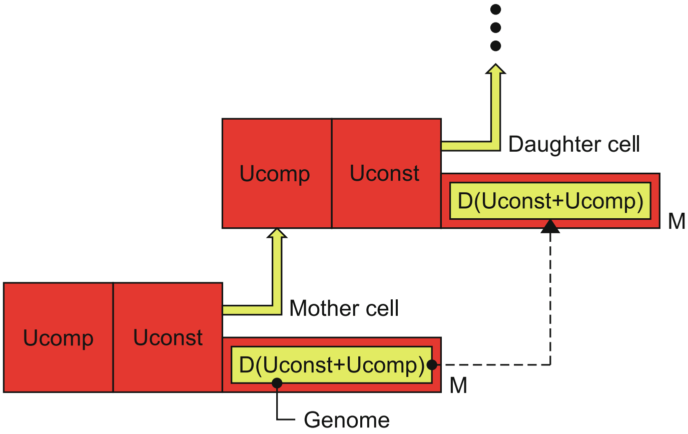
If we consider that the size of von Neumann's constructor is of the order of several hundred thousand elements, we can easily understand why a hardware realization of such a machine is not really feasible. In fact, as part of our research, we did realize a hardware implementation of a set of elements of von Neumann's automaton [3,35]. By carefully designing the hardware structure of each element, we were able to considerably reduce the amount of memory required to host the transition rules. Nevertheless, our system remains a demonstration unit, as it consists of a few elements only, barely enough to illustrate the behavior of a tiny subset of the entire machine.

It is also worth mentioning that von Neumann went one step further in the design of his universal constructor. If we consider the universal constructor from a biological viewpoint, we can associate the memory tape with the genome, and thus the entire constructor with a single cell (which would imply a parallel between the automaton's elements and molecules). However, the constructor, as we have described it so far, has no functionality outside of self-reproduction. Von Neumann recognized that a self-replicating machine would require some sort of functionality to be interesting from an engineering point of view, and postulated the presence of a *universal computer* (in practice, a universal Turing machine, an automaton capable of performing any computation) alongside the universal constructor (Fig. 3). Von Neumann's constructor can thus be regarded as a unicellular organism, containing a genome stored in the form of a memory tape, read and interpreted by the universal constructor (the mother cell) both to determine its operation and to direct the construction of a complete copy of itself (the daughter cell).

Von Neumann's Successors

The extreme size of von Neumann's universal constructor has so far prevented any kind of physical implementation (apart from the small demonstration unit we mentioned). But further, even the simulation of a cellular automaton of such complexity was far beyond the capability of early computer systems. Today, such a simulation is starting to be conceivable. Umberto Pesavento, a young Italian high school student, developed a simulation of von Neumann's entire universal constructor [27]. The computing power available did not allow him to simulate either the entire self-replication process (the length of the memory tape needed to describe the automaton would have required too large an array) or the Turing machine necessary to implement the universal computer, but he was able to demonstrate the full functionality of the constructor.

Considering the rapid advances in computing power of modern computer systems, we can assume that a complete simulation could be envisaged with today's technology. In fact, an effort is currently under way [4] to implement a complete specimen of the constructor. To achieve this goal, Buckley is revisiting and analyzing in detail the operation of the constructor. To give an idea of the scope of this work, Buckley's results indicate that the interpretercopier (without the tape) is bounded by a region of 751 × 1048 = 787.048 cells.



Self-Replication and Cellular Automata, Figure 3
By extension, von Neumann's universal constructor can include a universal computer and still be capable of self-replication

The impossibility of achieving a physical realization did not however deter some researchers from trying to continue and improve von Neumann's work [2,15,22]. Arthur Burks, for example, in addition to editing von Neumann's work on self-replication [5,44], also made several corrections and advances in the implementation of the cellular model. Codd [9], by altering the states and the transition rules, managed to simplify the constructor by a considerable degree. Vitanyi [43] studied the possibility of introducing sexual reproduction in von Neumann's approach. However, without in any way lessening these contributions, we can say that no major theoretical advance in the research on self-reproducing automata occurred until C. Langton, in 1984, opened a second stage in this field of research.

Self-Replication for Artificial Life

While the *implementation* of von Neumann's universal constructor faced insurmountable (at the time) technological hurdles, the same could not be said of the *theoretical* contribution that his approach represented as an attempt to study a biologically-inspired process within the world of computing systems.

In this context, the main drawback of von Neumann's work lay in the inability to achieve self-replication without resorting to an extremely complex simulation of a complete machine. Von Neumann's Universal Constructor was so complex because it tried to implement self-reproduction as a particular case of construction universality, i. e. the capability of constructing any other automaton, given its description. C. Langton approached the problem somewhat differently, by attempting to define the simplest cellular automaton, commonly known as *Langton's loop* [14], capable exclusively of self-reproduction.

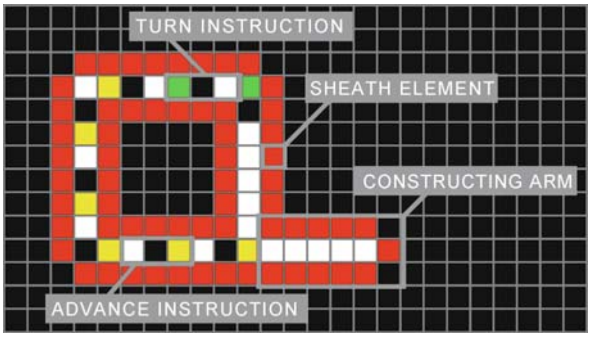
Langton's loop had a major impact on research in self-replication by introducing a new way to think about this process in more "abstract" terms as a study of the application of biologically-inspired mechanisms to computing, exemplifying the field known as *Artificial Life*. In this context, rather than the replicating machine, it is the process of self-replication itself that becomes the object of study.

This novel approach generated research that can be considered fundamentally different from that of von Neumann and started discussion on topics such as the analogy with cellular division and with the reproduction of individuals in a population (e.g, in [17], Section V.B), the difference between trivial and non-trivial self-replication in cellular automata (e. g., in automata such as those described in [16]), or the connections between evolution and self-replication (e.g, in the work of Sayama [17]).

Langton's Loop

As a consequence of his approach, Langton's Loop is orders of magnitude simpler than von Neumann's constructor. In fact, it is loosely based on one of the simplest organs (an organ in this context can be seen as a self-supporting structure capable of a single sub-task) in Codd's automaton: the *periodic emitter* (itself derived from von Neumann's periodic pulser), a relatively simple structure capable of generating a repeating string of a given sequence of pulses.

Langton's loop (Fig. 4) is named after the dynamic storage of data inside a square sheath (red in the figure). The data is stored as a sequence of instructions for directing the constructing arm, coded in the form of a set of three states. The data turns counterclockwise in permanence within the sheath, creating a loop.



Self-Replication and Cellular Automata, Figure 4
The initial configuration of Langton's Loop (iteration 0)

The two instructions in Langton's loop are extremely simple. One instruction (uniquely identified by the yellow element in the figure) tells the arm to advance by one position (Fig. 5), while the other (green in the figure) directs the arm to turn 90 degrees to the left (Fig. 6). Obviously, after three such turns, the arm has looped back on itself (Fig. 7), at which stage a messenger (the pink element) starts the process of severing the connection between the parent and the offspring, thus concluding the replication process.

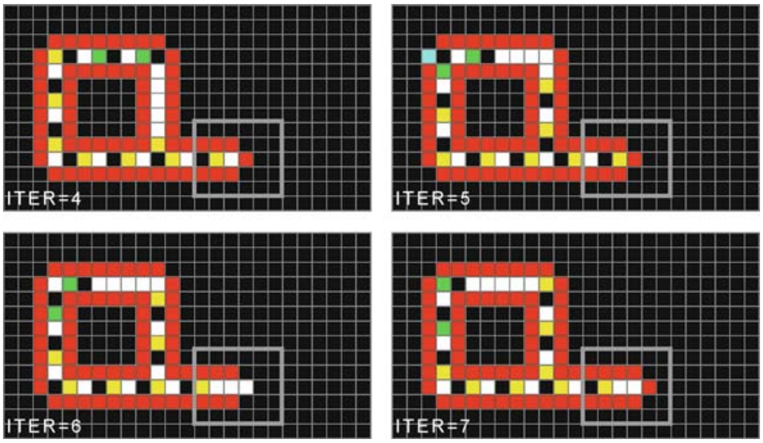
Once the copy is over, the parent loop proceeds to construct a second copy of itself in a different direction (to the north in this example), while the offspring itself starts to reproduce (to the east in this example). The sequential nature of the self-reproduction process generates a spiraling pattern in the propagation of the loop through space (Fig. 8): as each loop tries to reproduce in the four cardinal directions, it finds the place already occupied either by its parent or by the offspring of another loop, in which case it dies (the data within the loop is destroyed).

Langton's loop uses 8 states for each of the 86 non-quiescent cells making up its initial configuration, a 5-cell neighborhood, and a few hundred transition rules (the exact number depends on whether default rules are used and whether symmetric rules are included in the count). Further simplifications to Langton's automaton were introduced by Byl [6], who eliminated the internal sheath and reduced the number of states per cell, the number of transition rules, and the number of non-quiescent cells in the initial configuration. Reggia et al. [29] managed to remove also the external sheath, thus designing the smallest self-replicating loop known to date. Given their modest complexity, at least relative to von Neumann's automaton, all of the mentioned automata have been thoroughly simulated.

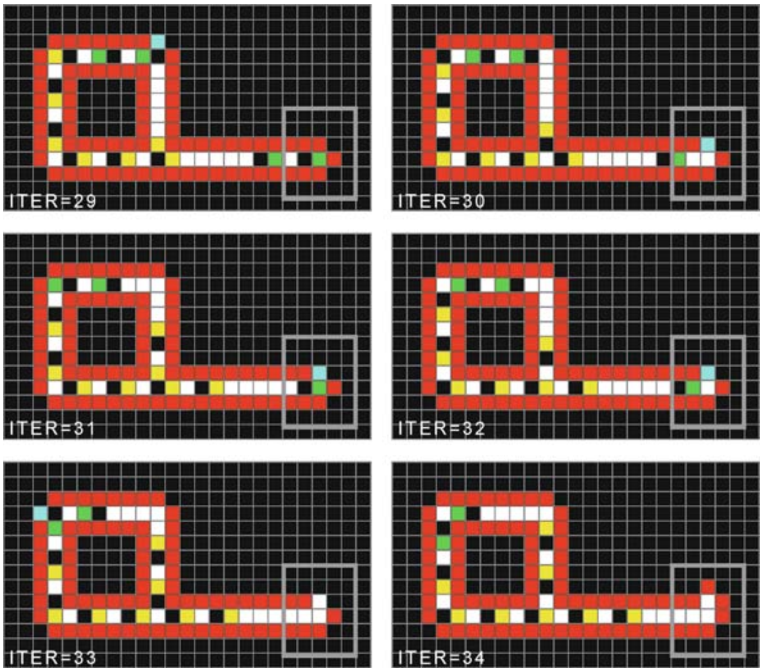
Langton's loop has been used as the basis for several approaches, mostly aimed at studying the properties of self-replication within a cellular system in the context of artificial life. Sayama [32] introduced structural dissolution (whereby a loop can destroy itself, in addition to replicating) to obtain colonies of loops that are dynamically stable and exhibit a potentially evolvable behavior. Nehaniv [21] extended Langton's approach to asynchronous cellular automata, while Sipper [34] developed a self-replicating loop in a non-uniform CA (i. e., a CA where the transition rules are not necessarily identical in all cells).

Perrier's Loop

In the context of applying self-reproduction to the replication of computing machines, and hence return to von Neumann's original goals, the main weakness of Langton's loop resides in the absence of any functionality beyond self-reproduction itself. To overcome this limitation, Per-



Self-Replication and Cellular Automata, Figure 5
The constructing arm advances by one space



Self-Replication and Cellular Automata, Figure 6
The constructing arm turns 90 degrees to the left

rier and Zahnd developed a relatively complex automaton (Fig. 9) in which a two-tape Turing machine was appended to Langton's loop [26].

This automaton exploits Langton's loop as a sort of "carrier" (Fig. 10): the first operation of Perrier's loop is to allow Langton's loop to build a copy of itself (iteration 128: note that the copy is limited to one dimension, since the second dimension is taken up by the Turing machine). The main function of the offspring is to determine the location of the copy of the Turing machine (iteration 134). Once the new loop is ready, a "messenger" runs back to the parent loop and starts to duplicate the Turing machine (iterations 158 and 194), a process completely disjoint from the operation of the loop. When the copy is finished (iteration 254), the same messenger activates the Turing machine in the parent loop (the machine had to be inert during the replication process in order to obtain a perfect copy). The process is then repeated in each offspring until the space is filled (iteration 720: as the automaton exploits Langton's loop for replication, meeting the boundary of the array causes the last machine to crash).

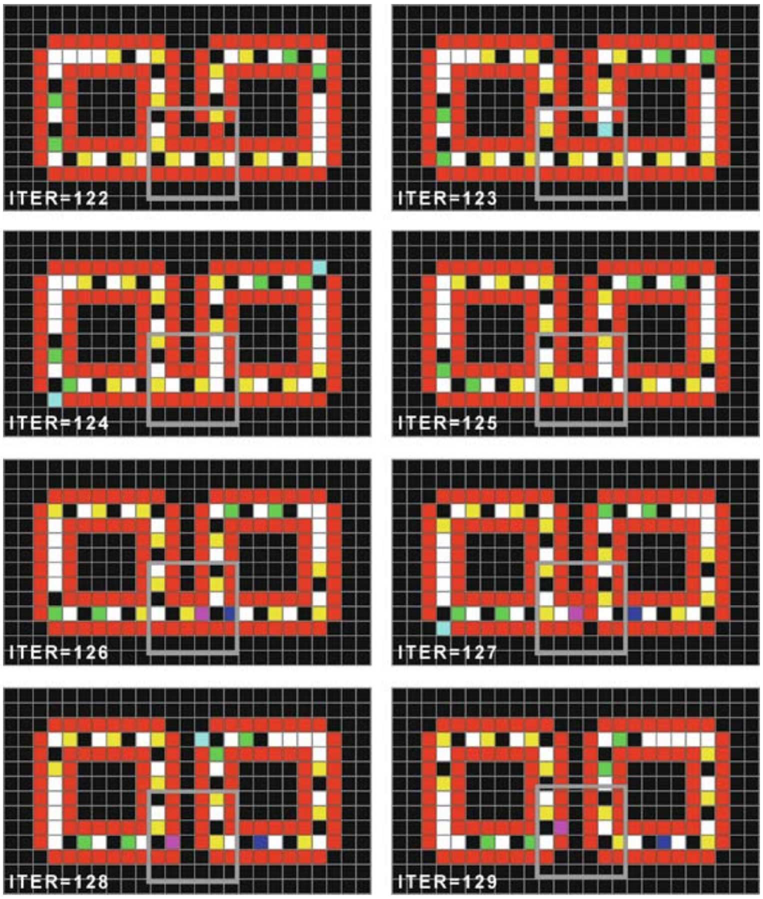
Perrier's automaton implements a self-replicating Turing machine, a powerful construct which is unfortunately handicapped by its complexity: in order to implement a Turing machine, the automaton requires a very considerable number of additional states (more than 60), as well as an important number of additional transition rules. This kind of complexity, while still relatively minor compared to von Neumann's universal constructor, is nevertheless too important to be really considered for an actual implementation.

Tempesti's Loop

Always in the context of achieving self-reproduction of computing machines, and beside the lack of functionality mentioned in Subsect. "Perrier's Loop", another problem of Langton's loop is that it is not well adapted to finite CA arrays. Its self-reproduction mechanism assumes that there is enough space for a copy of the loop, and the entire loop becomes nonfunctional otherwise (Fig. 8).

To overcome this limitation and move a step closer to the realization of self-replicating machines, we developed a self-replicating loop designed specifically to exist in a finite, but arbitrarily large, space, and at the same time capable, unlike Langton's loop, to have a functionality in addition to self-replication.

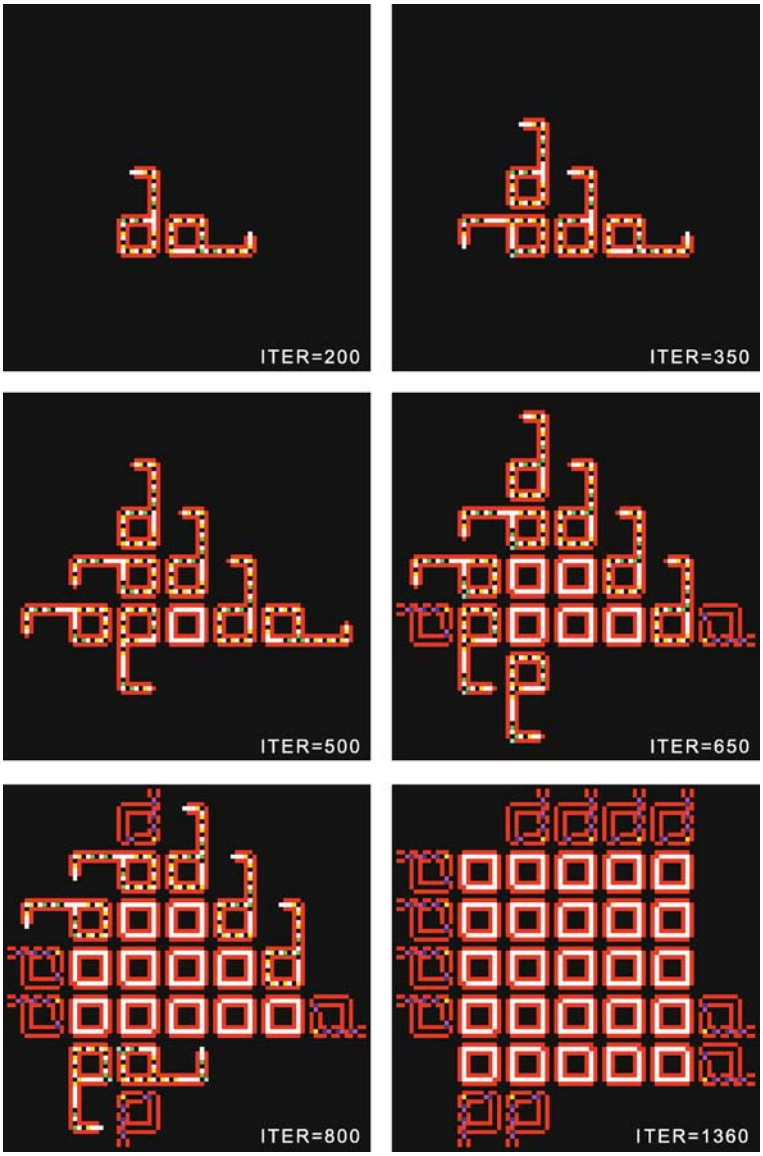
In designing our self-replicating automaton [39,40], we did maintain some of the more interesting features of Langton's loop. In particular, we preserved the structure based on a square loop to dynamically store information. Such storage is convenient in CA because of the locality of



Self-Replication and Cellular Automata, Figure 7
The copy is complete and the connection from parent to offspring is severed

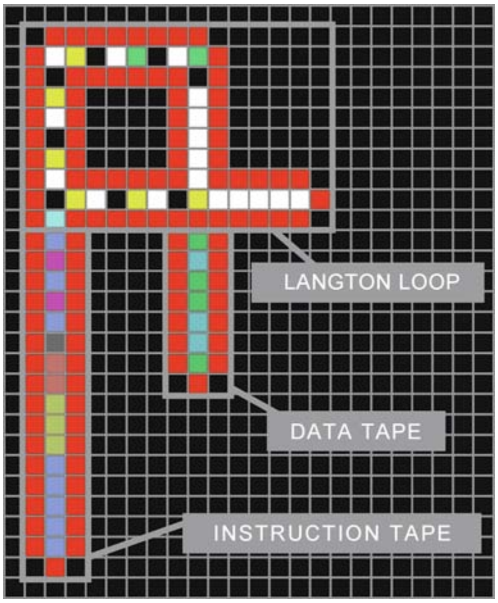
the rules. Also, we maintained the concept of constructing arm, in the tradition of von Neumann and his successors, even if we introduced considerable modifications to its structure and operation. While preserving some of the more interesting features of Langton's loop, we nevertheless introduced some basic structural alterations (Fig. 11):

- As in Byl's version of Langton's loop, we use only one sheath. In addition, four *gate elements* (in the same state as the sheath) at the four corners of the automaton enable or disable the replication process.
- We extend four constructing arms in the four cardinal directions at the same time, and thus create four copies of the original automaton in the four directions in parallel. When the arm meets an obstacle (either the boundary of the array or an existing copy of the loop), it simply retracts and puts the corresponding gate element in the closed position.
- The arm does not immediately construct the entire loop. Rather, it constructs a sheath of the same size as the original. Once the sheath is ready, the data circulating in the loop is duplicated and the copy is sent along the constructing arm to wrap around the new sheath. When the new loop is completed, the constructing arm retracts and closes the gate.
- As a consequence, we use only four of the elements circulating in the loop to control the self-replication process. The others can be used as a "program", i. e., a set of states with their own transition rules which will then be applied alongside the self-reproduction to execute some function.
- Unlike Langton's loop, our loop does not "die" once duplication is achieved, as the circulating data remains untouched by the self-reproduction process. This feature is a requirement for implementing functions which work after the copy has finished.



Self-Replication and Cellular Automata, Figure 8
Propagation pattern of Langton's loop

We use a 9-element neighborhood (the element itself plus its 8 neighbors) and the basic configuration of the loop (Fig. 11) requires five states plus at least one data state. State 0 (black) is the *quiescent* state: it represents the inactive background. State 1 (white) is the *sheath* state, that is the state of the elements making up the sheath and the four gates. State 2 (red) is the *activation* state or *control* state. The four gate elements are in state 2, as are the messengers which will be used to command the constructing arm and the tip of the constructing arm itself for the first phase of construction, after which the tip of the arm will switch to state 3 (light blue), the *construction* state. State 3 will construct the sheath that will host the offspring, signal the parent loop that the sheath is ready, and lead the duplicated data to the new loop. State 4 (green), the destruction state, will destroy the constructing arm once the copy is completed. In addition to these states, two additional *data* states (light and dark grey) represent the information stored in the loop. In this example, they are inactive, while the next section describes a loop where they are used to store an executable program.



Self-Replication and Cellular Automata, Figure 9
A two-tape Turing machine appended to Langton's loop (iteration 0)

The initial configuration is in the form of a square loop wrapped around a sheath. The size of the loop is variable, and for our example is set to 8 × 8. Once the iterations begin, the data starts turning counterclockwise around the loop. Nothing happens until the first control element (red) reaches a corner of the loop, where it checks the status of the gate. Since the gate is open, the control element splits into two identical elements: the first continues turning around the loop, while the second starts extending the arm (Fig. 12).

The arm advances automatically by one position every two iterations. Once the arm has started extending, each control element that arrives to a corner will again split and one of the copies will start running along the arm, advancing twice as fast. When the first of these messengers reaches the tip of the arm, the tip, which was until then in state 2, passes to state 3 and continues to advance at the same speed. This transformation tells the arm that it has reached the location of the offspring loop and to start constructing the new sheath. The next three messengers will force the tip of the arm to turn left, while the fourth causes the sheath to close upon itself (Fig. 13). It then runs back along the arm to signal to the original loop that the new sheath is ready. Once the return signal arrives at the corner of the original loop, it causes a copy of the data in the loop to run along the arm and wrap itself around the new sheath. Once the second copy has completed the loop (Fig. 14), it sends a destruction signal (green) back along the arm. The signal will destroy the arm until it reaches the corner of the original loop, where it closes the gate to avoid further copies.

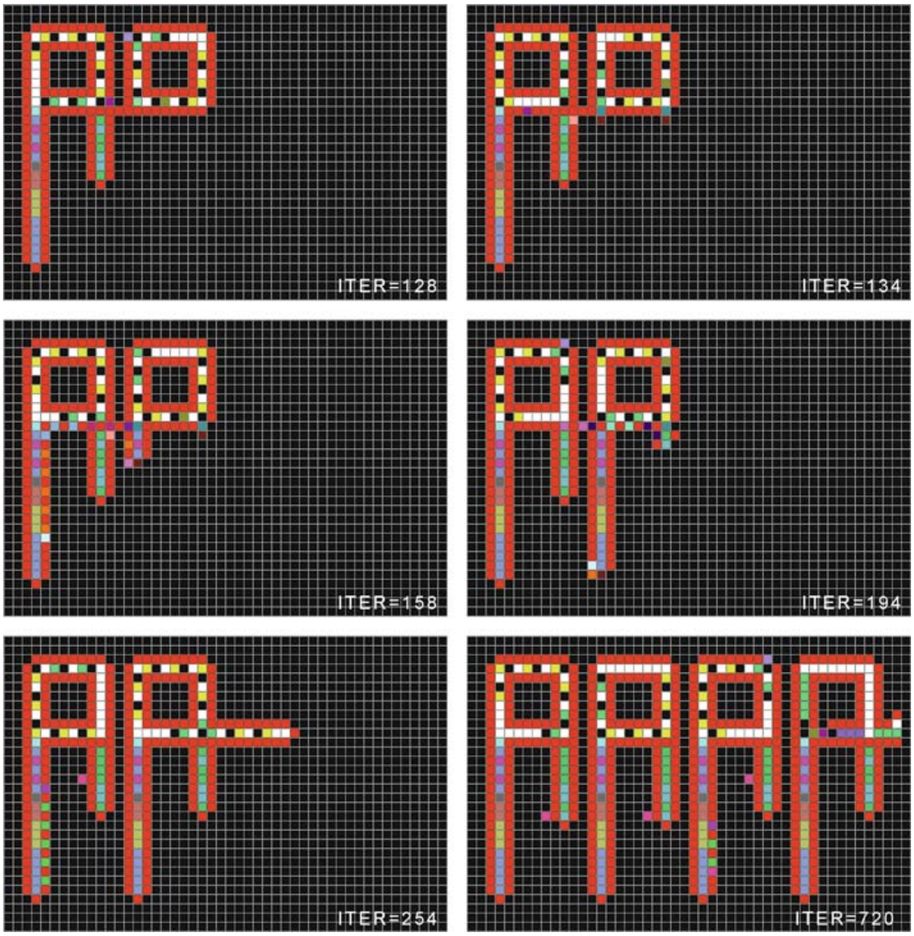
After 121 time periods the gates of the original automaton will be closed and it will enter an inactive state, with the understanding that it will be ready to reproduce itself again should the gates be opened. The main advantage of the new mechanism is that it becomes relatively simple to retract the arm if an obstacle (either the boundary of the array or another loop) is encountered, and therefore our loop is perfectly capable of operating in a finite space.

In Fig. 15, we illustrate an example of how the data states can be used to carry out operations alongside self-reproduction. The operation in question is the construction of three letters, LSL (the acronym of Logic Systems Laboratory, where the research was made), in the empty space inside the loop. Obviously this is not a very useful operation from a computational point of view, but it is a far from trivial construction task which should suffice to demonstrate the capabilities of the automaton.

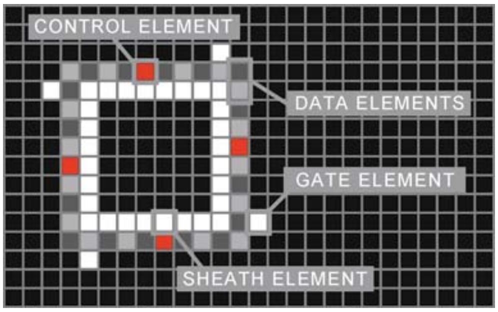
As should be obvious, while our loop owes to von Neumann the concept of constructing arm and to Langton (and/or Codd) the basic loop structure, it is in fact a very different automaton, endowed with some of the properties of both. We have seen that von Neumann's automaton is extremely complex, while Langton's loop is very simple. The complexity of our automaton is more difficult to estimate, as it depends on the data circulating in the loop. The number of non-quiescent elements making up the initial configuration depends directly on the size of the circulating program. The more complex (i. e. the longer) the program, the larger the automaton (it should be noted, however, that the complexity of the self-reproduction process does not depend on the size of the loop). The number of transition rules is obviously a function of the number of data states: in the basic configuration (i. e., one data state), the automaton needs 692 rules (173 rules rotated in the four directions), assuming that, by default, all elements remain in the same state. The complexity of the basic configuration is therefore in the same order as that of Langton's and Byl's loops, with the proviso that it is likely to increase drastically if the data in the loop is used to implement a complex function.

Other Approaches to Self-Replication

Von Neumann's and Langton's structures represent the main landmarks in the study of self-replication in com-



Self-Replication and Cellular Automata, Figure 10
Self-replication of the Turing machine



Self-Replication and Cellular Automata, Figure 11
The initial configuration of our loop (iteration 0)

puting machines. It can safely be said that all other approaches refer, directly or indirectly, to these two systems. However, there exist some approaches to self-replication that cannot be easily reduced to simple variations on one of these two themes, either because they specifically take into consideration some issues that are not addressed by Langton and von Neumann, or because they occur in environments that are considerably different from the two original approaches.

In this section, we will deal in depth with one example, the *Tom Thumb algorithm* that, while referring back to von Neumann insofar as its goal is the implementation of self-replicating logic circuits, is specifically designed to operate efficiently in the kind of digital devices that are available today. The algorithm approaches cellular automata from a slightly unconventional angle [37], with the objective of a hardware realization of self-replication within a programmable logic device, or FPGA [41].

In the second part of the section, we will look at a set of approaches to self-replication that represent notable extensions to the approaches of von Neumann and Langton, because of different mechanisms (self-inspection), operat-

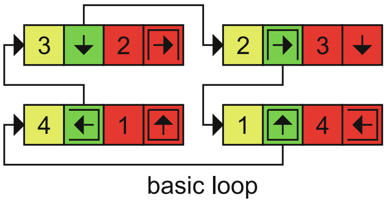
Self-Replication in Hardware: The Tom Thumb Algorithm

In past years, we have devoted considerable effort to research on self-replication, studying this process from the point of view of the design of high-complexity multi-processor systems (with particular attention to next-generation technologies such as nanoelectronics). When considering self-replication in this context, Langton's loop and its successors share several weaknesses. Notably, besides the lack of functionality of Langton's loop (remedied only partially by its successors), which severely limits its usefulness for circuit design, each of these automata is characterized by a very loose utilization of the resources at its disposal: the majority of the elements in the cellular array remain in the quiescent state throughout the entire self-replication process.

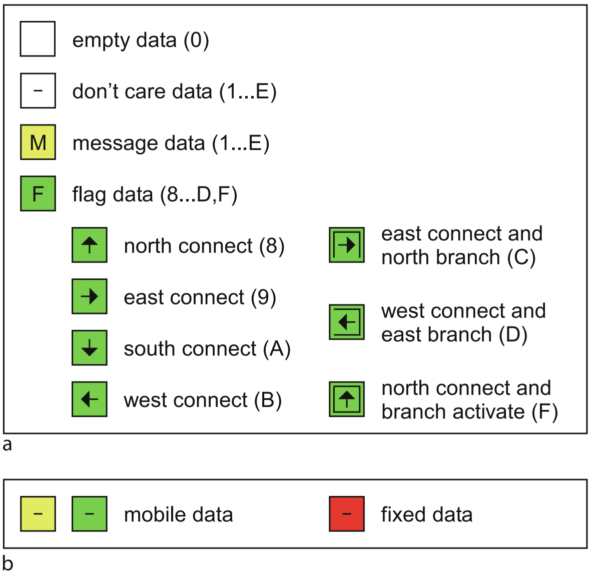
A new loop was then developed specifically to address these very practical issues. In fact, the system is targeted to the implementation of self-replication within the context of digital circuits realized with programmable logic devices (the states of the cellular automaton can then be seen as the configuration bits of the elements of the device). The new loop is based on an original algorithm, the so-called *Tom Thumb algorithm* [18,19].



Self-Replication and Cellular Automata, Figure 16
Tom Thumb algorithm: basic loop

The minimal loop compatible with this algorithm is made up of four cells, organized as a square of two rows by two columns (Fig. 16). Each cell is able to store in its four memory positions four hexadecimal characters of an artificial *genome* (defined as the information required for the construction of the loop). The whole loop thus embeds 16 such characters.

The original genome for the minimal loop is organized as another loop, the *basic loop*, of eight hexadecimal characters, i. e. half the number of characters in the minimal



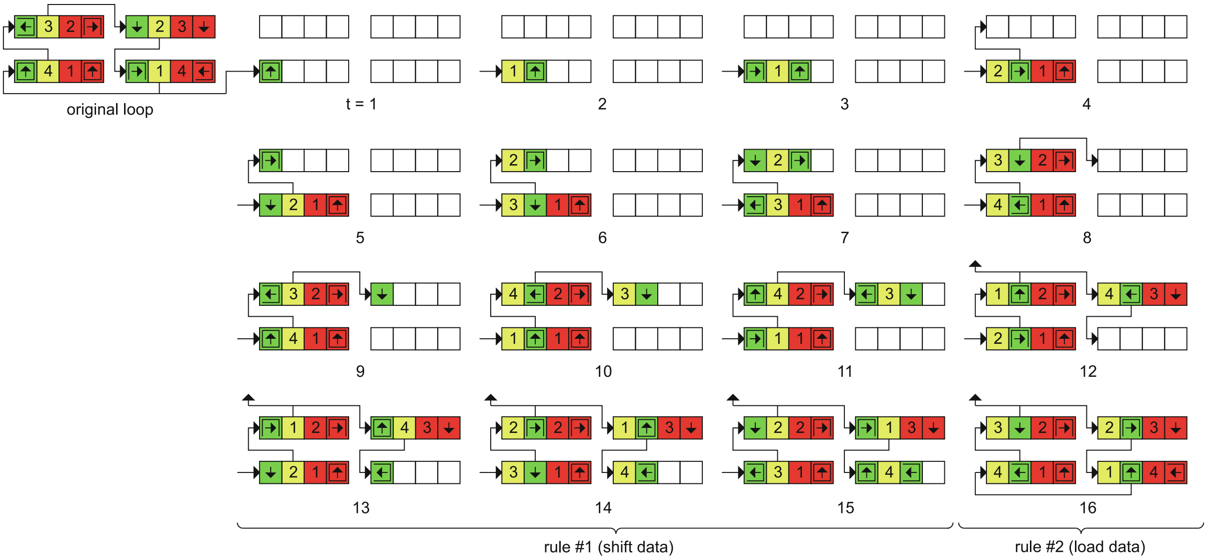
Self-Replication and Cellular Automata, Figure 17
a Graphical and hexadecimal representations of the 15 characters forming the alphabet of the artificial genome. b Graphical representation of the status of each character

loop, moving counterclockwise by one character at each time step.

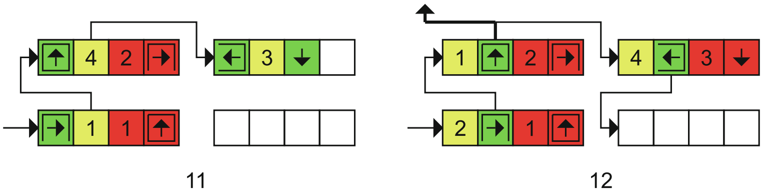
The 15 hexadecimal characters that compose the alphabet of the artificial genome are detailed in Fig. 17a. They are either *empty data* (0), *message data* ($M = 1 \dots E$), or *flag data* ($F = 8 \dots D, F$). Message data will be used to configure our final artificial organism, while flag data are indispensable for constructing the skeleton of the loop. Furthermore, each character is given a status and will eventually be *mobile data*, moving indefinitely around the loop, or *fixed data*, definitely trapped in a memory position of a cell (Fig. 17b). It is important to note that, while in this simple example the message data can take value from 1 to E, the Tom Thumb algorithm is perfectly scalable in this respect, that is, the size of the message data can be increased at will, while the flag data remain constant. This is a crucial observation in view of the exploitation of this algorithm in a programmable logic device, where the message data (the configuration data for the programmable elements of the circuit) are usually much more complex.

At each time step ($t = 1, 2, \dots$), a character of the *original loop* is sent to the lower leftmost cell (Fig. 18). The construction of the loop, i. e., storing the fixed data and defining the paths for mobile data, depends on two rules:

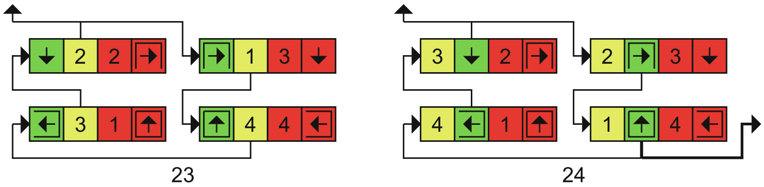
- If the four, three, or two rightmost memory positions of the cell are empty (blank squares), the characters are shifted by one position to the right (rule #1: shift data).
- If the rightmost memory position is empty, the characters are shifted by one position to the right (rule #2: load data). In this situation, the two rightmost characters are trapped in the cell (fixed data), and a new connection is established from the second leftmost position toward the northern, eastern, southern or western cell, depending on the fixed flag information (in Fig. 18, at



Self-Replication and Cellular Automata, Figure 18
Construction of a first specimen of the loop



Self-Replication and Cellular Automata, Figure 19
Creation of a new daughter loop to the north (rule #3)



Self-Replication and Cellular Automata, Figure 20
Creation of a new daughter loop to the east (rule #4)

time $t = 4$, the fixed flag F = F determines a northern connection).

At time $t = 16$, 16 characters, i. e., twice the contents of the basic loop, have been stored in the 16 memory positions of the loop (Fig. 18). Eight characters are fixed data, forming the *phenotype* of the final loop, and the eight remaining ones are mobile data, composing a copy of the original genome, i. e., the *genotype*. Both *interpretation* (the construction of the cell) and *copying* (the duplication of the genetic information) have been therefore achieved.

The fixed data trapped in the rightmost memory positions of each cell remind us of the pebbles left by Tom Thumb for memorizing his way in the famous children's story, an analogy that gives our algorithm its name.

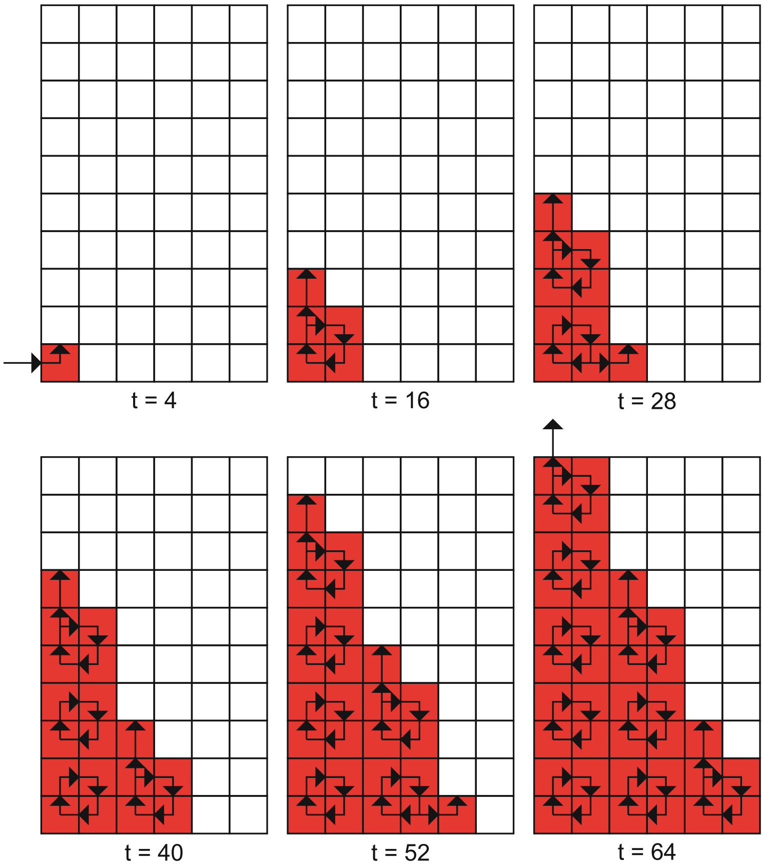
In order to grow loops in both horizontal and vertical directions, the mother loop should be able to trigger the construction of two daughter loops, northward and eastward. Two new rules are then necessary:

- At time $t = 11$ (Fig. 19), we observe a pattern of characters which is able to start the construction of the northward daughter loop; the upper leftmost cell is characterized by two specific flags, i. e., a fixed flag in the rightmost position, indicating a north branch (F = C) and the branch activation flag (F = F), in the leftmost position (rule #3: daughter loop to the north). The new path to the northward daughter loop will start from the second leftmost memory position ($t = 12$).
- At time $t = 23$ (Fig. 20), another particular pattern of characters starts the construction of the eastward daughter loop; the lower rightmost cell is characterized by two specific flags, i. e., a fixed flag indicating an east branch (F = D), in the rightmost position, and the branch activation flag (F = F), in the leftmost position (rule #4: daughter loop to the east). The new path to the eastward daughter loop starts from the second leftmost memory position ($t = 24$).

When two or more paths are activated simultaneously, a clear priority should be established between the different paths. Three growth patterns were chosen (Fig. 21), leading to four more rules:

- For loops in the lower row a collision occurs between the closing path, inside the loop, and the path entering the lower leftmost cell. The westward path has priority over the eastward path (rule #5).
- With the exception of the bottom loop, the inner path (i. e. the westward path) has priority over the northward path (rule #6) for the loops in the leftmost column.
- For all other loops, two types of collisions may occur: between the northward and eastward paths (2-signal collision) or between these two paths and a third one, the closing path (3-signal collision). In this case, the northward path will have priority over the eastward path (2-signal collision), and the westward path will have priority over the two other ones (3-signal collision)(rules #7 and #8).

We finally opted the following hierarchy: an east to west path has priority over a south to north path, which has priority over a west to east path.



Self-Replication and Cellular Automata, Figure 21
Growth of a colony of minimal loops represented at different time steps

The results of such a choice are as follows (Fig. 21): a closing loop has priority over all other outer paths, which makes the completed loop entirely independent of its neighbors, and the loops will grow bottom-up vertically. This choice is quite arbitrary and may be changed according to other specifications.

Unlike its predecessors, the Tom Thumb loop has been developed with a specific purpose beyond the theoretical study of self-replication. We believe that, in the not-so-distant future, circuits will reach densities such that conventional design techniques will become unwieldy. Should such an hypothesis be confirmed, self-replication could become an invaluable tool, allowing the engineer to design a single processing element, part of an extremely large array that would build itself through the duplication of the original element.

Current technology does not, of course, provide a level of complexity that would render this kind of process necessary. However, programmable logic devices (already among the densest circuits on the market) can be used as a first approximation of the kind of circuits that will become available in the future. Our loop is then targeted to the implementation of self-replication on this kind of device.

To this end, our loop introduces a number of features that are not present in any of the historical self-replicating loops we presented. Most notably, the structure of the loop (that is, the path used by the configuration data) is determined by the sequence of flags in the genome, implying that structures of almost any shape and size can be constructed and replicated using this algorithm, as long as the loop can be closed and that there is space for the daughter organisms. In practice, this implies that, if the Tom Thumb algorithm is used for the configuration logic of a programmable device, any of its configurations, and hence any digital circuit, can be made capable of self-replication.

In addition, particular care was given to develop a self-replication algorithm that is *efficient* (in the sense that it fully exploits the underlying medium, rather than leaving the vast majority of elements inert as past algorithms did), *scalable* (all the interactions between the elements are purely local, implying that organisms of any size can be implemented), and amenable to a *systematic design process*. These features are important requirements for the design of highly-complex systems based on either silicon or molecular-scale components.

Different Techniques and Environments

Von Neumann's and Langton's automata share a common basic technique to obtain self-replication: the construction of the new machine is directed through the *interpretation* of a description, coded as a sequence of states. In the case of von Neumann, this description (which, in biological terms, is usually identified as the genome of the artificial organism) is stored within the memory tape, which is read and interpreted by the universal constructor to build a copy of the machine. In Langton's case, the description is stored in the mobile data that runs within the sheath of the loop.

This mechanism of interpretation, while standard in many approaches, is not however unique: some examples of self-replicating CA exploit a different mechanism, that of *self-inspection*. In these approaches, instead of reading and interpreting a description, the self-replicating automaton inspects itself and produces a copy of what it finds. While less general than the universal constructor (obviously, the machine can only build an exact copy of itself), the functionality of this approach is similar to that of Langton's loop. Indeed, the most representative example of self-inspection is that of a self-replicating loop [12]. A more recent example is a variation of the Tom Thumb algorithm, where self-inspection was used to self-replicate a small processor within a field-programmable gate array [30].

And while the Tom Thumb algorithm targets in priority silicon-based circuits, other approaches have tried to explore alternative environments that, in some way, might more closely resemble the kind of technologies that will be available in the future. An example is Morita and Imai's study of self-replication in the context of reversible cellular automata [20] (in a reversible CA, every configuration has at most one predecessor), inspired by reversible logic in digital circuits.

Similarly, Peper et al. [24,38] have developed self-replicating structures in Self-Timed Cellular Automata (STCA). This kind of automata do not rely on a global synchronization mechanism to update the states of the cells, but rather the state transitions only occur when triggered by transitions in neighboring cells. The basic assumption in this work is that STCA is a model that might more closely resemble molecular-scale nanoelectronic devices.

A final example in this context is the three-dimensional extension of self-replication, usually based on the assumption that silicon, with its rigidly two-dimensional structure, will one day be superseded by a technology that can exploit all three dimensions. In this context, Imai et al. [13] have extended their reversible approach, with the assumption that reversible logic is more amenable to an extension to three dimensions than conventional logic because of the greatly reduced power dissipation. Stauffer at al. [36] have also shown that the Data and Signal Cellular Automaton (DSCA) approach, designed to simplify the implementation of CA in digital hardware, can be extended to realize self-replication in three dimensions.

The study of self-replicating CA in the context of new technologies holds the promise of one day bringing a major contribution to computation. To determine how self-replication might be useful in this context, some attempts have been made at using self-replicating structures for computation. An example of this approach is the work of Chou and Reggia [8], who use self-replication as a mechanism to obtain massively parallel machines which can potentially be used to solve hard problems (the example used in the paper is the NP-complete problem of satisfiability).

An attempt was also made to perform computation using Tempesti's loops. In alternative to embedding a complex program, this kind of loops are used to perform computation by inter-loop communication. Using the *collision-based computing* paradigm, Petraglio et al. [28] have shown that it is possible to implement arithmetic operations by passing messages from one loop to another after building a network structure through self-replication. This approach, while valuable from a theoretical standpoint, shares however the same weakness of other loop-based computing approaches in that the poor utilization of resources makes a physical realization of such a system highly impractical.

Another problem to be solved for a practical implementation of self-replicating structures is their design: few approaches have attempted to define a precise methodology to define and create self-replicating structures. In this context, several researchers have attempted to use evolutionary techniques to find automatically self-replicating machines. In this context, the work of Sayama et al. has gone through several iterations [31,32,33] in an attempt to define loops that evolve through the self-replication process towards "fitter" individuals. Chou and Reggia [7], on the other hand, use evolution to find novel self-replicating structures within a CA, whereas Pan and Reggia [23] studied the conditions in which self-replicating structures might spontaneously emerge in a cellular space.

Future Directions

Historically, self-replication in cellular automata began as a paradigm to achieve fault tolerance in computing devices. In the following decades, much of the emphasis shifted towards a more "theoretical" approach where self-replication was considered as part of a more general investigation into the application of biologically-inspired mechanisms to computing. And while the latter approach remains an active research topic, the original paradigm was somewhat set aside because technology would not allow a practical implementation of self-replication in digital hardware.

More recently, however, advances in electronic devices (notably with the introduction of programmable devices, or FPGAs), together with emerging technological issues have rekindled interest in self-replication in a context similar to von Neumann's original work. In particular, the drastic device shrinking, low power supply levels, and increasing operating speeds, which accompany the technological evolution of silicon to deeper submicron levels, significantly reduce the noise margins and increase the soft-error rates [42]. In addition, the nascent field of nanoelectronics holds great promise for the future of computing devices, but introduces extremely high fault rates (e. g., [25]) and complex layout issues.

Thus, self-replication is currently attracting a considerable amount of attention for the same reasons that initially pushed von Neumann to investigate it as a possible solution to reliability and layout issues. Fault tolerance and self-organization are thus becoming the focal point of research in the field and the features of molecular-scale electronics seem to imply that self-replication at the device level will be an extremely useful paradigm in next-generation devices.

Article Outline

Glossary

Dereferencing Dereferencing a URI is using the URI to identify the object or resource it refers to.

Folksonomy 'Folksonomy' is a neologism applied to structures that emerge from the practice of 'tagging' Web content. In some Web 2.0 applications, users can apply a tag (a descriptive term) to content such as a photograph or video clip. The tags need only be meaningful to the individual tagger, but if a large enough number of users tag content, descriptive structures analogous to more formal ontologies can emerge that are meaningful to wide communities.

GRDDL Gleaning Resource Descriptions from Dialects of Languages (GRDDL, pronounced 'griddle') is a mechanism for helping bootstrap the Semantic Web, by extracting RDF from XML documents, using transformations expressed in XSLT. GRDDL became a W3C recommendation in 2007.

Metadata Metadata is data about data. In the context of the Semantic Web, metadata are also called 'markup' or 'annotations'. Because one aim of the Semantic Web is to support machine processing of information, metadata are helpful in describing the content of data. For example, metadata attached to a series of numerals could explain that it represents a zip code or a height or a population figure.

Ontology An ontology defines, describes and constrains the concepts and relationships that are used in some particular domain of knowledge. Ontologies may therefore have an important role in data sharing, for example by providing a means of expressing which concepts (in the ontology) are referred to by particular terms (in a set of databases, which may use widely differing vocabularies).

OWL The Web Ontology Language (OWL) is a language for describing and sharing ontologies on the Web. It is an extension of RDF, and has three variants. OWL Full is maximally expressive and compatible with RDF (any legal RDF document is a legal OWL Full document), but is undecidable. OWL DL is based on a series of restrictions of OWL Full which support efficient reasoning, at the cost of losing the strong connection with RDF (not all RDF documents are legal OWL DL documents). OWL Lite is even more restricted in expressivity, but is easier to grasp. OWL became a W3C recommendation in 2004.

RDF The Resource Description Framework (RDF) is a standard framework for representing data on the Web, representing it in a three-place relation, of subject-relation-object form, called a *triple*. It uses URIs to refer not only to the two items related, but also to the relationship asserted between them. In this way it extends the linking structure of the Web by allowing the nature of the link asserted to be described. Its syntax is XML-based, to support syntactic interoperability between the two. RDF became a W3C recommendation in 1999.

RDF(S) RDF Schema (RDF(S) or RDFS) is a language for representing information on the Web. It is an extension of RDF to allow the description of the relationships which can be asserted between resources using RDF. So, for instance, RDF allows the assertion of the relationship 'author' between, say, 'Herman_Melville' and 'Moby_Dick', but RDF(S) is required to assert the properties of the 'author' relationship (e. g. that every document has at least one author, or that the 'author' relationship is the inverse of the 'written_by' relationship). RDF(S) became a W3C recommendation in 2004.

Rules and RIF Rules govern the transformation of, and inference from, data. In particular, when data are being shared, it may be useful to make basic inferences over the data (for example, to determine whether two names refer to the same object or different objects). Rule-based knowledge such as this cannot be expressed in individual data stores, and may be hard to express in an ontology. The Rule Interchange Format (RIF) is a language, not complete at the time of writing, to express the most common or basic types of rule.

SPARQL SPARQL is a special query language designed specifically for querying data stored in RDF ('SPARQL' is a recursive acronym standing for 'SPARQL Protocol And RDF Query Language', and is pronounced 'sparkle'). SPARQL became a W3C recommendation in January 2008.

Triples and triplestores A triple is a statement in RDF, consisting of a subject, an object, and a binary predicate that relates them. Each item of the triple is identified by a URI reference (or can be a string literal, such as a date or a number or name). A knowledge repository which contains RDF triples is called a triplestore. Triplestores may need to contain several millions of triples, and so need to be able to support fast querying at these potentially very large scales.

URI A Uniform Resource Identifier (URI) is a string of characters for identifying an abstract or physical object or resource. There are different URI schemes (i. e. different ways to restrict the syntax of a URI to make it meaningful). A Uniform Resource Locator (URL) is a particular type of URI that identifies its object by means of its access mechanism or 'location' in the network. URIs are important in that they act as a standard way of referring to objects on the Web.

W3C The World Wide Web Consortium (W3C) is an international non-profit consortium which coordinates the development of Web standards, founded in 1994 under the directorship of Sir Tim Berners-Lee. The W3C groups together all the bodies involved in specifying Semantic Web standards into the Semantic Web Activity. A W3C working group works on a standard for a particular formalism, and when the standard is judged by the working group to be in a final form, fit for purpose and properly interoperable with other W3C standards, it ratifies the formalism by recommending it. Hence a W3C recommendation is an important standard.

Web of data The Web of Data is another way of referring to or explaining the vision of the Semantic Web, which emphasises the idea of creating links between data rather than documents (as on the current World Wide Web). Linking data, as with linking documents, enables them to be reused in interesting or unexpected contexts (when the data are interpreted using explicit semantic theories of the sort provided by ontologies). RDF is the anticipated mechanism for creating the links between data; dereferencing one or more of the URIs in an RDF triple will lead to descriptions of the resources referred to, which in turn are likely to contain further triples, which can again lead to dereferencing and so on.

Web science Web Science is the multidisciplinary activity of trying to understand the two-way dynamic relationship between Web technology and wider society, in order to ensure that the technological changes made to the Web (including the Semantic Web) are generally beneficial rather than otherwise.

XML The eXtensible Markup Language (XML) is a language for allowing users to tag or mark up content using tags of their own devising (for instance based on a particular vocabulary used in a small community of practice). As such, XML can serve as a basic data exchange format between applications. It is an advance on other well-known markup languages (such as HTML, a standard language for marking up content for display on the Web) in that it separates instructions to do with content and document structure from those to do with formatting. It is a basic language for representing and exchanging structured information.

Definition of the Subject

The Semantic Web is a proposed extension to the World Wide Web (WWW) that aims to provide a common framework for sharing and reusing data across applications. The most common interfaces to the World Wide Web present it as a Web of Documents, linked in various ways including hyperlinks. But from the data point of view, each document is a black box – the data are not given independently of their representation in the document. This reduces its power, and also (as most information needs to be extracted from documents by a human agent) inhibits the use of automatic information processing methods on the Web. The Semantic Web is an effort, steered by the World Wide Web Consortium, to develop a set of protocols, formalisms and standards to transform the Web into a *Web of Data*. Links would be between data, and data could be accessed independently of the applications that created them. This would allow both the sharing of data, and the amalgamation of data from different sources, using heterogeneous formats, in new contexts.

Introduction

The idea of the Semantic Web (SW), of exploiting the possibilities for serendipitous reuse of linked data, dates back at least to Sir Tim Berners-Lee's plenary talk at the first International World Wide Web Conference at CERN in Geneva in 1994 [33]. In that talk, Berners-Lee argued that there is too little machine-readable information on the WWW as was currently constituted. "The meaning of the documents is clear to those with a grasp of (normally) English, and the significance of the links is only evident from the context around the anchor. To a computer, then, the Web is a flat, boring world devoid of meaning. This is a pity, as in fact documents on the Web describe real objects and imaginary concepts, and give particular relationships between them. … Adding semantics to the Web involves two things: allowing documents which have information in machine-readable forms, and allowing links to be created with relationship values. Only when we have this extra level of semantics will we be able to use computer power to help us exploit the information to a greater extent than our own reading." Indeed, the original vision of the WWW was intended to support greater machine understanding of people's work and interactions; the 'flat' understanding of the world that the WWW produces in machines is a first step towards the richer vision.

The SW was from the beginning conceived as a set of layered standards and formalisms (see Sect. "The Layered Model of the Semantic Web" for details). The development of the Resource Description Framework (RDF) in the 1990s was a key technology [80]. RDF is an important formalism, as it allows expression not only *of* the link between two objects, but also about the *nature* of the link itself. Hence, one can follow a chain of links not only via the objects linked, but also the types of links involved. In the WWW of documents, links connect documents written in the Hypertext Markup Language HTML; in the SW, links in RDF connect not only documents but arbitrary things (objects and relationships) identified by the Uniform Resource Identifiers (URIs [38]) in the RDF triples representing the data.

The ability to move between data linked in such a way opens up the possibility of exposing data to the Web, and then being able to access such data from any application. As a simple example, consider personal information such as one's bank statements, information-based resources such as digital photographs, and an application such as a calendar or diary. Each of these depends on data which is controlled by the applications that use them. But in a genuine Web of Data, we could link these data in a productive way – something as simple as being able to present one's financial information in one's calendar. The metadata in one's photographs often includes information about the time of their creation; an application able to get at the photograph metadata and the data on one's calendar might be able to suggest where the photo was taken, and its possible location. The ability to use all these data in a constructive way is impossible without a Web of linked data to enable applications to move between the data sources.

In this way, the SW changes our model of the value of information. Currently, it is generally presumed that the value of information stems from its *scarcity* – people and organizations gain value from information they have gathered, and are given monopoly rights to exploit that information via such legal contrivances as copyright, intellectual property rights, licensing, and so on. Even when organizations do not resort to the law, they will make great investments in protecting trade secrets. However, this scarcity-based model seems inadequate for the digital age.

In the first place, as economist William Baumol has argued, the social benefits from unlicensed use of 'protected' knowledge and innovation, were already large in the predigital economy, and indeed account for much of our wealth today: "some 80 percent of the benefits [innovation] may – i. e. change round brackets to square, as this is an editorial interpolation by us plausibly have gone to persons who made no direct contribution to innovation. The rather startling implication of all this is that the spillovers of innovation, both direct and indirect, can be estimated to constitute well over half of current [US] GDP – and it can even be argued that this is a very conservative figure" (see p. 135 in [32]). And secondly, the Internet and the Web have made it harder to preserve monopoly rights to information, as copying and distribution reduces the marginal cost to producers to close to zero. Although many media companies have taken rearguard action to protect their intellectual property, so simple is the distribution model on the Web that the basis of the value of information is rapidly switching from scarcity to *abundance*. It is the large quantity of data, that can be placed in novel and unintended contexts with little cost, that makes it increasingly valuable in the age of digital technologies – and it is this abundance that the SW is designed to foster.

One of the major drivers of the SW has been the transformation of science into *e-science*, a computer-enabled, data-heavy view of science as the analysis of the very large quantities of information that improved instrumentation, larger computer power, more prevalent sensor networks and greater memory storage have released. Several disciplines have seized on the opportunity to exploit such data, which are often available only in diverse and heterogeneous datasets. In particular, interdisciplinary research is growing in importance, requiring data developed in different disciplines, using a confusion of vocabularies and methods of collection. Methods for dealing with such large and heterogeneous datasets are required in many areas, including the life sciences, climate research, medicine and epidemiology, and genomics, to name but four, which explains the interest in many of these fields in the SW.

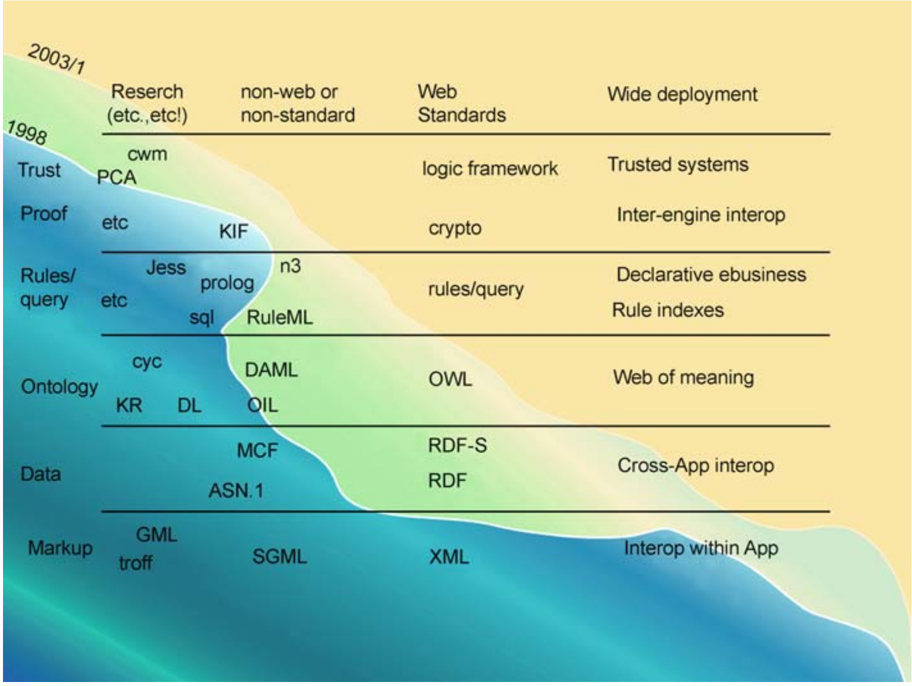
The use of the SW in such large, public projects was perhaps predictable, but much debate and discussion has focused more on the individual's interface to it. We discuss this in more detail below, but one reason for this was that the landmark publication for the public view of the SW, an article in *Scientific American* for 2001, written by Berners-Lee, James Hendler and Ora Lassila [37], developed the idea of a Web of Data with a number of household gadgets interfacing with it. The possibilities envisaged in their scenario included: a telephone that turned down the volume of all local devices with volume controls when it rang; an agent that could plan a program of medical care; and a calendar that could integrate this information to adjust a set of appointments. The point of the article was not the impressive set of agents, but rather the Web of Data that sat underneath them. However, many readers focused on the gadgets, and – given that such gadgets are not at the time of writing very common or effective – have concluded either that the SW has been a failure, or that it was an unrealistic vision from the beginning (see Sect. "Controversies").

In 2006, a further publication by Berners-Lee, together with Nigel Shadbolt and Wendy Hall, appeared in the publication *IEEE Intelligent Systems* de-emphasising the agents and focusing on the idea of the SW as a Web of Data or actionable information [101]. This paper argued that the agents described in 2001 could only flourish when standards for data sharing are well-established. The need for such standards, and for SW technologies in general, was growing, thanks to developments such as e-science, information-based medicine, and e-government.

Since the late 1990s, the World Wide Web Consortium (W3C), under the direction of Berners-Lee, has led the drive to create the standards. Figure 1 shows a diagrammatic representation of the progress of the SW in the development of its layered standards (the hierarchically-arranged layers are marked in Fig. 1 down the left hand column as markup/data/ontology etc.). The development of each layer goes through a long, sometimes tortuous, process of research and discussion. Initial stages of research, sometimes competitive, after some time produce a rough consensus about the general properties of a formalism to implement a layer. At that point, consideration is undertaken about creating a Web standard by the W3C.

To create a standard, a group, representative of stakeholders from academe and private enterprise, is assembled by the W3C, which first creates a *working draft*, which is released under that status for review by the community. Commentary is welcomed, and the draft may be changed dramatically. Once the group responsible for the standard is satisfied that it is fully capable of doing what it required, it is released as a *candidate recommendation*, when it is critiqued in terms of the practicability of its implementation. The next stage is to become a *proposed recommendation*, when it is submitted to the W3C advisory council. Finally, it is released as a W3C recommendation. It generally takes years to negotiate these various stages. Currently, the markup language XML, the data representation and interchange languages RDF and RDF(S), and the ontology language OWL are full recommendations. The next layer up from the ontology layer is that of rules and querying: the query language SPARQL became a W3C recommendation in January 2008 [96], while the rule expression language RIF is at the time of writing at the working draft stage [41].

Figure 1 represents the historical progress of the SW in terms of a 'wave' rolling over 'dry land'. The depth of the 'sea' indicates the extent to which SW standards have been accepted and been deployed widely. The SW wave is traveling from the bottom left of the diagram to the top



Semantic Web, Figure 1
The wave of development of the Semantic Web [51]

right; the net result of this is that the lower levels of the SW are coming into being and wide acceptance ahead of the higher levels. RDF is, at the time of writing, reasonably widely deployed; SPARQL has recently become a recommendation; trust (the highest level represented here) is still a research issue, and the consensus about what form a standard to represent and promote trust in data is still in the process of formation.

Linking Data

The underlying aim of the SW is to allow data to be explored and queried on the Web, analogously to the way that documents are currently investigated online. One precondition for this is obviously the publishing of data on the Web, but another is to create the links that allow data to be explored. RDF allows representation of data in such a way that anything referred to in the data can be linked to, and from. If URIs are used to name things, common naming schemes are allowed to emerge; one of the most important is the Hypertext Transfer Protocol (HTTP [59]), which affords a straightforward mechanism for people to look up the names. In a properly linked Web of Data, the URI, once looked up, should provide access to useful information about the resource named, as well as useful links out to other data.

Links can be made using various mechanisms, the simplest of which is to use a URI that points to another. For example (taken from [35]), someone might describe some relationships in RDF as follows:

```
<rdf:Description about="#albert"
   <fam:child rdf:Resource="#brian">
   <fam:child rdf:Resource="#carol">
</rdf:Description>
```

This RDF is about three resources given the local identifiers '#albert', '#brian' and '#carol', and might be placed in a file called '<http://example.org/smith>'. The architecture of the Web can use these names to provide a global identifier for the three resources; for instance "http://example.org/smith#albert" refers to #albert, and so on. And now there is a global identifier, links can be made. For instance, a document '<http://example.org/jones>' might contain the following RDF:

```
<rdf:Description about="#denise"
   <fam:child rdf:Resource="#edwin">
   <fam:child rdf:Resource=
                        "http://example.org/smith#carol">
</rdf:Description>
```

Here a series of relationships between resources #denise, #edwin and #carol have been asserted, but the datum about #carol makes it possible to link to the data in the other file. Someone following the link dereferences the URI, i. e. decomposes 'http://example.org/smith#carol' into two parts: the part before the '#' which gives the name and location of the file; and '#carol' which is the local identifier in that file. Hence the information about #carol in the first file can be accessed thanks to the link included in the second file. The series of links between different resources can be represented, at least on a small scale, graphically, as in Fig. 3. This is the simplest way of linking data, though there are others [35]. And if the URI used for reference is created under a widely-supported system in a community, then the prospects for linking data are that much larger.

One of the main drivers of the SW is the vast quantity of data available in the form of relational databases (RDBs) (RDBs), which often exist in isolation from each other. Each database has its own value, but as argued above, the major source of informational value in the digital age is abundance, the possibilities for serendipitous reuse of data by placing it in fruitful contexts. To that end, a key aim of the SW is to harvest the large amount of data held in RDBs – a much larger quantity than is currently available in the document Web – and to support its amalgamation. The net result will be to facilitate the treatment of all the data as, in effect, sitting in a single queryable database.

Much of the current Web is supported by larger databases that sit below the level of what can be seen on a webpage; these databases are known as the *deep Web*, as opposed to the *shallow Web* on webpages. So, for instance, when one looks at one's bank statement on the shallow Web, the webpage that the bank's site creates uses a much larger quantity of data about one's bank account than is visible at any one time. Hence an alternative way of looking at this role for the SW is as a method for allowing users to query the whole of the deep Web, rather than simply the information released onto the shallow Web by the current set of implemented applications.

An RDB consists of a series of *tables*, which consist of *rows* or *records* of individual data items. Each record consists of a set of values of *fields* or *attributes*. The records (rows) and fields (columns) together can be conceived as a table or matrix (m records and n fields give us an $m \times n$ matrix) [50]. So, for instance, each record may represent an individual person, while a particular field may represent zip codes. The value placed in the zip code field of a person's record is therefore the value of that person's zip code. This tabular structure for RDBs can be mapped straightforwardly into an RDF representation. The record can be seen as the subject of an RDF triple, the field name is a link or property type, while the value of that field is the object of the triple. Hence the person who is represented by the record in the example RDB above would be represented by the first item of the triple; the zip code field would be represented by a zip_code property the second item of the triple; and the value of the zip code would be the third item. In that way, each cell of the RDB matrix is represented by an individual RDF triple, and the total set of triples would represent the entire database [34].

Having said that, there are additional factors about RDBs that are harder to capture in the RDF, and there are many open questions about the export of RDB. For instance, it may be that the database is definitive – that is, the institution holding the data has some responsibility for the data. It may be that the State of Texas holds a database of all Texas vehicle registration numbers; any car not on the database is not, as a matter of definition, registered in Texas. On a smaller scale, some RDBs allow a primary field for a unique identifier for the record, which also holds a significance beyond the particular piece of data. There are various ways of modeling these context-based properties of RDBs, perhaps most likely devolving the representation of such matters to the applications that use the data, via the ontologies, rules or query types that they use. See [34] for a worked example of methods to expose an RDB to the Web.

The process of exposing databases to the Web should not be too prescriptive – the whole point of the Web is as a decentralized collection of linked information, whether in the form of data or documents. The links are entirely democratic, and can be made between any pair of data items, or any pair of documents. This is where the power of the Web's ability to promote serendipitous reuse comes in. Attempting to fix the methods or languages used, or to 'police' the links made, will blur this vision, and create bottlenecks impeding information flow. Indeed, the widespread use of the Web is largely down to its non-prescriptive nature – prescription will simply drive users, who will not want particular information management strategies forced upon them, from the Web.

The result is a particularly untidy situation, unusual in the history of information management. If data, information or knowledge is generated within a single organization or affiliation (the usual situation for information managers before the growth of the Web), then information systems can trade on a number of simplifying assumptions. The size of such repositories can be assumed to be small or medium, and representation schemes would be planned and homogeneous. The quality of information would be likely to be high, and managers' trust in it correspondingly high. But on the Web scale, these assumptions fail. The amount of data available for query may be extremely high, and represented in highly heterogeneous ways – rarely in the optimal way for the manager's task in hand. Information quality, and trust in that quality, would be very variable. Linking data using common URI schemes will never work perfectly, precisely because there are deliberately no enforcement mechanisms on the Web, and people cannot be forced to use any particular naming convention.

It is primarily for this reason that ontologies have always played a central role in the vision of the SW [57]. It is the ontology that puts the 'semantic' into 'Semantic Web'. Ontologies specify the vocabulary, concepts and relationships of a domain. They must be a rationalization of current practice, and managed and endorsed by a community. They act as a specification of the terms used in discussion. But they should not be too prescriptive – terms change over time, others are in constant dispute. Ontologies need to develop as a discipline or domain develops. Different areas will have different requirements of ontologies; some sciences will have large, publicly-managed ontologies which act as a public vocabulary standard, while others will make do with small, lightweight ontologies that only define the relationships between a few terms. The ontological requirements of any individual application may be quite small; the question for the application developer is whether to develop a small special-purpose ontology for her own individual purposes, or alternatively whether to reuse a larger, better-known ontology that may overspecify vocabulary for her purposes. Much will depend on the usual practices of her wider community. It should be noted that the SW project does *not* require a single overarching ontology, referring to and prescribing everything.

The ontology is key to being able to deal with heterogeneous datasets as described above; the data, and the terms used in it, must be mapped onto other terms held in common. Once this has been done, then databases can be understood in common terms – and, most crucially, the information they hold amalgamated and processed by machines. It is of course obvious to a human user that if one database of people has a field *ZC*, while another has a field *zip_code*, that there is at least a good chance that the two fields refer to the same attribute of people, viz., the zip codes of their addresses; a computer will merely try, and fail, to match the strings identifying each field. But if the computer is referred to an ontology and given mappings from the terms used in the two databases to the ontology's terms, then it can be told about the equivalence, and accordingly its inference space is opened up (for instance, it could make some inferences from the fact that $ZC(X) = zip\_code(y)$). Machine processing of this heterogeneous, distributed data is made possible by ontologies.

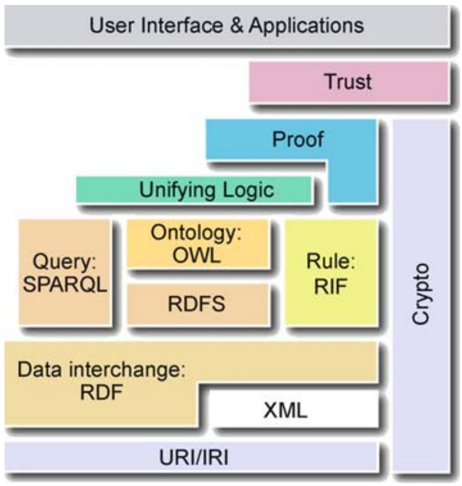
There are, of course, several issues pertaining to the use of ontologies in the SW, some of which will be discussed in greater detail in the Sect. "Controversies". The development of an ontology for an application is a (potentially large) initial cost to an application developer, and it is likely that ontologies, especially well-known ones, will be reused. To that end, searching for ontologies is likely to be a growth area in the future; there are already specialized search engines, such as Swoogle, dedicated to this task [8,54]. It may also be that one application might use several ontologies (for instance, an interdisciplinary scientific application may well reuse well-known ontologies from each discipline that it crosses). In that case, mappings *between* the ontologies will be important, and such mappings, as opposed to the ontologies themselves, could become the semantic basis for the application [78].

Building an ontology from scratch is always an option, especially if the application requires only relatively lightweight ontological apparatus [89]; again, special-purpose tools, such as Protégé are already available and well-used in the SW community [6,90]. Generating an ontology from an RDB can be done semi-automatically, and then mappings (which will be fairly straightforward, given the method of ontology generation) defined between the database and the ontology [105]. The problem is more complex if the aim is to map a legacy database onto an existing ontology. In particular, the mappings between the database and the ontology can be expected to be quite complex, and therefore very expressive languages will be required to describe them, such as the language R_2O [31].

The Layered Model of the Semantic Web

The Web, as a decentralized construction, cannot be created by fiat or prescription, which would limit its growth and create bottlenecks for information mobility. But to allow the Web of Data to reach fruition at the scale envisaged, several related tasks are required to be performed [101]. As discussed above, the W3C has devoted resources over the last few years to developing formalisms and standards to allow these tasks to be addressed, and the tasks themselves have also been arranged in a series of layers, depicted in a hierarchical diagram. The diagram has evolved with the vision of the SW, but is not dissimilar to its first incarnation, and at the time of writing is seen as in Fig. 2.

As noted above, and in Fig. 1, the development of these layers has been bottom-up, concentrating on the lower levels before work begins on those further up. The lower layers are now often the subject of W3C recommendations, while work on the upper layers remains generally more theoretical, and contains more open research questions.



Semantic Web, Figure 2
The layered view of the Semantic Web [39]

At the lowest level we have URIs (and IRIs, Internationalized Resource Identifiers, which are generalizations of URIs allowing non-ASCII characters to be used [56]). URIs identify resources in a global way – in other words, they are interpreted consistently across applications, unlike individual naming conventions, and therefore are central to the vision of a Web of Data [38]. Using a URI to identify a resource (whether that resource be a piece of information, a real-world object, an abstract concept, etc.) allows others to use the same identifier to link to the resource, refer to it, or retrieve a representation of it; this shifts the emphasis online from documents to data, and allows direct machine processing of data. If the URI scheme used is the Hypertext Transfer Protocol (http), then that is particularly helpful as http guides the user as to the location of the resource (although there are several other URI schemes, and indeed users can invent their own).

This ability to refer globally is why the export of data from RDBs to the SW should be facilitated, as noted above, by exporting database objects as first-class objects identified with URIs. A number of SW applications have diverged from this vision by not releasing their data onto the Web, but instead archiving them in inaccessible files (at least sometimes because of privacy concerns); Berners-Lee in particular has complained about this tendency [35]. However, this has happend at least sometimes because of privacy concerns.

The next layer up from names is that of markup and data interchange – the realm of XML and RDF. The eXtensible Markup Language (XML [44]) is a metalanguage for markup – in other words, a way of supporting communication and data interchange within communities by defining specialized vocabularies – commonly used in a number of sectors.

XML, like the Hypertext Markup Language (HTML) that underpins the current Web, is descended from the Standard Generalized Markup Language (SGML), an international standard for defining system-independent methods of representing information, and so has no conceptual connection to the SW. The main language for data interchange on the SW, on the other hand, RDF, is specially designed for the task, by assigning specific URIs to the fields in its triples. Figure 3 shows an RDF graph of nodes and arcs made up of several triples – each triple consists of two labeled nodes, from which is pointing a labeled directed arc. The two nodes are the first and third elements of the triple; the arc is the second (it points *from* the first element *to* the third). The use of URIs to refer to the properties as well as the objects is an important step to providing semantics – it enables us to reason about and link to relationships as well as objects.

Figure 3 shows four triples, all 'about' an individual called Eric Miller, identified by 'http://www.w3.org/People/EM/contact#me'. If we look at these triples clockwise from the right, the first represents a connection between Miller, the property of 'having the name ...' (which is referred to by the URI 'http://www.w3.org/2000/10/swap/pim/contact#fullName'), and a character string 'Eric Miller'. The second links Miller, by the property of having a mailbox, to the value of that property, which is his email address given using the common 'mailto:' URI scheme. The third again links Miller with a personal title, the property given as an http URI, and the title as a character string. The fourth triple provides some vocabulary in RDF – it refers to a namespace (an RDF document defining expressive resources which are imported by the RDF graph in Fig. 3) which defines some important relations – and in effect says that Miller (the first object in the triple) is an instance of (a relationship which is the second object in the triple) a person (a class which is the third object in the triple).

Based as it is on triples, RDF is simple yet powerful, exploiting the resources of the common subject/predicate/object structure, and its basis in URIs is very important for the SW. It is a minimalist knowledge representation language for the Web – there are some types of knowledge that cannot be represented in RDF, or only represented with difficulty. For instance, a predicate with more than two arguments has to be represented in a somewhat awkward way as a conjunction of two-argument predicates, while statements about hierarchical class relationships, say, need a further formalism. Furthermore, although the graph structure is quite intuitive, the actual

Semantic Web, Figure 3
An RDF graph representing Eric Miller [83]

syntax of RDF is based on XML (it is called RDF/XML) and, although it is well-suited to machine processing, it is not very easy for the human to read (see especially pp. 68–69 in [27]).

The growth in use of RDF has led to the need for special-purpose data stores for holding large quantities of RDF triples (often a set of data will be represented by millions of triples). Such data stores are known as *triplestores*, and need to provide not only storage, but efficient means of reasoning over and retrieving the data that will scale to the large sizes that will be needed. Examples of triplestores include JENA [4], 3store [7,67] and Oracle 11*g* [16].

Greater expressivity is required than is given in RDF, and to that end there another layer upwards which allows the expression of important information about the vocabularies used to express data. As we can see in Fig. 2, the layer here is relatively complex, and contains four boxes, RDFS, Ontology, Rules and Query. These between them provide representation and capabilities that are essential for putting the SW to use.

RDF Schema (RDFS, and sometimes RDF(S) [47]) provides a basic set of tools for producing structured vocabularies that allow different users to agree on particular uses of terms. An extension of RDF, it adds a few modelling primitives with a fixed meaning (such as class, subclass and property relations, and domain and range restriction). It is a basic ontology language that has been adopted fairly widely, and although fairly minimal it can express important constraints on vocabularies.

RDFS is deliberately minimal, and concentrates on expressing subclass and property hierarchies, with various restrictions on these, but the research community, including the Web Ontology Working Group of W3C, identified a number of requirements for greater expressivity for ontologies. As a couple of examples, RDFS allows the stating of subclass relationships, but not, say, that two classes are disjoint; neither does it allow class cardinality restrictions (e. g. a person has *exactly two* parents). As can be seen in Fig. 1, early research efforts into ontology languages led to two leading candidates being developed: DAML (DARPA Agent Markup Language [84]), and OIL (Ontology Interchange Language or Ontology Inference Layer [58]). These two, combined as DAML+OIL [94], became the seed for the W3C ontology language OWL. Unsubstantiated rumor suggests that the fact that it is called 'OWL' and not 'WOL' is an arcane joke: in A. A. Milne's *Winnie-the-Pooh* stories, Owl, who is wise and unusually literate for a forest-dweller, spells his name W-O-L. It is more likely that this is a post hoc rationalization of the naming decision.

The needs of ontology languages are great and potentially problematic. Expressivity is an issue. Even at the level of RDF, its reification mechanism allows the modeler to make statements about statements – an expressive possibility that can lead to logical problems. RDFS has even more powerful modelling primitives, including 'rdfs:Class', the class of all classes. OWL [85] is a strong language for representing concepts and their relations, and its creators needed to wrestle with the inevitable trade-off between expressivity and efficient reasoning support, with two particular constraints demanded by the Semantic Web. First, there is the strong decentralization and lack of enforcement mechanisms on the Web, so that people cannot be forced to use a language they do not want to. Creating a language this powerful, for all purposes, may well have resulted in it not being used at all. Those who need great expressivity might be inclined to use their own favorite non-standard language, while those who want efficient reasoning might prefer to revert to RDFS. The second constraint is that the layered view of the SW (Fig. 2) makes it desirable that OWL should be an extension of RDFS – it should use the RDF interpretation of classes and properties and add primitives to provide richer expressivity. However, this cannot be the basis for OWL, because the addition of powerful reasoning to the expressive power of RDFS (to define such items as the class of all classes) would result in a language very hard to control.

To pick their way between these various pitfalls, the developers of OWL created three separate languages, OWL Full, OWL DL and OWL Lite [85]. OWL Full is the complete language, a full set of OWL primitives, which can be combined with RDF and RDFS in arbitrary ways. This includes the possibility that an OWL Full ontology could augment or alter the meaning of a pre-defined RDF, RDFS or OWL term (for instance, one could put a cardinality constraint on the size of the class of all classes, thereby limiting the number of possible classes that could be constructed). OWL Full is compatible with RDF, so that any legal RDF document is an OWL Full document. The downside of all this expressivity is that the language is undecidable, which rules out the possibility of complete reasoning support.

OWL DL is intended to be open to computational support, and is a sublanguage of OWL Full (so that any legal OWL DL ontology is a legal OWL Full ontology). OWL DL is so named because it is based on *description logic*, a type of knowledge representation language used to describe the knowledge definitive of a particular application domain [29], and is designed to be complete and decidable (in particular, application of OWL's constructors to each other is restricted). This does mean that full compatibility with RDF is lost: although every legal OWL DL document is a legal RDF document, the inverse is not true.

OWL Lite is a very lightweight language to support users requiring a classification hierarchy with simple constraints. Reasoning support should be relatively efficient, and it is intended to provide a straightforward migration route for bringing thesauri and taxonomies to the SW. A legal OWL Lite ontology is also a legal OWL DL ontology, but the cost of ease of reasoning is a lack of expressivity, so for instance enumerated classes, statements of disjointness and assignment of arbitrary cardinality constraints (i. e. restrictions of class cardinality to any number other than 0 and 1) are disallowed.

Even though the relationship between OWL and RDF is complex, its roots in RDF allow OWL to exploit RDF's linking capabilities to allow ontologies to be distributed across systems. When constructing an ontology in OWL, the developer can refer to terms in other ontologies, which then encourages the sharing of terminology across distributed data sources. Sharing ontologies is not always sufficient when it comes to data sharing – an organization may find that nearly all of an imported ontology is adequate, but it needs extra identifiers and descriptions, and in such a case it should be allowed to add them, rather than build a new ontology from scratch [70]. This ability to assemble distributed ontologies is central to the SW vision.

Expressing ontological relations vital, but having achieved a representation of the domain with semantics, one still needs to make inferences. OWL has some inferential support, such as subsumption and classification, but there are several inferential methods that will be required on the SW. Hence, work is currently ongoing on the Rule Interchange Format (RIF), which is intended to allow a variety of rule-based formalisms, ranging from Horn-clause logics, higher order logics and production systems, to be used [41]. Various insights from Artificial Intelligence (AI) have also been adapted for use for the SW for various purposes, including temporal (time-based) logic, causal logic and probabilistic logics [30,75,101,102].

And given the domain description at its desired level of expressivity and a means of making inferences, then the next important function at this level is the ability to query the data. Query language SPARQL works in effect by constructing a graph of RDF-like triples that may contain variables, which is then matched against the RDF graph to be queried; the query is successful if there is a subgraph of the RDF graph which matches the query when RDF terms are substituted for its variables [96].

Sitting on top of these layers are further layers with a unifying logic, proof systems and trust systems. As can be seen from Fig. 1, these upper layers remain topics of exploratory research.

Trust is perhaps key to widespread application of the SW. If information is being drawn from heterogeneous sources, then it is important that users are able to trust such sources if they are to act on the inferences that result. Trust will of course depend on the criticality of the inferences – trust entails risk, and a risk-averse user will naturally trust fewer sources [42,92]. Measuring trust, however, is a complex problem [62]. A key parameter is that of the provenance of data, a statement of the conditions under which data were produced (including statements about the methods of production and the organization that carried them out). Methods are appearing to describe provenance [63], but more needs to be discovered about how information spreads across the Web, and therefore how it can be tracked and understood [39].

Related issues include respect for intellectual property, and the privacy of data subjects. In each case the reasoning abilities of the SW can be of value, and initiatives are currently under way to try to exploit them [93]. Protocols that allow users to express their own privacy preferences, and to enable those who wish to reuse information to reason about those preferences, are being created under the program of research into the Policy Aware Web [108]. Creative Commons is an initiative for representing copyright policies and preferences based on RDF to promote reuse where possible (current standard copyright assumptions are deliberately restrictive with respect to reuse) [2]. Cryptography protocols to protect information and privacy will also play an important role at all levels, as shown in Fig. 2.

Applications

The top layer of Fig. 2 is that of a user interface and applications. This recognizes the fact that if the SW cannot be used easily, and integrated into people's workflows in order to add value to their informational transactions, then it will not attract a large user base, without which the network effects already seen in the development of the World Wide Web will not transpire. Network effects are those positive benefits that increase in certain communication systems faster than its user base expands. In the same way as a telephone system is of limited value to a handful of people and enormous value to a large number, a few people exposing data to the SW is unlikely to make much of a difference, whereas if scalable SW technologies were applied to something like the quantity of data to be found currently in the Deep Web, the gains would be immense.

One not entirely frivolous way of expressing the need for the top layer of the SW is to say that its user base needs to grow quickly, and what is needed is a 'killer app', in other words an application that will meet a felt need and create a perception of the technology as 'essential'. Less ambitiously, the SW's spread depends not only on having an impressive set of formalisms, but also the tools to use the linked data [26].

Bootstrapping

One particular user issue is the importance of bootstrapping content for the SW. Even if RDF began to be published routinely, the amount of legacy content on the Web would dwarf new data for some time, and to make this legacy accessible to SW technology some automation of the process of creating RDF from other formats is required. CS AKTive Space [98], discussed in more detail below, amassed a large quantity of information about the state of computer science research in the United Kingdom through a relatively laborious process of harvesting information from the webpages of computer science departments in British universities without necessarily acting as a source, and using natural language processing and an ontology to interpret the data. The application was very successful, but the researchers were SW researchers, and the process is likely to be too onerous to be repeated on a large scale by non-experts. Assumptions can be made about webpage structure (for example, about regular layouts generated from a database by an individual website), and tools have been developed to exploit them [82].

An important development in this field is GRDDL (Gleaning Resource Descriptions from Dialects of Languages) which became a W3C recommendation in September 2007, and which allows the extraction of RDF from XML and XHTML (a further markup language) documents using transformations expressed in XSLT, an extensible stylesheet language based on XML. It is hoped that such extraction could allow bootstrapping of some of the hoped-for SW network effects, given the amount of XML and XHTML data in the Deep Web [52].

Annotating documents and data with metadata about their content, provenance and other useful dimensions (even including the emotional dimension to content – [100]) is also important for the effort to bring more content into the range of SW technologies [64]. Multimedia are a particular focus for research into annotation [106]. Manual annotation is a great burden for information holders, and a major initial cost for the SW, so methods of automating annotation have been investigated by a number of research teams in order to increase the quantity of annotated data available without excessive expenditure of resources [64,65,107].

In addition, as a large quantity of the Web is actually written in natural language, some have seen a role for natural language processing (NLP), and information extraction (IE), for analyzing this text statistically. So large is the Web's store of written language (two thousand billion words) that it can function as a corpus which dwarfs the most ambitious attempts of dedicated corpus builders in computational linguistics of only a few years ago [79]. And given this, and the need for automating or semi-automating annotation, NLP techniques, augmented by ontologies and training with humans, can be used to extracted machine-readable structured information from plain text [43,48,49,76]. There have also been attempts to build ontologies using NLP techniques, another of the major anticipated bottlenecks for the SW [45]. See also the Subsect. "Commercial and Non-academic Applications" for some examples of SW applications using NLP.

Application Areas

Predicting which particular applications will succeed is unscientific and usually inaccurate. In fact, as it is the rich information contexts that the web of linked data provides that will increase the value of individual pieces of data, one way in which such growth can be encouraged is to focus on small communities with pressing information-processing requirements, and various more-or-less common goals; such communities can be the 'killer apps', or, more accurately, the early adopters of the technology, exactly as the high energy physics discipline played a vital role in the development of the WWW (cf. e. g. [20]). A series of case studies and use cases is maintained at [21].

The most promising of these communities is *e-science*, the data-driven, computationally-intensive pursuit of science in highly distributed computational environments [72]. Large quantities of data are created by analysis and experiments in disciplines such as particle physics, meteorology and the life sciences. Furthermore, in many contexts, different communities of scientists will come together to perform interdisciplinary work, so that data from various fields (e. g. genomics, clinical drug trials and epidemiology) varying not only in vocabulary, but also in the scale of description, need to be integrated. Many scientific disciplines have created large-scale and robust ontologies for this and other purposes. The most well-known of these is the Gene Ontology, a controlled vocabulary to describe gene and gene product attributes in organisms, and related vocabularies developed by Open Biomedical Ontologies. Others include the Protein Ontology, the Cell Cycle Ontology, MeSH (Medical Subject Headings, used to index life science publications), SNOMED (Systematized Nomenclature of Medicine) and AGROVOC (agriculture, forestry, fisheries and food). For more examples and references see [101].

E-government is another important application area, where heterogeneous information of varying quality is deployed widely. Government information varies in provenance, confidentiality and "shelf life" (some information will be good for decades or even centuries, while other information can be out of date within hours), while it can also have been created by various levels of government (national/federal, regional, state, city, parish). Privacy and security are also obviously important factors in this space. Integrating government information in a timely way is clearly an important challenge (see for instance a pilot study for the United Kingdom's Office of Public Sector Information, exploring the use of SW technologies for disseminating, sharing and reusing data held in the public sector [25]).

Academic Applications

Many applications for the SW have been developed with the specific purpose of bringing the SW to maturity. These are often written up in conferences such as the regular World Wide Web Conferences, the International Semantic Web Conferences (ISWC), the European Semantic Web Conferences (ESWC), as well as several one-off conferences and workshops, and can be found in the proceedings (usually online) of any of these. See also the *Journal of Web Semantics* [22].

One initiative of interest here is the Semantic Web Challenge [1], which runs annually alongside the ISWC. This is a good-natured competition to find applications that show SW technology in the best light and which can act as benchmarks for the research community. These applications, therefore, are to some extent an objective list of applications through the years that use semantic technologies to solve real-world problems involving heterogeneous real-world data. The winners of the SW Challenges from its inception, 2003, to the time of writing, 2007, are as follows.

2003: CS AKTive Space (University of Southampton) is an application to explore the UK Computer Science Research domain across multiple dimensions for multiple stakeholders, allowing the tracking of the activities of all agents from funding agencies to individual researchers, using information harvested from the Web, and mediated through an ontology [98].

2004: Flink (Vrije Universiteit Amsterdam) is a 'Who's Who' of the SW which allows the interrogation of information gathered automatically from Web-accessible resources about researchers who have participated in ISWC conferences [86].

2005: CONFOTO (appmosphere web applications, Germany) is a browsing and annotation service for conference photographs [88].

2006: MultimediaN E-Culture Demonstrator (Vrije Universiteit Amsterdam, Centre for Mathematics and

Computer Science, Universiteit van Amsterdam, Digital Heritage Netherlands and Technical University of Eindhoven) searches, navigates and annotates media collections interactively, using digital representations of items from the collections of several well-known museums and art repositories [99].

2007: Revyu.com (Open University) is a reviewing and rating site specifically designed for the SW, allowing reviews of any kind of resource, content or event to be integrated and interlinked with data from other sources (in particular, other reviews, which proliferate on the Web) [69].

A typical SW application will generate a new ontology for its application domain (e. g. art, as with MultimediaN or computer science, as with CS AKTive Space), and use it to interrogate large stores of data, whether legacy data or freshly harvested. This strand of research is tending to confirm the hypothesis that ontologies have an important role in mediating the integration of data from heterogeneous sources.

Commercial and Non-academic Applications

SW applications are generally presented using custom-built interfaces. This suggests a very important area for future research, the development of scalable visualizers capable of navigating the graph of connected information expressed in RDF. As can be seen, the importance of applications and user interfaces was made clear in the layered SW diagram (Fig. 2). However, we shouldn't expect to 'see' the SW in a special browser, in the way that we can see the Web of Documents through browsers such as Internet Explorer, Netscape or Mozilla Firefox. Rather, SW technologies, facilitating the exploration of data, may well work at the back end of websites to improve the user experience. Examples of such sites pointed to by the W3C include Sun's white paper collection site [18], Nokia's developers' discussion forum [11], Oracle's virtual press room [5], and Harper's online magazine [13].

There is an increasing number of applications supporting deeper querying of linked data. The DBpedia [28] is based on the collaborative encyclopedia Wikipedia created by volunteers, and is intended to extract structured information from Wikipedia allowing much more sophisticated querying. Sample queries given on the DPpedia website include a list of people influenced by Friedrich Nietzsche, and the set of images of American guitarists. DBpedia uses RDF, and is also interlinked with other data sources on the Web. When accessed in late 2007, the DBpedia dataset contained 103 million RDF triples. Other examples of linked data applications include the DBLP bibliography of scientific papers [23], and the GeoNames database which represents descriptions of millions of geographical features in RDF [12].

As well as existing organizations using semantic technologies to improve user experience, and applications exploiting linked data, commercial firms are beginning to appear whose business model is based on the possibilities of the SW. Garlik [24] aims to provide individual consumers with more power over their digital data. It reviews what is held about people, harvesting data from the open Web, and represents this in a people-centric structure. Natural Language Processing is used to find occurrences of people's names, sensitive information, and relations to other individuals and organisations (Declaration of interest: Wendy Hall is Chair of the Garlik Advisory Board). Twine [19] aims to facilitate knowledge and information sharing, and to organize that information using various SW technologies (also, like Garlik, using NLP). Twine's developer Nova Spivack coined the term 'knowledge networking' to describe the sharing process, analogous to the Web 2.0 idea of 'social networking'.

Controversies

The SW has been controversial during its history, with several commentators arguing that it is based upon unrealistic expectations, or repeats the mistakes of other initiatives. The arguments against the SW have tended to appear more in the blogosphere rather than the academic world, perhaps because people in the SW world are genuinely enthusiasts while those without confidence in the SW project are doing other things. The pro-SW website GetSemantic supports a wiki page of arguments against the SW, with references and responses [3]. In this section, we will examine three of the most prominent arguments raised against the SW.

The Semantic Web Repeats the Mistakes of "Good Old-Fashioned Artificial Intelligence"

It has been argued that the SW is basically a throwback to the project to program machine intelligence [77] which was jokingly christened by John Haugeland 'GOFAI' (Good Old-Fashioned AI). GOFAI proved impossible: so much of human intelligence is implicit, context-dependent and situated that writing down everything a computer needs to know to produce output that exhibits human-like intelligence is out of the question [68].

One attempt to work around this problem is the Cyc project, set up in 1984, which aims to produce a gigantic ontology that will encode all common-sense knowledge, in order to support human-like reasoning by machines (i. e. GOFAI) [81]. The project has always aroused controversy, but it is fair to say that over two decades later, Cyc is not nearing completion and has not widely perceived as a solution for the GOFAI problem. The implicit nature of common-sense knowledge arguably makes it impossible to write it all down.

Many commentators have argued that the SW is basically a re-creation of the (misconceived) GOFAI idea, that the aim is to create machine intelligence over the Web, to allow machines to reason about Web content in such a way as to exhibit intelligence [77]. This, however, is a misconception, possibly abetted by the strong focus in the 2001 *Scientific American* article on an agent-based vision of the SW [37], although co-author of that article James Hendler has stated very firmly that he believes that the article was radically misinterpreted, and that no-one "can … say we're advocates of the big AI vision when we explicitly make it clear we're pushing for something else" [71]. The *Scientific American* article states that "Traditional knowledge-representation systems typically have been centralized, requiring everyone to share exactly the same definition of common concepts such as 'parent' or 'vehicle'. But central control is stifling, and increasing the size and scope of such a system rapidly becomes unmanageable" [37].

The SW is not GOFAI reheated, but rather an attempt to facilitate sharing of, and context-based machine reasoning over, content (and therefore the provision of machine-readable data on the Web). The aim is not to bring a single ontology, such as Cyc, to bear on all problems (implicitly defining or anticipating all problems and points of view), but to allow data to be interrogated in ways that were not anticipated by their creators. Different ontologies will be appropriate for different purposes; composite ontologies can be assembled from distributed parts [78,85] and it is frequently very basic ontologies (defining simple terms such as 'customer', 'account number' or 'account balance') that add most value to content. In this respect, the situation in the SW simply mirrors offline life where people from different communities and disciplines can and do interact without making any kind of common *global* ontological commitment [36,39,101]. The engineering challenge, as Berners-Lee et al. argue, is to allow independent consistent data systems to be connected locally without requiring global consistency [40].

Yorick Wilks, accepting that the SW is not an attempt to recreate GOFAI, argues that this is both a gain and a loss: a gain because the knowledge representation structures the SW proposes are computationally tractable, as opposed to the various GOFAI formalisms; a loss because DAML+OIL (and presumably by extension OWL) is less sophisticated than those formalisms, and may not have the representational power for the complexity of the world, whether common-sense or scientific [109]. Equally, as both Wilks and Berners-Lee point out, many in the SW world began their research careers in artificial intelligence, as Shadbolt et al. argue that "it will draw on some key insights, tools and techniques derived from 50 years of AI research" [101].

Ontologies

Ontologies, as we have seen, are vital for the SW vision of a Web of Data, but are perceived by many as expensive to develop and hard to maintain. The ideal conceptual apparatus is relative to the task in hand, and different ontologies are appropriate for different tasks. Classifications are also made relative to some background assumptions, and impose those assumptions onto the resulting ontology. To that extent, the expensive development of ontologies reflects the world view of the ontology builders, not necessarily the users. They are top-down and authoritarian, and therefore opposed to the Web ethos of decentralization and open conversation. They are fixed in advance, and so they don't work very well to represent knowledge in dynamic, situated contexts. [95] argues, for instance, that ontologies do not capture the situated processes of scientific research, the social construction of knowledge or the emergence and evolution of understanding over time, and presents an alternative way of representing this knowledge. [104] implicitly endorses this view, showing how there are issues in biology that OWL DL is not well-equipped to handle.

Other papers have made the point that some types of knowledge are more naturally modeled in ontologies than others, and, while not opposing the use of ontologies, warn against too strong a reliance on them for knowledge representation. [61] argues that ontologies cannot be too ambitious, and attempts to reify the context of an ontology (i. e. to provide context-independent accounts of knowledge) will be undermined by knowledge's situated nature. [91] argues that the social context of knowledge requires application builders to be maximally receptive to diverse types of heterogeneous reasoning, which might use knowledge that is hard to capture in hierarchical structures. See also [46] for a series of short essays debating this point.

A related critical point is that the Web as a decentralized, linked information structure must reflect the pragmatic needs of its large, heterogeneous user base which includes very many people who are naive in their understanding of computing issues. The infrastructure has to be usable widely, which argues for simplicity. The rich linking structure of the Web of Documents, combined with statistically-based search engines such as Google, is much more responsive to the needs of unsophisticated users. The SW, in contrast, demands new information representation, markup and publishing practices, and corporations and information owners need to invest in new technologies. Not only that, but current statistical methods will scale up as the number of users and interactions grows, whereas logic-based methods such as those advocated by the SW, on the other hand, scale less well (cf. e. g. [111]).

The dispute has been fueled by the flowering since 2005 or so of the so-called 'Web 2.0' paradigm (of systems, communities and services facilitating collaboration and information-sharing among users). In particular, it has been argued that the meaningful structures that emerge when sufficiently large numbers of users 'tag' content with key words, structures which have been called 'folksonomies', resulting in a structure of connections and classifications emerging without central control, 'really' express the assumptions of the users, and furthermore in such a way as to respect their familiar patterns of communication and workflow. Meanwhile, ontologies 'really' express the needs of the ontology developers and their sponsors [103].

However, folksonomies are much less expressive than ontologies; they are basically variants on keyword searches. A tag 'SF' may refer to science fiction or San Francisco, even if we make the unrealistic assumption of a monoglot English user community. In a multilingual environment such as the Web, further ambiguity is possible – for instance, 'SF' might refer to the Swiss television station Schweizer Fernsehen. Furthermore, the semantics of Web 2.0 are relatively shallow, with few links and very sparse hierarchies.

When a community is large enough and the benefits clear enough to provide incentives to work together, then a large-scale ontology building and maintenance program is justified. It is true that large fixed costs will tend to skew the effort involved towards authorities who may be unrepresentative [91], but Shadbolt et al. argue explicitly that "the ontologies that will furnish the Semantics for the Semantic Web must be developed, managed, and endorsed by committed practice communities. Whether the subject is meteorology or bank transactions, proteins or engine parts, we need concept definitions we can use" [101].

It is of course an undecided question as to whether this community involvement will transpire, but in a recent note, Berners-Lee argues that such conditions will be perhaps more frequently encountered than sceptics believe. On the broad assumption that the size of an ontology-building team increases on the order of the log of the size of the ontology's user community, and that the resources needed to build an ontology increase on the order of the square of community size, the cost per individual of ontology building will diminish rapidly as community size increases. These assumptions are explicitly intended to be indicative rather than realistic [36].

More to the point, not all ontologies need be of great size and expressive depth. It is certainly not the case that the SW requires a single ontology of all discourse on the model of Cyc. Such an ontology, even if possible, would not scale, and in a decentralized structure like the Web its use could not be enforced. Even in complex scientific domains, [74] argues, using a case study from the field of medical informatics, that ontologies should be firmly based on work practices in the domain. In more mundane applications, we should expect a lot of use of small-scale, *shallow* ontologies defining just a few terms that nevertheless are widely applicable [36].

For example, the machine-readable Friend-of-a-Friend (FOAF) ontology is intended to describe people, their activities and their relations to other people. It is not complex, and publishing a FOAF profile is a fairly simple matter for which there are dedicated tools [15]. The resulting network of people has become very large indeed. A survey performed in 2004 discovered over 1.5 million documents using the FOAF ontology [55].

In any case, ontologies and folksonomies serve different purposes. Folksonomies are based on word tags, whereas the basis for ontology reference is via a URI. One of the main aims of ontology definition is to *remove* ambiguity – not globally, for this may well be impossible, but rather within the particular context of the application. Folksonomies will necessarily inherit the ambiguity from the natural language upon which they are based. Nevertheless, a strong possibility that has been considered is to use cheaply-gathered folksonomies as starting points for ontology development, gradually morphing the Web 2.0 structures into something with greater precision and less ambiguity [73,87].

Symbol Grounding

An important aspect of the SW is that URIs must be interpreted consistently. However, terms and symbols are highly variable in their definitions and use through time and space. The SW project will be boosted by processes whereby URIs are given to objects by communities and individuals, endorsed by the user community, who ensure consistency. Responsible URI 'ownership' is critical to the smooth functioning of the SW [101].

But the process of ensuring a fixed and known link between a symbol and its referent, which has been called *symbol grounding*, is at best hard [66], and at worst impossible [110]. Meanings do not stay fixed, but alter, often imperceptibly. They are delineated not only by logical definitions in terms of necessary and sufficient conditions, but also by procedures, technologies and instrumentation, and alter subtly as practice alters.

Any attempt to fix the reference of URIs is a special case of symbol grounding, and is consequently hard to do globally. Attempting to resist the alteration in community practices and norms, and reformulation of meanings of terms, would be doomed. This is understood by leading developers of the SW, who agree that "communities and practice will change norms, conceptualizations, and terminologies in complex and sociologically subtle ways. We shouldn't be surprised or attempt to resist these reformulations" [101]. But there is an important issue, as the same authors concede. "The issue for a Semantic Web built (in a community-driven way) is to know when parts need revision" [101].

Yorick Wilks has argued that Natural Language Processing techniques are essential for grounding the SW, because of the preponderance of text-based content on the Web. NLP is a vital procedural bridge from texts to knowledge representation, usually via automatic information extraction [109]. Berners-Lee has argued in response to Wilks, at a Web Science Workshop in 2005 that the SW was necessarily based on logic and firm definitions (even if those definitions were imperfect, or highly situated and task-relative), not words, use patterns or statistics. Though meanings are not fully stable, they can be stable *enough* relative to individual applications and in particular contexts to allow the SW approach to work [10]. In the case of large-scale, deep ontologies describing sciences, that perhaps will be where the SW is likely to add most value, the Berners-Lee view is reminiscent of that of Hilary Putnam that scientists are 'guardians' of meaning, who determine the 'true' referent of a word like 'water' [97]. But Berners-Lee agrees that ontologies will need to evolve – some quite quickly, and that such meanings cannot be fixed irrevocably; nevertheless, for the purposes of particular applications, this is unlikely to be a problem in practice [101].

Future Directions

The SW is a work in progress, though Shadbolt et al. argue that the need for shared semantics and a Web of Data have increased, and furthermore that the SW is "attainable" [101]. This final section will sketch some of the anticipated directions of future SW work.

Standards

The most obvious future direction is to continue the research as planned. The development of the SW has been conceived as a tide rolling over a beach, covering some areas fully, enveloping other areas more slowly (Fig. 1). As has been noted, the upper layers of the SW, looking at trust, logic and proof, are relatively underdeveloped, and are the focus for exploratory research at the cutting edge. The lower layers of the SW are in place and deployed widely. The middle layers are more or less in place; OWL and SPARQL are complete, while RIF is progressing, and should become a W3C recommendation in the fullness of time.

The Semantic Grid

Grid computing is a type of distributed computing designed to apply computational power from a number of different distributed, complete computers working in parallel, and in cooperation, on a single problem. For some extremely data-heavy problems requiring a lot of computation (particularly in e-science), grid computing is an important time-saving solution. Particular issues in grid computing include the problems of coordinated resource sharing, distributed problem-solving and the creation of 'virtual organisations' to pool data and share outcomes. The SW, of course, is another distributed computing paradigm where data sharing is a key issue – with the SW, a Web of Data, sharing is the whole point. A third distributed paradigm – software agents – is also a relevant factor.

This synergy has led to a research strand to apply semantic technologies to the problems of grid computing, adding meaning via ontologies and RDF metadata annotations to the grid. Information and services for the grid are thereby given well-defined meaning, which enables the interaction between humans and computers to be better coordinated. In particular, all the components, services and resources are adequately described for machine processing. The use of semantics to describe grid resources is known as the *Semantic Grid*, and research is ongoing [17,53,60,72].

The Policy-Aware Web

As is clear in Fig. 2, trusted systems are very important to the development of the SW. There are two reasons for this. First, if someone is reasoning with heterogeneous data harvested from the Web, then they will need to trust the data they have harvested and are using. As noted above, research is ongoing into methods for specifying the provenance of such data [63]. The second reason is that people will not release their data if they thought it would be misused; the importance of data privacy in our digital age is easily underestimated [93]. The *policy-aware Web* is an initiative designed to rectify this problem.

The assumption behind the policy-aware Web is that inflexible and simplistic security systems and access control for the decentralized environment of the Web has hampered its development. Insufficiently sophisticated controls have made people reluctant to share data, particularly with other parties with which they do not have preexisting information-sharing policies. Furthermore, the Web of Documents is rather coarse-grained for detailed security: the security decision to be made is to grant access to an entire website or page, or not, because policy control mechanisms for access at a finer-grained level aren't available. Thus, despite increasing amounts of useful information residing on the Web in a machine-retrieval form, reluctance to share that information remains.

The aim of policy-aware Web technology is to provide for the publication of access policies in a way that allows significant transparency for sharing among partners without requiring pre-agreement. In addition, greater control over information release can be placed in the hands of the information owner, allowing discretionary (rather than mandatory) access control to flourish. Policies would be another kind of metadata attached to information, and those wishing to use that information would be able to reason about them. For instance, one should be able to specify that the information can only be used by the agent gaining access, and that that agent should not pass the information on. Or it may be specified that the information should be deleted after a certain period of time. Or if it is to be used in a certain manner, then data should be anonymized.

Enforcement of these policies is another matter, but at present the research effort is focused on how to express such policies, and on creating theorem provers to reason about them. The result should be a much more fine-grained security picture, with greater transparency and accountability of information use [108].

Web Science

Although since its inception the Web has revolutionized communication, collaboration and education (particularly within science), relatively little is known about the way it develops. There is a growing feeling among researchers across a number of disciplines that a clear research agenda aimed at understanding the current, evolving and potential Web is needed to assure its continued growth. Such researchers want to model the Web, understand the architectural principles that have provided for its growth, and be as sure as possible that it supports the basic social values of trustworthiness, privacy, and respect for social boundaries, and their solution is to chart out a research agenda that targets the Web as a primary focus of attention [39,40].

This agenda has been dubbed *Web Science*, a combination of analysis of the Web and its dynamics, and synthesis of new languages and protocols. The Web is an engineered space created via formally specified languages but, as humans are the creators of Web pages and links between them, their interactions form emergent patterns in the Web at a macroscopic scale. These human interactions are, in turn, governed by social conventions and laws. Web Science is, therefore, inherently interdisciplinary; its goal is to both understand the growth of the Web and to create approaches allowing new powerful and more beneficial patterns to occur.

Such a research area does not yet exist in a coherent form. Within computer science Web-related research has largely focused on information retrieval algorithms and the algorithms for the routing of information through the underlying Internet. Outside of computing, researchers grow ever more dependent on the Web, but there is no concerted agenda for exploring emerging trends on the Web. Nor are those outside computer science fully engaged with the emerging Web research community to focus more specifically on the needs of science and of society as a whole, while preserving the essential invariants of the Web experience: decentralization to avoid social and technical bottlenecks, openness to the reuse of information in unexpected ways, and freedom and equality of information as it passes across the Web.

Despite excitement about the SW, the majority of the world's data is locked in large data stores and is not published as an open web of inter-referring resources. As a result, the reuse of information has been limited. Substantial research challenges arise in changing this situation. We have already discussed the need for policy controls, and for tools to allow scientists to exploit data when it emerges. But on top of that, releasing data is both a technical and a social problem, and understanding how to free data to the SW is a matter of understanding society in relation to the Web (in social, legal and economic terms) and the Web in relation to society. This is the foundation of the emerging Web Science agenda which it is hoped will inform the development of the SW [101]. The recent foundation of the Web Science Research Initiative (WSRI [9]), a joint venture between the Massachusetts Institute of Technology and the University of Southampton, is intended to drive the agenda on, acting as a focus (e. g. advising in particular on curricula to support it).

Article Outline

Abstract

This article discusses spin transport in systems with spin-orbit interactions and how it can be understood in a semiclassical picture. I will first present a semiclassical wave-packet description of spin transport, which explains how the microscopic motion of carriers gives rise to a spin current. Due to spin non-conservation the definition of the spin current has some arbitrariness. In the second part I will briefly review the physics from a density matrix point of view, which makes clear the relationship between spin transport and spin precession and the important role of scattering.

Glossary

Extrinsic effect An effect which has an explicit dependence on the form or strength of the disorder potential.

Intrinsic effect An effect which does not depend explicitly on the form and strength of the disorder potential.

Semiclassical theory A theory in which a particle's position and momentum are considered simultaneously.

Spin-orbit interaction A relativistic interaction between the spin of a particle and its momentum (which is associated with its orbital motion.)

Steady-state spin current A flow of spins induced by an electric field.

Steady-state spin density A net spin density induced by an electric field.

Definition of the Subject

Spin transport refers to the physical movement of spins across a sample and, if spin were a conserved quantity, one could make a straightforward distinction between spin-up and spin-down charge currents. The recent upsurge of interest in spin transport is, however, motivated by systems in which spin is not conserved due to the presence of spin-orbit interactions, which give rise to spin precession. Here, due to non-conservation of spin the spin current is not well defined [1,2,3]. Spin transport in these cases usually does not involve charge transport as the charge currents in the direction of spin flow cancel out. Finally, in certain materials, spin currents are accompanied by steady-state spin densities. The appearance of a spin density is not a transport phenomenon, but it is a steady-state process and is intimately connected to spin transport.

The word *semiclassical* as used in this work refers to theories which consider the position and momentum of a particle simultaneously. Semiclassical pictures are intuitive and useful in descriptions of transport, particularly in inhomogeneous systems and in spatially dependent fields, which typically vary on length scales much larger than atomic size.

In recent years, steady progress has been made towards realization of convenient semiconducting ferromagnets and spin injection into semiconductors from ferromagnetic metals [4,5,6,7] yet spin injection from a ferromagnetic metal into a semiconductor is hampered by the resistivity mismatch between the two [8]. This is one factor, in addition to basic science, motivating the search for an understanding of the way spins are manipulated electrically. The last few years have seen many experimental advances in spin transport, and spin currents have been measured directly [9,10] and indirectly [11,12,13,14,15].

Introduction

Novel physical phenomena that may lead to improved memory devices and advances in quantum information processing are closely related to spin-orbit interactions [16]. Spin-orbit interactions are present in the band structure and in potentials due to impurity distributions. Spin-orbit coupling is in principle always present in impurity potentials and gives rise to skew scattering. Band structure spin-orbit coupling may arise from the inversion asymmetry of the underlying crystal lattice [17] (bulk inversion asymmetry), from the inversion asymmetry of the confining potential in two dimensions [18] (structure inversion asymmetry), and may be present also in inversion symmetric systems [19].

Although many observations in this entry are general, the discussion will focus on non-interacting spin-1/2 electron systems, which are pedagogically easier. The Hamiltonian of these systems typically contains a kinetic energy term and a spin-orbit coupling term, $H_{\boldsymbol{k}} = (\hbar^2 k^2)/(2m^*) + H^{\mathrm{so}}_{\boldsymbol{k}}$, where m^* is the electron effective mass. In spin-1/2 electron systems, band structure spin-orbit coupling can always be represented as a Zeeman-like interaction of the spin with a wave vector-dependent effective magnetic field $\boldsymbol{\Omega}_{\boldsymbol{k}}$, thus $H^{\mathrm{so}}_{\boldsymbol{k}} = (1/2)\boldsymbol{\sigma} \cdot \boldsymbol{\Omega}_{\boldsymbol{k}}$. Common examples of effective fields are the Rashba spin-orbit interaction, [18] which is often dominant in quantum wells with inversion asymmetry, and the Dresselhaus spin-orbit interaction, [17] which is due to bulk inversion asymmetry. The spin operator is given by $s^\sigma = (\hbar/2)\sigma^\sigma$, where σ^σ is a Pauli spin matrix. The spin current operator in these systems will be taken to be $\hat{\jmath}^\sigma_i = (1/2)\{s^\sigma, v^i\}$, where the velocity operator is $v^i = (1/\hbar)\partial H_{\boldsymbol{k}}/\partial k_i$.

An electron spin at wave vector $\mathbf{k}$ precesses about the effective field $\boldsymbol{\Omega}_{\boldsymbol{k}}$ with frequency $\Omega_{\boldsymbol{k}}/\hbar \equiv |\boldsymbol{\Omega}_{\boldsymbol{k}}|/\hbar$ and is scattered to a different wave vector within a characteristic momentum scattering time τ_p. I will assume in this work that $\varepsilon_F \tau_p/\hbar \gg 1$, where ε_F is the Fermi energy, which is equivalent to the assumption that the carrier mean free path is much larger that the de Broglie wavelength. Within this range, the relative magnitude of the spin precession frequency $\Omega_{\boldsymbol{k}}$ and inverse scattering time $1/\tau_p$ define three qualitatively different regimes. In the ballistic (clean) regime no scattering occurs and the temperature tends to absolute zero, so that $\varepsilon_F \tau_p \to \infty$ and $\Omega_{\boldsymbol{k}} \tau_p/\hbar \to \infty$. The weak scattering regime is characterized by fast spin precession and little momentum scattering due to, e. g., a slight increase in temperature, yielding $\varepsilon_F \tau_p/\hbar \gg \Omega_{\boldsymbol{k}} \tau_p/\hbar \gg 1$. In the strong momentum scattering regime $\varepsilon_F \tau_p/\hbar \gg 1 \gg \Omega_{\boldsymbol{k}} \tau_p/\hbar$. I will concentrate on effects originating in the band structure, the observation of which requires the assumption that the materials under study are in the weak momentum scattering regime. Electric fields will be assumed uniform.

The first part of this article will present a semiclassical theory of spin transport, identifying the terms responsible for spin currents in the microscopic dynamics of carriers. Spin non-conservation as a result of spin precession leads to several possible definitions of the spin current, which emerge out of the spin equation of continuity. The second part presents a different point of view, which explains aspects not easily captured in the semiclassical approach. The steady-state density matrix is shown to contain a contribution due to precessing spins and one due to conserved spins. Steady state corrections $\propto \tau_p$ are associated with the *absence* of spin precession and give rise to spin densities in external fields [20,21,22,23,24,25,26,27,28]. Steady state corrections independent of τ_p are associated with spin precession and give rise to spin currents in external fields [1,2,3,9,10,11,12,13,14,15,29,30,31,32,33,34,35,36,37,38,39,40,41,42,43,44,45,46]. Scattering between these two distributions induces significant corrections to steady-state spin currents.

Spin Currents in Electric Fields

Wave-Packet Picture of Spin Transport

This section presents a semiclassical theory of spin transport valid for a general spin-orbit system. The semiclassical method is a suitable approach to the study of transport, because, typically, in the relevant systems the external fields vary smoothly on atomic length scales. All information about the system is taken to be contained in the band structure, thus allowing a description of spin transport which does not make reference to the detailed form of the spin-orbit interaction.

The system under study is regarded as as a collection of carriers, whose semiclassical dynamics in a non-degenerate band i are described by a wave packet [47], with its charge centroid having coordinates $(\mathbf{r}_c, \mathbf{k}_c)$

$$|w_i\rangle = \int \mathrm{d}^3 k \; a(\mathbf{k}, t) \mathrm{e}^{i\mathbf{k}\cdot\hat{\mathbf{r}}} |u_i(\mathbf{r}_c, \mathbf{k}, t)\rangle \; . \qquad (1)$$

In the above, the function $a(\mathbf{k}, t)$ is a narrow distribution sharply peaked at $\mathbf{k}_c$, the phase of which specifies the center of charge position $\mathbf{r}_c$, while $|u_i(\mathbf{r}_c, \mathbf{k}, t)\rangle$ are lattice-periodic Bloch wave functions. The size of the wave packet in momentum space must be considerably smaller than that of the Brillouin zone. In real space, this implies that the wave packet must stretch over many unit cells.

The external electric field drives the center of the wave packet in k-space according to the semiclassical equations of motion

$$\begin{aligned} \hbar\dot{\mathbf{r}}_c &= \frac{\partial \varepsilon_i}{\partial \mathbf{k}_c} - q\mathbf{E} \times \boldsymbol{\Omega}_i \\ \hbar\dot{\mathbf{k}}_c &= q\mathbf{E} \; , \end{aligned} \qquad (2)$$

with q the charge of the carriers, ε_i the band energy, and the Berry curvature

$$\boldsymbol{\Omega}_i = i\left\langle \frac{\partial u_i}{\partial \mathbf{k}} \right| \times \left| \frac{\partial u_i}{\partial \mathbf{k}} \right\rangle . \tag{3}$$

The electric field also gives rise to an adiabatic correction to the wave functions, which mixes the states making up the wave packet. The wave functions $|u_i\rangle$ therefore have the following form:

$$|u_i\rangle = |\phi_i\rangle - \sum_j \frac{\langle \phi_j | i\hbar \frac{\mathrm{d}}{\mathrm{d}t} | \phi_i \rangle}{\varepsilon_i - \varepsilon_j} |\phi_j\rangle \, , \tag{4}$$

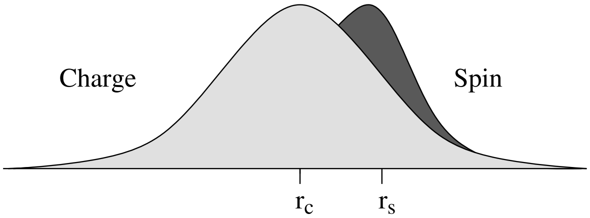
where the ϕ_i are the unperturbed Bloch eigenstates. The $|u_i\rangle$ form a complete set and retain the Bloch periodicity.

The distribution of carriers is described by a function f. When scattering is present, the distribution function satisfies the following equation:

$$\frac{\partial f}{\partial t} + \dot{\mathbf{r}}_c \cdot \frac{\partial f}{\partial \mathbf{r}_c} + \dot{\mathbf{k}}_c \cdot \frac{\partial f}{\partial \mathbf{k}_c} = \left(\frac{\mathrm{d}f}{\mathrm{d}t} \right)_{\mathrm{coll}} , \tag{5}$$

where $(\frac{\mathrm{d}f}{\mathrm{d}t})_{\mathrm{coll}}$ is the usual collision term. In independent bands, in the relaxation time approximation, the collision term takes the form $(f_0 - f)/\tau_p$, with f_0 the equilibrium distribution and τ_p the momentum relaxation time. In the Boltzmann theory, the change in the distribution function with time arises through the drift terms, which are determined from the semiclassical equations of motion, as well as through scattering with other carriers, with localized impurities or with phonons. For transport in a nondegenerate band, it is consistent to ignore interband scattering effects in the weak scattering limit. In this case the relaxation time is a scalar quantity. The effects of interband coherence due to scattering will be explored in the next section.

In order to obtain expressions for macroscopic quantities of interest, such as densities and currents, one needs to carry out a coarse graining by averaging over microscopic fluctuations. In classical dynamics this coarse graining is performed by means of a sampling function, which is smooth and has a significant magnitude only in a finite range [48]. This range is large compared to atomic dimensions, but small compared to the scale of variation of the distribution function. Moreover, it has a rapidly converging Taylor expansion over distances of atomic dimensions, and its form does not need to be specified. This method has a close analog in wavepacket dynamics, where the sampling function is replaced by a δ-function.



Semiclassical Spin Transport in Spin-Orbit Coupled Systems, Figure 1
For a particle of finite extent the charge and spin distributions in real space in general do not coincide. The same is true of the charge and spin distributions in reciprocal space

It is crucial to recognize that, in general, the center of spin and the center of charge are distinct (Fig. 1), since the wave packet samples a range of wave vectors and the spin is usually a function of $\mathbf{k}$. Following the line of thought outlined above, the spin density is defined to be (henceforth $\mathbf{k}_c$ will be abbreviated to $\mathbf{k}$)

$$S^\sigma(\mathbf{R}, t) = \iint \mathrm{d}^3k \mathrm{d}^3r_c f(\mathbf{r}_c, \mathbf{k}, t) \, \langle \delta(\mathbf{R} - \hat{\mathbf{r}}) \hat{s}^\sigma \rangle \, , \tag{6}$$

where the bracket indicates quantum mechanical averaging over the wave packet with charge centroid $(\mathbf{r}_c, \mathbf{k})$. As the δ-function has operator arguments, it will be regarded as a *sampling operator*, whose expectation value yields a spatial average, evaluated at position $\mathbf{r}$. To account for the fact that spin is not conserved (Fig. 2), a new quantity is introduced, which will be referred to as the torque density, defined by

$$\mathcal{T}^\sigma(\mathbf{R}, t) = \iint \mathrm{d}^3k \mathrm{d}^3r_c f(\mathbf{r}_c, \mathbf{k}, t) \, \langle \delta(\mathbf{R} - \hat{\mathbf{r}}) \hat{\tau}^\sigma \rangle \, . \tag{7}$$

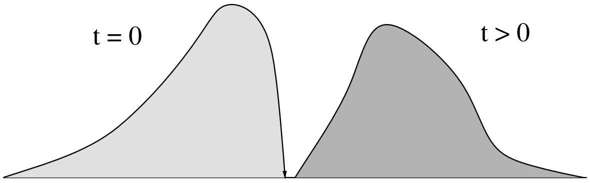
$\hat{\tau}^\sigma$ in the above stands for the rate of change of the spin operator, given by $i/\hbar[\hat{H}, \hat{s}^\sigma]$, and symmetrization of products of non-commuting operators has been assumed. Finally, the microscopic spin current density is defined as:

$$\boldsymbol{\mathcal{J}}^\sigma(\mathbf{R}, t) = \iint \mathrm{d}^3k \mathrm{d}^3r_c f(\mathbf{r}_c, \mathbf{k}, t) \langle \delta(\mathbf{R} - \hat{\mathbf{r}}) \hat{s}^\sigma \hat{\mathbf{v}} \rangle \, . \tag{8}$$

We obtain the following continuity equation for the spin density and current:

$$\frac{\partial S^\sigma}{\partial t} + \nabla \cdot \boldsymbol{\mathcal{J}}^\sigma = \mathcal{T}^\sigma + \mathcal{F}^\sigma \, . \tag{9}$$

The equation of continuity contains a bulk source term, which coincides with the torque density and acts as a mechanism for spin generation. Similar source terms are associated with nonconserved quantities, for example,



Semiclassical Spin Transport in Spin-Orbit Coupled Systems, Figure 2
In the presence of spin-orbit interactions the spin distribution of a particle changes in time. The horizontal axis may represent position or wave vector

in quantum electrodynamics and in Maxwell's equations. The last term in (9) represents the scattering contribution, which will be discussed further below.

Let us discuss the terms in the equation of continuity, beginning with the spin density. The argument of the sampling operator can be expressed as $[\mathbf{r}-\mathbf{r}_c-(\hat{\mathbf{r}}-\mathbf{r}_c)]$, and, as the second term is of atomic dimensions, the sampling operator can be written as a Taylor expansion about $(\hat{\mathbf{r}}-\mathbf{r}_c)$. The density can therefore be re-expressed, in terms of macroscopic quantities, as

$$S^{\sigma}(\mathbf{R},t)=\rho^{s\sigma}(\mathbf{R},t)-\nabla_{\mathbf{R}}\cdot\mathbf{P}^{s\sigma}(\mathbf{R},t)\,, \tag{10}$$

where summation over repeated indices has been assumed. In the above, the monopole density is given by

$$\begin{aligned}\rho^{s\sigma}(\mathbf{R},t)&=\iint \mathrm{d}^3k\mathrm{d}^3r_c f(\mathbf{r}_c,\mathbf{k},t)\langle\hat{s}^{\sigma}\rangle\delta(\mathbf{R}-\mathbf{r}_c)\\&=\int \mathrm{d}^3k f\langle\hat{s}^{\sigma}\rangle|_{\mathbf{r}_c=\mathbf{R}}\,,\end{aligned}\tag{11}$$

where f in the second line, and henceforth, is to be understood as $f(\mathbf{R},\mathbf{k},t)$, and the dipole density is

$$\begin{aligned}\mathbf{P}^{s\sigma}(\mathbf{R},t)&=\iint \mathrm{d}^3k\mathrm{d}^3r_c f\langle(\hat{\mathbf{r}}-\mathbf{r}_c)\hat{s}^{\sigma}\rangle\delta(\mathbf{R}-\mathbf{r}_c)\\&=\int \mathrm{d}^3k f\mathbf{p}^{s\sigma}|_{\mathbf{r}_c=\mathbf{R}}\,.\end{aligned}\tag{12}$$

The average spin of the wave packet has been denoted by $\langle\hat{s}^{\sigma}\rangle$, and the spin-dipole is defined to be $\mathbf{p}^{s\sigma}=\langle(\hat{\mathbf{r}}-\mathbf{r}_c)\hat{s}^{\sigma}\rangle|_{\mathbf{r}_c=\mathbf{R}}$. It will be seen that the first term in the density is the average of a monopole density located at $\mathbf{r}_c$, while the dipole term is the average of a point dipole density located at $\mathbf{r}_c$, and similarly for higher orders. The dipole must be understood as the average of the quantum mechanical dipole operator, as an exact analogy with the electric dipole of classical electrodynamics cannot be made. The density can thus be viewed as a collection of point multipoles, located at the centroid of each wave packet. The microscopic distribution of spin is important at the molecular level, but at the macroscopic level the effect of this molecular distribution is replaced by a sum of multipoles. Since the center of spin is different from the center of charge, in principle all multipoles are present.

Following a similar manipulation and using the Boltzmann equation, the torque density is re-expressed as:

$$\mathcal{T}^{\sigma}(\mathbf{R},t)=\rho^{\tau\sigma}(\mathbf{R},t)-\nabla\cdot\mathbf{P}^{\tau\sigma}(\mathbf{R},t)\tag{13}$$

with the torque monopole density

$$\begin{aligned}\rho^{\tau\sigma}(\mathbf{R},t)&=\iint \mathrm{d}^3k\mathrm{d}^3r_c f(\mathbf{r}_c,\mathbf{k},t)\langle\hat{\tau}^{\sigma}\rangle\delta(\mathbf{R}-\mathbf{r}_c)\\&=\int \mathrm{d}^3k f\langle\hat{\tau}^{\sigma}\rangle|_{\mathbf{r}_c=\mathbf{R}}\,,\end{aligned}\tag{14}$$

and the torque dipole density

$$\begin{aligned}\mathbf{P}^{\tau\sigma}(\mathbf{R},t)&=\iint \mathrm{d}^3k\mathrm{d}^3r_c f(\mathbf{r}_c,\mathbf{k},t)\langle(\hat{\boldsymbol{R}}-\mathbf{r}_c)\hat{\tau}^{\sigma}\rangle|_{\mathbf{r}_c=\mathbf{R}}\\&=\int \mathrm{d}^3k f\mathbf{p}^{\tau\sigma}|_{\mathbf{r}_c=\mathbf{R}}\,.\end{aligned}\tag{15}$$

In analogy with the spin dipole, the torque dipole has been defined as $\mathbf{p}^{\tau\sigma}=\langle(\hat{\mathbf{r}}-\mathbf{r}_c)\hat{\tau}^{\sigma}\rangle|_{\mathbf{r}_c=\mathbf{R}}$. The torque density is therefore also a sum of multipole moments, that is, the moments of a point spin source located at $\mathbf{r}_c$. Even in the case when the center of $\langle\hat{s}^{\sigma}\rangle$ coincides with the center of charge, $\langle\hat{\tau}^{\sigma}\rangle$ may not be centered at $\mathbf{r}_c$, with the result that the higher order terms in the torque density are in general present. The second and higher terms of $\mathcal{T}^{\sigma}$ cancel exactly the analogous terms in the continuity equation which come from the current.

Since only the gradient of the spin current appears in the equation of continuity, in the expansion of the sampling operator we keep the leading term

$$\mathcal{J}^{s}(\mathbf{R},t)=\int \mathrm{d}^3k f\langle\hat{\mathbf{v}}\hat{s}^{\sigma}\rangle|_{\mathbf{r}_c=\mathbf{R}}\,.\tag{16}$$

Keeping terms to first order in $(\hat{\boldsymbol{r}}-\mathbf{r}_c)$, the current can be decomposed into the following:

$$\mathcal{J}^{s\sigma}=\mathbf{C}^{s\sigma}+\mathbf{D}^{s\sigma}-\mathbf{P}^{\tau\sigma}\,.\tag{17}$$

The convective term $\mathbf{C}^{s\sigma}$ represents the spin being transported along with the wave packet

$$\begin{aligned}\mathbf{C}^{s\sigma}(\mathbf{R},t)&=\iint \mathrm{d}^3k\mathrm{d}^3r_c f(\mathbf{r}_c,\mathbf{k},t)\dot{\mathbf{r}}_c\langle\hat{s}^{\sigma}\rangle\delta(\mathbf{R}-\mathbf{r}_c)\\&=\int \mathrm{d}^3k f\mathbf{c}^{s\sigma}|_{\mathbf{r}_c=\mathbf{R}}\,,\end{aligned}\tag{18}$$

while $\mathbf{D}^{s\sigma}$ comes from the rate of change of the spin dipole, which has already been introduced. It has the form:

$$\mathbf{D}^{s\sigma}(\mathbf{R},t) = \int \mathrm{d}^3k f \frac{\mathrm{d}\mathbf{p}^{s\sigma}}{\mathrm{d}t}\Big|_{\mathbf{r}_c=\mathbf{R}} . \tag{19}$$

$\mathbf{P}^{\tau\sigma}$ is the torque dipole introduced above. The corresponding monopole term appears in the source term of the continuity equation, as will emerge below. The presence of the torque dipole here is to be contrasted with the absence of an analogous term in classical electrodynamics. There, an electric dipole arises from the placement of two charges a small distance from each other, but the charge itself is conserved.

Finally, we come to the source term in (9). The first part, composed of the torque density, has already been discussed. The second term, denoted by $\mathcal{F}^\sigma$, becomes, in the relaxation time approximation

$$\mathcal{F}^\sigma = \frac{S_0^\sigma - S^\sigma}{\tau_p} = \frac{1}{\tau_p}\int \mathrm{d}^3k (f_0 - f)\langle \hat{s}^\sigma\rangle , \tag{20}$$

where τ_p is the momentum relaxation time and f_0 the equilibrium distribution, which is usually the Fermi–Dirac distribution function.

Based on the continuity equation alone, there is some flexibility in defining the current and the source. In systems in which spin is conserved, the torque density becomes, to first order in $(\hat{\boldsymbol{r}} - \mathbf{r}_c)$, a pure divergence, which can be incorporated into a redefinition of the spin current. This current, henceforth referred to as the spin transport current, is only due to the convective and spin dipole contributions:

$$\mathbf{J}^{t\sigma}(\mathbf{R},t) = \mathbf{C}^{s\sigma}(\mathbf{R},t) + \mathbf{D}^{s\sigma}(\mathbf{R},t) . \tag{21}$$

With respect to this spin transport current, the continuity equation takes the following form:

$$\frac{\partial S^\sigma}{\partial t} + \nabla\cdot\mathbf{J}^{t\sigma} = \frac{\mathrm{d}}{\mathrm{d}t}\int \mathrm{d}^3k f\langle \hat{s}^\sigma\rangle . \tag{22}$$

In the steady state under a constant electric field, the distribution function is composed of an equilibrium part, independent of the field, and a non-equilibrium part, which is first order in the field. Henceforth, terms in the spin current and source which depend on the equilibrium distribution function will be referred to as intrinsic, whereas the terms depending on the nonequilibrium shift in the distribution will be referred to as extrinsic. For example, the integrand in Eq. (16) can be decomposed into a zero order spin-velocity, $\mathbf{v}\langle\hat{s}^\sigma\rangle$, where $\mathbf{v}$ is the usual group velocity of the band, and a first order correction. Therefore, there will be a contribution to the current from the non-equilibrium part of the distribution and the zero order spin-velocity, which has been discussed extensively in previous work [29,30,31,32,33]. There will also be a contribution from the equilibrium distribution and the first order correction to the spin-velocity, which is referred to as the intrinsic contribution. In the wave packet formalism presented here this effect arises from the change in wave functions induced by the electric field, rather than from the change in distribution functions that is responsible for most conventional transport effects. The intrinsic spin current is calculated from (16) using the equilibrium distribution and the expectation values of the spin and spin dipole operators in a Bloch state perturbed to first order in $\mathbf{E}$.

In its turn, the source in (9) can be decomposed into intrinsic and extrinsic contributions. The present entry considers homogeneous systems, so that all the gradient terms vanish, and the torque density is simply $f\langle\hat{\tau}^\sigma\rangle$. The zeroth order contribution to this term is null, as the Bloch wave functions are eigenstates of the Hamiltonian. Thus, to first order in the electric field, we find that $\langle\hat{\tau}^\sigma\rangle$ is simply given by $(e\mathbf{E}/\hbar)\cdot(\partial\langle\hat{s}^\sigma\rangle/\partial\mathbf{k})$. One is thus justified in replacing f by its equilibrium value f_0, in which case this term is purely intrinsic. The second term in the source, $\mathcal{F}^\sigma$, which depends on the nonequilibrium shift in the distribution function, is entirely extrinsic.

The extrinsic source term takes into account the effect of scattering, and is a term which usually appears in the equation of continuity. The intrinsic source accounts for the effect of all spin-nonconserving terms, and must be present even in a clean system, if the Hamiltonian contains spin-dependent contributions. In general, in addition to the rate of change of spin arising from the spin-dependent terms in the Hamiltonian, scattering processes may alter the orientation of the spin, with the result that any one spin component is not conserved, and the orientation of spins is randomized over a longer time period. For a uniform steady-state system, the current is constant and the intrinsic source term must vanish. However, near the boundary of the system, or at an interface with a different semiconductor with (for example) weaker spin-orbit interactions, the spin current driven by an electric field will vary spatially and $\mathcal{T}$ must reach a non-zero value.

Let us take a closer look at the spin dipole and torque dipole, which are seen to be the main mechanisms responsible for generating the spin current. Because of its narrow distribution in $\mathbf{k}$, the mean spin of the wave packet is $\langle w_i|\hat{s}^\sigma|w_i\rangle = \langle u_i|\hat{s}^\sigma|u_i\rangle$, where it is understood that the wave vector of the Bloch function is set at $\mathbf{k}_c$ and $\hat{s}^\sigma$ is an arbitrary projection of the spin vector operator. The spin dipole of the wave packet, defined relative to the charge center of the wave packet is given, in terms of Bloch functions, by the expression:

$$\mathbf{p}_i^{s\sigma} = \frac{i}{2}\left[\left\langle u_i|\hat{s}^\sigma|\frac{\partial u_i}{\partial \mathbf{k}}\right\rangle - \left\langle \frac{\partial u_i}{\partial \mathbf{k}}|\hat{s}^\sigma|u_i\right\rangle\right] - \left\langle u_i|i\frac{\partial u_i}{\partial \mathbf{k}}\right\rangle \langle u_i|\hat{s}^\sigma|u_i\rangle \ . \quad (23)$$

Interestingly, the spin dipole is independent of the wave packet width. The expression is also invariant under a local gauge transformation, in the sense that if $|u_i\rangle$ is modified by a phase factor $e^{i\alpha(\mathbf{k})}$ the spin dipole is unchanged.

The torque dipole term has a special interpretation in the case of spin transport. The rate of change of spin is equivalent to a torque, and the torque dipole represents the moment exerted by this torque about the center of the wave packet. The semiclassical expression for the torque moment is

$$\mathbf{p}_i^{\tau\sigma} = \frac{i}{2}\left[\left\langle u_i|\dot{\hat{s}}^\sigma|\frac{\partial u_i}{\partial \mathbf{k}}\right\rangle - \left\langle \frac{\partial u_i}{\partial \mathbf{k}}|\dot{\hat{s}}^\sigma|u_i\right\rangle\right] - \left\langle u_i|i\frac{\partial u_i}{\partial \mathbf{k}}\right\rangle \left\langle u_i|\dot{\hat{s}}^\sigma|u_i\right\rangle \ . \quad (24)$$

The torque moment has the same gauge invariance properties as the spin dipole, and like the spin dipole it also does not depend on the wave packet width.

It is important to note that the spin current, $\mathcal{J}^\sigma$, can be simplified to:

$$\mathcal{J}^\sigma(\mathbf{R}, t) = \int \mathrm{d}^3k f \,\mathrm{tr}\langle u_i|\hat{s}^\sigma \hat{\mathbf{v}}|u_i\rangle \ , \quad (25)$$

which is the semiclassical equivalent of the Kubo formula for spin currents.

Density Matrix Picture of Spin Transport

Semiclassical theory provides a straightforward, intuitive picture of the way spin currents arise in the course of carrier dynamics in an electric field. The theory was developed for independent bands. It turns out that interband coherence arising from scattering is crucial in spin transport, and is difficult to treat semiclassically. Although the semiclassical theory can be generalized to multiple bands [49,50], it is more instructive to examine spin transport from a different point of view that is closer in outlook to the philosophy underlying the Kubo formula (with which the semiclassical theory agrees.) This will shed some light on additional issues, such as the relationships between spin currents and spin precession, between spin currents and spin densities, the complex effect of disorder and the vanishing of spin current in certain systems.

A large, uniform system of non-interacting spin-1/2 electrons is represented by a one-particle density operator $\hat{\rho}$. The expectation value of an observable represented by a Hermitian operator $\hat{O}$ is given by $\mathrm{tr}(\hat{\rho}\hat{O})$ and $\hat{\rho}$ satisfies the quantum Liouville equation

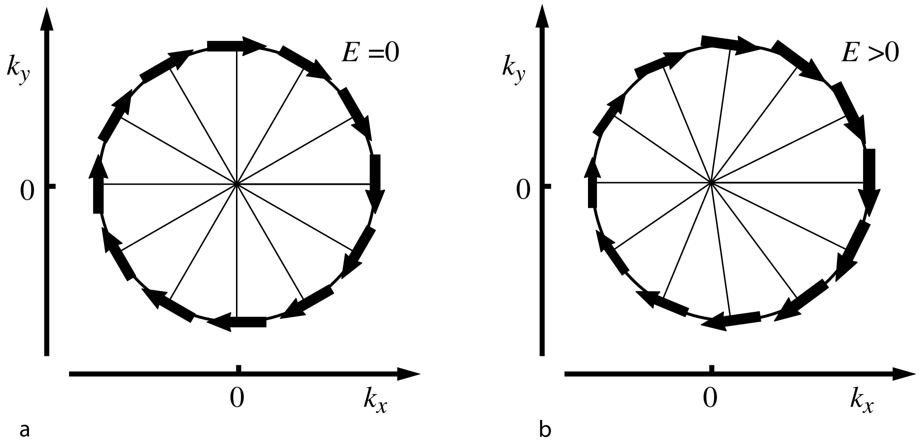
$$\frac{\mathrm{d}\hat{\rho}}{\mathrm{d}t} + \frac{i}{\hbar}[\hat{H} + \hat{U}, \hat{\rho}] = 0\,. \quad (26)$$

The Liouville equation is projected onto a set of time-independent states of definite wave vector $\{|\mathbf{k}\rangle\mathbf{s}\}$, which are not assumed to be eigenstates of the Hamiltonian $\hat{H}$. The matrix elements of $\hat{\rho}$ in this basis will be written as $\rho_{\mathbf{k}\mathbf{k}'} \equiv \rho_{\mathbf{k}\mathbf{k}'}^{ss'} = \langle \mathbf{k}s\hat{\rho}|\mathbf{k}'s'\rangle$. Spin indices are not shown explicitly, and $\rho_{\mathbf{k}\mathbf{k}'}$ is a matrix in spin space, referred to as the density matrix. In this work we require the expectation values of operators which are diagonal in wave vector, and will thus require the part of the density matrix diagonal in wave vector, $\rho_{\mathbf{k}\mathbf{k}} \equiv f_\mathbf{k} = n_\mathbf{k}\mathbb{1} + S_\mathbf{k}$. In the presence of a constant uniform electric field $\mathbf{E}$, $f_\mathbf{k} = f_{0\mathbf{k}} + f_{E\mathbf{k}}$, where the equilibrium density matrix $f_{0\mathbf{k}}$ is given by the Fermi–Dirac distribution, and the correction $f_{E\mathbf{k}}$ is due to the $\mathbf{E}$. We subdivide $f_{0\mathbf{k}} = n_{0\mathbf{k}}\mathbb{1} + S_{0\mathbf{k}}$ and $f_{E\mathbf{k}} = n_{E\mathbf{k}}\mathbb{1} + S_{E\mathbf{k}}$. The spin-dependent part of the nonequilibrium correction to the density matrix $S_{E\mathbf{k}}$ is interpreted as the spin density induced by $\mathbf{E}$. The equations governing the time evolution of $n_{E\mathbf{k}}$ and $S_{E\mathbf{k}}$ is [51]

$$\begin{aligned}\frac{\partial n_{E\mathbf{k}}}{\partial t} + \hat{J}_0(n_{E\mathbf{k}}) &= \frac{e\mathbf{E}}{\hbar}\cdot\frac{\partial n_{0\mathbf{k}}}{\partial \mathbf{k}} \\ \frac{\partial S_{E\mathbf{k}}}{\partial t} + \frac{i}{\hbar}[H_\mathbf{k}, S_{E\mathbf{k}}] + \hat{J}_0(S_{E\mathbf{k}}) &= \frac{e\mathbf{E}}{\hbar}\cdot\frac{\partial S_{0\mathbf{k}}}{\partial \mathbf{k}} - \hat{J}_s(n_{E\mathbf{k}}) \\ &\equiv \Sigma_{E\mathbf{k}}\,,\end{aligned} \quad (27)$$

where the scalar part of the scattering operator $\hat{J}_0$ and its spin-dependent part $\hat{J}_s$ have been defined in [51]. The equation for $n_{E\mathbf{k}}$ has the well-known solution $n_{E\mathbf{k}} = (e\mathbf{E}\tau_p/\hbar)\cdot(\partial n_{0\mathbf{k}}/\partial\mathbf{k})$, in other words, $n_{E\mathbf{k}}$ describes the shift of the Fermi sphere in the presence of the electric field $\mathbf{E}$, with the momentum relaxation time τ_p. It is seen from Eq. (27) that spin-dependent scattering gives rise to a renormalization of the driving term in the equation for $S_{E\mathbf{k}}$. This renormalization has no analog in charge transport.

We need to find the expectation value of the spin current operator $\hat{\mathcal{J}}_i^\sigma$ defined in the introduction. In the systems under study the spin current operator can be written as $\hat{\mathcal{J}}_i^\sigma = \hbar k_i s^\sigma/m^* + (1/4\hbar)\partial\Omega^\sigma/\partial k_i\mathbb{1}$. We need to determine $S_{E\mathbf{k}}$. To this end we remember that an electron spin at wave vector $\mathbf{k}$ precesses about an effective magnetic field $\boldsymbol{\Omega}_\mathbf{k}$. The spin can be resolved into components parallel



Semiclassical Spin Transport in Spin-Orbit Coupled Systems, Figure 3
Effective field $\boldsymbol{\Omega}_k$ at the Fermi energy in the Rashba model [18] a without ($E = 0$) and b with an external electric field ($E > 0$)

and perpendicular to $\boldsymbol{\Omega}_{\mathbf{k}}$. In the course of spin precession the component of the spin parallel to $\boldsymbol{\Omega}_{\mathbf{k}}$ is conserved, while the perpendicular component is continually changing. Corresponding to this decomposition of the spin is an analogous decomposition of the spin distribution $S_{E\mathbf{k}}$ into a part representing conserved spin and a part representing precessing spin, denoted by $S_{E\mathbf{k}\|}$ and $S_{E\mathbf{k}\perp}$ respectively. There is an analogous decomposition of the source on the RHS of Eq. (27) into $\Sigma_{E\mathbf{k}\|}$ and $\Sigma_{E\mathbf{k}\perp}$. This decomposition is carried out by introducing projection operators $P_\|$ and $P_\perp$ as described in [51], giving for $S_{E\mathbf{k}\|}$ and $S_{E\mathbf{k}\perp}$ in the weak momentum scattering limit

$$\frac{\partial S_{E\mathbf{k}\|}}{\partial t} + P_\| \hat{J}_0(S_{E\mathbf{k}}) = \Sigma_{E\mathbf{k}\|} \,, \tag{28a}$$

$$\frac{\partial S_{E\mathbf{k}\perp}}{\partial t} + \frac{i}{\hbar}[H_{\mathbf{k}}, S_{E\mathbf{k}\perp}] = \Sigma_{E\mathbf{k}\perp} - P_\perp \hat{J}_0(S_{E\mathbf{k}}) \,. \tag{28b}$$

Equation (28b) shows that scattering mixes the distributions of conserved and precessing spins. This is so because when one spin at wave vector $\mathbf{k}$ and precessing about $\boldsymbol{\Omega}_{\mathbf{k}}$ is scattered to wave vector $\mathbf{k}'$ and precesses about $\boldsymbol{\Omega}_{\mathbf{k}'}$, its conserved component changes, a process which alters the distributions of conserved and precessing spin. Equations (28a,28b) can be solved straightforwardly if one assumes the impurity potential to be short-ranged, obtaining [51]

$$S_{E\mathbf{k}\|} = \Sigma_{E\mathbf{k}\|}\tau_p + P_\|(1 - \bar{P}_\|)^{-1}\bar{\Sigma}_{E\mathbf{k}\|}\tau_p \,, \tag{29a}$$

$$S_{E\mathbf{k}\perp} = \frac{\boldsymbol{\Omega}_{\mathbf{k}} \times (\boldsymbol{\Sigma}_{E\mathbf{k}\perp}\tau_p + P_\perp \bar{\mathbf{S}}_{E\mathbf{k}\|}) \cdot \boldsymbol{\sigma}\tau_p}{2\hbar(1 + \Omega_{\boldsymbol{k}}^2\tau_p^2/\hbar^2)} - \frac{(\Sigma_{E\mathbf{k}\perp}\tau_p + P_\perp \bar{S}_{E\mathbf{k}\|})}{1 + \Omega_{\mathbf{k}}^2\tau_p^2/\hbar^2} \,. \tag{29b}$$

The correction $S_{E\mathbf{k}\|}$ does not give rise to a spin current. Inspection of Eq. (29a) shows that integrals of the form $\int \mathrm{d}\theta \hat{\jmath}_i^\sigma S_{E\mathbf{k}\|}$ contain an odd number of powers of $\mathbf{k}$ and are therefore zero. It can, however, give rise to a nonequilibrium spin density, since integrals of the form $\int \mathrm{d}\theta \hat{s}^\sigma S_{E\mathbf{k}\|}$ contain an even number of powers of $\mathbf{k}$ and may be nonzero. Similarly $S_{E\mathbf{k}\perp}$ does not lead to a nonequilibrium spin density. The expectation value of the spin operator yields integrals of the form $\int \mathrm{d}\theta \hat{s}^\sigma S^{(0)}_{E\mathbf{k}\perp}$, which involve odd numbers of powers of $\mathbf{k}$ and are therefore zero. This term does, however, give rise to nonzero spin currents, since integrals if the form $\int \mathrm{d}\theta \hat{\jmath}_i^\sigma S_{E\mathbf{k}\perp}$ contain an even numbers of powers of $\mathbf{k}$ and may be nonzero. Therefore, in the absence of spin-orbit coupling in the scattering potential, nonequilibrium spin currents arise from spin precession (as outlined by Sinova et al. [35]), and nonequilibrium spin densities from the absence of spin precession. The dominant contribution to the nonequilibrium spin density in an electric field exists because in the course of spin precession a component of each individual spin is preserved. For an electron with wave vector $\mathbf{k}$, this spin component is parallel to $\boldsymbol{\Omega}_k$. In equilibrium the average of these conserved components is zero. When an electric field is applied the Fermi surface is shifted and the average of the conserved spin components may be nonzero, as illustrated in Fig. 1. This argument explains why the nonequilibrium spin density $\propto \tau_p^{-1}$ and *requires* scattering to balance the drift of the Fermi surface. Although spin densities in electric fields require band structure spin-orbit interactions and therefore spin precession, the dominant contribution arises as a result of the absence of spin precession.

Systems in which $\boldsymbol{\Omega}_{k}$ is linear in $\mathbf{k}$ are special, in that the spin current as defined in this section vanishes [39, 40,41,42,43,44,45,46]. This is because of the renormalization of the driving term on the RHS of Eq. (28b) for $S_{E\mathbf{k}\perp}$, in other words because of scattering from the conserved spin distribution to the precessing spin distribution. In Eq. (29b) it is also clear that if $\Sigma_{E\mathbf{k}\perp}\tau_p + P_{\perp}\bar{S}_{E\mathbf{k}\|}$ vanishes, then all the contributions to $S_{E\mathbf{k}\perp}$ also vanish. Since $\bar{S}_{E\mathbf{k}\|}$ effectively represents a steady-state spin density, we see that the presence of this spin density tends to diminish the spin current. In systems with energy dispersion linear in $\mathbf{k}$ it cancels the spin current completely.

Future Directions

Whereas the community appears to be in agreement that spin currents exist and are measurable, many questions remain unanswered. Theoretically, intrinsic and extrinsic effects (such as due to skew scattering and side jump) have not been studied on the same footing for an arbitrary form of band structure spin-orbit interactions. The relative magnitude of intrinsic and extrinsic spin currents in such a general system remains to be determined. Also, different definitions of the spin current give results that often differ by a sign [1,2]. The relationship between spin current and spin accumulation at the boundary is not clear, again thanks to the non-conservation of spin. It appears that what happens at the boundary is sensitive to the type of boundary conditions assumed. Thus so far as quantitative interpretation of experimental data is concerned, theory has some way to go.

Despite tremendous progress, experiment is still searching for a reliable way to *measure*, as opposed to *detect*, spin currents directly. Practically, the question of what to do with spin once it has been transported/generated remains. The revolutionary electronic device that harnesses spin currents for a practical purpose remains to be made, and the challenge of its design confronts experimentalists and theorists alike.

Article Outline

Glossary

Deep water A surface wave is said to be in deep water if its wavelength is much shorter than the local water depth.

Internal wave A internal wave travels within the interior of a fluid. The maximum velocity and maximum amplitude occur within the fluid or at an internal boundary (interface). Internal waves depend on the density-stratification of the fluid.

Shallow water A surface wave is said to be in shallow water if its wavelength is much larger than the local water depth.

Shallow water waves Shallow water waves correspond to the flow at the free surface of a body of shallow water under the force of gravity, or to the flow below a horizontal pressure surface in a fluid.

Shallow water wave equations Shallow water wave equations are a set of partial differential equations that describe shallow water waves.

Solitary wave A solitary wave is a localized gravity wave that maintains its coherence and, hence, its visibility through properties of nonlinear hydrodynamics. Solitary waves have finite amplitude and propagate with constant speed and constant shape.

Soliton Solitons are solitary waves that have an elastic scattering property: they retain their shape and speed after colliding with each other.

Surface wave A surface wave travels at the free surface of a fluid. The maximum velocity of the wave and the maximum displacement of fluid particles occur at the free surface of the fluid.

Tsunami A tsunami is a very long ocean wave caused by an underwater earthquake, a submarine volcanic eruption, or by a landslide.

Wave dispersion Wave dispersion in water waves refers to the property that longer waves have lower frequencies and travel faster.

Definition of the Subject

The most familiar water waves are waves at the beach caused by wind or tides, waves created by throwing a stone in a pond, by the wake of a ship, or by raindrops in a river (see Fig. 1). Despite their familiarity, these are all different types of water waves. This article only addresses shallow water waves, where the depth of the water is much smaller than the wavelength of the disturbance of the free surface. Furthermore, the discussion is focused on gravity waves in which buoyancy acts as the restoring force. Little attention will we paid to capillary effects, and capillary waves for which the primary restoring force is surface tension are not covered.

Although the history of shallow water waves [15,20,22] goes back to French and British mathematicians of the eighteenth and early nineteenth century, Stokes [71] is considered one of the pioneers of hydrodynamics (see [21]). He carefully derived the equations for the motion of incompressible, inviscid fluid, subject to a constant vertical gravitational force, where the fluid is bounded below by an impermeable bottom and above by a free surface. Starting from these fundamental equations and by making further simplifying assumptions, various shallow water wave models can be derived. These shallow water models are widely used in oceanography and atmospheric science.

This article discusses shallow water wave equations commonly used in oceanography and atmospheric science. They fall into two major categories: Shallow water wave models with wave dispersion are discussed in Sect. "Completely Integrable Shallow Water Wave Equations" Most of these are completely integrable equations that admit smooth solitary and cnoidal wave solutions for which computational procedures are outlined in Sect. "Computation of Solitary Wave Solutions". Sect. "Shallow Water Wave Equations of Geophysical Fluid Dynamics" covers classical shallow water wave models without dispersion. Such hyperbolic systems can admit shocks. Sect. "Water Wave Experiments and Observations" addresses a few experiments and observations. The article concludes with future directions in Sect. "Future Directions".

Introduction

The initial observation of a solitary wave in shallow water was made by John Scott Russell, shown in Fig. 2. Russell was a Scottish engineer and naval architect who was conducting experiments for the Union Canal Company to design a more efficient canal boat.

In Russell's [63] own words: "I was observing the motion of a boat which was rapidly drawn along a narrow channel by a pair of horses, when the boat suddenly stopped – not so the mass of water in the channel which it had put in motion; it accumulated round the prow of the vessel in a state of violent agitation, then suddenly leaving it behind, rolled forward with great velocity, assuming the form of a large solitary elevation, a rounded, smooth and well-defined heap of water, which continued its course along the channel apparently without change of form or diminution of speed. I followed it on horseback, and overtook it still rolling on at a rate of some eight or nine miles an hour, preserving its original figure some thirty feet long and a foot to a foot and a half in height. Its height gradually diminished, and after a chase of one or two miles I lost it in the windings of the channel. Such, in the month of August 1834, was my first chance interview with that singular and beautiful phenomenon which I have called the Wave of Translation."

Russell built a water tank to replicate the phenomenon and research the properties of the solitary wave he had observed. Details can be found in a biography of John Scott Russell (1808–1882) by Emmerson [27], and in review articles by Bullough [15], Craik [20], and Darrigol [22], who pay tribute to Russell's research of water waves.

In 1895, the Dutch professor Diederik Korteweg and his doctoral student Gustav de Vries [47] derived a partial differential equation (PDE) which models the solitary wave that Russell had observed. Parenthetically, the equation which now bears their name had already appeared in seminal work on water waves published by Boussinesq [13,14] and Rayleigh [59]. The solitary wave was considered a relatively unimportant curiosity in the field of nonlinear waves. That all changed in 1965, when Zabusky and Kruskal realized that the KdV equation arises as the continuum limit of a one dimensional anharmonic lattice used by Fermi, Pasta, and Ulam [29] to investigate "thermalization" – or how energy is distributed among the many possible oscillations in the lattice. Zabusky and Kruskal [78] simulated the collision of solitary waves in a nonlinear crystal lattice and observed that they retain their shapes and speed after collision. Interacting solitary waves merely experience a phase shift, advancing the faster and retarding the slower. In analogy with colliding particles, they coined the word "solitons" to describe these elastically colliding waves. A narrative of the discovery of solitons can be found in [77].

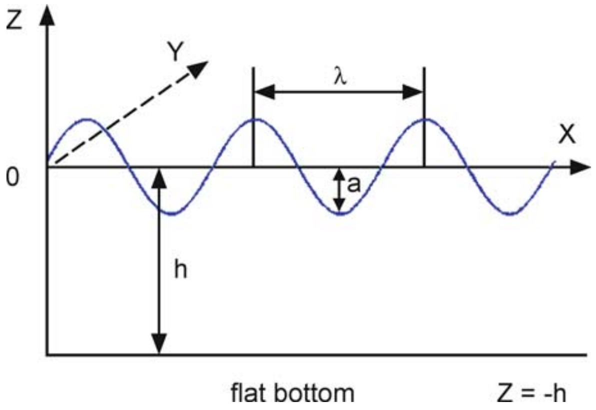
Shallow Water Waves and Solitary Waves, Figure 3
Recreation of a solitary wave on the Scott Russell Aqueduct on the Union Canal. Photograph courtesy of Heriot–Watt University

Since the 1970s, the KdV equation and other equations that admit solitary wave and soliton solutions have been the subject of intense study (see, e. g., [23,30,60]). Indeed, scientists remain intrigued by the physical properties and elegant mathematical theory of the shallow water wave models. In particular, the so-called completely integrable models which can be solved with the Inverse Inverse scattering transform (IST). For details about the IST method the reader is referred to Ablowitz et al. [3], Ablowitz and Segur [2], and Ablowitz and Clarkson [1]. The completely integrable models discussed in the next section are infinite-dimensional Hamiltonian systems, with infinitely many conservation laws and higher-order symmetries, and admit soliton solutions of any order.

As an aside, in 1995, scientists gathered at Heriot–Watt University for a conference and successfully recreated a solitary wave but of smaller dimensions than the one observed by Russell 161 years earlier (see Fig. 3).

Completely Integrable Shallow Water Wave Equations

Starting from Stokes' [71] governing equations for water waves, completely integrable PDEs arise at various levels of approximation in shallow water wave theory. Four length scales play a crucial role in their derivation. As shown in Fig. 4, the wavelength λ of the wave measures the distance between two successive peaks. The amplitude a measures the height of the wave, which is the varying distance between the undisturbed water to the peak of the wave. The



Shallow Water Waves and Solitary Waves, Figure 4
Coordinate frame and periodic wave on the surface of water

depth of the water h is measured from the (flat) bottom of the water up to the quiescent free surface. The fourth length scale is along the Y-axis which is along the crest of the wave and perpendicular to the (X, Z)-plane.

Assuming wave propagation in water of uniform (shallow) depth, i. e. h is constant, and ignoring dissipation, the model equations discussed in this section have a set of common features and limitations which make them mathematically tractable [68]. They describe (i) long waves (or shallow water), i. e. $h \ll \lambda$, (ii) with relatively small amplitude, i. e. $a \ll h$, (iii) traveling in one direction (along the X-axis) or weakly two-dimensional (with a small component in the Y-direction). Furthermore, the small effects must be comparable in size. For example, in the derivation of the KdV and Boussinesq equations one assumes that $\varepsilon = a/h = O(h^2/\lambda^2)$, where ε is a small parameter ($\varepsilon \ll 1$), and O indicates the order of magnitude.

The Korteweg–de Vries Equation

The KdV equation was originally derived to describe shallow water waves of long wavelength and small amplitude. In the derivation, Korteweg and de Vries assumed that all motion is uniform in the Y-direction, along the crest of the wave. In that case, the surface elevation (above the equilibrium level h) of the wave, propagating in the X-direction, is a function only of the horizontal position X (along the canal) and of time T, i. e. $Z = \eta(X, T)$.

In terms of the physical parameters, the KdV equation reads

$$\frac{\partial\eta}{\partial T} + \sqrt{gh}\frac{\partial\eta}{\partial X} + \frac{3}{2}\frac{\sqrt{gh}}{h}\eta\frac{\partial\eta}{\partial X} + \frac{1}{2}h^2\sqrt{gh}\left(\frac{1}{3} - \frac{\mathcal{T}}{\rho g h^2}\right)\frac{\partial^3\eta}{\partial X^3} = 0\,, \quad (1)$$

where h is the uniform water depth, g is the gravitational acceleration (about 9.81m/sec^2 at sea level), ρ is the density, and $\mathcal{T}$ stands for the surface tension. The dimensionless parameter $\mathcal{T}/\rho g h^2$ is called the *Bond number* which measures the relative strength of surface tension and the gravitational force.

Keeping only the first two terms in (1), the speed of the associated linear (long) wave is $c = \sqrt{gh}$. This is indeed the maximum attainable speed of propagation of gravity-induced water waves of infinitesimal amplitude. The speed of propagation of the small-amplitude solitary waves described by (1) is slightly higher. According to Russell's empirical formula the speed equals $\sqrt{g(h+k)}$, where k is the height of the peak of the solitary wave above the surface of undisturbed water. As Bullough [15] has shown, Russell's approximate speed and the true speed of solitary waves only differ by a term of $O(k^2/h^2)$.

The KdV equation can be recast in dimensionless variables as

$$u_t + \alpha u u_x + u_{xxx} = 0\,, \quad (2)$$

where subscripts denote partial derivatives. The parameter α can be scaled to any real number. Commonly used values are $\alpha = \pm 1$ or $\alpha = \pm 6$.

The term u_t describes the time evolution of the wave propagating in one direction. Therefore, (2) is called an *evolution* equation. The nonlinear term $\alpha u u_x$ accounts for steepening of the wave, and the linear dispersive term u_{xxx} describes spreading of the wave. The linear first-order term $\sqrt{gh}\frac{\partial\eta}{\partial X}$ in (1) can be removed by an elementary transformation. Conversely, a linear term in u_x can be added to (2).

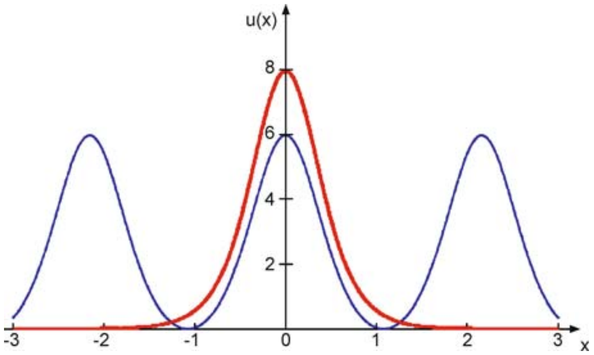
The nonlinear steepening of the water wave can be balanced by dispersion. If so, the result of these counteracting effects is a stable solitary wave with particle-like properties. A solitary wave has a finite amplitude and propagates at constant speed and without change in shape over a fairly long distance. This is in contrast to the concentric group of small-amplitude capillary waves, shown in Fig. 1, which disperse as they propagate.

The closed-form expression of a solitary wave solution is given by

$$u(x,t) = \frac{\omega - 4k^3}{\alpha k} + \frac{12k^2}{\alpha}\operatorname{sech}^2(kx - \omega t + \delta) \quad (3)$$

$$= \frac{\omega + 8k^3}{\alpha k} - \frac{12k^2}{\alpha}\tanh^2(kx - \omega t + \delta)\,, \quad (4)$$

where the wave number k, the angular frequency ω, and δ are arbitrary constants.



Shallow Water Waves and Solitary Waves, Figure 5
Solitary wave (red) and periodic cnoidal (blue) wave profiles

Requiring that $\lim_{x\to\pm\infty} u(x,t) = 0$ for all time leads to $\omega = 4k^3$. Then (3) and (4) reduce to

$$\begin{aligned} u(x,t) &= \frac{12k^2}{\alpha}\operatorname{sech}^2(kx - 4k^3t + \delta) \\ &= \frac{12k^2}{\alpha}[1 - \tanh^2(kx - 4k^3t + \delta)] \,. \end{aligned} \tag{5}$$

The position of the hump-type wave at $t = 0$ is depicted in Fig. 5 for $\alpha = 6,\ k = 2$, and $\delta = 0$. As time changes, the solitary wave with amplitude $2k^2 = 8$ travels to the right at speed $v = \omega/k = 4k^2 = 16$. The speed is exactly twice the peak amplitude. So, the higher the wave the faster it travels, but it does so without change in shape. The reciprocal of the wavenumber k is a measure of the width of the sech-square pulse.

As shown by Korteweg and de Vries [47], Eq. (2) also has a simple periodic solution,

$$u(x,t) = \frac{\omega - 4k^3(2m-1)}{\alpha k} + \frac{12k^2m}{\alpha}\operatorname{cn}^2(kx - \omega t + \delta; m), \tag{6}$$

which they called the *cnoidal wave* solution since they involve the Jacobi elliptic cosine function, cn, with modulus $m\,(0 < m < 1)$. The wavenumber k gives the characteristic width of each oscillation in the "cnoid."

Three cycles of the cnoidal wave are depicted in Fig. 5 at $t = 0$. The graph corresponds to $\alpha = 6, k = 2, m = 3/4, \omega = 16$, and $\delta = 0$. Using the property $\lim_{m\to 1} \operatorname{cn}(\xi; m) = \operatorname{sech}(\xi)$, one readily verifies that (6) reduces to (3) as m tends to 1. Pictorially, the individual oscillations then stretch infinitely far apart leaving a single-pulse solitary wave.

The celebrated KdV equation appears in all books and reviews about soliton theory. In addition, the equation has been featured in, e. g., Miura [52] and Miles [51].

Regularized Long-Wave Equations

A couple of alternatives to the KdV equation have been proposed. A first alternative,

$$u_t + u_x + \alpha u u_x - u_{xxt} = 0 \,, \tag{7}$$

was proposed by Benjamin, Bona, and Mahony [7]. Hence, (7) is referred to as the BBM or regularized long-wave (RLW) equation.

Equation (7), which has a solitary wave solution,

$$u(x,t) = \frac{\omega - k - 4k^2\omega}{\alpha k} + \frac{12k\omega}{\alpha}\operatorname{sech}^2(kx - \omega t + \delta), \tag{8}$$

was also derived by Peregrine [57] to describe the behavior of an undular bore (in water), which comprises a smooth wavefront followed by a train of solitary waves. An undular bore can be interpreted as the dispersive analog of a shock wave in classical non-dispersive, dissipative hydrodynamics [26].

The linear dispersion relation for the KdV equation, $\omega = k(1 - k^2)$, can be obtained by substituting $u(x,t) = \exp[i(kx - \omega t + \delta)]$ into $u_t + u_x + u_{xxx} = 0$. The linear phase velocity, $v_p = \omega/k = 1 - k^2$, becomes negative for $|k| > 1$, thereby contradicting the assumption of unidirectional propagation. Furthermore, the group velocity $v_g = d\omega/dk = 1 - 3k^2$ has no lower bound which implies that there is no limit to the rate at which shorter ripples propagate in the negative x-direction.

The BBM equation, where $\omega = k/(1 + k^2), v_p = 1/(1 + k^2)$, and $v_g = (1 - k^2)/(1 + k^2)^2$, was proposed to get around these objections and to address issues related to proving the existence of solutions of the KdV equation. The dispersion relation of (7) has more desirable properties for high wave numbers, but the group velocity becomes negative for $|k| > 1$. In addition, the KdV and BBM equations are first order in time making it impossible to specify both u and u_t as initial data.

To circumvent these limitations, a second alternative,

$$u_t + u_x + \alpha u u_x + u_{xtt} = 0 \,, \tag{9}$$

was proposed by Joseph and Egri [45] and Jeffrey [43]. It is called the time regularized long-wave (TRLW) equation and its solitary wave solution is given by

$$u(x,t) = \frac{\omega - k - 4k\omega^2}{\alpha k} + \frac{12\omega^2}{\alpha}\operatorname{sech}^2(kx - \omega t + \delta). \tag{10}$$

The TRLW equation shares many of the properties of both the KdV and BBM equations, at the cost of a more complicated dispersion relation, $\omega = (-1 \pm \sqrt{1 + 4k^2})/2k$ with two branches. Only one of these branches is valid because the derivation of the TRLW equation shows that (9) is unidirectional, despite the two time derivatives in u_{xtt}.

Bona and Chen [8] have shown that the initial value problem for the TRLW equation is well-posed, and that for small-amplitude, long waves, solutions of (9) agree with solutions of either (2) or (7). As a matter of fact, all three equations agree to the neglected order of approximation over a long time scale, provided the initial data is properly imposed (see also [9]).

Fine-tuning the dispersion relation of the KdV equation comes at a cost. In contrast to (2), the RLW and TRLW equations are no longer completely integrable. Perhaps that is why these equations never became as popular as the KdV equation.

The Boussinesq Equation

The classical Boussinesq equation,

$$\eta_{TT}-c^2\eta_{XX}-\frac{3c^2}{h}\left(\eta_X^2+\eta\eta_{XX}\right)-\frac{c^2h^2}{3}\eta_{XXXX}=0, \quad (11)$$

was derived by Boussinesq [12] to describe gravity-induced surface waves as they propagate at constant (linear) speed $c=\sqrt{gh}$ in a canal of uniform depth h.

In contrast to the KdV equation, (11) has a second-order time-derivative term. Ignoring all but the first two terms in (11), one obtains the linear *wave* equation, $\eta_{TT}-c^2\eta_{XX}=0$, which describes both left-running and right-running waves. However, (11) is *not* bi-directional because in the derivation Boussinesq used the constraint $\eta_T=-c\eta_X$, which limits (11) to waves traveling to the right.

In dimensionless form, the Boussinesq equation reads

$$u_{tt}-c^2u_{xx}-\alpha u_x^2-\alpha uu_{xx}-\beta u_{xxxx}=0\,. \quad (12)$$

The values of the parameters $c, \alpha>0$, and β do not matter, but the sign of β matters. Typically, one sets $c=1, \alpha=3$, and $\beta=\pm1$.

A simple solitary wave solution of (12) is given by

$$u(x,t)=\frac{\omega^2-c^2k^2-4\beta k^4}{\alpha k^2}+\frac{12\beta k^2}{\alpha}\operatorname{sech}^2(kx-\omega t+\delta)\,. \quad (13)$$

The equation with $\beta=1$ is a scaled version of (11) and thus most relevant to shallow water wave theory. Mathematically, (12) with $\beta=1$ is ill-posed, (even without the nonlinear terms), which means that the initial value problem cannot be solved for arbitrary data. This shortcoming does not happen for (12) with $\beta=-1$, which is therefore nicknamed the "good" Boussinesq equation [50]. Nonetheless, the classical and good Boussinesq equations are completely integrable.

The "improved" or "regularized" Boussinesq equation (see, e. g., [10]) has $\beta=1$ but u_{xxtt} instead of u_{xxxx}, which improves the properties of the dispersion relation. Like (12), the regularized version describes uni-directional waves. The regularized Boussinesq equation and other alternative equations listed in the literature (see, e. g., Madsen and Schäffer [49]) are not completely integrable.

Bona et al. [10,11] analyzed a family of Boussinesq systems of the form

$$\begin{aligned} w_t+u_x+(uw)_x+\alpha u_{xxx}-\beta w_{xxt}&=0\,,\\ u_t+w_x+uu_x+\gamma w_{xxx}-\delta u_{xxt}&=0\,, \end{aligned} \quad (14)$$

which follow from the Euler equations as first-order approximations in the parameters $\varepsilon_1=a/h\ll1$, $\varepsilon_2=h^2/\lambda^2\ll1$, where the Stokes number, $S=\varepsilon_1/\varepsilon_2=a\lambda^2/h^3\approx1$.

In (14) $w(x,t)$ is the non-dimensional deviation of the water surface from its undisturbed position; $u(x,t)$ is the non-dimensional horizontal velocity field at a height θh (with $0\le\theta\le1$) above the flat bottom of the water. The constant parameters α through δ in (14) satisfy the following consistency conditions: $\alpha+\beta=\frac{1}{2}(\theta^2-\frac{1}{3})$ and $\gamma+\delta=\frac{1}{2}(1-\theta^2)\ge0$. Solitary wave solutions of various special cases of (14) have been computed by Chen [18].

Boussinesq systems arise when modeling the propagation of long-crested waves on large bodies of water (such as large lakes or the ocean). The Boussinesq family (14) encompasses many systems that appeared in the literature. Special cases and properties of well-posedness of (14) are addressed by Bona et al. [10,11].

1D Shallow Water Wave Equation

The so-called one-dimensional (1D) shallow water wave equation,

$$v_{xxt}+\alpha vv_t-v_t-v_x+\beta v_x\int_{\infty}^{x}v_t(y,t)dy=0\,, \quad (15)$$

can be derived from the classical shallow water wave theory (see Sect. "Shallow Water Wave Equations of Geophysical Fluid Dynamics") in the Boussinesq approximation. In that approximation one assumes that vertical variations of the static density, ρ_0, are neglected, except the buoyancy term proportional to $d\rho_0/dz$, which is, in fact, responsible for the existence of solitary waves. The integral term in (15) can be removed by introducing the potential u. Indeed, setting $v=u_x$, Eq. (15) can be written as

$$u_{xxxt}+\alpha u_xu_{xt}-u_{xt}-u_{xx}+\beta u_{xx}u_t=0\,. \quad (16)$$

The equation is completely integrable and can be solved with the IST if and only if either $\alpha = \beta$ [41] or $\alpha = 2\beta$ [3]. When $\alpha = \beta$, Eq. (16) can be integrated with respect to x and thus replaced by

$$u_{xxt} + \alpha u_x u_t - u_t - u_x = 0 \,. \tag{17}$$

Closed-form solutions of (15), and in particular of (17), have been computed by Clarkson and Mansfield [19].

The Camassa–Holm Equation

The CH equation, named after Camassa and Holm [16,17],

$$\begin{aligned} u_t + 2\kappa u_x + 3uu_x - \alpha^2 u_{xxt} + \gamma u_{xxx} \\ - 2\alpha^2 u_x u_{xx} - \alpha^2 u u_{xxx} = 0 \,, \end{aligned} \tag{18}$$

also models waves in shallow water. In (18), u is the fluid velocity in the x-direction or, equivalently, the height of the water's free surface above a flat bottom, and κ, γ and α are constants. Retaining only the first four terms in (18) gives the BBM Eq. (7). Setting $\alpha = 0$ reduces (18) to the KdV equation.

The CH equation admits solitary wave solutions, but in contrast to the hump-type solutions of the KdV and Boussinesq equations, they are implicit in nature (see, e. g., [44]). In the limit $\kappa \to 0$, Eq. (18) with $\gamma = 0, \alpha = 1$ has a cusp-type solution of the form $u(x,t) = c\exp(-|x - ct - x_0|)$. The solution is called a peakon since it has a peak (or corner) where the first derivatives are discontinuous. The solution travels at speed $c > 0$ which equals the height of the peakon.

The Kadomtsev–Petviashvili Equation

In their 1970 study [46] of the stability of line solitons, Kadomtsev and Petviashvili (KP) derived a 2D-generalization of the KdV equation which now bears their name. In dimensionless variables, the KP equation is

$$(u_t + \alpha u u_x + u_{xxx})_x + \sigma^2 u_{yy} = 0 \,, \tag{19}$$

where y is the transverse direction. In the derivation of the KP equation, one assumes that the scale of variation in the y-direction (along the crest of the wave as shown in Fig. 4) is much longer than the wavelength along the x-direction.

The solitary wave and periodic (cnoidal) solutions of (19) are, respectively, given by

$$u(x,t) = \frac{k\omega - 4k^4 + \sigma^2 l^2}{\alpha k^2} + \frac{12k^2}{\alpha}\operatorname{sech}^2(kx + ly - \omega t + \delta), \tag{20}$$

Shallow Water Waves and Solitary Waves, Figure 6
Periodic plane waves in shallow water, off the coast of Lima, Peru. Photograph courtesy of A. Segur

and

$$\begin{aligned} u(x,t) = {} & \frac{k\omega - 4k^4(2m-1) - \sigma^2 l^2}{\alpha k^2} \\ & + \frac{12k^2 m}{\alpha}\operatorname{cn}^2(kx + ly - \omega t + \delta; m) \,. \end{aligned} \tag{21}$$

As shown in Fig. 6, near a flat beach the periodic waves appear as long, quasilinear stripes with a cn-squared cross section. Such waves are typically generated by wind and tides.

The equation with $\sigma^2 = -1$ is referred to as KP1, whereas (19) with $\sigma^2 = 1$ is called KP2, which describes shallow water waves [67]. Both KP1 and KP2 are completely integrable equations but their solution structures are fundamentally different (see, e. g., [65], pp. 489–490).

Shallow Water Wave Equations of Geophysical Fluid Dynamics

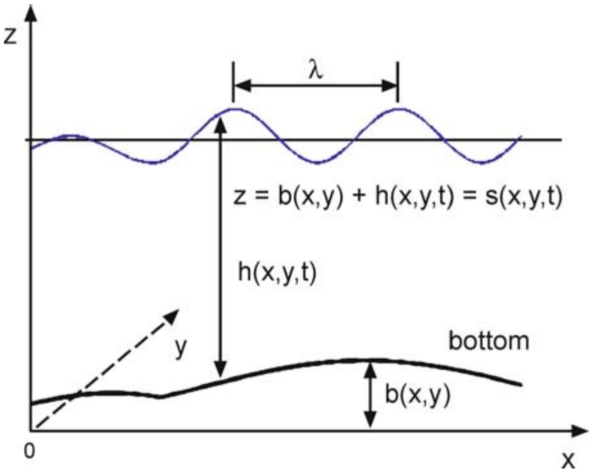
The shallow water equations used in geophysical fluid dynamics are based on the assumption $D/L \ll 1$, where D and L are characteristic values for the vertical and horizontal length scales of motion. For example, D could be the average depth of a layer of fluid (or the entire fluid) and L could be the wavelength of the wave.

The geophysical fluid dynamics community (see, e. g., [55,72,73]) uses the following 2D shallow water equations,

$$u_t + uu_x + vu_y + gh_x - 2\Omega v = -gb_x \,, \tag{22}$$

$$v_t + uv_x + vv_y + gh_y + 2\Omega u = -gb_y, \tag{23}$$

$$h_t + (hu)_x + (hv)_y = 0, \tag{24}$$



Shallow Water Waves and Solitary Waves, Figure 7
Setup for the geophysical shallow water wave model

to describe water flows with a free surface under the influence of gravity (with gravitational acceleration g) and the Coriolis force due to the earth's rotation (with angular velocity Ω.) As usual, $\mathbf{u} = (u, v)$ denotes the horizontal velocity of the fluid and $h(x, y, t)$ is its depth. As shown in Fig. 7, $h(x, y, t)$ is the distance between the free surface $z = s(x, y, t)$ and the variable bottom $b(x, y)$. Hence, $s(x, y, t) = b(x, y) + h(x, y, t)$. Eqs. (22) and (23) express the horizontal momentum-balance; (24) expresses conservation of mass. Note that the vertical component of the fluid velocity has been eliminated from the dynamics and that the number of independent variables has been reduced by one. Indeed, z no longer explicitly appears in (22)–(24), where u, v, and h only depend on x, y, and t.

A shortcoming of the model is that it does not take into account the density stratification which is present in the atmosphere (as well as in the ocean). Nonetheless, (22)–(24) are commonly used by atmospheric scientists to model flow of air at low speed.

More sophisticated models treat the ocean or atmosphere as a stack of layers with variable thickness. Within each layer, the density is either assumed to be uniform or may vary horizontally due to temperature gradients. For example, Lavoie's rotating shallow water wave equations (see [24]),

$$\boldsymbol{u}_t + (\boldsymbol{u} \cdot \nabla)\boldsymbol{u} + 2\boldsymbol{\Omega} \times \boldsymbol{u} = -\nabla(h\theta) + \tfrac{1}{2} h \nabla\theta \,, \qquad (25)$$

$$h_t + \nabla \cdot (h\boldsymbol{u}) = 0 \,, \qquad (26)$$

$$\theta_t + \boldsymbol{u} \cdot (\nabla\theta) = 0 \,, \qquad (27)$$

consider only one active layer with layer depth $h(x, y, t)$, but take into account the forcing due to a horizontally varying potential temperature field $\theta(x, y, t)$. Vector $\boldsymbol{u} = u(x, y, t)\boldsymbol{i} + v(x, y, t)\boldsymbol{j}$ denotes the fluid velocity and $\boldsymbol{\Omega} = \Omega\boldsymbol{k}$ is the angular velocity vector of the Earth's rotation. $\nabla = \frac{\partial}{\partial x}\boldsymbol{i} + \frac{\partial}{\partial y}\boldsymbol{j}$ is the gradient operator, and $\boldsymbol{i}$, $\boldsymbol{j}$, and $\boldsymbol{k}$ are unit vectors along the x, y, and z-axes.

Lavoie's equations are part of a family of multi-layer models proposed by Ripa [61] to study, for example, the effects of solar heating, fresh water fluxes, and wind stresses on the upper equatorial ocean. A study of the validity of various layered models has been presented by Ripa [62]. The more sophisticated the models become the harder they become to treat with analytic methods so one has to apply numerical methods. Numerical aspects of various shallow water models in atmospheric research and beyond are discussed in e. g. [48,75,76].

Computation of Solitary Wave Solutions

As shown in Sect. "Completely Integrable Shallow Water Wave Equations", solitary wave solutions of the KdV and Boussinesq equations (and like PDEs), can be expressed as polynomials of the hyperbolic secant (sech) or tangent (tanh) functions, whereas their simplest period solutions involve the Jacobi elliptic cosine (cn) function.

There are several methods to compute exact, analytic expressions for solitary and periodic wave solutions of nonlinear PDEs. Two straightforward methods, namely the direct integration method and the tanh-method, will be discussed. Both methods seek traveling wave solutions. By working in a traveling frame of reference the PDE is replaced by an ordinary differential equation (ODE) for which one seeks closed-form solutions in terms of special functions.

In the terminology of dynamical systems, the solitary wave solutions correspond to heteroclinic or homoclinic trajectories in the phase plane of a first-order dynamical system corresponding to the underlying ODE (see, e. g., [6]). The periodic solutions are bounded in the phase plane by these special trajectories, which correspond to the limit of infinite period and modulus one.

Other more powerful methods, such as the aforementioned IST and Hirota's method (see, e. g., [40]) deal with the PDE directly. These methods allow one to compute closed-form expressions of soliton solutions (in particular, solitary wave solutions) addressed elsewhere in the encyclopedia.

Direct Integration Method

Exact expressions for solitary wave solutions can be obtained by direct integration. The steps are illustrated for the KdV equation given in (2). Assuming that the wave travels to the right at speed $v = \omega/k$, Eq. (2) can be put into a traveling frame of reference with independent variable $\xi = k(x - vt - x_0)$. This reduces (2) to an ODE, $-v\phi' + \alpha\phi\phi' + k^2\phi''' = 0$, for $\phi(\xi) = u(x,t)$. A first integration with respect to ξ yields

$$-v\phi + \frac{\alpha}{2}\phi^2 + k^2\phi'' = A\,, \tag{28}$$

where A is a constant of integration. Multiplication of (28) by ϕ', followed by a second integration with respect to ξ, yields

$$-\frac{v}{2}\phi^2 + \frac{\alpha}{6}\phi^3 + \frac{k^2}{2}\phi'^2 = A\phi + B\,, \tag{29}$$

where B is an integration constant. Separation of variables and integration then leads to

$$\int_{\phi_0}^{\phi} \frac{d\phi}{\sqrt{a\phi^2 - b\phi^3 + \tilde{A}\phi + \tilde{B}}} = \pm\int_{\xi_0}^{\xi} d\xi\,, \tag{30}$$

where $a = v/k^2$, $b = \alpha/3k^2$, $\tilde{A} = 2A/k^2$, and $\tilde{B} = 2B/k^2$.

The evaluation of the elliptic integral in (30) depends on the relationship between the roots of the function $f(\phi) = a\phi^2 - b\phi^3 + \tilde{A}\phi + \tilde{B}$. In turn, the nature of the roots depends on the choice of $\tilde{A}$ and $\tilde{B}$. Two cases lead to physically relevant solutions.

Case 1: If the three roots are real and distinct, then the integral can be expressed in terms of the inverse of the cn function (see, e. g., [25] for details). This leads to the cnoidal wave solution given in (6).

Case 2: If the three roots are real and (only) two of them coincide, then the tanh-squared solution follows. This happens when $\tilde{A} = \tilde{B} = 0$. Integrating both sides of (30) then gives

$$\begin{aligned}\int_{\phi_0}^{\phi} \frac{d\phi}{\phi\sqrt{a - b\phi}} &= -\frac{2}{\sqrt{a}}\,\mathrm{Arctanh}\left[\frac{\sqrt{a - b\phi}}{\sqrt{a}}\right] + C\\ &= \pm(\xi - \xi_0)\,.\end{aligned} \tag{31}$$

where, without loss of generality, C and ξ_0 can be set to zero. Solving (31) for ϕ yields

$$\phi(\xi) = \frac{a}{b}\left(1 - \tanh^2\left(\frac{\sqrt{a}}{2}\xi\right)\right) = \frac{a}{b}\mathrm{sech}^2\left(\frac{\sqrt{a}}{2}\xi\right). \tag{32}$$

Returning to the original variables, one gets

$$\phi(\xi) = \frac{3v}{\alpha}\mathrm{sech}^2\left(\frac{\sqrt{v}}{2k}\xi\right)\,, \tag{33}$$

or

$$u(x,t) = \frac{3v}{\alpha}\mathrm{sech}^2\left(\frac{\sqrt{v}}{2}(x - vt - x_0)\right)\,, \tag{34}$$

where v is arbitrary. Setting $v = \omega/k = 4k^2$, where k is arbitrary, and $\delta = -kx_0$, one can verify that (34) matches (5).

The Tanh Method

If one is only interested in tanh- or sech-type solutions, one can circumvent explicit integration (often involving elliptic integrals) and apply the so-called tanh-method. A detailed description of the method has been given by Baldwin et al. [5]. The method has been fully implemented in *Mathematica*, a popular symbolic manipulation program, and successfully applied to many nonlinear differential equations from soliton theory and beyond.

The tanh-method is based on the following observation: all derivatives of the tanh function can be expressed as polynomials in tanh. Indeed, using the identity $\cosh^2\xi - \sinh^2\xi = 1$ one computes $\tanh'\xi = \mathrm{sech}^2\xi = 1 - \tanh^2\xi$, $\tanh''\xi = -2\tanh\xi + 2\tanh^3\xi$, etc. Therefore, all derivatives of $T(\xi) = \tanh\xi$ are polynomials in T. For example, $T' = 1 - T^2$, $T'' = -2T + 2T^3$, and $T''' = -2T + 8T^2 - 6T^4$.

By applying the chain rule, the PDE in $u(x,t)$ is then transformed into an ODE for $U(T)$ where $T = \tanh\xi = \tanh(kx - \omega t + \delta)$ is the new independent variable. Since all derivatives of T are polynomials of T, the resulting ODE has polynomial coefficients in T. It is therefore natural to seek a polynomial solution of the ODE. The problem thus becomes algebraic. Indeed, after computing the degree of the polynomial solution, one finds its unknown coefficients by solving a nonlinear algebraic system.

The method is illustrated using (2). Applying the chain rule (repeatedly), the terms of (2) become $u_t = -\omega(1 - T^2)U'$, $u_x = k(1 - T^2)U'$, and

$$\begin{aligned}u_{xxx} = k^3(1 - T^2)\big[&-2(1 - 3T^2)U'\\ &- 6T(1 - T^2)U'' + (1 - T^2)^2U'''\big]\,,\end{aligned} \tag{35}$$

where $U(T) = U(\tanh(kx - \omega t + \delta)) = u(x,t)$, $U' = dU/dT$, etc.

Substitution into (2) and cancellation of a common $1 - T^2$ factor yields

$$\begin{aligned}&-\omega U' + \alpha kUU' - 2k^3(1 - 3T^2)U'\\ &\quad - 6k^3T(1 - T^2)U'' + k^3(1 - T^2)^2U''' = 0\,.\end{aligned} \tag{36}$$

This ODE for $U(T)$ has polynomial coefficients in T. One therefore seeks a polynomial solution

$$U(T) = \sum_{n=0}^{N} a_n T^n \,, \tag{37}$$

where the integer exponent N and the coefficients a_n must be computed.

Substituting T^N into (36) and balancing the highest powers in T gives $N = 2$. Then, substituting

$$U(T) = a_0 + a_1 T + a_2 T^2 \tag{38}$$

into (36), and equating to zero the coefficients of the various power terms in T, yields

$$\begin{aligned} a_1(\alpha a_2 + 2k^2) &= 0 \,, \\ \alpha a_2 + 12k^2 &= 0 \,, \\ a_1(\alpha k a_0 - 2k^3 - \omega) &= 0 \,, \\ \alpha k a_1^2 + 2\alpha k a_0 a_2 - 16k^3 a_2 - 2\omega a_2 &= 0 \,. \end{aligned} \tag{39}$$

The unique solution of this nonlinear system for the unknowns a_0, a_1 and a_2 is

$$a_0 = \frac{8k^3 + \omega}{\alpha k}, \;\; a_1 = 0, \;\; a_2 = -\frac{12k^2}{\alpha} \,. \tag{40}$$

Finally, substituting (40) into (38) and using $T = \tanh(kx - \omega t + \delta)$ yields (4).

The solitary wave solutions and cnoidal wave solutions presented in Sect. "Completely Integrable Shallow Water Wave Equations" have been automatically computed with a *Mathematica* package [5] that implements the tanh-method and variants.

A review of numerical methods to compute solitary waves of arbitrary amplitude can be found in Vanden-Broeck [74].

Water Wave Experiments and Observations

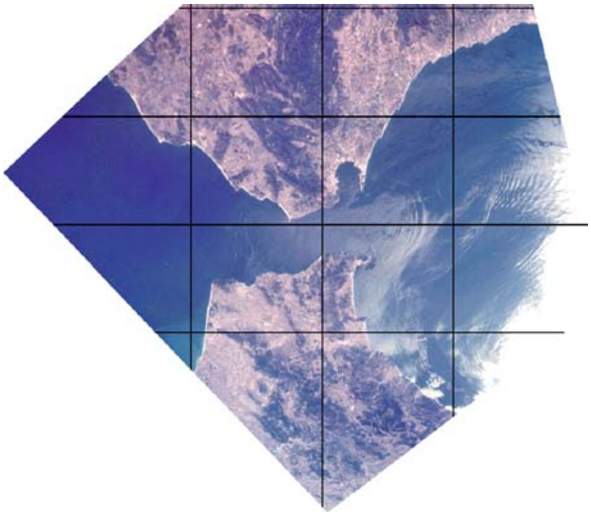
Through a series of experiments in a hydrodynamic tank, Hammack investigated the validity of the BBM equation [35] and KdV equation as models for long waves in shallow water [36,37,38] and long internal waves [69]. Their research addressed the question: Would an initial displacement of water, as it propagates forward, eventually evolve in a train of localized solitary waves (solitons) and an oscillatory tail as predicted by the KdV equation? Based on the experimental data, they concluded that (i) the KdV dynamics only occurs if the waves travel over a long distance, (ii) a substantial amount of water must be initially displaced (by a piston) to produce a soliton train, (iii) the water volume of the initial wave determines the shape of the leading wave in the wave train, and (iv) the initial direction of displacement (upward or downward piston motion) determines what happens later. Quickly raising the piston causes a train of solitons to emerge; quickly lowering it causes all wave energy to distribute into the oscillatory tail, as predicted by the theory.

Several other researchers have tested the validity of the KdV equation and variants in laboratory experiments (see, e. g., [39,60]). Bona et al. [9] give an in-depth evaluation of the BBM Eq. (7) with and without dissipative term u_{xx}. Their study includes (i) a numerical scheme with error estimates, (ii) a convergence test of the computer code, (iii) a comparison between the predictions of the theoretical model and the results of laboratory experiments. The authors note that it is important to include dissipative effects to obtain reasonable agreement between the forecast of the model and the empirical results.

Water tank experiments in conjunction with the analysis of actual data, allows researchers to judge whether or not the KdV equation can be used to model the dynamics of tsunamis (see [67]). Tsunami research intensified after the December 2004 tsunami devastated large coastal regions of India, Indonesia, Sri Lanka, and Thailand, and killed nearly 300,000 people.

Apart from shallow water waves near beaches, the KdV equation and its solitary wave solution also apply to internal waves in the ocean. Internal solitary waves in the open ocean are slow waves of large amplitude that travel at the interface of stratified layers of different density. Stratification based on density differences is primarily due to variations in temperature or concentration (e. g. due to salinity gradients). For example, absorption of solar radiation creates a near surface thin layer of warmer water (of lower density) above a thicker layer or colder, denser water. The smaller the density change, the lower the wave frequency, and the slower the propagation speed. If the upper layer is thinner than the lower one, then the internal wave is a wave of depression causing a downward displacement of the fluid interface.

Internal solitary waves are ubiquitous in stratified waters, in particular, whenever strong tidal currents occur near irregular topography. Such waves have been studied since the 1960s. An early, well-documented case deals with internal waves in the Andaman Sea, where Perry and Schimke [58] found groups of internal waves up to 80 m high and 2000 m long on the main thermocline at 500 m in 1500 m deep water. Their measurements were confirmed by Osborne and Burch [53] who showed that internal waves in the Andaman Sea are generated by tidal flows and can travel over hundreds of kilometers.



Shallow Water Waves and Solitary Waves, Figure 8
Three solitary wave packets generated by internal waves from sills in the Strait of Gibraltar. Original image STS41G-34-81 courtesy of the Earth Sciences and Image Analysis Laboratory, NASA Johnson Space Center (http://eol.jsc.nasa.gov). Ortho-rectified, color adjusted photograph courtesy of Global Ocean Associates

Strong internal waves can affect biological life and interfere with underwater navigation. Understanding the behavior of internal waves can aid in the design of offshore production facilities for oil and natural gas.

The near-surface current associated with the internal wave locally modulates the height of the water surface. Hence, the internal wave leaves a "signature" or "footprint" at the sea surface in the form of a packet of solitary waves (sometimes called current rips or tide rips). These visual manifestations appear as long, quasilinear stripes in satellite imagery or photographs taken during space flights. Over 50 case studies and hundreds of images of oceanic internal waves can be found in "An Atlas of Internal Solitary-like Waves and Their Properties" [42].

Figure 8 shows a photograph of three solitary waves packets which are the surface signature of internal waves in the Strait of Gibraltar. The photograph was taken from the Space Shuttle on October 11, 1984. Spain is to the North, Morocco to the South. Alternate solitary wave packets move toward the northeast or the southeast. The amplitude of these waves is of the order of 50 m; their wavelength is in the range of 500–2000 m. The separation between the packets is approximately 30 km. Waves of longer wavelengths and higher amplitudes have traveled the furthest. The number of oscillations within each packet increases as time goes on. Solitary wave packets can reach 200 km into the Western Mediterranean sea and live for more than two days before dissipating. A in-depth study of solitary waves in the Strait of Gibraltar can be found in Farmer and Armi [28].

The KdV model is applicable to stratified fluids with two layers and internal solitary waves if (i) the ratio of the amplitude a to the upper layer depth h is small, and (ii) the wavelength λ is long compared with the upper layer depth. More precisely, $a/h = O(h^2/\lambda^2) \ll 1$. A detailed discussion of internal solitary waves and additional references can be found in Garrett and Munk [31], Grimshaw [32,33,34], Helfrich and Melville [39], Apel et al. [4], and Pelinovsky et al. [56]. The last three papers discuss a variety of other theoretical models including the extended KdV equation (also known as Gardner's equation or combined KdV-modified KdV equation) which contains both quadratic and cubic nonlinearities. Solitary wave solutions of the extended KdV equation can be found in Scott ([65], p. 856), Helfrich and Melville [39], and Apel et al. [4]. A review of laboratory experiments with internal solitary waves was published by Ostrovsky and Stepanyants [54].

As discussed in the review paper by Staquet and Sommeria [70], internal gravity waves also occur in the atmosphere, where they are often caused by wind blowing over topography and cumulus convective clouds. Internal gravity waves reveal themselves as unusual cloud patterns, which are the counterpart of the solitary wave packets on the ocean's surface.

Future Directions

For many shallow water wave applications, the full Euler equations are too complex to work with. Instead, various approximate models have been proposed. Arguably, the most famous shallow water wave equations are the KdV and Boussinesq equations.

The KdV equation was originally derived to describe shallow water waves in a rectangular channel. Surprisingly, the equation also models ion-acoustic waves and magneto-hydrodynamic waves in plasmas, waves in elastic rods, mid-latitude and equatorial planetary waves, acoustic waves on a crystal lattice, and more (see, e. g., [64,65,66]). The KdV equation has played a pivotal role in the development of the Inverse Scattering Transform and soliton theory, both of which had a lasting impact on twentieth-century mathematical physics.

Historically, the classical Boussinesq equation was derived to describe the propagation of shallow water waves in a canal. Boussinesq systems arise when modeling the propagation of long-crested waves on large bodies of water (e. g. large lakes or the ocean). As Bona et al. [10] point out, a plethora of formally-equivalent Boussinesq systems can be derived. Yet, such systems may have vastly different mathematical properties. The study of the well-posedness of the nonlinear models is of paramount importance and is the subject of ongoing research.

Shallow water wave theory allows one to adequately model waves in canals, surface waves near beaches, and internal waves in the ocean (see [4]). Due to their widespread occurrence in the ocean (see [42]), solitary waves and "solitary wave packets" (solitons) are of interest to oceanographers and geophysicists. The (periodic) cnoidal wave solutions are used by coastal engineers in studies of sediment movement, erosion of sandy beaches, interaction of waves with piers and other coastal structures.

Apart from their physical relevance, the knowledge of solitary and cnoidal wave solutions of nonlinear PDEs facilitates the testing of numerical solvers and aids in stability analysis.

Shallow water wave models are widely used in atmospheric science as a paradigm for geophysical fluid motions. They model, for example, inertia-gravity waves with fast time scale dynamics, and wave-vortex interactions and Rossby waves associated with slow advective-timescale dynamics.

This article has reviewed commonly used shallow water wave models, with the hope of bridging two research communities: one that focuses on nonlinear equations with dispersive effects; the other on nonlinear hyperbolic equations without dispersive terms. Of common concern are the testing of the theoretical models on measured data and further validation of the equations with numerical simulations and laboratory experiments. A fusion of the expertise of both communities might advance research on water waves and help to answer open questions about wave breaking, instability, vorticity, and turbulence. Of paramount importance is the prevention of natural disasters, ecological ravage, and damage to man-made structures due to a better understanding of the dynamics of tsunamis, steep waves, strong internal waves, rips, tidal currents, and storm surges.

Article Outline

Glossary

Babbling equilibrium An equilibrium in which the sender's strategy is independent of type and the receiver's strategy is independent of signal.

Behavior strategy A strategy for an extensive-form game that specifies the probability of taking each action at each information set.

Behavioral type A player in a game who is constrained to follow a given strategy.

Cheap-talk game A signaling game in which players' preferences do not depend directly on signals.

Condition D1 An equilibrium refinement that requires out-of-equilibrium beliefs to be supported on types that have the most to gain from deviating from a fixed equilibrium.

Divinity An equilibrium refinement that requires out-of-equilibrium beliefs to place relatively more weight on types that gain more from deviating from a fixed equilibrium.

Equilibrium outcome The probability distribution over terminal nodes in a game determined by equilibrium strategy.

Handicap principle The idea that animals communicate fitness through observable characteristics that reduce fitness.

Incomplete information game A game in which players lack information about the strategy sets or payoff functions of their opponents.

Intuitive criterion An equilibrium refinement that requires out-of-equilibrium beliefs to place zero weight on types that can never gain from deviating from a fixed equilibrium outcome.

Nash equilibrium A strategy profile in a game in which each player's strategy is a best response to the equilibrium strategies of the other players.

Neologism-proof equilibrium An equilibrium that admits no self-signaling set.

Pooling equilibrium A signaling-game equilibrium in which each all sender types send the same signal with probability one.

Receiver In a signaling game, the uninformed player.

Self-signaling set A set of types C with the property that precisely types in the set C gain from inducing the best response to C relative to a fixed equilibrium.

Sender In a signaling game, the informed agent.

Separating equilibrium A signaling-game equilibrium in which sender types sent signals from disjoint subsets of the set of available signals.

Signaling game A two-player game of incomplete information in which one player is informed and the other in not. The informed player's strategy is a type-contingent message and the uninformed player's strategy is a message-continent action.

Single-crossing condition A condition that guarantees that indifferent curves from a given family of preferences cross at most one.

Spence-Mirrlees condition A differential condition that orders the slopes of level sets of a function.

Standard signaling game A signaling game in which strategy sets and payoff functions satisfy monotonicity properties.

Type In an incomplete information game, a variable that summarizes private information.

Verifiable information game A signaling game with the property that each type has a signal that can only be sent by that type.

Definition of the Subject

Signaling games refer narrowly to a class of two-player games of incomplete information in which one player is informed and the other is not. The informed player's strategy set consists of signals contingent on information and the uninformed player's strategy set consists of actions contingent on signals. More generally, a signaling game includes any strategic setting in which players can use the actions of their opponents to make inferences about hidden information. The earliest work on signaling games was Spence [72]'s model of educational signaling and Zahari [76]'s model of signaling by animals. During the 1980s researchers developed the formal model and identified conditions that permitted the selection of unique equilibrium outcomes in leading models.

Introduction

The framed degree in your doctor's office, the celebrity endorsement of a popular cosmetic, and the telephone message from an old friend are all signals. The signals are potentially valuable because they allow you to infer useful information. These signals are indirect and require interpretation. They may be subject to manipulation. The doctor's diploma tells you something about the doctor's qualifications, but knowing where and when the doctor studied does not prove that she is a good doctor. The endorsement identifies the product with a particular lifestyle, but what works for the celebrity may not work for you. Besides, the celebrity was probably paid to endorse the product and may not even use it. The phone message may tell you how to get in touch with your friend, but is unlikely to contain all of the information you need to find him – or to evaluate whether you'll meet to discuss old times or to be asked a favor. While the examples all involve signaling, the nature of the signaling is different. The doctor faces large penalties for misrepresenting her credentials. She is not required to display all of her diplomas, but it is reasonable to assume that degrees are not forged. The celebrity endorsement is costly – certainly to the manufacturer who pays for the celebrity's services and possibly to the celebrity himself, whose reputation may suffer if the product works badly. It is reasonable to assume that it is easier to obtain an endorsement of a good product, but there are also good reasons to be skeptical about the claims. In contrast, although a dishonest or misleading message may lead to a bad outcome, leaving a message is not expensive and the content of the message is not constrained by your friend's information. The theory of signaling games is a useful way to describe the essential features of all three examples.

Opportunities to send and evaluate signals arise in many common natural and economic settings. In the canonical example (due to Spence [72]), a high-ability worker invests in education to distinguish herself from less skilled workers. The potential employer observers educational attainment, but not innate skill, and infers that a better educated worker is more highly skilled and pays a higher wage. To make this story work, there must be a reason that low-ability workers do not get the education expected of a more highly skilled worker and hence obtain a higher wage. This property follows from an assumption that the higher the ability the worker, the easier it is for her to produce a higher signal.

The same argument appears in many applications. For example, a risk-averse driver will purchase a lower cost, partial insurance contract, leaving the riskier driver to pay a higher rate for full insurance (Rothschild and Stiglitz [65] or Wilson [75]). A firm that is able to produce high-quality goods signals this by offering a warranty for the goods sold (Grossman [37]) or advertising extensively. A strong deer grows extra large antlers to show that it can survive with this handicap and to signal its fitness to potential mates [76].

Game theory provides a formal language to study how one should send and interpret signals in strategic environments. This article reviews the basic theory of signaling and discusses some applications. It does not discuss related models of screening. Kreps and Sobel [43] and Riley [64] review both signaling and screening.

Section "The Model" describes the basic model. Section "Equilibrium" defines equilibrium for the basic model. Section "The Basic Model" limits attention to a special class of signaling game. I give conditions sufficient for the existence of equilibria in which the informed agent's signal fully reveals her private information and argue that one equilibrium of this kind is prominent. The next three sections study different signaling games. Section "Cheap Talk" discusses models of costless communication. Section "Verifiable Information" discusses the implications of the assumptions that some information is verifiable. Section "Communication about Intentions" briefly discusses the possibility of signaling intentions rather than private information. Section "Applications" describes some applications and extensions of the basic model. Section "Future Directions" speculates on directions for future research.

The Model

This section describes the basic signaling game. There are two players, called S (for sender) and R (for receiver). S knows the value of some random variable t whose support is a given set T. t is called the **type** of S. The prior beliefs of R are given by a probability distribution $\pi(\cdot)$ over T; these beliefs are common knowledge. When T is finite, $\pi(t)$ is the prior probability that the sender's type is t. When T is uncountably infinite, $\pi(\cdot)$ is a density function. Player S learns t and sends to R a signal s drawn from some set M. Player R receives this signal, and then takes an action a drawn from a set A. (It is possible to allow A to depend on s and S to depend on t.) This ends the game: The payoff to i is given by a function $u^i : T \times M \times A \to \mathbb{R}$.

This canonical game captures the essential features of the classic applications of market signaling. In the labor-market signaling story due to Spence [72] a worker wishes to signal his ability to a potential employer. The worker has information about ability that the employer lacks. Direct communication about ability is not possible, but the worker can acquire education. The employer can observe the worker's level of education and use this to form a judgment about the worker's true level of ability. In this application, S is a worker; R represents a potential employer (or a competitive labor market); t is the student's productivity; s is her level of education; and a is her wage.

Equilibrium

Defining Nash equilibrium for the basic signaling game is completely straightforward when T, S, and A are finite sets. In this case a behavior strategy for S is a function $\mu : T \times M \to [0, 1]$ such that $\sum_{s \in M} \mu(t, s) = 1$ for all t. $\mu(t, s)$ is the probability that sender-type t sends the signal s. A behavior strategy for R is a function $\alpha : M \times A \to [0, 1]$ where $\sum_{a \in A} \alpha(s, a) = 1$ for all s. $\alpha(s, a)$ is the probability that R takes action a following the signal s.

Proposition 1 *Behavior strategies (α^*, μ^*) form a Nash Equilibrium if and only if for all $t \in T$*

$$\mu(t,s) > 0 \ \textit{implies} \ \sum_{a \in A} U^S(t,s,a)\alpha(s,a) = \max_{s' \in S} \sum_{a \in A} U^S(t,s',a)\alpha(s',a) \quad (1)$$

and, for each $s \in S$ such that $\sum_{t \in T} \mu(t,s)\pi(t) > 0$, if $\sum_{t \in T} \mu(t,s)\pi(t) > 0$, then

$$\alpha(s,a) > 0 \ \textit{implies} \ \sum_{t \in T} U^R(t,s,a)\beta(t,a) = \max_{a' \in A} \sum_{t \in T} U^R(t,s,a')\beta(t,a')\,, \quad (2)$$

where

$$\beta(t,s) = \frac{\mu(t,s)\pi(t)}{\sum_{t' \in T} \mu(t',s)\pi(t')}\,. \quad (3)$$

Condition (1) states that the S places positive probability only on signals that maximize expected utility. This condition guarantees that S responds optimally to R's strategy.

Condition (2) states that R places positive probability only on actions that maximize expected utility, where is taken with respect to the distribution $\beta(\cdot, s)$ following the signal s. Condition (3) states that $\beta(\cdot, s)$ accurately reflects the pattern of play. It requires that R's beliefs be determined using S's strategy and the prior distribution whenever possible. Equilibrium refinements also require that R has beliefs following signals s that satisfy

$$\sum_{t \in T} \mu(t, s)\pi(t) = 0\,, \tag{4}$$

that is are sent with probability zero in equilibrium. Specifically, sequential equilibrium permits $\beta(\cdot, m)$ to be an arbitrary distribution when Eq. (4) holds, but requires that Eq. (2) holds even for these values of s. This restriction rules out equilibria in which certain signals are not sent because the receiver responds to the signal with an action that is dominated.

The ability to signal creates the possibility that R will be able to draw inferences about S's type from the signal. Whether he is able to do so is a property of the equilibrium. It is useful to define two extreme cases.

Definition 1 An equilibrium (α^*, μ^*) is called a separating equilibrium if each type t sends different signals. That is, M can be partitioned into sets M_t such that for each t, $\sum_{s \in M_t} \mu(t, s) = 1$. An equilibrium (α^*, μ^*) is called a pooling equilibrium if there is a single signal s^* that is sent by all types with probability one.

In a separating equilibrium, R can infer S's private information completely. In a pooling equilibrium, R learns nothing from the sender's signal. This definition excludes other possible situations. For example, all sender types can randomize uniformly over a set of two or more signals. In this case, the receiver will be able to draw no inference beyond the prior from a signal received in equilibrium. More interesting is the possibility that the equilibrium will be partially revealing, with some, but not all of the sender types sending common signals.

It is not difficult to construct pooling equilibria for the basic signaling game. Take the labor market model and assume S sends the message s^* with probability one and that the receiver responds to s^* with his best response to the prior distribution and to all other messages with the best response to the belief that t is the least skilled agent. Provided that the least skilled agent prefers to send s^* to sending the cheapest alternative signal, this is a Nash Equilibrium outcome.

The Basic Model

The separating equilibrium is a benchmark outcome for signaling games. When a separating equilibrium exists, then it is possible for the sender to share her information fully with the receiver in spite of having a potential conflict of interest.

Existence of separating equilibria typically requires a systematic relationship between types and signals. An appropriate condition, commonly referred to as the single-crossing condition, plays a prominent role in signaling games and in models of asymmetric information more generally.

In this section I limit attention to a special class of signaling game in which there is a monotonic relationship between types and signals. In these models, separating equilibria typically exist.

I begin by stating the assumption in the environment most commonly seen in applications. Assume that the sets T, S, and A are all real intervals.

Definition 2 $U^S(\cdot)$ satisfies the single-crossing condition if $U^S(t, s, a) \le U^S(t, s', a')$ for $s' > s$ implies that $U^S(t', s, a) < U^S(t', s', a')$ for all $t' > t$.

In a typical application, $U^S(\cdot)$ is strictly decreasing in its second argument (the signal) and increasing in its third argument (R's response) for all types. Consequently indifference curves are well defined in $M \times A$ for all t. The single-crossing condition states that indifference curves of different sender types cross once. If a lower type is indifferent between two signal-action pairs, then a higher type strictly prefers to send the higher signal. In this way, the single-crossing condition links signals to types in such a way as to guarantee that higher types send weakly higher signals in equilibrium.

Note two generalizations of Definition 2. First, the assumption that the domain of $U^S(\cdot)$ is the product of intervals can be replaced by the assumption that these sets are partially ordered. In this case, weak and strict order replace the weak and strict inequalities comparing types and actions in the statement of the definition. Second, it is sometimes necessary to extend the definition to mixed strategies. In this case, the ordering of A induces a partial ordering of distributions of A through first-order stochastic dominance.

When one thinks of the single-crossing condition geometrically, it is apparent that it implies a ranking of the slopes of the indifference curves of the sender. Suppose that $U^S(\cdot)$ is smooth, strictly increasing in actions and strictly decreasing in signals so that indifference curves are well defined for each t. Writing the indifference curve as $\{(s, \bar{a}(s; t))\}$, it must be that $U^S(t, s, \bar{a}(s; t)) \equiv 0$, so that the slope of the indifference curve of a type t sender is

$$\bar{a}_1(s;t) = -\frac{U_2^S(t,s,a)}{U_3^S(t,s,a)}\,, \tag{5}$$

where $\bar{a}_1(s;t)$ is the partial derivative of $\bar{a}(s;t)$ with respect to the first argument, and $U_k^S(\cdot)$ denotes the partial derivative of $U^S(\cdot)$ with respect to its kth argument. Under these conditions, the single-crossing condition is implied by the requirement that the right-hand side of Eq. (5) is decreasing in t. The differentiable version of the single-crossing condition is often referred to as the Spence–Mirrlees condition. Milgrom and Shannon [57] contains general definitions of the single-crossing and Spence–Mirrlees conditions and Edlin and Shannon [26] provides a precise statement of when the conditions are equivalent.

To provide a simple construction of a separating equilibrium, limit attention to a standard signaling game in which the following conditions hold.

1. $T = \{0, \ldots, K\}$ is finite.
2. A and M are real intervals.
3. Utility functions are continuous in action and signal.
4. $U^S(\cdot)$ is strictly increasing in action and strictly decreasing in signal.
5. The single-crossing property holds.
6. The receiver's best-response function is uniquely defined, independent of the signal, and strictly increasing in t so that it can be written $BR(t)$.
7. There exists $\bar{s} \in S$ such that $U^S(K, \bar{s}, BR(K)) < U^S(K, s_0^*, BR(0))$.

Conditions 1 and 2 simplify exposition, but otherwise are not necessary. It is important that T, M, and A be partially ordered so that some kind of single-crossing condition applies. Conditions 4–6 impose a monotone structure on the problem so that higher types are more able to send high signals, and that higher types induce higher (and uniformly more attractive) actions. These conditions imply that in equilibrium higher types will necessarily send weakly higher signals. Condition 7 is a boundary condition that makes sending high signals unattractive. It states that the highest type of sender would prefer to be treated like the lowest type rather than use the signal $\bar{s}$. These properties hold in many standard applications. Condition 6 would be satisfied if $U^R(t,s,a) = -(a-t)^2$.

Separating Equilibrium

To illustrate these ideas, consider a construction of a separating equilibrium.

Proposition 2 *The standard signaling game has a separating equilibrium.*

One can prove the proposition by constructing a possible equilibrium path and confirming that the path can be part of a separating equilibrium.

Step 1. t_0 selects the signal s_0^* that maximizes $U^S(t_0, s, BR(t_0))$.

Step 2. Suppose that s_i^* have been specified for $i = 0, \ldots, k-1$ and let $U^*(t_i) = U^S(t_i, s_i^*, BR(t_i))$. Define s_k^* to solve:

$$\max U^S(t_k, s, BR(t_k)) \text{ subject to } U^S(t_{k-1}, s, BR(t_k)) \leq U^*(t_{k-1})\,.$$

Provided that the optimization problems in Steps 1 and 2 have solutions, the process inductively produces a signaling strategy for the sender and a response rule for the receiver defined on $\{s_0^*, \ldots, s_K^*\}$. When $BR(\cdot)$ is strictly increasing, the single-crossing condition implies that the signaling strategy is strictly increasing. To complete the description of strategies, assume that the receiver takes the action $BR(t_k)$ in response to signals in the interval $[s_k, s_{k+1})$, $BR(t_0)$ for $s < s_0^*$, and $BR(t_K)$ for $s > s_K^*$. By the definition of the best-response function, the receiver is best responding to the sender's strategy. When the boundary condition fails, a fully separating equilibrium need not exist, but when M is compact, one can follow the construction above to obtain an equilibrium in which the lowest types separate and higher types pool at the maximum signal in M (see Cho and Sobel [22] for details).

In the construction, the equilibrium involves inefficient levels of signaling. When $U^S(\cdot)$ is decreasing in the signal, all but the lowest type of sender must make a wasteful expenditure in the signal in order to avoid being treating as having a lower quality. The result that expenditures on signals are greater than the levels optimal in a full-information model continue to hold when $U^S(\cdot)$ is not monotonic in the signal. The sender inevitably does no better in a separating equilibrium than she would do if R had full information about t. Indeed, all but the lowest type will do strictly worse in standard signaling games. On the other hand, the equilibrium constructed above has a constrained efficiency property: Of all separating equilibria, it is Pareto dominant from the standpoint of S. To confirm this claim argue inductively that in any separating equilibrium if t_j sends the signal s_j, then $s_j \geq s_j^*$, with equality only if all types $i < j$ send s_i^* with probability one.

Mailath [49] provides a similar construction when T is a real interval. In this case, the Spence–Mirrlees formulation of the single-crossing condition plays an important role and the equilibrium is a solution to a differential equation.

Multiple Equilibria and Selection

Section "Equilibrium" ended with the construction of a pooling equilibrium. A careful reconsideration of the argument reveals that there typically are many pooling equilibrium outcomes. One can construct a potential pooling outcome by assuming that all sender types send the same signal, that the receiver best responds to this common signal, and responds to all other signals with the least attractive action. Under the standard monotonicity assumptions, this strategy profile will be an equilibrium if the lowest sender type prefers pooling to sending the cheapest available out-of-equilibrium message. Section "Separating Equilibrium" ended with the construction of a separating equilibrium. There are also typically many separating equilibrium outcomes. Assume that types $t = 0, \dots, r-1$ send signals $s^*(t)$, type r sends $\tilde{s}(k) > s^*(k)$, and subsequent signals $\tilde{s}^*(t)$ for $t > r$ solve:

$$\max U^S(t_k, s, BR(t_k)) \text{ subject to}$$
$$U^S(t_{k-1}, s, BR(t_k)) \le U(t_{k-1}, \tilde{s}, BR(t_{k-1})) .$$

In both of these cases, the multiplicity is typically profound, with a continuum of distinct equilibrium outcomes (when M is an interval). The multiplicity of equilibria means that, without refinement, equilibrium theory provides few clear predictions beyond the observation that the lowest type of sender receives at least $U^*(t_0)$, the payoff it would receive under complete information, and the fact that the equilibrium signaling function is weakly increasing in the sender's type. The first property is a consequence of the monotonicity of S's payoff in a and of R's best response function. The second property is a consequence of the single-crossing condition.

This section describes techniques that refine the set of equilibria. Refinement arguments that guarantee existence and select unique outcomes for standard signaling games rely on the Kohlberg–Mertens [42] notion of strategic stability. The complete theory of strategic stability is only available for finite games. Consequently the literature applies weaker versions of strategic stability that are defined more easily for large games. Banks and Sobel [8], Cho and Kreps [21], and Cho and Sobel [22] introduce these arguments.

Multiple equilibria arise in signaling games because Nash equilibrium does not constrain the receiver's response to signals sent with zero probability in equilibrium. Specifying that R's response to these unsent signals is unattractive leads to the largest set of equilibrium outcomes. (In standard signaling games, S's preferences over actions do not depend on type, so the least attractive action is well defined.) The equilibrium set shrinks if one restricts the meaning of unsent signals. An effective restriction is condition D1, introduced in Cho and Kreps [21]. This condition is less restrictive than the notion of universal divinity introduced by Banks and Sobel [8], which in finite games is less restrictive than Kohlberg and Mertens's notion of strategic stability.

Given an equilibrium (α^*, μ^*), let $U^*(t)$ be the equilibrium expected payoff of a type t sender and let $D(s,t) = \{a \colon u(t,s,a) \ge U^*(t)\}$ be the set of pure-strategy responses to s that lead to payoffs at least as great as the equilibrium payoff for player t. Given a collection of sets, $X(t), t \in T$, $X(t^*)$ is maximal if it not a proper subset of any $X(t)$.

Definition 3 Behavior strategies (α^*, μ^*) together with beliefs β^* satisfy D1 if for any unsent message s, $\beta(\cdot, s)$ is supported on those t for which $D(s,t)$ is maximal.

In standard signaling games, $D(s,t)$ is an interval: all actions greater than or equal to a particular action will be attractive relative to the equilibrium. Hence these sets are nested. If $D(s,t)$ is not maximal, then there is another type t' that is "more likely to deviate" in the sense that there exists out-of-equilibrium responses that are attractive to t' but not t. Condition D1 requires that the receiver place no weight on type t making a deviation in this case. Notice if $D(s,t)$ is empty for all t, then D1 does not restrict beliefs given s (and any choice of action will support the putative equilibrium). Condition D1 is strong. One can imagine weaker restrictions. The intuitive condition (Cho and Kreps [21]) requires that $\beta(t,s) = 0$ when $D(t,s) = \phi$ and at least one other $D(t',s)$ is non empty. Divinity (Banks and Sobel [8]) requires that if $D(t,s)$ is strictly contained in $D(t',s)$, then $\beta(t',s)/\beta(t,s) \ge \pi(t')/\pi(t)$, so that the relative probability of the types more likely to deviate increases.

Proposition 3 *The standard signaling game has a unique separating equilibrium outcome that satisfies Condition D1.*

In standard signaling games, the only equilibrium outcome that satisfies Condition D1 is the separating outcome described in the previous section. Details of the argument appear in Cho and Sobel. The argument relies on two insights. First, types cannot be pooled in equilibrium because slightly higher signals will be interpreted as coming from the highest type in the pool. Second, in any separating equilibrium in which a sender type fails to solve Step 2, deviation to a slightly lower signal will not lower R's beliefs.

The refinement argument is powerful and the separating outcome selected receives prominent attention in the literature. It is worth pointing out that the outcome has one unreasonable property. The separating outcome described above depends only on the support of types, and not on the details of the distribution. Further, all types but the lowest type must make inefficient (compared to the full-information case) investments in signal in order to distinguish themselves from lower types. The efficient separating equilibrium for a sequence of games in which the probability of the lowest type converges to zero does not converge to the separating equilibrium of the game in which the probability of the lowest type is zero. In the special case of only two types, the (efficient) pooling outcome may be a more plausible outcome when the probability of the lower type shrinks to zero. Grossman and Perry [38] and Mailath, Okuno-Fujiwara, and Postlewaite [50] introduce equilibrium refinements that select the pooling equilibrium in this setting. These concepts share many of the same motivations of the refinements introduced by Banks and Sobel and Cho and Kreps. They are qualitatively different from the intuitive criterion, divinity, and Condition D1, because they are not based on dominance arguments and lack general existence properties.

Cheap Talk

Models in which preferences satisfy the single-crossing property are central in the literature, but the assumption is not appropriate in some interesting settings. This section describes an extreme case in which there is no direct cost of signaling.

In general, a cheap-talk model is a signaling model in which $u^i(t, s, a)$ is independent of s for all (t, a). Two facts about this model are immediate. First, if equilibrium exists, then there always exists an equilibrium in which no information is communicated. To construct this "babbling" equilibrium, assume that $\beta(t, s)$ is equal to the prior independent of the signal s. R's best response will be to take an action that is optimal conditional only on his prior information. Hence R's action can be taken to be constant. In this case, it is also a best response for S to send a signal that is independent of type, which makes $\beta(t, s)$ the appropriate beliefs. Hence, even if the interests of S and R are identical, so that it there are strong incentives to communicate, there is a possibility of complete communication break down.

Second, it is clear that non-trivial communication requires that different types of S have different preferences over R's actions. If it is the case that whenever some type t prefers action a to action a' then so do all other types, then (ruling out indifference), it must be the case that in equilibrium the receiver takes only one action with positive probability. To see this, note that otherwise one type of sender is not selecting a best response. The second observation shows that cheap talk is not effective in games, like the standard labor-market story, in which the sender's preferences are monotonic in the action of the receiver. With cheap communication, the potential employee in the labor market will always select a signal that leads to the higher possible wage and consequently, in equilibrium, all types of workers will receive the same wage.

A Simple Cheap-Talk Game

There are natural settings in which cheap talk is meaningful in equilibrium. To describe examples, I follow the development of Crawford and Sobel [24] (Green and Stokey [35] independently introduced a similar game in an article circulated in 1981). In this paper, A and T are the unit interval and M can be taken to be the unit interval without loss of generality. The sender's private information or type, t, is drawn from a differentiable probability distribution function, $F(\cdot)$, with density $f(\cdot)$, supported on $[0, 1]$. S and R have twice continuously differentiable von Neumann–Morgenstern utility functions $U^i(a, t)$ that are strictly concave in a and have a strictly positive mixed partial derivative. Let $i = R, S, a^i(t)$ denotes the unique solution to $\max_a U^i(a, t)$ and further assume that $a^S(t) > a^R(t)$ for all t. (The assumptions on $U^i(\cdot)$ guarantee that $U^i(\cdot)$ is well defined and strictly increasing.)

In this model, the interests of the sender and receiver are partially aligned because both would like to take a higher action with a higher t. The interests are different because S would always like the action to be a bit higher than R's ideal action. In a typical application, t represents the idea action for R, such as the appropriate expenditure on a public project. Both R and S want actual expenditure to be close to the target value, but S has a bias in favor of additional expenditure.

For $0 \le t' < t'' \le 1$, let $\bar{a}(t', t'')$ be the unique solution to $\max_a \int_{t'}^{t''} U^R(a, t)\mathrm{d}F(t)$. By convention, $\bar{a}(t, t) = a^R(t)$.

Without loss of generality, limit attention to pure-strategy equilibria. The concavity assumption guarantees that R's best responses will be unique, so R will not randomize in equilibrium. An equilibrium with strategies (μ^*, α^*) **induces** action a if $\{t\colon \alpha^*(\mu^*(t)) = a\}$ has positive prior probability. Crawford and Sobel [24] characterize equilibrium outcomes.

Proposition 4 *There exists a positive integer N^* such that for every integer N with $1 \le N \le N^*$, there exists at least one equilibrium in which the set of induced actions has cardinality N, and moreover, there is no equilibrium* *which induces more than N^* actions. An equilibrium can be characterized by a partition of the set of types, $t(N) = (t_0(N), \ldots, t_N(N))$ with $0 = t_0(N) < t_1(N) < \ldots < t_N(N) = 1$, and signals m_i, $i = 1, \ldots, N$, such that for all $i = 1, \ldots, N-1$*

$$U^S(\bar{a}(t_i, t_{i+1}), t_i)) - U^S(\bar{a}(t_{i-1}, t_i), t_i)) = 0\,, \tag{6}$$

$$\mu(t) = m_i \ \text{for} \ \ t \in (t_{i-1}, t_i]\,, \tag{7}$$

and

$$\alpha(m_i) = \bar{a}(t_{i-1}, t_i)\,. \tag{8}$$

Furthermore, essentially all equilibrium outcomes can be described in this way.

In an equilibrium, adjacent types pool together and send a common message. Condition (6) states that sender types on the boundary of a partition element are indifferent between pooling with types immediately below or immediately above. Condition (7) states that types in a common element of the partition send the same message. Condition (8) states that R best responds to the information in S's message.

Crawford and Sobel make another monotonicity assumption, which they call condition (M). (M) is satisfied in leading examples and implies that there is a unique equilibrium partition for each $N = 1, \ldots, N^*$, the ex-ante equilibrium expected utility for both S and R is increasing in N, and N^* increases if the preferences of S and R become more aligned. These conclusions provide justification for the view that with fixed preferences "more" communication (in the sense of more actions induced) is better for both players and that the closer are the interests of the players the greater the possibilities for communication.

As in the case of models with costly signaling, there are multiple equilibria in the cheap-talk model. The multiplicity is qualitatively different. Costly signaling models have a continuum of Nash Equilibrium outcomes. Cheap-talk models have only finitely many. Refinements that impose restrictions on off-the-equilibrium path signals work well to identify a single outcome in costly signaling models. These refinements have no cutting power in cheap-talk models because any equilibrium distribution on type-action pairs can arise from signaling strategies in which all messages are sent with positive probability. To prove this claim, observe that if message m' is unused in equilibrium, while message m is used, then one can construct a new equilibrium in which R interprets m' the same way as m and sender types previously sending m randomize equally between m and m'.

In the basic model messages take on meaning only through their use in an equilibrium. Unlike natural language, they have no external meaning. There have been several attempts to formalize the notion that messages have meanings that, if consistent with strategic aspects of the interaction, should be their interpretation inside the game. The first formulation of this idea is due to Farrell [28].

Definition 4 Given an equilibrium (α^*, σ^*) with sender expected payoffs $u^*(\cdot)$, the subset $G \subset T$ is self signaling if $G = \{t \colon U^S(t, BR(G)) > u^*(t)\}$.

That is, G is self signaling if precisely the types in G gain by making a statement that induces the action that is a best response to the information that $t \in G$. (When $BR(t)$ is not single valued it is necessary to refine the definition somewhat and permit the possibility that $U^S(t, BR(G)) = u^*(t)$ for some t. See Matthews, Okuno-Fujiwara, and Postlewaite [51].) Farrell argues that the existence of a self-signaling set would destroy an equilibrium. If a subset G had available a message that meant "my type is in G," then relative to the equilibrium R could infer that if he were to interpret the message literally, then it would be sent only by those types in G (and hence the literal meaning would be accurate). With this motivation, Farrell proposes a refinement.

Definition 5 An equilibrium (α^*, σ^*) is neologism proof if there exist no self-signaling sets relative to the equilibrium.

Rabin [62] argues convincingly that Farrell's definition rules out too many equilibrium outcomes. Indeed, for leading examples of the basic cheap-talk game, there are no neologism-proof equilibria. Specifically, in the Crawford–Sobel model in which S has a bias towards higher actions, there exist self signaling sets of the form $[t, 1]$. On the other hand, Chen, Kartik, and Sobel [20] demonstrate that the N^*-step equilibrium always satisfies the no incentive to separate (NITS) condition:

$$U^S(\alpha^*(\mu^*(0)), 0) \geq U^S(a^R(0), 0)\,, \tag{9}$$

and that under condition (M) this is the only equilibrium that satisfies Condition (9).

NITS states that the lowest type of sender prefers her equilibrium payoff to the payoff she would receive if the receiver knew her type (and responded optimally). [41] introduced and named this condition. The NITS condition can be shown to rule out equilibria that admit if self-signaling sets of the form $[0, t]$. Chen [19] and Kartik [41] show that the condition holds in the limits of perturbed versions of the basic cheap-talk game.

Inequality (9) holds automatically in any perfect Bayesian equilibrium of the standard signaling model. This follows because when R's actions are monotonic in type and S's preferences are monotonic in action, the worst outcome for S is to be viewed as the lowest type. This observation would not be true in Nash Equilibrium, where it is possible for R to respond to an out-of-equilibirum message with an action $a < BR(0)$.

Variations on Cheap Talk

In standard signaling models, there is typically an equilibrium that is fully revealing. This is not the case in the basic cheap-talk model. This leads to the question of whether it is possible to obtain more revelation in different environments.

One possibility is to consider the possibility of signaling over many dimensions. Chakraborty and Harbaugh [18] consider a model in with T and A are multidimensional. A special case of their model is one in which the components of T are independent draws from the same distribution and A involves taking a real-valued action for each component of T. If preferences are additively separable across types and actions, Chakraborty and Harbaugh provide conditions under which categorical information transmission, in which the S transmits the order of the components of T, is credible in equilibrium even when it would not be possible to transmit information if the dimensions were treated in isolation. It may be credible for S to say "$t_1 > t_2$," even if she could not credibly provide information about the absolute value of either component of t.

Communication is non-trivial if some Sender type strictly prefers to induce one equilibrium action over another. Non-trivial communication requires that different types have different preferences over outcomes. In standard signaling models, the heterogeneity arises because different sender types have different costs of sending messages. In cheap-talk models, the heterogeneity arises with one-dimensional actions if different sender types have different ideal actions. With multi-dimensional actions, heterogeneity could come simply from different sender types having different preferences over the relative importance of the different issues. Another simple variation is to assume the existence of more than one sender. In the two-sender game, nature picks t as before, both senders learn t and simultaneously send a message to the receiver, who makes a decision based on the two messages. The second sender has preferences that depend on type and the receiver's action, but not directly on the message sent. In this environment, assume that $M = T$, so that the set of available messages (this is essentially without loss of generality). One can look for equilibria in which the senders report honestly. Denote by $a^*(t, t')$ R's response to the pair of messages (t, t'). If an equilibrium in which both senders report honestly exists, then R's response to identical messages, $a^*(t, t) = a^R(t)$, and it must be the case that there exists a specification of $a(t, t')$ for $t \neq t'$ such that for all $i = 1$ and 2 and $t \neq t'$,

$$U^{S_i}(t, a^*(t, t)) \geq U^{S_i}(t, a^*(t, t')) \,. \tag{10}$$

It is possible to satisfy Condition (10) if the biases of the senders are small relative to the set of possible best responses. Krishna and Morgan [45] studies a one-dimensional model of information transmission with two informed players. Ambrus and Takahashi [1] and Battiglini [9] provide conditions under which full revelation is possible when there are two informed players and possibly multiple dimensions of information.

In many circumstances, enriching the communication structure either by allowing more rounds of communication [2,29], mediation [10], or exogenous uncertainty [16] enlarges the set of equilibrium outcomes.

Verifiable Information

Until now, the focus has been on situations in which the set of signals available does not depend on the true state. There are situations in which this assumption is not appropriate. There may be laws that ban false advertisement. The sender may be able to document details about the value of t. Models of this kind were first studied by Grossman [37] and Milgrom [56]. For example, if t is the sender's skill at playing the piano, then if there is a piano available t could demonstrate that she has skill at least as great as t (by performing at her true ability), but she may not be able to prove that her skill is no more than t (the receiver may think that she deliberately played the piano badly).

To model these possibilities, suppose that the set of possible messages is the set of all subsets of T. In this case, messages have "literal" meanings: When the sender uses the message $s = C \in T$, this can be interpreted as a statement of the form: "my type is in C." If senders cannot lie, then $M(t)$ must be the set of subsets of T that contain t. If type t is verifiable, then $\{t\} \in M(t')$ if and only if $t' = t$. If there are no additional costs of sending signals, this model can be viewed as a variation of cheap talk models in which the message space depends on t. In general, one can treat verifiable information models as a special case of the general signaling game in which the cost of sending certain signals is so large that these signals can be ruled out. Lying is impossible if $M(t) = \{C \subset 2^T : t \in C\}$. In this setting, it is appropriate to require equilibria to be consistent with the signaling structure.

Definition 6 The equilibrium (σ^*, α^*) is rationalizable if

$$\alpha(C, a) > 0 \text{ implies } \sum_{t \in T} U^R(t, s, a)\beta(t, a) = \max_{a' \in A} \sum_{t \in T} U^R(t, s, a')\beta(t, a') , \quad (11)$$

where $\beta(t, a) = 0$ if $t \notin C$.

Compared to (2), (11) requires that beliefs place positive probability only on types capable of sending the message "my type is an element of C."

Proposition 5 *Suppose that A and T are linearly ordered, that the receiver's best response function is increasing in type, and that all sender types prefer higher actions. If lying is not possible, then in any rationalizable equilibrium* (α^*, μ^*) , $\alpha^*(s, BR(t)) = 1$ *whenever* $\mu^*(t, s > 0)$.

Grossman [37] and Milgrom [56] present versions of this proposition. Seidman and Winter [68] generalize the result.

Provided that the receiver responds to the signal $\{t\}$ with $BR(t)$, each type can guarantee a payoff of $BR(t)$. On the other hand, if any type receives a payoff greater than $BR(t)$, then some higher type must be doing worse. Another way to make the same point is to notice that the highest type $\{\bar{t}\}$ has a weakly dominant strategy to reveal her type by announcing $\{\bar{t}\}$. Once this type is revealed, the next highest type will want to reveal herself and so on. Hence verifiable information will be revealed voluntarily in an environment where cheap talk leads to no revealing and costly signaling will be compatible with full revelation, but at the cost of dissipative signaling.

The full-revelation result depends on the assumption that the sender and receiver share a linear ranking over the quality of information. Giovannini and Seidmann [31] discuss more general settings in which the ability to provide verifiable information need not lead to full revelation.

Communication About Intentions

In a simple signaling game, signals potentially provide information about private information. Another possibility is to add a round of pre-play communication to a given game. Even if the game has complete information, there is the possibility that communication would serve to select equilibria or permit correlation that would otherwise be infeasible. Farrell and Rabin [63]'s review article discusses this literature in more detail.

Aumann [3] argues that one cannot rely on pre-play communication to select a Pareto-efficient equilibrium. He considers a simple two-player game with Pareto-ranked equilibria and argues that no "cheap" pre-play signal would be credible.

Ben-Porath and Dekel [11] show that adding a stage of "money burning" (a signal that reduces all future payoffs by the same amount) when combined with an equilibrium refinement can select equilibria in a complete information game. Although no money is burned in the selected equilibrium outcome, the potential to send costly signals creates dominance relationships that lead to a selection.

Vida [74] synthesizes a literature that compares the set of equilibrium outcomes available when communication possibilities are added to a game to the theoretically larger set available if there is a reliable mediator available to collect information and recommend actions to the players.

Applications

Economic Applications

There is an enormous literature that uses signaling models in applications. Riley's [64] survey contains extended discussion of some of the most important applications. What follows is a brief discussion of some central ideas.

In a simple signaling game, one informed agent sends a single signal to one uninformed decision maker. This setting is reach enough to illustrate many important aspects of signaling, but it plainly limited. Interesting new issues arise if there are many informed agents, if there are many decision makers, and if the interaction is repeated. Several of the models below add some or all of these novel features to the basic model.

Advertising Advertisements are signals. Models similar to the standard model can explain situations in which higher levels of advertisement can lead consumers to believe the quality of the good is higher. In a separating equilibrium, advertising expenditures fully reveal quality. As in all costly signaling models, it is not important that there be a direct relationship between quality and signal, it is only necessary that firms with higher quality have lower marginal costs of advertising. Hence simply "burning money" or sending a signal that lowers utility by an amount independent of quality and response can be informative. The consumer may obtain full information in equilibrium, but someone must pay the cost of advertising. There are other situations where it is natural for the signal to be linked to the quality of the item. Models of verifiable information are appropriate in this case. When the assumptions of Proposition 5 hold, one would expect consumers to obtain all relevant information through disclosures without wasteful expenditures on signaling. Finally, cheap talk plays a role in some markets. One would expect costless communication to be informative in environments where heterogeneous consumers would like to identify the best product. Cheap talk can create more efficient matching of product to consumer. Here communication is free although in leading models separating equilibria do not exist.

Limit Pricing Signaling models offer one explanation for the phenomenon of limit pricing. An incumbent firm have private information about its cost. Potential entrants use the pricing behavior of the firm to draw inferences about the incumbent's cost, which determines profitability of entry. Milgrom and Roberts [54] construct an equilibrium in which the existence of incomplete information distorts prices: Relative to the full information model, the incumbent charges lower prices in order to signal that the market is relatively unprofitable. This behavior has the flavor of classical models of limit pricing, with one important qualification. In a separating equilibrium the entrant can infer the true cost of the incumbent and therefore the low price charged by the incumbent firm fails to change the entry decision.

Bargaining Several authors have proposed bargaining models with incomplete information to study the existence and duration of strikes [30,71]. If a firm with private information about its profitability makes a take-it-or-leave it offer to a union, then the strategic interaction is a simple signaling model in which the magnitude of the offer may serve as a signal of the firm's profitability. Firms with low profits are better able to make low wage offers to the union because the threat of a strike is less costly to a firm with low profits than one with high profits. Consequently settlement offers may reveal information. Natural extensions of this model permit counter offers. The variation of the model in which the uninformed agent makes offers and the uninformed agent accepts and rejects is formally almost identical to the canonical model of price discrimination by a durable-goods monopolist [4,39].

Finance Simple signaling arguments provide potential explanations for firms' choices of financial structure. Classic arguments due to Modigliani and Miller [58] and imply that firms' profitability should not depend on their choice of capital structure. Hence this theory cannot organize empirical regularities about firm's capital structure. The Modigliani–Miller theorem assumes that the firm's managers, shareholders, and potential shareholders all have access to the same information. An enormous literature assumes instead that the firm's managers have superior information and use corporate structure to signal profitability.

Leland and Pyle [47] assume that insiders are risk averse so they would prefer to diversify their personal holdings rather than maintain large investments in their firm. The value of diversification is greater the lower the quality of the firm. Hence when insiders have superior information than investors, there will be an incentive for the insiders of highly profitable firms to maintain inefficiently large investments in their firm in order to signal profitability to investors.

Dividends are taxed twice under the United States tax code, which raises the question of why firms would issue dividends when capital gains are taxed at a lower rate. A potential explanation for this behavior comes from a model in which investors have imperfect information about the future profitability of the firm and profitable firms are more able than less profitable firms to distribute profits in the form of dividends (see [14]).

Reputation Dynamic models of incomplete information create the opportunity for the receiver to draw inferences about the sender's private information while engaging in an extended interaction. Kreps and Wilson [44] and Milgrom and Roberts [55] provided the original treatments of reputation formation in games of incomplete information. Motivated by the limit pricing, their models examined the interaction of a single long-lived incumbent facing a sequence of potential entrants. The entrants lack information about the willingness of the incumbent to tolerate entry. Pricing decisions of the incumbent provide information to the entrants about the profitability of the market.

In these models, signals have implications for both current and future utility. The current cost is determined by the effect the signal has on current payoffs. In Kreps–Wilson and Milgrom–Roberts, this cost is the decrease in current profits associated with charging a low price. In other models (for example [59,70]) the actual signal is costless, but it has immediate payoff implications because of the response it induces. Signals also have implications for future utility because inferences about the sender's private information will influence the behavior of the opponents in future periods. Adding concern for reputation to a signaling game will influence behavior, but whether it leads to more or less informative signaling depends on the application.

Signaling in Biology

Signaling is important in biology. In independent and almost contemporaneous work, Zahavi [76] proposed a signaling model that shared the essential features of Spence [72]'s model of labor-market signaling. Zahavi observed that there are many examples in nature of animals apparently excessive physical displays. It takes energy to produce colorful plumage, large antlers, or loud cries. Having a large tail may actually make it harder for peacocks to flea predators. If a baby bird makes a loud sound to get his mother's attention, he may attract a dangerous predator. Zahavi argued that costly signals could play a role in sexual selection. In Zahavi's basic model, the sender is a male and the receiver is a female of the same species. Females who are able to mate with healthier males are more likely to have stronger children, but often the quality of a potential mate cannot be observed directly. Zahavi argued that if healthier males could produce visible displays more cheaply than less healthy males, then females would be induced to use the signals when deciding upon a mate. Displays may impose costs that "handicap" a signaler, but displays would persist when additional reproductive success compensates for their costs. Zahavi identifies a single-crossing condition as a necessary condition for the existence of costly signals.

The development of signaling in biology parallels that in economics, but there are important differences. Biology replaces the assumption of utility maximization and equilibrium with fitness maximization and evolutionary stability. That is, their models do not assume that animals consciously select their signal to maximize a payoff. Instead, the biological models assume that the process of natural selection will lead to strategy profiles in which mutant behavior has lower reproductive fitness than equilibrium behavior. This notion leads to static and dynamic solution concepts similar to Nash Equilibrium and its refinements. Fitness in biological models depends on contributions from both parents. Consequently, a full treatment of signaling must take into account population genetics. Grafen [34] discusses these issues and Grafen [33] and Siller [69] provide further theoretical development of the handicap theory. Finally, one must be careful in interpreting heterogeneous quality in biological models. Natural selection should operate to eliminate the least fit genes in a population. To the extent that this arises, there is pressure for quality variation within a population to decrease over time. The existence of unobserved quality variations needed for signaling may be the result of relatively small variations about a population norm.

While most of the literature on signaling in biology focuses on the use of costly signals, there are also situations in which cheap talk is effective. A leading example is the "Sir Philip Sidney Game," originally developed by John Maynard Smith [53] to illustrate the value of costly communication between a mother and child. The child has private information about its level of hunger and the mother must decide to feed the child or keep the food for itself. Since the players are related, survival of one positively influences the fitness of the other. This creates a common interest needed for cheap-talk communication. There are two ways to model communication in this environment. The first is to assume that signaling is costly, with hungrier babies better able to communicate their hunger. This could be because the sound of a hungry baby is hard for sated babies to imitate or it could be that crying for food increases the risk of predation and that this risk is relatively more dangerous to well fed chicks than to starving ones (because the starving chicks have nothing to lose). This game has multiple equilibria in which signals fully reveal the state of the baby over a range of values (see [46,53]). These papers look at a model in which both mother and child have private information. Alternatively, Bergstrom and Lachmann [13] study a cheap-talk version of the game. Here there may be an equilibrium outcome in which the baby bird credibly signals whether or not he is hungry. Those who signal hunger get fed. The others do not. Well fed baby birds may wish to signal that they are not hungry in order to permit the mother to keep food for herself. Such an equilibrium exists if the fraction of genes that mother and child share is large and the baby is already well fed.

Political Science

Signaling games have played an important role in formal models of political science. Banks [7] reviews models of agenda control, political rhetoric, voting, and electoral competition. Several important models in this area are formally interesting because they violate the standard assumptions frequently satisfied in economic models. I describe two such models in this subsection.

Banks [6] studies a model of agenda setting in which the informed sender proposes a policy to a receiver (decision-maker), who can either accept or reject the proposal. If the proposal is accepted, it becomes the outcome. If not, then the outcome is a fall-back policy. The fall-back policy is known only to the sender. In this environment, the sender's strategy may convey information to the decision maker. Signaling is costly, but, because the receiver's set of actions in binary, fully revealing equilibria need not exist. Refinements limit the set of predictions in this model to a class of outcomes in which only one proposal is accepted in equilibrium (and that this proposal is accepted with probability one), but there are typically a continuum of possible equilibrium outcomes.

Matthews [52] develops a cheap-talk model of veto threats. There are two players, a Chooser (C), who plays the role of receiver, and a Proposer (P), who plays the role of sender. The players have preferences that are represented by single-peaked utility functions which depend on the real-valued outcome of the game and an ideal point. P's ideal point is common knowledge. C's ideal point is her private information, drawn from a prior distribution that has a smooth positive density on a compact interval, $[\underline{t}, \bar{t}]$. The game form is simple: C learns her type, then sends a cheap-talk signal to P, who responds with a proposal. C then either accepts or rejects the proposal. Accepted proposals become the outcome of the game. If C rejects the proposal, then the outcome is the status quo point.

As usual in cheap-talk games, this game has a babbling outcome in which C's message contains no information and P makes a single, take-it-or-leave-it offer that is accepted with probability strictly between 0 and 1. Matthews shows there may be equilibria in which two outcomes are induced with positive probability (size-two equilibria), but size $n > 2$ (perfect Bayesian) equilibria never exist. In a size-two equilibrium, P offers his ideal outcome to those types of C whose message indicates that their ideal point is low; this offer is always accepted in equilibrium. If C indicated that his ideal point is high, P makes a compromise offer that is sometimes accepted and sometimes rejected.

Future Directions

The most exciting developments in signaling games in the future are likely to come from interaction between economics and other disciplines.

Over the last ten years the influence of behavioral economists have led the profession to rethink many of its fundamental models. An explosion of experimental studies have already influenced the interpretation of signaling models and have led to a re-examination of basic assumptions. There is evidence that economic actors lack the strategic sophistication assumed in equilibrium models. Further, economic agents may be motivated by more than their material well being. Existing experimental evidence provides broad support for many of the qualitative predictions of the theory (Banks, Camerer, and Porter [5] and Brandts and Holt [17]), but also suggests ways in which the theory may be inadequate.

The driving assumption of signaling models is that when informational asymmetries exist, senders will attempt to lie for strategic advantage and that sophisticated receivers will discount statements. These assumptions may be reconsidered in light of experimental evidence that some agents will behave honestly in spite of strategic incentives to lie. For example, Gneezy [32] and Hurkens and Kartik [40] present experimental evidence that some agents are reluctant to lie even when there is a financial gain from doing so. There is evidence from other disciplines that some agents are unwilling or unable to manipulate information for strategic advantage and that people may be well equipped to detect these manipulations in ways that are not captured in standard models (see, for example, Ekman [27] or Trivers [73]). Experimental evidence and, possibly, results from neuroscience may demonstrate that the standard assumption that some agents cannot manipulate information for their strategic advantage (or that other agents have ability to see through deception) will inform the development of novel models of communication that include behavioral types. Several papers study the implications of including behavioral types into the standard paradigm. The reputation models of Kreps and Wilson [44] and Milgrom and Roberts [54] are two early examples. Papers on communication by Chen [19], Crawford [23], Kartik [41], and Olszewski [61] are more recent examples. New developments in behavioral economics will inform future theoretical studies.

There is substantial interest in signaling in philosophy. Indeed, the philosopher David Lewis [48] (first published in 1969) introduced signaling games prior to the contributions of Spence and Zahavi. Recently linguists have been paying more attention to game-theoretic ideas. Benz, Jäger and Van Rooij [12] collects recent work that attempts to formalize ideas from linguistic philosophy due to Grice [36]. While there have been a small number of contributions by economists in this area (Rubinstein [66] and Sally [67] are examples), there is likely to be more active interaction in the future.

Finally, future work may connect strategic aspects of communication to the actual structure of language. Blume [15], Cucker, Smale, Zhou [25], and Nowak and Krakauer [60] present dramatically different models on how structured communication may result from learning processes. Synthesizing these approaches may lead to fundamental insights on how the ability to send and receive signals develops.

Acknowledgments

I thank the Guggenheim Foundation, NSF, and the Secretaría de Estado de Universidades e Investigación del Ministerio de Educación y Ciencia (Spain) for financial support and Jose Penalva for his comments. I am grateful to the Departament d'Economia i d'Història Econòmica and Institut d'Anàlisi Econòmica of the Universitat Autònoma de Barcelona for hospitality and administrative support.

Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface

Albert A. M. Holtslag, Gert-Jan Steeneveld
Department of Meteorology and Air Quality,
Wageningen University, Wageningen, The Netherlands

Article Outline

Glossary

Atmospheric boundary layer The Atmospheric Boundary Layer (ABL) is the lower part of the atmosphere which is directly influenced by the presence of the earth's surface. As such its major characteristics are turbulence and the diurnal cycle.

Diurnal cycle The depth of the dry atmospheric boundary layer (ABL) can vary over land between tens of meters during night up to kilometers during daytime (see Fig. 2). Over sea the depth is often typical a few hundred meters and rather constant on the time scale of a day.

Turbulence Turbulence in the atmospheric boundary layer is the three-dimensional, chaotic flow of air with time scales typically between a second and an hour. The corresponding length scales are from a millimeter up to the depth of the boundary layer (or more in the case of clouds). Turbulence in the ABL originates due to friction of the flow and heating (convection) at the surface.

Definition of the Subject

In this article we deal with the single column modeling of the Atmospheric Boundary layer (ABL) and the the complex interactions which may occur with the land surface. As such we review the major characteristics of the ABL over land, and summarize the basic parameterizations for the represesentation of atmospheric turbulence and the surface fluxes. The modeling principles are illustrated with the outcome of single-column models for a variety of conditions using field data and fine-scale model results. Our emphasis is on stable conditions which occur over land at night-time under clear skies. For readers not familiar with atmospheric turbulence and meteorological definitions, some background and basic definitions are also given.

Introduction

The Atmospheric Boundary Layer (ABL) is generally characterized by turbulence. Because of its capability to mix air with different properties efficiently, the representation of turbulence is directly relevant for atmospheric and environmental modeling. For instance, turbulence directly impacts on the transfer of momentum, sensible heat, water vapor, ozone, and methane, among many other quantities, between the earth's surface and the atmosphere. Turbulence also defines the mixing of properties inside the atmospheric boundary layer, the transfer of quantities between the boundary layer and the clear or cloudy atmosphere aloft, and the mixing inside clouds.

Turbulence in the ABL is mainly due to the mechanical turbulence by vertical wind shear and turbulence by convection. Most of the atmosphere above the ABL is not turbulent, although turbulence can occur throughout the whole atmosphere. For instance, cumulus-type clouds, which may grow into thunderstorms, are always turbulent through convection produced by the heat released due to the condensation of water vapor. Turbulence can also occur in clear air above the ABL; most of this is produced in layers of strong vertical wind shear at the boundary between air masses (so-called 'Clear-Air Turbulence').

Because of the mixing capacity of turbulence, modeling atmospheric boundary layers is also relevant for many practical applications. For instance, chimney plumes are diluted and spread over larger volumes than they would be without turbulence. As such, strong local peaks of pollution are prevented and otherwise clean air is polluted. In practice turbulence may also cause engineering problems, because it shakes structures such as bridges, towers, and airplanes, causing failure of such systems in extreme cases. Turbulent fluctuations in the horizontal motions during severe storms can be fatal to tall buildings or bridges, particularly if resonance (e. g., forcing of a system at its natural frequency) occurs.

The correct formulation of the overall effects by turbulence, either inside or outside the atmospheric boundary layer, is an essential part of atmospheric models dealing with the prediction and study of weather, climate and air quality. These models are based on solving the equations dealing with atmosphere behavior. With state-of-the-art computers, the number of grid points in atmospheric models is limited to a number of typically 10^8 or so. This implies that on the regional and global scale the atmospheric model equations are usually applied too fairly large ‘air boxes’. Such boxes are often in the order of ten to hundred kilometers wide and ten to a few hundred meters thick. In these large boxes, smaller scale motions make air parcels interact and mix. For example, if a hot parcel is located next to a cold parcel, turbulent motion at their boundaries will heat the cool and cool the hot parcel. Thus, a closure formulation is needed to reproduce mixing by the turbulent motions into the model-resolved scales using the equations for the larger-scale ‘mean’ motions. It is important to realize that the closure formulation needs to be expressed in terms of variables available in the modeling context. This is called a ‘parameterization’.

In this contribution we provide an overview of the modeling principles, the turbulent closures and parameterizations in use for of the atmospheric boundary layer, where we emphasize the modeling and parameterization of turbulence in the atmospheric boundary layer without clouds. Additionally we discuss the performance of models in current use [7,28], and we study the impact of the surface boundary condition over land [18].

Background

Atmospheric models for the forecasting and study of weather, climate, and air quality are typically based on integration of the basic equations governing atmospheric behavior. These equations are the gas law, the equation of continuity (mass), the first law of thermodynamics (heat), the conservation equations for momentum (the so-called “Navier–Stokes equations”), and usually equations expressing the conservation of moisture, trace gases and air pollutants. At one extreme, atmospheric models may deal with the world’s climate and climate change; at the other, they may account for the behavior of local flows at coasts, in mountain-valley areas, or even deal with individual clouds. This all depends on the selected horizontal modeling domain and the available computing resources.

Since there is an enormous range of scales in atmospheric motion and turbulence, there is a need to separate the scales of atmospheric turbulence from larger-scale motions. Let C denote an atmospheric variable, such as specific humidity. Then $\overline{C}$ represents a mean or “smoothed” value of C, typically taken on a horizontal scale of order 10 (or more) km and a corresponding time scale in the order of 10 min to one hour. A local or instantaneous value of C would differ from $\overline{C}$. Thus, we have

$$C = \overline{C} + c\,. \tag{1}$$

Here c represents the smaller-scale fluctuations. Note that we use lower case for the latter (often primes are used as well to indicate fluctuations). In principle, the fluctuations around the mean motion also reflect gravity waves and other smaller scale motions, in addition to turbulence. Gravity waves often co-exist with turbulence or are generated by turbulence. If the wind at the same time is weak, there may be no turbulence at all. Anyhow, if turbulence exists, it is usually more important for most atmospheric applications, because it mixes more efficiently than the other small-scale motions.

To make the mathematical handling of c tractable, it must satisfy the so-called “Reynolds postulates”. These require, for example, that $\overline{c} = 0$ and that small- and larger-scale values must not be correlated. After a quantity has been averaged to create a larger-scale quantity, further averaging should produce no further changes, in order for this postulate to apply. The mean of the summation of two variables A and C will produce $\overline{A \pm C} = \overline{A} \pm \overline{C}$. A further condition is that a mean variable $\overline{C}$ must be differentiable, since differentials show up in the atmospheric equations (see below). In practice, not all these conditions are rigorously satisfied. If the Reynolds postulates are fulfilled, then the averaging for the product of two variables provides

$$\overline{AC} = \overline{A}\,\overline{C} + \overline{ac}\,. \tag{2}$$

The second term at the right hand side of Eq. (2) is known as the turbulent covariance. Similarly, the turbulence variance of a quantity is given by $\overline{C^2} - (\overline{C})^2$ (which is the square of the standard deviation).

If in Eq. (2), the variable A represents one of the velocity components (U, V, W in the x, y, z direction, respectively), then $\overline{AC}$ is the total flux of C and the second term at the right hand side of Eq. (2) represents a turbulent flux of C. For instance, $\overline{uc}$ and $\overline{wc}$ are the horizontal and vertical turbulent fluxes of the variable C, respectively. Here u and w are the turbulent fluctuations of the horizontal and vertical velocities. Near the surface, the mean vertical wind $\overline{W}$ is usually small, and thus the total vertical fluxes are normally dominated by the turbulent contributions.

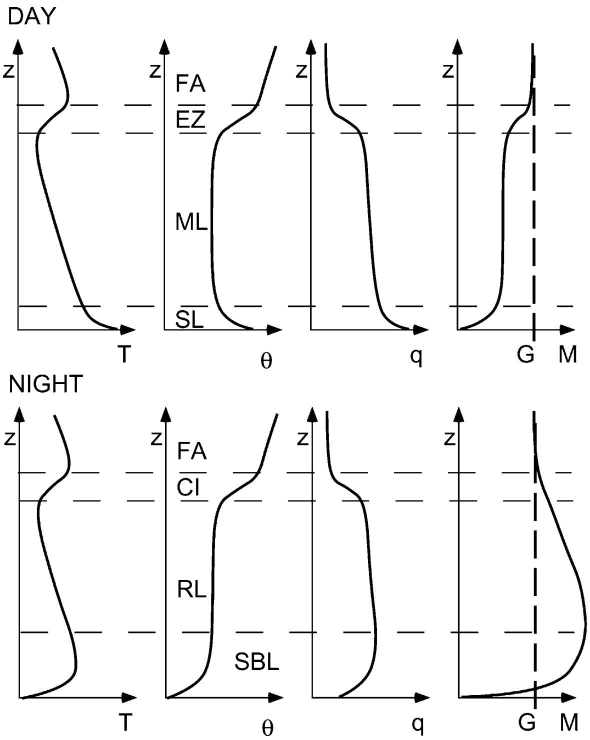
Atmospheric Boundary-Layer Structure

Turbulent fluctuations, variances and fluxes of variables are influenced by the vertical boundary-layer structure. Here the variation of temperature in the atmospheric boundary-layer plays an important role. Since pressure decreases with altitude, air parcels, which are forced to rise (sink), do expand (compress). According to the first law of thermodynamics, a rising (sinking) parcel will cool (warm) if there is no additional energy source such as condensation of water vapor. Then this is called a dry adiabatic process.

It can be shown that in the atmospheric boundary layer, the temperature (T) variation with height for a dry adiabatic process is $\mathrm{d}T/\mathrm{d}z = -g/C_\mathrm{p}$ (here g is gravity constant and C_p is specific heat at constant pressure). The value for g/C_p is approximately 1 K per 100 m. An atmospheric layer which has such a temperature variation with height, is called neutral for dry air (at least when there is no convection arising from other levels). In that case $\Theta = T + (g/C_\mathrm{p})z$ is constant, where Θ is called the potential temperature (Note that the previous definition for potential temperature is not accurate above the boundary layer). Since air normally contains water vapor and because moist air is lighter than dry air, we have to correct for the influence of this on vertical motions. Consequently, a virtual potential temperature is defined as $\Theta_\mathrm{v} = \Theta(1 + 0.61q)$, where q is the specific humidity (defined as the mass of water vapor per unit mass of moist air).

In a neutral layer with constant Θ_v, vertical motions of moist (not saturated) air can maintain themselves. If the virtual potential temperature of the atmospheric layer increases with height, vertical displacements are suppressed. This is called a stable condition (or 'inversion'). At the other hand, when the virtual potential temperature decreases with height, vertical fluctuations may be accelerated. Consequently this is called an unstable condition. Thus in considerations with turbulent fluctuations and atmospheric stability, we have to deal with the virtual potential temperature and not with the actual temperature. Similarly, the vertical flux of sensible heat is connected to turbulent fluctuations of (virtual) potential temperature; e. g. it reads as $\overline{w\theta_\mathrm{v}}$ (in m K/s). The latter relates directly to the energy per time and unit area H by $H = \rho C_\mathrm{p}\overline{w\theta_\mathrm{v}}$ (in W/m^2), where ρ is density of the air (in kg/m^3).

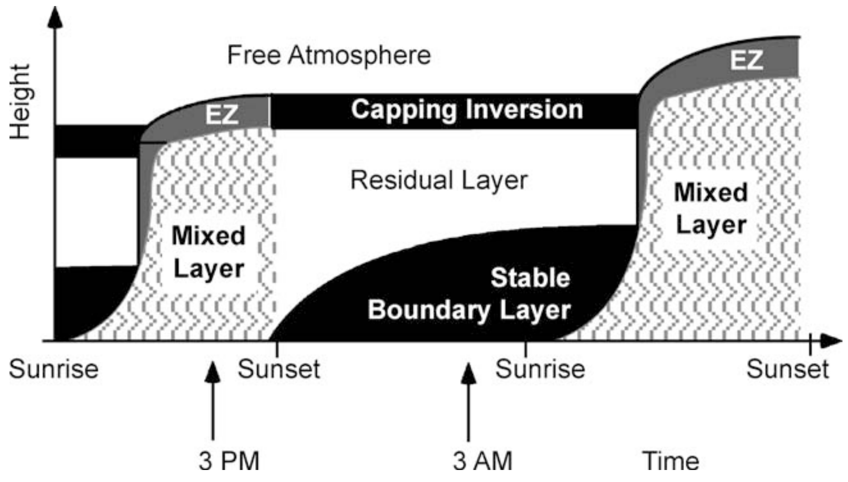
Figure 1 (after [30]), provides the typical, idealized, mean vertical profiles for temperature T, potential temperature Θ, specific humidity q, in addition to the horizontal wind M (defined by $M^2 = U^2 + V^2$). These profiles apply for an atmospheric boundary layer over land in clear sky conditions in the afternoon and around midnight. Note that in the free atmosphere the horizontal wind is mostly a result of the acting of the larger scale pressure differences and the Coriolis force due to the rotation of the earth (but other effects may play a role as well). The resulting wind is known as the 'geostrophic' wind and indicated with G in Fig. 1 (see dashed line). In the daytime boundary layer the actual wind is smaller due to surface friction, while at clear nights the actual wind away from the surface may be substantially stronger than G due to inertial effects (resulting in the so-called 'low level jet').



Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 1
Idealized vertical profiles of mean variables in the Atmospheric Boundary Layer over land in fair weather (after [30]). See text for additional information

The temporal variation of the mean boundary-layer profiles over land can be quite substantial due to the strong diurnal variation of solar incoming radiation and the nighttime cooling at the land surface. During daytime the turbulent boundary layer may grow to several kilometers into the non-turbulent 'free atmosphere' (indicted as FA in Fig. 1). At night the turbulent part of the stable boundary layer (SBL) may only extend up to a few hundred meters or less (the lowest dashed line in the lower figure). An idealized picture for the temporal variation of the boundary layer over land is given in Fig. 2 (after [30]). Here the arrows with local time indications refer to the day and nighttime figures of Fig. 1.

Figure 1 also indicates that the boundary layer during daytime shows a three-layer structure: an unstable 'surface layer (SL)', a 'well-mixed layer (ML)' with rather uniform (virtual) potential temperature, and a stably-stratified 'entrainment zone (EZ)'. In the latter zone, turbulence acts to exchange heat, momentum, water-vapor and trace gasses



Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 2
Idealized diurnal evolution of the Atmospheric Boundary Layer over land in fair weather (after [30])

between the boundary layer and the free atmosphere. During nighttime, often the vertical structure of the previous day persists above the SBL. As such a ‘residual layer (RL)’ with sporadic turbulence (remaining from the previous day) can be identified as well as a ‘capping inversion (CI)’.

Modeling Basics

The challenge of modeling the atmospheric boundary layer is the prediction of the temporal variation of the vertical and horizontal structures in response to the influence of the major processes acting in the atmosphere and at the earth’s surface. As such the governing equations have to be integrated. In practice, the variables are split into ‘mean’ larger-scale motions and smaller-scale fluctuations as in Eq. (1). Inserting this into the basic equations and after averaging this provides a set of equations for the behavior of the larger-scale (mean) variables. The larger-scale variables are then used explicitly in atmospheric models. This can be demonstrated as follows below.

The general character of any of the budget equations dealing with atmospheric motions is

$$\frac{\mathrm{D}C}{\mathrm{D}t} = S_i \,. \tag{3a}$$

Here S_i represents the subsequent sources and sinks for the variable C (such as radiation or chemistry effects). The notation $\mathrm{D}C/\mathrm{D}t$ represents the total rate of change for the variable C by local changes ($\partial/\partial t$), and changes transported with the fluid motion in the three directions. As such, we have

$$\frac{\partial C}{\partial t} + U\frac{\partial C}{\partial x} + V\frac{\partial C}{\partial y} + W\frac{\partial C}{\partial z} = S_i \,. \tag{3b}$$

Here U, V, W are the wind speeds in the three directions x, y, z, respectively.

If in the atmospheric motion each variable is split into a mean component and a fluctuation then (3b) provides after Reynolds-averaging, some algebraic manipulations and simplifying assumptions, a budget equation for the mean variable $\overline{C}$. This reads as

$$\begin{aligned}\frac{\mathrm{D}\overline{C}}{\mathrm{D}t} &= \frac{\partial\overline{C}}{\partial t} + \overline{U}\frac{\partial\overline{C}}{\partial x} + \overline{V}\frac{\partial\overline{C}}{\partial y} + \overline{W}\frac{\partial\overline{C}}{\partial z}\\ &= \overline{S_i} - \frac{\partial\overline{uc}}{\partial x} - \frac{\partial\overline{vc}}{\partial y} - \frac{\partial\overline{wc}}{\partial z}\,.\end{aligned} \tag{4}$$

We may note that in the derivation of (4), single terms representing fluctuations have disappeared (as above in Eq. (2)). However, terms involving the product of two fluctuations did remain.

Thus because the basic equations are nonlinear, the budget equations for the mean variables contain terms involving smaller-scale motions. The latter terms are of the form of a divergence of fluxes produced by such motions in the three directions and appear as the last three terms in Eq. (4). These motions are said to be sub-grid and consequently, closure formulations or parameterizations are needed to introduce mixing by the smaller-scale, sub-grid, motions into the equations for the larger-scale motions (as resolved by the model). Note that additional terms may also appear in (4) when the source or sink term S_i incorporates nonlinear effects (such as in the case of chemistry).

The atmospheric model equations can also be applied on much smaller spatial and temporal scales then discussed here, for instance by using vertical and horizontal grid elements of 10 to 100 m, and time steps of seconds only. It is important to realize that in such cases a significant part of the turbulent fluctuations are resolved by the model equations. This type of modeling is nowadays known as 'Large-eddy simulation (LES)'. This has become a powerful and popular tool in the last decade to study turbulence in clear and cloudy boundary layers under well-defined conditions. It is important to realize that in the case of LES the simplifying assumptions leading to Eq. (2) are normally not valid.

A special and simple form of Eq. (4) arises for horizontally homogeneous conditions. In such cases the terms including horizontal derivatives are negligible. If in addition the mean vertical wind is small and if there are no other sources and sinks, then (4) provides

$$\frac{\partial \overline{C}}{\partial t} = -\frac{\partial \overline{wc}}{\partial z} \, . \tag{5}$$

This equation is known as the one-dimensional, vertical diffusion equation. It shows that the local time rate of change for the mean of a variable (such as temperature or wind) at a certain height, is given by the divergence of the turbulent (corresponding heat or momentum) flux in the vertical direction. As such, information on the turbulent flux may produce a local forecast of the variation of a mean variable (but only under the simplifications mentioned).

Equation (5) can be seen as the basis of a single-column model where only local information of the atmosphere is relevant. However, normally the other terms in (4) are also relevant, in particular the terms with mean wind speed (the so-called "advection terms"). This means that in general the budget equations for momentum, heat, and the various scalars are closely coupled in any atmospheric model. Still one can solve for the local time rate of change in a single column model once the advection terms are known form observations or other means. This approach is widely adopted to study atmospheric boundary layers in comparison with observations on a local scale.

Before we proceed with more detailed parameterizations for the fluxes in the boundary layer, let us deal with the derivation of the surface fluxes. These fluxes enter as boundary conditions when solving the budget equations for all the relevant mean variables (in any approach). It is important to realize that near the surface, the average wind must vanish because the mean wind is zero at the earth's surface. At the other hand, we know from observations that the fluxes of heat, momentum and trace gasses are nonzero. Consequently, it is convenient to model an 'effective' surface flux $\overline{wc_0}$ of a conserved variable due to the combined effect of molecular diffusion and turbulence at the surface. This can be achieved by writing

$$\overline{wc_0} = \beta_t w_t (C_0 - C_a) \, . \tag{6}$$

Here C_0, and C_a are the values of the transported variable at the surface and in the air, respectively; β_t is a transfer coefficient, and w_t is an effective transport velocity representing the turbulence. For example, in near-neutral conditions the effective transport velocity is well represented by the well-known surface friction velocity u_{*0}. Then it can be shown that $\beta_t = \kappa / \ln(z/z_0)$, where κ is the 'Von Karman' constant (often specified as $\kappa \cong 0.4$), z is the corresponding height of C_a in the lowest part of the boundary layer and z_0 is the so-called surface roughness length for the variable C. We refer to the literature for a more detailed treatment (e. g., Beljaars and Holtslag [4]).

Local Mixing Parameterization

To solve the budget Eq. (4) for all the mean atmospheric variables involved, the terms involving turbulent fluxes need to be parametrized. As mentioned before, this means that the fluxes need to be expressed in terms of available mean model quantities, both in the atmosphere and at the surface. Once this has been achieved, the atmospheric model equations can be integrated. Thus, starting with proper initial values, new values can be calculated for the following time step and so on.

The most frequently used parameterization for environmental and atmospheric models, is known as first-order closure or often also called K-theory. In this theory it is assumed that the flux $\overline{wc}$ of a variable C in the vertical direction z, is down the vertical gradient of the mean concentration of C per unit mass. Thus

$$\overline{wc} = -K_c \frac{\partial \overline{C}}{\partial z} \, . \tag{7}$$

Here, K_c is known as the 'eddy-diffusivity' or mixing coefficient for the variable C. Similarly, the horizontal fluxes can be represented in terms of horizontal gradients. Note that the corresponding eddy-diffusivities typically are not constant, but that they generally depend on properties of the flow and the variable of interest. This also means that normally no analytic solutions are possible, not even for the simple case in which Eqs. (5) and (8) are combined.

We may note that the dimension of an eddy-diffusivity is a length scale ℓ times a velocity scale. These are proportional to the products of effective eddy sizes and eddy velocities in the corresponding directions. Often a diagnostic expression is used for the eddy-diffusivity, on basis of what is called 'mixing length theory' (in analogy with molecular diffusion). The result reads as

$$K_c = \ell^2 S f(\mathrm{Ri})\,. \tag{8}$$

Here S is vertical wind shear (that is the variation of mean horizontal wind with height). Note that the combination ℓS in Eq. (9) has units of velocity. In Eq. (8), $f(\mathrm{Ri})$ denotes a functional dependence on local stability as represented by the gradient Richardson-number Ri defined by

$$\mathrm{Ri} = \frac{g}{\overline{\Theta_\mathrm{v}}} \frac{\partial\overline{\Theta_\mathrm{v}}/\partial z}{(\partial\overline{U}/\partial z)^2 + (\partial\overline{V}/\partial z)^2}\,. \tag{9}$$

Here g is the acceleration due to gravity, and $\overline{\Theta_\mathrm{v}}$ is the mean 'virtual potential temperature'.

The specification of the length scale ℓ is not at all straightforward, except near the surface where so-called 'surface-layer similarity theory' (see cited literature) provides that $\ell \propto z$. A frequently used form for ℓ is:

$$\frac{1}{\ell} = \frac{1}{\kappa z} + \frac{1}{\lambda}\,. \tag{10}$$

Here λ is a turbulent length scale, which should be valid for the turbulence far above the surface. We note that the latter has a rather empirical nature and consequently there is no agreement on the specification of λ in the literature.

Equation (8) is a diagnostic equation, which indicates that the eddy-diffusivity may variy with height, wind speed, stability, et cetera. In combination with the flux parameterization of Eq. (7), it follows that the flux at a certain height depends on the local gradient of the mean variable involved. Consequently the approach is referred to as a 'diagnostic local mixing approach'. Such an approach is mostly suitable for relatively homogeneous conditions with neutral and stable stratification, and is not so suitable for cases with convection (see non-local mixing parameterizations below).

More Advanced Mixing Parameterizations

A physically realistic alternative to the diagnostic approach is to relate the eddy-diffusivity of Eq. (7) to the actual turbulent kinetic energy of the flow, by using the prognostic turbulent kinetic energy equation and an appropriate choice for the turbulent length scale. It is important to realize that the kinetic energy of atmospheric motion per unit of mass E is given by the half of the sum of the velocities squared in the three directions (as in classic mechanics), e. g. $E = (U^2 + V^2 + W^2)/2$. Similar as with respect to Eq. (2), we can separate between the Mean Kinetic Energy $\overline{E}$ of the mean atmospheric motions and the Turbulent Kinetic Energy (TKE or e) of the smaller-scale fluctuating motions by turbulence. Thus e is given by $e = (\overline{u^2} + \overline{v^2} + \overline{w^2})/2$.

The prognostic equation for e reads in its basic form as:

$$\frac{\mathrm{D}e}{\mathrm{D}t} = -\overline{uw}\frac{\partial\overline{U}}{\partial z} - \overline{vw}\frac{\partial\overline{V}}{\partial z} + \frac{g}{\overline{\Theta_\mathrm{v}}}\overline{w\theta_\mathrm{v}} + D - \varepsilon\,. \tag{11}$$

Here $\mathrm{D}e/\mathrm{D}t$ is the total variation of e with time (the sum of local variations and those transported with the mean air motion). The two terms at the immediate right hand side of (11) represent the shear production of turbulence. These depend primarily on vertical variations of wind or, near the ground, on wind speed and surface roughness. The terms are almost always positive. The third term in Eq. (11) represents the rate of production or breakdown of turbulence by buoyancy effects (such as heat convection). It depends directly on density effects, which can be written in terms of the virtual potential temperature $\overline{\Theta_\mathrm{v}}$, and its turbulent flux $\overline{w\theta_\mathrm{v}}$. The term D in Eq. (11) represents divergence and pressure redistribution terms. These have a tendency to cancel near the surface. Finally, the term ε reflects the molecular dissipation of turbulence into heat and this term is always positive. In fact ε is typically proportional to e/τ, where τ is the characteristic time scale for the turbulent mixing process.

Using Eq. (11), turbulent kinetic energy can be calculated for given mean profiles when the corresponding fluxes are calculated using Eq. (7) for all fluxes involved. In this approach the diffusivities are typically calculated with equations of the form

$$K_c = \alpha_c \ell \sqrt{e}\,. \tag{12}$$

Here α_c is a constant depending on the variable of interest. The length scale is typically calculated with a similar type of diagnostic equation as (10) provides. This approach is known as the 'TKE-length scale approach' and it is an example of so-called 1.5 order closure. Sometimes a prognostic equation is used for the length scale as well, but such an approach is more popular in engineering applications then in the atmospheric sciences.

It can be shown that Eq. (8) is a solution of (11) and (12) in stationary conditions and when other simplifications are made such as the neglect of the influences by advection and turbulence divergence in the TKE equation. A more advanced turbulence scheme is known as 'second-order closure'. In such an approach, prognostic equations are developed for the fluxes and variances themselves. Such equations have a very similar structure as Eq. (12) for kinetic energy. Unfortunately, new unknowns are present in these equations. These must be related to the other variables in the model equations, always involving assumptions. Thus, second-order closure involves many more than the original equations and is therefore computationally more time consuming ('expensive') than first-order and 1.5 order closure.

One may expect that a model with 1.5 or second-order closure would produce more realistic results then a model with a first order closure. However, in practice this is often not the case, because of complex model interactions and the difficulty of representing all the relevant details with sufficient accuracy (see also below). That is the reason why diagnostic approaches remain popular. Nevertheless, second order equations are useful to gain insight in the governing physics, and after simplification useful extensions of the basic parameterizations may be achieved.

We continue our discussion with mixing parameterizations which have been proposed for boundary-layers with strong atmospheric convection. In such cases, the turbulent flux of a conserved quantity is typically not proportional to the local gradient alone as predicted by Eq. (7). In fact, in a large part of the ABL the mean gradients are small in conditions with dry convection, in particular for potential temperature (see Fig. 1). Then the fluxes depend mostly on the mixing characteristics of the large eddies across the ABL. Theories are available, which have modified K-theory to allow for the influence of convection, for example by including additional terms at the right hand side of Eq. (8) For details we refer to the literature (e. g., Holtslag and Moeng [15]).

In the next sections we apply the modeling concepts above and compare their results with field observations. In addition we present results from model intercomparison studies, and illustrate the role of boundary conditions.

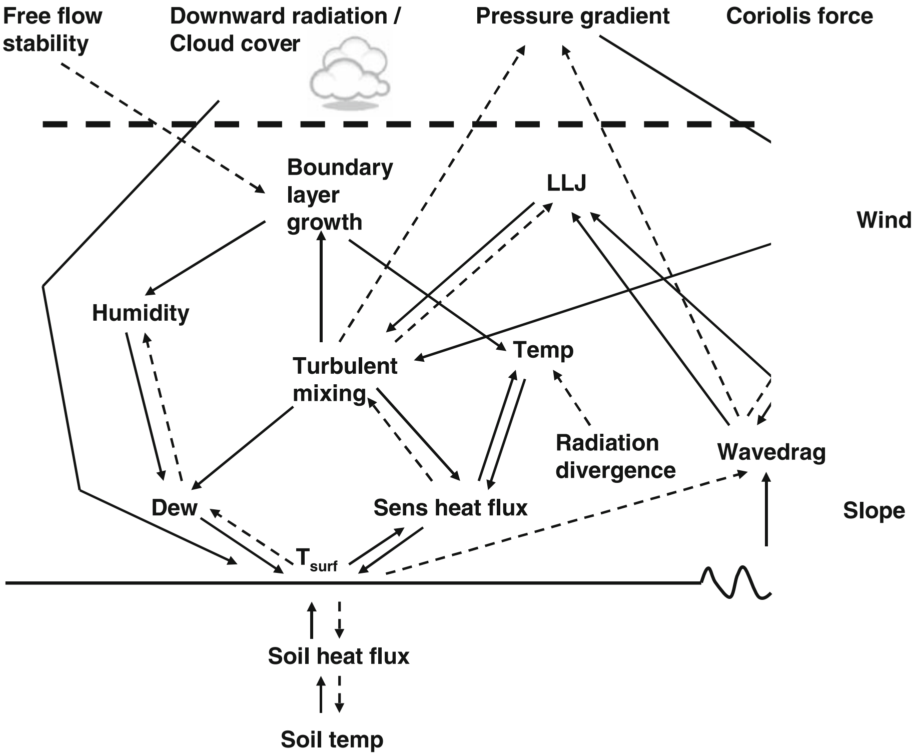
Intercomparison of Single Column Models for Stable Conditions

Atmospheric models for weather and climate need to make an overall representation of the smaller-scale boundary-layer and near surface processes. This appears to be more successful during daytime (e. g. Ek and Holtslag [10]; Holtslag and Ek [17]) then during nighttime stable conditions over land. The modeling of the stable boundary layer over land is rather complex because of the many different physical processes which are "at work" in stable conditions [21]. These small-scale processes are: clear air radiation divergence, drainage flow, generation of gravity waves and shear instabilities, fog and dew formation, the occurrence of a low-level jet and generation of discontinuous or intermittent turbulence [33]. In addition, the phenomenology of stable atmospheric boundary layers is quite divers, e. g. shallow and deep boundary layers with continuous turbulence through most of their depth, and on the other hand boundary layers with intermittent turbulence or even laminar flow.

The small-scale processes influence the vertical and horizontal exchange of quantities between the surface and the atmosphere as well as the mixing in the atmosphere on a variety of scales. In addition, it is known that turbulent mixing in stratified flow has an inherent non-linear character and may, as such, trigger positive feedbacks. These positive feedbacks, in turn, may cause unexpected transitions between totally different SBL regimes (e. g. van de Wiel et al. [34]).

Figure 3 depicts the interactions between relevant processes in the stable boundary layer. The non-linear behavior of the system is seen in e. g. the surface sensible heat-flux (H). A sudden change of the surface temperature can result in 2 different impacts on H. First, in weakly stable conditions (with strong wind and sufficient turbulence), a surface temperature decrease will provide a larger heat flux since H is proportional to the temperature difference between the surface and the atmosphere. The larger heat-flux from the atmosphere to the surface compsensates for the stronger cooling. In contrast for stronger stably stratified conditions, a surface temperature decrease will provide a stronger stratification and inhibits turbulent mixing, and consequently H will decrease. This allows for even stronger surface cooling (positive feedback). Note that a similar diagram for the daytime boundary layer can be found in Ek and Holtslag [10].

Having in mind the above mentioned complexity, one should not be surprised that atmospheric models encounter large forecast errors for stable conditions [20,24]. One strategy to improve model performance is to provide different models the same forecasting task, and analyze which model descriptions are in favor for which atmospheric stability. Recently such an intercomparison of boundary-layer schemes for stable conditions was made within the GEWEX Atmospheric Boundary Layer Study ('GABLS'). This GEWEX project aims to improve the understanding and the representation of the atmospheric boundary layer in regional and large-scale climate models [14]. A rather simple case was selected as a benchmark to review the state of the art and to compare the skills of single column (1D) models [7] and Large–Eddy Simulation models [3]. In this case a stable boundary layer is driven by an imposed, uniform geostrophic wind, with a specified constant surface-cooling rate over (homogeneous) ice. The case is initialized with $\theta = 265\,\mathrm{K}$ for $0 < z < 100$ and a lapse rate of 1 K/100 m aloft.



Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 3
Interaction diagram for the processes and variables in the stable atmospheric boundary layer over land (after [26])

It turns out that with the same initial conditions and model forcings, the models indicate a large range of results for the mean temperature and wind profiles. Figure 4 shows the mean profiles for several models after nine hours of constant surface cooling (sufficient to achieve a quasi-steady state). The variable results achieved are strongly related to the details of the boundary-layer mixing schemes [7]. An important finding is that the models in use at operational weather forecast and climate centers (as depicted at the left hand side of Fig. 4) typically allow for enhanced mixing resulting in too deep boundary layers, while the typical research models (at the right hand sides) show less mixing in more in agreement with the 'Large Eddy Simulation' results for this case [3].

Because of the enhanced mixing in weather and climate models, these models tend to show a too strong surface drag, too deep boundary layers, and an underestimation of the wind turning in the lower atmosphere [19]. At the other hand, by decreasing the mixing and surface drag, a direct impact on the atmospheric dynamics ('Ekman pumping') is noted (e. g. Beljaars and Viterbo [5]). Consequently, cyclones may become too active, corresponding in too high extremes for wind and precipitation, etc.

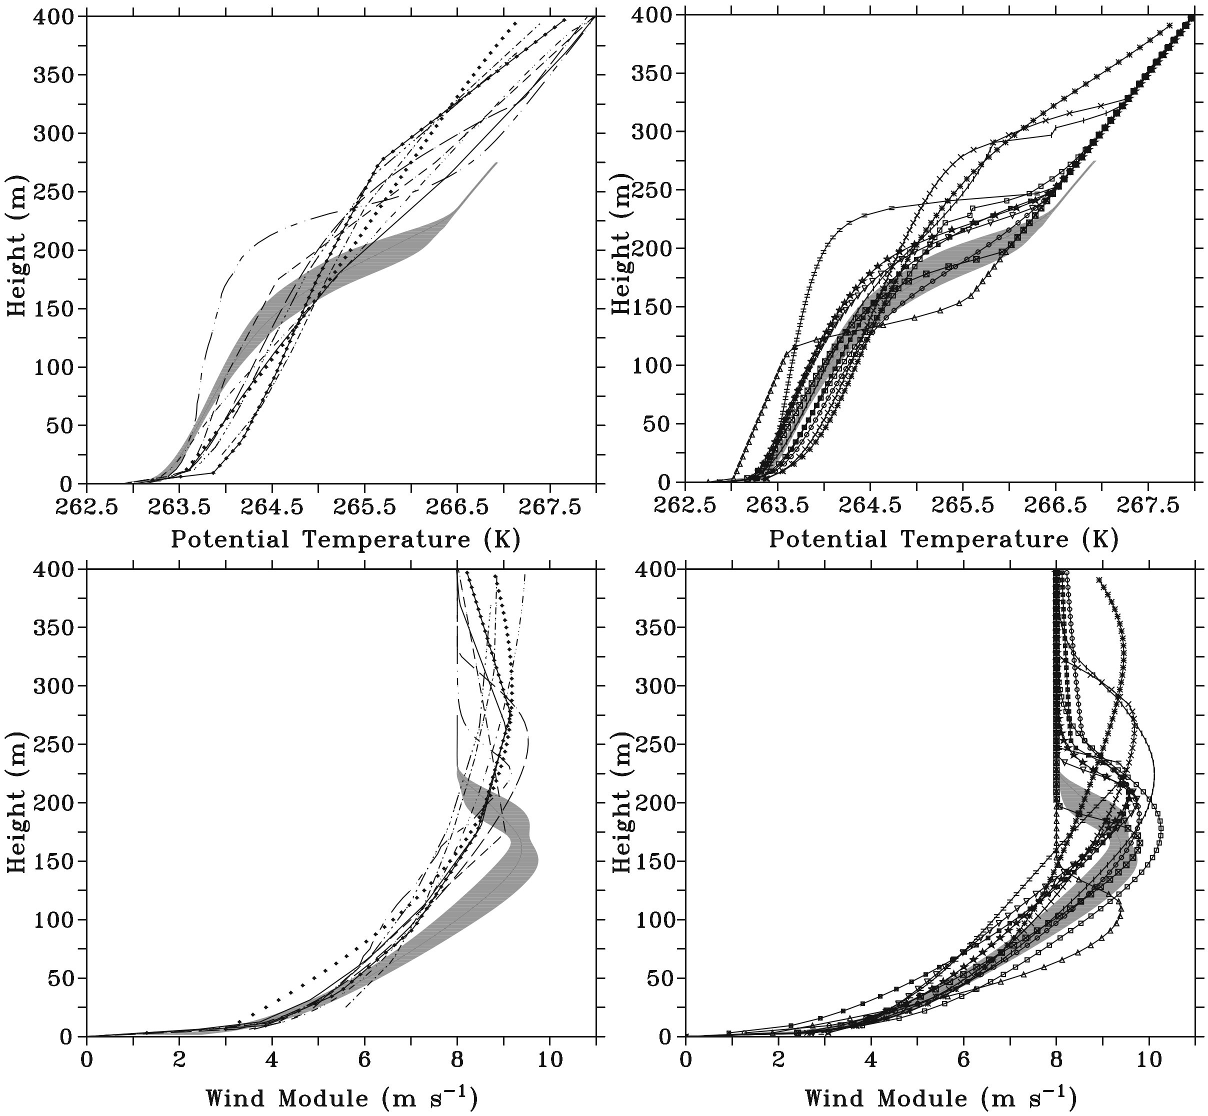
Modeling Boundary Layers over Land

To study the interactions of the ABL with the land surface we utilize the model by Duynkerke [9] with the extensions and modifications by Steeneveld et al. [28]. This model has been validated against tower observations at Cabauw, The Netherlands and later with CASES-99 field observations [1,28], and also participated in the GABLS model comparison in the previous section.

Instead of prescribing the surface temperature, and to enable interaction between the ABL and the land surface, the model is extended with a soil and a vegetation layer The soil temperature evolution is calculated by solving the diffusion equation (using a grid spacing of 1 cm) and the heat flux G_h from the soil to vegetation is calculated by:

$$G_h - (1 - f_{veg})K^{\downarrow} = r_g(T_{veg} - T_{s0})\,. \tag{13}$$

In Eq. (13) $K^{\downarrow}$ is the incoming shortwave (solar) radiation, T_{veg} represents the vegetation surface temperature, and T_{s0} the soil temperature just below the vegetation. We use a vegetation fraction $f_{veg} = 0.9$ and conductance $r_g = 5.9\,\mathrm{W m^{-2}} K^{-1}$, which are consistent with the obser-



Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 4
Modeled potential temperature and wind profiles by an ensemble of column models (after 9 h). *Grey areas* indicate the ensemble of Large Eddy Simulation results [3]. *Left panel* shows the results for first order closure models and the *right panel* for higher order closure models (after [7])

vations of CASES99 [28]. Initial soil and surface temperatures are also taken from the CASES99 observations.

Subsequently, the evolution of T_{veg} is computed by solving the surface energy budget for the vegetation layer:

$$C_{\text{v}} \frac{\partial T_{\text{veg}}}{\partial t} = Q^{*} - G_{\text{h}} - H - L_{\text{v}} E \, . \tag{14}$$

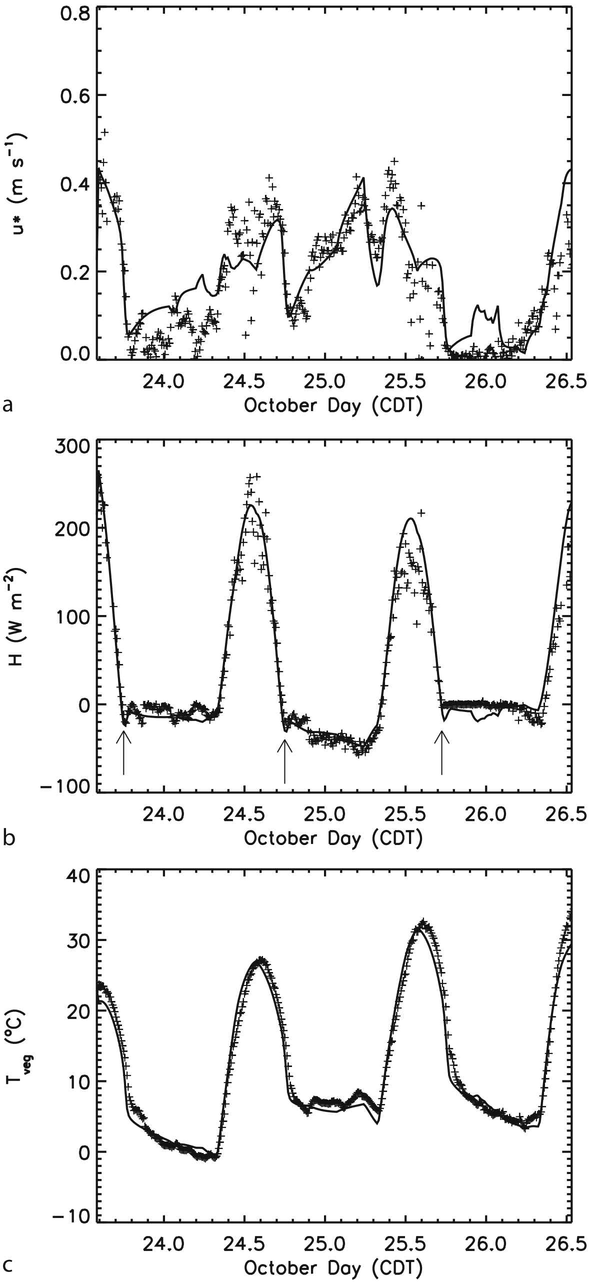
Here C_{v} is the heat capacity of the vegetation layer per unit of area ($C_{\text{v}} = 2000\,\text{Jm}^{-2}K^{-1}$, van de Wiel [34]), Q^{*} is the net radiation, H is the sensible heat flux and $L_{\text{v}}E$ the latent heat flux. The turbulent fluxes are calculated basically with the format of Eq. (6) above. Finally, Q^{*} is calculated by adopting the Garratt and Brost [12] radiation scheme. Note that Eqs. (13) and (14) provide a rather strong coupling of the atmosphere to the vegetated land surface for the current parameter setting which is found to be important [28].

Model forecasts have been compared with CASES-99 observations for contrasting diurnal cycles (i. e. for different wind speeds) for 23–26 Oct. 1999. Note that the model is only initialized once and that the total run comprises three full days. We distinguish between "radiative nights" with weak winds and small turbulent mixing, when radiative cooling dominates the SBL development. On the contrary, so-called "continuous turbulent" nights are characterized by strong winds. The final archetype is the so called "intermittently turbulent" night where turbulent episodes alternate with calm periods, when the radiative and turbulent forcings are of similar order of magnitude. Here we restrict ourselves to the results for surface fluxes, surface vegetation temperature, and vertical profiles of temperature and wind speed during nighttime. The diurnal cycle of the modeled net radiation Q^* (the balance of all incoming and outgoing short- and longwave radiative fluxes) agrees with the observations (not shown). Net radiation amounts typically $Q^* = 400\,\mathrm{Wm^{-2}}$ during daytime and $Q^* = -70\,\mathrm{Wm^{-2}}$ during nighttime.

The friction velocity (u_*) shows a clear diurnal cycle: u_* is large during the day and small at night, which is in general well captured by the model (Fig. 5a). Looking in more detail we find that during weak winds (1st and 3rd night) the model tends to overestimate u_*. The model lacks a clear turbulence collapse as observed during the first (intermittent) night. In the period 24 Oct., 700 CDT – 25 Oct., 1700 CDT the model performs well, while during the last (radiative) night u_* is slightly too high until midnight but follows the collapse at the end of the night. The overall bias amounts to $0.03\,\mathrm{ms^{-1}}$ for the last night. Sodar observations show much smaller wind speeds at 200 m AGL (which is above the SBL during this night) than the imposed **G**. This may suggest that **G** was overestimated, and this consequently may explain the bias in u_*. In general it is known that models correctly predict u_* for strong winds, but overestimate u_* for weak winds [25,32].

The sensible heat flux differs substantially between day ($\sim 250\,\mathrm{Wm^{-2}}$ here) and night (between 0 and $-60\,\mathrm{Wm^{-2}}$ depending on the wind speed). In the first (intermittent) night, the modeled $H = -14.1\,\mathrm{Wm^{-2}}$ on average, while –9.1 $\mathrm{Wm^{-2}}$ was observed. However, the model does not simulate the observed intermittent character of the surface fluxes (Fig. 5b). Some models with more resolution [23,36] were also able to reproduce intermittent turbulence. On the other hand, the models by Sharan and Gopalakrishnan [25] and Derbyshire [8] did not show any intermittency. This subject needs further investigation.

Just after the day-night transition to the intermittent night, the observed magnitude of H shows a clear maximum (see arrows in Fig. 5b), which is well reproduced by the model. This maximum is caused by a sudden reversal of the stratification near the surface due to longwave radiation emission during the day-night transition, and is maintained by residual turbulence of the convective boundary layer. This is an often observed *realistic feature* (e. g. during 11 of the 30 nights for CASES-99 and in FIFE observations shown by [6]). However, most model-



Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 5
Modeled and observed (+) friction velocity (a), surface sensible heat flux (b), and surface vegetation temperature (c) for three diurnal cycles in CASES-99 (after [28])

ing studies rarely show these minima. The reproduction of this detailed feature emphasizes the realism of the model outcome.

During the turbulent night (24–25 Oct.), the predicted H follows the observations. The specific minimum during the day-night transition (24 Oct., 1900 CDT) is present here as well. Radiative flux divergence dominates the last (radiative) night and the observed H is approximately zero. The model slightly overestimates the magnitude of H (–2.9 Wm^{-2}), mainly caused by an overestimation of u_*. This causes a weaker stratification and thus a larger magnitude of H. The second half of this night the model gives good results.

Reliable prediction of T_{veg} is a common problem for large-scale models. Some models show unphysical decoupling of the atmosphere from the surface resulting in so-called "runaway cooling" of T_{veg}. On the other hand, the pragmatic enhanced mixing approach which is commonly used for very stable conditions, leads to overestimation of T_{veg}. For both day- and nighttime T_{veg} *is simulated in very good agreement with the data, despite the fact that we cover a broad range of stability* (Fig. 5c).

We conclude that the present model generates surface fluxes which are in good agreement with observations, because of the detail in the description of the surface scheme, the soil heat flux and radiation physics (with high resolution). In general, the model is also able to estimate temperature and wind profiles (see results and discussion in Steeneveld et al. [28]). To examine the robustness of the results, we performed some sensitivity analysis on the initial conditions and model parameters. Disturbing the initial temperature (by 1 K), wind profiles (by 5%), soil temperature and vegetation temperature (both by 1 K) do not affect the results seriously. Also model re-initialization every 24 h (1400 CDT) with observed radiosonde information showed hardly any impact on the results (not shown).

Impact of Land Surface Conditions on Model Results

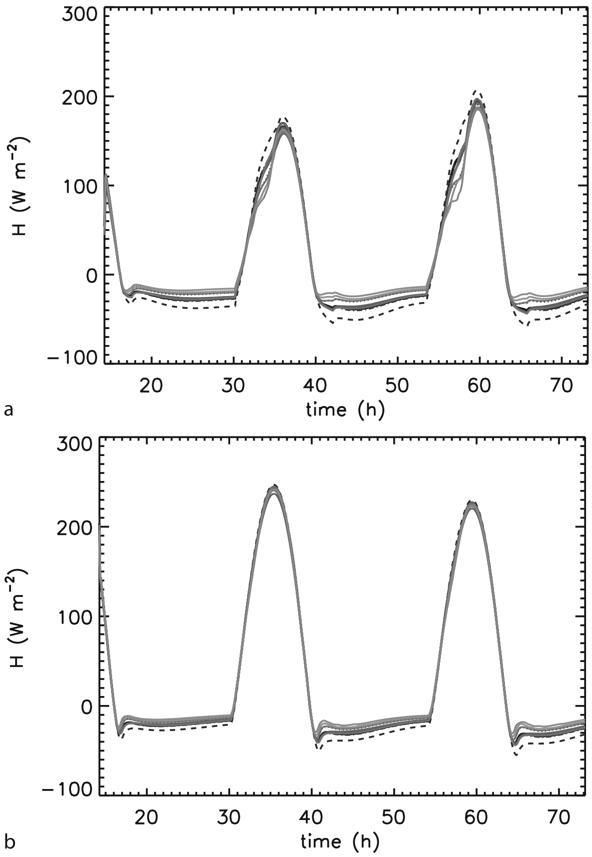
Inspired by the result in the previous section that a coupling with the land surface is necessary to obtain satisfactory model results, we now analyze the difference in variability of model results during model intercomparisons, as function of the chosen boundary condition. At first we use the first-order closure model and vary the parameters in the turbulence scheme for stable conditions in a reasonable range to mimic the apparent variability among boundary-layer models. As such first model runs are performed with a prescribed surface temperature as inspired by (but not identical to) the observations in CASES99 [22] and as described in the GABLS2 case description [31]. Subsequently, the model runs are repeated, but then using an interactive prognostic heat budget equation for the surface temperature (Eq. (14)).

To study the impacts of parameter values on the model results, reference runs are made for coupled and uncoupled cases with alternative permutations in some of the parameter settings for stable conditions. The parameter modifications are chosen such that they cover a realistic range in comparison with existing models of the stable boundary layer [7]. The local starting time in the model runs is 14.00 LT on October 22, 1999 (rather than 16.00 LT in the GABLS2 runs). The duration of all runs is 59 hours (so that the axis of all the figures indicates 14.00 until 73.00 h, covering a period of 2.5 diurnal cycles). In all model runs the roughness length for heat z_{oh} and momentum z_{om} (3 mm and 3 cm respectively), and the canopy resistance are constant, and the geostrophic wind is taken at a reference value of 9.5 ms^{-1} (as in Svensson and Holtslag [31]). The reference model set up has 50 logarithmically distributed layers and the first atmospheric model level is at 2 m.

The model results for all parameter permutations are presented for the sensible heat flux (Fig. 6), In the upper sub-frame of the figure (labeled a) the results achieved with the uncoupled model are given (using prescribed surface temperature). Overall the variety of results in the upper frame is comparable to the variety within the GABLS2 intercomparison study in stable conditions for the uncoupled models (see Svensson and Holtslag [31]). Thus we have a range of –15 to –50 Wm^{-2} for the sensible heat flux (at the end of the first night e. g. at the time of 30 h). The variability is a result of the range of parameters chosen above and the impact is apparently sufficient to mimic the different parameterizations for stable conditions in the models used within GABLS2.

Next we repeat all model runs and allow for surface feedback using Eqs. (13) and (14). The results for the sensible heat flux with the coupled model are given in the lower frame (Fig. 6b). Now we have a range of –10 to –25 Wm^{-2} (again the values apply for the end of the first night e. g. at the time of 30 h). Thus it appears that the variety of model results is *smaller* for the sensible heat flux in the coupled case. At the same time it appears that the variability appears to be somewhat larger for friction velocity and boundary-layer depth, which seems to be related to the larger variability in the near surface air temperature and wind speed.

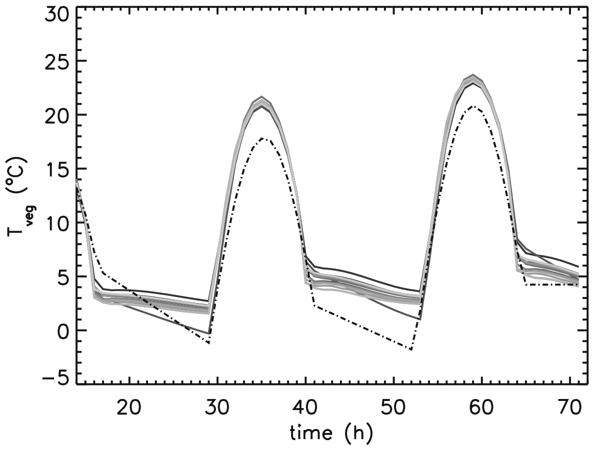
During daytime the sensible heat fluxes are rather similar for all model runs within one category (either coupled or uncoupled), but the maximum values differ. In addition, due to the coupling the sensible heat fluxes show



Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 6
Time series of an ensemble of model results for the sensible heat flux in a model intercomparison study with a prescribed surface temperatures, and b by solving the surface energy budget (after [18])

a more smooth behavior in the morning hours as compared with the uncoupled results. Thus, surface feedback is influencing the model results and is also able to compensate for some variation in the model parameter values. Note also that the variability in the friction velocities of the first night remains during the morning hours in the uncoupled runs, but not so much in the coupled case.

In Fig. 7 the surface temperatures are given as specified for the uncoupled case (the dashed line), and the temperatures as calculated in the various interactive model runs (various gray lines). It is seen that the latter ones are quite different from each other (in particular at night). It is also important to note that the surface temperature by the ensemble of coupled model runs is clearly different from the specified temperature in the uncoupled case. This impacts also on the absolute values and the range of air temperatures and the wind speeds.



Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 7
Time series of an ensemble of modeled surface temperature for coupled runs. *Dash-dotted line*: prescribed surface temperature in the uncoupled case (after [18])

Thus it is apparent that the treatment of the surface temperature impacts strongly on the outcome of the boundary-layer model results and their variety (see also Basu et al. [2]). By repeating the uncoupled model runs with a specified surface temperature as given by the ensemble mean value of the interactive runs, we achieve basically the same variety of model outputs for the potential temperature and wind as for the coupled cases. This confirms that in model evaluation studies the surface temperature should be taken consistent with the value of the geostrophic wind (although this may be model dependent).

Summary

In this paper a summary is given of the basic approaches for the modeling and parameterization of turbulence in the atmospheric boundary layer. The treated approaches are in current use in regional and global-scale models for the forecasting and study of weather, climate and air quality. Here we have shown the results of such approaches by using single column models in comparison with field data and fine-scale model results. We have also studied the impact of the surface temperature condition on the variability of results by an atmospheric boundary-layer model. From the coupled model results we achieve that surface feedback can compensate for some of the variety introduced by changing model parameters. Generally much work needs still to be done before we have a full understanding of the complexity of atmospheric turbulence and the interactions with the land surface. A better understanding of atmospheric turbulence hopefully also contributes to our capability in refining and unifying the turbulence parameterizations for modeling of the atmospheric boundary layer in response to the different type of surfaces which are found in reality.

Acknowledgments

This contribution is a compilation of earlier works by the authors, in particular the works by Holtslag [13], Steeneveld et al. [28] and Holtslag et al. [18].

Article Outline

Glossary

Strombolian activity Is a kind of volcanic activity consisting of discrete, intermittent ejections of gas and magma fragments. The height reached by the ejecta seldom exceeds a few hundred meters above the volcanic crater. They consist mostly of molten magma fragments that partially quench as they fly. Strombolian explosions are intermediate between small Hawaiian eruptions and stronger Plinian eruptions. This kind of activity takes its name from the Stromboli volcano (Southern Italy) famous for its perpetual activity consisting of repeated moderate explosions (usually about 10 every hours).

Gas slug A bubble whose diameter is close to the diameter of the conduit where it is flowing. The shape and the motion of the slug is largely controlled by the conduit walls.

Modeling A simplified representation of a system aimed at reproducing some of its features. Mathematical models describe a system through a set of variables related by analytical relations. When these relations are too complex to be solved exactly, they can be solved using approximate numerical methods. Actually these numerical techniques often involve the massive use of computers. An alternative kind of modeling (analogue modeling) involves the use of versions of the system under study rescaled to fit spatial and temporal laboratory scales. Different materials are used to simulate original ones. For instance silicon oil is often used to simulate magma. The scaling relationships are rigorously stated in order to get physically meaningful results.

Computational fluid dynamics A set of mathematical, numerical and computational tools aimed at simulating complex fluid flows on computers. It developed simultaneously with computer science starting from the 1950s mostly with the aim of solving engineering problems. Today CFD spans a wider range of fields, from aeronautics to chemical engineering, to astrophysics to geophysics and much more. The most recent developments of CFD are related with the increase in computer performances and with the wider use of parallel computers.

Diffuse interface theory A molecular theory for describing the variation of the chemical composition across the interface on the basis of a rigorous thermodynamical approach. Starting from the definition of a free-energy function dependent on the chemical composition and its gradient, it is possible to compute all the chemical-physical properties of the interface. Beyond its physical meaning, this theory can be used also as a numerical tool for modeling of multiphase flows.

Very-long-period events (VLP) Seismic events recorded on active volcanoes and geothermal systems having a typical period of 10^2–10^0 s. Their observation and study began during the 1990s, with the spreading of seismic broadband sensors and have shown to be one of the most powerful tools for investigating the geometries of volcanic conduits and the dynamics of volcanic eruptions. Until now they have been observed in tens of volcanoes with different eruptive styles such as: Aso (Japan), Erebus (Antarctica), Kilauea (Hawaii), Popocatepetl (Mexico), Sakurajima (Japan), Stromboli (Italy).

Moment-tensor Tensor representation of the force systems acting on seismic sources. It can be applied to common earthquake sources (rupturing faults) as well as to volcanic sources (fluid filled conduits). In the former case its trace is null, which from a physical point of view, means that there is no netvolume change during common earthquakes. On the other hand in volcanic sources volumetric variations are very common and furthermore they are accompanied also by a single force component, related to the net acceleration of center of mass of the fluid filling the conduit.

Definition of the Subject

Among the eruptive styles, the Strombolian activity is one of the more easy to study because of its repetitive behavior. For this reason large amount of data can be comfortably collected. Strombolian volcanoes are like natural laboratories repeating the same experiment (individual explosions) many times each day.

The development of quantitative models of eruptive dynamics is driven by the comparison of experimental observations and synthetic data obtained through mathematical, numerical or analogue modeling.

Since Strombolian activity offers a profuse amount of interesting seismic signals, during the last decades there has been growing attention on seismological techniques aimed at retrieving the conduit geometry and the eruption dynamics from the seismological recordings. One of these techniques, the source function inversion, is able to retrieve a summary of the forces acting on the volcanic conduit during the VLP event generation [5]. The comparison of observed source functions with synthetic ones, obtained through numerical modeling, allow us to put constraints on the proposed models.

Quantitative models, able to fit seismological observations, are a powerful tool for interpreting seismic recordings and therefor the seismological monitoring of active volcanoes.

Introduction

In this paper we discuss the mechanism of generation of Very-Long-Period events related to Strombolian explosions. This eruptive style, occurring in many basaltic volcanoes worldwide, is characterized by the ascent and the bursting of large gas slugs. The mechanism of formation, ascent and explosion of bubbles and slugs and their relation to eruptive activity has been studied from a theoretical point of view and by means of analogue simulations. Here we introduce results from numerical simulations, focusing on the pressure variations induced on the conduit walls and responsible for the generation of seismic signals.

We will first illustrate the main features of the fluid dynamics related to Strombolian eruptive activity (Sect. "Slug Flow and Strombolian Activity") and an overview of the numerical modeling (Sect. "Numerical Modeling") Then we will show results obtained using simple conduit model (Sect. "Bubble Ascent", Sect. "Slug Ascent in a Vertical Pipe" and Sect. "Slug Ascent in a Pipe with a Flare") and we will compare the synthetic source functions with actual observations (Sect. "Seismological Constraints on Numerical Models").

Slug Flow and Strombolian Activity

A fundamental distinction can be made between eruptive regimes on the basis of the magma viscosity. In silicic systems, the magma viscosity ($>10^5$ Pa s) is too high to allow an independent motion of gas bubbles [18]. They can only grow by diffusion processes and expand under the effects of pressure variations until fragmentation occurs. In basaltic magmas the viscosity ($<10^3$ Pa s) allows independent motion of the gas bubbles leading to a different behavior with the possibility of bubble coalescence, splitting and turbulent fluid flow [11]. Theoretical laboratory and numerical studies have been published in order to understand the dynamics of Strombolian eruption in terms of gas/magma interaction [12,24].

The distinction between free bubble ascent and slug flow can be made using the ratio between the average bubble diameter d and the conduit diameter D [7]: the parameter λ (Table 1). Values of λ higher than 0.6 are related to slug flow. The range of behavior exhibited by slug flow depends on the physical properties of the fluids (density, viscosity, surface tension) and on the geometry of the conduit (diameter, shape, inclination). It is possible to define adimensional parameters for describing the particular flow regime (see Table 1). The Reynolds number is the ratio between inertial and viscous forces. Low values of Re are typical of laminar flows, while higher values are related to turbulent regimes. The Froude number Fr is the ratio between inertial and gravitational forces. The Eotvos number Eo is the ratio between buoyancy and surface tension effects. The values of Eo determines the bubble shape. High values of Eo are related to distorted bubble shapes, while lower values to sub-spherical shapes. The Morton number Mo has a similar meaning. The dimensionless inverse viscosity N_f assess the relative importance of viscous effects.

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Table 1
Symbols used in the text

Symbol	Meaning
d	Average bubble diameter
D	Conduit diameter
L	Distance between the top of the bubble and the magma/air interface in the initial conditions.
U	Terminal slug velocity
λ	$\lambda = \frac{d}{D}$
g	Gravity
ρ	Liquid density
$\Delta\rho$	Difference between gas and liquid densities
μ	Dynamic viscosity
ν	Kinematic viscosity $\nu = \frac{\mu}{\rho}$
σ	Surface tension
γ	Isothermal expansion ratio
Re	Reynolds number $Re = \frac{Ud}{\nu}$
Fr	Froude number $Fr = \frac{U}{\sqrt{gD}}\sqrt{\frac{\rho}{\Delta\rho}}$
Mo	Morton number $Mo = \frac{g\mu^4\Delta\rho}{\rho^2\sigma^3}$
Eo	Eotvos number $Eo = \frac{\Delta\rho g D^2}{\sigma}$
N_f	Dimensionless inverse viscosity $N_f = \left(\frac{Eo^3}{Mo}\right)^{\frac{1}{4}}$

Viscous flows are characterized by $N_f < 2$ while inertial flows by $N_f > 200$ [9].

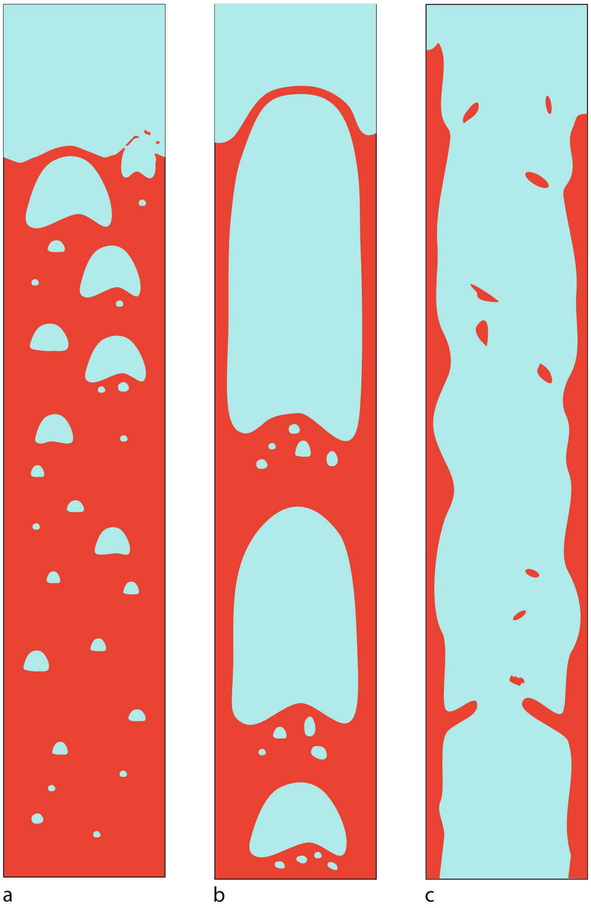
The ascent of gas in a basaltic system has been studied both from a theoretical and an experimental point of view. Observations of basaltic systems have shown that usually the flow conditions are transitional between viscous dominated and inertia dominated systems [17]. This puts constraints on the parameter range to explore both in numerical and analogue modeling. The range of adimensional numbers for basaltic systems, summarized from [17] and [9] is reported in Table 2.

For a basaltic system with given physical properties another variable plays a fundamental role in determining the physics of the flow: the gas/magma volumetric ratio. Flows are characterized by a low ratio consist of isolated bubbles rising with minor interaction between them and the conduit walls (Fig. 1a). In this regime bubbles rise assuming a shape that depends on their size and on the magma viscosity. Surface tension effect depends on the size of the bubbles and the ascent velocity depends on both the bubble size and the magma viscosity. In the range allowed for basaltic systems, larger bubbles have shapes ranging from dimpled ellipsoidal cap to spherical cap, while smaller bubbles have shapes ranging from spherical to ellipsoidal [7]. For higher gas/magma ratios bubbles begin to interact and to coalesce forming gas slugs occupying most of the conduit diameter (Fig. 1b). The ascent of gas slugs is strongly controlled by the conduit walls. During their passage, the magma is completely mixed and the motion of smaller bubbles is dominated by the fluid vorticity released (in a transitional regime) in their wake. For even higher gas/magma ratios (Fig. 1c) the slugs coalesce forming an almost continuous (turbulent) gas flow at the center of the conduit, while walls remains wet with a magma film. The high velocity of the flow produces instabilities on the surface of the magma film pulling out small fragments carried away from the gas.

Bubbly flows are related to effusive and to moderate Hawaiian explosive activity. Each single bubble explodes at the magma/air interface ejecting small magma fragments resulting from the shattering of the liquid film around the bubble. The bubble is usually overpressurized because of surface tension, viscous and inertial effects [23]. Slug flows are related instead to intermittent Strombolian activity.

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Table 2
Range of adimensional numbers for flows related to basaltic systems (from [17] and [9])

Parameter	Range
Fr	$0.1 \div 0.345$
Re	$5 \div 31^3$
Eo	$51^5 \div 71^7$
Mo	$51^5 \div 101^{10}$
N_f	$16 \div 5000$



Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 1
Schematic representation of gas/magma flows in basaltic systems. a represents bubbly flow, b slug flow and c annular flow

Each slug exploding at the magma/air interface generates a jet of gas of short duration (from a few seconds to some tens of seconds) [24]. The main Strombolian explosion can be followed by minor bursts caused by the smaller bubbles trapped behind the slug wake. Annular flows are related to continuous lava fountains with the central gas jet carrying molten magma fragments [11].

The nature of the flow can change along the conduit because of the gas expansion due to the magmastatic pressure decrease. This expansion makes the gas/magma volumetric ratio increase along the conduit. At the base of the conduit, where the gas starts to exolve from the magma there is always a bubbly flow. As the pressure decreases the flow can change into slug flow. This can be made easier by an inclined conduit [4] and by constrictions [12] that force the bubbles to coalesce even at lower gas/magma ratios than those required in a straight vertical conduit. The total gas flow can change in the conduit because of variations in the deep feeding system or because of non-linear instabilities due to the complex shape of the conduit system [11,12].

The expansion of bubbles and slugs is a fundamental factor to take into account when studying Strombolian activity [17]. Assuming a simple ideal isothermal state equation for the gas we get the relative volumetric change for a bubble rising in a magma with density ρ:

$$\frac{V_0}{V} = \frac{P_{\text{atm}} + \rho g h}{P_{\text{atm}}} \,. \qquad (1)$$

It is easy to show that the expansion ratio in the upper few hundreds of meters is more than one order of magnitude.

The flow regime can change also horizontally, for instance in a subvertical dike the flow rate can be higher on one side, leading to a slug flow, and lower on the other side, leading to a bubbly flow. This explains the coexistence of effusive and Strombolian activity observed during some basaltic eruptions.

Numerical Modeling

The aim of this work is to investigate the pressure variations induced by a gas bubble rising in a magma-filled volcanic conduit. This phenomenon has been also investigated by means of analogue laboratory models [9,10, 12,17].

The major drawback of analogue modeling, in this context, is that it provides only a limited number of pressure time series: one for each sensor. Numerical modeling provides a different point of view giving the full set of scalar (density), vector (velocity) and tensor (pressure) quantities over the whole computational domain. This allows quantitative inferences on the flow regimes and on the elastodynamic wavefield generated (see Sect. "Seismological Constraints on Numerical Models").

The modeling of two-phase systems as gas magma is not a simple task in computational fluid dynamics (CFD) [6]. Taking into account surface tension effects at the liquid-gas interface can be done in two different ways. The first consists in explicitly tracking the time evolution of the gas-liquid interface [22]. In situations involving complex flows with extensive occurrences of bubble coalescence and splitting, these methods show a rapid increase in computational effort. Another category of methods model the gas-liquid systems using the diffuse-interface theory. These methods consider two scalar fields, defining the relative local concentrations of the two components and a modified advection-diffusion equation for

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Table 3
Description and adimensional numbers for the six simulations presented in the text

Sim.	Description	Comp. domain (pts.)	λ	γ	*Re*	log(*Mo*)	*Eo*	*Fr*	N_f

3A	Slug ascent in vertical pipe with a flare (low viscosity)	60 × 600	0.8	5.3	1.83×10^3	0	9×10^4	0.35	5.19×10^3
3B	Slug ascent in vertical pipe with a flare (high viscosity)	60 × 600	0.8	5.3	1.68×10^2	4	9×10^4	0.32	5.19×10^2

modeling the physical-chemical interaction between them. This is done using a thermodynamically consistent definition of a free-energy function that takes into account the phase equilibria. This approach leads to smooth interfaces where the concentration of one phase gradually decreases while the other increases. The thickness of these interfaces depends on the numerical method and on the surface tension value [25]. From a numerical point of view this problem can be faced using Lattice Boltzmann Methods (LBM) [20] or by classic CFD [6]. Here we use the latter. Some details about the numerical method are reported in the Appendices.

In our models we have not considered the mechanical interaction between the fluid phases and the elastic conduit walls. The exchange of linear momentum between them is a significant factor in the generation of seismic waves [3] in seismo-volcanic sources. However in conduits having ratios between the linear dimension and thickness lower than 10^1–10^2 the effect of the motion of the conduit walls does not affect significantly the fluid flow. Furthermore we show in Sect. "Seismological Constraints on Numerical Models" that we will not compare the result of the simulation directly with seismograms, but with an equivalent system of forces acting on the conduit walls.

In the following we present results of some elementary two-dimensional conduit models focusing on the slug flow regime which occurs during Strombolian activity. The numerical simulations generate snapshots of the physical quantities (composition, density, pressure and velocity) along all the point of the discretized computational domain. The effective computational domains for each simulation are showed in Table 3. In all the simulations we start from a static fluid with a bubble in the lower part of the conduit and a gas/magma interface in the upper part. The boundary conditions keeps a constant pressure value at the bottom and the top of the model. The no-slip boundary conditions are implemented along the conduit walls.

The adimensional numbers for each simulation are reported in Table 3. Velocities for determining *Re* and *Fr* are computed when the bubble/slug is moving in a steady state after a transient due to the initial conditions. These velocity values U are also used for normalizing times:

$$t^* = t \frac{U}{L} , \tag{2}$$

where L is the distance between the top of the bubble and the magma/air interface. So (2) represents a normalization for the virtual time the bubble needs to reach the surface in an ideal steady motion. We can also normalize distances:

$$x^* = x \frac{1}{D} , \tag{3}$$

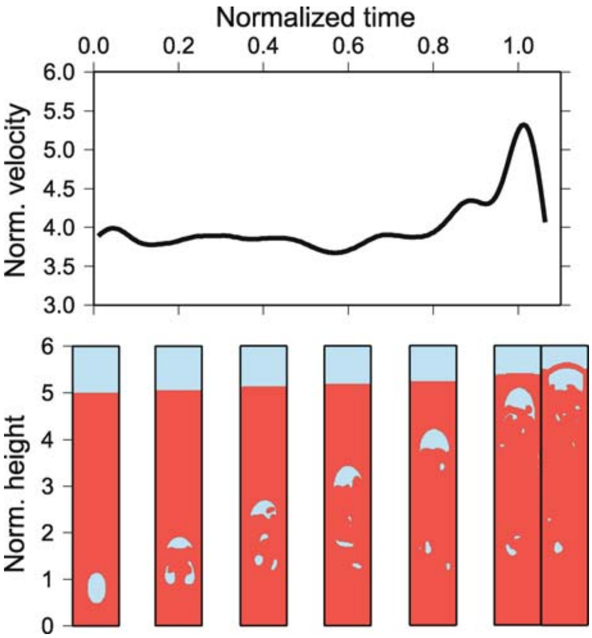
where D is the conduit diameter. We can define then normalized velocities as:

$$v^* = \frac{\partial x^*}{\partial t^*} . \tag{4}$$

In our simulations we have also defined an isothermal expansion ratio γ which is the ratio between the bubble volume at the initial conditions and its volume at (simulated) atmospheric pressure.

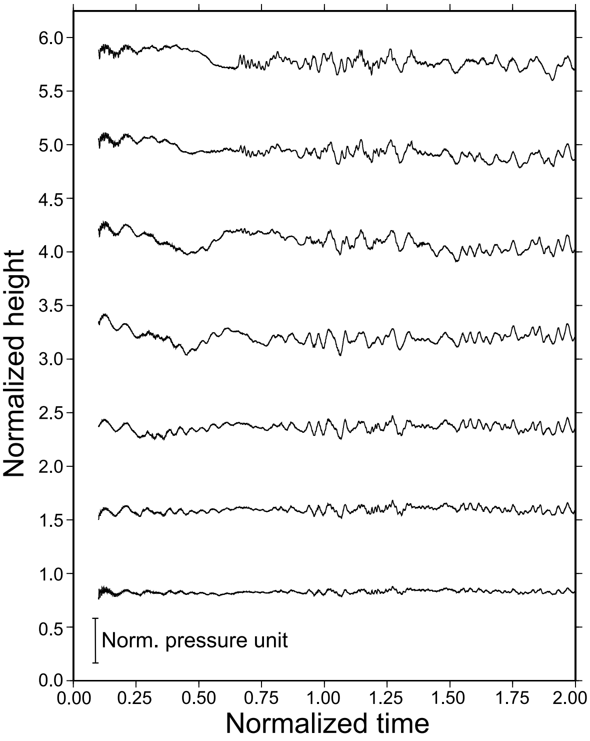
Bubble Ascent

We first consider the ascent of a single bubble in a vertical conduit. In the first simulation (1A in Table 3) the initial shape of the bubble is an ellipse (see Fig. 2). As the simulation evolves the bubble becomes unstable splitting into three smaller bubbles. The two smaller lateral bubbles are embedded in a symmetric vortex structure. As the flow



Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 2

Ascent and bursting of a gas bubble (simulation 1A in Table 3). Time, height and velocity are normalized according to (2), (3) and (4)



Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 3

Time series of pressure variations for simulation 1A. The represented pressure values are normalized by the external atmospheric pressure P_0. Each time series represents the recording of a virtual sensor located at the center of the conduit at the height of its first point (see *scale on the left*)

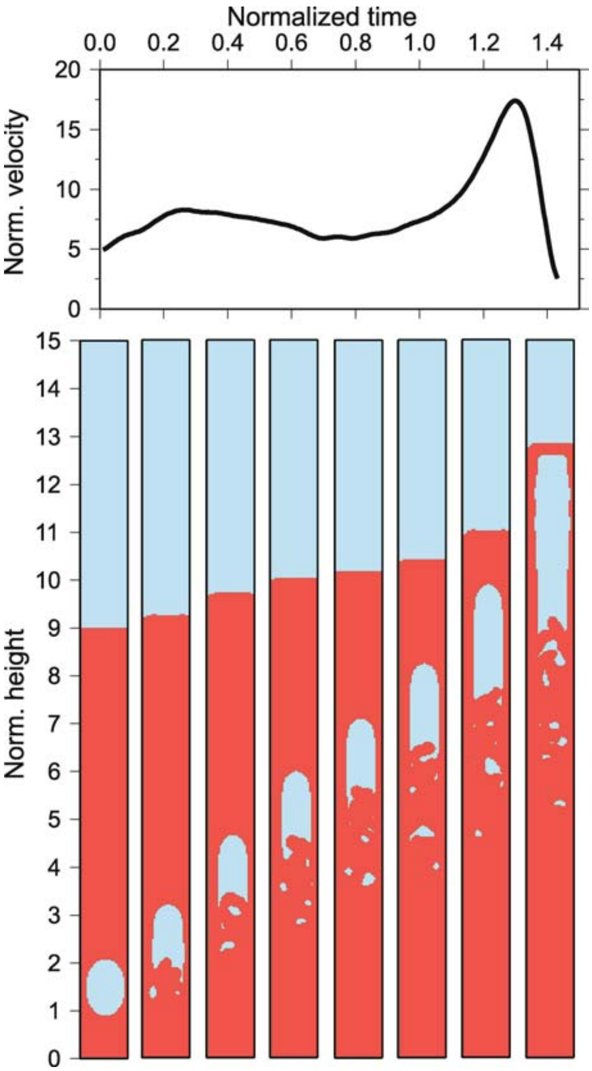
evolves the symmetry is broken and a turbulent wake develops behind the largest bubble. This one rises with an almost steady velocity (Fig. 2 top) with a spherical cap shape. In the final part of the simulation, the bubble suffers an expansion that made the bubble accelerate ($t > 0.8$) and causes the flow to become transitional toward the slug flow regime. Then the bubble reaches the surface and a curved liquid film develops above the bubble just before bursting. This phase is accompanied by a sudden deceleration of the bubble ascent ($t > 1.0$). The pressure variations in the conduit are modest, with a lack of low frequency oscillations. Also the pressure transients generated by the bubble burst are limited (Fig. 3).

The adimensional number for this simulation (Table 3) is in a range related to transitional flow regimes typical of basaltic systems [9,17]. An increase of an order of magnitude of the viscosity (1B in Table 3) makes the flow still in the transitional regime (Table 3). The high values of the Eotvos number indicates that the surface tension effect is not relevant in the flow dynamics [7] in both cases.

Slug Ascent in a Vertical Pipe

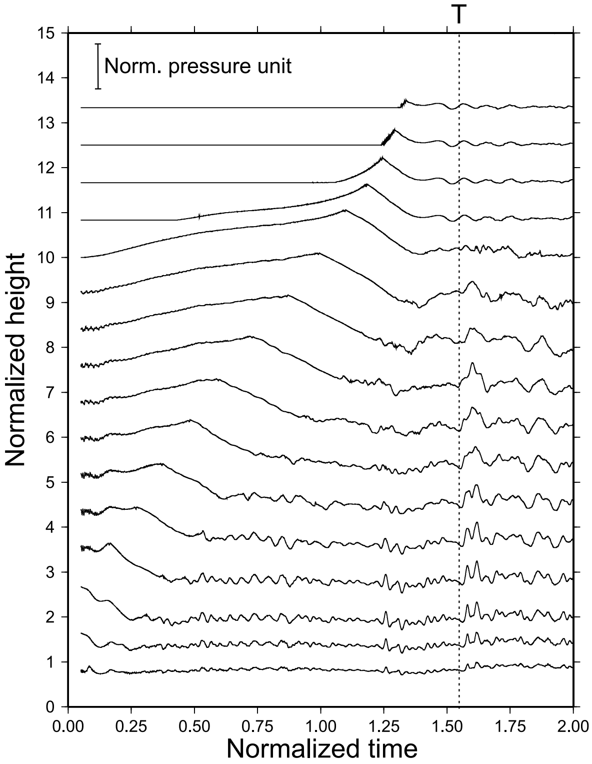
In these simulations (2A and 2B in Table 3) we model the ascent of a single slug in a vertical pipe. Again we start from an elliptical shape of the bubble. After an initial transient the typical slug shape develops (Fig. 4) and a turbulent wake appears behind the slug. As the slug rises it suffers a volume expansion. In the slug flow regime the liquid is pushed upward causing an overall increase of the hydrostatic pressure in the conduit. After the bursting of the slug the liquid film on the wall falls down to the original hydrostatic level. The slug expansion causes a significant acceleration of the liquid for $t > 1.0$ (Fig. 4). The velocity drops as the slug reaches the bursting point and the liquid film develops.

The major feature in the pressure pattern is the slow ramp-like increase followed by a drop (Fig. 5). The increase reflects the rise of the hydrostatic head above the slug while the gradual decrease is related to the passage of the slug. The bursting of the slug generates a moderate pressure transient in the conduit (marker “T” in Fig. 5) and damped resonant oscillations in the uppermost part of the pipe, filled with gas (above norm. height 11 in Fig. 5).



Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 4

Ascent and bursting of a single gas slug in a straight pipe (simulation 2A in Table 3)



Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 5

Time series of pressure variations for simulation 2A. *T* marks the most significant transient in the pressure patterns

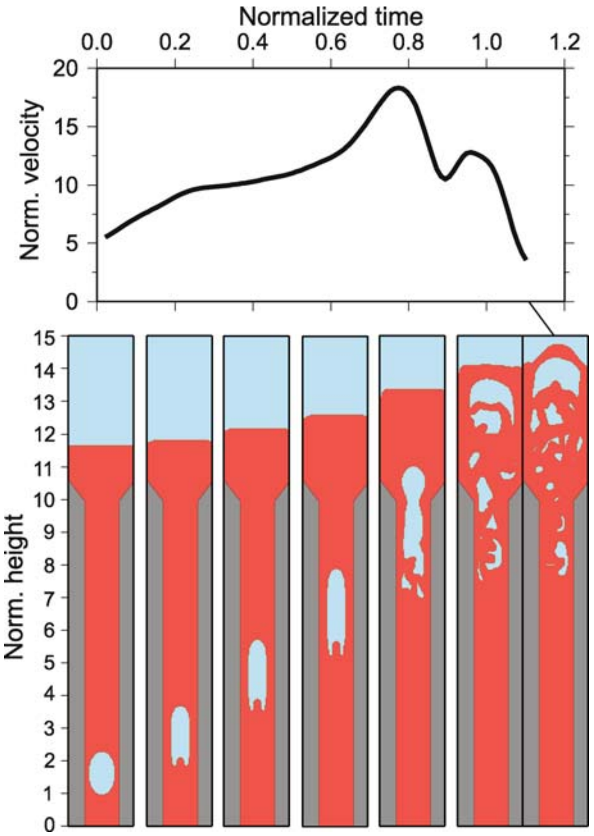
The simulated pressure pattern fits very well the observations of analogue modeling [9]. Both the pressure increase linked to the rise of the hydrostatic head and the pressure drop related to the passage of the slug are in good agreement. Together with these long period variations they observe also oscillatory pressure transients just before the slug approaches the surface and after the bursting. The simulations presented here lack this feature because of an intrinsic limit in the numerical method that does not model explicitly the interface (see Appendix).

The overall behavior of simulation 2B, where a tenfold increase of the liquid viscosity (Table 3) is very similar to 2A. The only remarkable difference is the lack of high frequency oscillations in the pressure (as the transient "T" in Fig. 5) due to the greater viscous damping effect.

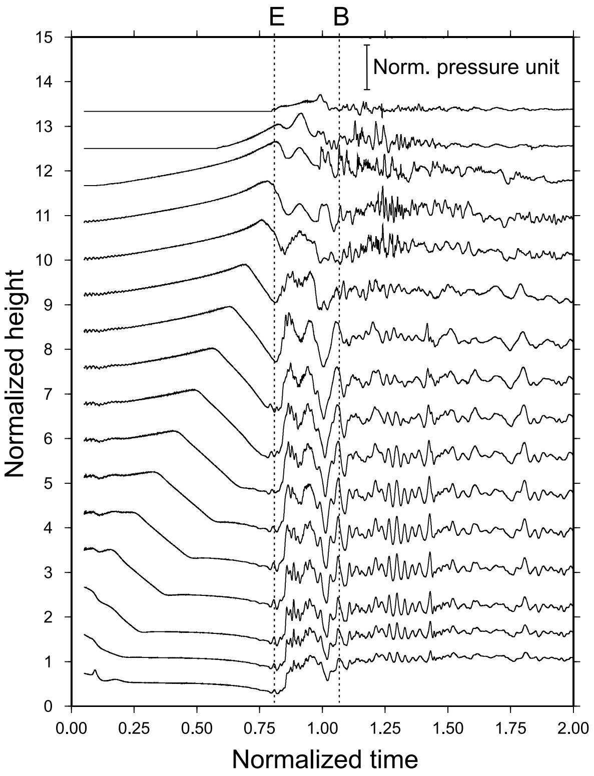
Slug Ascent in a Pipe with a Flare

In this set of simulations (3A and 3B in Table 3) we model again the ascent of a single slug in a pipe. However in this case the width of the pipe doubles after a norm. height of 10. In the first part of the simulation, the behavior is similar to the one illustrated in Sect. "Slug Ascent in a Vertical Pipe". As the slug nose enters in the flare (Fig. 6) is starts to expand rapidly making the fluid accelerate upward. The expansion of the slug in the flare is followed by its breakup because of the development of strong turbulence. The velocity of the top of the slug increases until the slug passes through the flare then it drops because of the change in the conduit diameter.

The pressure pattern shows a major difference, compared with simulation 2A (Fig. 7). As the slug passes through the flare there is a sudden pressure increase



Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 6
Ascent and bursting of a single gas slug in a pipe with a flare (simulation 3A in Table 3)



Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 7
Time series of pressure variations for simulation 3A. *E* marks the entering of the slug in the upper conduit while *B* marks the bursting of the main bubble at the magma surface

recorded along the whole conduit. The pressure then drops when the slug expansion has terminated. This strong pressure pulse is clearly related to the varying fluid flow regime as the slug enters the upper conduit and it deserves a closer analysis. In Fig. 8 we have represented the fluid dynamic regime during the slug expansion together with the related pressure variations. We observe that the pressure rises when most of the slug has passed through the flare. The strong acceleration induces turbulence both in the lower and the upper sections of the conduit. The upward acceleration first causes the disruption of the lower part of the slug leaving behind the main bubble a set of smaller ones, whose motion is driven by the fluid turbulence. When the slug has entered in the upper conduit it suffers another splitting due both to the induced vorticity and to the change in the boundary conditions. The behavior of the slug for $t^* > 0.8$ is characterized by a flow regime with a smaller value of λ and so it is similar to the initial part ($t^* < 0.2$) of simulation 1A.

Similar fluid dynamics behavior and pressure patterns have been observed in analogue simulations by [10]. In particular, the breakup of the slug and the generation of a positive pressure pulse as it passes through the flare are observed in analogue models within a wide range of fluid viscosities and conduit widenings.

As in the previous case the simulation with higher liquid viscosity (3B in Table 3) shows a similar behavior. Higher viscosities reduce the fluid vorticity leading to less fragmented slugs.

Seismological Constraints on Numerical Models

Seismological data analysis is a powerful tool for putting constraints on the geometry and the dynamics of volcanic systems. Non-stationary fluid flow in volcanic conduits generates pressure variations on the conduit walls and then seismic waves propagating toward the Earth's surface where they are recorded by seismometers. The frequency band of seismic signals recorded in volcanic ar-

Detail of the conduit during the slug expansion phase. Each snapshot represents the normalized pressure variations (see the *color scale* on the bottom) and the local fluid velocity vectors. The *thick contours* are the bubble interfaces. The pressure values represented above are measured at the virtual sensor indicated by a *black star* in the snapshots

eas spans a wide range: from the Ultra-Long-Period (ULP) band ($>10^2$)s, the Very-Long-Period (VLP) band (10^2–10^0 s) and the Long-Period (LP) band (10^0–10^1 s) [5].

From a formal point of view this can be expressed considering the elastodynamic field generated by a general extended source, whose external surface is Σ:

$$u_n(\mathbf{x}, t) = \iint_\Sigma [f_q * G_{np} + m_{pq} * G_{np,q}] \mathrm{d}\Sigma \,, \quad (5)$$

where $u_n(\mathbf{x}, t)$ is the nth component of the ground displacement recorded at the position $\mathbf{x}$, f_q is the body-force distribution over Σ, m_{pq} is the moment density tensor and G_{np} are the Green's functions. In (5) we take into account all the details of the source dynamics. However the density of actual seismic networks is not sufficient for retrieving every minor feature of the seismic sources. Volcano monitoring networks usually have a limited extension (10^3–10^4 m) and the wavelengths associated with ULP and VLP signals are higher. Therefore the analysis of such signals the seismic source (i. e. the part of the volcanic conduit responsible of seismic wave generation) can be represented as a point [5]. Under the assumption of a point source we can express (5) as [5]:

$$u_n(\mathbf{x}, t) = F_q * G_{np} + M_{pq} * G_{np,q} \,, \quad (6)$$

where:

$$F_q = \iint_\Sigma f_q \mathrm{d}\Sigma \quad (7)$$

and:

$$M_{pq} = \iint_\Sigma m_{pq} \mathrm{d}\Sigma \,. \quad (8)$$

In common earthquake sources the single force component F_q is null. In volcanic sources, the acceleration of the center of mass of the fluid makes this component noteworthy.

The inversion of the recorder waveforms $\mathbf{u}(\mathbf{x}, t)$, after the numerical computation of the Green's functions $\mathbf{G}$ allows the retrieval of the single force and moment tensor components of (6) [14]. **F** and **M** are a synthesis of the force systems acting on volcanic conduits and then can be used for discriminating among numerical models on the basis of their fit with observations.

Numerical simulations provide the pressure tensor field **P** over the whole computational domain. The pressure tensor can be used for computing the forces acting on each point of the conduit walls multiplying it for the unit vector normal to the wall $\hat{\mathbf{n}}$:

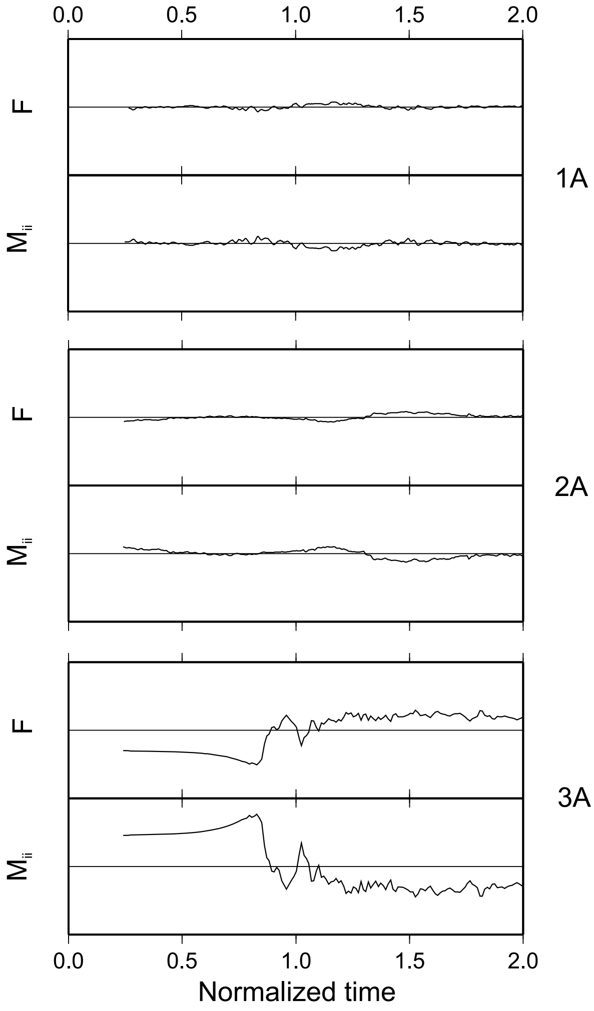
$$\mathbf{f} = \mathbf{P}\hat{\mathbf{n}} \,. \quad (9)$$

These values can be integrated numerically using an expression similar to (7) to get the single force component **F**. Then using the definition of moment they can be used for retrieving also the equivalent moment tensor:

$$M_{pq} = \iint_\Sigma \left(f_q - \frac{F_q}{\Sigma} \right) r_p \mathrm{d}\Sigma \,, \quad (10)$$

where **r** is the arm formed by the force respect to an arbitrary origin **O**.

In Fig. 9 we have represented the vertical force component and the moment tensor isotropic component (that is the trace $M_{xx} + M_{zz}$) for the three simulations with lower liquid viscosity. The represented values are normalized.



Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 9
Vertical force and isotropic component for simulations 1A, 2A and 3A of the moment tensor for simulations 1A, 2A and 3A (see Table 3)

In the first case (1A) we note the absence of significant signals. There are only minor oscillations related to fluid dynamics instability during the bubble ascent. The rise of a bubble smaller than the conduit dimension seems not to be able to generate VLP signals. Therefore a repetitive bursting of small bubbles at the magma/air interface can be responsible for the generation of continuous infrasonic and seismic tremor recorded in some basaltic volcanoes [16].

In the second case, again, the signal amplitudes are quite low. It is evident that there is an anticorrelation between the vertical force and the isotropic moment. The vertical acceleration of the slug ($1.0 < t^* < 1.3$ in Fig. 4) causes a downward reaction force as well as an increase in the conduit pressure. The bursting ($t^* > 1.3$) causes a downward acceleration of the liquid and a pressure decrease. A similar effect, although with a minor magnitude, is also evident in 1A (Fig. 9).

In the third case the signal amplitude increases dramatically, about five times higher than 2A. The slug entering in the upper, wider portion of the conduit is marked by a downward force and a positive moment. At the end of the expansion phase ($t^* > 0.8$) there is a sudden inversion of the trends in both quantities, followed again by a positive downward peak of the force and positive of the momentum ($1.0 < t^* < 1.1$). This peak occurs when two pieces of the original slug coalesce again (Fig. 8) leading to a sudden, but limited in time, upward acceleration. In real cases the dynamics can be even more complex with multiple slugs or slug fragments entering in the upper conduit and interacting with each other. In this case during the main expansion phase, the lower conduit is filled almost exclusively with liquid (Fig. 6). If we suppose the simultaneous presence of many vertically aligned slugs in the lower conduit, then the pressure variations induced by the expansion of the topmost one would influence the lower ones in a complex non-linear mechanism still to investigate.

The signals presented in Fig. 9 need to be scaled to an actual time scale to be compared with real seismic signals source functions. In basaltic volcanoes the dimensions of the upper conduit is of the order of 10^2 m while the ascent velocities of the slugs are of the order of 10^0–10^1 m/s. This gives a scaling factor of about 10^1–10^2 *s*. Since the simulated transients have a normalized duration of about 10^{-1} the actual simulated signals should have a characteristic period of 10^0–10^1 *s*. These values are within the range of VLP and LP signals [5].

The patterns observed in simulation 3A (Fig. 9) closely matches the results obtained by [4] for the source function of VLP events at the Stromboli volcano. Thus this result, together with analogue simulations [10], strongly supports the hypothesis that VLP events at Stromboli are generated by the passage of a gas slug through a conduit widening and its subsequent expansion and bursting. The long ramp-like signals in both force and moment for $t^* < 0.8$ in Fig. 9 has a characteristic period longer than the VLP signals recorded and analyzed by [4]. Recordings at Stromboli, using a seismic sensor with a wider frequency range [13] interestingly suggested in some seismic signals a similar ramp having a length of more than 60 *s*, compatible with our scaling. This long ramp is related to the slow and gradual increase in the magmastatic head due to the continuous expansion of the ascending slug.

Conclusions

The rapid expansion of the gas slugs in the uppermost part of the conduit plays a fundamental role, both in the eruptive dynamics and the seismic wave generation process. We have focused on the role of conduit geometry in the fluid dynamics of gas slug ascent and its implication in the generation of seismic signals. In one of the simulations (3A) we have shown that the system of forces acting on the conduit is able to generate seismic waves with a higher efficiency compared with other cases. This observation can be generalized to more complex geometry such as an alternating of widening and narrowing [10]. The passage of slugs can occur also in very complex conduits [17]. In this case it is possible that pressure transients are generated in different positions along the conduit.

Future Directions

A deeper understanding of the relationship between slug ascent dynamics and seismic signals generation would require more advanced modeling techniques in various three-dimensional geometries, testing how the effect of changes in slug volumes and magma properties can affect the generation of seismic signals.

These studies are an important step toward more advanced seismic monitoring techniques of active basaltic volcanoes aimed at assigning in real time a volcanological meaning to variations in observed LP and VLP seismic signals.

Appendix A – Fluid Dynamics of a Two-Phase System

Definition of a Two-Phase System

A fluid two-phase system can be described using two scalar fields n_a and n_b, representing the local molar densities of the two components a and b. The actual local density ρ is then:

$$\rho = m_\mathrm{a} n_\mathrm{a} + m_\mathrm{b} n_\mathrm{b} \,, \tag{11}$$

where m_a and m_b are the molecular weight of the two phases. As it will be shown in the following, it is convenient to describe the system using an alternative representation based on the variables:

$$n = n_\mathrm{a} + n_\mathrm{b} \,, \tag{12}$$

and

$$\phi = n_\mathrm{a} - n_\mathrm{b} \,. \tag{13}$$

ϕ defines the local composition of the fluid. It can span the range $[-n, +n]$ with the value $-n$ representing a pure b composition and $+n$ a pure a composition. The relation between n, ϕ and ρ is:

$$\rho = \tfrac{1}{2}\left[m_\mathrm{a}(n+\phi) + m_\mathrm{b}(n-\phi)\right] \,. \tag{14}$$

The values of m_a and m_b are set so that in reference conditions the value of n is always equal to 1. So for instance, if we consider pure water at ambient conditions $m_\mathrm{w} = 1000$ kg/mol.

State Equation

We assume that pure phases obey to a simple isothermal ideal gas state equation like:

$$P = \rho c^2 \,, \tag{15}$$

where P is the pressure and c is the sound speed. We assume that the pressure is zero in the reference state, so the state equation for the component a is:

$$P = m_\mathrm{a}(n-1)\,c_\mathrm{a}^2 \,. \tag{16}$$

A similar relation holds for b. Since along interfaces the composition varies continuously, we should define a state equation for a mixture that satisfies two requirements: the state equation for pure phases must match (16) and the isobaric contours in the (ϕ, n) plane must be straight lines. This second requirement follows from the consideration that diffusion processes between the components follows straight paths in this domain. In most of the actual Lattice Boltzmann literature, this question is not issued because the proposed implementations are almost isobaric $(n \simeq 1)$ [21,25,26]. A suitable choice for the state equation is then:

$$P(n,\phi) = \frac{1}{4}\left[\Lambda + \sqrt{16 m_\mathrm{a} m_\mathrm{b} c_\mathrm{a}^2 c_\mathrm{b}^2 (n-1) + \Lambda^2}\right] \tag{17}$$

with:

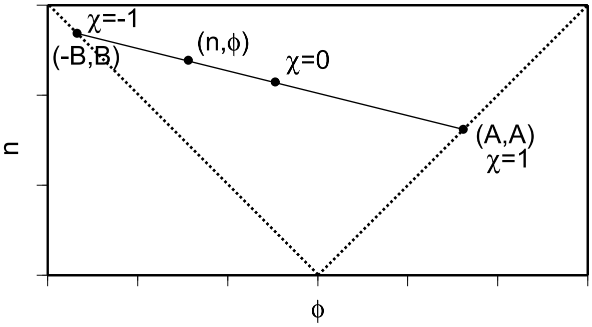
$$\Lambda = m_\mathrm{a} c_\mathrm{a}^2 (n+\phi-2) + m_\mathrm{b} c_\mathrm{b}^2 (n-\phi-2) \,. \tag{18}$$

In Fig. 11 an example contour plot of isobaric lines is shown. We can define another parameter χ as:

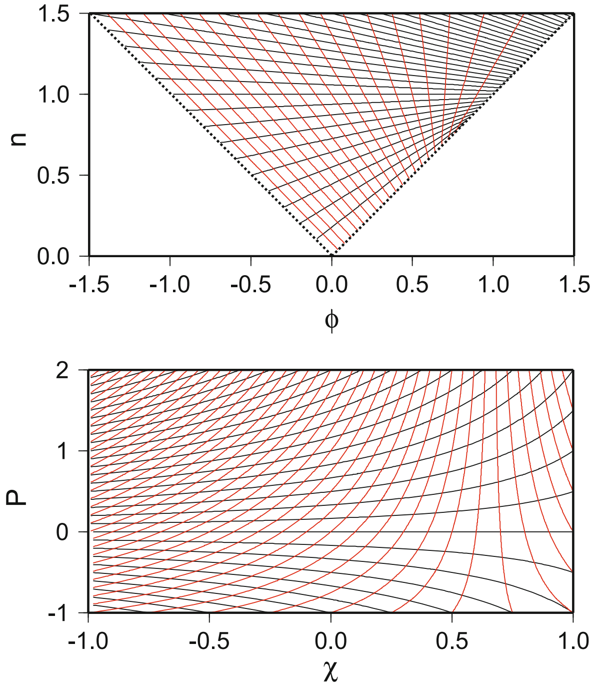
$$\chi(n,\phi) = -1 + 2\sqrt{\frac{(\phi+B)^2 + (n-B)^2}{(A+B)^2 + (A-B)^2}} \,, \tag{19}$$

where:

$$A = \frac{P(n,\phi)}{m_\mathrm{a} c_\mathrm{a}^2} + 1 \,, \tag{20}$$



Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 10
Definition of χ. See text for details



Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 11
In the upper panel, isolines of χ (*red lines*) and P (*black lines*) are represented in the (n, ϕ) domain. In the lower panel isolines of n (*black lines*) and ϕ (*red lines*) are represented in the (χ, P) domain. These plots represent a two-phase system where $m_a c_a^2 = 5$ and $m_b c_b^2 = 1$

and

$$B = \frac{P(n, \phi)}{m_b c_b^2} + 1 \,. \tag{21}$$

The actual meaning of χ is shown in Fig. 10. It is the rescaled ratio of the distance between the points (ϕ, n) and $(-B, B)$ and the distance between the points (A, A) and $(-B, B)$. So $\chi = -1$ along the line $\phi = -n$ and $\chi = 1$ along $\phi = n$. In practice χ is related to the local composition of the fluid. In Fig. 10 the relation between ϕ, n, P and χ is represented. This relation can be inverted and the system (χ, P) can be used as well as the (ϕ, n) coordinate system. In the following we show that the former is the best choice for describing chemical equilibria.

Chemical Equilibria and the Diffuse Interface Theory

The chemical equilibrium between the two phases can be described using a physically consistent thermodynamic approach [2,8,26]. We define a Ginzburg–Landau free energy functional for an heterogeneous mixture as [15]:

$$\mathcal{F} = \int \left[\psi(n, \phi) + \frac{\kappa_n}{2} (\nabla n)^2 + \frac{\kappa_\phi}{2} (\nabla \phi)^2 \right] \mathrm{d}V \,, \tag{22}$$

where κ_n and κ_ϕ are parameters related to the surface tension. The system reaches its final thermodynamical equilibrium making the free energy minimum.

We can rewrite (22) in the (χ, P) representation:

$$\mathcal{F} = \int \left[\psi(\chi, P) + \frac{\kappa_\chi}{2} (\nabla \chi)^2 \right] \mathrm{d}V \,. \tag{23}$$

Note that we have set $\kappa_P = 0$. This implies that surface tension effects are independent of the absolute pressure. In this paper we set:

$$\psi(\chi, P) = \alpha \left(\frac{\chi^4}{4} - \frac{\chi^2}{2} \right) + P \ln \frac{P}{P_0} \,, \tag{24}$$

where P_0 is an arbitrary reference pressure value. Using this definition of ψ we note that this function has two minima for $\chi = \pm 1$, corresponding to the two equilibrium compositions. Starting from an heterogeneous mixture, the system evolves by creating domains having a quite homogeneous composition separated by interfaces where the composition varies smoothly. The equilibrium is reached when the chemical potential:

$$\mu = \frac{\delta \mathcal{F}}{\delta \chi} \,, \tag{25}$$

is everywhere equal to zero [2,26]. So, in our case, using (23) and (24) we obtain the condition of chemical equilibrium for a plane interface orthogonal to the x-direction:

$$\mu = \frac{\partial \psi}{\partial \chi} - \kappa_\chi \frac{\partial^2 \chi}{\partial x^2} \,. \tag{26}$$

Assuming the boundary conditions $\psi(x) = 0$ and $\frac{\partial \chi}{\partial x} = 0$ for $x = \pm\infty$ and $\chi(0) = 0$, the previous ODE can be integrated giving the expression of the spatial variation of the composition through an equilibrium interface:

$$\chi(x) = \tanh\left(\frac{2x}{\xi}\right), \tag{27}$$

where the interface thickness ξ is the width where the 96% of variation occurs. Its value is:

$$\xi = 2\sqrt{-\frac{2\kappa_\chi}{\alpha}}. \tag{28}$$

On the basis of the definition of surface tension σ [25]:

$$\sigma = \int_{-\infty}^{+\infty} \mathcal{F}(x)\,\mathrm{d}x, \tag{29}$$

we can write:

$$\sigma = \frac{2}{3}\sqrt{-2\alpha\kappa_\chi}. \tag{30}$$

Using (28) and (30) we can also retrieve useful inverse relations:

$$\alpha = 3\frac{\sigma}{\xi}, \tag{31}$$

and

$$\kappa_\chi = \frac{3}{8}\sigma\xi. \tag{32}$$

We should emphasize that in real physical systems expression (27) describes an actual interface having a thickness whose order of magnitude is of molecular scale. In this work we use the diffuse interface theory as a numerical tool for modeling of two-phase systems. In other words, we use unphysical interfaces having a macroscopic thickness (usually $10^{-3} \div 10^{-1} m$).

Cahn–Hilliard and Mass Conservation Equations

The time evolution under non-equilibrium conditions can be expressed by two Cahn–Hilliard equations [2,26]:

$$\frac{\mathrm{D}n}{\mathrm{D}t} = \Gamma\nabla^2\mu_n, \tag{33}$$

$$\frac{\mathrm{D}\phi}{\mathrm{D}t} = \Gamma\nabla^2\mu_\phi. \tag{34}$$

These equations are similar to common advection-diffusion equations with Γ being a diffusion coefficient and the operator $\mathrm{D}/\mathrm{D}t$ the substantial derivative. The explicit expressions for the chemical potentials μ_n and μ_ϕ are:

$$\mu_n = \frac{\delta\mathcal{F}}{\delta n} = \frac{\delta\mathcal{F}}{\delta\chi}\frac{\partial\chi}{\partial n} = \mu_\chi\frac{\partial\chi}{\partial n}, \tag{35}$$

$$\mu_\phi = \frac{\delta\mathcal{F}}{\delta\phi} = \frac{\delta\mathcal{F}}{\delta\chi}\frac{\partial\chi}{\partial\phi} = \mu_\chi\frac{\partial\chi}{\partial\phi}. \tag{36}$$

with:

$$\mu_\chi = \frac{\delta\mathcal{F}}{\delta\chi} = \alpha\chi(\chi^2-1) - \kappa_\chi\nabla^2\chi. \tag{37}$$

Then the Cahn–Hilliard Eqs. (33) and (34) can be rewritten as:

$$\frac{\mathrm{D}}{\mathrm{D}t}\begin{pmatrix} n \\ \phi \end{pmatrix} = \Gamma\nabla^2\mu_\chi\begin{pmatrix} \frac{\partial\chi}{\partial n} \\ \frac{\partial\chi}{\partial\phi} \end{pmatrix} \tag{38}$$

On the basis of the definitions of n (12) and ϕ (13), we can state that the previous equation expresses the mass transfer of components a and b because of chemical disequilibria. Since we are dealing with a compressible flow, we should obviously account for this in the mass balances. Then, following basic fluid dynamics [1], we can rewrite (38) in explicit form as:

$$\frac{\partial n}{\partial t} = -\mathbf{v}\nabla n - n\nabla\cdot\mathbf{v} + \frac{\partial\chi}{\partial n}\Gamma\nabla^2\mu_\chi \tag{39}$$

$$\frac{\partial\phi}{\partial t} = -\mathbf{v}\nabla\phi - \phi\nabla\cdot\mathbf{v} + \frac{\partial\chi}{\partial\phi}\Gamma\nabla^2\mu_\chi. \tag{40}$$

Thermodynamic Pressure Tensor

It can be shown, from statistical mechanics that the pressure tensor can be obtained from (23) [8,15]:

$$P_{ij}^{th} = p_0\delta_{ij} + \kappa_\chi\frac{\partial\chi}{\partial x_i}\frac{\partial\chi}{\partial x_j}, \tag{41}$$

where the isotropic component is:

$$p_0 = P\frac{\delta\mathcal{F}}{\delta P} + \chi\frac{\delta\mathcal{F}}{\delta\chi} - \left(\psi(\chi,P) + \frac{\kappa_\chi}{2}(\nabla\chi)^2\right). \tag{42}$$

so:

$$p_0 = P + \alpha\left(\frac{3}{4}\chi^4 - \frac{1}{2}\chi^2\right) - \kappa\chi(\nabla^2\chi) - \frac{\kappa}{2}(\nabla\chi)^2 \tag{43}$$

The tensor $\mathbf{P}^{th}$ describes the stresses induced by spatial variation in density and composition and has to be added to the viscous stress tensor $\boldsymbol{\tau}$.

Conservation Equations

Let us now apply the results of the previous section for building a system of fluid dynamics equations suitable for a numerical implementation. Together with the mass conservation Eqs. (39) and (40) we need the conservation equation for the linear momentum [1]:

$$\rho \frac{\mathrm{d}\mathbf{v}}{\mathrm{d}t} = \nabla \cdot \mathbf{P} + \rho \mathbf{g} \,, \tag{44}$$

where $\mathbf{P} = -\mathbf{P}^{th} + \boldsymbol{\tau}$ is the full pressure tensor of (41), $\mathbf{g}$ is the gravity and $\boldsymbol{\tau}$ is the viscous stress tensor that, for a Newtonian fluid is:

$$\tau_{ij} = \lambda e_{kk} \delta_{ij} + 2\mu e_{ij} \,, \tag{45}$$

with λ and μ the bulk and shear viscosities and e_{ij} is the strain rate tensor expressed by:

$$e_{ij} = \frac{1}{2} \left(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right) \,. \tag{46}$$

Appendix B – Numerical Implementation

Transformed Equations

A common problem in the numerical solution of the conservation Eqs. (33) and (34) is the output of values having no physical meaning (for instance negative densities for one of the components) with bad effects on the numerical stability of the code. This is due to the fact that both variables are defined over a limited range of values that are $n \in [0, +\infty[$ and $\phi \in [-n, +n]$. These conditions are not explicit in the conservation equations, but this problem can be overcome by making simple changes of variable:

$$n = \mathrm{e}^{l} \,, \tag{47}$$

$$\phi = \mathrm{e}^{l} \tanh q \,. \tag{48}$$

Using the new variable l instead of n the conservation Eq. (39) become:

$$\frac{\partial l}{\partial t} = -\mathbf{v} \cdot \nabla l - \nabla \cdot \mathbf{v} + \frac{1}{\mathrm{e}^{l}} \left(\frac{\partial \chi}{\partial n} \right) \Gamma \nabla^2 \mu \,. \tag{49}$$

Substituting (48) in (40) we first obtain:

$$\frac{\partial q}{\partial t} = -\mathbf{v} \cdot \nabla q - \frac{1}{2} \sinh 2q \left(\frac{\partial l}{\partial t} + \mathbf{v} \cdot \nabla l + \nabla \cdot \mathbf{v} \right) + \frac{1}{\mathrm{e}^{l}} \cosh^2 q \left(\frac{\partial \chi}{\partial \phi} \right) \Gamma \nabla^2 \mu \,. \tag{50}$$

Using (49) and some algebraic manipulation the previous expression become:

$$\frac{\partial q}{\partial t} = -\mathbf{v} \cdot \nabla q - \frac{1}{\mathrm{e}^{l}} \cosh q \left[\frac{\partial \chi}{\partial n} \sinh q + \frac{\partial \chi}{\partial \phi} \cosh q \right] \cdot \Gamma \nabla^2 \mu \tag{51}$$

Boundary and Initial Conditions

Equations (49) and (51) have to be solved setting proper boundary and initial conditions.

The no-slip boundary condition, implemented along the conduit walls is:

$$\mathbf{v} = 0 \,. \tag{52}$$

Another boundary condition is set along the walls:

$$\nabla \phi \cdot \mathbf{n} = 0 \,. \tag{53}$$

This is the neutral wetting condition [25] and it is needed in order to avoid the wall to behave sticky respect to one of the phases.

At the conduit top and bottom conditions of constant pressure are implementer. On the top the pressure is kept to a reference atmospheric value, while at the bottom it is kept at the hydrostatic pressure value, computed on the initial conditions.

In the initial conditions we set $\mathbf{v} = 0$ and the computational domain is composed of domains having a homogeneous composition separated by smooth interfaces, close to the equilibrium solution of (27). At the top of the model a gas domain represents the atmosphere, while the remaining part of the conduit is filled with magma. A small elliptical gas bubble in hydrostatic equilibrium is placed in the lower part of the conduit. The details are specified for each set of simulations.

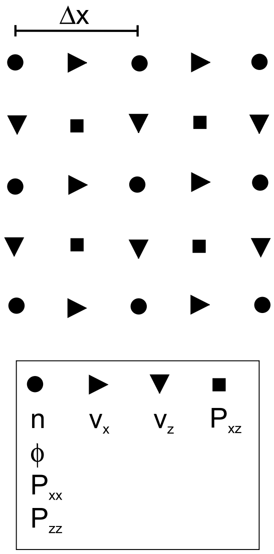
Finite Difference Implementation

Equations (49), (51) and (44) are discretized on a regular grid and the differential equations are transformed in finite-difference equations [19]. Scalar, vector and tensor quantities are discretized on staggered grids [6] (Fig. 12). Scalar quantities (l, q, μ and P_{ii}) are defined at integer grid steps (x_i, z_j). Velocities are staggered half grid step along x and z directions, that is v_x is defined at $(x_{i+1/2}, z_j)$ and v_z at $(x_i, z_{j+1/2})$. The deviatoric part of the pressure tensor P_{xz} is defined at grid points $(x_{i+1/2}, z_{j+1/2})$. This allows a second-order accuracy in the computation of spatial derivative.

We apply also a staggering in time. At the time step k we first solve (49) and (51). Then the current values of l and q are updated:

$$l_{i,j}^{(k)} = l_{i,j}^{(k-1)} + \frac{\mathrm{d}l}{\mathrm{d}t}^{(k)} \Delta t \,, \tag{54}$$

$$q_{i,j}^{(k)} = q_{i,j}^{(k-1)} + \frac{\mathrm{d}q}{\mathrm{d}t}^{(k)} \Delta t \,. \tag{55}$$



Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 12
Spatial scheme of the staggered grid used in the computation. *Circle* represents the isotropic grid (density, composition and isotropic pressure), *rightward triangles* are the grids for v_x while *downward triangles* are for v_z. *Squares* are the grids used for discretizing P_{xz}

Using these new values the full pressure tensor $\mathbf{P}^{(k)}$ is computed using the discretized version of (41), (42) and (43). At the time step $k + 1/2$ (44) is solved and the values of the local velocities are updated.

The computation of $\frac{dl}{dt}^{(k)}$ and $\frac{dq}{dt}^{(k)}$ requires the values of $l^{(k-1)}$, $q^{(k-1)}$ and $v^{(k-1/2)}$. On the other hand the computation of $v^{(k+1/2)}$ requires the values of $l^{(k)}$, $q^{(k)}$ and $v^{(k-1/2)}$.

The time step Δt is chosen in order to satisfy a stability condition. Since we are dealing with isothermal flows with a very low Mach number, the condition can be expressed by:

$$\Delta x < \Delta t \; c_{\max} \, , \qquad (56)$$

where $c_{\max}$ is the highest sound speed among the two components. In our simulations we have set:

$$\Delta x = 6 \; \Delta t \; c_{\max} \, , \qquad (57)$$

Article Outline

Glossary

Conservative, dissipative Conservative dynamical systems (on a compact phase space) are those that preserve a finite measure equivalent to volume. Hamiltonian dynamical systems are important examples of conservative systems. Systems that are not conservative are called dissipative. Finding physically meaningful invariant measures for dissipative maps is a central object of study in smooth ergodic theory.

Distortion estimate A key technique in smooth ergodic theory, a distortion estimate for a smooth map f gives a bound on the variation of the jacobian of f^n in a given region, for n arbitrarily large. The jacobian of a smooth map at a point x is the absolute value of the determinant of derivative at x, measured in a fixed Riemannian metric. The jacobian measures the distortion of volume under f in that metric.

Hopf argument A technique developed by Eberhard Hopf for proving that a conservative diffeomorphism or flow is ergodic. The argument relies on the Ergodic Theorem for invertible transformations, the density of continuous functions among integrable functions, and the existence of stable and unstable foliations for the system. The argument has been used, with various modifications, to establish ergodicity for hyperbolic, partially hyperbolic and nonuniformly hyperbolic systems.

Hyperbolic A compact invariant set $\Lambda \subset M$ for a diffeomorphism $f : M \to M$ is hyperbolic if, at every point in Λ, the tangent space splits into two subspaces, one that is uniformly contracted by the derivative of f, and another that is uniformly expanded. Expanding maps and Anosov diffeomorphisms are examples of globally hyperbolic maps. Hyperbolic diffeomorphisms and flows are the archetypical smooth systems displaying chaotic behavior, and their dynamical properties are well-understood. Nonuniform hyperbolicity and partial hyperbolicity are two generalizations of hyperbolicity that encompass a broader class of systems and display many of the chaotic features of hyperbolic systems.

Sinai–Ruelle–Bowen (SRB) measure The concept of SRB measure is a rigorous formulation of what it means for an invariant measure to be "physically meaningful". An SRB measure attracts a large set of orbits into its support, and its statistical features are reflected in the behavior of these attracted orbits.

Definition of the Subject

Smooth ergodic theory is the study of the statistical and geometric properties of measures invariant under a smooth transformation or flow. The study of smooth ergodic theory is as old as the study of abstract ergodic theory, having its origins in Bolzmann's Ergodic Hypothesis in the late 19th Century. As a response to Boltzmann's hypothesis, which was formulated in the context of Hamiltonian Mechanics, Birkhoff and von Neumann defined ergodicity in the 1930s and proved their foundational ergodic theorems. The study of ergodic properties of smooth systems saw an advance in the work of Hadamard and E. Hopf in the 1930s their study of geodesic flows for negatively curved surfaces. Beginning in the 1950s, Kolmogorov, Arnold and Moser developed a perturbative theory producing obstructions to ergodicity in Hamiltonian systems, known as Kolmogorov–Arnold–Moser (KAM) Theory. Beginning in the 1960s with the work of Anosov and Sinai on hyperbolic systems, the study of smooth ergodic theory has seen intense activity. This activity continues today, as the ergodic properties of systems displaying weak forms of hyperbolicity are further understood, and KAM theory is applied in increasingly broader contexts.

Introduction

This entry focuses on the basic arguments and principles in smooth ergodic theory, illustrating with simple and straightforward examples. The classic texts [1,2] are a good supplement.

The discussion here sidesteps the topic of ▶ Kolmogorov–Arnold–Moser (KAM) Theory, which has played an important role in the development of smooth ergodic theory. For reasons of space, detailed discussion of several active areas in smooth ergodic theory is omitted, including: higher mixing properties (Kolmogorov, Bernoulli, etc.), finer statistical properties (fast decay of correlations, Central Limit Theorem, large deviations), smooth thermodynamic formalism (transfer operators, pressure, dynamical zeta functions, etc.), the smooth ergodic theory of random dynamical systems, as well as any mention of infinite invariant measures. The text [3] covers many of these topics, and the texts [4,5,6] treat random smooth ergodic theory in depth. An excellent discussion of many of the recent developments in the field of smooth ergodic theory is [7].

This entry assumes knowledge of the basic concepts in ergodic theory and of basic differential topology. The texts [8] and [9] contain the necessary background.

The Volume Class

For simplicity, assume that M is a compact, boundaryless C^∞ Riemannian manifold, and that $f\colon M \to M$ is an orientation-preserving, C^1 map satisfying $m(D_x f) > 0$, for all $x \in M$, where

$$m(D_x f) = \inf_{v \in T_x M, \|v\|=1} \|D_x f(v)\| \,.$$

If f is a diffeomorphism, then this assumption is automatically satisfied, since in that case $m(D_x f) = \|D_{f(x)} f^{-1}\|^{-1} > 0$. For non-invertible maps, this assumption is essential in much of the following discussion. The Inverse Function Theorem implies that any map f satisfying these hypotheses is a covering map of positive degree $d \geq 1$.

These assumptions will avoid the issues of infinite measures and the behavior of f near critical points and singularities of the derivative. For most results discussed in this entry, this assumption is not too restrictive. The existence of critical points and other singularities is, however, a complication that cannot be avoided in many important applications. The ergodic-theoretic analysis of such examples can be considerably more involved, but contains many of the elements discussed in this entry. The discussion in Sect. "Beyond Uniform Hyperbolicity" indicates how some of these additional technicalities arise and can be overcome. For simplicity, the discussion here is confined almost exclusively to discrete time evolution. Many, though not all, of the the results mentioned here carry over to flows and semiflows using, for example, a cross-section construction (see Chap. 1 in [2]).

Every smooth map $f\colon M \to M$ satisfying these hypotheses preserves a natural measure *class*, the measure class of a finite, smooth Riemannian volume on M. Fix such a volume ν on M. Then there exists a continuous, positive *jacobian* function $x \mapsto \mathrm{jac}_x f$ on M, with the property that for every sufficiently small ball $B \subset M$, and every measurable set $A \subset B$ one has:

$$\nu(f(A)) = \int_B \mathrm{jac}_x f \, d\nu(x) \,.$$

The jacobian of f at x is none other than the absolute value of the determinant of the derivative $D_x f$ (measured in the given Riemannian metric). To see that the measure class of ν is preserved by f, observe that the Radon–Nikodym derivative $\frac{d f_* \nu}{d\nu}(x)$ at x is equal to $\sum_{y \in f^{-1}(x)} (\mathrm{jac}_y f)^{-1} > 0$. Hence $f_* \nu$ is equivalent to ν, and f preserves the measure class of ν.

In many contexts, the map f has a natural *invariant* measure in the measure class of volume. In this case, f is said to be *conservative*. One setting in which a natural invariant smooth measure appears is Hamiltonian dynamics. Any solution to Hamilton's equations preserves a smooth volume called the *Liouville measure*. Furthermore, along the invariant, constant energy hypermanifolds of a Hamiltonian flow, the Liouville measure decomposes smoothly into invariant measures, each of which is equivalent to the induced Riemannian volume. In this way, many systems of physical or geometric origin, such as billiards, geodesic flows, hard sphere gases, and evolution of the n-body problem give rise to smooth conservative dynamical systems. See ► Dynamics of Hamiltonian Systems.

Note that even though f preserves a smooth measure class, it might not preserve any measure in that measure class. Consider, for example, a diffeomorphism $f\colon S^1 \to S^1$ of the circle with exactly two fixed points, p and q, $f'(p) > 1 > f'(q) > 0$. Let μ be an f-invariant probability measure. Let I be a neighborhood of p. Then $\bigcap_{n=1}^{\infty} f^{-n}(I) = \{p\}$, but on the other hand, $\mu(f^{-n}(I)) = \mu(I) > 0$, for all n. This implies that $\mu(\{p\}) > 0$, and so μ does not lie in the measure class of volume. This is an example of a dissipative map. A map f is called *dissipative* if every f-invariant measure with full support has a singular part with respect to volume. As was just seen, if a diffeomorphism f has a periodic sink, then f is dissipative; more generally, if a diffeomorphism f has a periodic point p of period k such that $\mathrm{jac}_p f^k \neq 1$, then f is dissipative.

The Fundamental Questions

For a given smooth map $f\colon M \to M$, there are the following fundamental questions.

1. Is f conservative? That is, does there exist an invariant measure in the class of volume? If so, is it unique?
2. When f is conservative, what are its statistical properties? Is it ergodic, mixing, a K-system, Bernoulli, etc.? Does it obey a Central Limit Theorem, fast decay of correlations, large deviations estimates, etc.?
3. If f is dissipative, does there exist an invariant measure, not in the class of volume, but (in some sense) natural with respect to volume? What are the statistical properties of such a measure, if it exists?

There are several plausible ways to "answer" these questions. One might fix a given map f of interest and ask these questions for that specific f. What tends to happen in the analysis of a single map f is that either:

- the question can be answered using "soft" methods, and so the answer applies not only to f but to perturbations of f, or even to *generic* or *typical* f inside a class of maps; or
- the proof requires "hard" analysis or precise asymptotic information and cannot possibly be answered for a specific f, but can be answered for a large set of f_t in a typical (or given) parametrized family $\{f_t\}_{t\in(-1,1)}$ of smooth maps containing $f = f_0$.

Both types of results appear in the discussion that follows.

Lebesgue Measure and Local Properties of Volume

Locally, any measure in the measure class of volume is, after a smooth change of coordinates, equivalent to Lebesgue measure in $\mathbb{R}^n$. In fact, more is true: Moser's Theorem implies that locally any Riemannian volume is, after a smooth change of coordinates, *equal* to Lebesgue measure in $\mathbb{R}^n$. Hence to study many of the local properties of volume, it suffices to study the same properties for Lebesgue measure.

One of the basic properties of Lebesgue measure is that every set of positive Lebesgue measure can be approximated arbitrarily well in measure from the outside by an open set, and from the inside by a compact set. A consequence of this property, of fundamental importance in smooth ergodic theory, is the following statement.

Fundamental Principle #1: Two disjoint, positive Lebesgue measure sets cannot mix together uniformly at all scales.

As an illustration of this principle, consider the following elementary exercise in measure theory. First, some notation. If ν is a measure and A and B are ν-measurable sets with $\nu(B) > 0$, the *density of A in B* is defined by:

$$\nu(A\colon B) = \frac{\nu(A \cap B)}{\nu(B)} \, .$$

Proposition 1 *Let $\mathcal{P}_1, \mathcal{P}_2, \ldots$ be sequence of (mod 0) finite partitions of the circle S^1 into open intervals, with the properties: a) any element of $\mathcal{P}_n$ is a (mod 0) union of elements of $\mathcal{P}_{n+1}$, and b) the maximum diameter of elements of $\mathcal{P}_n$ tends to 0 as $n \to \infty$.*

Let A be any set of positive Lebesgue measure in S^1. Then there exists a sequence of intervals $I_1, I_2, \ldots$, with $I_n \in \mathcal{P}_n$ such that:

$$\lim_{n\to\infty} \lambda(A\colon I_n) = 1 \, .$$

Proof Assume that Lebesgue measure has been normalized so that $\lambda(S^1) = 1$. Fix a (mod 0) cover of $S^1 \setminus A$ by pairwise disjoint elements $\{J_i\}$ of the union $\bigcup_{n=1}^{\infty} \mathcal{P}_n$ with the properties:

$$\lambda(J_1) \geq \lambda(J_2) \geq \cdots \, , \text{ and}$$

$$\lambda\left(\bigcup_{i=1}^{\infty} J_i\right) = \sum_{i=1}^{\infty} \lambda(J_i) < 1 \, .$$

For $n \in \mathbb{N}$, let U_n be the union of all the intervals J_i that are contained in $\mathcal{P}_n$, and let $V_n = \bigcup_{i=1}^{n} U_n$. This defines an increasing sequence of natural numbers $i_1 = 1 < i_2 < i_3 < \cdots$ such that $U_n = \bigcup_{i=i_n}^{i_{n+1}-1} J_n$ and $V_n = \bigcup_{i=1}^{i_{n+1}-1} J_n$.

For each n, the interval I_n will be chosen to be an element $\mathcal{P}_n$, disjoint from V_n, in which the density of $\bigcup_{i=n+1}^{\infty} U_i$ is very small (approaching 0 as $n \to \infty$). Since $(S^1 \setminus A) \cap I_n$ is contained in $\bigcup_{i=n+1}^{\infty} U_i$, this choice of I_n will ensure that the density of A in I_n is large (approaching 1 as $n \to \infty$).

To make this choice of I_n, note first that the density of $\bigcup_{i=n+1}^{\infty} U_i$ inside of $S^1 \setminus V_n$ is:

$$\frac{\lambda(\bigcup_{i=n+1}^{\infty} U_i)}{\lambda(S^1 \setminus V_n)} = \frac{\sum_{i=i_{n+1}}^{\infty} \lambda(J_i)}{1 - \sum_{i=1}^{i_{n+1}-1} \lambda(J_i)} = a_n .$$

Note that, since $\sum_{i=1}^{\infty} \lambda(J_i)1$, one has $a_n \to 0$ as $n \to \infty$. Since the density of $\bigcup_{i=n+1}^{\infty} U_i$ inside of $S^1 \setminus V_n$ is at most a_n, there is an interval I_n in $\mathcal{P}_n$, disjoint from V_n, such that the density of $\bigcup_{i=n+1}^{\infty} U_i$ inside of I_n is at most a_n. Then

$$\lim_{n\to\infty} \lambda(A\colon I_n) \geq \lim_{n\to\infty} 1 - a_n = 1 .$$

□

In smooth ergodic theory, it is often useful to use a variation on Proposition 1 (generally, in higher dimensions) in which the partitions $\mathcal{P}_n$ are nested, dynamically-defined partitions. A simple application of this method can be used to prove that the doubling map on the circle is ergodic with respect to Lebesgue measure, which is done in Sect. "Lebesgue Measure and Local Properties of Volume".

Notice that this proposition does not claim that the intervals I_n are nested. If one imposes stronger conditions on the partitions $\mathcal{P}_n$, then one can draw stronger conclusions.

A very useful theorem in this respect is the Lebesgue Density Theorem. A point $x \in M$ is a *Lebesgue density point* of a measurable set $X \subseteq M$ if

$$\lim_{r\to 0} m(X\colon B_r(x)) = 1 ,$$

where $B_r(x)$ is the Riemannian ball of radius r centered at x. Notice that the notion of Lebesgue density point depends only on the smooth structure of M, because any two Riemannian metrics have the same Lebesgue density points. The Lebesgue Density Theorem states that if A is a measurable set and $\widehat{A}$ is the set of Lebesgue density points of A, then $m(A \,\Delta\, \widehat{A}) = 0$.

Ergodicity of the Basic Examples

This section contains proofs of the ergodicity of two basic examples of conservative smooth maps: irrational rotations on the circle and the doubling map on the circle. See ► Ergodic Theory: Basic Examples and Constructions for a more detailed description of these maps. These proofs serve as an elementary illustration of some of the fundamental techniques and principles in smooth ergodic theory.

Rotations on the circle. Denote by S^1 the circle $\mathbb{R}/\mathbb{Z}$, which is an additive group, and by λ normalized Lebesgue-Haar measure on S^1. Fix a real number $\alpha \in \mathbb{R}$. The rotation $R_\alpha\colon S^1 \to S^1$ is the translation defined by $R_\alpha(x) = x + \alpha$. Since translations preserve Lebesgue-Haar measure, the map R_α is conservative. Note that R_α is a diffeomorphism and an isometry with respect to the canonical flat metric (length) on S^1.

Proposition 2 *If $\alpha \notin \mathbb{Q}$, then the rotation $R_\alpha\colon S^1 \to S^1$ is ergodic with respect to Lebesgue measure.*

Proof Let A be an R_α-invariant set in S^1, and suppose that $0 < \lambda(A) < 1$. Denote by A^c the complement of A in S^1. Fix $\varepsilon > 0$. Proposition 1 implies that there exists an interval $I \subset S^1$ such that the density of A in I is large: $\lambda(A\colon I) > 1 - \varepsilon$. Similarly, one may choose an interval J such that $\lambda(A^c\colon J) > 1 - \varepsilon$. Without loss of generality, one may choose I and J to have the same length. Since α is irrational, R_α has a dense orbit, which meets the interval I. Since R_α is an isometry, this implies that there is an integer n such that $\lambda(R_\alpha^n(I) \,\Delta\, J) < \varepsilon\lambda(I)$. Since $\lambda(I) = \lambda(J)$, this readily implies that $|\lambda(A\colon R_\alpha^n(I)) - \lambda(A\colon J)| < \varepsilon$. Also, since A is invariant, and R_α is invertible and preserves measure, one has:

$$\lambda(A\colon R_\alpha^n(I)) = \lambda(R_\alpha^n(A)\colon R_\alpha^n(I)) = \lambda(A\colon I) > 1 - \varepsilon .$$

But for ε sufficiently small, this contradicts the facts that $\lambda(A\colon J) = 1 - \lambda(A^c\colon J) < \varepsilon$ and $|\lambda(A\colon R_\alpha^n(I)) - \lambda(A\colon J)| < \varepsilon$. □

Note that this is not a proof of the strongest possible statement about R_α (namely, minimality and unique ergodicity). The point here is to show how "soft" arguments are often sufficient to establish ergodicity; this proof uses no more about R_α than the fact that it is a transitive isometry. Hence the same argument shows:

Theorem 1 *Let $f\colon M \to M$ be a transitive isometry of a Riemannian manifold M. Then f is ergodic with respect to Riemannian volume.*

One can isolate from this proof a useful principle:

Fundamental Principle #2: Isometries preserve Lebesgue density at all scales, for arbitrarily many iterates.

This principle implies, for example, that a smooth action by a compact Lie group on M is ergodic along typical (nonsingular) orbits. This principle is also useful in studying area-preserving flows on surfaces and, in a refined form, unipotent flows on homogeneous spaces. In the case of surface flows, ergodicity questions can be reduced to a study of interval exchange transformations. See the entry ► Ergodic Theory: Basic Examples and Constructions for a detailed discussion of interval exchange transformations and flows on surfaces. ► Ergodic Theory, Introduction to contains detailed information on unipotent flows.

Doubling map on the circle. Let $T_2 \colon S^1 \to S^1$ be the doubling map defined by $T_2(x) = 2x$. Then T_2 is a degree-2 covering map and endomorphism of S^1 with constant jacobian $\mathrm{jac}_x T_2 \equiv 2$. Since $\frac{d(T_2)_*\lambda}{d\lambda} = \frac{1}{2} + \frac{1}{2} = 1$, T_2 preserves Lebesgue-Haar measure. The doubling map is the simplest example of a hyperbolic dynamical system, a topic treated in depth in the next section.

As with the previous example, the focus here is on the property of ergodicity. It is again possible to prove much stronger results about T_2, such as Bernoullicity, by other methods. Instead, here is a soft proof of ergodicity that will generalize readily to other contexts.

Proposition 3 *The doubling map $T_2 \colon S^1 \to S^1$ is ergodic with respect to Lebesgue measure.*

Proof Let A be a T_2-invariant set in S^1 with $\lambda(A) > 0$. Let $p \in S^1$ be the fixed point of T_2, so that $T_2(p) = p$. For each $n \in \mathbb{N}$, the preimages of p under T_2^{-n} define a (mod 0) partition $\mathcal{P}_n$ into 2^n open intervals of length 2^{-n}; the elements of $\mathcal{P}_n$ are the connected components of $S^1 \setminus T_2^{-n}(\{p\})$. Note that the sequence of partitions $\mathcal{P}_1, \mathcal{P}_2, \ldots$ is nested, in the sense of Proposition 1. Restricted to any interval $J \in \mathcal{P}_n$, the map ${T_2}^n$ is a diffeomorphism onto $S^1 \setminus \{p\}$ with constant jacobian $\mathrm{jac}_x(T_2^n) = (T_2^n)'(x) = 2^n$.

Since A is invariant, it follows that $T_2^{-n}(A) = A$. Fix $\varepsilon > 0$. Proposition 1 implies that there exists an $n \in \mathbb{N}$ and an interval $J \in \mathcal{P}_n$ such that $\lambda(A \colon J) > 1 - \varepsilon$. Note that $T_2^n(A \cap J) \subset A$. But then

$$\begin{aligned}\lambda(A) &\geq \lambda(T_2^n(A \cap J)) \\ &= \int_{A \cap J} \mathrm{jac}_x(T_2^n)\, \mathrm{d}\lambda(x) \\ &= 2^n \lambda(A \cap J) \\ &= 2^n \lambda(A \colon J)\lambda(J) \\ &> 2^n(1-\varepsilon)\lambda(J) = 1 - \varepsilon\,.\end{aligned}$$

Since ε was arbitrary, one obtains that $\lambda(A) = 1$. □

In this proof, the facts that the intervals in $\mathcal{P}_n$ have constant length 2^{-n} and that the jacobian of ${T_2}^n$ restricted to such an interval is constant and equal to 2^n are not essential. The key fact really used in this proof is the assertion that the ratio:

$$\frac{\lambda(T_2^n(A \cap J) \colon T_2^n(J))}{\lambda(A \colon J)}$$

is bounded, *independently of n*. In this case, the ratio is 1 for all n because T_2 has constant jacobian.

It is tempting to try to extend this proof to other expanding maps on the circle, for example, a C^1, λ-preserving map $f \colon S^1 \to S^1$ with $d_{C^1}(f, T_2)$ small. Many of the aspects of this proof carry through *mutatis mutandis* for such an f, save for one. A C^1-small perturbation of T_2 will in general no longer have constant jacobian, and the *variation* of the jacobian of f^n on a small interval can be (and often is) unbounded. The reason for this unboundedness is a lack of control of the modulus of continuity of f'. Hence this argument can fail for C^1 perturbations of T_2. On the other hand, the argument still works for C^2 perturbations of T_2, even when the jacobian is not constant.

The principle behind this fact can be loosely summarized:

Fundamental Principle #3: On controlled scales, iterates of C^2 expanding maps distort Lebesgue density in a controlled way.

This principle requires further explanation and justification, which will come in the following section. The C^2 hypothesis in this principle accounts for the fact that almost all results in smooth ergodic theory assume a C^2 hypothesis (or something slightly weaker).

Hyperbolic Systems

One of the most developed areas of smooth ergodic theory is in the study of hyperbolic maps and attractors. This section defines hyperbolic maps and attractors, provides examples, and investigates their ergodic properties. See [10,11] and ► Hyperbolic Dynamical Systems for a thorough discussion of the topological and smooth properties of hyperbolic systems.

A *hyperbolic structure* on a compact f-invariant set $\Lambda \subset M$ is given by a Df-invariant splitting $T_\Lambda M = E^u \oplus E^s$ of the tangent bundle over Λ and constants $C, \mu > 1$ such that, for every $x \in \Lambda$ and $n \in \mathbb{N}$:

$$\begin{aligned} & v \in E^u(x) \implies \|D_x f^n(v)\| \geq C^{-1}\mu^n \|v\|\,, \\ \text{and} \quad & v \in E^s(x) \implies \|D_x f^n(v)\| \leq C\mu^{-n}\|v\|\,. \end{aligned}$$

A hyperbolic attractor for a map $f \colon M \to M$ is given by an open set $U \subset M$ such that: $f(U) \subset \overline{U}$, and such that the set $\Lambda = \bigcap_{n \geq 0} f^n(U)$ carries a hyperbolic structure. The set Λ is called the *attractor*, and U is an *attracting region*. A map $f \colon M \to M$ is *hyperbolic* if M decomposes (mod 0) into a finite union of attracting regions for hyperbolic attractors. Typically one assumes as well that the restriction of f to each attractor Λ_i is topologically transitive.

Every point p in a hyperbolic set Λ has smooth *stable manifold* $\mathcal{W}^{\mathrm{s}}(p)$ and *unstable manifold* $\mathcal{W}^{\mathrm{u}}(p)$, tangent, respectively, to the subspaces $E^s(p)$ and $E^{\mathrm{u}}(p)$. The set $\mathcal{W}^{\mathrm{s}}(p)$ is precisely the set of $q \in M$ such that $d(f^n(p), f^n(q))$ tends to 0 as $n \to \infty$, and it follows that $f(\mathcal{W}\mathrm{s}(p)) = \mathcal{W}^s(f(p))$. When f is a diffeomorphism, the unstable manifold $\mathcal{W}^{\mathrm{u}}(p)$ is uniquely defined and is the stable manifold of f^{-1}. When f is not invertible, local unstable manifolds exist, but generally are not unique. If Λ is a transitive hyperbolic attractor, then every unstable manifold of every point $p \in \Lambda$ is dense in Λ.

Examples of Hyperbolic Maps and Attractors

Expanding Maps The previous section mentioned briefly the C^r perturbations of the doubling map T_2. Such perturbations (as well as T_2 itself) are examples of *expanding maps*. A map $f\colon M \to M$ is *expanding* if there exist constants $\mu > 1$ and $C > 0$ such that, for every $x \in M$, and every nonzero vector $v \in T_x M$:

$$\|D_x f^n(v)\| \geq C\mu^n \|v\| ,$$

with respect to some (any) Riemannian metric on M. An expanding map is clearly hyperbolic, with $U = M$, E^s the trivial bundle, and $E^u = TM$. Any disk in M is a local unstable manifold for f.

Anosov Diffeomorphisms A diffeomorphism $f\colon M \to M$ is called *Anosov* if the tangent bundle splits as a direct sum $TM = E^u \oplus E^s$ of two Df-invariant subbundles, such that E^u is uniformly expanded and E^s is uniformly contracted by Df. Similarly, a flow $\varphi_t\colon M \to M$ is called Anosov if the tangent bundle splits as a direct sum $TM = E^u \oplus E^0 \oplus E^s$ of three $D\varphi_t$-invariant subbundles, such that E^0 is generated by $\dot{\varphi}$, E^u is uniformly expanded and E^s is uniformly contracted by $D\varphi_t$. Like expanding maps, an Anosov diffeomorphism is an Anosov attractor with $\Lambda = U = M$.

A simple example of a conservative Anosov diffeomorphism is a hyperbolic linear automorphism of the torus. Any matrix $A \in SL(n, \mathbb{Z})$ induces an automorphism of $\mathbb{R}^n$ preserving the integer lattice $\mathbb{Z}^n$, and so descends to an automorphism $f_A\colon T^n \to T^n$ of the n-torus $T^n = \mathbb{R}^n/\mathbb{Z}^n$. Since the determinant of A is 1, the diffeomorphism f_A preserves Lebesgue-Haar measure on T^n. In the case where none of the eigenvalues of A have modulus 1, the resulting diffeomorphism f_A is Anosov. The stablebundle E^s at $x \in T^n$ is the parallel translate to x of the sum of the contracted generalized eigenspaces of A, and the unstable bundle E^u at x is the translated sum of expanded eigenspaces.

In general, the invariant subbundles E^u and E^s of an Anosov diffeomorphism are integrable and tangent to a transverse pair of foliations $\mathcal{W}^u$ and $\mathcal{W}^s$, respectively (see, e. g [12]. for a proof of this). The leaves of $\mathcal{W}^s$ are uniformly contracted by f, and the leaves of $\mathcal{W}^u$ are uniformly contracted by f^{-1}. The leaves of these foliations are as smooth as f, but the tangent bundles to the leaves do not vary smoothly in the manifold. The regularity properties of these foliations play an important role in the ergodic properties of Anosov diffeomorphisms.

The first Anosov flows to be studied extensively were the geodesic flows for manifolds of negative sectional curvatures. As these flows are Hamiltonian, they are conservative. Eberhard Hopf showed in the 1930s that such geodesic flows for surfaces are ergodic with respect to Liouville measure [14]; it was not until the 1960s that ergodicity of all such flows was proved by Anosov [15]. The next section describes, in the context of Anosov diffeomorphisms, Hopf's method and important refinements due to Anosov and Sinai.

DA Attractors A simple way to produce a non-Anosov hyperbolic attractor on the torus is to start with an Anosov diffeomorphism, such as a linear hyperbolic automorphism, and deform it in a neighborhood of a fixed point, turning a saddle fixed point into a source, while preserving the stable foliation. If this procedure is carried out carefully enough, the resulting diffeomorphism is a dissipative hyperbolic diffeomorphism, called a *derived from Anosov (DA)* attractor. Other examples of hyperbolic attractors are the Plykin attractor and the solenoid. See [10].

Distortion Estimates

Before describing the ergodic properties of hyperbolic systems, it is useful to pause for a brief discussion of distortion estimates. Distortion estimates are behind almost every result in smooth ergodic theory. In the hyperbolic setting, distortion estimates are applied to the action of f on unstable manifolds to show that the volume distortion of f along unstable manifolds can be controlled for arbitrarily many iterates.

The example mentioned at the end of the previous section illustrates the ideas in a distortion estimate. Suppose that $f\colon S^1 \to S^1$ is a C^2 expanding map, such as a C^2 small perturbation of T_2. Then there exist constants $\mu > 1$ and $C > 0$ such that $(f^n)'(x) > C\mu^n$ for all x and n.

Let d be the degree of f. If I is a sufficiently small open interval in S^1, then for each n, $f^{-n}(I)$ is a union of d disjoint intervals. Furthermore, each of these intervals has diameter at most $C^{-1}\mu^{-n}$ times the diameter of I. It is now possible to justify the assertion in Fundamental Principle #3 in this context.

Lemma *There exists a constant $K \geq 1$ such that, for all $n \in \mathbb{N}$, and for all $x, y \in f^{-n}(I)$, one has:*

$$K^{-1} \leq \frac{(f^n)'(x)}{(f^n)'(y)} \leq K\,.$$

Proof Since f is C^2 and f' is bounded away from 0, the function $\alpha(x) = \log(f'(x))$ is C^1. In particular, α is Lipschitz continuous: there exists a constant $L > 0$ such that, for all $x, y \in S^1$, $|\alpha(x) - \alpha(y)| < Ld(x, y)$. For $n \geq 0$, let $\alpha_n(x) = \log((f^n)'(x))$. The Chain Rule implies that $\alpha_n(x) = \sum_{i=0}^{n-1} \alpha(f^i(x))$.

The expanding hypothesis on f implies that for all $x, y \in f^n(I)$ and for $i = 0, \ldots, n$, one has $d(f^i(x), f^i(y)) \leq C^{-1}\mu^{i-n} d(f^n(x), f^n(y)) \leq C^{-1}\mu^{i-n}$. Hence

$$\begin{aligned}
|\alpha_n(x) - \alpha_n(y)| &\leq \sum_{i=0}^{n-1} |\alpha(f^i(x)) - \alpha(f^i(y))| \\
&\leq L \sum_{i=0}^{n-1} d(f^i(x), f^i(y)) \\
&\leq L \sum_{i=0}^{n-1} C^{-1}\mu^{i-n} \\
&< LC^{-1}\mu^{-1}(1 - \mu^{-1})^{-1}\,.
\end{aligned}$$

Setting $K = \exp(LC^{-1}\mu^{-1}(1 - \mu^{-1})^{-1})$, one now sees that $(f^n)'(x)/(f^n)'(y)$ lies in the interval $[K^{-1}.K]$, proving the claim. □

In this distortion estimate, the function $\alpha\colon M \to \mathbb{R}$ is called a *cocycle*. The same argument applies to any Lipschitz continuous (or even Hölder continuous) cocycle.

Ergodicity of Expanding Maps

The ergodic properties of C^2 expanding maps are completely understood. In particular, every conservative expanding map is ergodic, and every expanding map is conservative. The proofs of these facts use Fundamental Principles #1 and 3 in a fairly direct way.

Every C^2 conservative expanding map is ergodic with respect to volume. The proof is a straightforward adaptation of the proof of Proposition 3 (see, e. g [2].). Here is a description of the proof for $M = S^1$. As remarked earlier, the proof of Proposition 3 adapts easily to a general expanding map $f\colon S^1 \to S^1$ once one shows that for every f-invariant set A, and every connected component J of $f^{-n}(S^1 \setminus \{p\})$, the quantity

$$\frac{\lambda(f^n(A \cap J)\colon f^n(J))}{\lambda(A\colon J)}$$

is bounded independently of n. This is a fairly direct consequence of the distortion estimate in Lemma 6.1 and is left as an exercise.

The same distortion estimates show that every C^2 expanding map is conservative, preserving a probability measure ν in the measure class of volume. Here is a sketch of the proof for the case $M = S^1$. To prove this, consider the push-forward $\lambda_n = f_*^n \lambda$. Then λ_n is equivalent to Lebesgue, and its Radon–Nikodym derivative $d\lambda_n \setminus d\lambda$ is the density function

$$\rho_n(x) = \sum_{y \in f^{-n}(x)} \frac{1}{\mathrm{jac}_y f^n}\,.$$

Since $f_*^n\lambda$ is a probability measure, it follows that $\int_{S^1} \rho_n \, \mathrm{d}\lambda = 1$. A simple argument using the distortion estimate above (and summing up over all d^n branches of f^{-n} at x) shows that there exists a constant $c \geq 1$ such that for all $x, y \in S^1$,

$$c^{-1} \leq \frac{\rho_n(x)}{\rho_n(y)} \leq c\,.$$

Since the integral of ρ_n is 1, the functions ρ_n are uniformly bounded away from 0 and ∞. It is easy to see that the measure $\nu_n = \frac{1}{n}\sum_{i=1}^{n} f_*^i\lambda$ has density $\frac{1}{n}\sum_{i=1}^{n} \rho_i$. Let ν be any subsequential weak* limit of ν_n; then ν is absolutely continuous, with density ρ bounded away from 0 and ∞. With a little more care, one can show that ρ is actually Lipschitz continuous.

As a passing comment, the ergodicity of ν and positivity of ρ imply that ν is the unique f-invariant measure absolutely continuous with respect to λ. With more work, one can show that ν is exact. See [2] for details.

Ergodicity of Conservative Anosov Diffeomorphisms

Like conservative C^2 expanding maps, conservative C^2 Anosov diffeomorphisms are ergodic. This subsection outlines a proof of this fact. Unlike expanding maps, however, Anosov diffeomorphisms need not be conservative. The subsection following this one describe a type of invariant measure that is "natural" with respect to volume, called a Sinai-Ruelle-Bowen (or SRB) measure. The central result for hyperbolic systems states that every hyperbolic attractor carries an SRB measure.

The Hopf Argument In the 1930s Hopf [14] proved that the geodesic flow for a compact, negatively-curved surface is ergodic. His method was to study the Birkhoff averages of continuous functions along leaves of the stable and unstable foliations of the flow. This type of argument has been used since then in increasingly general contexts, and has come to be known as the Hopf Argument.

The core of the Hopf Argument is very simple. To any $f\colon M \to M$ one can associate the *stable equivalence relation* $\sim_s$, where $x \sim_s y$ iff $\lim_{n\to\infty} d(f^n(x), f^n(y)) = 0$. Denote by $W^s(x)$ the stable equivalence class containing x. When f is invertible, one defines the *unstable equivalence relation* to be the stable equivalence relation for f^{-1}, and one denotes by $W^u(x)$ the unstable equivalence class containing x.

The first step in the Hopf Argument is to show that Birkhoff averages for continuous functions are constant along stable and unstable equivalence classes. Let $\phi\colon M \to \mathbb{R}$ be an integrable function, and let

$$\overline{\phi} = \limsup_{n\to\infty} \frac{1}{n} \sum_{i=1}^{n} \phi \circ f^i \,. \tag{1}$$

Observe that if ϕ is continuous, then for every $x \in M$ and $x' \in W^s(x)$, $\lim_{n\to\infty} |\phi(f^n(x)) - \phi(f^i(x'))| = 0$. It follows immediately that $\overline{\phi}_f(x) = \overline{\phi}_f(x')$. In particular, if the limit in (1) exists at x, then it exists and is constant on $W^s(x)$.

Fundamental Principle #4: Birkhoff averages of continuous functions are constant along stable equivalence classes.

The next step of Hopf's argument confines itself to the situation where f is conservative and Anosov. In this case, f is invertible, the stable equivalence classes are precisely the leaves of the stable foliation $\mathcal{W}^s$, and the unstable equivalence classes are the leaves of the unstable foliation $\mathcal{W}^u$. Since f is conservative, the Ergodic Theorem implies that for every L^2 function ϕ, the function $\overline{\phi}_f$ is equal (mod 0) to the projection of ϕ onto the f-invariant functions in L^2. Since this projection is continuous, and the continuous functions are dense in L^2, to prove that f is ergodic, it suffices to show that the projection of any continuous function is trivial. That is, it suffices to show that for every continuous ϕ, the function $\overline{\phi}_f$ is constant (a.e.).

To this end, let $\phi\colon M \to \mathbb{R}$ be continuous. Since the f-invariant functions coincide with the f^{-1}-invariant functions, one obtains that $\overline{\phi}_f = \overline{\phi}_{f^{-1}}$ a.e. The previous argument shows $\overline{\phi}_f$ is constant along $\mathcal{W}^s$-leaves and $\overline{\phi}_{f^{-1}}$ is constant along $\mathcal{W}^u$-leaves. The desired conclusion is that $\overline{\phi}_f$ is a.e. constant. It suffices to show this in a local chart, since the manifold M is connected. In a local chart, after a smooth change of coordinates, one obtains a pair of transverse foliations $\mathcal{F}_1$, $\mathcal{F}_2$ of the cube $[-1,1]^n$ by disks, and a measurable function $\psi\colon [-1,1]^n \to \mathbb{R}$ that is constant along the leaves of $\mathcal{F}_1$ and constant along the leaves of $\mathcal{F}_2$.

When the foliations $\mathcal{F}_1$ and $\mathcal{F}_2$ are smooth (at least C^1), one can perform a further smooth change of coordinates so that $\mathcal{F}_1$ and $\mathcal{F}_2$ are transverse coordinate subspace foliations. In this case, Fubini's theorem implies that any measurable function that is constant along two transverse coordinate foliations is a.e. constant. This completes the proof in the case that the foliations $\mathcal{W}^s$ and $\mathcal{W}^u$ are smooth. In Hopf's original argument, the stable and unstable foliations were assumed to be C^1 foliations (a hypotheses satisfied in the examples he considered, due to low-dimensionality. See also [16], where a pinching condition on the curvature, rather than low dimensionality, implies this C^1 condition on the foliations.)

Absolute Continuity For a general Anosov diffeomorphism or flow, the stable and unstable foliations are not C^1, and so the final step in Hopf's orginal argument does not apply. The fundamental advance of Anosov and Anosov-Sinai was to prove that the stable and unstable foliations of an Anosov diffeomorphism (conservative or not) satisfy a weaker condition than smoothness, called *absolute continuity*. For conservative systems, absolute continuity is enough to finish Hopf's argument, proving that every C^2 conservative Anosov diffeomorphism is ergodic [15,17].

For a definition and careful discussion of absolute continuity of a foliation $\mathcal{F}$, see [13]. Two consequences of the absolute continuity of $\mathcal{F}$ are:

1. (AC1) If $A \subset M$ is any measurable set, then
$$\lambda(A) = 0 \iff \lambda_{\mathcal{F}(x)}(A) = 0\,, \qquad \text{for} \quad \lambda - \text{a.e. } x \in M\,,$$
where $\lambda_{\mathcal{F}(x)}$ denotes the induced Riemannian volume on the leaf of $\mathcal{F}$ through x.
2. (AC2) If τ is any small, smooth disk transverse to a local leaf of $\mathcal{F}$, and $T \subset \tau$ is a 0-set in τ (with respect to the induced Riemannian volume on τ), then the union of the $\mathcal{F}$ leaves through points in T has Lebesgue measure 0 in M.

The proof that $\mathcal{W}^s$ and $\mathcal{W}^u$ are absolutely continuous has a similar flavor to the proof that an expanding map has a unique absolutely continuous invariant measure (although the cocycles involved are Hölder continuous, rather than Lipschitz), and the facts are intimately related.

With absolute continuity of the stable and unstable foliations in hand, one can now prove:

Theorem 2 (Anosov) *Let f be a C^2, conservative Anosov diffeomorphism. Then f is ergodic.*

Proof By the Hopf Argument, it suffices to show that if ψ^s and ψ^u are L^2 functions with the following properties:

1. ψ^s is constant along leaves of $\mathcal{W}^s$,
2. ψ^u is constant along leaves of $\mathcal{W}^u$, and
3. $\psi^s = \psi^u$ a.e.,

then ψ^s (and so ψ^u as well) is constant a.e.

This is proved using the absolute continuity of $\mathcal{W}^u$ and $\mathcal{W}^s$. Since M is connected, one may argue this locally. Let G be the full measure set of $p \in M$ such that $\psi^s = \psi^u$. Absolute continuity of $\mathcal{W}^s$ (more precisely, consequence (AC1) of absolute continuity described above) implies that for almost every $p \in M$, G has full measure in $\mathcal{W}^s(p)$. Pick such a p. Then for almost every $q \in \mathcal{W}^s(p)$, $\psi^s(q) = \psi^u(p)$; defining G' to be the union over all $q \in \mathcal{W}^s(p) \cap G$ of $\mathcal{W}^u(q)$, one obtains that ψ^s is constant on $G \cap G'$. But now, since $\mathcal{W}^s(p) \cap G$ has full measure in $\mathcal{W}^s(p)$, the absolute continuity of $\mathcal{W}^u$ (consequence (AC2) above) implies that G' has full measure in a neighborhood of p. Hence ψ^s is a.e. constant in a neighborhood of p, completing the proof. □

SRB Measures

In the absence of a smooth invariant measure, it is still possible for a map to have an invariant measure that behaves naturally with respect to volume. In computer simulations one observes such measures when one picks a point x at random and plots many iterates of x; in many systems, the resulting picture is surprisingly insensitive to the initial choice of x. What appears to be happening in these systems is that the trajectory of almost every x in an open set U is converging to the support of a singular invariant probability measure μ. Furthermore, for any open set V, the proportion of forward iterates of x spent in V appears to converge to $\mu(V)$ as the number of iterates tends to ∞.

In the 1960s and 70s, Sinai, Ruelle and Bowen rigorously established the existence of these physically observable measures for hyperbolic attractors [18,19,20]. Such measures are now known as Sinai-Ruelle-Bowen (SRB) measures, and have been shown to exist for non-hyperbolic maps with some hyperbolic features. This subsection describes the construction of SRB measures for hyperbolic attractors.

An f-invariant probability measure μ is called an *SRB (or physical) measure* if there exists an open set $U \subset M$ containing the support of μ such that, for every continuous function $\phi\colon M \to \mathbb{R}$ and λ-a.e. $x \in U$,

$$\lim_{n\to\infty} \frac{1}{n} \sum_{i=1}^{n} \phi(f^i(x)) = \int_M \phi \, d\mu \, .$$

The maximal open set U with this property is called the *basin* of f. To exclude the possibility that the SRB measure is supported on a periodic sink, one often adds the condition that at least one of the Lyapunov exponents of f with respect μ is positive. Other definitions of SRB measure have been proposed (see [21]). Note that every ergodic absolutely continuous invariant measure with positive density in an open set is an SRB measure. Note also that an SRB measure for f is not in general an SRB measure for f^{-1}, unless f preserves an ergodic absolutely continuous invariant measure.

Every transitive Anosov diffeomorphism carries a unique SRB measure. To prove this, one defines a sequence of probability measures ν_n on M as follows. Fix a point $p \in M$, and define ν_0 to be the normalized restriction of Riemannian volume to a ball B^u in $\mathcal{W}^u(p)$. Set $\nu_n = \frac{1}{n}\sum_{i=1}^{n} f_*^i \nu_0$. Distortion estimates show that the density of ν_n on its support inside $\mathcal{W}^u$ is bounded, above and below, independently of n. Passing to a subsequential weak* limit, one obtains a probability measure ν on M with bounded densities on $\mathcal{W}^u$-leaves.

To show that ν is an SRB measure, choose a point $q \in M$ in the support of ν. Since ν has positive density on unstable manifolds, almost every point in a neighborhood of q in $\mathcal{W}^u(q)$ is a regular point for f (that is, a point where the forward Birkhoff averages of every continuous function exist). A variation on the Hopf Argument, using the absolute continuity of $\mathcal{W}^s$, shows that ν is an ergodic SRB measure.

A similar argument shows that every transitive hyperbolic attractor admits an ergodic SRB measure. In fact this SRB measure has much stronger mixing properties, namely, it is Bernoulli. To prove this, one first constructs a Markov partition [22] conjugating the action of f to a Bernoulli shift. This map sends the SRB measure to a Gibbs state for a mixing Markov shift (see ► Pressure and Equilibrium States in Ergodic Theory). A result that subsumes all of the results in this section is:

Theorem 3 (Sinai, Ruelle, Bowen) *Let $\Lambda \subset M$ be a transitive hyperbolic attractor for a C^2 map $f\colon M \to M$. Then f has an ergodic SRB measure μ supported on Λ. Moreover: the disintegration of μ along unstable manifolds of Λ is equivalent to the induced Riemannian volume, the Lyapunov exponents of μ are all positive, and μ is Bernoulli.*

Beyond Uniform Hyperbolicity

The methods developed in the smooth ergodic theory of hyperbolic maps have been extended beyond the hyperbolic context. Two natural generalizations of hyperbolicity are:

- partial hyperbolicity, which requires uniform expansion of E^u and uniform contraction of E^s, but allows central directions at each point, in which the expansion and contraction is dominated by the behavior in the hyperbolic directions; and
- nonuniform hyperbolicity, which requires hyperbolicity along almost every orbit, but allows the expansion of E^u and the contraction of E^s to weaken near the exceptional set where there is no hyperbolicity.

This section discusses both generalizations.

Partial Hyperbolicity

Brin and Pesin [23] and independently Pugh and Shub [24] first examined the ergodic properties of partially hyperbolic systems soon after the work of Anosov and Sinai on hyperbolic systems. One says that a diffeomorphism $f\colon M \to M$ of a compact manifold M is *partially hyperbolic* if there is a nontrivial, continuous splitting of the tangent bundle, $TM = E^{\mathrm{s}} \oplus E^{\mathrm{c}} \oplus E^{\mathrm{u}}$, invariant under Df, such that E^{s} is uniformly contracted, E^{u} is uniformly expanded, and E^c is dominated, meaning that for some $n \geq 1$ and for all $x \in M$:

$$\|D_x f^n|_{E^s}\| < m(D_x f^n|_{E^c}) \leq \|D_x f^n|_{E^c}\| < m(D_x f^n|_{E^u}).$$

Partial hyperbolicity is a C^1-open condition: any diffeomorphism sufficiently C^1-close to a partially hyperbolic diffeomorphism is itself partially hyperbolic. For an extensive discussion of examples of partially hyperbolic dynamical systems, see the survey article [25] and the book [26]. Among these examples are: the time-1 map of an Anosov flow, the frame flow for a compact manifold of negative sectional curvature, and many affine transformations of compact homogeneous spaces. All of these examples preserve the volume induced by a Riemannian metric on M.

As in the Anosov case, the stable and unstable bundles E^s and E^u of a partially hyperbolic diffeomorphism are tangent to foliations, again denoted by $\mathcal{W}^s$ and $\mathcal{W}^u$ respectively [23]. Brin-Pesin and Pugh-Shub proved that these foliations are absolutely continuous.

A partially hyperbolic diffeomorphism $f\colon M \to M$ is *accessible* if any point in M can be reached from any other along an *su-path*, which is a concatenation of finitely many subpaths, each of which lies entirely in a single leaf of $\mathcal{W}^s$ or a single leaf of $\mathcal{W}^u$. Accessibility is a global, topological property of the foliations $\mathcal{W}^u$ and $\mathcal{W}^s$ that is the analogue of transversality of $\mathcal{W}^u$ and $\mathcal{W}^s$ for Anosov diffeomorphisms. In fact, the transversality of these foliations in the Anosov case immediately implies that every Anosov diffeomorphism is accessible. Fundamental Principle #4 suggests that accessibility might be related to ergodicity for conservative systems.

Conservative Partially Hyperbolic Diffeomorphisms Motivated by a breakthrough result with Grayson [27], Pugh and Shub conjectured that accessibility implies ergodicity, for a C^2, partially hyperbolic conservative diffeomorphism [28]. This conjecture has been proved under the hypothesis of center bunching [29], which is a mild spectral condition on the restriction of Df to the center bundle E^{c}. Center bunching is satisfied by most examples of interest, including all partially hyperbolic diffeomorphisms with $\dim(E^c) = 1$. The proof in [29] is a modification of the Hopf Argument using Lebesgue density points and a delicate analysis of the geometric and measure-theoretic properties of the stable and unstable foliations.

In the same article, Pugh and Shub also conjectured that accessibility is a widespread phenomenon, holding for an open and dense set (in the C^{r} topology) of partially hyperbolic diffeomorphisms. This conjecture has been proved completely for $r = 1$ [30], and for all r, with the additional assumption that the central bundle E^{c} is one dimensional [31].

Together, these two conjectures imply the third, central conjecture: in [28]:

Conjecture 1 (Pugh–Shub) *For any $r \geq 2$, the C^r, conservative partially hyperbolic diffeomorphisms contain a C^r open and dense set of ergodic diffeomorphisms.*

The validity of this conjecture in the absence of center bunching is currently an open question.

Dissipative Partially Hyperbolic Diffeomorphisms There has been some progress in constructing SRB-type measures for dissipative partially hyperbolic diffeomorphisms, but the theory is less developed than in the conservative case. Using the same construction as for Anosov diffeomorphisms, one can construct invariant probability measures that are smooth along the $\mathcal{W}^u$ foliation [32]. Such measures are referred to as u-Gibbs measures. Since the stable bundle E^{s} is not transverse to the unstable bundle E^{u}, the Anosov argument cannot be carried through to show that u-Gibbs measures are SRB measures.

Nonetheless, there are conditions that imply that a u-Gibbs measure is an SRB measure: for example, a u-Gibbs measure is SRB if it is the unique u-Gibbs measure [33], if the bundle $E^s \oplus E^c$ is nonuniformly contracted [34], or if the bundle $E^u \oplus E^c$ is nonuniformly expanded [35]. The proofs of the latter two results use Pesin Theory, which is explained in the next subsection.

SRB measures have also been constructed in systems where E^c is nonuniformly hyperbolic [36], and in (noninvertible) partially hyperbolic covering maps where E^c is 1-dimensional [37]. It is not known whether accessibility plays a role in the existence of SRB measures for dissipative, non-Anosov partially hyperbolic diffeomorphisms.

Nonuniform Hyperbolicity

The concept of Lyapunov exponents gives a natural way to extend the notion of hyperbolicity to systems that behave hyperbolically, but in a nonuniform manner. The fundamental principles described above, suitably modified, apply to these nonuniformly hyperbolic systems and allow for the development of a smooth ergodic theory for these systems. This program was initially proposed and carried out by Yakov Pesin in the 1970s [38] and has come to be known as *Pesin theory*.

Oseledec's Theorem implies that if a smooth map f satisfying the condition $m(D_x f) > 0$ preserves a probability measure ν, then for ν-a.e. $x \in M$ and every nonzero vector $v \in T_x M$, the limit

$$\lambda(x, v) = \lim_{n \to \infty} \frac{1}{n} \sum_{i=1}^{n} \log \| D_x f^i(v) \|$$

exists. The number $\lambda(x, v)$ is called the *Lyapunov exponent at x in the direction of v*. For each such x, there are finitely many possible values for the exponent $\lambda(x, v)$, and the function $x \mapsto \lambda(x, \cdot)$ is measurable. See the discussion of Oseledec's Theorem in ▶ Ergodic Theorems.

Let f be a smooth map. An f-invariant probability measure μ is *hyperbolic* if the Lyapunov exponents of μ-a.e. point are all nonzero. Observe that any invariant measure of a hyperbolic map is a hyperbolic measure.

A conservative diffeomorphism $f: M \to M$ is *nonuniformly hyperbolic* if the invariant measure equivalent to volume is hyperbolic. The term "nonuniform" is a bit misleading, as uniformly hyperbolic conservative systems are also nonuniformly hyperbolic. Unlike uniform hyperbolicity, however, nonuniform hyperbolicity allows for the *possibility* of different strengths of hyperbolicity along different orbits.

Nonuniformly hyperbolic diffeomorphisms exist on all manifolds [39,40], and there are C^1-open sets of nonuniformly hyperbolic diffeomorphisms that are not Anosov diffeomorphisms [41]. In general, it is a very difficult problem to establish whether a given map carries a hyperbolic measure that is nonsingular with respect to volume.

Hyperbolic Blocks As mentioned above, the derivative of f along almost every orbit of a nonuniformly hyperbolic system looks like the derivative down the orbit of a uniformly hyperbolic system; the nonuniformity can be detected only by examining a positive measure set of orbits. Recall that Lusin's Theorem in measure theory states that every Borel measurable function is continuous on the complement of an arbitrarily small measure set. A sort of analogue of Lusin's theorem holds for nonuniformly hyperbolic maps: every C^2, nonuniformly hyperbolic diffeomorphism is uniformly hyperbolic on a (noninvariant) compact set whose complement has arbitrarily small measure. The precise formulation of this statement is omitted, but here are some of its salient features.

If μ is a hyperbolic measure for a C^2 diffeomorphism, then attached to μ-a.e. point $x \in M$ are transverse, smooth stable and unstable manifolds for f. The collection of all stable manifolds is called the *stable lamination* for f, and the collection of all unstable manifolds is called the *unstable lamination* for f. The stable lamination is invariant under f, meaning that f sends the stable manifold at x into the stable manifold for $f(x)$. The stable manifold through x is contracted uniformly by all positive iterates of f in a neighborhood of x. Analogous statements hold for the unstable manifold of x, with f replaced by f^{-1}.

The following quantites vary measurably in $x \in M$:

- the (inner) radii of the stable and unstable manifolds through x,
- the angle between stable and unstable manifolds at x, and
- the rates of contraction in these manifolds.

The stable and unstable laminations of a nonuniformly hyperbolic system are absolutely continuous. The precise definition of absolute continuity here is slightly different than in the uniformly and partially hyperbolic setting, but the consequences (AC1) and (AC2) of absolute continuity continue to hold.

Ergodic Properties of Nonuniformly Hyperbolic Diffeomorphisms Since the stable and unstable laminations are absolutely continuous, the Hopf Argument can be applied in this setting to show:

Theorem 4 (Pesin) *Let f be C^2, conservative and nonuniformly hyperbolic. Then there exists a (mod 0) partition $\mathcal{P}$ of*

M into countably many f-invariant sets of positive volume such that the restriction of f to each $P \in \mathcal{P}$ is ergodic.

The proof of this theorem is also exposited in [42]. The countable partition can in examples be countably infinite; nonuniform hyperbolicity alone does not imply ergodicity.

The Dissipative Case As mentioned above, establishing the existence of a nonsingular hyperbolic measure is a difficult problem in general. In systems with some global form of hyperbolicity, such as partial hyperbolicity, it is sometimes possible to "borrow" the expansion from the unstable direction and lend it to the central direction, via a small perturbation. Nonuniformly hyperbolic attractors have been constructed in this way [43]. This method is also behind the construction of a C^1 open set of nonuniformly hyperbolic diffeomorphisms in [41].

For a given system of interest, it is sometimes possible to prove that a given invariant measure is hyperbolic by establishing an *approximate* form of hyperbolicity. The idea, due to Wojtkowski and called the *cone method*, is to isolate a measurable bundle of cones in TM defined over the support of the measure, such that the cone at a point x is mapped by $D_x f$ into the cone at $f(x)$. Intersecting the images of these cones under all iterates of Df, one obtains an invariant subbundle of TM over the support of f that is nonuniformly expanded.

Lai-Sang Young has developed a very general method [44] for proving the existence of SRB measures with strong mixing properties in systems that display "some hyperbolicity". The idea is to isolate a region X in the manifold where the first return map is hyperbolic and distortion estimates hold. If this can be done, then the map carries a mixing, hyperbolic SRB measure. The precise rate of mixing is determined by the properties of the return-time function to X; the longer the return times, the slower the rate of mixing.

More results on the existence of hyperbolic measures are discussed in the next section.

An important subject in smooth ergodic theory is the relationship between entropy, Lyapunov exponents, and dimension of invariant measures of a smooth map. Significant results in this area include the Pesin entropy formula [45], the Ruelle entropy inequality [46], the entropy-exponents-dimension formula of Ledrappier–Young [47,48], and the proof by Barreira-Pesin-Schmeling that hyperbolic measures have a well-defined dimension [49]. ► Hyperbolic Dynamical Systems contains a discussion of these results; see this entry there for further information.

The Presence of Critical Points and Other Singularities

Now for a discussion of the aforementioned technical difficulties that arise in the presence of singularities and critical points for the derivative.

Singularities, that is, points where Df (or even f) fails to be defined, arise naturally in the study of billiards and hard sphere gases. The first subsection discusses some progress made in smooth ergodic theory in the presence of singularities.

Critical points, that is, points where Df fails to be invertible, appear inescapably in the study of noninvertible maps. This type of complication already shows up for noninvertible maps in dimension 1, in the study of unimodal maps of the interval. The second subsection discusses the technique of parameter exclusion, developed by Jakobson, which allows for an ergodic analysis of a parametrized family of maps with criticalities.

The technical advances used to overcome these issues in the interval have turned out to have applications to dissipative, nonhyperbolic, diffeomorphisms in higher dimension, where the derivative is "nearly critical" in places. The last subsection describes extensions of the parameter exclusion technique to these near-critical maps.

Hyperbolic Billiards and Hard Sphere Gases

In the 1870s the physicist Ludwig Boltzmann hypothesized that in a mechanical system with many interacting particles, physical measurements (observables), averaged over time, will converge to their expected value as time approaches infinity. The underlying dynamical system in this statement is a Hamiltonian system with many degrees of freedom, and the "expected value" is with respect to Liouville measure. Loosely phrased in modern terms, Boltzmann's hypothesis states that a generic Hamiltonian system of this form will be ergodic on constant energy submanifolds. Reasoning that the time scales involved in measurement of an observable in such a system are much larger than the rate of evolution of the system, Boltzmann's hypothesis allowed him to assume that physical quantities associated to such a system behave like constants.

In 1963, Sinai revived and formalized this ergodic hypothesis, stating it in a concrete formulation known as the Boltzmann-Sinai Ergodic Hypothesis. In Sinai's formulation, the particles were replaced by N hard, elastic spheres, and to compactify the problem, he situated the spheres on a k-torus, $k = 2, 3$. The Boltzmann-Sinai Ergodic Hypothesis is the conjecture that the induced Hamiltonian system on the $2kN$-dimensional configuration space is ergodic on constant energy manifolds, for any $N \geq 2$.

Sinai verified this conjecture for $N = 2$ by reducing the problem to a billiard map in the plane. As background for Sinai's result, a brief discussion of planar billiard maps follows.

Let $D \subset \mathbb{R}^s$ be a connected region whose boundary ∂D is a collection of closed, piecewise smooth simple curves the plane. The *billiard map* is a map defined (almost everywhere) on $\partial D \times [-\pi, \pi]$. To define this map, one identifies each point $(x, \theta) \in \partial D \times [-\pi, \pi]$ with an inward-pointing tangent vector at x in the plane, so that the normal vector to ∂D at x corresponds to the pair $(x, \pi/2)$. This can be done in a unique way on the smooth components of ∂D. Then $f(x, \theta)$ is obtained by following the ray originating at (x, θ) until it strikes the boundary ∂D for the first time at (x', θ'). Reflecting this vector about the normal at x', define $f(x, \theta) = (x', \pi - \theta')$.

It is not hard to see that the billiard map is conservative. The billiard map is piecewise smooth, but not in general smooth: the degree of smoothness of f is one less than the degree of smoothness of ∂D. In addition to singularities arising from the corners of the table, there are singularities arising in the *second* derivative of f at the tangent vectors to the boundary.

In the billiards studied studied by Sinai, the boundary ∂D consists of a union of concave circular arcs and straight line segments. Similar billiards, but with convex circular arcs, were first studied by Bunimovich [51]. Sinai and Bunimovich proved that these billiards are ergodic and nonuniformly hyperbolic. For the Boltzmann-Sinai problem with $N \geq 3$, the relevant associated dynamical system is a higher dimensional billiard table in euclidean space, with circular arcs replaced by cylindrical boundary components.

In a planar billiard table with circular/flat boundary, the behavior of vectors encountering a flat segment of boundary is easily understood, as is the behavior of vectors meeting a circular segment in a neighborhood of the normal vector. If the billiard map is ergodic, however, every open set of vectors will meet the singularities in the table infinitely many times. To establish the nonuniform hyperbolicity of such billiard tables via conefieds, it is therefore necessary to understand precisely the fraction of time orbits spend near these singularities. Furthermore, to use the Hopf argument to establish ergodicity, one must avoid the singularities in the second derivative, where distortion estimates break down. The techniques for overcoming these obstacles involve imposing restrictions on the geometry of the table (even more so for higher dimensional tables), and are well beyond the scope of this paper.

The study of hyperbolic billiards and hard sphere gases has a long and involved history. See the articles [50] and [52] for a survey of some of the results and techniques in the area. A discussion of methods in singular smooth ergodic theory, with particular applications to the Lorentz attractor, can be found in [53]. Another, more classical, reference is [54], which contains a formulation of properties on a critical set, due to Katok–Strelcyn, that are useful in establishing ergodicity of systems with singularities.

Interval Maps and Parameter Exclusion

The logistic family of maps $f_t\colon x \mapsto tx(1-x)$ defined on the interval $[0, 1]$ is very simple to define but exhibits an astonishing variety of dynamical features as the parameter t varies. For small positive values of t, almost every point in I is attracted under the map f_t to the sink at -1. For values of $t > 4$, the map has a repelling hyperbolic Cantor set. As the value of t increases between 0 and 4, the map f_t undergoes a cascade of period-doubling bifurcations, in which a periodic sink of period 2^n becomes repelling and a new sink of period 2^{n+1} is born. At the accumulation of period doubling at $t \approx 3.57$, a periodic point of period 3 appears, forcing the existence of periodic points of all periods. The dynamics of f_t for t close to 4 has been the subject of intense inquiry in the last 20 years.

The map f_t, for t close to 4, shares some of the features of the doubling map T_2; it is 2-to-1, except at the critical point $\frac{1}{2}$, and it is uniformly expanding in the complement of a neighborhood of this critical point. Because this neighborhood of the critical point is not invariant, however, the only invariant sets on which f_t is uniformly hyperbolic have measure zero. Furthermore, the second derivative of f_t vanishes at the critical point, making it impossible to control distortion for orbits that spend too much time near the critical point.

Despite these serious obstacles, Michael Jakobson [55] found a method for constructing absolutely continuous invariant measures for maps in the logistic family. The method has come to be known as *parameter exclusion* and has seen application far beyond the logistic family. As with billiards, it is possible to formulate geometric conditions on the map f_t that control both expansion (hyperbolicity) and distortion on a positive measure set. As these conditions involve understanding infinitely many iterates of f_t, they are impossible to verify for a given parameter value t.

Using an inductive formulation of this condition, Jakobson showed that the set of parameters t near 4 that fail to satisfy the condition at iterate n have exponentially small measure (in n). He thereby showed that for a positive Lebesgue measure set of parameter values t, the map f_t has an absolutely continuous invariant measure [55]. This measure is ergodic (mixing) and has a positive Lyapunov exponent. The delicacy of Jakobson's approach is confirmed by the fact that for an open and dense set of parameter values, almost every orbit is attracted to a periodic sink, and so f_t has no absolutely continuous invariant measure [56,57]. Jakobson's method applies not only to the logistic family but to a very general class of C^3 one-parameter families of maps on the interval.

Near-Critical Diffeomorphisms

Jakobson's method in one dimension proved to extend to certain highly dissipative diffeomorphisms. The seminal paper in this extension is due to Benedicks and Carleson; the method has since been extended in a series of papers [59,60,61] and has been formulated in an abstract setting [62].

This extension turns out to be highly nontrivial, but it is possible to describe informally the similarities between the logistic family and higher-dimensional "near critical" diffeomorphisms. The diffeomorphisms to which this method applies are crudely hyperbolic with a one dimensional unstable direction. Roughly this means that in some invariant region of the manifold, the image of a small ball under f will be stretched significantly in one direction and shrunk in all other directions. The directions of stretching and contraction are transverse in a large proportion of the invariant region, but there are isolated "near critical" subregions where expanding and contracting directions are nearly tangent.

The dynamics of such a diffeomorphism are very close to 1-dimensional if the contraction is strong enough, and the diffeomorphism resembles an interval map with isolated critical points, the critical points corresponding to the critical regions where stable and unstable directions are tangent.

An illustration of this type of dynamics is the Hénon family of maps $f_{a,b}\colon (x,y) \mapsto (1 - ax^2 + by, x)$, the original object of study in Benedicks-Carlesson's work. When the parameter b is set to 0, the map $f_{a,b}$ is no longer a diffeomorphism, and indeed is precisely a projection composed with the logistic map. For small values of b and appropriate values of a, the Hénon map is strongly dissipative and displays the near critical behavior described in the previous paragraph. In analogy to Jakobson's result, there is a positive measure set of parameters near $b = 0$ where $f_{a,b}$ has a mixing, hyperbolic SRB measure.

See [63] for a detailed exposition of the parameter exclusion method for Hénon-like maps.

Future Directions

In addition to the open problems discussed in the previous sections, there are several general questions and problems worth mentioning:

- What can be said about systems with everywhere vanishing Lyapunov exponents? Open sets of such systems exist in arbitrary dimension. Pesin theory carries into the nonuniformly hyperbolic setting the basic principles from uniformly hyperbolic theory (in particular, Fundamental Principles #3 and 4 above). To what extent do properties of isometric and unipotent systems (for example, Fundamental Principle #2) extend to conservative systems all of whose Lyaponov exponents vanish?
- Can one establish the existence of and analyze in general the conservative systems on surfaces that have two positive measure regimes: one where Lyapunov exponents vanish, and the other where they are nonzero? Such systems are conjectured exist in the presence of KAM phenomena surrounding elliptic periodic points.
- On a related note, how common are conservative systems whose Lyapunov exponents are nonvanishing on a positive measure set? See [64] for a discussion.
- Find a broad description of those dissipative systems that admit finitely (or countably) many physical measures. Are such systems dense among all dissipative systems, or possibly generic among a restricted class of systems? See [41,65] for several questions and conjectures related to this problem.
- Extend the methods in the study of systems with singularities to other specific systems of interest, including the infinite dimensional systems that arise in the study of partial differential equations.
- Carry the methods of smooth ergodic theory further into the study of smooth actions of discrete groups (other than the integers) on manifolds. When do such actions admit (possibly non-invariant) "physical" measures?

There are other interesting open areas of future inquiry, but this gives a good sample of the range of possibilities.

Article Outline

Glossary

Attractor A sub space of the state space of a certain system that the system does not leave anymore. If the sub space consists of only one point it is a point attractor.

Dialectical relation A relation between two persons or generally two sides representing a tension and a mutual dependency. In more contemporary terms a dialectical relation is a certain form of feed back relation.

Homo oeconomicus An actor who acts according to the assumptions of rational choice.

Homo sociologicus The assumption that man is basically a being following social rules in contrast to *homo oeconomicus*.

Meta rules Rules that operate on rules of interaction and change these rules.

Rational choice The theoretical assumption that man is a rational and egoistical actor, who tries to maximize his profit and selects in a certain situation the best strategies.

Socialization The biographical process by which an individual learns and internalizes the cultural norms and social rules of his specific society. The result is a social actor.

Social-cognitive systems Complex dynamical systems that consist of social actors and contain at least two different levels, namely a social level and a cognitive one.

Socio-cultural evolution The development of societies in the mutually interdependent dimensions of social structure and culture.

Universal modeling schema A schema that consists of different interdependent levels and each level is modeled as a complex dynamical system.

Definition of the Subject

Social-cognitive systems certainly belong to the most complex systems that we know. The reason for this complexity is due to the fact that social-cognitive systems at least consist of two different levels, namely a social and a cognitive one that permanently interact and mutually influence each other. In terms of the social and cognitive sciences, social-cognitive systems consist of social actors who interact and whose actions are determined by certain social rules. Yet these actors are also complex dynamical systems, i. e., cognitive ones. The cognitive processes of the individual actors also influence the specific actions. The social rules determine in some part the cognitive processes that in turn generate the according actions. But also in turn the cognitive processes may determine the actions in such a way that the social rules are influenced and even changed. That is for example the case in times of revolutions and/or political reforms. In this sense social-cognitive systems are determined by a permanent interdependent dynamics between these levels and that is why a modeling and precise analysis of these systems is rather difficult. In addition, social-cognitive systems are able to adapt to changing environmental conditions. This means that these systems are able to change their rules and structure.

Introduction

Social-cognitive complexity, although of course not in this term, has been the subject of social thinking since the beginning of reflections on society and social actions. Already one of the earliest works on society in human history, namely Plato's *Politeia* (The Republic), emphasizes the importance of the interdependency of mind and social structure: A certain desired social structure, i. e. the differentiation of society into different social classes, can be generated and reproduced only by influencing the minds of the social actors via education. A suited education cares for the adequate thinking of the individuals, which in turn guarantees the production and reproduction of the class structure by the social actions of the educated actors. The class structure finally determines the minds of the individuals and produces the wished forms of socially determined thinking. Plato's ideal society is certainly not a paradigm for democratic societies but the logic of Plato's arguments already demonstrates the necessity to take account of both social and cognitive levels if one wants to understand society and the socially determined actions of human beings. It is not by chance that all authors who thought about utopian societies also stressed the importance of education, i. e. the influencing of minds to produce and reproduce social structures, for example Huxley and Orwell.

More than two millennia later, Karl Marx in his theory of Historical Materialism [27] dealt in a similar way with the subject of social-cognitive complexity. He postulated a "dialectical" relation between consciousness or mind respectively and social structure – the social conditions (*soziale Verhältnisse*) in his terms. The social conditions determine the minds of social actors and produce that way an ideological consciousness; accordingly the social actors reproduce the social conditions by their ideologically determined actions. That is the essence of Marx's famous base-superstructure theorem: the social conditions determine the consciousness, which in turn produces the ideological parts of society (In the German original: *Das gesellschaftliche oder materielle Sein bestimmt das Bewusstsein*). Yet in times of societal crisis the consciousness of certain social actors, namely the members of revolutionary classes, the consciousness is able to overcome the ideological constraints and produces by the social actions of revolution a new social structure. In such times historical progress is generated by the determination of social structures by the social minds of the revolutionary actors. That is why Marx called the relationship between mind and social structure a dialectical one: both sides of the relationship form a dynamical tension, influence the other and are influenced in turn by the other. If one substitutes the philosophical term of dialectic by the more precise contemporary term of feed back, one may say that Marx postulated social-cognitive systems as systems whose dynamics is characterized by permanent feed back loops between a social and a cognitive level. To be sure, although Marx frequently stressed the importance of mathematically formulated theories he never could think of transforming the venerable concept of dialectic into a mathematical framework.

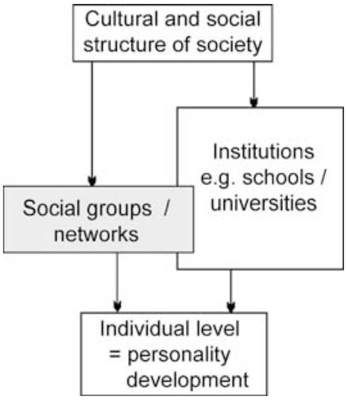
Marx had in principle captured the whole problem of social-cognitive complexity although only in an informal manner and formulated in classical philosophical terms. Yet his monumental approach was certainly not suited as a common foundation for the development of the social and cognitive sciences. Nearly at the same time the French sociologist Emile Durkheim, one of the founding fathers of modern sociology, postulated that social phenomena must only be explained by other *social* phenomena, which is one of the most important theoretical premises of the contemporary social sciences. As a consequence social scientists only deal with *social* complexity and consciously often neglect the influence of cognitive factors on social processes. Accordingly cognitive scientists only deal with *cognitive* complexity and neglect the impact of social factors on cognitive processes. Paradigmatic in this sense is the great work of Jean Piaget [34,35] who defined cognitive development as a principally autonomous process that can only be slowed down or accelerated by its social environment. With a famous expression of the German social theorist Niklas Luhmann one can say that the different disciplines of social-cognitive complexity reduced the complexity of their subject by concentrating on only one level of the two-level problem [26].

Matters became even more complicated when social theorists discovered that society is not a homogenous system but must itself be differentiated into different levels. The most basic differentiation is of course that of a micro-level and a macro-level [1,22]. In addition it is possible and sometimes necessary to introduce a meso-level, that is a middle range level of social reality. For example, if the micro-level is constituted by individual social actors or their actions respectively, if the macro-level is defined as a whole society or even an aggregation of societies like, e. g. the European Union, then a meso-level may consist of certain institutions, political parties and the like.

An additional complication and hence another increase of complexity must be accepted by taking account of the fundamental difference between social structure and culture. It is not possible for this article to mention all the numerous definitions of culture social theorists have developed in the last century. Following Habermas [15] and Giddens [12] it is sufficient to define the social structure of a society as the set of all social rules that are valid in a certain society and culture as the sum of all accepted knowledge, beliefs, world views, etc. in that society. By considering that fundamental distinction and by taking into account the different levels of society we apparently obtain a multi-dimension system, namely a system consisting of different levels that contain two dimensions – the socio-structural one and the cultural one. It is no wonder that social theorists concentrated on the social level of social-cognitive complexity, because this level is complex enough.

The main problem with such multi-level approaches is of course that the relations between the different levels and hence their interactions could usually be described only in an informal and frequently metaphorical manner. When a social theorist draws a graphical schema with different levels and additionally two dimensions the schema itself explains nothing but just states a problem. Somehow the levels interact and somehow individual actions are determined by the levels above, but in general this *somehow* cannot be precisely explained. To be sure, there are a lot of empirical studies that try, e. g., to analyze the impact of certain social structure on specific actions. But there is no general precise theory of links between the different levels of society [1].

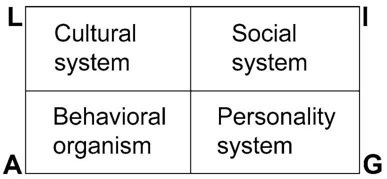
Yet despite these difficulties in several fields of the social and cognitive sciences not only the different levels of society but also the cognitive level of individual actors is taken into account. That is especially the case in socio-psychology and in particular in theories of socialization. The analysis of processes of socialization indeed demands that cognitive levels and social levels alike must be considered, if one understands socialization as the process by which the individual mind is formed according to the social structure and the cultural norms and values of a particular society. Although in the general models of processes of socialization the relation between the social levels and the cognitive one is expressed only one-sided, i. e., only the determination of the personality by social structure is taken into account in contrast to Marx, at least it is suited to speak of attempts to capture the whole social-cognitive complexity of social reality. Such a model of socialization is shown in Fig. 1; it is a shortened version of a more complex model of Geulen and Hurrelmann [11].



Cultural and social structure of society
Institutions e.g. schools / universities
Social groups / networks
Individual level = personality development

Social Cognitive Complexity, Figure 1
A multi-level model of socialization

The well-known classical study of Berger and Luckmann "The Social Construction of Reality" is a paradigmatic example of such attempts [6] that in contrast to most one-sided models assumes a mutual interdependency of social and cognitive levels: According to them there is, in the tradition of Marx, a dialectical relation between the subjective social reality and the objective one. The subjective social reality consists of the internalized social rules and cultural values that constitute the personal identity, i. e. the individual personality. The objective social reality is generated by the according social actions and interactions of the socialized individual actors. Because the structure of this reality mirrors that of the individual personality the individual actions reproduce the objective reality, which was the determining factor of the constitution of the subjective reality. As in the case of Marx we have again a permanent feedback between the social and the cognitive level. Younger individuals participate in this process by taking over the structure of objective reality from their elders, by reproducing this structure in their own actions, and so forth. Although the theory of Berger and Luckmann does not deal with social progress, i. e., changes of social structure and culture, their model demonstrates how in principle it is possible to describe the interdependency



Social Cognitive Complexity, Figure 2
The general action system

of social and cognitive levels, even if only in an informal manner.

The most famous attempt to capture social-cognitive complexity in a whole model is certainly the well-known model of Parsons [8,29,32] of the differentiation of the action system. A simplified version is shown in Fig. 2.

The general assumption of Parsons is that each system is differentiated into four subsystems according to the famous AGIL-schema; the same logic of differentiation is valid for the subsystems and so forth. A means Adaptation, G stands for Goal Orientation, I is Integration, and L means Latent Pattern Maintenance. (The explanation of the AGIL-schema cannot be done in this article [29,33]). The picture shows that the social subsystems (social and cultural systems) constitute together with the cognitive subsystems (personality and behavioral system) the whole action system. The specific form of interaction between the four subsystems is called interpenetration, which roughly means that the four systems influence each other. For example, personalities are formed via socialization by the social and cultural subsystems, social and cultural systems are reproduced by personalities and according behavior and so on. Yet again we only have an informal theory, although the general logic of the AGIL-differentiation is certainly a great achievement.

To put it into a nutshell, the problem of dealing with social-cognitive complexity and not reducing the problem to one level is seen by many theorists. Yet the theoretical models are always just informal descriptions of the problem and programmatic foundations, if one looks at them from a precise, i. e. mathematical point of view.

Social-Cognitive Complexity, Algorithms, and Bottom Up Models

Despite many attempts to formulate the complexity of social-cognitive systems in a mathematical way for a long time it was not possible to transfer the mathematical tools of, e. g., mathematical physics to the problems of social reality. The use of statistical methods in empirical social research and experimental psychology is of course a well tested method since many decades. The problem was and frequently still is the mathematical formulation of *theoretical* models. Apparently the use of in particular differential equations is not suited for the problems one has to deal with in the social and cognitive realms. To be sure, simple cases can be analyzed in a mathematical way e .g. [5], but the complexity of social-cognitive systems in the sense of the great theorists mentioned in the preceding section could not be captured by models founded on the classical methods of the calculus.

The reasons for this are the peculiarities of social-cognitive systems. They are constituted, as was mentioned in the definition, by several levels that permanently interact and thus must be characterized by a multi-dimensional dynamics. In addition, social-cognitive systems are able to change their specific rules and structure by adapting to varying environmental conditions. It is of course possible to undertake a time series analysis in order to find some regularity in the historical development of such systems, but a time series analysis just describes a system's behavior in a phenomenological manner and gives no explanation. To make matters worse, even if one has found some regularity by a careful time series analysis the system may change its behavior via the varying of its rules; accordingly the time series will change and the analysis becomes worthless for the next time span. It is no wonder that more than once social and cognitive scientists alike believed that it would never be possible to develop a mathematical science of social and cognitive systems.

Fortunately things have changed by the development of new mathematical tools for the analysis of complex systems and in particular by the emergence of complex computer programs. These new mathematical modeling techniques, as cellular automata, Boolean networks, evolutionary algorithms, and artificial neural nets are on a first sight rather different methods but on a second sight they have much in common:

a) All modeling techniques are heuristically oriented to some natural processes as the reproductive capacity of living systems in the case of cellular automata and Boolean nets, the logic of biological evolution in the case of evolutionary algorithms, and the cognitive processes of the brain in the case of artificial neural nets. Sometimes these new mathematical tools are put together under the a bit misleading name of Soft Computing [48] but it would be more appropriate to call them nature oriented algorithms.
b) All these algorithms are very well suited for the construction of so-called bottom up models [24]. This term is used in contrast with top down models and means that the model construction is done by starting at the level of the elements of the system that shall be mod-

eled. Accordingly the units of the models represent the elements of the respective systems. The dynamics of the empirical system is represented by certain rules of interaction and the thus caused behavior of the whole model. The model's behavior is generated as an emergent consequence of the local interactions of the units of the model. This procedure allows constructing the respective model by *immediately* transferring the empirical observations of the system's elements and their rules of local interaction into the model. It is not necessary to make an abstract representation of the whole system by an aggregation of the elements.

For example, the modeling of a social group via a cellular automaton [21] can be done the following quite natural way: The cells of the cellular automaton represent the different individual members of the group and their specific rules of interaction determined by the group's social hierarchy are represented by the rules of transitions of the cellular automaton. It is then possible, at least in some cases, to predict the group's behavior by according simulation runs of the cellular automaton, as we did in several successful cases. The work of many researchers demonstrated that in particular cellular automata are very well suited for the analysis of social groups [13,16,25,30,39,41,43].

c) The capability of social-cognitive systems to adapt, i. e. to change their specific rules of interaction in order to fulfill certain environmental conditions can be modeled by the hybridization of the respective models, i. e., by the coupling of different modeling tools and such the constructing of a hybrid model [14]. In order to manage a successful adaptation adaptive systems must have not only rules of interaction but also meta rules, namely additional rules that operate on (*meta*) the rules of local interaction and change them according to the environmental demands. The best-known example for such adaptive capabilities is of course the changing of genomes by the genetic operators of mutation and recombination and by the force of natural selection in biological evolution. In this example the rules are those of individual epigenesis and ontogenesis; the meta rules are the genetic operators, steered by selection, that change the genome by variation.

A mathematical model of these processes of adaptation can be quite easily done by the construction of a hybrid system, consisting of several Boolean or logical nets respectively, representing the individual genotypes [18], and a genetic algorithm that operates on the rules of the Boolean nets and their specific topology.

Another example for adaptation is the case of political reforms. In nearly all advanced societies the *official* social rules of interaction are defined by laws and bureaucratic prescriptions. In parliamentary societies the meta rules are defined by the competence of the parliaments to change the laws and prescriptions by discussions and votes of majority. The meta rules then are given by the rules of procedure by which the parliaments have to operate. A variation of the rules of interaction by parliamentary decisions is done when the internal or external conditions of the society demand a changing of social structure. It can be demonstrated that democratic societies are more adaptive than dictatorships because dictatorial societies are both unwilling and unable to change their structure because of the resulting unrest and the danger for the ruling elite to lose its power [19].

An according model for such phases of political changing could, e. g. be constructed by the coupling of a cellular automaton (the model for the population) and an evolutionary strategy (the meta rules).

d) In contrast with a pure time series analysis bottom up models are able to explain, i. e. they can reduce observed phenomena to causes, namely to previous events that are causally linked to the observed event. In cases of complex systems such previous events can be either a previous state of the system. In that case the explanation consists of naming this particular previous state and the rules that generated the present state from the previous one. Or the previous event is an external disturbance of the system. Then the explanation consists of naming the disturbance and the reaction of the system's rules to the disturbance, i. e. to the externally changed state of the system. The third and most difficult case is that of an operation of the system's meta rules, their variation of the rules of interaction, and the generation of the present state via the changed rules of interaction. To be sure, the analysis and explanation of all different cases by the construction of an according valid model needs a lot of information about the empirical system. Yet a thorough explanation of such complex systems as socio-cognitive ones can only be done by the construction of models and simulation runs that use these new mathematical tools. To be sure, explanations of this kind can principally also be done by top down models and have been successfully done in physics and chemistry. Only the third case needs the distinction between rules and meta rules and hence demands models constructed the way sketched above.

Theoretical Foundations

The social sciences are, unfortunately, characterized by a multitude of different theoretical approaches that cannot be enumerated in this article. Yet for attempts to construct mathematical models of social or even social-cognitive processes there are two main approaches, namely the Rational Choice approach (abbreviated RC) e .g. [17] and a social systems theory approach, founded on social rules and structure. Both are based on certain anthropological foundations about the nature of man or social actors respectively.

The RC-approach is based on the assumption that man is basically an egoistical being who always tries to maximize his own profit without caring for others. This assumption has a venerable tradition and it goes at least back to the Leviathan of Hobbes, namely the question how social order is possible in a world of egoists. The term "rational" means that a social actor tries to find the optimal strategies in each action situation, i. e., he analyzes, which action as means could serve him best for his maximum welfare as goal. Hence each social action situation is considered by an actor as a situation in a strategic game like chess or poker: he rationally analyzes the different possible strategies and chooses the best – therefore rational choice.

The RC-approach has a great advantage for the purpose of mathematical model construction in the social sciences, namely the famous Theory of Games by von Neumann and Morgenstern [45]. Game theory was originally developed for the mathematical analysis of economical decision problems and already Max Weber stated that economical actions are a paradigm of rational actions, oriented to the most favorable proportion between different means and the goal of profit maximizing e .g. [46] (Oscar Morgenstern was an economist). But soon the partisans of RC-approaches generalized this idea and tried to capture the logic of social action in general by game theoretical models.

Usually game theoretical models are based on a so-called pay-off matrix. Because most RC-theorists distinguish only between two forms of behavior, namely cooperation and defection, a pay-off matrix is a two-dimensional one. A characteristic a pay-off matrix that is frequently used for the analysis of social dilemmas, in particular the famous Prisoner's Dilemma (PD), is the following one:

	C	D
C	3	0
D	5	1

C of course stands for cooperation and D for defection. As usual the matrix-values show the result of the combination of the two different action strategies. For example, the combination DC = 5 means that a defective player D gets five points while the cooperative player gets zero points (CD = 0). Accordingly a cooperative player gets three points if the other is also cooperative; the other gets three points too (CC = 3). The absolute values of course are arbitrary; the only condition for strategic games of the PD-type is that DC > CC > DD > CD.

In a famous study about *The Evolution of Cooperation* based on a tournament of different computer programs, i. e. programs that simulated winning strategies, Axelrod [2] showed that the best strategy was *Tit for Tat* (TFT). TFT can roughly be translated as "I do the same to you as you to me". TFT is a very simple strategy because the first player *A* always starts with a cooperative action and waits for the response of the other player *B*. If *B* is also cooperative then *A* keeps his cooperative actions. If *B* is defective then *A* switches his strategy and becomes defective too as long as *B* acts in a defective manner. The first cooperative action of *B* then is answered by *A* with an also cooperative action and so forth. Axelrod used for his own analysis a cellular automaton and confirmed his results later by using a genetic algorithm [3].

TFT is basically a cooperative strategy because each player who acts according to TFT always takes account of the strategies of his opponent and becomes defective only if his opponent does the same. Hence Axelrod concluded that the emergence of cooperation in a world of rational egoists is not only possible but also even probable because it can be mathematically shown that a cooperative strategy like TFT is the most favorable one for an egoistic rational player. In this sense the old question of Hobbes could finally be answered by the methods of mathematical game theory.

Despite the fact that the results of Axelrod are not so generally valid as Axelrod believed [9,19,31] it is no wonder that many partisans of the RC-approach saw these results as confirmation for the RC-approach and for the necessity to study social dilemmas by game theoretical methods. Sometimes it seemed that the social sciences had to be reduced to game theoretical analysis of decision problems. Yet these studies neglect several important difficulties.

Some time ago Lord Dahrendorf [7] formulated the important distinction between *homo oeconomicus* and *homo sociologicus*. *Homo oeconomicus* is the rational and egoistical actor, i. e. the basis of RC. *Homo sociologicus* in contrast is the social actor who orientates his actions to social rules and norms. He may be or not be an egoistical being but the important point is that his actions must be understood as the consequences of certain social rules that are valid in a specific situation. *Homo oeconomicus* understands a social action situation as a decision problem for finding the optimal strategy; his rationality, therefore, is the calculation for the optimal proportion between means and ends. The rationality of *homo sociologicus* on the other hand is an interpretative one: he must understand the situation in order to know, which rules determine the situation and which according actions he has to perform.

It is important to see that the question of Hobbes, which Axelrod and other partisans of RC tried to answer with a game theoretical analysis of social dilemmas, does not arise with the assumption of *homo sociologicus* as the basic nature of *homo sapiens*. Man is, according to this position, a social being by nature, i. e., his human nature is defined not only by characteristics like language or consciousness but also by his sociality. The basic question is then not how social order is possible at all – the question Hobbes answered by introducing the law enforcing state – but *how the construction* of social order is performed and how and why certain forms of social order were changed and others were not. Dahrendorf of course named this pair of concepts in this manner because he was convinced that *homo sociologicus* is the normal aspect of man as a social being; *homo oeconomicus* is a rather special case in situations where either no valid social rules exist, or where some actors deliberately decide *not to* follow the respective rules, or where social rules leave some space of freedom, which must be filled out by individual decisions.

It is not an arbitrary decision if one chooses the option for one anthropological option or the other. There are many reasons for the validity of the *homo sociologicus* position:

a) Studies in behavioral biology teach us that nearly all biological species consist of social beings, whether predators, prey, or plants; there are exceptions as, e. g., otters that live as loners but these are indeed exceptions. From anthropological studies it is to be learned that all our hominid ancestors lived in social communities and that socio-cultural evolution would not have been possible without human sociality [37]. Therefore, one may safely assume that human sociality is part of our biological heritage and not something humans had to create [47].
b) Social rules, and in particular social institutions, are important tools to reduce the complexity of the world and in particular that of the social world. Without accepted rules each new situation would be a new decision problem that has to be calculated anew. In contrast to that, social institutions offer a relief of the burden of new decisions because they enable actions by just following the rules [6,10,44]. That is particularly favorable if the rules have been proven in past situations. Hence, the evolution of social rules is more probable than Hobbes' famous *bellum omnium contra omnes* ("The war of all against all").
c) By following social rules it is possible to gain a social reputation as being reliable. Such a reputation frequently is favorable if others are undecided if they should trust an actor or not.
d) Finally, countless social studies have demonstrated that social actors mostly are rule-obeying beings. In a strict sense the social sciences could not have been as successful as they are if they would not have made the basic assumption of *homo sociologicus*.

These considerations do not mean that RC is wrong but that it is incomplete. There are certainly cases where social actors indeed act as egoistical rational players in a strategic game as for example in cases of social deviance or political revolutions. In particular, it is obviously a characteristic of modern democratic societies that the respective social rules nearly always leave a space of freedom for individual decisions. The social role of a teacher, for example, defines the necessity to act in a pedagogical way and to evaluate the efforts of the pupils. But it is an individual decision of the teacher if he mainly fosters the pupils or mainly acts as a critical evaluator of the pupils' performances. In this sense RC is an apt theory for some peculiarities of modern societies but it is not a general theory of human social action.

The consequence of these meta theoretical considerations is the following: The construction of mathematical models of social systems and of course of cognitive systems too must be founded on the basic logical unit of *rule*, either social rules or cognitive ones. To be sure, the elements of social systems are individual actors if one follows the bottom up modeling approach. Yet these actors are determined by the respective rules of their social systems; their actions, hence, must be understood as the result of the application of the rules valid in the respective situation. Certainly actors can be in error about the specific rules and/or they can decide to be socially deviant. In these cases it is particularly important to analyze the cognitive processes that lead the actor to social deviance. Yet the center of model construction and model interpretation must be the according rules.

We shall see in one example below that also in cases of social conformity the respective cognitive processes must be taken into account if one wants to understand how certain conformity emerged. Therefore, the interdependency of social and cognitive processes must be always be *principally* taken into account, although frequently it is possible to understand and even predict social behavior without considering the according cognitive processes.

A Universal Modeling Schema

The considerations of the preceding sections can be summarized in form of a universal modeling schema that captures the interdependency of different levels, the bottom up principle, and the logical dominance of the rule concept.

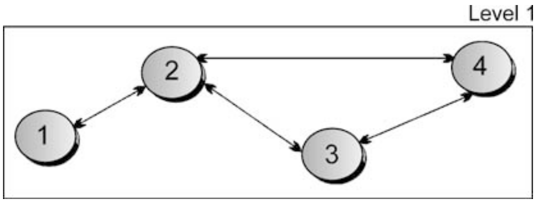
The basic *social* level of the schema consists of individual social actors who interact according to certain social rules. One may visualize this level, e. g., as the grid of a two-dimensional cellular automaton or the structure of a Boolean net. The level constitutes a dynamical complex system whose behavior depends, as usual, on the specific interaction rules, the initial states, and eventually operations of certain meta rules. Figure 3 shows such a level, which we may call level 1:

The concentration on this level and the neglect of a cognitive one apparently follows the mentioned methodical demand of Durkheim – social phenomena must only be explained by other social phenomena. Social actions are exclusively understood by the reconstruction of the respective rules that determined the actions. It is well known that many social processes can be understood and explained by taking into account only this level.

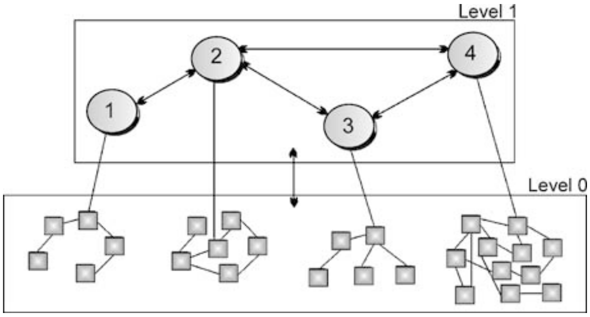
However, particularly in cases of social deviance, but not only there, the knowledge about the respective rules is not sufficient. Because social actors act with respect to certain rules *and* their particular thinking, worldviews etc. in many cases an according cognitive level must considered too. For example, the deeds of religious fanatics can only be understood if one reconstructs their fundamentalist worldviews and the according individual legitimization of criminal acts. In such cases social actors must also be considered as complex dynamical systems, i. e. cognitive ones with according cognitive rules and elements. The schema has to be extended as is shown in Fig. 4; the cognitive level may be called level 0.

Level 0 and level 1 already allow the modeling of many social processes, in particular those where an interplay of social and cognitive dynamics must be taken into account. Yet often even these two levels are not enough, as was mentioned in the introduction, because it is frequently necessary to model aggregations of individual actors. If, for example, one wants to analyze the political situation in a certain country with respect to the different political parties, then the concept of party of course means a certain institution consisting of specific rules and all party members. The interaction between such parties – coalitions, conflicts and so on – should be modeled on another level, namely level 2, the level of aggregations of actors (Fig. 5).

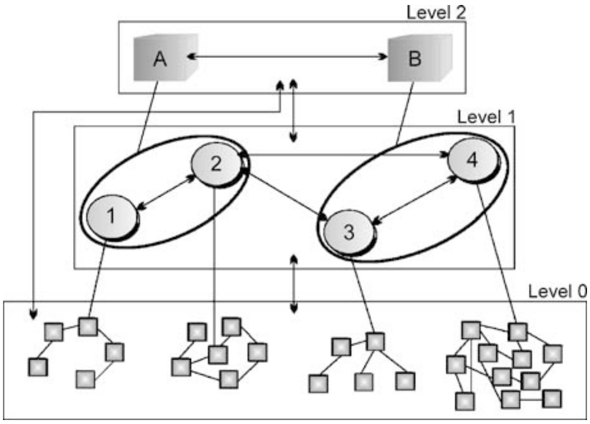
Note that level 2 must also be understood as a complex dynamical system with its own specific rules and elements. The elements there are usually called collective actors. All the three levels, hence, constitute certain complex systems whose dynamics is determined a) by the respective rules, elements, and initial states, b) by the eventual operation of meta rules that change the rules and in consequence the generation of states, and c) the interdependency between the different levels. This interdependency is visualized in



Social Cognitive Complexity, Figure 3
The social level as a complex dynamical system



Social Cognitive Complexity, Figure 4
Social actors modeled as cognitive complex systems



Social Cognitive Complexity, Figure 5
Social actors (level 1) modeled as cognitive complex systems (level 0) and as aggregations (level 2)

the pictures by the arrows that represent the mutual influences.

In contrast to many schemas of multi level models, e. g. the schema shown in the introduction, it must be noted that there is *in principle* a permanent feedback between all different levels. The action of individual actors (level 1) generate and reproduce the collective actors on level 2, yet collective actors in turn influence and determine the individual actors. A member of a political party acts *as* a party member. Accordingly the cognitive processes of individual actors determine their actions but these cognitive processes in turn are influenced by the result of the actions on the one hand and the collective actors the individual actor is a part of on the other. A party member not only acts but also thinks in concepts of the respective party. In addition, individual cognitive processes may directly influence collective actors, particularly in times of social and/or political change. History is full of the impact of individual cognitive processes on whole institutions, if the individual actors operate as reformers or revolutionaries.

It is certainly possible to extend even the schema shown in Fig. 5 by either adding a third social level, consisting of aggregations of collective actors, or by adding a second cognitive level by distinguishing between, e. g. conscious and unconscious thinking. Such extensions would lead to four- or even five-level models. Yet in most cases of social-cognitive modeling it is sufficient to operate with one, two or three levels. To be sure, it is always a question of the specific research interest how many levels and which ones one must take account of. The schema, after all, is just a *schema*, that is a frame work to guide the modeling processes when dealing with socio-cognitive processes – and not only these. The construction of a certain concrete model for a specific problem might be still a difficult task, in particular if one has to evaluate the validity of the specific model.

It is rather evident that this modeling schema can practically be applied to all complex social-cognitive processes. Yet the schema is in an even more ambitious sense a *universal* schema. This is a consequence from the mathematical characteristics of the algorithms mentioned in Sect. "Social-Cognitive Complexity, Algorithms, and Bottom Up Models". Imagine for example that level 1 is modeled by a cellular automaton, level 0 by one or several types of artificial neural networks, and level 3 again by a cellular automaton or a Boolean net. It is known from mathematical investigations that cellular automata are potentially equivalent to Universal Turing machines [36], which roughly means that no formal system is more general than such systems. This is the so-called Church–Turing thesis, which no mathematician seriously doubts. A corollary, the *physical* Church–Turing thesis, states that each physical, i. e. empirical system can be modeled via the use of a suited Universal Turing machine or an equivalent system. Although the physical Church–Turing thesis has not been proven in an exact mathematical manner nobody doubts this thesis either.

Without great difficulties it can be shown that each neural net and each Boolean net is equivalent to an according cellular automaton – the mappings between cellular automaton and the two classes of nets are injective. Hence principally each complex system can be modeled by using this schema *and* by using one or several of the mentioned algorithms. An important consequence from these considerations is the fact that a mathematical science of social-cognitive systems is not only possible but also that there is for each problem a general way how to treat it in a mathematical manner. The schema, therefore, can be understood as a constructive mapping from socio-cognitive phenomena to mathematical structures. The universality of the modeling schema is a constructive proof of the possibility of mathematical social and cognitive sciences.

Examples

These considerations show that and how mathematical models of social-cognitive processes can be constructed. Yet the most convincing proof is of course the demonstration of concrete examples, i. e., the models of specific complex social-cognitive systems. More detailed descriptions of these and other examples can be found in [20] and [21].

The Differentiating of Social Groups into Subgroups

A certain social group that consist of more than, say, three or four members is usually not a homogenous entity but is differentiated into several subgroups. The criteria for the generation of such subgroups are, of course, not always the same. In working teams for example the different qualifications of the members might be a criterion for the forming of specialized sub-teams. Yet in many informal groups a principle is certainly valid that may be called Homans' Principle [17] and that can be stated as follows: "Members of a social group favor interactions with people they like and they avoid interactions, if possible, with people they do not like." Everyday experience shows that this principle is indeed in many social groups an important criterion.

Since the foundation of sociometry by Moreno [28] the usage of a so-called sociomatrix or Moreno matrix respectively for the representation of social relations has become customary. If one wants to represent the mutual feelings of the members of a certain group via a sociomatrix the matrix may be:

	a	*b*	*c*
a	0	1	−1
b	1	0	1
c	−1	0	0

The matrix is coded with three values. Value 1 means a positive feeling or a liking respectively, value 0 means neutral or indifferent feelings, and −1 means negative feelings or disliking respectively. Hence the matrix can be understood as member *a* likes *b* and dislikes *c*, member *b* likes *a* and *c*, and member *c* dislikes *a* and is indifferent to *b*. The usage of such a sociomatrix as a mirror of the emotional structure of a certain group can be very important for, e. g. teachers, group leaders, group therapists or trainers of sport teams.

According to the Homans principle our research group COBASC constructed a cellular automaton with the goal to simulate and predict the emerging of different subgroups in specific groups, which we called in honor to Moreno the Moreno-CA (COBASC is the abbreviation for *Computer Based Analysis of Social Complexity*). It is a two-dimensional cellular automaton whose cells represent the members of the particular group that shall be modeled. The state of the cells represent the emotional states of the group member that range from "very dissatisfied" to "very satisfied." The cells state is dependent of the eight adjacent cells (a "Moore neighborhood") in the following way: the values of the emotional relations of the center cell to the eight cells of the Moore neighborhood are summed up; the emotional state of the center cell then is the arithmetical mean of these values. (The cells are usually modeled as squares; hence there are eight adjacent cells). The values of the emotional relations are coded as 1, 0, or −1 as in the example above. The task of each cell is to find a Moore neighborhood where its own emotional state is a maximum. Accordingly the rules of the Moreno-CA are:

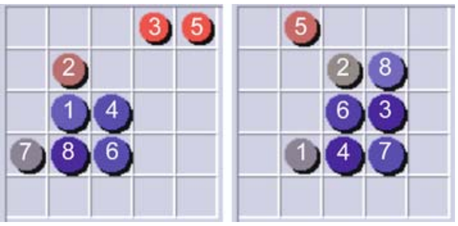
a) Place as many cells on the grid as there are group members; the rest of the grid's cells are free places.
b) Compute the emotional state for each "member" cell; vacant cells get the value 0.
c) Let each cell look on the grid for a Moore neighborhood where it can obtain a maximum state value.
d) Move each cell into that neighborhood.
e) If an attractor state, preferably a point attractor, has been reached, stop; if no attractor state could be reached after a certain number of runs, stop too. (A point attractor is a state the system will not leave although the rules are still operating; an attractor of longer period consists of several different states that the system will generate in cyclic order.)

The last rule is necessary because it can happen that the group reaches no attractor state at all or only those with rather long periods [21]. Factually the rules are a bit more complicated but this simplified version is the essence.

We validated this model with different social groups and obtained in all cases very satisfactory results. One empirical example shall serve to illustrate the methodical procedure:

With the permission of the teacher we asked a group of eight pupils of a primary school, with which pupils they would like to share a room in a youth hostel, with which pupils they would not share a room under any circumstances, and with which pupils they would share or not, according to the circumstances in the youth hostel. (It is often problematic to ask children (in this case 10 years old) directly if they like or dislike other children. That is why we chose this procedure of asking). These answers were transferred in the respective sociomatrix of the group. Afterwards the pupils were ordered to go into a strange classroom and choose places in order to wait for the teacher. The hypothesis was of course that the pupils would choose places according to their emotional relations to the other pupils. Then the values of the factual sociomatrix were inserted into the Moreno-CA; it reached a point attractor after 8 runs. The prediction of the program was then compared with the factual sitting order of the pupils (Fig. 6).

The program of course did not predict the absolute spatial distribution of the pupils in the classroom, for example if one pupil prefers to sit at a window. The Moreno-CA just predicts the relative positions of the pupils, i. e., which pupils are sitting together or which pupils are outsiders and are sitting alone. A comparison of the factual distribution and the prediction of the cellular automaton shows that the program indeed correctly prognosticated the sitting order for nearly all pupils with the exception of



Social Cognitive Complexity, Figure 6
The factual sitting order of the pupils (*left side*) and the prediction of the Moreno-CA

pupil 3. He is factually sitting besides the outsider pupil 5. However, the teacher of the children could give an explanation for this error of the program: Pupil 3 is known to be a practical jester who wanted to win the applause of the other children by teasing the outsider. Such melancholy character traits of course the program could not know.

We inserted the same sociomatrix into another program, namely a so-called self-organizing map or Kohonen feature map respectively (see next example). This is a special type of artificial neural nets. This net obtained even better results than the Moreno-CA because it placed pupil 3 beside pupil 5. An explanation for this result is given in [21].

To be sure, we did not want to predict just sitting orders of children in a classroom. The social experiment and the simulation by the two programs should show which subgroups existed in the whole group of children; this differentiation would become visible in the little experiment. The teacher, by the way, confirmed the results of the experiment and the prediction because according to her thorough knowledge the group of pupils factually consisted of an outsider and a homogenous group of all other pupils.

With respect to the modeling schema of the previous section this model uses only level 1, namely the social one. To be sure, in an implicit way, the emotional state of the children also plays a decisive role: there are no explicit social rules in this situation and the desire of the children to be in the neighborhood of their friends and to avoid other children is, according to Homans' principle, the main determination of the factual behavior. But in the model it was sufficient to represent the children as finite state automata, i. e., units whose state values are a direct consequence of their respective social milieu – in the model the Moore neighborhood. The Moreno-CA and the social experiment with the children demonstrate that indeed in many cases it is sufficient to construct models with only one level, in particular the social one.

Socialization by Learning from a Model

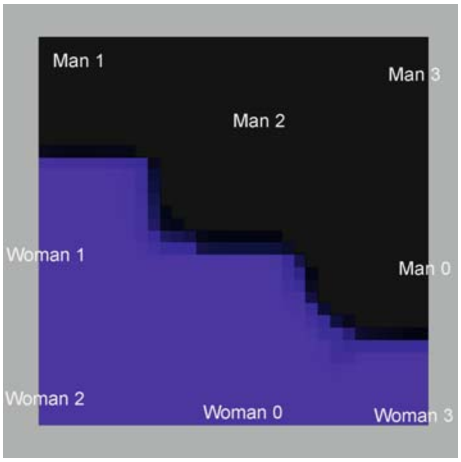
In Sect. "Introduction" it was demonstrated why theories of socialization always must take account of both social level(s) and the cognitive one. The social level represents the social milieu that is decisive for the specific socialization process; if one wants to explain the particular characteristics of this milieu one must consider additional social levels. The cognitive level of course represents the personality or identity of the individual that is formed or influenced by the respective milieu. The term formed though does not necessarily mean that socialization is a passive process. The socialized individual has the task to actively construct a worldview consisting of cultural values, social rules, and a culture specific knowledge.

One of the most known theories of socialization is the theory of learning from a model by Albert Bandura [4]. This theory states that socialization is to a high degree dependent on other people in the social milieu, who can act as models, i. e. as paradigms. The socialized individual perceives these models as positive or negative examples for its form of thinking and behavior. In other words, young people and children do not learn cultural values and specific forms of social behavior by internalizing general rules but by concrete examples they can observe and imitate. (There is a striking similarity between the socialization theory of Bandura and the cognitive theory of prototypes by Eleanor Rosch [23], which can only be mentioned here.)

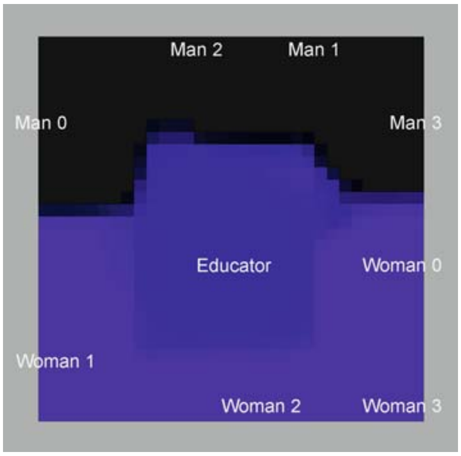
We applied this theory to a real case, namely a male youth from the *Ruhrgebiet*, an industrial area in the West of Germany. The youth, who shall be named Tom, of course a fictitious name, grew up in a workers family; he told us his story in an interview that was performed by one of our students. The father was an aggressive and violent man who often hit Tom's mother and frequently got involved in brawls and fights in the pubs. The mother was a submissive person who tried to keep up the family by working as a cleaner. Tom, therefore, had to care for his two younger sisters, which he very much disliked although he liked his sisters. When Tom was 10 years old his father left the family and disappeared. At the time of the interview Tom was 17 years old and had never heard any more from his father. Because Tom joined a gang of hooligans and got into trouble with the authorities and because the mother was unable to care for the two girls and Tom alike, Tom was admitted to a hostel of delinquent youths.

Despite the behavior of the father Tom adored him because *the father was a real man*. "Real" men are not afraid of other men, they become violent and hit if they feel insulted and in particular they dominate women, if necessary also by violence. "Real" women, on the other hand, are submissive and obedient to their men; they cook, wash and care for the children while real men work outside the house. As a consequence Tom developed a dichotomous worldview: men are strong and women are weak; women should obey and men command. The worlds of men and women must not be mixed in the sense that women take over tasks of men and men in turn care for the household. Consequently Tom despises the educators in the hostel because the female educators try to give orders to young men like Tom and the male educators perform household tasks like cleaning and cooking.

Tom apparently obtained his worldview by learning from the positive model of his father – "I want to be a man



Social Cognitive Complexity, Figure 7
The reconstruction of a dichotomous worldview: female versus male clusters



Social Cognitive Complexity, Figure 8
Increasing the female cluster by adding other "real women" and "false" men

like my father" – and the negative model of his mother. He also remarked that most men he met in his childhood were similar to his father and the women were similar to his mother. Hence he was early influenced by a homogenous milieu, where men and women all occupied the same gender specific roles.

For a simulation of Tom's biography with the result of a dichotomous worldview we used a Self-Organizing Map (SOM) or Kohonen Feature Map respectively that belongs to the class of neural networks, which learn in a non-supervised manner. In contrast to the forms of supervised learning non-supervised learning is not determined by externally given targets but the learning process is characterized by an internal logic. To put it into a nutshell, non-supervised learning is the ordering of a set of data according to certain internal criteria. There are different types of SOMs; we used a so-called Ritter–Kohonen model [38]. The technical details do not matter here; they can be looked up in any textbook on neural nets. The main intention of the simulation was to reconstruct the genesis of Tom's worldview and to demonstrate the according behavior in the present. Hence we inserted formal representations of the father and the mother as positive and negative models and inserted additional persons into the SOM. The SOM then constructed clusters of the different persons who are distinguished according to the criterion "real men" versus "real women". A first result is shown in Fig. 7.

The spatial nearness on the screen represents similarities or differences between the clustered persons respectively.

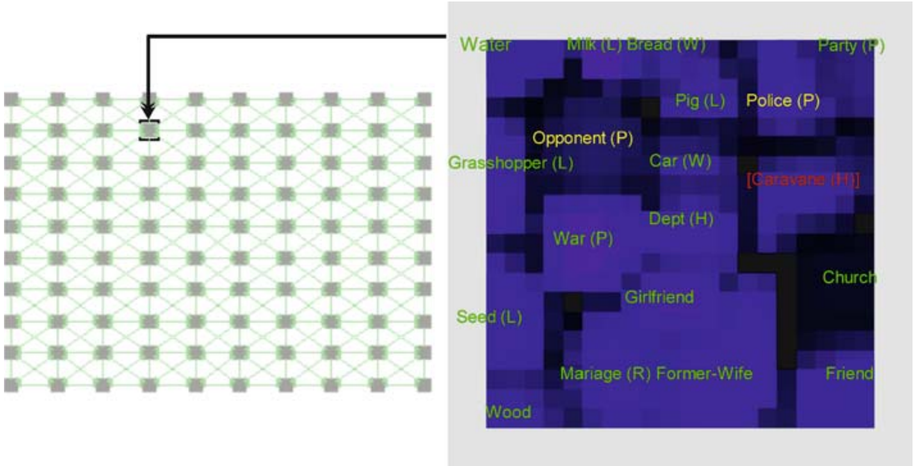
Afterwards we inserted other persons who differed from the first in certain personal respects. In particular we inserted formal representations of male educators who had female characteristics like cooking or cleaning. The SOM placed these men near the female cluster according to Tom's worldview: Tom does not accept these educators as real men but sees them more as women in male disguise. This is shown in Fig. 8.

The SOM apparently is able to simulate the important parts of Tom's socialization processes. As a SOM is a purely deterministic algorithm the successful simulation of Tom's cognitive genesis must be seen as a deterministic process too. Tom, so to speak, had no chance to become another person because the social circumstances determined his biography in a complete way.

The model uses only level 0, i. e., the cognitive one. Yet the social level is implicitly present too because of the inputs we inserted to the program; these inputs represent the social milieus in which Tom grew up and presently lives. In addition, the worldview of Tom has certainly social consequences not only for his biography. His membership in a hooligan gang, where he feels at home, indicates that his biography is representative for many youth members of such gangs. The according consequences for societal problems are obvious. In this respect the example of Tom also contains level 2, e. g. the level of collective actors like the different hooligan gangs and the social institutions that have to deal with them.

Modeling Social-Cultural Evolution

The last example is a rather complex model whose theoretical foundations and historical arguments can be read up in [20]. In contrast to the two preceding examples that be-



Social Cognitive Complexity, Figure 9
Cognitive state of an individual actor and his place in the artificial society

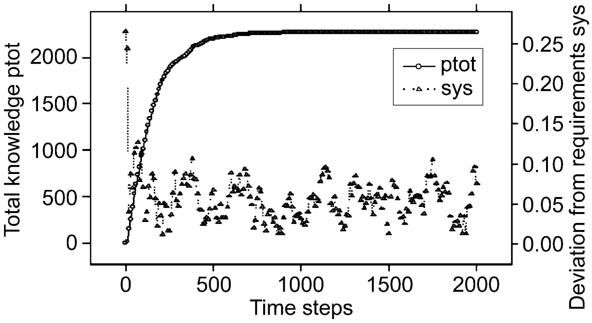
long to the field of micro-sociology this model deals with the evolution of whole societies. The basic assumption is that socio-cultural evolution is generated by creative inventions of individual actors and by the acceptance of these new ideas by the respective society. The social structure and the cultural norms of a society may promote or hinder the generation and acceptance of new ideas. In particular, the decisive factor is the degree of role autonomy for the occupants of creative roles like engineers, artisans, artists or scientists. If this degree is sufficiently high then the respective society evolves, i. e. increases its cultural capacity and generates social structures that are more efficient to deal with the problems of the society than old ones. If the degree is low, then the society stagnates, i. e. it becomes caught in a cultural and socio-structural attractor.

Comparative studies of the history of many societies always showed the same results, namely an early blossoming and cultural growth, then a period of consolidation, and finally stagnation or even regression, i. e. the return to some previous states [40,42]. According to our theoretical assumptions in these cases the degree of role autonomy was not high enough to allow an unhindered evolution. Only one case is known where apparently cultural evolution did not get caught in an attractor, namely the culture of European Modernity that was the historical basis for the contemporary Western culture. Historical studies confirm our hypothesis: In all cases of socio-cultural evolution the degree of role autonomy was much lower than in the European Modernity and the Western culture in general.

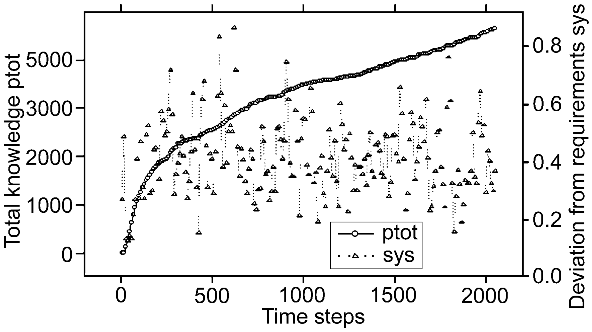
To validate these considerations by the use of a mathematical model we constructed the so-called socio-cultural-cognitive algorithm (SCCA). The model consists of a) a social level that is constructed as a cellular automaton. As usual the cells represent individual actors, i. e. members of a certain society. The rules of the cellular automaton determine the degree of role autonomy, i. e. the proportional ability of the actors to learn and create new ideas on the second level. b) The second level is a cognitive one: Each cell consists of a combination of different neural networks, namely several so-called bi-directional associative nets (BAM) and a SOM from the type used in example "Socialization by Learning from a Model". The task of the BAM is to associate observed characteristics from certain objects with the according semantic concepts – small, furry, and meowing is associated with cat. The task of the SOM is to order the concepts into a semantical network. These cognitive processes can be performed either in the way of learning, i. e. taking over new concepts from other actors, or by creating new concepts. The sum of the results of the individual cognitive processes is defined as the state or level that the respective culture has reached. Figure 9 shows an individual actor and its place on the grid of the cellular automaton.

The degree of role autonomy is inserted into the rules of the cellular automaton. We did many experiments with different values of this degree. The most important result is that in most cases the according culture indeed showed an evolutionary pattern known from human history, in particular described by the great British historian Arnold Toynbee (Fig. 10).

Only in the few cases with a high degree of role autonomy our model showed an evolutionary path known from the history of European Modernity. This is shown in Fig. 11.



Social Cognitive Complexity, Figure 10
A normal path (Toynbee path) of cultural evolution



Social Cognitive Complexity, Figure 11
A "Western development"

Societies with a sufficient high degree of role autonomy are not hindered in their cultural development although of course such societies may be stopped in their evolution by external forces. That could have been the reason for the final stagnation of the ancient Greek culture that also was characterized by a high degree of role autonomy for the occupants of the creative roles. Our model confirms that such societies are very seldom, which may be indeed the main reason for the fact, as Toynbee [42] observed, that the overwhelming majority of historically known societies stagnation was their inevitable fate.

The model is characterized by interplay of the two levels with consequences for a third one because the social structure determines the individual creative processes that in turn determine the fate of the whole society. In addition, sufficient developments on the cognitive level may also change the social structure: the better the cognitive improvements are, the higher becomes the degree of role autonomy on the social level. Such a rule is confirmed too by historical observations of the European history: In the Middle Ages the degree of role autonomy was not much higher than in contemporary cultures like feudal China or the Islamic societies. By the cultural progress during European Modernity the degree of role autonomy permanently increased. The model, hence, shows the consequences of such interdependent dynamics of the different levels that may explain important courses of history with respect to the fate of whole cultures.

Conclusions and Future Directions

The general possibility of a mathematically formulated science of social and cognitive processes was demonstrated in the Universal Modeling Schema and the fact that suited formal models like cellular automata or neural networks are equivalent to Universal Turing Machines. How many levels one needs for a concrete model, which ones, and how the relations between the levels are to be formulated is of course a question of the specific research problem. Constructing models of socio-cognitive processes will never be a trivial task. The modeling schema gives general orientations, but the detailed knowledge of the problem and in particular of the empirical data is always a necessary condition for the construction of social-cognitive models. That is of course a truism if it is stated in such a general manner but one that must always be taken into account. In particular, the knowledge about model construction and of suited algorithms never substitutes the profound knowledge about the specific fields of research.

The general relation between a social level and a cognitive one can also be stated in terms of individual actors. If one takes for example a most basic social situation, i. e. the communicative interaction between an actor A and another actor B, and if one assumes that during the interaction neither the social rules of this situation nor the cognitive processes of the actors change, then this interaction can be written the following way:

If f designates the set of social rules decisive for this situation and if g_A and g_B designate the cognitive processes of A and B respectively, then

$$f(A) = g_B(B)\,.$$

In other words, the application of the social rules f on the personality of A causes A to send an appropriate message to B, who in turn is moved to perform the cognitive processes g_B. In this case the social level determines the cognitive one, as is certainly the case in most forms of everyday communication. Accordingly the equations can be written if the cognitive processes determine the social rules, for example if a student becomes more intelligent than his professor by the teaching of the professor. (For general formulations of these equations see also [21]).

The most important problem for a socio-cognitive science that operates with mathematical models and according computer simulations is without doubt the proper relation between theory, formal model and simulation program. A complete research program that has to take care of all three components follows the order: theory construction or theory selection respectively – transformation of the theory into a suited model – construction of a simulation program – comparing the results of the simulation runs with known empirical data. If everything went right, the last step will be a confirmation of the whole process. Yet since Murphy's law we know that each step may contain errors and if the data are not compatible with the simulation results then the error(s) may be in the theory, the model, the simulation program, or in several of the steps.

In particular the fundamental role of theory has frequently been neglected in the many attempts to construct a mathematical or computational respectively social science by using computer models of socio-cognitive phenomena. The mentioned dominance of RC-models on the foundations of Game Theory is just one indicator for this problem. Yet the social and cognitive sciences are much more than theories about rational and egoistical players in strategic games. Therefore, the most important problem for the future is the careful analysis of the research program formulated in the three or four steps mentioned above. Only then the use of mathematical models and suited simulation programs will be the methodical basis for a real socio-cognitive science.

Yet we have no alternative to the development of such sciences. If this research program is not successful we will always be the unconscious slaves of the social conditions we produced ourselves, in particular of a future we did not wish for. A science of the complex socio-cognitive reality is certainly not a sufficient condition for the solving of all our social problems. But it is a necessary condition for the task that we must understand our own species, that is to understand our own social and cognitive processes.

Article Outline

Glossary

Self-organization Self-organization lies behind all structure and pattern formation in nature's complex systems, including the human brain. Self-organization is a principle governing a system where no agent-like entity is ordering the elements, telling them where and what to do. In self-organizing systems, low-dimensional dynamics are revealed by changing one (or more) control parameter(s) whose role is simply to move the system through a series of state changes without prescribing its behavioral patterns.

Coordination dynamics Coordination dynamics seeks the laws, principles and mechanisms underlying the coordinated behavior of different kinds of components at multiple levels of description (molecules, cells, circuits, etc). It is an overarching conceptual framework that describes, explains and predicts how patterns of coordination form and change at multiple levels of brain and behavior. The brain, mind and behavior are linked by virtue of sharing a common underlying coordination dynamics.

Information exchange A remarkable fact is that in contrast to classical dynamics that deal with fundamental quantities such as mass, length and time and their relations, coordination dynamics is informational in nature, dealing with informational quantities of a relational kind that couple different parts of a system or different systems.

Phase transitions Phase transitions are the true illustration that a system is self-organizing. They are spontaneous qualitative pattern changes occurring as parameters are changed quantitatively. When they occur, abrupt switches from one coordinated pattern to another are observed and the dynamics of the entire self-organizing system is dominated by one or a few collective variables: the order parameters.

Stability Stability is a key concept in coordination dynamics. Here the stability is of coordination or collective variables. The (loss of) stability of a self-organizing system indicates whether a phase transition is to occur. In order to evaluate the stability of a system, one can perturb it and measure the time it takes for the system to return to its initial state, i. e. its *relaxation time*. A number of other converging measures have been used to measure stability in coordination dynamics such as *switching time* (the time it takes for the system to switch from one pattern to another when phase transitions occur) and *critical fluctuations* (the increase of variability of the collective variable in the vicinity of the phase transition).

Definition of the Subject

Social Coordination Dynamics (SCD) explores, at both behavioral and neural levels, the mechanisms mediating the formation and dissolution of bonds between individuals. SCD applies the concepts, methods and tools of informationally coupled self-organizing systems (coordination dynamics) to quantify real time social processes. Just as coordination dynamics deals with how the parts of complex systems work together in a meaningful way to achieve goals, so SCD aims to understand the interplay of forces operating at both individual and collective levels to produce effective social behavior. SCD offers a novel perspective and new metrics to explore systematically a fundamental form of human bonding (or lack thereof), and the self-organizing processes that underlie its persistence and change over space and time. SCD therefore complements recent developments in several fields such as sociology, social cognitive neuroscience, behavioral economics, game theory and neuroeconomics.

Introduction

Coordination can be broadly defined as a functional ordering among interacting components in space and time. Coming in many guises, coordination represents one of the most striking features of living organisms. The science of coordination, *Coordination Dynamics* (abbreviated CD) [36,37,38,41] stems from a complex systems framework based on the theory and methods of informationally coupled self-organizing dynamical systems (see ► Coordination Dynamics). CD explores a number of basic coordination phenomena that cut across a wide range of levels, creatures and functions. Of particular relevance to social coordination are: (i) patterned states of coordination remain stable in time despite perturbations; (ii) component parts and processes (dis)engage in a flexible fashion depending on functional demands and/or changes in environmental conditions; (iii) multiple coordination states exist rendering living things *multi-functional*, effectively satisfying the same (or different) set of circumstances; (iv) switching from partially to fully coordinated states and vice versa is commonplace; (v) selection of coordination patterns is tailored to suit the current needs of the organism; (vi) coordination patterns adapt to changing internal and external contingencies; (vii) depending on a balance between competitive and cooperative processes, learning may take the form of abrupt transitions from one coordinated pattern to another; and (viii) the system may remain in the current pattern of coordination even when conditions change thus exhibiting memory.

The foregoing list contains some of the core aspects of CD reflecting its inherently nonlinear and emergent character. Such phenomena appear so spontaneously and so consistently as to suggest the existence of an underlying lawfulness or regularity that transcends the multitude of differences between different systems and the settings in which they can be observed [41,45].

Coordination achieves its pinnacle in the vast array of cells and connections called the human brain, and in the collection of human beings we call society [41,45]. How social interactions form and change in complex systems and contexts is of great interest to many disciplines, particularly psychology, biology, physics, economics and the social sciences. The primary focus of the present article is to review recent work investigating the coordination dynamics of individuals interacting with each other in real time. At the core of all personal relationships is how the other becomes intertwined with the self. *Social coordination* is the tendency of two or more individuals to coordinate their ongoing actions with each other based on mutual information exchange. *Social Coordination Dynamics* (abbreviated SCD) is a theoretical-empirical framework that investigates the behavioral and neural dynamics of bond formation between individuals, operationalized in terms of how they spontaneously synchronize their behavioral and neural patterns [82,99].

Synchronization is a form of spontaneous pattern formation that operates according to general principles of self-organization described by nonlinear dynamics [25,26,72]. Following on Huygens's analysis of two clocks synchronizing on a wall, many studies have framed the problem of mutual synchronization in terms of a network of oscillators each of whose individual behavior is altered by nearest neighbor interaction [5,7,30,57,106,107]. Under that framework synchronization has been observed among very different entities in a broad range of physical, biological and social systems. Human brains (and behavior) have proven no exception to these principles [19,27,41,50,51,89]. Experiments have revealed that humans exchange information – whether uni- or multimodal in nature – to spontaneously adopt and switch coordination patterns (e. g. [37,53,58]).

The validity of the measures and constructs from coordination dynamics are worth mentioning because they speak to the appropriateness of a dynamical framework for investigating social situations. Whereas it is easy to justify the physical existence of linkages between components in the coordinated behavior of a single entity, no such linkage typically exists between people. *Social coordination occurs via information exchange*, typically through vision, touch and sound. Emotional interactions may also be involved. A natural measure that describes this informational exchange is the relative phase between coordinating behaviors. The relative phase is an informational variable whose dynamics and has been shown to capture quantitatively coordinated patterns of brain and behavior among different kinds of components, events and processes (see ► Coordination Dynamics [26,40,41]). For coupled rhythmic behaviors, the relative phase dynamics is often adequate not only for uncovering basic mechanisms underlying synergy formation and behavioral change but also the strength and directionality of influences during social interaction ([82,99]; see also [62,87]) for recent reviews.

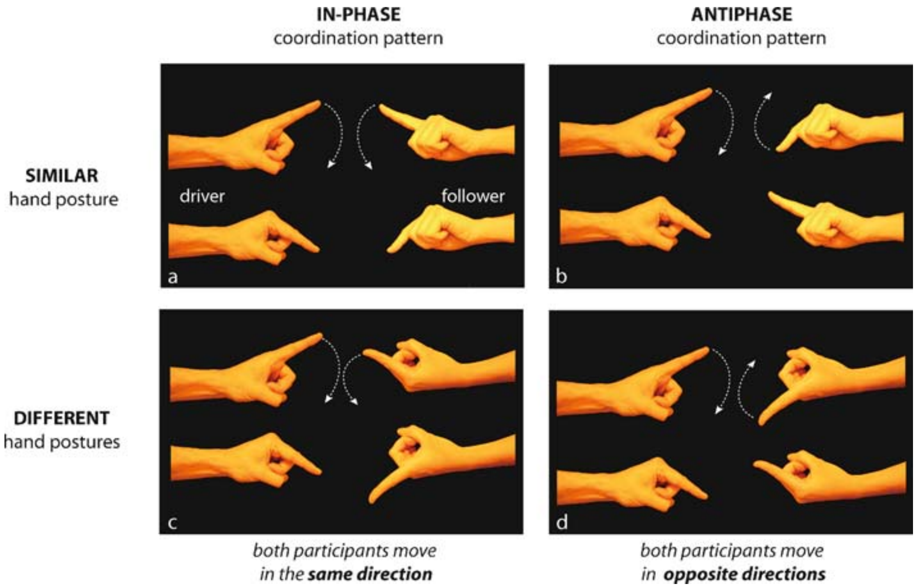
Intentional Interpersonal Coordination

Among the many phenomena of human social coordination, one that most of us have experienced is the synchronized clapping of an audience. Néda and colleagues [70,71] have investigated why applause occurs in unison, with individual "clappers" sometimes acting as a single synchronized ensemble. Although synchronized clapping may vary little from one situation to another, the mechanisms governing the phenomenon are nuanced and context-dependent, even within the same audience. An illustration of this context-dependence comes from the world-famous *New Year's Concert* given every year by the Vienna Philarmonic Orchestra in Austria. Traditionally the concert ends with the Radetzky March by Johann Strauss Jr. This piece of classical music is performed in quite an unusual way. For instance, the conductor leads not only the orchestra but also the audience. Upon a visual cue from the maestro, the audience claps in synchrony with the music. The collective clapping is synchronized both with the music and the visual signals given by the conductor. The reader who is not really into classical music might prefer the example of the song *'We will rock you'* by Queen. Except for a final and unique guitar solo, this song is constituted by a powerful rhythm and a poignant vocal performance by lead singer Freddie Mercury. When this very rhythmic song was performed live, the audience intentionally coordinated its movements with the sound of the drums and the pattern of movements visually provided by the singer. People were therefore intentionally clapping their hands on the first two beats and extending their arms on the third. In the coordination dynamics literature, this is referred to as *intentional sensorimotor coordination* of individuals with external events.

Several studies have employed the sensorimotor coordination tasks to investigate interpersonal coordination dynamics for the case when a person intentionally synchronizes her movements with another by means of visual information exchange see [62] for a review. Following the bimanual and sensorimotor paradigms introduced by Kelso and colleagues [36,37,46,48], Schmidt, Carello and Turvey [88] asked two individuals sitting next to each other to swing their legs in an in-phase or antiphase fashion with respect to the leg movements of the other member of the dyad. As movement frequency was increased (or decreased) by means of an auditory metronome, they found many of the predicted features of nonequilibrium phase transitions [27,47,89]: (i) *differential stability* between the two coordination patterns; (ii) *phase transitions* from the less stable coordination pattern (antiphase) to the more stable one (in-phase); (iii) *critical fluctuations* (i. e. increase in coordination variability) in the vicinity of the transition region and (iv) *hysteresis* (i. e. a sensitivity to the history of the system). All such hallmarks of coordination dynamics (and others such as *critical slowing down* in the vicinity of transitions) have been repeatedly found in a huge number of studies covering various experimental settings. Those settings include, but are not restricted to inter- (e. g. [36,37]) and intra-limb coordination (e. g. [9]) and coordination beween a limb and its uni- (e. g. [3,9,48]) or multi-modal environment [58] to name only a few. The main contribution of Schmidt and colleagues' research was to demonstrate that coordination phenomena found within a person's brain or body, extend to the interactions between people. It is noteworthy that the observed effects extend outside the typical laboratory setting to include coordination phenomena between an individual and an animal as in Lagarde and colleagues' investigation of the coordination dynamics of the horse–rider system [59]. In this unique experiment horses were ridden while walking, trotting and running on a treadmill. The movement dynamics of the horse, the rider and the horse–rider pair were recorded and analyzed revealing that the human–animal dyad exhibits similar coordination dynamics to human interpersonal coordination [59]. In this respect, it cannot be overemphasized that coordination dynamics deals with emergent cooperative effects across very different coordinating elements from neurons to muscles to limbs to people and across the animal–environment divide ([41,42]; for an excellent discussion, see Turvey [100] and commentaries in Vallacher and Nowak [101]). Both the 'intrinsic dynamics' of the individual elements and the nature of the coupling between different elements must be identified for a full account of the phenomena observed.

Several experiments by Schmidt and co-workers, as well as by other groups, have explored the effects on interpersonal coordination of variables such as the manipulation of objects (e. g. hand-held pendulums) or visual surroundings ([74,86]; see [87] for a recent review). Incorporating both aspects de Rugy and colleagues developed a neuro-mechanical model of visually mediated intentional interpersonal coordination [16]. Their model consists of two cross-coupled neuro-mechanical units, each composed of a neural oscillator driving a wrist-pendulum system moved by a different person. Taken individually, each unit reproduces the natural tendency of the participants to freely oscillate close to resonance frequency. When cross-coupled through the vision of movements of the other individual, each person entrains the other as they adopt a common frequency influenced by their own mechanical properties. Although important, neuromechanical properties are not the only factors that determine the stability of coordination patterns between individuals: attentional load and egocentric constraints also influence interpersonal coordination dynamics [96,97].

A series of experiments has investigated whether the motoric and perceptual constraints that shape the dynamics of inter- and intra-limb coordination play a similar role in the coordination between people (e. g. [12,13,53,58,66,78]). In intrapersonal bimanual coordination the preference for co-activation of homologous muscles appears to be mediated by general principles of symmetry in neural organization such as reciprocal connectivity between homologous brain areas. In a study by Oullier and colleagues [76] investigating the relative role of visual/directional and motor (a) symmetries in interpersonal coordination, two participants made index finger flexions while seated facing each other. One acted as a driver (D) by synchronizing to a metronome that systematically increased in rate. The second participant, or follower (F), was required to coordinate finger movements with D via visual coupling only. F participated in four conditions (Fig. 1) determined by a combination of coordination pattern (in-phase or antiphase) and hand posture (supination or pronation). The relative phase requirement was defined by the spatial configuration (i. e. the position of the endpoint of the finger). In this way, co-activation of homologous muscles (finger flexion by F and D) produced both an in-phase and antiphase relationship between the effector endpoints depending on the experimental condition. If purely directional constraints [92] determine the stability of interpersonal coordination, and D functions only as a generic rhythmic stimulus, perceptual antiphase coordination should display decreased stability regardless of the relative hand position of the participants. Contrary to this hypothesis, a strong role was found for interpersonal homologous muscle co-activation. Coordination between individuals was most stable when they were activating similar muscle groups such that co-flexion was always more stable regardless of the resulting spatial pattern. Directional constraints played only a modulatory role. These initial results are at odds with the concept of social coordination as a form of simple perceptual-motor coupling. Rather, it appears that perception of homologous muscular activation acts as a constraint on coordinative stability, creating a "functional homology" to bimanual coordination. Thus, social coordination may be differentiated from



Social Coordination, from the Perspective of Coordination Dynamics, Figure 1
Participants show a preference for homologous muscular activation, irrespective of the visuospatial congruency of their movement. Each column describes a possible configuration of interpersonal coordination. The left participant is paced with a metronome whose frequency increases (driver). Oullier and colleagues [76] studied the frequency at which the right subject (follower) loses stability in each condition. In columns a and b, both subjects are in the same hand position. The pattern a (both flex then both extend: in-phase coordination) is more stable than the pattern b (when one extends the other flexes: anti-phase coordination). In columns c and d, the participants adopt a different hand posture. The pattern d (both flex then both extend: anti-phase coordination) is more stable than the pattern c (where both subjects move in the same direction). These results suggest that coordinative stability is not purely governed by visuospatial congruency (cf. [67]). Rather, the embodiment of the other's movement leads the follower to adopt an anatomically homologous movement. This pattern of behavior is unique to the fact that the follower and the entity with which he/she coordinates are both humans [76]

simple perceptual-motor coupling by virtue of the biological and functional relevance provided when viewing another person.

Although all these studies have employed comparable experimental settings and the common theoretical framework of coordination dynamics with the aim of better understanding intentional interpersonal coordination, it is not yet clear whether spontaneous mutual entrainment actually occurs in a true two-way interaction, or whether one individual simply acts as a pacing stimulus or 'driver' for the other (e. g. [48]). A similar concern can be raised regarding the behavior of the audience during the Radetzky March at the New Year's Concert in Vienna. It seems unlikely that audience members spontaneously synchronized with each other while music was played, since their primary intent was to respond by clapping in rhythm with the music and with the visual cues coming from the stage. This process has been well described in human movement (neuro)science and coordination dynamics and occurs when an individual intentionally coordinates his movements with external physical stimuli [3,41,48]. A sensorimotor interpretation of audience participation is strengthened by results of an experiment in which the auditory metronome used to pace the interpersonal coordination was silenced at times [76]. The study revealed that the presence of an external pacing stimulus (an auditory metronome in that case) actually reduced interpersonal coordinative stability regardless of the adopted directional or muscular pattern adopted. Oullier and colleagues [76] provided evidence for stronger mutual entrainment when no external information could perturb the dyadic interactions, analogous to what the music and the conductor would do during a concert. Hence, from an experimental perspective, this phenomenon is not social interaction per se but rather sensorimotor coordination to an external event. In the case of the "observed" audience clapping in unison *during* the performance, one could argue that the audience is constituted by a collection of individuals coordinating mainly with the music and the conductor with little contribution from neighbor-to-neighbor interactions, (A similar concern can be raised in the study by Schmidt and co-workers [88] as participants were instructed to intentionally coordinate with each other *and* with an auditory metronome. Hence, one participant could serve as a visual metronome to the other (and reciprocally) and/or the phase transitions observed could either be interpersonal in nature (from interpersonal antiphase to in-phase) or from syncopation to synchronization as in a single individual coordinating with an auditory metronome (cf. [48]).

A different scenario, however, is characteristic of the end of the performance, when the audience expresses its approval of the orchestra and conductor through applause. At this moment each person applauds according to her preferred/intrinsic pace with no driving stimuli – whether visual or auditory – coming from the stage. In spite of the absence of pacing information, the audience quickly and spontaneously entrains to a common rhythm such that everyone is clapping in unison. Note that at this moment, the only information that can alter an individual's behavior is the sound (and possibly the vision) of the movements made by their neighbors [70,71]. Thus, we have units involved in individual rhythmic behaviors communicating via, at least, one means of information exchange. According to Winfree [108], this is a minimum requirement for self-organized spontaneous synchronization to emerge (see also [41]). In that case, any collective pattern that emerges is more likely to be unintentional compared to situations where the audience follows the conductor and the music.

Issues in Quantifying Spontaneous Interpersonal Coordination

An abundant literature exists addressing unintentional interpersonal coordination in experimental paradigms ranging from people swinging pendulums [86], dancing [33], walking [102] or rocking chairs [84] to performing joint Fitts' tasks [69], talking to each other [83,91] or even boxing [60]. However, many questions remain regarding the nature of the behavioral and neural processes mediating the formation and dissolution of unintended synchronous behavior between individuals and how such processes may be quantified [2,55].

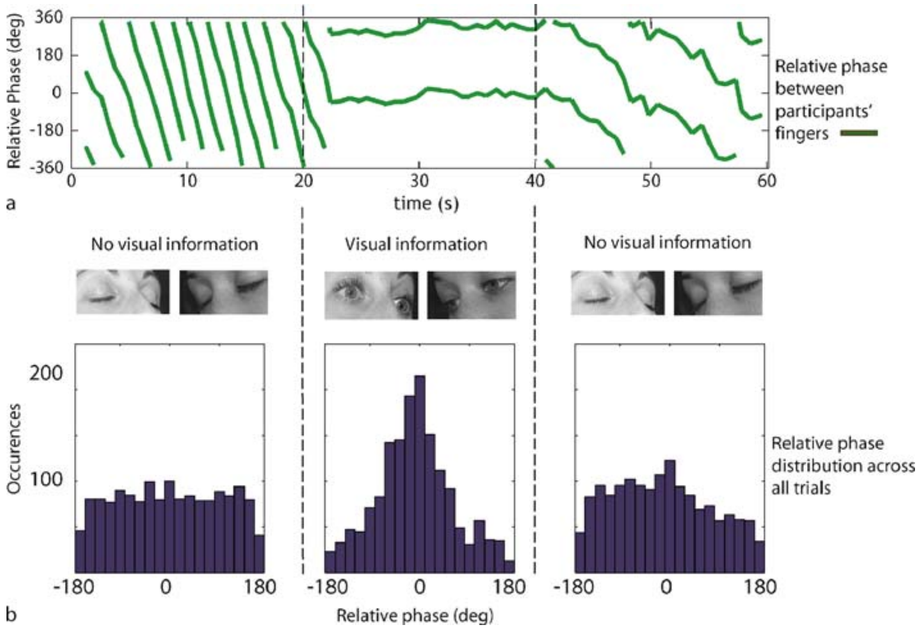
Oullier and colleagues [82] have identified three major problems in investigating spontaneous synchronization in social settings. First, even when the source and nature of the coupling has been identified, it is difficult to manipulate experimentally relevant variables such as the coupling strength (e. g. [71]). Almost by definition, spontaneous behavior is not externally goal directed or explicitly controlled. Most of the results reporting unintentional synchronization in humans are based on observation and categorization methods that rely primarily on the experimenter's appreciation of a given exemplar behavior rather than a quantitative measure of coupling and individual behavior (e. g. [4,14]).

A second problem is the challenge of complexity, both in terms of the large number of units to analyze (e. g. thousands of pairs of clapping hands [71]) and the complexity of the behavior itself (e. g. mother-infant synchronization [14]). Such compositional and behavioral complexity has hindered experimental attempts to record and quantify both the individual and social dynamics. Even the reduction in dimensional complexity afforded in coordinated behavior can only go so far in elucidating the relationship between group behavior and the individual units of which it is composed.

A third problem comes from the possibility that any change in a person's behavior induced by interacting with another may persist even after the encounter is over. So far, there has been very little precise quantification of the mutual influence people have on each other's behavior a posteriori, i. e. how individual behavior is affected after the social encounter when people no longer exchange information (but see Sect. "Social Memory and the Dependence on Initial Conditions").

Human Spontaneous Synchronization

In behavioral experiments that revealed spontaneous interpersonal synchronization, Oullier and colleagues [77, 80,82] explored coordinative patterns that emerge only as a function of visual information exchange. The main hypothesis was that even without instructions to do so, spontaneous synchronization between partners would occur as soon as they coupled visually while moving in front of each other. On the other hand, spontaneous interpersonal coordination should disappear whenever exchange of information is no longer possible. In Oullier et al.'s behavioral experiments, pairs of participants executed movements while in full view (or not) of each other's ongoing actions as well as their own [77,80,82]. Each member of the dyad executed movements at their own preferred frequency and amplitude without any external pacing from a metronome or any other sort. Movements were required to be as smooth and continuous as possible throughout an experimental trial. What is important here is that participants were not given any instructions regarding the way to move with respect to each other. The experimental protocol consisted of participants moving with no vision of the other's movements before being allowed to see their own actions at the same time as they saw the other person's. Finally, visual information was removed again. Experi-



Social Coordination, from the Perspective of Coordination Dynamics, Figure 2

Relative phase between the movements of two individuals. a This panel illustrates the evolution of the relative phase as a function of time in a representative trial of the SCD paradigm. *Left column* No visual information exchange, each individual moves independently, movements are uncoordinated. *Middle column* as soon as people exchange visual information, they spontaneously couple. Their relative phase is therefore close to 0° . *Right column* When visual information is removed, they are no longer synchronized. b This panel represents distributions of relative phase for all the subjects and all the trials (adapted from [82])

mental trials were therefore equally partitioned into three contiguous segments each of equal duration within which both subjects either were allowed to exchange information with each other or not. When visual information was available, participants looked at each other's finger motion and were also able to see their own finger [77,80,82].

In SCD, following theories of cooperative phenomena in open systems [25,26] a central idea is that the behavior of a complex dyadic system may be captured by the value of a low-dimensional collective variable known as the *order parameter*. In the vicinity of critical points, emergent behavior is governed by the dynamics of this collective variable e. g. [25,41]. In experimental cases the order parameters are not known in advance but have to be discovered. For the situation of social coordination as in many other cases treated by CD, an appropriate order parameter describing the system dynamics is the relative phase ϕ between the movements of each member of the pair [80,82]. The relative phase measure allows for a reduction of a potentially very high dimensional system (e. g. where one has to consider, among other components, the neurons, joints and muscles of both individuals) as it captures the macroscopic spatio-temporal behavioral pattern (see Fig. 2). Even at an overt behavioral level, four degrees of freedom (position and velocity of each component) may be compressed onto a single relative phase value that summarizes the organization of the dyadic system. Quantitative evaluation of spontaneous synchrony is also provided by the FFT power spectrum overlap between the movements of each person. The spectrum overlap measures the percentage of movement frequencies common to both partners in a pair [82]. Defined as the area of intersection between each participant's normalized spectral plots, it serves an indicator of the strength of the frequency entrainment between the two participants (see Fig. 4).

When no visual exchange was allowed, each subject produced movements independently at their own frequency. As a result, the relative phase ϕ between the subjects' finger motions exhibited phase wrapping (Fig. 2, left column). However, following a simple auditory cue to open their eyes, subjects spontaneously adopted in-phase motion, ϕ stabilizing around 0° (Fig. 2, middle column). On a signal to close the eyes again, the individual movement frequencies diverged and ϕ fell back into phase wrapping (Fig. 2, right column). These initial results were corroborated by a subsequent more extensive study, in which the order of the vision and no-vision segments was changed. Once again, spontaneous synchronization emerged as soon as vision of the other's movements was allowed [82]. Overall, results reveal that with visual information exchange, participants tend to mutually couple at a common phase and frequency, whereas in the absence of vision, participants' movement trajectories diverge and behave independently. Such emergent mutual coupling is truly a result of spontaneous social interaction and may be distinguished from previous dyadic studies in which one person may simply be intentionally tracking (or driving) the other [16,77,88,97] or maintaining their own rhythm [86].

Why does spontaneous interpersonal coordination occur at all? Compelling examples stretching from human evolution through religious ritual and sports to political, war and economical strategy suggest that *keeping together in time* is one of the most powerful ways to create and sustain communities and communication [65]. Moreover, *not* moving in synchrony may be too costly for the dyad see, (e. g., [56]).

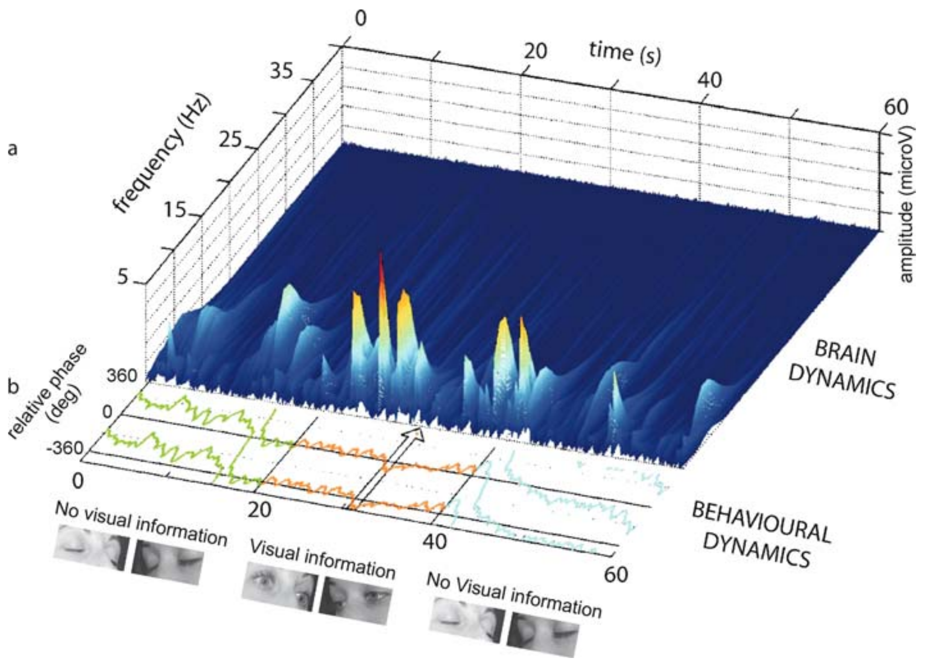
In order to better understand which features of visual information exchange may facilitate spontaneous social coordination one has to bear in mind that human movements can be unintentionally affected by the vision of an object oscillating in the environment. This is illustrated by experiments using the moving-room paradigm in which the walls of the room move but not the floor (e. g. [61,75,78]). Body sway of the observer's couples in time spontaneously with small oscillatory motions of the room. In addition, experimental data show that the mere observation of the movements of another person interferes with one's execution of a similar action [54]. Interestingly, such interference is less noticeable when the movements observed are not generated by humans [15]. In the latter work, one of the members of the dyad was replaced by a computer-generated moving hand, the trajectory of which was driven either by a sinusoidal function or a pre-recorded real finger trajectory. The stimulus movement frequency in the study by de Guzman and coworkers [15] was fixed at either 10% below or 10% above the subject's self-paced rate as determined at the start of the experiment. Results revealed that the human–avatar coordination was strongest when the latter was an image of a hand driven by real movement data. The weakest coupling occurred when the visual stimulus followed a sinusoidal trajectory. Unlike the interpersonal situation [82], spontaneous synchronization was not found for all trials and, when it happened, was supported by a significantly lower frequency overlap [15]. One may invoke a one-way coupling to explain these findings, since the motion of the computer generated hand could not be influenced by the movement of the participant. Taken together, the foregoing results support the hypothesis that biological relevance in general, and biological motion in particular – including its natural variation– play a key role in social coordination.

Shared Behavioral and Neural Social Coordination Dynamics

One explanation for the emergence of spontaneous social coordination may be found at the neurophysiological level. For instance, some areas of the brain are known to be associated with the perception (but not the execution) of biological motion including the posterior superior temporal sulcus (abbreviated STS) [1,23,24,31]. STS is known to be a major source of visual information for the so-called *human mirror system* (abbreviated HMS) [85]. Originally identified in monkeys, *mirror neurons* are (sensori)motor neurons discharging both when one performs a given action and sees the same action performed by someone else. They have been identified primarily in the ventral premotor cortex and the rostral region of the inferior parietal lobule [20]. The HMS constitutes a neural mechanism that is automatically activated by the sight of somebody else's actions, even when the observer does not make overt movements. The main idea is that during observation the HMS provides a simulation of the actions of other people potentially providing a basis for understanding the intentions of others [31].

Since the foregoing behavioral experiments allow participants to both produce and observe movement at the same time it seems possible that the HMS is at least partially involved in the spontaneous coordination observed. In order to investigate this question, Tognoli and colleagues [99] recorded brain activity of each member of the dyad using a specially designed dual-electroencephalography (EEG) system. Each participant wore a 60-electrode EEG-cap that enabled simultaneous recording of their brains to accompany kinematic measurements of their behavior.

To grasp the significance of the work by Tognoli and colleagues, we need to revert to earlier studies conducted within the framework of Coordination Dynamics have employed instabilities in coordination as a means to uncover the link between the dynamics of behavior and the dynamics of the brain [39,42], with the goal of relating levels by virtue of their *shared dynamical properties* (e. g. [19,39,49,50,52]). In such research, the high temporal resolution of electroencephalography (EEG) and magnetoencephalography (MEG) was exploited to quantify the relationship between the large scale neural dynamics emerging from billions of interconnected neurons and the behavioral dynamics revealed in experiments on coordi-



Social Coordination, from the Perspective of Coordination Dynamics, Figure 3

Relation between Phi_2 and social coordination. a Time-frequency spectrum from electrode CP4 (located over parietal brain regions) from a single trial. Phi_2 is low before and after vision but increases during vision. b Corresponding relative phase between finger movements. Synchronized in-phase behavior is observed during visual contact. Notice the temporary disengagement of the rhythm when coordination is lost briefly (adapted from [99])

nation [41]. Observed features of the dynamics expressed at both levels of description such as multistability and phase transitions (i. e. the spontaneous switch from one pattern to another due to loss of stability), were taken as evidence that principles of self-organization govern pattern formation in both brain and behavior [26,41]. Of particular initial interest was the identification of qualitative changes in the pattern of neural activity that occurred simultaneously with transitions between behavioral patterns [19,49,50,63,104]. On the basis of this work, an exciting hypothesis is that the transitions from uncoordinated to spontaneous coordination observed in the SCD paradigm may be accompanied by similar events at the brain level.

In an effort to shed new light on how social processes are integrated in the brain, Tognoli and colleagues [99] identified several neural mechanisms or *neuromarkers* that appear and disappear with the emergence and dissolution of coordinated behavior between two people. Interestingly, these social neuromarkers consist of brain rhythms in the 10 Hz frequency range located over right centro-parietal areas of the cerebral cortex. In particular, a social brain rhythm termed the *Phi Complex* consists of two components: the first, Phi_1, increases during independent behavior i. e. before information exchange between members of the dyad. When subjects saw each other's finger movements and coordinated together, Phi_1 disappeared and Phi_2, a different rhythm within the same frequency band appeared (Fig. 3) [99].

In a subsequent study, Tognoli and colleagues [98] explored the dynamics of the *Phi Complex* by instructing participants to *intentionally* synchronize when visual information exchange was allowed. In this case, participants interact to accomplish a shared goal. Again, Phi_1 appeared during uncoordinated behavior and Phi_2 when social coordination occurred. Analysis of dyads who participated in both experiments [98,99] revealed that the amplitude of Phi_2 was higher during intentional than spontaneous coordination. Thus, Phi_2 appears to be a neural signature of social coordination whether it emerges spontaneously or not.

The cortical location of the *Phi Complex* appears to be consistent with neuro-anatomical sources within the human mirror system. One of the conclusions drawn by Tognoli and colleagues is that Phi_1 might have an inhibiting role on the mirror system. Previous claims by Brass and Heyes [8] have argued that the mirror system is always active by default and thus must be inhibited in non-social contexts. Hence Phi_1 could inhibit Phi_2, the latter being seen as a facilitator of social coordination that participates in information exchange between the motor cortex and the mirror system [98,99].

In summary, experiments using dual high density electrode arrays to record and measure brain activity from two persons in conjunction with motion capture technology, have allowed an exploration of shared behavioral and neural social coordination dynamics [98,99]. Transitions from uncoordinated dyadic behavior to interpersonal synchronization have been demonstrated to accompany the emergence of a new brain rhythm – the Phi complex – located in the human mirror system. Such work suggests that SCD may serve as a novel framework for identifying behavioral and neural signatures in reciprocal interactions and allows for a more dynamical approach to the study of the mirror neuron system.

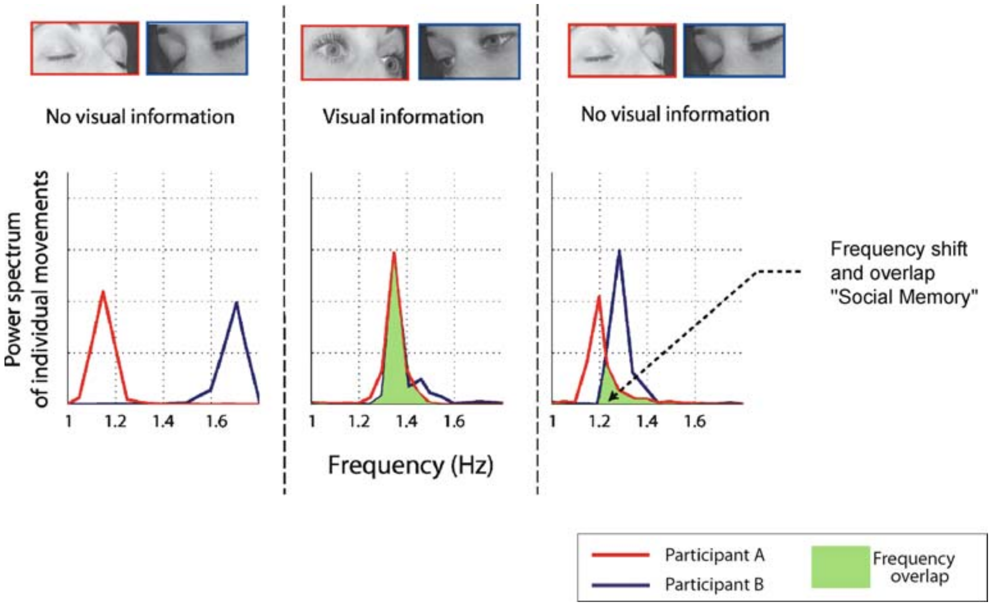
Social Memory and the Dependence on Initial Conditions

At first blush, the emergence of spontaneous coordination between individuals [77,80,82,99] might be seen as an instantiation of mutual entrainment that entails nothing more than a couple of oscillators and a medium of information exchange [41,108]. In such generic cases, once the coupling is removed, each oscillator should return to its own intrinsic frequency, that is, any influence of the interaction should disappear. However, the situation between two people is different (see Fig. 4). Theoretically, in a typical coupled clocks scenario, there should be no difference between the movement periods of the 'clocks' before or after coupling-induced synchronization. However, a serendipitous experimental finding [82] was the consistent and persistent influence of the social interaction on subsequent rhythmic behavior despite the absence of information exchange between the pair (Fig. 4). This remnant of a prior social interaction may qualify as a kind of *social memory* [82].

Social memory is thought to play an important role in human actions, and, to a larger extent, on the way we live [32]. In the context of SCD, social memory implies that the intrinsic parameters of the individual components have been altered by virtue of the social interaction. Mathematically [42], one may represent the situation before the interaction as follows:

$$\begin{aligned} \ddot{x}_1 + i_1(x_1, \dot{x}_1, a_1) + \omega_1^2 x_1 &= 0 \\ \ddot{x}_2 + i_2(x_2, \dot{x}_2, a_2) + \omega_2^2 x_2 &= 0\,. \end{aligned} \qquad (1)$$

Where x_1 and x_2 represent the coordinating components,



Social Coordination, from the Perspective of Coordination Dynamics, Figure 4

Evidence for social memory. Illustrated is an example of frequency overlap between the movements of both subjects in a representative trial of the SCD paradigm. *Left column* no vision of each other's movements; each individual moves at their own intrinsic frequency so there is no frequency overlap. *Middle column* visual information is exchanged between participants, causing spontaneous synchronization to occur at a common frequency (and phase, see Fig. 2). *Right column* visual information is no longer exchanged but individuals do not revert back to their initial intrinsic frequency. This remnant of frequency overlap as a result of prior social interaction suggests a kind of 'social memory' (adapted from [82])

$i_{1,2}$, $a_{1,2}$ and $\omega_{1,2}$ refer to individually chosen intrinsic parameters such as the chosen frequency and amplitude.

During the interaction, the system is visually coupled, F_1 and F_2 representing a coupling function such as the well-known HKB-coupling [27,44]:

$$\begin{aligned} \ddot{x}_1 + I_1(x_1, \dot{x}_1, A_1) + \omega_1^2 x_1 &= \mathrm{F}_1(x_1, \dot{x}_1, x_2, \dot{x}_2) \\ \ddot{x}_2 + I_2(x_2, \dot{x}_2, A_2) + \omega_2^2 x_2 &= \mathrm{F}_2(x_2, \dot{x}_2, x_1, \dot{x}_1)\,. \end{aligned} \tag{2}$$

Now notice that the interactive context has formed a coupling (the right hand side of Eq. (2)) but also led of a modification of the individual component parameters, I and A (on the left hand side of Eq. (2)). One may say that the boundary conditions of Eq. (1) have been altered by the social interaction.

After the interaction, the coupling function disappears (F_1 and F_2 terms on the right hand side are zero) and the system is "uncoupled" (cf. Fig. 1):

$$\begin{aligned} \ddot{x}_1 + I_1(x_1, \dot{x}_1, A_1) + \omega_1^2 x_1 &= 0 \\ \ddot{x}_2 + I_2(x_2, \dot{x}_2, A_2) + \omega_2^2 x_2 &= 0\,. \end{aligned} \tag{3}$$

However, notice in Eq. (3) the individual intrinsic parameters of the system which were modified by the interaction are still in place. Though uncoupled, the individual components are still affected by the interaction. How this internalization process occurs remains open to empirical investigation.

A benefit of the SCD paradigm is that one is able to quantify the strength and persistence of prior social influences on an individual's behavior. The finding that the modification of the neural network depends on which modality is engaged during the mutual encounter suggests that additional cortical areas may have been recruited and included into the initial global neural assembly due to social context [32]. However, beyond the Phi complex, and perhaps due to inherent limitations in spatial resolution, examination of the dual EEG data showed no evidence of further cortical engagement. Another possibility (in line with the foregoing mathematical analysis) is that the connectivity and dynamics of the initial network is modified by social interaction, and the new organization retained after the interaction is over. Recent evidence in support of this hypothesis suggests that two people engaging in a common task share a representation of each other's movement dynamics, including trajectory amplitude and frequency [6,17]. Such a (shared) representation may persist when vision is removed, i. e. when information exchange is no longer possible [21]. Moreover, representations at the neural level have been shown to be highly flexible and context-dependent [34,35], influenced both by environmental [105] and task demands [79].

The extent and duration of the carryover or remnant effects observed in behavioral experiments may reflect many factors, including the strength of the bond that is formed between people, place in the social hierarchy, the willingness of each participant to cooperate, gender differences, personality characteristics and the significance each participant attaches to the social encounter [32]. An additional finding from our work favors a motor contribution to social memory as well: the persistence effect was found to be independent of the duration of movement that followed the social encounter [82]. This hypothesis is strengthened by results showing that observation of another person performing movements generates a kinematically specific memory of the observed motions in primary motor cortex [95].

The systematic directionality effect observed in the SCD paradigm is revealing also [82]: the extent to which one member of the dyad is influenced by the other was shown to depend on initial conditions. Obviously for synchronization to occur, the person moving with the lowest/highest intrinsic movement frequency must speed up/slow down during information exchange. A surprising result is that the difference between the initial and the final intrinsic movement frequencies (vision absent) was always greater for the person starting with the higher compared to the lower movement frequency [82]. The extent to which initial, so-called 'intrinsic dynamics' determine behavior after the social encounter is over may be of great interest to understanding social interactions in more complex settings where hierarchical relations are involved.

An important problem in human social behavior concerns understanding the degree to which an individual influences the actions of a group (e. g. peer group, family, class) he/she is in. Due to several factors (personality, situational), a person (the leader) may affect the behavior of others more than the others affect her or him. The concept of leadership is commonly associated with interactions taking place in hierarchical settings such as typical organizations, but is actually broader than that. Strength of behavioral influence is overlooked because behavioral interactions have not been systematically studied. Contemporary complex systems approaches (e. g. [28]) view the formation of leader-follower roles as interactive and emergent but in so doing may have undermined the significance of individual dimensions. The approach of SCD is rather to ask: *What makes two people behave independently and what makes them behave as a unit?* The paradigm of social coordination dynamics exploits inherent asymmetry between two people during behavioral interactions and gauges, e. g. using directional coupling measures, which of the two has a stronger influence.

Future Directions

Human beings are social by nature, and interactions with others represent a substantial portion of their many daily activities. A common and well described consequence of interpersonal activity is that an individual's behavior, whether intentional or not, is modified by interactions with others [32]. Alterations of individual and collective behaviors range from imitation and mimicry to spontaneous synchronization, and have been observed in groups varying in size from dyads to thousands of individuals e. g. [4,68].

Social Coordination Dynamics investigates how the natural (uninstructed) social influence of one person on another evolves in real time and has led to a number of new findings. The first is that humans immediately and spontaneously coordinate their actions with each other when provided vision of the movements of the other together with their own. The second is that a specific brain rhythm underlies social coordination. Transitions from individual to coordinated social behavior are observed at both behavioral and brain levels.

The third finding is that an individual's intrinsic behavior is altered by social interaction: the effect of the previous social encounter persists when vision of the other's movements is no longer available. A fourth and final finding is that social coordination is affected by initial conditions, enabling one to predict which individual is most affected by the social encounter.

Insights into elementary forms of social interaction have been obtained by applying the concepts, methods and tools of coordination dynamics. A notable feature of coordination dynamics is its ability to uncover mechanisms and principles common to different kinds of complex systems at different levels of observation and to relate them by virtue of shared behavioral and neural dynamics [41]. SCD and its dynamical measures have proven to provide adequate quantification of the spontaneous coupling between individuals, the transition to loss of entrainment and the effect of the social encounter at both behavioral and brain levels. The same basic patterns of coordinated behavior and pattern dynamics (multistability, critical fluctuations accompanied by a temporary loss of stability, phase transitions, hysteresis and critical slowing down) have been observed within an individual, between an individual and the environment, and between individuals. In this respect SCD complements recent developments in social cognitive neuroscience, behavioral economics, game theory, socio-economics and neuroeconomics (e. g. [10,11,18,73,81,94,103]).

The field of *social neuroeconomics* serves to illustrate the benefits of considering SCD in contexts other than interpersonal sensorimotor interaction. Social neuroeconomics investigates the neural correlates of economical decision making [18]. One particular feature of this nascent field is that decision making processes are always studied in a body- and movement-independent fashion. Why is that? After all, from the very first months of life, individuals live vicariously through one another adopting, if only temporarily, a similar posture or tempo during interactions with a peer, or yawning [4,64,90]. As Henry Greely [22] recently reminded the readership of Science Magazine *"Human society is the society of human brains. Of course those brains are encased in, affected by, and dependent on the rest of the body, but our most important interactions are with other people's brains, as manifested through their bodies."* Although this statement sounds like common sense, thus far the coordination dynamics between bodies has remained unexplored in the field of social neuroeconomics. Yet how many times have we experienced the feeling that trusting someone will be difficult even before talking to them? Whether it was the way she moved or some other factor, body-related cues play a key role in modulating economic decisions (e. g. [93]). A scientific approach to "body language" might aim to understand how perceived actions of others affect the cognitive and emotional processes involved in economical decision-making. For instance, a finding such as the Phi Complex – especially the modulation of Phi$_2$ when individuals intentionally coordinate [98,99] – could turn to be crucial to better competition–cooperation mechanisms underlying decision in economic contexts such as public coordination games [29]. In sum, as a conceptual framework that encompasses the dynamics of both neural and behavioral levels, SCD promises to bridge the gaps between levels of analysis [41,81] and clear a path for new multi-level, interdisciplinary investigations of social interactions. Like synchronization itself, the function of SCD is to facilitate communication across heretofore unrelated fields.

Article Outline

Glossary

Network model A network model describes how an observed network structure with its data could be generated from probabilistic assumptions.

Network population A network population is a finite or infinite collection of existing or conceivable networks. For instance, the population could consist of network instances of a process changing with time, or the population could consist of network realizations in different sets of units.

Observation scheme An observation scheme describes what variables are known or can be observed for units and relations in the population and in the sample.

Population network A population network is a population of units equipped with relational structure between them. Usually several attributes are attached both to units and to pairs of units, and the network can be described as a valued graph on the population of units with vertex and edge or arc variables defined in the graph.

Sampling design A sampling design describes how units are sampled from a population of units and what the selection probabilities are for all the possible sample sequences or sample subsets. The sampling procedure is usually controlled by the investigator. If the sampling is not controlled by the investigator but voluntary or "controlled by nature", the sample network can be considered as an outcome of a probabilistic network model, and there is no clear separation between design-based and model-based inference.

Sampling frame A sampling frame is a list of identifying labels of all possible sample units.

Social network A social network is a network consisting of units and relations of interest in the social sciences. The term is used both for population networks and for networks belonging to a network population.

Survey sampling Survey sampling of networks refer to the investigation of networks sampled from a network population while survey sampling in networks refer to the investigation of sub-networks sampled from a population network. Survey sampling of networks is usually model-based with an infinite network population. Survey sampling in networks is usually design-based with a finite population network.

Definition of the Subject

Sampling in network analysis can refer either to the sampling of networks from a population of networks or to the sampling of one or more sub-networks from a population network. Sampling designs and model approaches based on probabilistic methods allow statistical tools to be developed for the analysis of data obtained in surveys carried out in a network setting.

From about the 1960s the rapid development of computers and computer power changed the scene for statistics and applied mathematics in general. New possibilities of processing large amounts of data by using fast computer algorithms for calculations, sorting, and searching contributed to an accelerated interest in computer science and discrete mathematics. Simulation techniques and other computer intensive numerical methods revolutionized the arsenal of tools available in statistics and other parts of applied mathematics. Graph theory was established not only as an expanding part of discrete mathematics but also became applied as a tool for investigating relational structures in the social sciences. Friendship, co-operation, dominance, support and other relations between individuals were studied as sociograms or as more general networks in which both the individuals and the relations were attributed with qualitative and quantitative variables like gender and age of the individuals and type and strength of the relations. Other network applications include transmission of infectious diseases between people, work scheduling and other planning, routing systems for transportation of goods, traffic flows in urban areas, information flows in communication channels, administrative and organizational structure, capital transfer and surveillance systems. Characteristic of such network applications is the inherent complexity of co-variation or correlation that could exist within and between variables defined for different elements of the network.

Introduction

Special sampling designs using network information for successive link tracing or sample adjustment have been described in the literature under various names such as multiplicity sampling, snowball sampling, and Respondent driven sampling. Such designs have been used for investigations of hard-to-reach populations of various kinds, like drug addicts, homeless people and individuals at risk for hiv-infection, tuberculosis, or hepatitis. Such designs have also been proved useful in investigations of rare properties of individuals in populations that could be sampled from available frames but would require very large samples with conventional sampling designs.

This presentation focuses on sampling designs in finite population networks and network models developed for survey sampling of social networks. Estimation methods are described that can be applied under different assumptions about what population data are known and what sample data can be observed.

The next three sections give background material of various kinds. A brief historical background is given that describes the development of a survey sampling theory for networks. Basic terminology and some general notation needed is then specified and serves the purpose of unifying and simplifying some of the concepts and arguments used later. A common and characteristic feature of network surveys is that they allow non-orthodox sampling methods. Hence it is important to specify when such methods are justified. Some fundamentals about sampling designs are given together with an overview of some standard designs.

After this background follows five sections on network sampling designs. Sections "Snowball Sampling Designs"–"Estimation Based on Network Walk Samples" treat snowball sampling designs and the important sub-class of network walk designs. For various special cases and modifications of basic snowball and walk samples, standard estimation methods are discussed. Section "Methods for Estimating Hidden Populations" is devoted entirely to the estimation of sizes and properties of hidden populations and rare parts of large populations.

The discussion of network designs is followed by a presentation of various probabilistic network models used especially in the social sciences. Some of these models are appropriate in combination with designs or as tools for deriving so-called model-assisted estimators. The main interest in these network models stems from their use when an observed network is considered as an instant of a network process or as a sample network from a super-population of networks.

Next there are two sections on sampling designs and models for bipartite networks. Bipartite networks have units of two kinds which generally require very different treatment so that it is not appropriate to consider them as special cases of networks. Section "Bipartite Network Sampling Designs" describes sampling designs and estimators in bipartite networks. A combination of sampling designs and random modeling in bipartite networks is illustrated in Sect. "A Bipartite Network Model for Crime Participation" which treats a specific criminological application.

Finally, Sect. "Future Directions" comments briefly on possible future directions for the development of network surveys in the social sciences.

Background

Some early attempts to incorporate graphs in a statistical investigation are the studies on sociograms [49], on snowball sampling [33], and on sampling in graphs [3]. Of particular interest is a paper by Stephan [60] pointing to the need for network methods in sample survey theory. He suggests the term nexus sampling for surveys that consider data from units as well as from relations between units. Sampling in populations with graph structure is also discussed in the articles [6,14], and a comprehensive monograph on statistical inference in graphs is the thesis [16].

An independent discussion of some first steps in network sampling is given in [34,42]. Various problems in survey sampling and estimation in networks were discussed in a series of papers during the 1970s and 1980s: [7,17,18,19,20,21,22,23,24,25,26,27,48]. These papers use essentially various network sampling designs and no elaborate probabilistic model assumptions.

The theory of random graphs developed mainly from two models introduced by Erdös and Renyi in 1959 and 1960 [12,13], the uniform graph with n vertices and N randomly selected edges among the unordered pairs of vertices, and the Bernoulli graph with n vertices and independent insertions of edges with a common probability p for all the unordered pairs of vertices. These random graphs have challenged many mathematicians, and there is now an extensive literature on combinatorial and asymptotic results for random graphs. A brilliant comprehensive reference on general graph theory is [11]. Monographs concentrating on random graphs are [4,37,46].

Statistical inference based on probabilistic network models without explicitly addressing the sampling design problem has been treated for some variants of Bernoulli graphs, but generally such models have too little structure to be of interest in a statistical context with network data. A network model with a more elaborate and flexible parametrization that make it applicable in the social sciences is the random digraph model of Holland and Leinhardt introduced in [36]. A comprehensive monograph with many references to the social network literature is [67]. The introduction of Markov graphs in [30] and the log-linear modeling of random networks in [47,57,68] have had a major impact on the development of statistical methods for social network analysis. The edited volumes [5,8] are good sources for the methodological development. Various aspects of network modeling and statistical inference from network samples are the topics of several theses in recent years. Well known to me are the following important contributions to the methodological development: [10,35,38,40,42,55,59,62].

Basic Terminology and Notation

Survey sampling concepts of basic importance are populations of units, sample selection, sampling designs, observation schemes, and variables of interest defined on the units. Two standard reference works for survey sampling in finite populations are [54,63]. In order to make network sampling possible, the population has to be equipped with a relational structure between its units. Usually it is given as a binary variable defined on the ordered pairs of units. A population with a binary relation can be represented as a graph in which the vertices represent the units and the edges (arcs) indicate the unordered (ordered) pairs of units that are related. In a network setting vertices and edges (arcs) are sometimes called nodes and links.

The population from which samples are drawn can be different from the target population of the survey. It can also be changing with time so that particular precautions need to be taken. Disregarding such complications we assume that there is a finite population of N units labeled by integers $1, \dots, N$. The population is denoted $U = \{1, \dots, N\}$. Samples are drawn from U either as ordered sequences of units with or without repetitions allowed or as subsets of U. In the first case, a sample sequence of m units drawn is denoted $u = (u_1, \dots, u_m)$, and in the second case a sample subset is denoted S. Both u and S are random entities when the sample is drawn according to a probability design. The probability design of u is given by a probability distribution over the set U^m of all ordered m-sequences of units from U, and the probability design of S is given by a probability distribution over the class of all subsets of U. If the size n of S is fixed, all subsets of other sizes have zero probability.

The observation scheme specifies which variables are known or observable. A variable defined on the units (a vertex variable) is given by a function x from U to some range space R. Formally,

$$x = \{(i, x_i) \colon i \in U\} \,,$$

is a set of pairs (i, x_i) assigning a value x_i in R to each unit i in U. If there is a specified ordering of the units, x could also be represented as a sequence of values ordered in the same way, e. g. an ordered sequence $(x_1, \dots, x_N)$ corresponding to the order $1, \dots, N$ of the units. The first representation is more convenient when restrictions to different subsets of U are considered. For any subset A of U we denote by

$$x(A) = \{(i, x_i) \colon i \in A\} \,,$$

the restriction of the variable x to units in A. In particular, $x(U) = x$ and $x(\emptyset) = \emptyset$. A binary variable x with $R = \{0, 1\}$ and, more generally, a K-category variable x with $R = \{0, \dots, K-1\}$ partitions the population U into K disjoint subsets

$$U_j = \{i \in U \colon x_i = j\} \quad \text{for} \quad j \in R \,.$$

A variable defined on the ordered pairs of units (an arc variable) is given by a function y from U^2 to some range space R. Formally,

$$y = \{(i, j, y_{ij}) \colon i \in U, j \in U\} \,,$$

is a set of triplets (i, j, y_{ij}) assigning a value y_{ij} in R to each ordered pair (i, j) in U^2. If there is a specified ordering of the units in U, y could also be represented as a matrix array (y_{ij}) with N rows and N columns ordered according to the unit-ordering. For any two subsets A and B of U we denote by

$$y(A, B) = \{(i, j, y_{ij}) \colon i \in A, j \in B\} \,,$$

the restriction of the variable y to ordered pairs of units (i, j) with $i \in A$ and $j \in B$. The set $y(A, B)$ is simply referred to as the set of values of y from A to B. In particular, $y(U, U) = y$ and $y(A, \emptyset) = y(\emptyset, B) = \emptyset$ for any subsets A and B of U. A binary variable y with $R = \{0, 1\}$ and, more generally, a K-category variable y with $R = \{0, \dots, K-1\}$ partitions U^2 into K disjoint subsets

$$\{(i, j) \in U^2 \colon y_{ij} = r\} \quad \text{for} \quad r \in R \,.$$

Sampling Designs

In order to gain general information about population units with access only to the information from a sample of units, it is evident that the sample should represent the population in some specified way. Even if the population is partitioned into subpopulations according to several attributes of the units, and the sample is selected so that some units from each subpopulation are included in the sample, one cannot be sure that the sample allows inference to be drawn with confidence about collective properties of all the population units.

Survey sampling theory is based on information from samples that are selected according to probabilistic designs. A sampling design that gives all population units a positive probability of being included in the sample is required to achieve a sample that is representative of the population. The essential property of a sampling design that makes it appropriate for population inference is that its inclusion probabilities should be known or estimable for all units. This allows sample data to be weighted so that they accurately represent population data. A probabilistic sampling design not only makes inference possible; it also makes it possible to specify how inference uncertainty can be judged and quantified. During the early days of survey sampling, the benefits of probabilistic sampling designs were not always properly understood and had to be emphasized. Today this is so well known that it may seem dubious if someone tries to use non-probability samples.

Therefore, it is important to clarify the legitimacy of network sampling designs that involve arbitrarily or conveniently selected samples. The essential principle is still that inclusion probabilities should be known or estimable. Some network sampling designs are based on an initial probability sample followed by sequential samples that may be systematically or probabilistically selected. As a consequence, it might be hard to estimate inclusion probabilities for the final network sample, but there are no doubts about its legitimacy.

When the network sample is generated from an initial sample that is not a probability sample, it is important that the sequential samples generated after the initial sample are selected according to specified probabilistic rules. Under some fairly general assumptions to be specified, the inclusion probabilities for the final network sample can be proved to converge towards limits that are independent of the way the initial sample was selected. Thus, the lack of knowledge about the initial conditions is compensated for by letting the network sample consist of several waves of units sequentially selected according to a known or estimable probability design. This wave design determines the limiting inclusion probabilities of the network sampling design, and the accuracy of these probabilities increases with the number of waves. As we will see later, it is possible to modify the probabilistic wave design so that the limiting inclusion probabilities of the network sample become uniform or equal to any other desired probability distribution over the population of units.

It is convenient to specify a few standard sampling designs and their inclusion probabilities which are fundamental for some of the estimators discussed later. Consider a population U of N units and a sample subset S selected according to a uniform probability design over the n-subsets of U. This design is specified as

$$S \sim \text{Unif}(n, U) .$$

It is often called simple random sampling without replacement. Thus, the probability that $S = s$ is equal to

$$P(s) = n!/N(N-1)\dots(N-n+1) ,$$

for any n-subset s of U. The probability of inclusion in S of a fixed unit i from U is equal to the sum of the selection probabilities $P(s)$ over all s containing unit i. It is equal to n/N and denoted by

$$\pi_i = n/N ,$$

for any i in U. The probability of inclusion in S of two distinct units i and j from U equals

$$\pi_{ij} = n(n-1)/N(N-1) ,$$

for any distinct i and j in U.

Another subset design called Bernoulli sampling with parameter $p(0 < p < 1)$ is specified as

$$S \sim \text{Bern}(p, U) ,$$

and is defined by selection probabilities

$$P(s) = p^n(1-p)^{N-n} ,$$

for any subset s of U of size n for $n = 0, 1, \dots, N$. Its inclusion probabilities are

$$\pi_i = p ,$$

for any i in U, and

$$\pi_{ij} = p^2 ,$$

for any distinct i and j in U. An important property of Bernoulli sampling is that its inclusion indicators

$I_i = I(i \in S)$ are independent. The inclusion indicators are 1 or 0 according to whether unit i is included in S or in its complement $U - S$.

A generalization of Bernoulli sampling is obtained if the inclusion indicators are independent but not necessarily identically distributed Bernoulli variables. The sampling design with independent Bernoulli(p_i) distributed inclusion indicators for i in U is sometimes called Poisson sampling (perhaps referring to the fact that the random sample size is approximately Poisson distributed with parameter $\lambda = p_1 + \cdots + p_N$). We specify this design as a Bernoulli sampling with general parameter $p = \{(i, p_i)\colon i \in U\}$ satisfying $0 < p_i < 1$ for all i in U; in short

$$S \sim \text{Bern}(p_i\colon i \in U)\,.$$

Its selection probabilities are

$$P(s) = \prod_{i \in s} p_i \prod_{j \in U-s} (1 - p_j)\,,$$

for any subset s of U, and its inclusion probabilities are

$$\pi_i = p_i\,,$$

for any i in U, and

$$\pi_{ij} = p_i p_j\,,$$

for any distinct i and j in U.

A probability design for a sample sequence $u = (u_1, \ldots, u_m)$ of m units independently drawn according to a uniform distribution over U has selection probabilities

$$P(i_1, \ldots, i_m) = 1/N^m\,,$$

for any sequence $(i_1, \ldots, i_m)$ in U^m. This design specified by

$$u_k \sim \text{Unif}(U) \quad \text{independent for } k = 1, \ldots, m\,,$$

is often called simple random sampling with replacement. Its inclusion probabilities are given by

$$\pi_i = 1 - (1 - 1/N)^m\,,$$

for any i in U, and

$$\pi_{ij} = 1 - 2(1 - 1/N)^m + (1 - 2/N)^m\,,$$

for any distinct i and j in U.

A generalization of this design to m independent identically distributed (IID) draws according to a probability distribution with N arbitrary positive probabilities $p(i)$ summing to 1 for i in U has selection probabilities

$$P(i_1, \ldots, i_m) = p(i_1) \ldots p(i_m)\,,$$

for any sequence $(i_1, \ldots, i_m)$ in U^m. We specify this design by

$$u_k \sim \text{IID}(p(i)\colon i \in U) \quad \text{for } k = 1, \ldots, m\,.$$

Its inclusion probabilities are

$$\pi_i = 1 - [1 - p(i)]^m\,,$$

for any i in U, and

$$\pi_{ij} = 1 - [1 - p(i)]^m - [1 - p(j)]^m + [1 - p(i) - p(j)]^m\,,$$

for any distinct i and j in U. A further generalization would allow the sequence of independent draws to be made according to different distributions.

For any probability design of a sample sequence $u = (u_1, \ldots, u_m)$ we define the inclusion count or multiplicity m_i of unit i as the number of draws equal to that unit. The multiplicities sum to m, and a positive multiplicity of a unit indicates its inclusion in the sample sequence. The set of distinct units in a sample sequence u is denoted by $s(u)$. This is a random subset of U of size $n(u)$ and expected size

$$\text{E} \;\; n(u) = \sum_{i \in U} \pi_i\,,$$

and variance

$$\text{Var} \;\; n(u) = \sum_{i \in U} \sum_{j \in U} (\pi_{ij} - \pi_i \pi_j)\,.$$

Any sample sequence $u = (u_1, \ldots, u_m)$ with $u_k \sim$ IID $(p(i)\colon i \in U)$ for $k = 1, \ldots, m$ has multiplicities $(m_1, \ldots, m_N)$ that are multinomially distributed with parameters m and $(p(1), \ldots, p(N))$. The number of distinct units $n(u)$ in u is a sum of independent Bernoulli(π_i)-variables, which is asymptotically Poisson($\sum_i \pi_i$). With dependent draws it is generally difficult to derive the simultaneous probability distribution of the multiplicities or the distribution of the number of distinct units in u.

Snowball Sampling Designs

Let the population $U = \{1, \ldots, N\}$ have a graph structure given by a binary variable y defined on the pairs of population units. Let the sets of units adjacent after and before unit i be

$$A_i = \{j \in U\colon y_{ij} = 1\} \quad \text{and} \quad B_i = \{j \in U\colon y_{ji} = 1\}\,,$$

for $i \in U$. For any subset s of U, we denote by $A(s)$ the union of the A_i for $i \in s$. A snowball sampling design starts with an initial subset S_0 of U. This subset can either be a convenience sample or the outcome of a probability sampling design with a known or unknown probability distribution P_0 over the class of all subsets of U. In the latter case there are selection probabilities $P_0(s) \geq 0$ summing to 1 for all subsets s of U. In the former case S_0 is equal to a fixed set s_0, and it is convenient to put $P_0(s_0) = 1$. Note that in either case we don't even know that all units in the population have positive probabilities of being included in the initial sample.

The snowball sample is obtained by successively extending the initial sample S_0 with units selected from the sets of units that are adjacent after previously joined units. More precisely, a first wave W_1 is selected according to a probability distribution over the class of subsets of

$$(U - S_0) \cap A(S_0)\ .$$

The union of the initial sample S_0 and the disjoint first wave W_1 is equal to the one-wave snowball S_1. Generally, the kth wave W_k is selected according to a probability distribution over the class of subsets of

$$(U - S_{k-1}) \cap A(W_{k-1})\ ,$$

for $k = 1, 2, \ldots$ with $W_0 = S_0$. The k-wave snowball S_k is the union of the $(k-1)$-wave snowball S_{k-1} and the kth wave W_k. The waves are disjoint and

$$W_k = S_k - S_{k-1} \quad \text{for} \quad k = 1, 2, \ldots$$

The k-wave snowball S_k is called saturated if the kth wave W_k is the last wave that is non-empty, so that the sequence of snowballs has reached an absorbing state

$$S_k = S_{k+1} = \cdots$$

According to the selections of the waves, it follows that the k-wave snowball S_k evolves as a stochastic process depending on the $(k-1)$-wave snowball S_{k-1} and the kth wave which depends on S_{k-1} and $W_{k-1} = S_{k-1} - S_{k-2}$. Thus, the snowball process S_k has a two-step memory: The probability distribution of S_k conditional on $S_0, \ldots, S_{k-1}$ depends on S_{k-1} and S_{k-2} only, for $k = 2, 3, \ldots$ Another equivalent way to express this is to say that the stochastic process with states consisting of the current snowball and its last wave (S_k, W_k) is a Markov chain.

The transition probabilities of this Markov chain are

$$\begin{aligned} P(S_{k+1} = s_{k+1}, W_{k+1} = w_{k+1} | S_k = s_k, W_k = w_k) \\ = P(W_{k+1} = w_{k+1} | S_k = s_k, W_k = w_k) \\ = P(w_{k+1} | s_k, w_k)\ , \end{aligned}$$

for s_{k+1} equal to the union of s_k and w_{k+1}. The Markov chain is assumed to be time-homogeneous so that the transition probabilities do not depend on the stage parameter k. The transition probabilities do depend on graph parameters

$$y(w_k, U - s_k) = \{(i, j, y_{ij}) \colon i \in w_k, j \in U - s_k\}\ ,$$

governing possible wave selections and possibly also on other parameters governing properties of the wave selections. Assume that saturation occurs at stage k or later. Then the sequence of snowball samples $(S_0, S_1, \ldots, S_k)$ has a probability distribution given by

$$\begin{aligned} P(S_0 = s_0, S_1 = s_1, \ldots, S_k = s_k) = P(s_0, s_1, \ldots, s_k) \\ = P_0(s_0) P(w_1 | s_0, w_0) P(w_2 | s_1, w_1) \\ \cdots P(w_k | s_{k-1}, w_{k-1})\ , \end{aligned}$$

for any strictly increasing subset sequence $(s_0, s_1, \ldots, s_k)$ with $s_j - s_{j-1} = w_j$ for $j = 1, 2, \ldots, k$ and $s_0 = w_0$.

The probability distribution of the k-wave snowball S_k is obtained by summing the probabilities $P(s_0, s_1, \ldots, s_k)$ over all strictly increasing subset sequences $(s_0, s_1, \ldots, s_{k-1})$ with s_{k-1} strictly included in s_k. The initial sample and each new wave need to contain at least one unit, so that s_k contains at least $k + 1$ units. If s_k contains more units, the sum is extended over all possible distributions of the non-initial units among the k waves.

In order to be able to perform such calculations, we need to specify the common sampling design of the waves. At stage k, the next wave W_{k+1} has a probability distribution over the class of subsets of that part of U that is not included in the current snowball S_k but is adjacent after its last wave W_k. Now the selection of a subset for W_{k+1} can be considered as obtained by the recruitment of new units made by units in W_k. Each unit i in W_k can recruit only from A_i, the set of units adjacent after unit i. Assume that the recruited set R_i is a Bernoulli sample with inclusion probabilities p_{ij} for j in A_i. The recruited sets R_i are assumed to be selected independently for all i in U. The union of the sets R_i recruited by the units i in W_k is the set $R(W_k)$. This set is a subset of $A(W_k)$, and the part of it that is not included in S_k is the new wave W_{k+1}. Thus

$$W_{k+1} = (U - S_k) \cap R(W_k)\ ,$$

where $R(W_k)$ as a union of independent Bernoulli samples is itself a Bernoulli sample conditional on W_k. The probability that unit j is included in $R(W_k)$ equals the probability that j is included in at least one of the R_i for i in W_k. This probability is denoted

$$p(W_k, j) = 1 - \prod (1 - p_{ij})\ ,$$

where the product is over i in W_k and j is a unit in $A(W_k)$. It follows that conditional on the current state of the Markov chain (S_k, W_k), the next wave W_{k+1} is a Bernoulli sample with inclusion probabilities

$$p(W_k, j) \quad \text{for} \;\; j \;\; \text{in} \;\; (U - S_k) \cap A(W_k) \, .$$

The transition probabilities of the Markov chain (S_k, W_k) can now be specified as

$$P(w_{k+1}|s_k, w_k) = \left[\prod p(w_k, j)\right]\left[\prod q(w_k, j)\right] \, ,$$

where the first product is over j in w_{k+1} and the second product is over j in $U - s_{k+1}$ with probabilities denoted $q(w_k, j) = 1 - p(w_k, j)$. The basic parameters here are the probabilities p_{ij} that unit i would recruit unit j. Only units j in A_i can be recruited, and only units i included in the initial sample or any of the waves will have an opportunity to recruit. We can interpret the parameters p_{ij} as probabilities of independent recruitment arcs in the population graph. When y is considered as specifying a fixed population graph, p_{ij} is zero whenever y_{ij} is zero. If all units in A_i should have the same probability of being recruited, we could put $p_{ij} = \alpha_i y_{ij}$ where α_i is a probability governing the recruitment or co-operation activity of unit i. If recruitment also depends on availability, status or attraction of the recruited unit, we could put $p_{ij} = \alpha_i \beta_j y_{ij}$. The parameters α_i and β_i for units i in U could be related to a categorical variable x defined on U. For a K-category variable x the parameters $\alpha_i = \alpha(x_i)$ and $\beta_i = \beta(x_i)$ have K possible values each, and the parametrization involves only $2K$ parameters.

Recruitment or selection of adjacent members of the population can be considered as a sampling performed by the investigator or by the respondent. The units of the population can be people that could be interviewed by the investigator. The units can also be geographical regions or other entities for which the adjacent units can either be observed directly or determined by interviews with some unit representative. In such cases when the investigator can get access to information about all units that are adjacent after a sampled unit, then the recruitment of further units can be made by the investigator. There are situations when information about adjacent units might be sensitive or embarrassing to the respondent. If the respondent is unwilling to release information about all adjacent units, a possibility might be to ask the respondent just to select some of them at random. Such respondent driven sampling might in some situations give more reliable data and could provide a reasonable way to avoid some problems of integrity. For a more thorough discussion of this, see, for instance, [53]. There are techniques developed with distribution of recruitment cards and various benefits to participants in order to help the investigator to get new waves of the sample. Even if respondent i provides only R_i and not A_i, information could be collected about out-degrees or other statistics needed for the respondent driven probability design of the wave sampling.

The combination of design based and model based probabilities are standard in survey sampling and should be so also when network sampling is applied. Respondent driven sampling could be such a case when a random graph approach would be appropriate for the wave sampling. An illustration of combination of design-based and model-based approaches to network surveys is given in [66].

Estimation Based on Snowball Samples

Estimation of population data from snowball sample data requires inclusion probabilities of all population units. Any fixed unit j is included in a k-wave snowball sample if it is included in the initial sample or in any of its k following waves. Since the initial sample and the waves are disjoint, their inclusion events are mutually exclusive, and the probability that the snowball includes j equals the sum of the probabilities that the initial sample or any of the waves include j:

$$P(j \in S_k) = P(j \in S_0) + P(j \in W_1) + \cdots + P(j \in W_k) \, .$$

Obviously this inclusion probability increases strictly with the number of waves until the snowball is saturated. If the initial sample is a convenience sample, its inclusion probability is 1 or 0 depending on whether j belongs to it or not. According to the results derived above for the conditional distribution of the next wave W_{k+1} given the current state (S_k, W_k), the conditional probability that a unit j not in S_k should be included in W_{k+1} is given by

$$p(W_k, j) = 1 - \prod (1 - p_{ij}) \, ,$$

where the product extends over units i in W_k. Therefore

$$P(j \in W_{k+1}) = \mathrm{E} \;\; [1 - I(j \in S_k)] p(W_k, j) \, ,$$

where the expectation is over outcomes of (S_k, W_k). The probability of inclusion of unit j in S_{k+1} is obtainable as the sum of the probabilities of inclusion in the waves, but usually it is easier to first consider the conditional probability of inclusion of j in S_{k+1} given the current state (S_k, W_k). This probability is given by $p(S_k, j)$ if we define $p(S_k, j) = 1$ for $j \in S_k$. This is achieved by defining $p_{jj} = 1$ for $j \in U$. Hence, the unconditional inclusion probability is given by

$$P(j \in S_{k+1}) = \mathrm{E}\ \ p(S_k, j) = 1 - \mathrm{E}\ \ \prod_i [1 - I(j \in S_k) p_{ij}] ,$$

where the expectation is over outcomes of S_k. Even if the initial sample and all the recruitment samples are independent Bernoulli samples, it doesn't follow that S_k is a Bernoulli sample, and we cannot carry out the expectation factor by factor to obtain a recurrence relation between single unit inclusion probabilities of the current and the next snowball. In fact, it can be shown that for distinct *i* and *j* in *U*

$$\pi_{ij}(k) \geq \pi_i(k) \pi_j(k) ,$$

where $\pi_j(k) = P(j \in S_k)$ and $\pi_{ij}(k) = P(i \in S_k \ \ \& \ \ j \in S_k)$ for $k = 0, 1, \ldots$ Equality holds true if and only if there are no units of positive probability of inclusion in S_0, which are *k* steps adjacent before both *i* and *j*. An approximation that deserves to be further investigated for snowballs with few waves is

$$\pi_j(k+1) = 1 - \prod_i [1 - \pi_i(k) p_{ij}] ,$$

or, equivalently, using logarithms

$$\log[1 - \pi_j(k+1)] = \sum_i \log[1 - \pi_i(k) p_{ij}] .$$

When the inclusion probabilities are not too close to 1, we can obtain a linear approximation to the recurrence relation by series expansions of the logarithmic functions:

$$\pi_j(k+1) = \sum_i \pi_i(k) p_{ij} .$$

Since the inclusion probabilities are fundamental for many estimators, it would be of interest to know if there are sampling designs for which this recurrence relation is an acceptable approximation.

Consider a one-wave snowball with Bernoulli samples as described above. There are several possibilities for data collection that need to be distinguished. Assume that the value of a vertex variable *x* and the degree are observed for sample units. If the units are identifiable and individual recruitments are observed, data consist of (i, x_i, y_i) for $i \in S_0$ and (j, x_j, y_j) for $j \in R_i$ and $i \in S_0$. Units have multiplicities 0 or 1 in S_0, but their multiplicities in S_1 might be larger and that applies also to units in S_0 if they are recruited in the first wave. If only collective recruitments are observed, data consist of (i, x_i, y_i) for $i \in S_0$ and (j, x_j, y_j) for $j \in R(S_0)$. In this case, multiplicities in S_1 can be 0, 1, or 2, and 2 applies only to units in S_0. If only collective recruitments not included in S_0 are observed, data consist of (i, x_i, y_i) for $i \in S_0$ and (j, x_j, y_j) for $j \in W_1$. Now multiplicities are never larger than 1. If units are not separated between S_0 and W_1, data consist of (i, x_i, y_i) for $i \in S_1$. Also in this case multiplicities are never larger than 1. If the units are not identifiable and individual recruitments are observed, data consist of (x_i, y_i) for $i \in S_0$ and (x_j, y_j) for $j \in R_i$ and $i \in S_0$ with no possibility to observe multiplicities and no possibility to reduce data to $R(S_0)$, W_1, or S_1. If only collective recruitments are observed, we cannot separate S_0 and W_1 and we don't know S_1 or any multiplicities. If only collective recruitments of units not included in S_0 are observed, we can separate S_0 and W_1 and we know S_1 and we know that no multiplicities are larger than 1. Without identities and without separation of S_0 and W_1, data consist of (x_j, y_j) for $j \in S_1$. Depending on the observation scheme available, different estimators can be used.

To illustrate various estimators, it is convenient to use snowball sample indicators $S_{kj} = I(j \in S_k)$ for $j \in U$ and $k = 0, 1, \ldots$ and recruitment indicators $z_{ij} = I(j \in R_i)$ for $i \in U$ and $j \in U$. According to our assumptions S_{0j} are Bernoulli(p_j) for $j \in U$, and z_{ij} are Bernoulli(p_{ij}) for $i \in U$ and $j \in U$, and all these variables are independent. Here $0 \leq p_j \leq 1$ for $j \in U$, and by allowing the values 0 and 1 initial convenience samples are possible. Recruitments are restricted by the presence of edges in the acquaintance graph, which implies that $0 \leq p_{ij} \leq y_{ij}$ for distinct *i* and *j* in *U*. For convenience we define $p_{jj} = 1$ for $j \in U$. Note that even if the acquaintance graph is undirected with $y_{ij} = y_{ji}$, the recruitment graph given by arc indicators z_{ij} is directed.

Consider the total $T = \sum x_i$ of a vertex variable *x* and the total $D = \sum y_i$ of degrees in the acquaintance graph. Let us specify $p_j = y_j / D$ and $p_{ij} = y_{ij} / y_i$ for $i \neq j$. Assuming *D* known and using only data from S_0, we have an unbiased estimator of *T* given by

$$T' = \sum_i (x_i S_{0i} / p_i) = \sum_i (x_i S_{0i} D / y_i) .$$

Similarly the total population size *N* has an unbiased estimator

$$N' = \sum_i (S_{0i} D / y_i) .$$

Without assuming *D* known, we have an asymptotically unbiased estimator of the population mean of *x* according to

$$T'/N' = \sum_i (x_i S_{0i} / y_i) \Big/ \sum_i (S_{0i} / y_i) .$$

Thus, the average of x-values in S_0 is weighted by reciprocal degrees.

Using individual recruitment data, an unbiased estimator of T is given by

$$\begin{aligned} T'' &= \sum_j \left(x_j \sum_i S_{0i} z_{ij} \Big/ \sum_i p_i p_{ij} \right) \\ &= \sum_i \sum_j (x_j S_{0i} z_{ij} D / y_j) \,. \end{aligned}$$

Also here the degree total D cancels from the asymptotically unbiased estimator of the population mean of x. We get

$$T''/N'' = \sum_i \sum_j (x_j S_{0i} z_{ij}/y_j) \Big/ \sum_i \sum_j (S_{0i} z_{ij}/y_j) \,.$$

Thus, the average of x-values in S_1 is counted with multiplicities and weighted by reciprocal degrees.

Using collective recruitments and only data from S_1, an unbiased estimator of T is given by

$$T''' = \sum_j [x_j S_{1j}/\pi_j(1)] \,,$$

where

$$\begin{aligned} \pi_j(1) &= 1 - \prod_i (1 - p_i p_{ij}) \\ &= 1 - \prod_i (1 - y_{ij}/D) = 1 - (1 - 1/D)^{y_i} \,. \end{aligned}$$

This time D does not appear as a factor in T''' or in the corresponding N''', so it does not cancel in the population mean estimator T'''/N'''. Replacing x_j by y_j in the estimators T', T'', and T''', we obtain D', D'', and D''' that all depend on D. The first two wouldn't provide any possibility to iteratively determine a value of a D-estimator. For D''' an iterative method would start with an initial value of D in $\pi_j(1)$, find D''', use this D''' for D in $\pi_j(1)$, find a new D''', etc. Convergence properties of such algorithms and properties of estimators that can be obtained from them haven't been explored. We will comment on similar iterative methods in Sect. "Estimation Based on Network Walk Samples".

When data from snowballs with more than one wave are available, it might be comparatively easy to set up estimators based on a first few waves, but more complicated to find the required inclusion probabilities for snowballs of many waves. An important technique described in [64] is to use Rao-Blackwellization to improve estimators based on data from only a few waves to obtain estimators based on all data. Rao-Blackwellization of an estimator requires extensive numerical calculations of its possible values for all arrangements of available data that are consistent with the reduced data remaining when multiplicities of sample units and order between the sample units are ignored. The expected value of an estimator conditional on a sufficient statistic in the form of the reduced data is the improved estimator. Sufficiency in survey sampling from a finite population was treated in [1]. More recent references are [9,44].

Network Walk Sampling Designs

Assume that the population $U = \{1, \ldots, N\}$ has a graph structure given by a binary variable y defined on the set of ordered pairs of population units. Let A_i and B_i be the sets of units adjacent after and before unit i. The size of A_i is the out-degree of unit i, and the size of B_i is the in-degree of unit i. When the graph is undirected, $A_i = B_i$ and out- and in-degrees are equal and called degrees.

A sampling design based on a random walk in a graph selects the sample as a sequence of units $u_1, u_2, \ldots$ according to a time-homogeneous Markov chain with transition probabilities

$$P(u_{k+1} = j | u_k = i) = P_{ij} \,,$$

that are independent of the stage parameter k for j in A_i and $k = 1, 2, \ldots$ If the graph is directed and strongly connected so that every unit has a directed path to every other unit, and if not all cycle lengths are multiples of a common factor larger than one, then the Markov chain will be irreducible and aperiodic. If the graph is undirected, connected, and contains at least one cycle of length one or three, then the Markov chain will be irreducible and aperiodic. A time-homogeneous, irreducible, and aperiodic Markov chain has a unique limiting distribution

$$\lim P(u_k = j | u_1 = i) = p_j > 0 \,,$$

independent of the initial unit i as k tends to infinity. The limiting distribution is equal to the stationary distribution that can be obtained by solving the equation system

$$p_j = \sum p_i P_{ij} \quad \text{for} \quad j = 1, \ldots, N \,,$$

subject to $\sum p_j = 1$. For instance, let the transition probability be $P_{ij} = y_{ij}/y_i$ for an undirected graph with degree y_i of unit i. This means that the transition from unit i is made with equal probabilities to each one of the y_i units that are adjacent to it. It follows that $p_i = y_i/(y_1 + \cdots + y_N)$. Hence, transition from any unit to one of its adjacent units according to a uniform probability distribution implies that the limiting probabilities of the units are proportional to their degrees.

If the limiting probabilities p_i for the units i in U cannot be determined from known or observable data, ergodic theory proves that they can be estimated by the relative frequencies in a long sample sequence obtained according to any time-homogeneous, irreducible, and aperiodic Markov chain. To be more specific, consider a sequence $u = (u_1, \dots, u_m)$ of length m. The multiplicities of the units are m_i for i in U. The relative multiplicity sequence $(m_1/m, \dots, m_N/m)$ converges towards the limiting distribution $(p_1, \dots, p_N)$ when m tends to infinity.

Let $n(u)$ be the size of the set $s(u)$ of distinct units in u. The probability π_i that unit i is included in $s(u)$ equals the probability that $m_i > 0$. The multiplicity sequence is a reduction of the information in the sample sequence u that ignores the order of selection. The set $s(u)$ is a further reduction that ignores both the order of selection and the multiplicities of the units selected.

The graph employed for random walk sampling determines the zero entries among the transition probabilities $P = (P_{ij})$. These network-induced transition probabilities determine the limiting stationary distribution $p = (p_1, \dots, p_N)$. If the initial unit u_1 is selected according to the stationary distribution p, this distribution applies to the marginal distribution of any position u_k of the walk. Another initial distribution implies that the stationary distribution is approached asymptotically on the walk for positions u_k as k increases. The limiting stationary distribution is important for appropriate weighting of data collected by network walk samples. Therefore, it is of special interest that it is possible to achieve any pre-assigned limiting distribution by adjusting the transition probabilities P induced by the network.

Assume that it is desirable to obtain a limiting distribution $q = (q_1, \dots, q_N)$ that is different from the stationary distribution p derived from the transition probabilities P. Modified new transition probabilities $Q = (Q_{ij})$ satisfying the reversibility condition $q_i Q_{ij} = q_j Q_{ji}$ would lead to the stationary distribution q, which is also the limiting distribution when transitions are made according to the new Q. If we define Q by

$$Q_{ij} = P_{ij} \min(1, q_j P_{ji} / q_i P_{ij}) \,,$$

for $i \neq j$ and

$$Q_{ii} = 1 - \sum_{i \neq j} Q_{ij} \,,$$

it follows that

$$q_i Q_{ij} = \min(q_i P_{ij}, q_j P_{ji}) = q_j Q_{ji} \,,$$

i. e. the reversibility condition is satisfied. To implement transitions according to Q, we can tentatively apply P and then decide to accept or reject a suggested transition from i to j with probability Q_{ij}/P_{ij} and $1 - Q_{ij}/P_{ij}$, respectively. More specifically, if the walk at stage k is in position $u_k = i$, and the next transition according to P would lead to unit j, the investigator might have to collect information from j to be able to calculate P_{ji} and compare it with P_{ij}. If $q_j P_{ji} \geq q_i P_{ij}$, then the transition to j has a probability valid also according to Q, and the walk is allowed to jump to $u_{k+1} = j$. Otherwise, the transition to j has not a valid probability according to Q, and, unless a transition is accepted, the walk has to stay at $u_k = i$ for another trial. Equivalently we could put $u_{k+1} = i$ and let the stage parameter count the number of trials instead of the number of jumps to other positions. Note that the probability that the modified walk stays for another trial equals the sum of the probabilities that the walk according to P jumps to a unit to be rejected, which is

$$\sum_{i \neq j} P_{ij}(1 - Q_{ij}/P_{ij}) = 1 - \sum_{i \neq j} Q_{ij} \,.$$

Consider the following illustrations for a directed network with transition probabilities $P_{ij} = y_{ij}/a_i$ for $j \in A_i$. Here the stationary probabilities can be difficult to find. Assume that we want a stationary distribution with probabilities q proportional to the out-degrees: $q_j = a_j/(a_1 + \cdots + a_N)$. The modified transition probabilities are

$$Q_{ij} = P_{ij} \min(1, q_j P_{ji} / q_i P_{ij}) = \min(y_{ij}, y_{ji})/a_i \,,$$

and only jumps to mutual contacts are accepted. We need to collect information about out-degrees and be able to verify mutuality. Assume instead that we want a stationary distribution proportional to in-degrees: $q_j = b_j/(b_1 + \cdots + b_N)$. Then

$$Q_{ij} = (y_{ij} y_{ji}/b_i) \min(b_i/a_i, b_j/a_j) \,.$$

Only jumps to mutual contacts are possible, and only those with $b_i/a_i \leq b_j/a_j$ have transition probabilities that are valid also according to Q. Thus, unit j can be rejected unless it is a mutual contact with at least the same ratio of out-degree to in-degree as unit i. In this case we need to collect information about out- and in-degrees and be able to verify mutuality. Finally, assume that a uniform limiting distribution $q_j = 1/N$ is wanted. Then

$$Q_{ij} = \min(P_{ij}, P_{ji}) = y_{ij} y_{ji} / \max(a_i, a_j) \,,$$

and j can be rejected unless it is a mutual contact that has at most the same out-degree as unit i. This case requires information about out-degrees and mutuality. Further illustrations are provided in [65]. A general presentation of methods for constructing transition kernels (probabilities or probability densities) with desired properties, including the Metropolis–Hastings algorithm and the Gibbs sampler, can be found in Sect. 3.6 of [39].

The random walk sampling discussed so far has been in undirected graphs that are connected or in directed graphs that are strongly connected. If the connectedness assumption is uncertain for the graph being employed, or if it is known that it is not valid, then the Markov chain is reducible, and the transitions cannot reach beyond the connected component induced by the initial sample. In order not to confine the chain to a part of the population only, transitions to adjacent units could sometimes be replaced by transitions to other units.

A way to control the balance between staying on the current walk and starting on a new one, is to use a mixture distribution for the transitions. Let $P' = (P'_{ij})$ be a matrix of probabilities for transitions to adjacent units, and let $P'' = (P''_{ij})$ be a matrix of probabilities for transitions to arbitrary units in the population. A mixture distribution with transition probabilities given by

$$P = \alpha P' + (1 - \alpha)P'' ,$$

where $0 < \alpha < 1$, is said to have a damping factor α measuring the proportion of transitions that are selected according to P'. For instance, $P'_{ij} = y_{ij}/a_i$ for j in A_i and $P''_{ij} = 1/N$ for j in U represent a mixture between uniform transitions from i to A_i and uniform transitions from i to U. The walk stops when it reaches a unit with $a_i = 0$. A slight modification is to define P'_{ij} also when $a_i = 0$, so that the walk is never forced to stop. For α close to 1, the damping effect will be small, and a population with a disconnected graph will be poorly represented by walk sample data. For decreasing α, the damping effect increases, the influence of the graph decreases, and the importance of having an appropriate matrix P'' increases. It might be appropriate to assume, for instance, that global transitions are made with probabilities proportional to out-degrees or in-degrees of the units, which would reflect that activity or attraction of the units is likely to influence the selections. In this way, the damping effect needed to handle a disconnected graph does not necessarily diminish the influence of the graph.

When network walk sampling is applied to webpage transitions in [70], a model is used that in our notation can be given as $P'_{ij} = y_{ij}/a_i$ if $a_i > 0$ and $P'_{ij} = 1/N$ if $a_i = 0$, and $P''_{ij} = p''_j$. Here p''_j reflects the web surfer's preferences for various pages, and the damping factor α reflects tendencies to use page links for surfing rather than own preferences.

Estimation Based on Network Walk Samples

Assume that sample data consist of the values of a variable x defined on the population of units. When units in the sample sequence can be identified, sample data consists of m values of x that can be referred to the units. The values (i, x_i, m_i) are known for all units i in $s(u)$. When units in the sample sequence cannot be identified, sample data consist of m values of x that cannot be referred to the units. Neither the multiplicities nor the set of distinct units can be determined. Sample data are restricted to the frequency distribution of the x-values.

There is an intermediate situation that could appear when sample data consist of the values of a variable x defined on U. If units in the sample sequence cannot be identified, it could still be possible to successively mark them in some way and observe when the same unit is sampled again. Data then consist of a sequence of m values on x that cannot be referred to the units but that can be partitioned into n sub-sequences of constant values belonging to the same unknown unit. Notice that the same value might appear in different sub-sequences. The multiplicities are known but their unit affiliations are not, and the number of distinct units is known but not their identities. The values (x_i, m_i) are known for n unknown distinct units i in U. If x is a K-category variable, the frequency distribution of these values (x_i, m_i) can be displayed in a K by m array representing available sample data when identities of units can not be observed but similarity between units is observed. Let $(n_1, \dots, n_m)$ be the marginal frequency distribution of the multiplicities. Then

$$n_1 + n_2 + \cdots + n_m = n ,$$

and

$$n_1 + 2n_2 + \cdots + mn_m = m .$$

Knowledge of the frequencies $(n_1, \dots, n_m)$ represents a reduction of the information in the multiplicity sequence that ignores the identities of the units. The marginal frequency distribution of the K-category variable x is the only information left when neither similarities nor identities between units can be observed.

Consider a network walk sample sequence $u = (u_1, \dots, u_m)$ obtained by a time-homogeneous, irreducible, and aperiodic Markov chain with transition probabilities $P_{ij} = y_{ij}/a_i$ for $j \in A_i$ and initial probabilities equal to the stationary probabilities $p_j = y_j/(y_1 + \cdots + y_N)$ for $j \in U$. The following reasoning applies asymptotically for large sample sequences even if the initial unit is not selected according to the stationary distribution. Data consist of the values of a vertex variable x and the degrees for each unit in the sample sequence u, but the units need not be identified. The population mean of x is $\mu = T/N$ where $T = x_1 + \cdots + x_N$. The mean of x in the sample sequence is

$$\sum_{i\in u}(x_i/m) = \sum_{i\in U}(m_i x_i/m)\ ,$$

where m_i is the unknown number of units equal to i in u. Since

$$\mathrm{E}\ m_i = mp_i = my_i/(y_1 + \cdots + y_N)\ ,$$

the sample mean is biased as an estimator of the population mean μ unless all degrees are equal. Now

$$T' = \sum_{i\in u}(x_i/mp_i) = \sum_{i\in U}(m_i x_i/mp_i)\ ,$$

has expected value T, and

$$N' = \sum_{i\in u}(1/mp_i) = \sum_{i\in U}(m_i/mp_i)\ ,$$

has expected value N. Moreover,

$$\mu' = T'/N' = \sum_{i\in u}(x_i/y_i)\Big/\sum_{i\in u}(1/y_i)\ ,$$

has asymptotically expected value μ for large values on m. The quantities T' and N' are not available from data since they contain the unknown total $D = y_1 + \cdots + y_N$ of all degrees. However, this total cancels in the ratio $\mu' = T'/N'$ so μ' is an asymptotically unbiased estimator of μ. We note that the estimator μ' is a weighted mean of the values of x in the sample sequence u with weights that are inversely proportional to the degrees.

The results obtained can be applied with $x_i = y_i$ to get an estimator of the average degree D/N in the population. Its estimator is

$$D'/N' = m\Big/\sum_{i\in u}(1/y_i)\ ,$$

which is the harmonic mean of the degrees in the sample sequence. The results can also be applied with $x_i = I(i \in U_1)$, i. e. with x as an indicator variable for a specific subset U_1 of U of unknown size N_1. Then $T = N_1$ and the relative size of U_1 has an asymptotically unbiased estimator

$$N_1'/N' = \sum_{i\in u}(x_i/y_i)\Big/\sum_{i\in u}(1/y_i)\ ,$$

which is the ratio between the sum of inverted degrees of units in the sample sequence that belong to U_1 and the sum of inverted degrees of all units in the sample sequence. The average degree in U_1 is given by

$$D_1/N_1 = \left[\sum_{i\in U} x_i y_i\right]\Big/\left[\sum_{i\in U} x_i\right]\ ,$$

where $x_i = I(i \in U_1)$, and it can be estimated by

$$D_1'/N_1' = \left[\sum_{i\in u} x_i\right]\Big/\left[\sum_{i\in u}(x_i/y_i)\right]\ ,$$

which is the harmonic mean of the degrees of the units in the sample sequence that belong to U_1. We note that the corresponding arithmetic mean is larger than or equal to the harmonic mean and therefore over-estimates the (arithmetic) population mean. This is because we oversample units with large degrees. The bias is reduced by taking the harmonic sample mean.

If the units in the sample sequence are identifiable, it is possible to observe the multiplicities and the set of distinct sample units $s(u)$. Should the inclusion probabilities $\pi_i = P(i \in s(u))$ be known, this would allow the population total T to be estimated by the unbiased estimator

$$T'' = \sum_{i\in s(u)} (x_i/\pi_i)\ .$$

Similarly, N would have an unbiased estimator

$$N'' = \sum_{i\in s(u)} (1/\pi_i)\ ,$$

and μ an asymptotically unbiased estimator

$$\mu'' = \left[\sum_{i\in s(u)} (x_i/\pi_i)\right]\Big/\left[\sum_{i\in s(u)} (1/\pi_i)\right]\ .$$

The inclusion probabilities $\pi_i = P(i \in s(u))$ are approximately $1 - \exp(-mp_i)$ and according to our assumptions about the Markov chain, the stationary probabilities are $p_j = y_j/D$ where $D = \sum y_j$ is the degree total. Now the average degree D/N was shown above to be estimated by the harmonic mean of the degrees in the sample sequence. Altogether, this allows us to set up the estimator N'' as a function of N, and by replacing N by N'' we might have a possibility to solve iteratively for N'' in the equations

$$N'' = \sum_{i\in s(u)} [1 - \exp 1\big/(-my_i/D')]\ ,$$

$$D' = mN''\Big/\sum_{i\in u}(1/y_i)\ .$$

Possibilities of finding estimators iteratively, when the inclusion probabilities are functions of some of the parameters we want to estimate, deserve further study.

Methods for Estimating Hidden Populations

Hidden populations usually refer to populations of human individuals sharing a stigmatizing, illegal, risky, or embarrassing behavior that make them hard to find. There are no lists or frames to sample them from. Investigation of such populations might be of interest to society and necessary for determining appropriate resources to be allocated for social support and other types of social action. Standard survey sampling methods that require population frames cannot be used to study homeless people, drug users, sexual workers, individuals exposed to criminal or medical risks, etc. Various alternative approaches are discussed in [61].

Convenience samples of such hidden populations might be obtained by social field workers or by the police. The information gained from such sources could indicate the need for further study and data collection to obtain reliable inference about the hidden population. Members of the hidden population that are approached by social field workers might not be unwilling to co-operate and give away information about other members of the hidden population. Several practical methods described in the literature use various kinds of payments and other benefits to individuals in the hidden population that help the investigator to reach other members of the population for interview. When respondents are willing to reveal which other members they know of, the investigator can select the waves of a snowball sample. Respondents might be more willing to co-operate if they are asked to select at random one or two of the other members they know of. Thus, respondent driven random walk or small wave snowball sampling can be applied to the population network.

In cases when members of hidden populations are not willing to reveal themselves, it might still be possible to get information about them by applying network sampling. Assume for instance that the hidden population of interest is part of a larger population that can be sampled conventionally. A respondent sampled from the larger population might without revealing names or identities be able and willing to give some information about how many members of the hidden subpopulation she knows about. Such local network information about the hidden subpopulation can sometimes be used to infer information about the entire hidden subpopulation. As an illustrative example, consider the following setup considered in [41].

The hidden population U_1 consists of an unknown number N_1 of individuals. In order to estimate N_1, a larger population U of N individuals is defined so that it comprises U_1 as a subset; U_1 is embedded in U in such a way that another subset U_2 of U can be assumed to be equally common in U_1 and in U. The subset U_2 should consist of individuals having some easily identified characteristic. Neither the size N of U nor the size N_2 of U_2 need to be known. Select a sample S from U with positive inclusion probabilities π_i for all i in U. Each respondent is asked whether she belongs to U_2 and whether she has some acquaintances in U_2. She is not asked whether she belongs to U_1 but only whether she has some acquaintances in U_1. Let x_1 and x_2 be indicator variables of the sets U_1 and U_2, i. e. $x_{jk} = I(j \in U_k)$ for $j = 1, \dots, N$ and $k = 1, 2$. Let further $y = (y_{ij})$ be the symmetric adjacency matrix of the acquaintance graph with degree y_i equal to the unknown number of acquaintances of individual i in U. This number is usually quite large and the respondent need not be asked to estimate it but rather to concentrate on giving reliable estimates of her numbers of acquaintances that belong to U_1 and U_2, say

$$a_{ik} = \sum_{j \in U} x_{jk} y_{ij} ,$$

for $i = 1, \dots, N$ and $k = 1, 2$. If the independence assumptions are met for x_1, x_2, and y, then it could be expected under a randomization model that proportionality is valid according to

$$a_{ik}/y_i = N_k/N \quad \text{for } k = 1, 2 \text{ so that } a_{i1}/a_{i2} = N_1/N_2 .$$

The sum of the numbers a_{ik} for $i \in U$ equals the degree sum in U_k, i. e.

$$\sum_{i \in U} a_{ik} = \sum_{j \in U} x_{jk} y_j = D_k .$$

The standard Horvitz–Thompson estimator of D_k is

$$D'_k = \sum_{i \in S} (a_{ik}/\pi_i) ,$$

for $k = 1, 2$. Similarly Horvitz–Thompson estimators of N and N_2 are given by

$$N' = \sum_{i \in S} (1/\pi_i) \quad \text{and} \quad N'_2 = \sum_{i \in S} (x_{i2}/\pi_i) .$$

From the proportionality assumption we get that the average degrees are equal in U, U_1, and U_2:

$$D/N = \sum_{i \in U} y_i/N = D_k/N_k ,$$

for $k = 1, 2$. Hence, N_1 can be estimated by

$$N'_1 = D'_1 N'_2 / D'_2 .$$

By summing $a_{i1}/a_{i2} = N_1/N_2$ over i in U_2 and over i in U we get

$$\sum_{i \in U} (a_{i1}x_{i2}/a_{i2}) = N_1 \quad \text{and} \quad \sum_{i \in U} (a_{i1}/a_{i2}) = NN_1/N_2\,,$$

which leads to two alternative estimators of N_1, namely

$$N_1'' = \sum_{i \in S} (a_{i1}x_{i2}/a_{i2}\pi_i)$$

$$\text{and} \quad N_1''' = (N_2'/N') \sum_{i \in S} (a_{i1}/a_{i2}\pi_i)\,.$$

Here the sums are understood to be over sample units $i \in S$ with acquaintances in U_2. Should $a_{i2} = 0$ we expect $y_i = 0$ and $a_{i1} = 0$. If the three estimators N_1', N_1'', and N_1''' turn out to give very different estimates, the assumptions underlying the calculations are doubtful and another approach is needed.

This example illustrates that properties of hidden groups that are hard to access can still be estimated if the hidden group is embedded in a convenient network. While snowball sampling and random walk sampling use the network to successively extend an initial sample, the hidden group example uses randomization assumptions about stable expected average network degrees as a possible bridge between different subgroup sizes. If the network assumptions needed for the randomization procedure are not valid, then a natural alternative approach would be to combine the probability design of the sampling with a probability model of the network.

An entirely different kind of hidden population are animal populations. In wildlife surveys the technique of catch-recapture sampling is an attempt to handle the lack of population frames. Bird counting, for instance, relies on marking the birds caught in a first sample by identifying rings before they are released again. After some time a new sample is taken, and the number of marked birds in the first sample is divided by the proportion of marked birds in the second sample to get an estimator of the size of the bird population. This idea can be elaborated on by specifying more carefully various assumptions about how the population changes with time and how the risk of being caught depends on different environmental factors that can be controlled for. Catch-recapture techniques have also been discussed as a tool in criminology surveys to estimate the number of offenders of specific types of crimes in different regions and in different periods of time. Such surveys cannot be carried out without a thorough model specification as a complement to the sampling design. In Sect. "Bipartite Network Sampling Designs" an illustration is given of utilizing network models and network sampling methods in a criminological setting.

Area sampling is another technique that can be used for counting animal populations and other populations distributed over geographical areas. A population region is partitioned into a number of area sites. Neighboring sites can be considered as adjacent vertices in a graph. The size of the area population is a vertex variable, and the total population size is a vertex variable total that can be estimated by a snowball sample of area sites with counts of their area populations.

Probabilistic Network Models

Survey sampling in finite populations distinguishes between design-based and model-based inference. Design-based inference uses probabilistic sampling designs but considers population data as fixed, while model-based inference also makes probabilistic assumptions about population data. Essential properties of population data might be summarized in a few parameters in an appropriate model and thereby allow a convenient and simplified description of the population. The graph employed in a network sampling design can be exposed to various unknown influences and uncontrolled effects that make it natural to try to capture its essential features in a random graph model. Random graph models can also be used to describe the outcome when a graph is sampled from a population of graphs, or when an observed graph is generated by some complex process, for instance, being an instant realization of a network changing with time. Random graphs useful for statistical data analysis need to be sufficiently rich in parameters so that meaningful fits can be made. However, too many degrees of freedom in the model make it vulnerable to accidental fits with no explanatory power.

A simple Bernoulli graph on $U = \{1, \ldots, N\}$ with a symmetric adjacency matrix $y = (y_{ij})$ has $N(N-1)/2$ independent edge indicators y_{ij} that are Bernoulli(p)-distributed for $1 \leq i < j \leq N$. The only parameter p represents edge density. A block model variant of the Bernoulli graph has a K-category vertex variable x and assumes y_{ij} to be independent and Bernoulli distributed with a parameter $p(x_i, x_j) = p(x_j, x_i)$ for $1 \leq i < j \leq N$. Now there are $(K+1)K/2$ parameters representing edge densities within and between different blocks of vertices. Depending on whether block affiliation is known, can be observed, or is not observable, the possibilities to estimate the parameters are very different. Statistical inference for stochastic block models is considered in many papers. An extensive account with many references can be found in [67].

For a directed graph on U with adjacency matrix y there are $N(N-1)/2$ dyads (y_{ij}, y_{ji}) for $1 \leq i < j \leq N$. The simple model with IID dyads has four parameters

$p_{00}, p_{01}, p_{10}, p_{11}$ that are probabilities $p_{kl} = P(y_{ij} = k, y_{ji} = l)$, and the probabilities sum to 1 leaving 3 degrees of freedom. More generally, with independent dyads and probabilities $P_{ijkl} = P(y_{ij} = k, y_{ji} = l)$, there are $2N(N-1)$ parameters subject to $N(N-1)/2$ restrictions $\sum_k \sum_l P_{ijkl} = 1$, which leaves $3N(N-1)/2$ degrees of freedom. Assuming a block structure with a K-category vertex variable x and $P_{ijkl} = p_{kl}(x_i, x_j) = p_{lk}(x_j, x_i)$ there are 2 degrees of freedom within each category of size larger than one and 3 degrees of freedom between any pair of distinct categories, in total $2K + 3K(K-1)/2 = K(3K+1)/2$ degrees of freedom. In particular, $x_i = i$ for $i = 1, \ldots, N$ implies that each category consists of only one vertex, and there are 3 degrees of freedom for each pair of vertices, i. e. $3N(N-1)/2$ degrees of freedom in total in accordance with the previous result. Thus, a categorization of 20 vertices based on two binary vertex variables reduces the degrees of freedom from 570 to 26, and a simple dichotomy reduces the degrees of freedom to 7, so block models represent a substantial simplification of dyad independence models. A practical approach might be to start with a rather large number of tentative vertex variables and apply cluster analysis to their dyad distributions in order to find how many of these distributions need to be distinguished. This technique is applied in [31,32].

The block model approach can be considered even if the category affiliation is uncertain and described by independent vertex variables x_i with a probability distribution $P(x_i = k) = p_k$ for $k = 1, \ldots, K$. Let N_k be the number of vertices in category k and N_{kl} the number of pairs of vertices in categories k and l, i. e. $N_{kl} = N_k N_l$ for $k \neq l$ and $N_{kk} = N_k(N_k - 1)/2$. The log-likelihood function when vertex variables and graph adjacencies are observed is given by

$$\log L = \sum_{k=1,\ldots,K} N_k \log p_k + \sum\sum_{1\leq k\leq l\leq K} \sum_{m=0,1} \sum_{n=0,1} N_{klmn} \log p_{mn}(k,l)\,,$$

where

$$N_{klmn} = \sum\sum_{1\leq i<j\leq N} I(x_i = k, x_j = l, y_{ij} = m, y_{ji} = n)\,.$$

This model has $K-1$ degrees of freedom in addition to the previous $K(3K+1)/2$, so in total $3(K+1)K/2 - 1$ degrees of freedom. This model is treated for instance in [45,58,69].

Consider now the model with independent dyads and probabilities $P_{ijkl} = P(y_{ij} = k, y_{ji} = l)$. A convenient way to re-parametrize this model is to introduce odds and an odds ratio. Let a_{ij} be the odds of y_{ij} when $y_{ji} = 0$, and let b_{ij} be the odds of y_{ij} when $y_{ji} = 1$:

$$a_{ij} = P_{ij10}/P_{ij00}, b_{ij} = P_{ij11}/P_{ij01}\,.$$

The ratio between these odds is

$$c_{ij} = b_{ij}/a_{ij} = P_{ij11}P_{ij00}/P_{ij01}P_{ij10}\,.$$

The corresponding odds of y_{ji} are

$$a_{ji} = P_{ji10}/P_{ji00} = P_{ij01}/P_{ij00}\,,$$
$$b_{ji} = P_{ji11}/P_{ji01} = P_{ij11}/P_{ij10}\,,$$

and the odds ratio is the same

$$c_{ji} = b_{ji}/a_{ji} = c_{ij}\,.$$

The three parameters a_{ij}, a_{ji}, c_{ij} are arbitrary non-negative numbers, and together with the normalizing constant

$$P_{ij00} = 1/(1 + a_{ij} + a_{ji} + a_{ij}a_{ji}c_{ij})\,,$$

we retain the other probabilities as

$$P_{ij10} = a_{ij}P_{ij00}\,, \quad P_{ij01} = a_{ji}P_{ij00}\,,$$
$$P_{ij11} = a_{ij}a_{ji}c_{ij}P_{ij00}\,.$$

Finally we put

$$\lambda_{ij} = -\log P_{ij00}\,, \quad \alpha_{ij} = -\log a_{ij}\,, \quad \gamma_{ij} = -\log c_{ij}\,,$$

where $\lambda_{ij} = \lambda_{ji} > 0$ and $\gamma_{ij} = \gamma_{ji}$. Using the three parameters $\alpha_{ij}, \alpha_{ji}, \gamma_{ij}$ and the normalizing constant λ_{ij} determined by them, it is possible to express the likelihood function L according to

$$-\log L = \sum\sum_{1\leqslant i<j\leq N} (\lambda_{ij} + \alpha_{ij}y_{ij} + \alpha_{ji}y_{ji} + \gamma_{ij}y_{ij}y_{ji})\,.$$

There are $3N(N-1)/2$ degrees of freedom represented by $\alpha_{ij}, \alpha_{ji}, \gamma_{ij}$ for $1 \leq i < j \leq N$. By introducing an out-degree effect α_i, an in-degree effect β_i, and a mutuality effect γ_i for each vertex, we assume that

$$\alpha_{ij} = \alpha_i + \beta_j\,, \gamma_{ij} = \gamma_i + \gamma_j\,.$$

Since $\alpha_{ij} = \alpha + \beta + \alpha_i - \alpha + \beta_j - \beta$ for arbitrary α and β, α_i and β_j are identifiable only up to a translation

$\alpha = -\beta$. If we introduce an arc density effect δ and put $\alpha_{ij} = \delta + \alpha_i + \beta_j$ we can impose the restrictions $\sum \alpha_i = 0$ and $\sum \beta_j = 0$. In this way we have reduced the degrees of freedom from $3N(N-1)/2$ to $3N - 1$, and the likelihood L is a log-linear function of the parameters given by

$$-\log L = \sum_{1 \le i < j \le N}\sum \lambda_{ij} + \delta \sum_{i \ne j}\sum y_{ij} + \sum_i \alpha_i \sum_j y_{ij} + \sum_j \beta_j \sum_i y_{ij} + \sum_i \gamma_i \sum_j y_{ij} y_{ji} ,$$

with out-degree, in-degree, and number of mutual arcs at each vertex as the sufficient statistics. A further reduction is obtained by assuming all mutuality effects equal, $\gamma_i = \gamma$, which leads to a model with $2N$ degrees of freedom. This is the original Holland–Leinhardt model for directed graphs introduced and investigated in [36]. Various extensions to valued graphs and block models are possible, and algorithms for model fitting and parameter estimation are described and illustrated in the reference book [67] and in several references given there.

Random graph models with probability distributions of exponential type have been suggested with more elaborate network statistics. Some examples of investigations of such models are [47,52,57,68].

Instead of specifying which statistics are likely to be essential for the application considered and use an exponential type model with these statistics as sufficient statistics, Frank and Strauss in [30] derived the sufficient statistics from basic assumptions about the dependence structure in the adjacency matrix. They specified a Markov dependence structure for the adjacency matrix y and proved that it implied a log-linear likelihood with certain sufficient statistics. The Markov assumption is that y_{ij} and y_{kl} are independent whenever i, j, k, l are all distinct, but dependence is possible between any arc indicators with some common vertex. The sufficient statistics are then given by star and triangle statistics. Adding a homogeneity assumption saying that isomorphic structures have the same probability, the sufficient statistics are given by star counts and triangle counts. Here stars and triangles should be understood in a broad sense so that they can consist of dyads of any type. The fundamental tool for this result in [30] is a theorem of Besag given in [2] together with a dependence graph specifying the dependencies among arc indicators in y. This dependence graph is in fact the so-called line-graph of the graph given by y. The maximal cliques of the dependence graph are the minimal sufficient statistics of y. Further exploration of these ideas can be found in the thesis [50] and the article [51].

Bipartite Network Sampling Designs

A bipartite network consists of vertices of two kinds and vertex and edge variables defined on them. If U is a set of N vertices of the first kind, and V is a set of M vertices of the second kind, different vertex variables could be defined on U and V. Edge variables are defined between U and V. As a simple example, take U as a set of households, V as a set of individuals, and define a binary edge variable y_{ij} that indicates whether individual j belongs to household i for $i \in U$ and $j \in V$. Each individual belongs to exactly one household. Assume that U is a target population, and that we are interested in some variable x defined on U. Only a sample S from V can be obtained. For each individual sampled, the value of x is reported that belongs to the individual's household. Thus

$$\sum_{i \in U} x_i y_{ij} ,$$

is reported by $j \in S$. If the sampling design has inclusion probabilities

$$\pi_j = P(j \in S) ,$$

the household total $T = \sum_{i \in U} x_i$ has a design unbiased estimator

$$T' = \sum_{j \in S}\sum_{i \in U} x_i y_{ij}/\pi_j = \sum_{i \in U} x_i \sum_{j \in S} y_{ij}/\pi_j .$$

If more than one individual from the same household are sampled, the estimator contains this household value x with multiplicity. If household identities are checked and no repeated household values should be used, another design unbiased estimator is available as

$$T'' = \sum_{i \in B(S)} x_i/P(i \in B(S)) ,$$

where $B(S)$ is the set of distinct households reported by individuals in S. The probability $P(i \in B(S))$ is equal to $P(S \cap A_i \neq \emptyset)$, where A_i is the set of individuals belonging to household i. This is the probability that none of those individuals are included in the sample S. If we introduce multiplicities m_i for the number of individuals in S belonging to household i, there is an alternative design unbiased estimator

$$T''' = \sum_{i \in U} x_i m_i/\mathrm{E}m_i ,$$

that requires the expected value of the multiplicity. Comparisons between these estimators and further results on bipartite network sampling can be found in Sirken's pioneering paper on multiplicity sampling [56].

The possibility to use bipartite networks in survey sampling is not confined to cases with sampling units that are different from the units in the target population. As an illustration of a more complex combination of sampling from both U and V, we consider in the next section a model approach to a simultaneous estimation of crime rates and offender activity that relies on a bipartite network model.

A Bipartite Network Model for Crime Participation

Consider crimes of a particular kind in a specified geographical region during a specified period of time, say assaults in Canada during year 2000. Let M denote the unknown total number of incidents and m the number known to the police. Thus, $M - m$ is an unknown so-called "dark figure" of incidents, and m is the number of identified incidents. The identified incidents involve r incidents reported to the police and $m - r$ incidents identified by other means. Let m_i be the number of identified incidents having i identified offenders, and let r_i be the number of reported incidents having i identified offenders for $i = 0, 1, \ldots$ Incidents with at least one identified offender are said to be cleared by the police. There are unidentified offenders for all the unidentified incidents, and there are unidentified co-offenders for the identified incidents. The unknown numbers of incidents M_{ij} with i actual offenders and j identified offenders for $j = 0, 1, \ldots, i$ and $i = 1, 2, \ldots$ involve many dark numbers in addition to $M - m$. The unknown numbers of incidents

$$M_i = \sum_{j=0,\ldots,i} M_{ij} \,,$$

with i actual offenders for $i = 1, 2, \ldots$ provide a partition of M that specifies the distribution of incidents according to size, i. e. their number of co-offenders.

The same offender can be involved in several offences. Let N denote the unknown total number of distinct individuals participating in the M offences. The known number n of distinct offenders identified in the cleared incidents imply that there is a dark number of $N - n$ non-identified offenders. The number of incidents in which an offender participates is called the activity of the offender. We need to distinguish between identified activity and actual activity. Let N_{ij} be the number of offenders with activity i and identified activity j for $j = 0, 1, \ldots, i$ and $i = 1, 2, \ldots$. The partition of N into the numbers

$$N_i = \sum_{j=0,\ldots,i} N_{ij} \,,$$

of offenders of activity i for $i = 1, 2, \ldots$ specifies the distribution of offenders according to activity. This distribution involves further dark numbers that cause its discrepancy from the known numbers n_j of identified offenders participating in j identified offences for $j = 1, 2, \ldots$

In order to estimate the distribution of incidents according to size and the distribution of offenders according to activity, a bipartite network model can be defined with the set U of M incidents as vertices of the first kind and the set V of N offenders as vertices of the second kind. Criminal participation can be specified by an edge from $i \in U$ to $j \in V$ if incident i involves offender j. Let A_i be the subset of V specifying the co-offenders of incident i, and let B_j be the subset of U specifying the re-offences of offender j.

Now we can consider the set of identified incidents as a sample S from U, and the set of identified co-offenders of identified incident $i \in S$ as a sample S_i from A_i. These samples have sampling designs depending on factors governing how incidents are reported to the police or identified by other means and how the co-offenders are identified. In a situation like this when sampling is not determined by the investigator it is natural to incorporate the sampling design in a probabilistic network model.

An approach taken in [28] specifies the incidents in U as generated by a homogeneous Poisson process with parameter λ representing the expected number of incidents per time unit. The sample S of identified incidents is a Bernoulli sample with inclusion probability α, which means that identified incidents occur according to a homogeneous Poisson process with parameter $\alpha\lambda$. The parameter α measures the proportion of identified incidents. At least for crimes with a victim, α can be estimated by comparing incidence reporting frequencies and incidence identifications by other means with incidence frequencies estimated from victimization studies.

The set V of offenders is assumed to consist of a fixed number N of individuals that have a positive probability of offending. Independently for each incident $i \in U$, a set A_i of co-offenders in that incident is selected from V according to some common probability sampling design with inclusion probabilities $\pi_j > 0$ for $j \in V$. The sampling design might involve unknown parameters reflecting what is known about structure and behavior in the population V. For each identified incident $i \in S$, a set S_i of identified co-offenders is modeled as an independent Bernoulli sample of A_i with parameter β governing the chance that the police can identify an offender. An optimistic and a pessimistic view of this chance distinguishes between whether or not the identification of one co-offender in an incident should imply the identification of all co-offenders in that incident.

With this model, it turns out to be possible to estimate simultaneously both the distribution of incidents according to size and the distribution of offenders according to activity. The basic results are the following. From the distribution of identified size among identified incidents, it is possible to estimate the parameter β and the distribution of true size among all incidents. Furthermore, if θ is the average identified activity among identified offenders and $\gamma = n/N$ is the unknown proportion of identified offenders, then identified activity has a Poisson$(\gamma\theta)$ distribution that is truncated at zero, and true activity has a Poisson$(\gamma\theta/\alpha\beta)$ distribution. This implies that

$$\gamma = 1 - \exp(-\theta\gamma) ,$$

from which γ can be solved, and N estimated by n/γ.

An interesting feature of this bipartite network model is that it makes explicit assumptions about both incident size and offender activity, and these assumptions lead to estimators of all the dark numbers related to unidentified incidents, unidentified offenders, and unidentified co-offenders in identified incidents. In particular, the estimator of the hidden population size N of offenders provides a special insight into how this estimator can be modified if not all parts of the distribution of identified activity are reliable. This also makes interesting connections with the literature that derives or suggests such modifications by using other approaches.

Future Directions

It is likely that the development of more sophisticated network models for specific applications will appear as improvements of Markov models and other network models belonging to the exponential family. Such development is also expected to contribute to more efficient algorithms for computer intensive estimation and goodness-of-fit testing of network models.

The developments of design-based inference methods that are appropriate for sampling of sub-networks from a finite population network are especially challenging for few-waves snowball sampling and for network walk sampling. The iterative estimation methods discussed in Sects. "Estimation Based on Snowball Samples" and "Estimation Based on Network Walk Samples" are examples of problems that deserve to be investigated further. More important is perhaps the need to develop efficient algorithms for Rao-Blackwellization of various initially obtained estimators and to gain more information about minimal sufficient statistics in various snowball sampling designs.

Article Outline

Glossary

Adjacent Two vertices are adjacent if they are connected by a line.

Arc An arc is a directed line. Formally, an arc is an ordered pair of vertices.

Attribute An attribute is a characteristic of a vertex measured independently of the network.

Bipartite network See: Two-mode network.

Clique A clique is a maximal complete subnetwork containing three vertices or more.

Complete A (sub)network is complete if it has maximum density: All possible lines occur.

Component A (weak) component is a maximal (weakly) connected subnetwork.

Degree The degree of a vertex is the number of lines incident with it.

Density Density of a simple network is the number of lines, expressed as a proportion of the maximum possible number of lines.

Digraph A digraph or directed graph is a graph containing one or more arcs.

Distance The distance from vertex u to vertex v is the length of the geodesic from u to v.

Edge An edge is an undirected line. Formally, an edge is an unordered pair of vertices.

Ego-network The ego-network of a vertex contains this vertex, its neighbors and all lines among the selected vertices.

Geodesic A geodesic is the shortest path between two vertices.

Graph A graph is a set of vertices and a set of lines between pairs of vertices.

Incident A line is defined by its two endpoints, which are the two vertices that are incident with the line.

Indegree The indegree of a vertex is the number of arcs it receives.

Line A line is a tie between two vertices in a network: Either an arc or an edge.

Loop A loop is a line that connects a vertex to itself.

Neighbor A vertex that is adjacent to another vertex is its neighbor.

Network A network consists of a graph and additional information on the vertices or the lines of the graph.

One-mode network In a one-mode network, each vertex can be related to each other vertex.

Outdegree The outdegree of a vertex is the number of arcs it sends.

Path A path is a semipath with the additional condition that none of its lines is an arc of which the end vertex is the arc's tail.

Reachable We say that a vertex is reachable from another vertex if there is a path from the latter to the former.

Semicycle A semicycle is a closed semipath ending at the vertex at which it starts.

Semipath A path is a closed sequence of lines such that the end vertex of one line is the starting vertex of the next line and no vertex in between the first and last vertex of the sequence occurs more than once.

Signed graph A signed graph is a graph in which each line carries either a positive or a negative sign.

Simple graph A simple undirected graph contains neither multiple edges nor loops. A simple directed graph does not contain multiple arcs.

Star-network A star-network is a network in which one vertex is connected to all other vertices but these vertices are not connected among themselves.

Strong component A strong component is a maximal subnetwork in which each pair of vertices is connected by a path.

Strongly connected A (sub)network is strongly connected if each pair of vertices is connected by a path.

Structural property A structural property is a characteristic (value) of a vertex that is a result of network analysis.

Triad A triad is a (sub)network consisting of three vertices.

Two-mode network In a two-mode network, vertices are divided into two sets and vertices can only be related to vertices in the other set.

Undirected graph An undirected graph does not contain arcs: All of its lines are edges.

Vertex (vertices) A vertex (singular of vertices) is the smallest unit in a network.

Weakly connected A (sub)network is weakly connected if each pair of vertices is connected by a semipath.

Definition of the Subject

Social network analysis (SNA) focuses on the structure of ties within a set of social entities or actors, e. g., persons, groups, organizations, and nations, or the products of human activity or cognition such as semantic concepts, web sites, and so on. In a graph theoretical approach, a social network is conceptualized as a graph, that is, a set of vertices (or nodes, units, points) representing social actors and a set of lines representing one or more social relations among them.

A network, however, is more than a graph because it contains additional information on the vertices and lines. Characteristics of the social actors, for instance a person's sex, age, or income, are represented by discrete or continuous attributes of the vertices in the network, and the intensity, frequency, valence, or type of social relation are represented by line weight or value, line sign, or line type. Formally (see pp. 94–95, 127–128 in [1]), a network **N** can be defined as $\mathbf{N} = (U, L, F_U, F_L)$ containing a graph $\mathbf{G} = (U, L)$, which is an ordered pair of a unit or vertex set U and a line set L, extended with a function F_U specifying a property of the units ($f\colon U \to X$) and a function F_L specifying a property of the lines ($f\colon L \to Y$). The set of lines L may be regarded as the union of a set of undirected edges E and a set of directed arcs $A (L = E \cup A)$. Each element e of E is an unordered pair of units u and v (vertices) from U, that is, $e(u\colon v)$, and each element a of A is an ordered pair of units u and v (vertices) from U, that is, $a(u\colon v)$.

The application of graph theory to social relations can be traced back to at least the 1940s (see pp. 69–72 in [2]) when the mathematician R. Duncan Luce and the engineer Albert Perry teamed up with the social psychologist Leon Festinger [3] and when the mathematician Frank Harary started his collaboration with Leon Festinger and afterwards with Dorwin Cartwright [4]. They extended pioneering work in SNA that had been done notably in sociometry [5,6] and anthropology [7,8,9]. In the 1960s, advances in graph theoretical approaches to SNA such as the contributions by Øystein Ore [10], Claude Flament [11], Frank Harary [12], and innovative applications such as Everett M. Rogers' work on the diffusion of innovations [13], prepared the ground for the rise of SNA in both the USA [14] and Europe [15] as a new set of methods or a new methodology [16] in the 1970s.

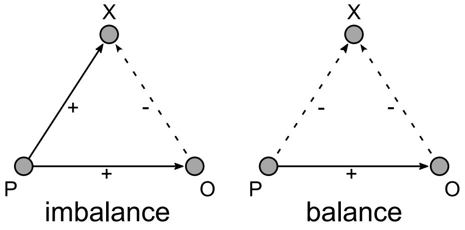
Introduction

The conceptualization of social systems as graphs and networks offered the opportunity for systematic investigation and theorizing of the structure of ties among social actors beyond the pair. Whereas classical sociology tended to make a quantum leap from the individual and the pair to the triple, group, or society [17], graph theory offered the tools to formally describe and visualize social structure consisting of three and more actors. This led to a new awareness of social structure as a system of ties that is both the product of human action and the context and condition for human action. Because this point of view is very relevant to the issue of complexity in social networks, it is briefly presented in the next paragraph.

The prevalent action theory in SNA conceptualizes collective behavior as the socially 'orchestrated' behavior of individuals or other actors. Actors adjust their behavior and attitudes, opinions, and beliefs to the behavior (etc.) of other members of the social system in which they participate. The system itself is not supposed to behave but it constrains actor behavior: It is the social context within which actors operate. As a network of ties, the system defines to whom an actor is exposed. The immediate contacts – the neighbors in graph theory – of an actor are usually most important to its behavior, but indirect contacts such as the neighbors' neighbors may be taken into account as well. In other words, an actor's local context or ego-network is likely to affect its behavior. At the same time, however, by ending ties or creating new ones, the individual changes both local network structure and overall network structure, that is, the system. Thus, individual action changes the local context for its neighbors' (neighbors' etc.) action. Complexity arises in the interplay between individual behavior and the system both as the overall structure of the network of social ties and as the local context for each actor within the system. To the actors, the change of network structure is not necessarily predictable, so the interplay between individual action and network structure may offer surprising results.

Let us turn to an example now, which is one of the earliest applications of graph theory to social networks. This example nicely illustrates both the transition from a focus on the tie within a single pair to the study of group structure in the social sciences and the interplay between local action and overall network structure. In 1946, the psychologist Fritz Heider formulated the theory of psychological balance [18], which stated among other things that a person (P) feels uncomfortable when he or she disagrees with his or her friend (O) on a particular topic (X). Person P is hypothesized to be stressed and to try to change this situation either by adapting its opinion on topic X, so it matches O's opinion, or by changing its opinion on O, regarding him or her no longer as a friend. Figure 1 represents both a situation of imbalance and a situation of balance as a signed digraph. The circles and arrows represent the vertices and arcs of the graph and the valence of the opinions or affections are shown both by the labels and the style of the arrows: Solid arcs show positive opinions or sentiments, dotted arcs show negative opinions or sentiments.

In 1956, the mathematician Frank Harary and the psychologist Dorwin Cartwright realized that psychological



Social Network Analysis, Graph Theoretical Approaches to, Figure 1
The principle of imbalance and balance conceptualized as signed digraphs

balance in this triad (three vertices and the lines among them) may be conceptualized as a specific pattern of arcs in a signed graph, viz., in a balanced triad, the $P - O - X$ semicycle (a closed semipath) always contains zero or an even number of negative arcs, whereas an imbalanced triad is characterized by a semicycle with an uneven number of negative arcs [4]. As a next step, replacing the topic by a third person and perceptions of liking or disliking (by the focal person P) by expressed liking or disliking as ties, they easily generalized this idea to a network of arbitrary size. They proved that a signed network is balanced if and only if all semicycles contain no or an even number of negative arcs.

In addition, they proved that a balanced network either contains one set of vertices with just positive arcs among them, or two sets of vertices with all positive arcs within the sets and all negative arcs between the sets, which is a polarized network. In 1967, this result was generalized to polarization among three or more groups by James A. Davis, who showed that a network can be partitioned into an arbitrary number of subsets of vertices such that all positive ties are within the subsets and all negative arcs are among the subsets if the network does not contain semicycles with exactly one negative line [19]. Figure 2 shows an example from Samuel F. Sampson's [20] study of a network of sentiments among novices in a monastery. It depicts the situation at the fourth measurement wave, which was highly polarized at that time. Vertex color indicates whether the novice had previously attended one particular seminary (black: Yes, white: No).

In this case, a mathematical relation was established between a behavioral hypothesis at the level of the individual, viz., adjusting ones affect relations such that ones situation is balanced, and overall network structure, viz., polarization. Individual behavior proved to have an unexpected outcome at the level of overall network structure and graph theoretical concepts, in this case semicycles, provided the link. In many cases, however, the link between individual behavior and overall network structure has not been established formally and is sometimes even hard to predict intuitively.

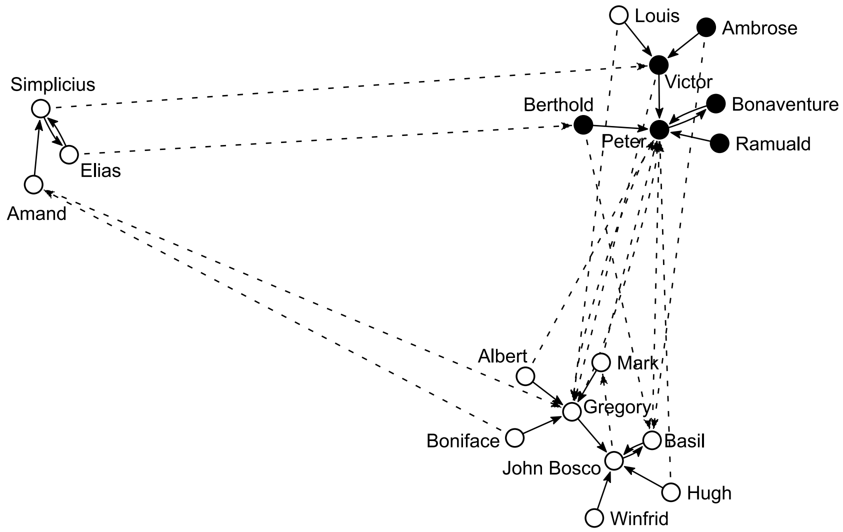
This entry of the encyclopedia aims to present an overview of graph theoretical approaches to SNA, highlighting the complex relations between individual action and overall network structure. It intends to explain why current developments focus on local structure rather than overall network structure to unravel the complexity of social networks. For each of the main topics in SNA (cohesion, brokerage, and prestige), behavioral hypotheses are presented stating why actors create, maintain or dissolve ties. The typical local structure of ties produced by this behavior is sketched in combination with graph theoretical indices for measuring it, and finally the expected consequences to the overall structure of the social network are discussed in combination with the graph theoretical measures developed for measuring them. Note that this approach more or less reverses the historical development of SNA, which focused on overall network structure first and gradually became more interested in the behavior of actors that created, maintained, or changed network structure.

Cohesion

One of the first intuitions in SNA concerns the tendency of human beings to form cohesive subgroups. This is a classical topic in the social sciences, see, for instance, George C. Homans' book *The Human Group* [21], and it was central to the sociometry tradition [22]. But where do cohesive subgroups come from and what do they do?

The first and most general behavioral hypothesis merely states that similar people tend to interact more easily and people who interact tend to become or perceive themselves as more similar provided that the interaction is characterized as positive, friendly, and so on. In SNA, this tendency is mainly known as homophily, a concept coined by Paul F. Lazarsfeld and Robert K. Merton [23,24], but it is known under other names in several scientific disciplines, e. g., the phenomenon of attribution [25] and affect control [26,27] in social-psychology, assortative or selective mixing in epidemiology and ecology ([28], p. 2 in [29]), and assortative mating in genetics with efforts at statistical modeling at least as early as 1985 [30].

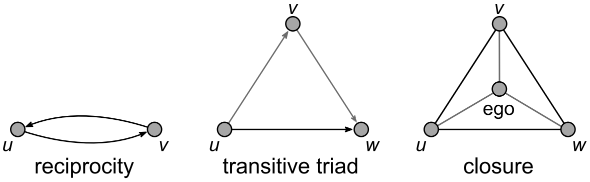
It is important to note that there are two sides to this behavioral hypothesis, a selection effect, that is, the impact of similarities on the ties that are created, sustained, or broken [31], and an influence effect [32], which hypothesizes that perceived or actual similarities such as the socially constructed identities or opinions [33] result from



Social Network Analysis, Graph Theoretical Approaches to, Figure 2
Almost perfect polarization in the network of sentiments among novices

the ties among actors. According to these hypotheses, people who are directly linked are or become more similar because of their interaction, so they become more likely to engage in ties and maintain ties among them. Thus, social groups form and persist as tightly linked sets of people that tend to share social and psychological characteristics, producing solidarity.

If we concentrate on the graph theoretical aspects of this behavioral hypothesis, that is, the structure of ties, and ignore the (dis)similarities among the actors for the moment, we find several characteristics of local structures that measure cohesive subgroup formation. At the level of a pair of actors, reciprocity of ties in directed networks signals subgroup formation: Both actors are hypothesized to choose each other when they are similar. At the level of the triple, transitivity results from tendencies toward cohesion. If actor u establishes a tie with actor v because they are similar, and actor v establishes a tie to actor w for the same reason, actors u and w are also similar, so actor u is expected to establish a tie with w as well, creating a so-called transitive triad (Fig. 3). Stated differently, the path from u via v to w is closed by an arc from u to w. In general, the closure of paths or semipaths both in directed and undirected networks signals cohesive subgroup formation at the local level. Closure within an ego-network may be calculated as the percentage of all possible ties among a vertex' neighbors that are present, which is one of the definitions of the clustering coefficient (see pp. 32–33 in [34]) but the concept of closure can be extended beyond a vertex' immediate neighbors, e. g., the number of semicycles of length 4 or larger in which a vertex is involved, e. g., balanced semicycles in signed networks.



Social Network Analysis, Graph Theoretical Approaches to, Figure 3
Reciprocity, transitivity, and closure in a directed ego-network

If we include vertex attributes in our measures of cohesive subgroup formation, we can calculate homophily quite simply as the probability or ratio of ties between vertices that share a particular characteristic to ties between vertices that do not. Extending this idea to the ego-network, the homogeneity of actors involved in an ego-network may be taken as a measure of tendencies toward homophily. For qualitative attributes of the actors, Blau's index of variability or heterogeneity [35] can be used ($1 - \sum p_i^2$) where p is the proportion of group members in a particular category and i is the number of different categories), which is conceptually related to the Herfindahl–Hirschman Index in economics measuring the extent of monopoly within an industry. It is interesting to note that Blau's theory hypothesizes that heterogeneity rather than homogeneity of actors within a group enhances the operation and efficiency of the group. If improving group efficiency is the aim of actors, we would have to use a behavioral hypothesis that is quite the opposite of the homophily hypothesis.

Tendencies toward cohesive subgroup formation at the level of actor behavior are most likely to produce sets of densely connected vertices in the overall network and, if we add attributes of the actors, the vertices within sets tend to have similar characteristics. In the most extreme case, the sets are disconnected, so the network consists of several weak components, that is, maximal weakly connected subnetworks, or they are connected only by ties with a negative social meaning, as in the example of polarization presented in the Introduction.

In the history of SNA, the concept of relatively densely connected subnetworks has yielded a large number of graph theoretical ways for identifying cohesive subgroups at the level of overall network structure. Limiting the discussion to one-mode networks, that is networks in which there can be a tie between any pair of vertices (for two-mode or bipartite networks, ▶ Social Network Analysis, Two-Mode Concepts in), Wasserman and Faust (see pp. 251–252 in [36]) distinguish 4 approaches to defining cohesive subgroups.

In the first and strictest approach, a cohesive subgroup is defined as a set of vertices in which all vertices are adjacent, that is, directly linked, to one another. In other words, cohesive subgroups are maximal complete subgraphs, which are called cliques [3].

The second approach is based on the notion of reachability and closeness of members within a subgroup. Members of a subgroup must be reachable in the sense that there are paths between them, i. e., a sequence of lines such that the end vertex of one line is the starting vertex of the next line (following the direction of the lines if they are arcs) such that no vertex in between the first and last vertex occurs more than once. In addition, the shorter the geodesics (shortest paths) between them, the closer the vertices are in a graph theoretical sense, so the more cohesive the subgroup is supposed to be.

The criterion of reachability does not necessarily yield very dense subgroups. In sparse networks, any maximal connected subgraph (strong component) may represent a cohesive subgroup: There is a path between each pair of vertices within a component. Increasing the required number of independent paths between any pair of vertices within a cohesive subgroup yields slightly denser subgroups, e. g., requiring at least two independent paths produces bi-components, which may be generalized to k-components for higher minimum numbers of independent (vertex-disjoint) paths between all vertices within a subgroup [37].

Focusing on graph-theoretical distance between vertices usually yields denser subgroups. One may, for instance, set a maximum n to the distance between any two vertices within a subgroup, which is the concept of an n-clique [38,39]. Adding the restriction that the diameter of an n-clique is n or less, one obtains n-clans [38,40]. Alternatively, one may define a cohesive subgroup as a maximal subgraph of diameter n, which is called an n-club [40].

The third approach focuses on the minimum number, strength, or multiplicity of ties among subgroup members. Subgraphs that are maximal with respect to the minimum number of neighbors within the subgraph are called k-cores [41] and a maximal subgraph with respect to the maximum number of vertices in the subgraph that are not adjacent are known as k-plex [42]. In a similar vein, restrictions can be imposed on the minimum strength or multiplicity of ties among members of a cohesive subgroup, generalizing Seidman's concept of a k-core to a valued core, which is called an m-core (see pp. 115–116 in [43]) or m-slice (see pp. 109–110 in[44]): Maximal connected subgraphs considering only lines with minimum value (or multiplicity) m.

In the fourth approach, cohesive subgroups are based on the relative frequency of ties among subgroup members in comparison to non-members: Cohesive subgroups are relatively dense sections within the network, that is, relative to the sections outside (and between) subgroups. An *LS* set [45] is a maximal subgraph such that any of its subsets has more ties to its complement within the *LS* set than to vertices outside the *LS* set. Borgatti, Everett and Shirey [46] generalized this idea to the concept of the lambda set, which requires the number of edge-disjoint paths between any pair of vertices within the lambda set to be larger than between any vertex within and any vertex outside the lambda set. A probabilistic version of plus-clusters in signed networks, discussed in the Introduction, can also be subsumed under this approach as it requires relatively many positive lines within cohesive subgroups and relatively many negative lines among cohesive subgroups [47]. Finally, clustering techniques and some types of blockmodels (see pp. 741–742 in [14]) also detect clusters of vertices that have relatively many ties within clusters and few among clusters. These models offer an alternative way for finding cohesive subgroups (see pp. 133–246 in [1]), ▶ Positional Analysis and Blockmodeling.

The large number of alternative measures for cohesive subgroups attests to the fact that behavioral tendencies at the actor level do not play out into nicely structured overall networks in a standard way. Especially the density of the social relation under investigation has an impact on the extent and ways in which cohesive subgroups can be found in the overall structure of the network. As a consequence, measures of network cohesion such as the clustering coefficient (averaged over all vertices in the network) can be quite uninformative about overall network structure: Loosely knit cohesive subgroups which are clearly identified by some of the techniques presented above, yield low clustering coefficients in a sparse network. Cohesion in a network is better summarized by calculating the percentage of vertices that are part of identified subgroups, the number and sizes of cohesive subgroups, and so on [48].

In addition to homophily, there is a second behavioral hypothesis related to cohesion in SNA. This hypothesis is based on the idea that social action is embedded in networks [49,50,51]. Named after the sociologist Georg Simmel, Simmelian ties are ties that are embedded in other ties, e. g., business ties are embedded in family ties, or in complete triads and cliques. They are hypothesized to enforce group norms and enhance trust, hence pressure people into the same behavior because the two actors involved in a tie share common neighbors who supervise their behavior.

Just as with the homophily hypothesis, the embeddedness hypothesis predicts that tightly connected actors will be more similar in their behavior and attitudes. In addition, it predicts that embedded ties are more stable and new ties are more likely to be established when they are embedded in existing cliques or existing ties. Closure again is an important indicator of tendencies to establish and maintain embedded ties but so is the multiplicity of relations: The extent to which a tie on one social relation duplicates a tie on another social relation. At the level of overall network structure, we should expect relatively dense sections, especially cliques, and in a multirelational network, that is, a network containing ties on two or more social relations, we should find that the same subsets of vertices are clustered on each relation. Graph-theoretical measures of the latter are rare. The stochastic blockmodeling technique developed by Krysztof Nowicki and Tom A.B. Snijders [52] is an example. See ► Social Networks, Algebraic Models for.

If data on vertex attributes are available, especially if they concern public behavior, that is, behavior that is easily noticed by third parties such as publicly expressed opinions and statements, Simmelian ties are hypothesized to produce a special effect. Involvement in different groups (cliques) then exposes actors to possibly conflicting sets of norms and loyalties, which may urge them to cut their ties with some or all of these groups [53]. In this case, actors are hypothesized to withdraw from stressful relations, so they discontinue ties that incorporate them into cliques (with a preference for cutting a minimum number of ties) or they discontinue ties such that they are no longer connected to actors voicing different opinions or norms. At the macro level, this would produce disconnected sets of cliques instead of overlapping cliques.

Centrality and Brokerage

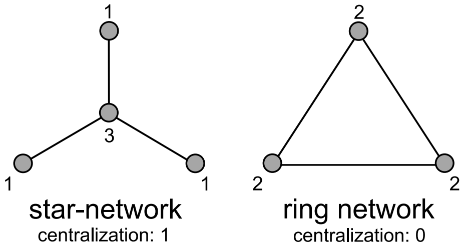
The notion of centrality in social networks has a long history in SNA. It is attributed to Alex Bavelas [54]. In discussions of centrality, network ties are usually regarded as channels for the exchange of information, goods, services, and so on. Being central in this exchange system has always been hypothesized to be related to influence and satisfaction. Centralization, as a characteristic of a network, has been linked to the efficiency of a network as an exchange system. More centralized groups, for example, have often been shown to be more efficient.

Linton C. Freeman [55] argued that the approaches to centrality are based on three ideas about what being central means: (1) being active within the network, that is, maintaining many ties, (2) being efficient or independent of go-betweens by having short distances to other vertices in the network, and (3) being an important go-between, that is, being part of many paths between other vertices in the network. Although alternative classifications and approaches exist, for instance, Noah E. Friedkin's alternative classification [56] and the formal graph theoretical approach to centrality by Stephen P. Borgatti and Martin G. Everett [57], Freeman's classification is used here, adding concepts of brokerage that have been developed elsewhere in SNA.

Activity

Being active or prominent in the network means that an actor has many ties, hence access to many sources of information (etc.). As a consequence, this actor is more attractive as a neighbor for other actors, which translates to the behavioral hypothesis that actors have a preference for ties with vertices that already have many ties. The degree of a vertex (the number of lines incident with a vertex), then, is the relevant graph theoretical measure of local structure, which is also known as degree centrality. Note that the concept of centrality expresses a structural property of a vertex.

Centralization is the corresponding structural property of a network and it is defined as the variation in the centrality scores of the vertices in the network because this variation shows the extent to which there is a center (very central vertices) and a periphery (vertices with very low centrality scores). The star and ring networks are defined



Social Network Analysis, Graph Theoretical Approaches to, Figure 4

Centrality and centralization in a star network and a ring network

as respectively the most and least centralized networks and they are known to exhibit the highest and lowest variation in centrality scores in simple networks, that is, networks without multiple lines (and loops in the case of a directed network). See Fig. 4 for an illustration, showing a star and a ring network labeling the vertices with their degree centrality scores.

From research on the power law in networks [58,59], discussed in another entry of this encyclopedia, it is known that preferential attachment to degree creates networks with a peculiar degree distribution, including many vertices with low or modest degree and few vertices with high degree. According to the definition of centralization in network analysis, this implies large variation in degree centrality scores, hence high degree centralization. In other words, the behavioral hypothesis of preference for high degree actors produces centralized overall network structure.

Note, however, that the way in which the 'power law networks' are assembled – growing from an initial seed without context – is hardly ever applicable to social networks, which usually have no discernable starting point (networks originate from networks) and are always constrained by the historical context. It remains to be seen whether power law distributions in empirical social networks are created by preferential attachment. Some results indicate that even though the degree distributions of cross-sectional snapshots of a large social network follow the power law, there is hardly any continuity in degree centrality of vertices over time, which does not suggest that the actors are driven by preferential attachment [60].

Efficiency and Weak Ties

The second approach to centrality focuses on graph theoretical distances between vertices. The central idea here is that actors try to improve access to information and efficient spreading of information by minimizing the number of go-betweens needed to reach or be reached by all other actors in the network. The behavioral hypothesis states that a vertex prefers to link to actors that give access to parts of the network that are presently remote to this vertex and that can only be reached through some or many go-betweens that may withhold or distort information. A minimum number of go-betweens yields maximum independence and maximum efficiency in the exchange network.

Graph theoretical measures of local structure focus on graph theoretical distance, that is, the minimum length of paths between vertices because path length equals the number of go-betweens in the network plus one. Linton Freeman's closeness centrality [55] is a straightforward implementation of this idea because it merely normalizes the average graph theoretical distance between a vertex and all other reachable vertices in the network. In addition, paths can be weighted by the centrality of the vertices on them, which is done by Phillip Bonacich's eigenvector centrality [61,62]. Finally, the difference between incoming paths and outgoing paths may be added, which is implemented in the version of closeness centrality developed by Thomas W. Valente and Robert K. Foreman [63].

Again, the normalized variation of closeness centrality scores of the vertices in the network yields the appropriate measure of centralization of overall network structure. It is not known yet, however, whether and how tendencies to reduce distances to other vertices at the level of individual actors in the network play out into the closeness centralization of the overall network. On the one hand, if the network contains some vertices with high closeness centrality, they offer rather short paths toward many vertices so they should attract a lot of new ties. This would enhance their centrality and possibly the variation in centrality scores although a general rise in closeness centrality scores of all vertices may also decrease the variation. On the other hand, if the network has low centralization, it is more likely that vertices connect directly to remote parts, reducing path lengths among remote parts, which would not raise the variation in closeness centrality scores and yield or sustain low closeness centralization of overall network structure.

The strength of weak ties argument proposed by Mark Granovetter [64,65] may be regarded as a special application of the notion of efficiency. In his research on finding a job, Granovetter noticed that relatively superficial ties, ties with infrequent contact, give access to new information because they are more likely to link you to someone with whom you are not linked directly or at a short distance. Strong or intense ties tend to be situated within cohesive subgroups, so they are more likely to offer redundant information already received through other ties. Granovetter is only interested in the effects of having weak ties, but if we turn his idea into a behavioral hypothesis, it suggests a preference to relate to distant vertices that are neither connected to yourself nor to your neighbors (or your neighbors' neighbors, and so on).

A tendency to connect to the most remote parts of the network means that actors tend to establish links to vertices at a large or maximum distance in the network. As in the case of maximizing closeness centrality, it is not clear whether this leads to identifiable patterns in overall network structure. It is quite obvious, however, that this tendency acts as a counterforce against tendencies toward cohesion as densely connected subnetworks: Actors are hypothesized to span gaps rather than to close local configurations. Different hypotheses must be developed for strong ties, which are hypothesized to contribute to subgroup formation, and weak ties linking remote parts. The weak ties will probably increase the number of links between dense parts of the network, increasing the *k*-connectivity (minimum number of node-independent paths between any two vertices) of the network. If so, we should expect high *k*-connectivity of the network if the weak ties hypothesis is true [37].

Control and Structural Holes

The third approach to centrality focuses on control over flows within the network: The more you are in between other vertices in the network, the more they depend on you to pass on information, the more you are able to control exchange within the network and profit from your control. Using this type of control is called brokerage.

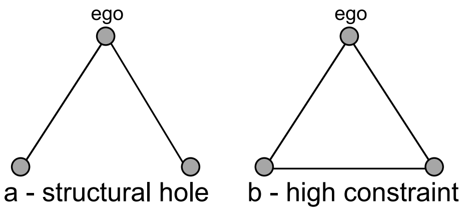
The notion of being in between other vertices has a straightforward translation to graph theory as being part of a path between two other vertices. Limiting paths to the shortest paths between vertices both Linton C. Freeman's [55] betweenness centrality and Jac M. Anthonisse's [66] rush of a vertex are based on the proportion of all geodesics between other vertices that include this vertex. This measure has been extended to handle directed ties [67,68]. Information centrality [69,70] takes into account all paths between vertices, not just the geodesics and flow betweenness [71] or entropy [72] also consider the values of lines. See Stephen P. Borgatti's [73] classification for more details.

Betweenness centralization as the normalized variation of betweenness centrality of the vertices in the network offers a measure of centralization at the network level and so do center-periphery blockmodels (see pp. 741–742 in [14]), e. g., in the world trade system, central countries are able to profit from the lack of trade among countries in the periphery [74,75,76,77]. The link between strategies for maximizing betweenness centrality by actors and the overall structure of the resulting network is unclear. It is not to be expected that control behavior will produce a highly centralized structure because no actor will be satisfied with low betweenness centrality and as a consequence high betweenness centrality for some vertices is unlikely. Therefore, the variation in betweenness centrality scores will not be high.

While betweenness centrality situates an actor with respect to all other actors in the network, Ronald S. Burt [78,79] proposed a local variant, focusing on control within the ego-network of an actor. His behavioral hypothesis rests on the *tertius gaudens* principle: The benefits that accrue to an actor that is in between two actors that are not directly linked because of the opportunity to broker information between them or, in a more malicious variant, to divide and conquer.

This hypothesis translates quite easily into graph theoretical structure. The absence of a tie between two neighbors of an actor is called a structural hole (Fig. 5a). The behavioral hypothesis states that actors try to increase the structural holes that they can exploit. At the same time, however, they try to minimize the structural holes through which they can be exploited. This means, among other things, that an actor will not end a tie to one of its neighbors if the two neighbors are directly linked (see Fig. 5b): That would create an opportunity to broker at the expense of the actor. In this situation, the actor is constrained in its opportunities to change ties.

Structural holes and constraint are the flip sides of the same coin. A tie with low constraint indicates that the tie is involved in (many) incomplete triads (such as Fig. 5a), so there are (many) structural holes offering the actor options for brokering. High constraint on a tie means that it is part of (many) complete triads (as in Fig. 5b), so there are few or no possibilities for brokerage. Because the presence or absence of ties among an actor's neighbors is key



Social Network Analysis, Graph Theoretical Approaches to, Figure 5
A structural hole (a) and a triad with high constraint (b)

to the argument, network analysts have also used the density of the ego-network without the ego as a proxy of constraint: The higher the density, the higher the constraint on the ego. Alternatively, betweenness centrality for ego-networks [80,81] can be used.

If the structural holes hypothesis governs actors' behavior, what overall network structure should we expect to find? A strong tendency toward brokerage at the micro level is not likely to produce a centralized network because each actor would try to maximize the number of structural holes around itself, which would yield a bipartite graph in the extreme case (no ties among any vertex' neighbors), or it would minimize its constraint by ending all ties to neighbors that have contacts outside ego's immediate neighborhood, which would produce a highly clustered network consisting of isolated cliques or isolated vertices in the extreme case.

In summary, the relation between local action and overall network structure is simple and clear only in the case of preferential attachment to high-degree vertices. Tendencies to maximize centrality that looks beyond the immediate neighbors such as closeness and betweenness centrality, do not necessarily yield centralized networks. Even for local structures, alternative hypotheses for actor's behavior are available that are unlikely to produce centralized networks, e. g., a preference to avoid constraint. The interplay between local action and overall structure is quite complex.

Prestige and Ranking

The preceding sections have not distinguished between directed and undirected networks. For prestige and ranking, however, the direction of ties is crucial because asymmetry in networks is assumed to be linked to social prestige [82]. The general idea here is that social inequalities are reflected and possibly created by asymmetric ties, e. g., everyone invites the most popular boy or girl in class but s/he doesn't return each invitation. Of course, the nature of the social relation determines the direction of choices; ties like "reports to" or "pays respect to" point toward higher levels in a hierarchy while "beating up" points in the opposite direction.

A central behavioral hypothesis concerns the popularity or attractiveness of actors. Actors tend to (want to) relate to actors with attractive structural properties or attributes, so attributes related to power or social status increase the probability that an actor will be chosen. From a constructivist point of view, however, being chosen often is also interpreted as a sign of importance and prestige, so receiving many choices (ties) increases the probability of receiving even more. In this way, networks may produce informal status hierarchies. The Matthew Effect, proposed by Robert K. Merton [83], comes to mind here: "For unto every one that hath shall be given, and he shall have abundance: But for him that hath not shall be taken away even that which he hath" (gospel of Matthew XXV, 29).

In graph theoretical terms, the structural attractiveness of an actor refers to the number of incoming arcs on vertices, which is simply the indegree of a vertex. This is called the popularity of a vertex and, of course, we must replace it by the vertex' outdegree if the relation is negative, e. g., submission, beating up, criticizing. If indirect choices must be taken into account as well, attractiveness is measured by proximity prestige [84], which is based on the average distance from all other vertices in the network – a directed variant of closeness centrality. Proximity prestige captures the idea that nominations or choices by actors who are themselves popular, contribute more to ones structural prestige. Bonacich's measure of power [62,85] adds the idea that power may also be derived from being connected to powerless actors rather than to other powerful people.

The popularity hypothesis is another example of preferential attachment to degree with the restriction that we focus either on indegree or outdegree. Therefore, the indegree (or outdegree) distribution of the overall network is expected to follow the power law and network structure will be characterized by high degree centralization.

Adding data on social attributes that make some actors more prestigious such as wealth, social class, beauty, and so on, we should expect preferential attachment to vertices that score high on these attributes. Note that vertex attributes play a slightly different role here than in the case of cohesion. Now we are concerned with attributes of (at least) ordinal level, expressing prestige that an actor possesses to a higher or lower degree. In the case of cohesion, we deal with nominal attributes, which merely express an identity. In contrast to homophily, the attributes of the actor who initiates the directed tie (the tail of the arc) does not matter here because the effect is solely related to structural characteristics or attributes of the actor at the receiving end of the tie (the arc's head).

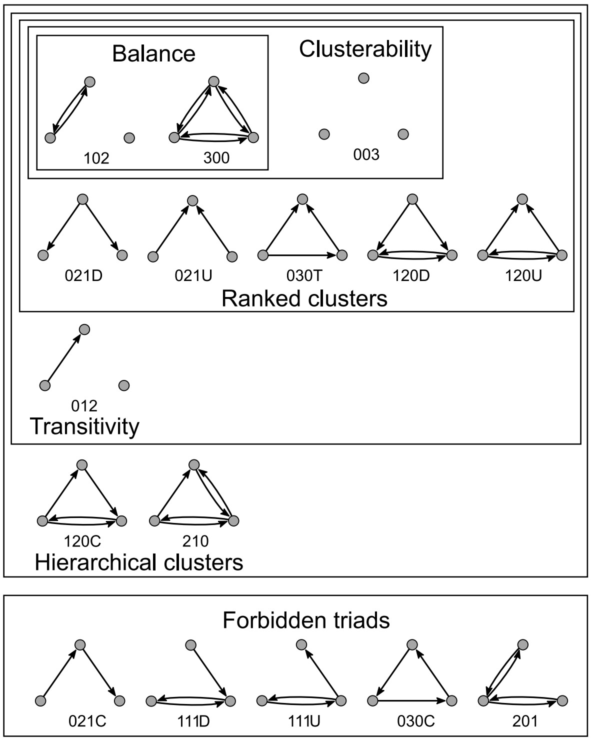
There is a second, slightly different behavioral hypothesis relating to deference or submission rather than attractiveness. The idea is that actors mainly tend to create positive ties to other actors in their own status group or to actors in a higher status group – the people they are looking up to – to consolidate and improve their social position. Similarly, they tend to direct negative ties to actors in lower status groups. Note the difference with attractiveness: It is hypothesized that actors choose upwardly but they need not prefer the most attractive (top) actors in the network as they are supposed to do according to the attractiveness hypothesis.

The main difference between attractiveness and deference is that the former only takes into account structural properties or attributes of the tie's receiver, whereas the characteristics of both the sender and receiver of the tie matter to the latter. This distinction has important consequences to the structure of the overall network. Whereas the attractiveness hypothesis yields centralized networks, the deference hypothesis yields layered networks. The layers consist of sets of vertices that are symmetrically linked, e. g., by reciprocal ties, while the ties between layers are asymmetric, all pointing in the same direction. This behavior may be both a consequence of a formal hierarchy, e. g., positions within an organization with formalized relations such as reports to, or actually show an informal social hierarchy, e. g., status differences between men and women in a particular social setting.

In simple directed networks, triads, that is, three vertices and the lines among them, are the key to measuring tendencies toward ranking at the local level. Translating the concepts of balance and clusterability (see Sect. "Introduction") from signed digraphs to unsigned digraphs, James A. Davis and Samuel Leinhardt [86,87] replaced positive ties by symmetric ties within cohesive subgroups and negative ties by no ties among subgroups. Thus, ties within a layer, either within clusters or among clusters, are symmetric. They assumed that asymmetric ties represent the ranking of clusters into a hierarchy, introducing the model of ranked clusters. Moreover, they showed that a network with a perfectly fitting ranked clusters model contains only certain types of triads, whereas other types do not occur (Fig. 6).

The ranked clusters model requires arcs from each vertex to all vertices on higher ranks. This requirement is usually too strict for empirical social networks and it is relaxed in the transitivity model proposed by Paul W. Holland and Samuel Leinhardt [88], which requires that clusters of vertices on different ranks are either completely linked or not linked at all, yielding a partial order, by simply adding one type of triad to the set of allowed triads (Fig. 6). Later, Eugene Johnsen [89] proposed the model of hierarchical clusters to account for asymmetries within clusters. Note the nesting of the models for overall network structure, which is why the sets of permitted triads is extended for more general models. Finally, it was shown that the models developed for unsigned digraphs could also be detected in incomplete signed digraphs using types of semicycles [90].

The triads characterizing ranked structures serve as models for tie creation, maintaining, and breaking behavior of actors under the deference hypothesis. For instance, triad 120U (Fig. 6) predicts that a member of a cluster is likely to establish or maintain a tie to an actor at a higher rank if its neighbors within the cluster have such a tie. In the perfect case, there is a one-to-one relation between sets of occurring types of triads and the overall structure of the network. Therefore, triad census [91,92], which is the frequency distribution of the sixteen types of triads in a directed network, offers an indication of overall network structure. In the imperfect case, the triad census of a network may be compared to the frequency distributions of triad types in randomly generated networks to test the tendency toward ranking.



Social Network Analysis, Graph Theoretical Approaches to, Figure 6
Triad types and balance-theoretic models

The triad census does not show the composition of the clusters and ranks; it does not identify the vertices belonging to particular clusters and ranks. This can be done in several ways. Realizing that ranks should be connected asymmetrically in directed networks, strong components cannot include more than one rank because vertices within strong components are by definition mutually reachable. Ties between strong components, then, are asymmetric, so it is easy to establish the ranking among strong components. Strong components, however, do not require a lot of symmetry in the ties; actually, no tie needs to be reciprocated. The symmetric-acyclic decomposition proposed by Patrick Doreian, Vladimir Batagelj and Anuška Ferligoj [93] does require at least some symmetric ties (mutual choices) within clusters because they define a symmetric cluster as a maximum subset of vertices that are directly or indirectly linked by symmetric ties. Generalized blockmodels [1] that are asymmetric with respect to off-diagonal blocks offer another way to identify hierarchical relations (see ► Positional Analysis and Blockmodeling).

Analyzing Complexity in Social Networks

The preceding sections presented behavioral hypotheses that have similar, different, or even opposite consequences for overall network structure. It is not plausible that one particular type of behavior dominates network formation. Therefore, it is not likely that overall structure of empirical social networks will display one particular form that can be hypothesized in advance or that behavioral tendencies can be adequately tested on particular characteristics of overall network structure. It has been shown, for example, that the degree distribution of a network does not reveal tendencies toward cohesive subgroup formation that are operative during network evolution [94].

Even if overall network structure displays certain characteristics, they may be produced by different types of behavior. Centralization in a social network, for instance, may arise from a tendency of actors to minimize paths to all other actors or from a preference for prestigious actors. Alternatively, it may be a by-product of cohesive subgroup formation: Actors that are marginal to the cohesive subgroups may directly or indirectly connect different subgroups, which gives them a central position with respect to betweenness. Furthermore, pronounced overall network patterns may occur only temporarily in empirical social networks when they create socially unstable situations. The polarization predicted by balance theory in Sampson's network of novices, used as an example in the Introduction, was only temporary. After this polarization and most likely due to it, many novices left the monastery. The network, so to speak, fell apart.

For these reasons, SNA increasingly focuses on local structure using overall network structure merely as a collection of (overlapping) local structures. Behavioral hypotheses translate much more directly to local structure, that is, to the ties of the actor and those of its neighbors (and possibly their neighbors), as we have seen in the preceding sections. Local structure is the part of the network that an actor can easily survey and actually change.

The latest developments in techniques for modeling network structure and evolution apply this actor-oriented approach either in statistical models, see ► Network Analysis, Longitudinal Methods of and ► Social Networks, Exponential Random Graph (p^*) Models for. The techniques test behavioral tendencies by relating the creation, maintenance, and ending of ties by individual actors to the local configuration of ties, to previous ties between the actor and the alter or to present ties on another social relation, and to characteristics of both the actor and the alter.

In principle, the actor-oriented approach is able to test all behavioral hypotheses presented in the preceding sections on characteristics of local structure in which the actors are embedded and properties of the actors themselves. If hypothesized local configurations appear more often than expected by chance, the underlying behavioral hypothesis is assumed to guide individual behavior at least to some extent. If the behavior in a set of actors or individual actor's behavior are in line with several behavioral hypotheses at the same time, the effect of each behavioral tendency can be separated. Thus, it is possible to link complex overall network structure to compound behavior of the actors in the network.

Future Directions

The techniques for analyzing local structure are in development. Models for the co-evolution of relations and quantitative attributes of vertices over time have just been introduced [95]. Not all behavioral hypotheses have been included yet, for instance, because they involve non-standard types of networks such as signed relations, and new ones are bound to be proposed. Incomplete data and external constraints on data collection or conceptual constraints on network structure such as two-mode networks (see ► Social Network Analysis, Two-Mode Concepts in) may limit the applicability of current models and spur the development of new ones.

If the actor-oriented approach is successful, will overall network structure become completely redundant? Will it only serve network exploration – looking for behavioral hypotheses rather than testing them – and for analyzing the consequences of network position on behavior, attitudes, or esteem, for instance, does the subgroup to which an actor belongs or its centrality correlate with its subsequent behavior or attitudes?

Let us return to the balance example, presented in the Introduction. The high degree of polarization among Sampson's novices was followed by the voluntary or forced exit of several novices. This suggests that people are able to survey overall network structure and draw conclusions from it, rather than just react to their local network environment. A highly polarized social group does not seem to be the kind of situation that we like to be living in. An actor's perception of overall network structure may also affect its behavior.

In this respect, the balance example is interesting because the original theory by Heider referred to perceptions of affect relations and unit relations (having characteristics or possessing items) rather than objectively measured relations. The importance of perception to network analysis is stressed in a more general way by Harrison White, who argues that social ties are stories [96]. According to him, people are linked into social networks by the stories that they tell about their ties. Thus, we should expect people to react to the ties as they remember and tell them rather than to the ties as they are observed by the researcher or registered in, for instance, membership lists.

A similar argument was made by David Krackhardt when he reconsidered balance theory [97]. According to him, we should measure each actor's perception of network structure, for which he proposed the concept of Cognitive Social Structures, compare these perceptions, and use them to explain why actors behave as they do. In his approach, actors are assumed to be able and active in forming impressions of overall network structure.

If humans are capable of imagining overall network structure, then communication of these perceptions may also play a role in network formation, including the accidental and deliberate distortions or simplifications that are likely to happen. This brings us to the link between network structure and mental categories such as social classifications or culture in a more general sense as argued by Ronald L. Breiger [98,99]. If, for example, members of the network perceive and discuss cohesive subgroups, they assign names and meanings to social configurations. Thus, social meanings and identities are created in the process of establishing social ties and interpreting them. The duality of social structure on the one hand and the structure of symbolic categories on the other hand as proposed by John W. Mohr [100], may be the essential condition for cultural meanings that are social in the sense that they affect actors' sense of identity and behavior.

These discrete and qualitative rather than continuous and quantitative classifications are very likely to affect the network behavior of actors: They define the categories that are experienced as being similar or dissimilar in the case of homophily and group formation, or superior versus inferior in the case of prestige and ranking. As a consequence, it is to be expected that the present focus on local structure will be complemented by a focus on overall network structure, especially perceived and communicated network structure.

Article Outline

Glossary

For the basic notions on graphs and networks see the Articlea Wouter de Nooy: ► Social Network Analysis, Graph Theoretical Approaches to.

Network consists of vertices linked by lines and additional data about vertices and/or lines.

Network decomposition identification of parts of network and their interconnections. Usually it is described by a partition of set of vertices or set of lines.

Time complexity of algorithm describes how the time needed to run the algorithm depends on the size of the input data.

Reduction of network a network obtained by shrinking each cluster from a given partition into a vertex.

Condensation a reduction for strong connectivity partition.

Cut a subnetwork of vertices/lines with values of selected property above given threshold.

Island a connected subnetwork of selected size of (locally) important, with respect to selected property, vertices/lines.

Pattern searching identification of all appearances of selected small subnetwork (pattern or fragment) in a given network.

Topological sort procedure to determine a compatible ordering in acyclic network.

Definition of the Subject

A *network* is based on two sets: a set of *vertices* (nodes), that represent the selected *units*, and a set of *lines* (links), that represent *ties* between units. Each line has two vertices as its *end-points*; if they are equal it is called a *loop*. Vertices and lines form a *graph*. A line can be *directed* – an *arc*, or *undirected* – an *edge*.

Additional data about vertices or lines are usually known – their *properties* (attributes). For example: name/label, type, value, position, … In general

$$\text{Network} = \text{Graph} + \text{Data}\,.$$

The data can be measured or computed.

Formally, a *network* $\mathcal{N} = (\mathcal{V}, \mathcal{L}, \mathcal{P}, \mathcal{W})$ consists of the following:

- A *graph* $\mathcal{G} = (\mathcal{V}, \mathcal{L})$, where $\mathcal{V}$ is the set of vertices and $\mathcal{L} = \mathcal{E} \cup \mathcal{A}$. $\mathcal{E} \cap \mathcal{A} = \emptyset$ is the set of lines. $\mathcal{A}$ is the set of *arcs* and $\mathcal{E}$ is the set of *edges*.
- $\mathcal{P}$ – set of *vertex value functions* or properties: $p\colon \mathcal{V} \to A$
- $\mathcal{W}$ – set of *line value functions* or weights: $w\colon \mathcal{L} \to B$

The size of a network/graph is expressed by two numbers: number of vertices $n = |\mathcal{V}|$ and number of lines $m = |\mathcal{L}|$. In a *simple undirected* graph (no parallel edges, no loops) $m \leq \frac{1}{2} n(n-1)$; and in a *simple directed* graph (no parallel arcs) $m \leq n^2$.

For a family of graphs $\mathbb{G}$, we define a *density* of graph $\mathcal{G}$ as $\gamma(\mathcal{G}) = \frac{m(\mathcal{G})}{m_{\max}(\mathbb{G})}$.

Introduction

Small networks (some tens of vertices) can be represented by a picture and analyzed by many algorithms (***UCINET***, ***NetMiner***). Also *middle size* networks (some hundreds of vertices), if they are not dense, can still be represented by a picture, but some analytical procedures can't be used.

Till 1990 most networks were small – they were collected by researchers using surveys, observations, archival records, etc. The advances in IT allowed one to create networks from the data already available in the computer(s) or by browsing on the Internet. *Large* networks became reality. Large networks are too big to be displayed in detail; special algorithms are needed for their analysis (Pajek). The availability of large data sets also provided incentives to the boost of theoretical research in (large) network analysis (not only in the social sciences).

A recent overview of social network analysis software is given in Huisman and Van Duijn [28].

Large Networks and Complexity of Algorithms

Large networks have several thousands or millions of vertices. The upper limit to their size is technologically dependent – they can be stored in computer's memory; otherwise we deal with a *huge* network (see Abello et al. [1]).

Large networks are usually sparse $m \ll n^2$; typically $m = O(n)$ or $m = O(n \log n)$, see Table 1.

A collection of large networks is available from Pajek's datasets.

The *time complexity* of an algorithm describes how the time needed to run the algorithm depends on the size of the input data. In computer science the problems for which only algorithms of exponential (or higher) complexity are known are considered hard or intractable, since the speed-up of a computer only additively increases the size of problems that can be solved in a given period of

time, but the problems for which an algorithm of polynomial complexity exists are considered 'nice'. When dealing with large instances of problems this isn't always true anymore. Let us look to time complexities of some typical algorithms in Table 2.

For the interactive use on large networks already quadratic algorithms, $O(n^2)$, are too slow – we have to restrict our 'toolbox' to a selection of efficient, *subquadratic* algorithms.

How can we deal with large structures? Already Romans knew – ***divide et impera*** (divide and conquer). In case of networks ***divide*** means the use of (recursive) *decomposition* of a large network into several smaller networks (see Fig. 1) that can be visualized and treated further using more sophisticated methods; ***impera*** means that we have to take care about the interlinks among so obtained parts.

Another approach is the use of different *statistical* quantities to describe the properties of a network and using probabilistic models to derive the answers to some questions.

Decompositions

Decompositions of a network are usually described by clusterings of vertices or lines. In the following we shall use mainly the clusterings of vertices.

A nonempty subset $C \subseteq \mathcal{V}$ is called a *cluster* (group). A nonempty set of clusters $\mathbf{C} = \{C_i\}$ forms a *clustering*.

Clustering $\mathbf{C} = \{C_i\}$ is a *partition* iff

$$\cup\mathbf{C} = \bigcup_i C_i = \mathcal{V} \quad \text{and} \quad i \neq j \Rightarrow C_i \cap C_j = \emptyset\,.$$

Clustering $\mathbf{C} = \{C_i\}$ is a *hierarchy* iff $C_i \cap C_j \in \{\emptyset, C_i, C_j\}$. In other words, in a hierarchy two clusters are either disjoint or is one contained in the other.

Hierarchy $\mathbf{C} = \{C_i\}$ is *complete*, iff $\cup\mathbf{C} = \mathcal{V}$; and is *basic* if for all $v \in \cup\mathbf{C}$ also $\{v\} \in \mathbf{C}$.

Contraction of cluster C in a graph $\mathcal{G}$ is called a graph $\mathcal{G}/C$, in which all vertices of the cluster C

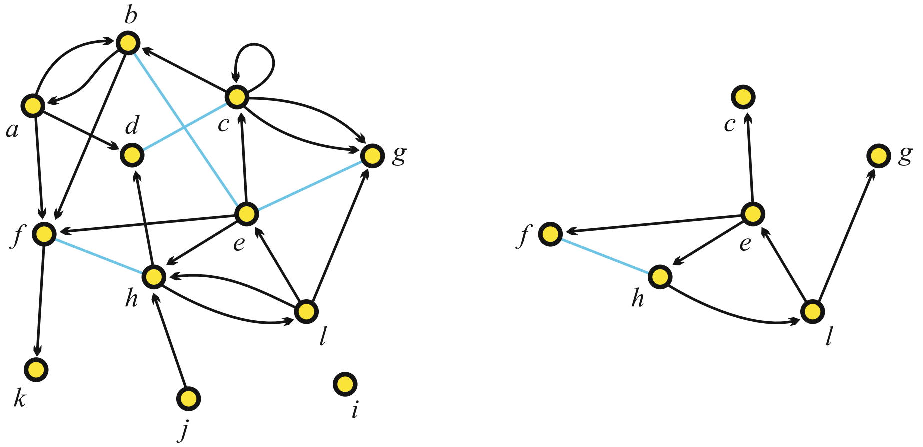
Snyder and Kick's international trade; matrix display and reduction



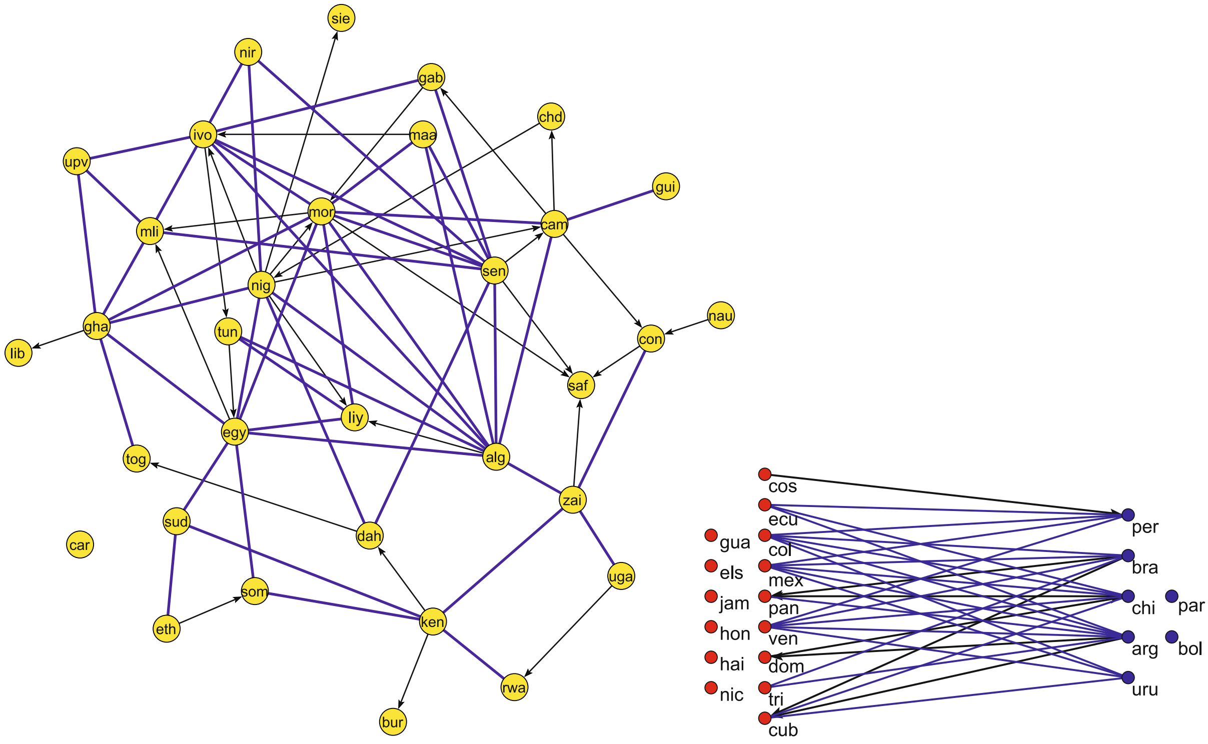
Social Network Analysis, Large-Scale, Figure 3
Graph and its subgraph

are replaced by a single new vertex, say c. More precisely: $\mathcal{G}/C = (\mathcal{V}', \mathcal{L}')$, where $\mathcal{V}' = (\mathcal{V} \setminus C) \cup \{c\}$ and $\mathcal{L}'$ consists of lines from $\mathcal{L}$ that have both end-points in $\mathcal{V} \setminus C$. Beside these it contains also a 'star' with the center c and: arc(v, c), if $\exists p \in \mathcal{L}, u \in C\colon\ p(v, u)$; or arc$(c, v)$, if $\exists p \in \mathcal{L}, u \in C\colon\ p(u, v)$. There is a loop (c, c) in c if $\exists p \in \mathcal{L}, u, v \in C\colon\ p(u, v)$.

In a network over graph $\mathcal{G}$, we have also to specify how the new values/weights are determined in the shrunk part of the network. Usually as the sum or maximum/minimum of the original values.

For a given partition if we contract all clusters except few selected we obtain their *context*; and if we contract all clusters we obtain the *reduction* of a given network.

On the left side of the Fig. 2 the *matrix display* of Snyder and Kick's [40] international trade network is presented. Vertices in the display are reordered according to the partition by (sub)continents. On the right side the



Social Network Analysis, Large-Scale, Figure 4
Africa cut-out and inter-links between South and Latin America

corresponding reduction of the network is presented. The lines in the reduction have the thickness proportional to the weights

$$w(C_i, C_j) = \frac{n(C_i, C_j)}{n(C_i) \cdot n(C_j)}$$

where $n(C_i, C_j)$ is the number of lines from cluster C_i to cluster C_j; and $n(C_i)$ is the number of lines inside the cluster C_i.

A *subgraph* $\mathcal{H} = (\mathcal{V}', \mathcal{L}')$ of a given graph $\mathcal{G} = (\mathcal{V}, \mathcal{L})$ is a graph which set of lines is a subset of set of lines of $\mathcal{G}$, $\mathcal{L}' \subseteq \mathcal{L}$, its vertex set is a subset of set of vertices of $\mathcal{G}$, $\mathcal{V}' \subseteq \mathcal{V}$, and it contains all end-vertices of $\mathcal{L}'$. The graph on the right side of Fig. 3 is a subgraph of the graph on the left side.

A subgraph can be *induced* by a given subset of vertices $\mathcal{V}'$, then $\mathcal{L}' = \mathcal{L}|\mathcal{V}'$ consists of all lines from $\mathcal{L}$ which have both end-points in $\mathcal{V}'$; or lines $\mathcal{L}'$, then $\mathcal{V}' = \mathcal{V}|\mathcal{L}'$ consists of all end-points of lines from $\mathcal{L}'$. It is a *spanning* subgraph iff $\mathcal{V}' = \mathcal{V}$.

On the left side of Fig. 4 the *cut-out* of African countries from the Snyder and Kick's network is presented – the induced subgraph by Africa cluster; and on the right side the *inter-links* between Latin America and South America – the induced subgraph by Latin America and South America clusters with inside cluster lines removed.

Connectivity

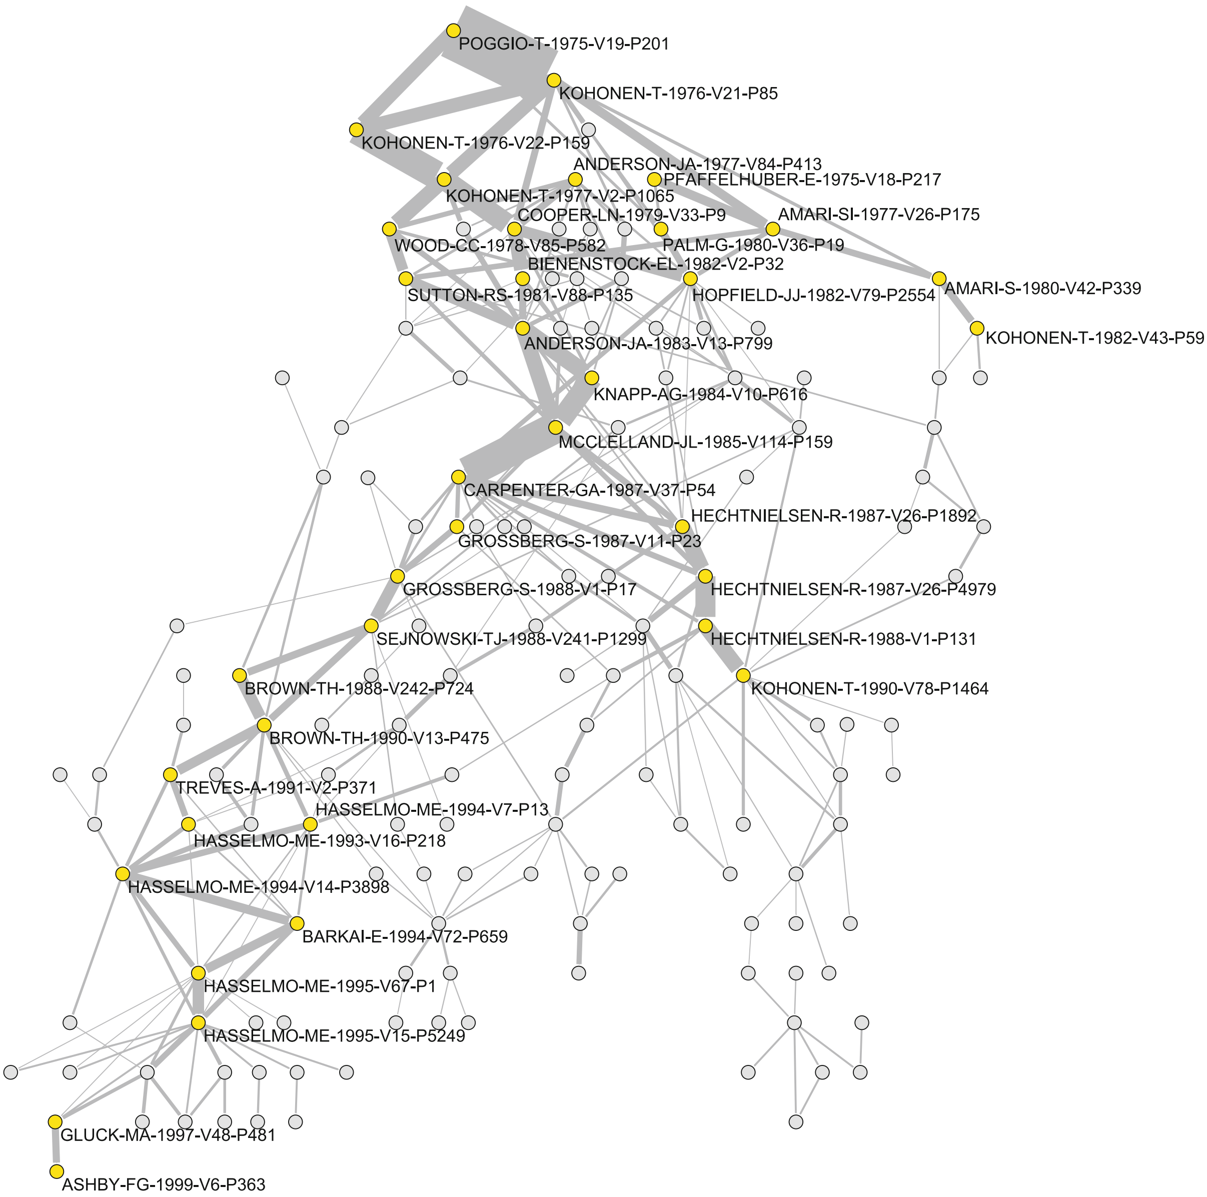
A *walk* from vertex u to vertex v is a sequence of lines $l(v_{i-1}, v_i)$, $i = 1, \dots, k$ such that $v_0 = u$ and $v_k = v$. k is called the *length* of the walk. If in the definition of a walk we don't care about the direction of its lines we get a *semiwalk*. A walk is *closed* iff $u = v$. A graph is *acyclic* iff it doesn't contain any closed walk. A walk in which all vertices are different is a *path*.

Vertex u is *reachable* from vertex v iff there exists a walk with initial vertex v and terminal vertex u. Vertex v is *weakly connected* with vertex u iff there exists a semiwalk with v and u as its end-vertices. Vertex v is *strongly connected* with vertex u iff they are mutually reachable.

Weak and strong connectivity are equivalence relations. Equivalence classes induce weak/strong *components* (See Fig. 5).

Reordering the vertices of network such that the vertices from the same class of weak partition are put together we get a matrix representation (left side of Fig. 6) consisting of diagonal blocks – weak components. The out-diagonal blocks are zero-blocks. Most problems can be solved separately on each component and afterward these solutions combined into final solution.

If we shrink every strong component of a given graph into a vertex, delete all loops and identify parallel arcs the obtained reduced graph, called also the *condensation* of a given graph, is acyclic [27]. For every acyclic



Social Network Analysis, Large-Scale, Figure 8
Main component of arc cut at level 0.007 of the SOM citation network

graph an *ordering/level* function $i \colon \mathcal{V} \to \mathbb{N}$ exists such that $(u, v) \in \mathcal{A} \Rightarrow i(u) < i(v)$. The procedure to determine such ordering is called *topological sort* [19]. Reordering in matrix display the vertices of a network by this ordering we obtain a representation as at the right side of Fig. 6 – the blocks below the diagonal are zero-blocks.

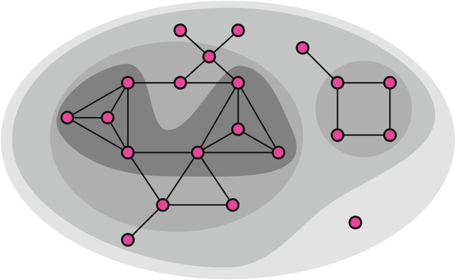
A directed graph, its condensation and its topologically ordered matrix display are presented in Fig. 7.

For several network analysis problems more efficient algorithms exist for acyclic networks.

Cuts

The basic approach to find interesting groups inside a network is to express our intentions (question) with an appropriate property/weight (measured or computed from network structure) and then identify the substructures of elements with the highest (lowest) values of the selected property. This approach is known as a method of *cuts*.

There exist several measures of importance of vertices in a network such as: degree, betweeness, closeness [16,24], hubs and authorities [30], clustering coefficient, …



Social Network Analysis, Large-Scale, Figure 9
Cores

The *degree* $\deg(v)$ of vertex v equals to the number of lines having vertex v as their end-point. The *maximum degree* of a graph is denoted by Δ. Similarly the in-degree $\operatorname{indeg}(v)$ of vertex v equals to the number of lines having vertex v as their terminal point, and the out-degree $\operatorname{outdeg}(v)\ldots$

The *vertex-cut* of a network $\mathcal{N} = (\mathcal{V}, \mathcal{L}, p)$, for a property $p\colon \mathcal{V} \to \mathbb{R}$, at selected level t is a subnetwork $\mathcal{N}(t) = (\mathcal{V}', \mathcal{L}(\mathcal{V}'), p)$, determined by the set

$$\mathcal{V}' = \{v \in \mathcal{V}\colon p(v) \geq t\}$$

and $\mathcal{L}(\mathcal{V}')$ is the set of lines from $\mathcal{L}$ that have both end-points in $\mathcal{V}'$.

The *line-cut* of a network $\mathcal{N} = (\mathcal{V}, \mathcal{L}, w)$, for a weight $w\colon \mathcal{L} \to \mathbb{R}$, at selected level t is a subnetwork $\mathcal{N}(t) = (\mathcal{V}(\mathcal{L}'), \mathcal{L}', w)$, determined by the set

$$\mathcal{L}' = \{e \in \mathcal{L}\colon w(e) \geq t\}$$

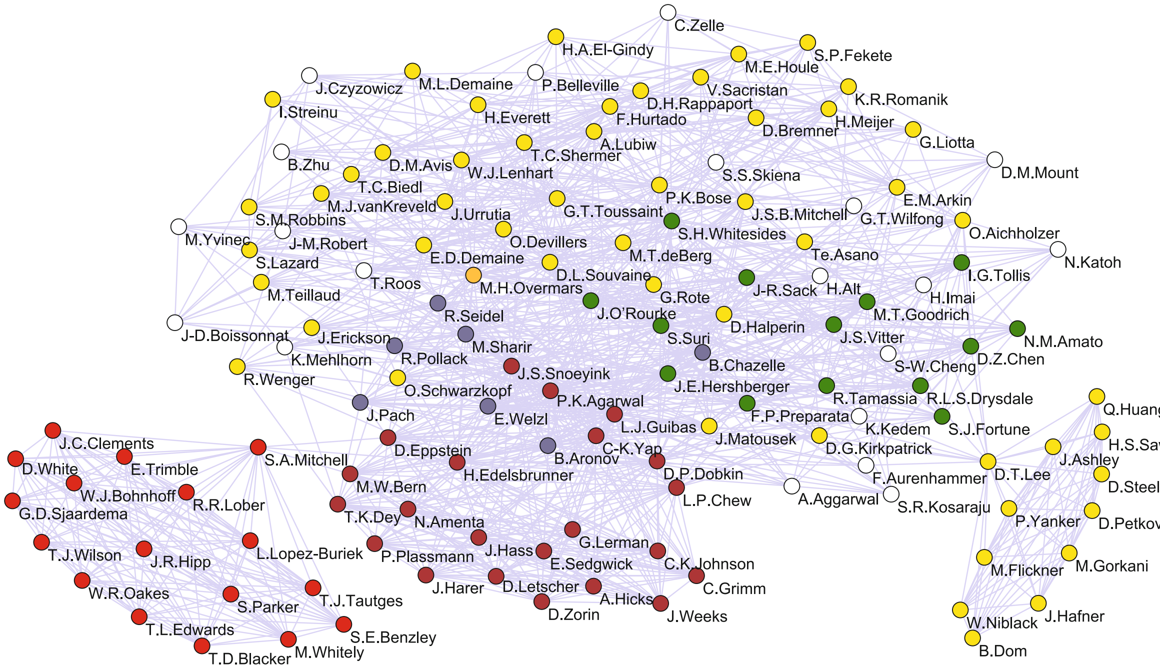
and $\mathcal{V}(\mathcal{L}')$ is the set of all end-points of the lines from $\mathcal{L}'$.

In the analysis of a cut $\mathcal{N}(t)$, we look at its components. Their number and sizes depend on t. Usually there are many small components. Often we consider only components of size at least k and not exceeding K. The components of size smaller than k are discarded as 'less interesting'; and the components of size larger than K are cut again at some higher level.

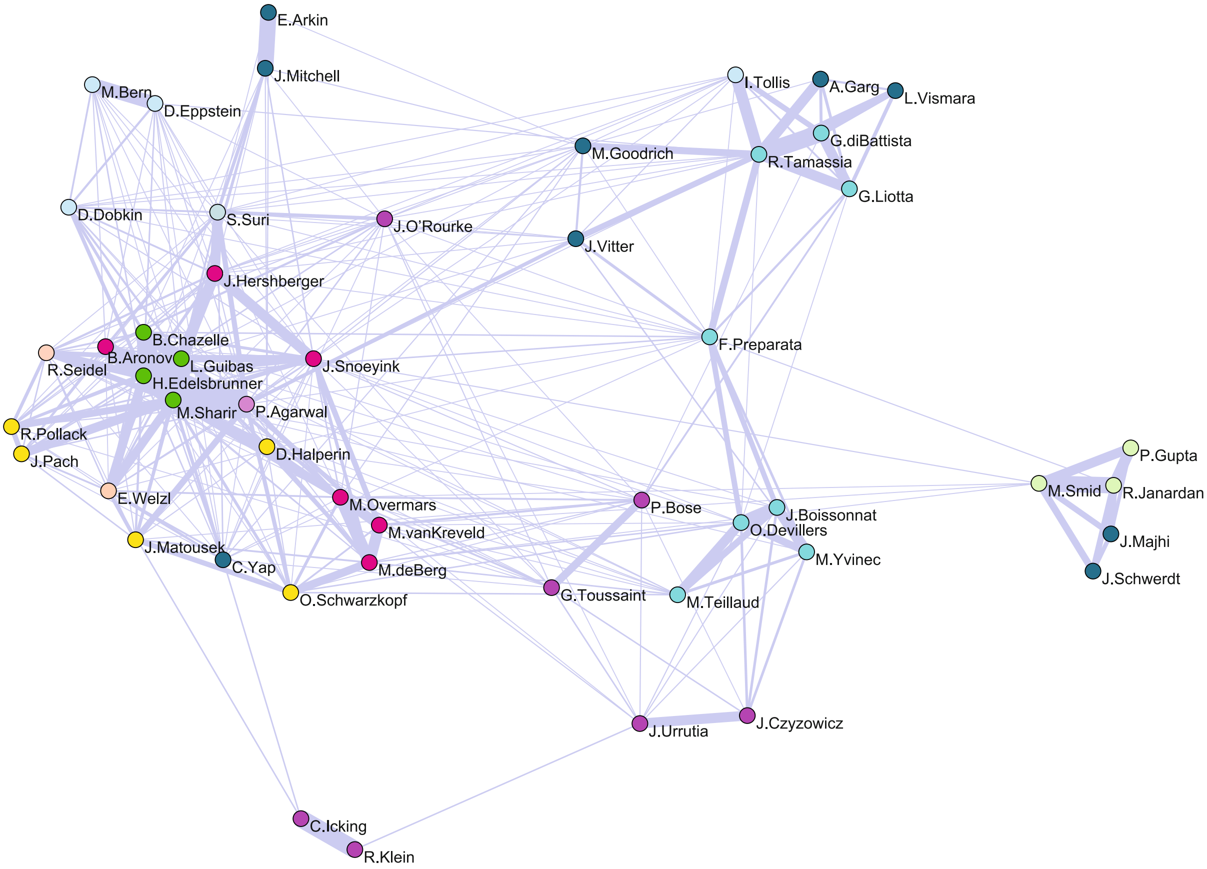
The values of threshold t and size bounds k and K are determined by inspecting the distribution of vertex/line-values and the distribution of component sizes and considering additional knowledge on the nature of network or goals of analysis.

The p_S-core at level 46 (see Fig. 11) of the collaboration network in the field of computational geometry is an example of vertex cut.

The citation network analysis started in 1964 with the paper of Garfield et al. [25]. In 1989 Hummon and Doreian [29] proposed three indices – weights of arcs that are proportional to the number of different source-sink paths passing through the arc. In Fig. 8 the main component



Social Network Analysis, Large-Scale, Figure 10
Cores of orders 10–21 in Computational Geometry collaboration network



Social Network Analysis, Large-Scale, Figure 11
p_S-core at level 46 in Computational Geometry collaboration network

of the arc cut at level 0.007 for SPC (search path count) weights of the SOM (selforganizing maps) citation network (4470 vertices, 12,731 arcs) is presented.

Dense Groups – Cores and Short Rings

Several notions were proposed in attempts to formally describe dense groups in graphs.

Clique of order k, $k \geq 3$, is a maximal complete subgraph (isomorphic to complete graph K_k – graph with k vertices and all possible edges among them).

Other notions are: s-plexes, s-clans, LS sets, lambda sets, cores, … (Wasserman and Faust [43]). For all of them, except for cores, it turned out that they are difficult (no fast algorithm exists) to determine.

The notion of core was introduced by Seidman in 1983 [38]. Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be a graph. A subgraph $\mathcal{H}_k = (\mathcal{W}, \mathcal{E}|\mathcal{W})$ induced by the set $\mathcal{W}$ is a *k-core* or a *core of order k* iff for all $v \in \mathcal{W}\colon \deg_{\mathcal{H}_k}(v) \geq k$, and $\mathcal{H}_k$ is a maximal subgraph with this property. The core of maximum order is also called the *main* core. The *core number* of vertex v is the highest order of a core that contains this vertex. In general graphs instead of the degree $\deg(v)$ we can also use: in-degree, out-degree, in-degree + out-degree, etc., determining different types of cores.

From Fig. 9, representing 0, 1, 2 and 3 core, we can see the following properties of cores:

- The cores are nested: $i < j \Longrightarrow \mathcal{H}_j \subseteq \mathcal{H}_i$. They form a hierarchy.
- Cores are not necessarily connected subgraphs.

An efficient algorithm for determining the cores hierarchy is based on the following property: If from a given graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ we recursively delete all vertices, and edges incident with them, of degree less than k, the remaining graph is the k-core.

The Fig. 10 presents the cores of orders 10 to 21 in the collaboration network ($n = 7343$, $m = 11{,}898$) for the field of computational geometry – two authors are linked iff they wrote a paper together. The weight of the edge equals to the number of joint papers.

The notion of core can be generalized to networks. Let $\mathcal{N} = (\mathcal{V}, \mathcal{E}, w)$ be a network, where $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ is a graph and weight $w\colon \mathcal{E} \to \mathbb{R}$ is a function assigning values to edges. A *vertex property function* on $\mathcal{N}$, or a *p-function* for short, is a function $p(v, U), v \in \mathcal{V}, U \subseteq \mathcal{V}$ with real values. Let $N_U(v) = N(v) \cap U$, where $N(v)$ is the set of neighbors of v. Besides degrees, here are some other examples of p-functions [13]:

$$
\begin{aligned}
p_S(v,U) &= \sum_{u \in N_U(v)} w(v,u), \text{ where } w\colon \mathcal{E} \to \mathbb{R}_0^+ \\
p_M(v,U) &= \max_{u \in N_U(v)} w(v,u), \text{ where } w\colon \mathcal{E} \to \mathbb{R} \\
p_k(v,U) &= \text{number of cycles of length } k \\
&\qquad \text{through vertex } v \text{ in } (U, \mathcal{E}|U) \\
p_\gamma(v,U) &= \frac{\deg(v,U)}{\max_{u \in N(v)} \deg(u)}, \text{ if } \deg(v) > 0; \\
&\qquad\qquad\qquad 0, \text{ otherwise} \\
p_\delta(v,U) &= \max_{u \in N_U^+(v)} \deg(u) - \min_{u \in N_U^+(v)} \deg(u) \\
p_a(v,U) &= \frac{1}{|N_U(v)|} \sum_{u \in N_U(v)} w(v,u), \text{ if } N_U(v) \neq \emptyset; \\
&\qquad\qquad\qquad 0, \text{ otherwise}
\end{aligned}
$$

The subgraph $\mathcal{H} = (C, \mathcal{E}|C)$ induced by the set $C \subseteq \mathcal{V}$ is a *p-core at level* p-core $t \in \mathbb{R}$ iff for all $v \in C\colon t \leq p(v, C)$ and C is a maximal such set.

The function p is *monotone*, iff it has the property

$$C_1 \subset C_2 \Rightarrow \forall v \in \mathcal{V}\colon (p(v, C_1) \leq p(v, C_2))$$

The degrees and the functions p_S, p_M, p_k, p_γ and p_δ are monotone; and p_a is not. For a monotone function the p-core at level t can be determined, as in the ordinary case, by successively deleting vertices with value of p lower than t; and the cores on different levels are nested

$$t_1 < t_2 \Rightarrow \mathcal{H}_{t_2} \subseteq \mathcal{H}_{t_1}$$

The p-function is *local*, iff $p(v, U) = p(v, N_U(v))$. The degrees, $p_S, p_M, p_\gamma, p_\delta$ and p_a are local; but p_k is **not** local for $k \geq 4$. For a local monotone p-function an $O(m \max(\Delta, \log n))$ algorithm for determining the p-core levels exists, assuming that $p(v, N_C(v))$ can be computed in $O(\deg_C(v))$.

Figure 11 presents the p_S-core at level 46 of the collaboration network in the field of computational geometry. Note, for example, that R. Klein (lower left) has in-core degree only 2, but its in-core sum of weights is at least 46 – he wrote most of his papers with C. Icking.

A k-ring is a simple closed chain of length k. Using k-rings we can define a weight of an edge e as $w_k(e) = \#$ of different k-rings containing the edge $e \in \mathcal{E}$.

Since for each edge e of complete graph K_r, $r \geq k \geq 3$ we have $w_k(e) = (r-2)!/(r-k)!$, the edges belonging to cliques have large weights. Therefore these weights can be used to identify the dense parts of a network. For example: all r-cliques of a network belong to $(r-2)$-edge cut for the weight w_3.

Related to triangular (3-rings) network is the notion of *triangular connectivity* that can be used to operationalize the notion of Granovetter's strong and weak ties [26]. This notion can be generalized to short cycle connectivity. For details see [14]. For efficient algorithms for computing triangles in networks see [10,39], and Latapy.

In Fig. 12 the edge-cut at level 16 of triangular network of Erdős collaboration graph (without Erdős, $n = 6926$, $m = 11{,}343$) is presented [9].

In directed networks there are two types of triangles or 3-rings (cyclic and transitive, see Fig. 14).

Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be a simple undirected graph. *Clustering* in vertex v is usually measured as a quotient between the number of lines in subgraph $\mathcal{G}^1(v) = \mathcal{G}(N(v))$ induced by the neighbors of vertex v and the number of lines in the complete graph on these vertices:

$$C(v) = \begin{cases} \dfrac{2|\mathcal{L}(\mathcal{G}^1(v))|}{\deg(v)(\deg(v)-1)}, & \deg(v) > 1 \\ 0, & \text{otherwise} \end{cases} .$$

For simple directed graphs, we have to omit the number 2.

So defined clustering coefficient attains largest values mostly on vertices of low degree – it is not useful for data analysis task. A better coefficient is obtained by the following correction

$$C_1(v) = \frac{\deg(v)}{\Delta} C(v)$$

where Δ is the maximum degree in graph $\mathcal{G}$. This measure attains its largest value in vertices that belong to an isolated clique of size Δ.

Islands

Islands are very general and efficient approach to determine the 'important' subnetworks in a given network with respect to a given property of vertices or lines. It is an improvement of the cuts approach. If we represent a given or computed value of vertices/lines as a height of vertices/

Social Network Analysis, Large-Scale, Figure 15
Cuts and islands

lines and we immerse the network into a water up to selected level we get *islands*. Varying the level we get different islands [45].

In the islands approach we select only maximal islands of sizes inside the given size bounds k to K, but on different levels. In this way we bypass the problems of the cuts approach: determining the 'right' threshold value and too small/large sizes of obtained components. Besides this we can also identify locally important islands with small heights – emerging groups. Very efficient algorithms exist to determine the islands hierarchy and to list all the islands of selected sizes. An island is *simple* iff it has only one peak.

As an example, let us take the Nber network of US Patents. It has 3,774,768 vertices and 16,522,438 arcs. We computed SPC weights in it and determined all (2,90)-islands. The reduced network has 470,137 vertices, 307,472 arcs and for different k: $C_2 = 187{,}610$, $C_5 = 8859$, $C_{30} = 101$, $C_{50} = 30$ islands. The main island turns out

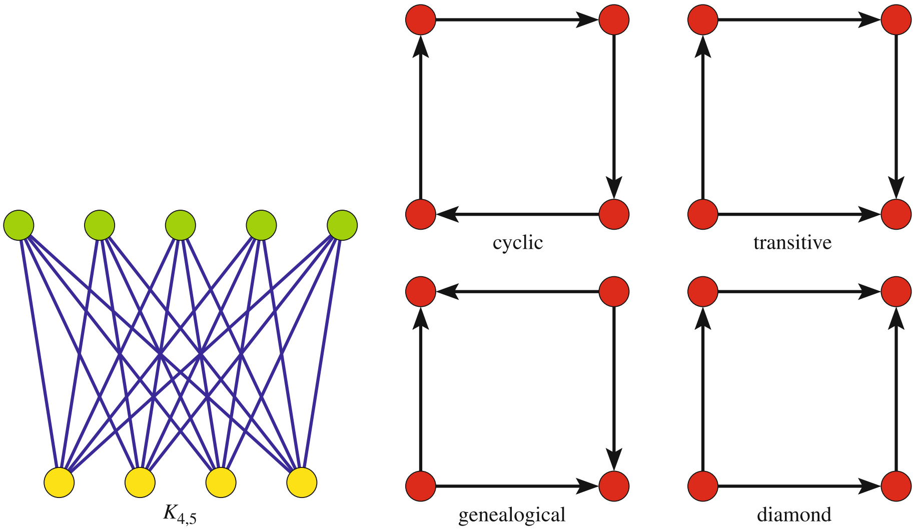
to be the island on the theme *LCD – Liquid crystal display*. In Fig. 16 four islands for transitivity triangular weight from *The Edinburgh Associative Thesaurus* network ($n = 23{,}219$, $m = 325{,}624$) are presented. From the left bottom island of words around the leader 'WORK' we see that the data were collected asking students.

Pattern Searching

If a selected *pattern* determined by a given graph does not occur frequently in a sparse network the straightforward backtracking algorithm applied for pattern searching finds all appearances of the pattern very fast even in



Social Network Analysis, Large-Scale, Figure 19
$K_{4,5}$ and directed 4-rings

the case of very large networks. Pattern searching was successfully applied to searching for patterns of atoms in large organic molecula (carbon rings) and searching for relinking marriages in genealogies (Batagelj and Mrvar [12]; Batagelj [6]).

The Fig. 17 presents three connected relinking marriages in the genealogy (represented as a p-graph) of Ragusan noble families. In a p-graph the vertices represent married couples or nonmarried individuals. A solid arc indicates the _ *is a son of* _ relation, and a dotted arc indicates the _ *is a daughter of* _ relation. In all three patterns a brother and a sister from one family found their partners in the same other family.

Two Mode Networks

A network $\mathcal{N} = (\mathcal{V}, \mathcal{L}, w)$ in which the set of vertices $\mathcal{V} = \mathcal{V}_1 \cup \mathcal{V}_2$ is composed of two disjoint sets $\mathcal{V}_1$ and $\mathcal{V}_2$, and $\mathcal{L}$ is a set of *lines* linking $\mathcal{V}_1$ and $\mathcal{V}_2$ is called a *two-mode* or bipartite network.

The two-mode networks often appear in applications, but till recently no directed methods for analysis of larger two-mode networks were available. To identify dense parts of two-mode network, we can use the adapted cores and short rings approaches (Ahmed et al. [3]).

The subset of vertices $C \subseteq \mathcal{V}$ is a (p, q)-core in a two-mode network $\mathcal{N} = (\mathcal{V}_1, \mathcal{V}_2; \mathcal{L})$, $\mathcal{V} = \mathcal{V}_1 \cup \mathcal{V}_2$ iff

a. in the induced subnetwork $\mathcal{H} = (C_1, C_2; \mathcal{L}(C))$, $C_1 = C \cap \mathcal{V}_1$, $C_2 = C \cap \mathcal{V}_2$ it holds for all $v \in C_1$: $\deg_{\mathcal{H}}(v) \geq p$ and for all $v \in C_2$: $\deg_{\mathcal{H}}(v) \geq q$;

b. C is the maximal subset of $\mathcal{V}$ satisfying condition **a**.

The two-mode cores have the following properties:

- $C(0, 0) = \mathcal{V}$
- $C(p, q)$ is not always connected
- $(p_1 \leq p_2) \wedge (q_1 \leq q_2) \Rightarrow C(p_2, q_2) \subseteq C(p_1, q_1)$.

To determine a (p, q)-core an algorithm similar to the ordinary core algorithm can be used: recursively remove from the first set all vertices of degree less than p, and from the second set all vertices of degree less than q. It can be implemented to run in $O(m)$ time.

The main question when applying the bipartite cores is what are the right values of p and q? The most interesting are the values on the 'border' that don't produce too large cores.

In Fig. 18 the (247,2)-core and (27,22)-core from the Internet Movie Database (two-mode network actors × movies, $n = 1{,}324{,}748 = 428{,}440 + 896{,}308$ vertices and $m = 3{,}792{,}390$ arcs) are presented. Both deal with wrestling.

In 2-mode network there are no 3-rings. The densest substructures are complete bipartite subgraphs $K_{p,q}$ – see $K_{4,5}$ on the left side of Fig. 19. They contain many 4-rings

$$w_4(e) = (p-1)(q-1)\,, \quad \text{for } \; e \in K_{p,q}\,.$$

There are four types of directed 4-rings – see the right side of Fig. 19. In the case of transitive rings we can count also on how many transitive rings the arc is a *shortcut*.

In the Internet Movie Database, we obtained for w_4 12,465 simple line islands on 56,086 vertices; 30 among

them have size at least 50. Two of them are presented on Fig. 20.

Multiplication of Networks

To a simple two-mode *network* $\mathcal{N} = (\mathcal{I}, \mathcal{J}, \mathcal{E}, w)$; where $\mathcal{I}$ and $\mathcal{J}$ are sets of *vertices*, $\mathcal{E}$ is a set of *edges* linking $\mathcal{I}$ and $\mathcal{J}$, and $w\colon \mathcal{E} \to \mathbb{R}$ is a *weight*; we can assign a *network matrix* $\mathbf{W} = [w_{i,j}]$ with elements: $w_{i,j} = w(i,j)$ for $(i,j) \in \mathcal{E}$ and $w_{i,j} = 0$ otherwise.

Given a pair of compatible networks $\mathcal{N}_A = (\mathcal{I}, \mathcal{K}, \mathcal{E}_A, w_A)$ and $\mathcal{N}_B = (\mathcal{K}, \mathcal{J}, \mathcal{E}_B, w_B)$ with corresponding matrices $\mathbf{A}_{\mathcal{I}\times\mathcal{K}}$ and $\mathbf{B}_{\mathcal{K}\times\mathcal{J}}$ we call a *product of networks* $\mathcal{N}_A$ and $\mathcal{N}_B$ a network $\mathcal{N}_A \star \mathcal{N}_B = \mathcal{N}_C = (\mathcal{I}, \mathcal{J}, \mathcal{E}_C, w_C)$, where $\mathcal{E}_C = \{(i,j)\colon i \in \mathcal{I}, j \in \mathcal{J}, c_{i,j} \neq 0\}$ and $w_C(i,j) = c_{i,j}$ for $(i,j) \in \mathcal{E}_C$. The product matrix $\mathbf{C} = [c_{i,j}]_{\mathcal{I}\times\mathcal{J}} = \mathbf{AB}$ is defined in the standard way

$$c_{i,j} = \sum_{k\in\mathcal{K}} a_{i,k} \cdot b_{k,j} \,.$$

In the case when $\mathcal{I} = \mathcal{K} = \mathcal{J}$ we are dealing with ordinary one-mode networks (with square matrices).

The standard matrix multiplication is too slow to be used for large networks. For sparse large networks, we can multiply much faster considering only nonzero elements. In general the multiplication of large sparse networks is a 'dangerous' operation since the result can 'explode' – it is not sparse. But in many interesting cases, we can assure that also the product is sparse. For example, we can prove:

If at least one of the sparse networks $\mathcal{N}_A$ and $\mathcal{N}_B$ has small maximal degree on K then also the resulting product network $\mathcal{N}_C$ is sparse.

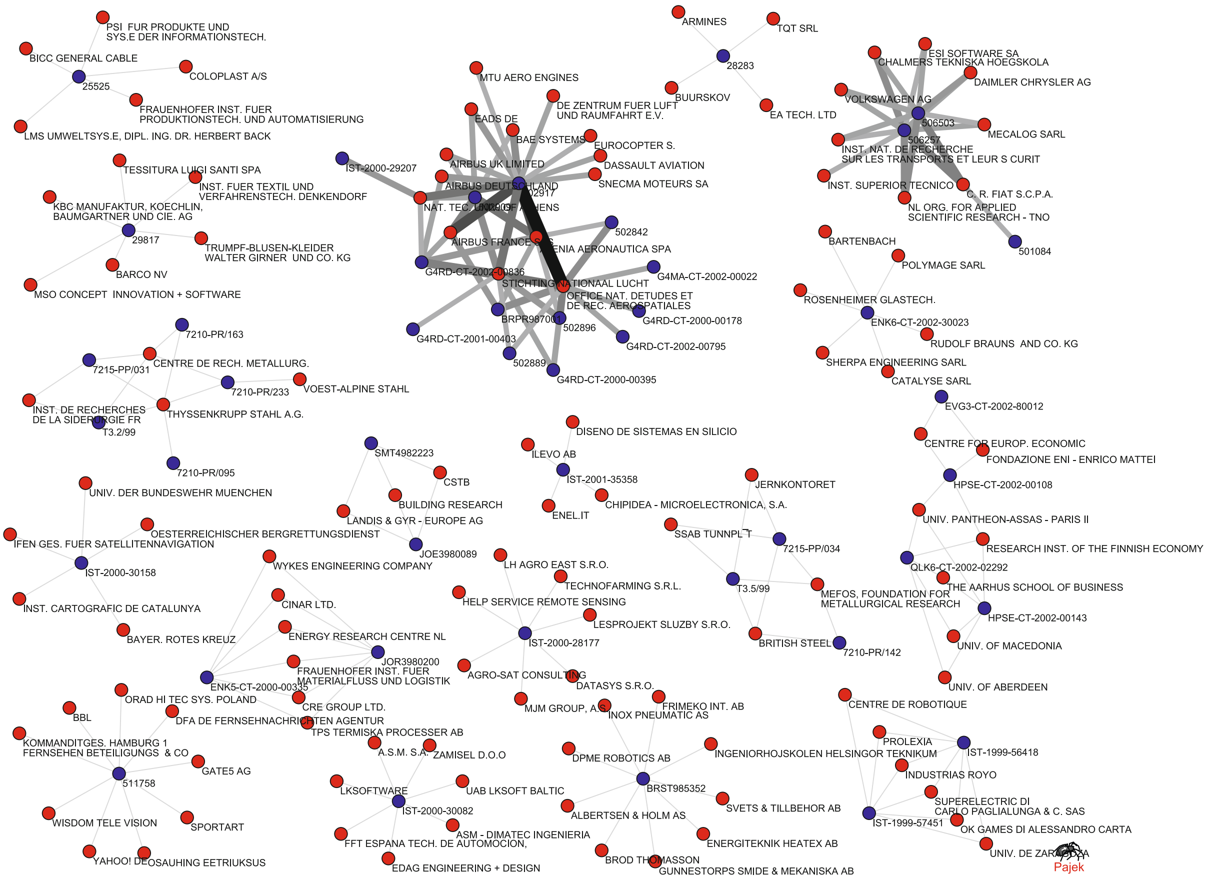
A more detailed analysis gives: Let for $k \in \mathcal{K}$ be $d_{\min}(k) = \min(\deg_A(k), \deg_B(k))$, $\Delta_{\min} = \max_{k\in\mathcal{K}} d_{\min}(k)$, $d_{\max}(k) = \max(\deg_A(k), \deg_B(k))$, $\mathcal{K}(d) = \{k \in \mathcal{K}\colon d_{\max}(k) \geq d\}$, and $d^* = \operatorname{argmin}_d (|\mathcal{K}(d)| \leq d)$. If for the sparse networks $\mathcal{N}_A$ and $\mathcal{N}_B$ the quantities $\Delta_{\min}$ and d^* are small then also the resulting product network $\mathcal{N}_C$ is sparse.

For example, using network multiplication we can in a given genealogy from the basic relations (P – parent-of, L – is a man, J – is a woman) compute all other kinship relations. For details see [12].

An important application of network multiplication is conversion of two-mode network to the corresponding one-mode networks. Often we transform a two-mode network $\mathcal{N}$ into an ordinary (one-mode) network $\mathcal{N}_1 = (\mathcal{I}, \mathcal{E}_1, w_1)$ or/and $\mathcal{N}_2 = (\mathcal{J}, \mathcal{E}_2, w_2)$, where $\mathcal{E}_1$ and w_1 are determined by the matrix $\mathbf{W}^{(1)} = \mathbf{W}\mathbf{W}^{\mathrm{T}}$, $w^{(1)}_{ij} = \sum_{k\in\mathcal{J}} w_{ik} \cdot w^{\mathrm{T}}_{kj}$ and $\mathbf{W}^{\mathrm{T}}$ is the transpose of matrix $\mathbf{W}$. Evidently the matrix $\mathbf{W}^{(1)}$ is symmetric $w^{(1)}_{ij} = w^{(1)}_{ji}$. There is an edge $(i,j) \in \mathcal{E}_1$ in $\mathcal{N}_1$, iff $N(i) \cap N(j) \neq \emptyset$. Its weight is $w_1(i,j) = w^{(1)}_{ij}$. The network $\mathcal{N}_2$ is determined in a similar way by the matrix $\mathbf{W}^{(2)} = \mathbf{W}^{\mathrm{T}}\mathbf{W}$.

The networks $\mathcal{N}_1$ and $\mathcal{N}_2$ are analyzed using standard methods for one-mode networks.

Another very important application of network multiplication is producing different networks from data tables. A *data table* $\mathcal{T}$ is a set of *records* $\mathcal{T} = \{T_k\colon k \in \mathcal{K}\}$,



Social Network Analysis, Large-Scale, Figure 21
The main two islands in ProjInst

where $\mathcal{K}$ is the set of *keys*. A record has the form $T_k = (k, q_1(k), q_2(k), \ldots, q_r(k))$ where $q_i(k)$ is the value of the *property* (attribute) $\mathbf{q}_i$ for the key k.

Suppose that the property $\mathbf{q}$ has the range $2^{\mathcal{Q}}$. For example: Authors[WasFau] = {S. Wasserman, K. Faust}, PubYear [WasFau] = {1994}, … If $\mathcal{Q}$ is finite (it can always be transformed in such set by partitioning the set $\mathcal{Q}$ and recoding the values) we can assign to the property $\mathbf{q}$ a two-mode network $\mathcal{K} \times \mathbf{q} = (\mathcal{K}, \mathcal{Q}, \mathcal{E}, w)$ where $(k, v) \in \mathcal{E}$ iff $v \in q(k)$, and $w(k, v) = 1$.

Also, for properties $\mathbf{q}_i$ and $\mathbf{q}_j$ we can define a two-mode network $\mathbf{q}_i \times \mathbf{q}_j = (\mathcal{Q}_i, \mathcal{Q}_j, \mathcal{E}, w)$ where $(u, v) \in \mathcal{E}$ iff $\exists k \in \mathcal{K}\colon (u \in q_i(k) \wedge v \in q_j(k))$, and $w(u, v) = \operatorname{card}\big(\{k \in \mathcal{K}\colon (u \in q_i(k) \wedge v \in q_j(k))\}\big)$.

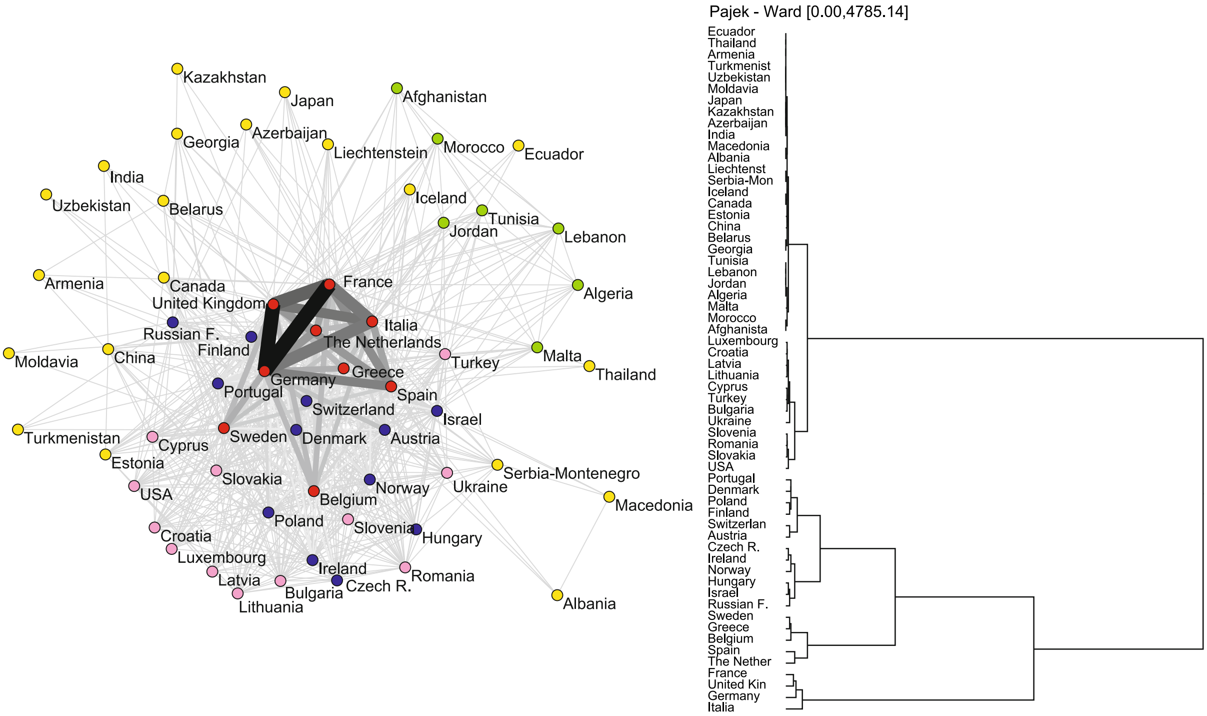
It holds $[\mathbf{q}_i \times \mathbf{q}_j]^{\mathrm{T}} = \mathbf{q}_j \times \mathbf{q}_i$ and $\mathbf{q}_i \times \mathbf{q}_j = [\mathcal{K} \times \mathbf{q}_i]^{\mathrm{T}} \star [\mathcal{K} \times \mathbf{q}_j] = [\mathbf{q}_i \times \mathcal{K}] \star [\mathcal{K} \times \mathbf{q}_j]$.

We can join a pair of properties $\mathbf{q}_i$ and $\mathbf{q}_j$ also with respect to the third property $\mathbf{q}_s$: we get a two-mode network $[\mathbf{q}_i \times \mathbf{q}_j]/\mathbf{q}_s = [\mathbf{q}_i \times \mathbf{q}_s] \star [\mathbf{q}_s \times \mathbf{q}_j]$.

For the meeting ***The Age of Simulation*** at Ars Electronica in Linz, January 2006, a dataset of EU projects on simulation was collected by FAS research, Vienna and stored in the form of Excel table. The rows are the descriptions of projects participants (idents) and columns correspond to different their properties. From this table three two-mode networks were produced: Project – $\mathbf{P}$ = [idents × projects]; Country – $\mathbf{C}$ = [idents × countries]; and Institution – $\mathbf{U}$ = [idents × institutions]; where $|\mathit{idents}| = 8869$, $|\mathit{projects}| = 933$, $|\mathit{institutions}| = 3438$, and $|\mathit{countries}| = 60$.

Since all three networks have the common set (idents) we can derive from them using network multiplication several interesting networks, such as: ProjInst – $\mathbf{W}$ = [projects × institutions] = $\mathbf{P}^{\mathrm{T}} \star \mathbf{U}$; Countries – $\mathbf{S}$ = [countries × countries] = $\mathbf{C}^{\mathrm{T}} \star \mathbf{C}$; and Institutions – $\mathbf{Q}$ = [institutions × institutions]/projects = $\mathbf{W}^{\mathrm{T}} \star \mathbf{W}$.

For identifying important parts of ProjInst network the 4-rings weights were computed and in the obtained



Social Network Analysis, Large-Scale, Figure 22
Collaboration among countries – graph and hierarchical clustering

network the line islands were determined. 101 islands were obtained, 18 of the size at least 5 (see Fig. 21). The two most important islands are: aviation companies and car companies.

In Fig. 22 the collaboration among countries is presented. For dense (sub)-networks we get better visualization by using matrix display. To determine the ordering of vertices we used Ward's clustering procedure with corrected Euclidean distance as dissimilarity measure [21]. The permutation determined by hierarchy can often be improved by changing the positions of clusters in the clustering tree. We get a typical center-periphery structure (see Fig. 23).
