Note that in matrix display some details become apparent, such as the collaboration inside the peripherical group Afghanistan, Morocco, Malta, Tunisia, Lebanon, Jordan and Algeria; or a collaboration of Russian Federation with ex-Soviet republics Turkmenistan, Uzbekistan, Moldavia, Kazakhstan, Azerbaijan and Japan.

Statistical Approach

There are many properties *computed* from the network data that give us different information about it. For example:

Global properties Number of vertices, lines (edges/arcs), components; diameter; centralization; maximum core number, …

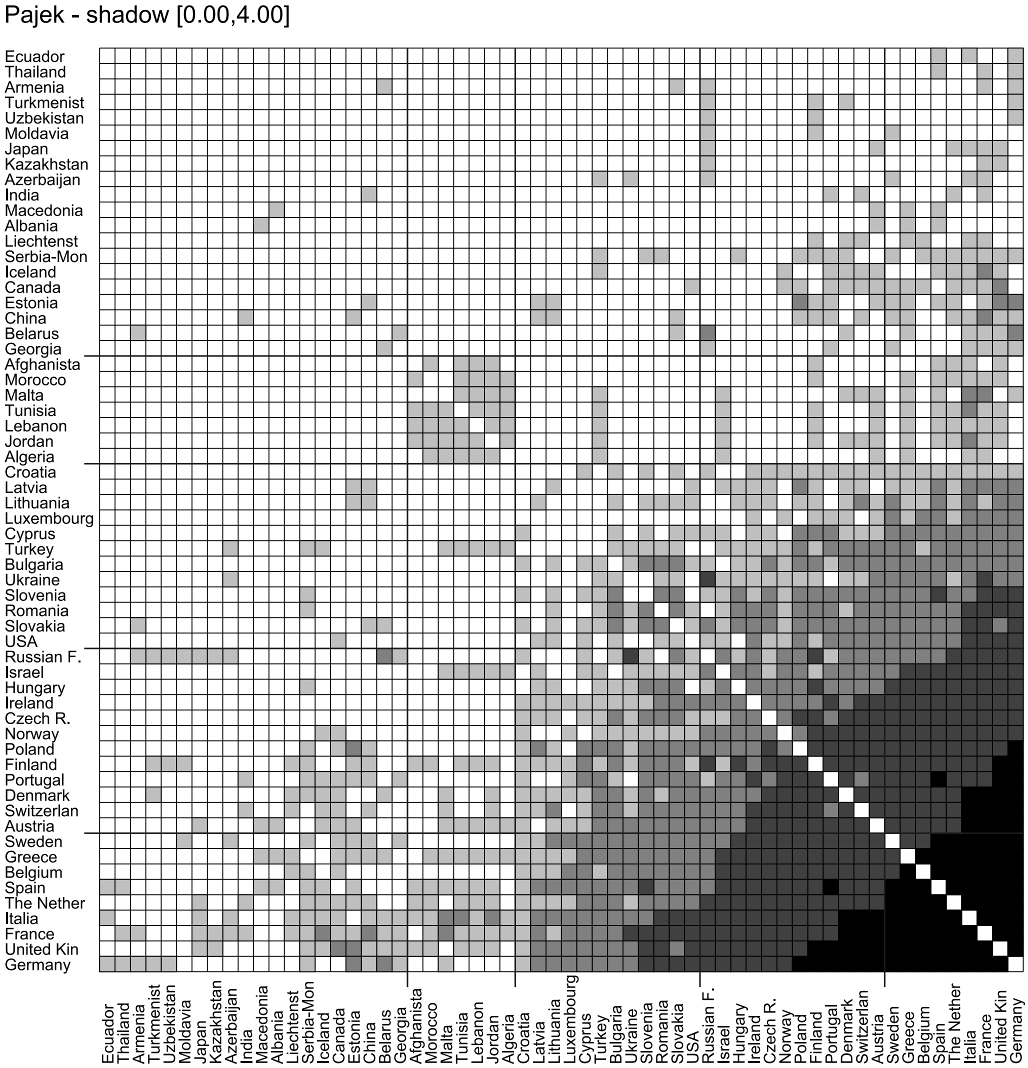
Local properties Degrees, core numbers, indices (betweeness, hubs, authorities, …). Usually we look at their *distributions* or *inspect* the values of interesting elements.

Another interesting task is searching for associations between computed (structural) data and input (measured) data.

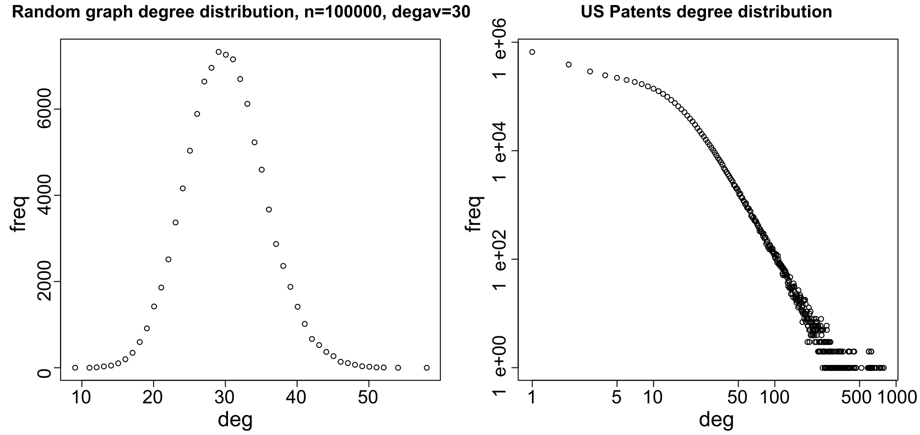
Paul Erdős and Alfréd Rényi introduced in 1959 the notion of random graph in which each pair of vertices is linked with a given probability p. The theory of ER random graphs is well developed (see [15]). Some characteristic results:

- The degree distribution is binomial (in the limit Poisson's) and most of the vertices have degree (very) close to the average degree;
- For $p \geq \frac{1}{n}$ cycles appear in the graph, and soon also the *giant component*;
- For $p \geq \frac{\log_2 n}{n}$ almost all graphs are connected.

Real-life networks are usually not random in the Erdős–Rényi sense. The analysis of their distributions gave new views about their structure.



Social Network Analysis, Large-Scale, Figure 23
Matrix display of collaboration among countries



Social Network Analysis, Large-Scale, Figure 24
Distributions: ER-random and US patents

On the left side of Fig. 24 a degree distribution in ER graph on $n = 100{,}000$ vertices with average degree $\overline{\deg} = 30$ is presented. On the right side a degree distribution for US patents citation network is presented (in log–log scale). Evidently this distribution is very far away from Poisson distribution.

In 1967 a psychologist Stanley Milgram made his experiment with letters. The letter should reach a target person. The persons involved in experiment were asked to send the letter with these instructions to his or her acquaintance that is supposed to be closer (in the acquaintances network) to the target person. The letter was sent from Boston to Omaha. The average length of the successful paths was six – *six degrees of separation*. The average path length on the internet is 19 clicks.

The networks in which the average shortest path length is small are called *small worlds*. Duncan Watts and Steven Strogatz developed in late 90-ties a procedure for construction of (random) small worlds by *rewiring* – an edge is randomly selected and one of its endpoints is attached to same other vertex. After each rewiring step the average length of geodesics is usually decreased because the rewiring creates shortcuts.

Albert-László Barabási from University of Notre Dame in 1998 analyzed several networks and noticed:

- The degree distribution follows the *power law* – the probability p_d that a vertex has a degree d equals to $p_d = cd^{-\gamma}$. In a log–log scale diagram it is represented by a line.
- In a network there exist some vertices with *large degree* (very improbable in ER graphs). These vertices link the network into a single component.

It turned out that most of real life networks (persons – e-mail, phone calls, sexual contacts (drug users, AIDS), collaboration; movie actors – playing in the same movie; proteins – interactions; words – semantic relations; ...) have such characteristics. Because for these networks their degree distribution has no natural scale they were named *scale-free* networks. For a discussion about the notion of scale-free network see [33].

The following was the first explanation (Barabási) of scale-free nature of many real-life networks:

- These networks are growing.
- In this process new vertices are added and linked with new edges to already existing vertices. The random selection of vertex to which a new vertex is attached is not uniform but follows the *preferential attachment* rule – the selection probability is proportional to the degree of a vertex.

Based on this model it can be shown the following:

- The degree distribution is the power law.
- The average length of geodesics is $O(\log n)$.
- These networks are resilient against random vertex or edge removals (random attacks), but quickly become disconnected when large degree nodes (Achilles' heel) are removed (targeted attacks).

Mark Granovetter noticed in 1973 that in social networks groups appear linked with *strong ties* [26]. They link in larger networks with *weak ties*. Also in other real-life networks vertices often form groups – the clustering coefficient is larger than in ER networks.

Several improvements and alternative models were proposed that also produce scale-free networks with some additional properties characteristic for real-life networks: copying [31], combining random and preferential attachment [37], R-mat [18], forest fire [32], aging, fitness, nonlinear preferences, ...

There are several applications of the scale-free networks theory. For example searching (Adamic et al. [2]) and spreading of epidemies (Barthélemy, Barrat, Pastor-Sattoras, Vespignani, Complex Networks Collaboratory).

For general overviews see [4,22,35,36].

Future Directions

In 2005 the support for *multi-relational* networks was introduced in Pajek. Combined with *temporal* networks it enables analysis of new kinds of networks – such as KEDS networks (*Kansas Event Data System* or *Tabari*). These networks are usually small in terms of vertices but can be (very) large in terms of lines – different interaction events among actors.

The last developed approach for analysis of large networks is adaptation of hierarchical clustering with relational constraints based on Ferligoj and Batagelj [23] to large networks. The basic idea to get a fast algorithm is to compute the dissimilarities between units (vertices) only for the linked pairs of units [11]. This approach is one of the possible approaches to analysis of spatial networks.

There are still several fields of social network analysis for which efficient approaches to deal with large networks have to be developed such as blockmodeling, probabilistic models, ...

In the near future new versions of network analysis software will appear using very large computer memories enabled by the new 64-bit computer architecture. A special challenge is development of methods and software for analysis of huge networks.

Article Outline

Glossary

Algebraic models Approaches to network analysis that use algebraic methods for studying sets of points to produce positional analyses such as blockmodels.

Agent-based computational models Models of dynamic systems that focus on agent-level properties, seeing system level changes as consequences of the interaction of rule-following agents.

Balance theories A number of related theories concerning both the psychological state of consonance or dissonance found in a person's ideas and affects and the equilibrium or disequilibrium of one person's relations with another. The exploration of the mathematical principles of these states.

Blockmodeling An approach to positional analysis that uses algebraic methods to construct image graphs in which blocks represent connections or the absence of a connection between sets of points.

Graph theory A basic method for the analysis of networks in which the relational properties of the members of a set are seen in terms of points and lines. Pairwise connections among points are used to generate and explore system-level phenomena such as density and centralization.

Diffusion processes The processes through which innovations and other changes spread through a network, the flow and pace of change being determined by the structure of the network.

Scaling methods Geometrical techniques for displaying and analyzing a network as a mapping of points located in a multidimensional space.

Small-world models Network models based on graphs of relatively low density but high reachability. Originated in psychological experiments on the communicative effectiveness of interpersonal acquaintance.

Definition of the Subject

The formal idea of using a network as a tool of analysis originated in electrical engineering as a way of envisaging and modeling the flows of electricity through national power grids and in domestic and industrial settings. It was merely a short step to the application of the idea in civil engineering, where water supply, drainage, roads and railways could all be regarded as networks. Much later this idea was central to electronic and computer systems engineering. Parallel methodological innovations had occurred in areas of physical geography, where river drainage systems had been envisaged as networks of flows that could be modeled in mathematical terms, and this led to interest among human geographers about the potential for applying the idea. The idea that social relationships could be seen as forming a network or reticule of relations that are capable of analysis in formal, mathematical terms suggested novel ways of considering social phenomena and promised insights that were unavailable through alternative approaches.

Social network analysis first emerged as an approach distinctive from statistical analysis within anthropology, social psychology, and sociology. It went on to influence theoretical and methodological developments in many other areas of social sciences. In all these areas, researchers took up mathematical models from graph theory, which they used to investigate structures of relations. Researchers who were working in the area of social network analysis soon began to broaden their framework of analysis by exploring the implications of other mathematical models, such as algebraic set theory, scaling methods, and statistical and stochastic methods. In this way, social network analysis became linked to the larger intellectual debates going on in other areas of the natural and social sciences where these same methods were being drawn upon, and a number of social network analysts have contributed to the development of these and other mathematical models. Social network analysts have promoted and undertaken the application of these ideas in many areas of sociology, most notably in economic sociology, political sociology, the study of family and kinship, community studies, the investigation of world systems, and numerous other areas.

Investigation into social networks has now become far more fashionable than ever before. However, it is in the nature of intellectual fashions that much of the new interest comes from those who are least familiar with the area. This is certainly true of social network analysis, where many newcomers were unaware of its long history. They were influenced, in particular, by the exaggerated claims to intellectual novelty that were being made by some physicists who have advocated random-network and small-world models as the basis of what they call a "new science of networks". Indeed, many people have assumed that social network analysis began de novo with these models and they know little about the applications already made using other models. Despite their exaggerated claims, the work of the physicists has provided us with some powerful new models, and these have had a major impact beyond the specifically social sphere – this fact will be apparent from considering chapters in a number of the sections in this *Encyclopedia*. However, the physicists have not provided a complete replacement for social network analysis, as they sometimes imply, but have offered a broadening of its range and concerns.

This overview article will discuss the development of social network analysis and will sketch the various mathematical models that have been used to explore the nature of complex social systems. It begins with an overview of the history of social network analysis and its main applications. This is followed by a consideration of graph theory, the earliest and principal approach to the study of social networks. The following sections look at later and more advanced methods: algebraic methods and blockmodeling, scaling methods and visualization techniques, statistical methods, agent-based computational methods, and finally the small-world methods of the physicists. The latter discussion will place the new social physics in the context of earlier discussions and it will show the variety of mathematical models that have a part to play in contemporary social network analysis. The various methods and models are considered in outline and without technical detail. The various specialist chapters included in this and other sections of the Encyclopedia cover these methods in greater detail.

The Development of Social Network Analysis

Social network analysis has a long history, though it appeared under its specific name only far more recently (see Chap. 2, p. 23 in [51]). Although structural thinking was central to classical sociology, the intellectual roots of a specifically network perspective can be traced back to those sociologists of the late nineteenth and early twentieth centuries who used the idea of a network of relations as a metaphor for understanding social relations as *structures* of relations. Georg Simmel and other German sociologists, in particular, wrote extensively on the "interweaving" of actions to form complex configurations or "webs" of connection. Their metaphorical usage of the idea drew explicitly from the textile industry and its ideas of the weft and warp of woven fabrics. The first proper usage of the actual word "network" in a sociological context, however, was in the work of the anthropologist Alfred Radcliffe-Brown [45], who used it to suggest a more formal focus for structural analysis. Simultaneously with this, a number of social psychologists working in the area of child study and field theory began to construct diagrams of social relations that they gradually formalized as "sociograms" to show the chains of positive and negative connections that they were finding among the individuals in their experimental studies.

The crucial social psychological work on social networks was that of the psychotherapist Jacob Moreno [41]. Following his arrival in the United States he began to combine psychodrama with studies of the influence of friendship choices on personality development among schoolchildren. His key innovation was to make use of sociograms to depict the friendship patterns that he was able to discover within small groups such as a school class or a neighborhood peer group. Moreno made many intellectual contacts, most importantly with the *Gestalt* psychologist Kurt Lewin, who had himself recently migrated to the United States. Moreno and Lewin exchanged many ideas – and the nature of the exchange became a matter of contention between them in later years. Lewin soon began to move towards a more social form of psychology that stressed the importance of looking at organized patterns of group relations in particular spheres of activity as forming systemic wholes. Such wholes could be seen, by analogy with electromagnetic and gravitational fields, as social fields through which influences are able to flow from one area or part to another. The aim of Lewin's field theory was to map and to explore the "dynamics" of these fields of interpersonal influence.

Both Moreno and Lewin used diagrammatic representations of social relations, but it was Moreno who invented the classic form of the sociogram. A sociogram consists of points, representing individuals, and lines, representing the social relationships among them. Moreno argued that these patterns of points and lines – later described more formally as "vertices" and "edges" – could be described as "social configurations" in which could be charted such things as the direction of friendship choices and their intensity. This work came to be referred to as "sociometry", and a journal with that name was founded in 1937. Through the work published in this journal, the ideas of Moreno and Lewin on configurations of social relations in small groups gradually gave rise to a more mathematically oriented approach that went under the name of "group dynamics". It was in this school of thought that ideas from graph theory – first formulated by René König [33] – began to be employed from the late 1940s, these ideas becoming the basis of a more formal and rigorous study of the properties of the social networks of small groups. By treating the sociogram as a graph, it proved possible to chart dyadic, triadic, and more complex structures and to analyze the states of "balance" and imbalance that existed among positive and negative relations within each network [3,13,28].

It was during the 1930s and 1940s that anthropological and sociological work also began to move in a similar direction. In 1929, the anthropologist W. Lloyd Warner, a former colleague of Radcliffe-Brown, had moved to Harvard University in order to work with the psychologist Elton Mayo on a series of experimental studies of work behavior. Their aim was to use the techniques already employed by anthropologists in studies of small tribes and villages, but to carry out new studies of small groups in the factory and office settings of urban societies. Influenced also by the early system theory constructed by the physiologists Lawrence Henderson and Walter Cannon, they began a series of empirical studies at the Hawthorne electrical works in Chicago. The so-called Hawthorne studies became a milestone in social research – not least because of their significance in developing the idea of the social network.

The Hawthorne studies [47] had begun as management-run investigations into worker efficiency and its relationship to the physical conditions of work. The early experiments examined such things as the consequences of changes in levels of heating and lighting and the provision of work breaks. The studies turned from physical to social factors under Warner and Mayo, and Mayo famously reported that the crucial factor in increasing worker productivity had been their involvement in the experiment itself. The paradoxical results showing increased productivity even when physical conditions worsened were interpreted as showing the high levels of satisfaction that workers felt simply from being part of the management experiment: it was the first time that anyone from management had shown any direct interest in them. Adopting more anthropological methods of observation in the bank wiring room, the researchers documented the gradual building of informal work group relations and forms of social solidarity among those in the experimental group. These informal relations ran in parallel with the formal relations of the managerial organization chart, and the researchers used sociograms to chart the informal social networks among workers.

The sociograms drawn by the Hawthorne researchers allowed them to identify "cliques" and other sub-groups within the larger group, and Warner went on to investigate this kind of group structure further in a series of investigations into community relations in the New England city of Newburyport (referred to as “Yankee City” in [59,60,61,62]), the Mississippi city of Natchez (“Old City” in [15]), and the Indiana city of Morris (“Jonesville” in [58]). In this work, Warner and his colleagues used network ideas to explore the formation of cliques, “crowds”, and “circles” among those they studied, and they examined these in relation to the more formal structures of economic and political life. Their investigations identified these social circles through a rough and ready use of the Venn diagrams of set theory and the methods of matrix display. Using these simple methods, they were able to identify such things as class divisions in clique membership and the effects of ethnicity on the structure of network relations.

It was during the late 1940s and early 1950s that a significant consolidation of the social network approaches that had been developing began to be forged. It was to be another decade, however, before a recognizable tradition of social network analysis was properly established. George Homans, a colleague of Warner and Mayo at Harvard, attempted a synthesis of the anthropological and sociological ideas as the basis of an alternative sociology to the system theory of Talcott Parsons [30]. Homans re-analyzed some of the earlier data using rudimentary techniques of matrix rearrangement, his aim being to bring out the clique structure more clearly. Homans’ method of manually “reshuffling” the 0s and 1s in a matrix to bring out blocks of high and low density was a pioneering move towards the more formal methods of blockmodeling that developed during the 1970s. Homans himself interpreted his data on social relations in terms of the frequency and duration of the relationships involved and went on to develop rational choice models of action to explain the findings [31].

The early 1950s also saw the development of more systematic anthropological work on social networks in Britain. The Manchester University anthropologist Max Gluckman established the Rhodes-Livingstone Institute in Northern Rhodesia (now Zambia) to study African social structures in village and town settings. An early associate of the Institute was John Barnes, who undertook independent fieldwork in Bremnes, Norway. It was here that he recognized the importance of the network metaphor – famously while observing the repaired fishing nets of the local fishermen – and he advocated the study of whole communities as networks of points and lines [2]. Elizabeth Bott, a student of Lloyd Warner and then working at the Tavistock Institute (associated with the Michigan Research Center for Group Dynamics), took up this metaphor in her own investigations into the kinship networks of London families [6,7]. Because of her position at the Tavistock, she was encouraged to link this to the work of Moreno and to the early field theory. This work was systematized by Siegfried Nadel and Clyde Mitchell. Nadel [42] aimed to establish a mathematical basis for social network research, but his early death prevented him from carrying this further. Mitchell [39], however, made the network idea the basis for a series of studies at the Rhodes-Livingstone Institute and set out a number of conceptual innovations – density, multiplexity, durability, direction, reachability and so forth – that echoed and took further the ideas of Homans.

By 1969, then, a clear body of network ideas had been established. in anthropology and social psychology, and this was coming to be organized around the mathematical theory of graphs. It was at this point, however, that an alternative framework began to develop in the United States, and this eventually subsumed the earlier approach in a comprehensive framework of social network analysis. John Boyd, François Lorrain, and Harrison White had begun to explore some aspects of Lévi-Strauss’s analysis of kinship structures using algebraic set theory [72], while Edward Laumann [34] and Joel Levine [35] began to use multidimensional scaling to investigate social structure. White moved to Harvard University and brought together a strikingly original group of young researchers who were interested in using mathematical methods to explore aspects of social networks and social relations.

One of the earliest products of this group was Mark Granovetter’s [26,27] influential argument about “the strength of weak ties” – the first, and most important, of the counter-intuitive results to come out of this more sophisticated form of network analysis. Granovetter’s argument held that the chances that a person will receive useful information from those in his or her social network is greater when a person has acquaintances rather than close and intimate friends. One’s intimates tend to have access to the same pool of information through their dense pattern of mutual connections. Acquaintances, on the other hand are connected to quite diverse and distant social networks and so can communicate a much greater range of information. Paradoxically, then, it is the weak acquaintanceship ties that are the “strongest” or most important carriers of information. Having a small number of acquaintances can be more useful in a job search than having a large number of intimates.

The ability of White’s group to pursue this program of social network analysis was made possible by the advances that were being made in computing technology and that were then becoming available in software programs. Earlier work had used manual techniques and so had been limited to relatively small groups. Mainframe computers and Fortran programming made possible the analysis of much larger data sets and the use of more powerful mathematics. As the members of the Harvard group spread to Graduate centers across North America, their work became a major influence within sociology and encouraged the global spread of formal social network analysis. Barry Wellman and Steven Berkowitz were particularly active in setting up the *International Network for Social Network Analysis* (http://www.insna.org/) and this became the basis for the founding of the journal *Social Networks* and for their own powerful syntheses in social network analysis [4,71] (see also [32]). Powerful methodological ideas and sociological applications were developed in the United States by Ronald Breiger, Ronald Burt [10,11], Patrick Doreian, and others. Social network analysis was pursued in Canada by Barry Wellman and Peter Carrington, by John Scott in Britain [51], by Rob Mokken and Frans Stokman in the Netherlands (the developers of the *Gradap* program used in [29]), and by Charles Crothers and Malcolm Alexander in Australia. Stanley Wasserman led the way in producing a standard textbook for social network methods [64] and other consolidating texts appeared [24,37]. By the 1990s, social network analysis had become one of the most strongly established research specialisms in Sociology, with a strong intellectual base, advanced methods and texts [12,18], and a comprehensive range of exemplary studies.

During the 1990s, however, a rather paradoxical development occurred. The exhaustion of many of the conventional research programmes in physics had led a number of theoretical physicists to search out new areas in which to apply their theories. In 1998, Duncan Watts and Steven Strogatz published a paper [68] that revisited some of the ideas on random networks that had grown out of Stanley Milgram's work on "small worlds" [38,56]. This caused a great stir among physicists and led Albértó-Laszlo Barabási to propose the building of a "new science of networks" with the potential for applications across the social sciences [1]. In apparent ignorance of the prior existence of social network analysis, he claimed that it was only during the 1990s – and thanks to physicists' models – that investigators had become aware of the fact that social networks have structures and show orderly patterns of development.

This claim startled and dumbfounded most sociologists working on social networks, for whom the existence of social structure was a fundamental axiom. They resented the ignoring of what they had already achieved and the misrepresentation of sociological understandings of the social world that it involved. Despite its shaky historiography, the arguments of Bárabasi and other social physicists had a major influence outside the discipline and among those in sociological specialisms that were, so far, untouched by social network analysis. Works by Duncan Watts were particularly important [66,67]. The new social physics of networks was especially well-received in the popular and scientific press and resulted in a number of popularizing works (see, for example [8]).

It is, nevertheless, true that the work of the physicists has certainly been responsible for a substantial growth of interest in social network analysis during the last decade. The reason for the appeal of this new work lies in its promise to provide a dynamic model of social networks, rather than the more static ones of the past. While the claim that social network analysis lacks a concern for dynamic processes is, perhaps, overstated, it is certainly the case that the new methods do seem to offer the possibility of a nuanced account of structural change in social networks. While much of the work is still presented without any recognition of prior sociological contributions, sociologists, for their part, are beginning to discuss how these ideas might enrich social network analysis. The arguments about network dynamics are, in fact, converging with some of the work on agent-based computational models already being undertaken within Sociology.

A very important issue that has arisen in the use of the mathematics of graphs is that of whether it provides a substantive *theory* or simply a *method* of analysis. Some researchers hold that the mathematical theorems that can be derived from graph theory can be directly translated into substantive theorems concerning particular domains of application. According to this point of view, sociological laws can be derived directly from mathematical laws. Those who see social network analysis as a method – perhaps a majority of those working in the area – hold that mathematical theorems provide simply the formal constraints to which social processes must conform: a knowledge of mathematics does not, in itself, obviate the need to study social phenomena empirically in order to understand the implications of these theorems for particular types of social relations.

The remainder of this overview article will set out the main intellectual strands within contemporary social network analysis. These areas are discussed in greater detail in the specialist articles in this and other sections of the *Encyclopedia*, and their mathematical bases will not be presented in any detail. The overview will concentrate on the general principles involved in each area and on the ways in which they relate to each other.

Graph Theory and Ideas of Balance

Graph theory, as already noted, is that branch of mathematics that had the earliest influence on the development of social network analysis (see ► Social Network Analysis, Graph Theoretical Approaches to). In graph theory, a graph or network is simply a collection of points (vertices) connected by lines (edges). Graph theory comprises a set of mathematical axioms and derivations that describe the actual and potential patterns formed by these points and lines. This basic model of a graph can be applied widely in many substantive domains: electrical wiring networks, river drainage networks, road and transportation networks, and computer networks have all been investigated using graph theory.

A basic graph consists of simple points and lines, but the lines in a graph can be assigned positive or negative attributes, directions, or numerical values, and the attributes of points can be recorded. Complex mathematical theorems can be constructed for each of the different types of graph. Some of the earliest work to use these ideas focused on the question of "balance" in graphs. Balance is a term that describes the pattern of signs and numerical values in a graph in terms of the reciprocity and transitivity of the relations. A graph of friendship relations, for example, might be unbalanced if two people who each like one another have opposite relationships to a third person. If, on the other hand, all three people liked one another with a similar intensity, the graph would be balanced. Balance theorists have analyzed complex graphs in terms of such "triads" of relations. By producing a census of triads and computing the balance or imbalance in each triad, it is possible to arrive at a calculation of the overall balance in the graph as a whole. Such ideas of balance have generally been assimilated to the idea of equilibrium analyzed in classical mechanical models. A graph that is in a state of disequilibrium, therefore, will be marked by tensions and stresses that push and pull it towards a state of equilibrium. Where a social network is mapped as an unbalanced graph, it can be hypothesized that the participants in the network will experience these stresses as push and pull factors on the social relations that they maintain with each other. The overall network can, therefore, be seen as a dynamic field of causal influences.

Much of the work that has been carried out using the idea of balance has considered focal actors to be the points of reference, and much of the early work that applied graph theory pursued such "ego-centric" ideas. From this point of view, the chosen actor is seen as a point that is "adjacent" to certain other points that comprise its immediate "neighborhood". Each point can, therefore, be given an adjacency score. Actors vary in terms of the number of others with whom they are connected – the number of friends, number of enemies, number of political associates, and so on. People or groups may, therefore, be more or less connected into their neighborhood of others and so they may be compared in terms of their adjacency scores. The early work of Moreno had identified school children as sociometric "stars" or "isolates" according to the number of friends they had. The stars were the especially popular class members, while the isolates had few or no friends in the class. The adjacent others may have more or fewer connections among themselves: my friends may or may not be friendly with each other, my business associates may or may not do business with each other, and so on. Thus, a basic ego-centric measure is the "density" of an actor's neighborhood. This measure is the number of links that actually exist among immediate contacts expressed as a proportion of the number of possible contacts that they could, in principle, sustain among themselves. Where a large proportion of connections intersect, the actor's neighborhood has a high density.

Researchers recognized fairly early on the importance of going beyond such ego-centric measures to more global or socio-centric measures of the network as a whole. In considering a village, for example, a researcher may want to know not only the distribution of individuals according to the densities of their friendship relations, but also the density of friendship connections in the village considered as a whole. Such measures of density would indicate the state of social cohesion or social solidarity in the network. The basic ego-centric measure of density can easily be extended to the network as a whole – if appropriate data are available – by computing the proportion of possible links within the village that are actually established. Calculations of density can also be made for large social networks that must be studied through sample investigations. If it can be assumed that the sample is representative, then the distribution of adjacency scores for sample members can be used to compute the overall density of the network.

Density has become one of the most widely used measures in studies that employ graph theory and it has been used to indicate the changing character of social solidarity and the state of "community" that exists in a group. Wellman's work [69,70] has demonstrated that growing amounts of geographical mobility have not led to a commensurate decline in community but have resulted, instead, in the transformation of patterns of solidarity. People in large cities, he shows, are likely to interact less frequently and less intensely with numerous others on a day to day basis as they move to live and work in other parts of the city. Thanks to cars, the telephone, and the internet, however, they are able to maintain more connections, but on a less frequent and less intense basis.

Particularly important measures of global connectedness within a graph are based on the "distance" from one point to another and the corresponding "centrality" that points have in the overall pattern of connection. The distance between two points in graph theoretical terms is simply the number of lines that must be traversed in moving from one point to another. Thus, two adjacent points stand at distance 1 from each other, while two points that are connected through a common neighbor are at distance 2 from each other. It is generally assumed that influence and communication within a social network attenuates with increasing distance. Nevertheless, the rate of attenuation and the particular level of distance that it is reasonable to regard as constituting a socially significant connection are quite variable from one type of network to another. Distant friends of friends, for example, may be insignificant, while distant financial donors to a political party or candidate may be more significant. The criteria of significance, it will be apparent, rests always on a sociological judgment and never on a mathematical measure alone.

The principal use of distance measures has been to assess the relative centrality or peripherality of points in a graph. A point whose average distance to all other points in the graph is low can be regarded as occupying a central position in the network as a whole, while a point with a very high average distance from all others is peripheral to it. Applications of these ideas in studies of interlocking directorships – the lines created when company directors sit on two or more company boards – have made great use of measures of centrality. They have to documented the existence of "hubs" within large spheres of adjacent companies. Such hubs – typically banks or other financial institutions – are the focal centers for business decision-making and for the allocation of credit at the level of the intercorporate network as a whole [50].

Users of graph theory have often distinguished between measures of centrality based on overall "closeness" and an idea of centrality based on "betweenness" [22]. A betweenness measure of centrality is one that is based on a calculation of the probability that any particular point lies on a path between any two other points. This latter measure can be used to operationalize the idea of the broker or intermediary, a person who may not be central in the network as a whole, but is an important point of contact between parts of the network.

A further extension of the ideas of distance and point centrality has been the attempt to measure the overall centralization of the graph as a whole. A measure of centrality grasps the extent to which a whole graph is organized around a small number of central points that constitute its structural center.

The early work of Warner and his associates was concerned with the formation of cliques within networks. Their use of this idea of the clique was, however, relatively loose and essentially commonsensical. Developments in graph theory have since made possible the construction of a number of structural concepts for sub-graphs that are both precise and distinct from each other. The most straightforward of these sub-graph concepts is that of the "component". A component is a maximally connected sub-graph, the set of all those points that are connected, directly or indirectly, by a continuous sequence of lines. A graph will typically consist of a number of such components, together with a variable number of completely isolated points. Component boundaries may, therefore, indicate the boundaries to the flow of communication, influence, or resources within the corresponding social network. A mapping of the size distribution of components will show the extent to which these flows are fragmented. It is also possible to map the internal structures of the various components by taking account of the sign, value, and direction of the constituent lines in order to uncover any blockages or distortions in the flow of communication, influence, or resources. Using a measure of value, for example, the nesting of intensely connected components within more weakly connected components can be disclosed. The "slicing" techniques available in many software packages allow contour maps of component structure to be built, the resulting map showing the peaks of intensity and the troughs or valleys that separate them.

Component structure can also be studied through an investigation of the "cycles" that it contains. A cycle is a path that returns to its own starting point, and a cyclic component consists of a set of intersecting cycles. A component may consist of a number of such cyclic components that are connected only through non-cyclic "bridges".

Cliques, as defined in graph theory, are sub-sets of points in which every possible pair of points is connected at a specified distance. Thus, a 1-clique is a sub-set of point in which all points are directly connected to each other. A 2-clique, on the other hand, is a sub-set of points that are connected through common neighbors. There is, therefore, a whole family of clique concepts based on varying distance measures. These are generically referred to as n-cliques and any large component in a graph will typically consist of many overlapping *n*-cliques, as well-connected points will tend to be members of large numbers of cliques. An analysis of cliques must always specify the value of n that will be used. Once more, the choice of a value for identifying cliques is not a matter that can be determined on mathematical grounds alone. The investigator must always decide on the sociological meaning – if any – that can be given to particular values of n.

This basic idea of the clique has been extended into a variety of related ideas, most notably called clans, clubs, plexes, and circles, each of which differs according to the precise criterion that defines sub-set membership. These various sub-graph and sub-set concepts are particularly important in studies of diffusion processes in social networks as they define the "obstacles" and barriers that prevent the smooth diffusion of ideas or resources. This was the insight that lay behind Granovetter's [26] recognition of the strength of weak ties: it is the possession of "weak" connections that bridge a person into sub-graphs that would otherwise be unable to transfer information to the person.

Most uses of graph theory in social network analysis have employed one-mode data. That is to say, they have transformed the initial bipartite or two-mode data into a simpler form. An initial incidence matrix showing, for example, the memberships of people (as columns) in particular organizations (as rows) is transformed into a column-by-column adjacency matrix of people and a row-by-row adjacency matrix of organizations. Thereafter, the analyses of the people and the organizations proceeds separately (see ► Social Network Analysis, Two–Mode Concepts in). Recently, however, attempts have been made to develop graph theory approaches to the analysis of two-mode data, treating the bipartite data as if it were one-mode data. The adjacency matrices are, in effect, seen as sub-matrices of a larger adjacency matrix in which people and organizations, for example, comprise *both* the columns and the rows. Once the larger matrix is generated, many of the conventional graph theory measures and visualization techniques can be applied to it. Not all such measures, however, are sensibly or usefully seen in two-mode terms.

Many of the more complex graph theoretical measures for whole graphs can be difficult, if not impossible, to use in large-scale networks where there is incomplete data. This is typically the case where a sampling methodology has been followed (see ► Social Network Analysis, Estimation and Sampling in).

Some network parameters can be estimated with sample data. If information on the neighborhood or neighborhood density of individuals are collected from a sample, for example, it is straightforward to compare estimates of these measures for the whole population. It would also be possible to estimate the density of the network as a whole from such sample data, as density is an adjacency-based measure. So long as the normal questions of sample size and representativeness are considered, such measures pose few problems. Matters are more complex, however, with many global network measures, where the structure of relations is more likely to be lost in the process of sampling. It is, for example, impossible to measure the number of separate components in a network using sample data. Some ingenious methods of estimation have, however, been suggested as being useful for such measures, so long as appropriate sampling designs are used.

An alternative to sampling is the adoption of explicit methods of data reduction that allow large-scale networks to be analyzed more easily. As Vladimir Batagelj shows in ► Social Network Analysis, Large-Scale, it is especially useful to have methods of visualization for such networks. The *Pajek* program [16] was designed specifically for this purpose. Large networks are those with thousands, or perhaps millions, of points and the computing time required for such networks has been a barrier to studying them. Batagelj uses recursive decomposition methods to divide a large network into several smaller ones. This can be achieved by the clustering of points or lines, compressing them into compound points or lines. Varying forms of reduction can be achieved by adopting different criteria for reduction: for example, collapsing all members of a component onto a point, or collapsing all members of a clique into a single point. Such reduced graphs can then be analyzed with the familiar techniques of graph theory. He also introduces a number of concepts specific to reduced networks. The concept of an island, for example, refers to peaks at specified cut-off levels on a measure of the properties of the compared points or lines.

Diffusion Processes

A key issue in sociological studies of influence has been the ways in which innovations and other social changes are diffused through the social relations that people have established. Similar processes of diffusion were investigated in geography and anthropology, and a number of investigators began to explore mathematical models of diffusion, that had already been begun to be applied in epidemiological studies of the spread of disease through a population [48,49] (see also [14]). Everett Rogers documented the existence of an S-curve describing the pace of innovation: a slow initial uptake was followed by more rapid adoption, and then a tailing-off as diffusion produced a relative saturation of the population and correspondingly fewer people available to take up the changes. The key parameters were the speed of the initial take-off and the speed of subsequent adoption.

Contemporary approaches to diffusion [57] begin from measures of spatial autocorrelation to investigate the speed of the spread of innovations (see ▶ Social Networks, Diffusion Processes in). Spatial autocorrelation is the correlation of a variable with itself measured spatially. That is, its dependence on neighboring points. Such models measure the extent to which changes spread through contiguous regions of space. Within networks, this idea is generalized to analyze contiguity in social network terms. It is in this way that a "contagion" model of social influence can be operationalized. Network parameters can be weighted in various ways in a model, taking, for example, direct links as more significant than indirect links, and predictive conclusions about the temporal and spatial spread of changes can be drawn. As Tom Valente shows, event history analysis has been used to allow more sophisticated temporal measures of diffusion, and this has become a key area of innovation within the area of diffusion studies. Such work is also now developing closely with the agent-based computational models discussed below.

Algebraic Models and Blockmodeling

The early work on network structures that was carried out by Harrison White and his associates [36,72] made use of algebraic ideas to model graphs of social relations. Their argument was that algebra provided a means for analyzing the properties of sets of points. This work laid the basis for what came to be known as blockmodeling. This is a way of exploring the relations among structurally defined positions in social networks, the positions being understood as "blocks" or sets of points with certain common relational attributes that make them, in crucial respects, structurally equivalent to each other [5,73]. This form of positional analysis has subsequently been elaborated and enlarged in a variety of ways, resulting in the production of a whole family of models for network structure.

An algebraic representation of a social network involves identifying a set of points that is defined by the specific relation that unites its members [43] (see ▶ Social Networks, Algebraic Models for). Thus, a network is seen as consisting of a set of ordered pairs. This approach can easily be generalized to explore situations in which more than one relation is involved and units can be understood as connected into multiple networks, each of which is defined by a particular type of relationship. From this point of view, a multiple network is a set of sets, and each set is defined by a "primitive relation" or generator that contributes to determining the overall network structure. Therefore, the individuals or groups that comprise the points in a social network are treated as standing in compound relations to each other. Paths in the network may be composed from lines that represent a variety of different relations. The basic step in identifying the structure of such a complex network is the multiplication of the initial binary relations to convert them into binary compound relations. The structure of relationships among all possible paths in a multiple network is termed a partially ordered semigroup and this comprises the underlying relational structure of the network. As with graph theory, this algebraic method allows such global properties of social networks to be linked to the local, egocentric properties of specific units within the network. Thus, the immediate environment of any particular member of the network can be seen as a "local role algebra" that represents the role set of the focal individual or group. Such an algebra defines the vectors that slice through the whole network and so summarize an ordering of the constituent relation vectors in which the individual point is involved.

The basic elements of blockmodeling are based on the ideas first set out by the anthropologist Nadel, who held that social network analysis must take account of social positions and their associated roles rather than simply with individuals [42] (see ▶ Positional Analysis and Blockmodeling). Graph theory is especially well-suited to the identification of individual-level phenomena and the characteristics of the social groups formed by individuals. It is much less well-suited to the identification of structural positions. For example, a large number of individuals may each occupy the socially determined position of "father", but a graph theoretical analysis of each individual male adult's connections to children will not easily identify this shared social role. This is because graph theory searches for clusters of connections based on distance measures. Blockmodeling, on the other hand, starts out from a recognition that individuals that occupy the same social position are "equivalent" or "substitutable" in some way. Thus, each father relates in similar ways to particular children, but the fathers do not all relate to the *same* children. Positions and their associated roles are enduring structural regularities among sets of points and differ markedly from cliques, components and other such subgraphs.

The typical strategy for constructing a blockmodel is to apply an algorithm to a bipartite, two-mode, matrix of individual-level data in order to reduce it to an "image graph" that comprises blocks of equivalent points. Though typically employing two-mode data, blockmodels can be produced for one-mode data and, with greater difficulty, for three-mode data. Simple binary data have been most widely used in blockmodeling, with valued data being handled by slicing procedures that partition the matrix into 1s and 0s on the basis of a chosen threshold of significance. Attempts are being made, however, to extend blockmodeling directly to valued data. Approaches to blockmodeling vary from each other in terms of the particular criteria that are used in the algorithm. The earliest approach – the CONCOR method of White and his associates – used iterated correlation measures to produce the image graph. In this method, repeated correlations computed on the rows and columns of the initial matrix converge towards a rearranged matrix that shows blocks of 0s and blocks of 1s. The blocks of 0s – "zero-blocks" – are the structural holes in the network that divide the various social positions (the blocks of 1s) from each other. Later work associated with Ronald Burt [9,10], has used simpler clustering approaches that are based on Euclidean distance measures calculated from path distances among pairs of points. Burt's method also allows the construction of an image graph for the identification of blocks of equivalent positions, and Burt terms this a social topology.

Applications of these ideas to intercorporate business connections has shown that blocks in networks of shareholdings and interlocking directorships can be seen as comprising structurally similar agents within the economy. The blocks uncovered in such an analysis are the dominant investors and subordinate enterprises that stand in similar relations to each other but may have few mutual or reciprocal connections among themselves. They are social positions but do not necessarily constitute social groups. The key text on blockmodeling has been produced by Doreian and colleagues [19].

The construction of an algebraic representation of a social network comprises a depiction of the "deep structure" of the network in the sense that was intended by Lévi-Strauss and many structuralist writers. The method allows a formal construction and representation of the deep structures that have, more typically, been identified through more purely interpretative means. As in these structuralist approaches, a key aim of algebraic network analysis is the identification of isomorphic subgroups and local role algebras across different empirical networks that can be compared for commonalities of structure. This comparative approach allows the formulation of statements concerning generic processes in social systems, modeled as lattices. Hierarchical structures, for example, may be common to a number of different empirical domains and may exhibit similar formal properties, regardless of their specific empirical content. Similarly, empirically variant role sets may exhibit a similarity of underlying structure, such as patterns of conflict or cooperation with different categories of others.

This approach does not, however, reduce the variation found in actual social networks to invariant mathematical properties. There can be no derivation of a network *theory* directly from a mathematical theory. As Pattison (see p. 135 in [43]) argues, algebraic approaches have sacrificed mathematical power in order to reflect more adequately the social relationships in the particular field under investigation. Algebraic methods have tended to be used – as shown in the discussion of blockmodeling – as methods of data reduction, as means for decomposing or fragmenting networks into simpler structural components. The construction of empirically relevant theories from these components is far more difficult and has, so far, rarely been pursued.

Scaling models and Visualization

Both graph theory and algebraic approaches offer rudimentary techniques for the visualization of social networks (see ► Social Network Visualization, Methods of). Graph theory, for example, is based around the idea of the sociogram of connected points. For any but the smallest networks, however, sociograms become a confused jumble of cross-cutting lines, and a rearrangement of points aimed at reducing the amount of overlap can actually destroy any visual representation of the structure of the network by distorting the distances between and the relative locations of the points. A blockmodeling approach to large networks reduces the amount of data to be handled and allows simple image graphs of the relations among blocks to be drawn, but this is limited to positional analysis and loses sight of the details that are present in the relations among the individual points. In both forms of analysis, therefore, social network analysts have tended to rely on the purely mathematical manipulation of large networks and many have almost abandoned the attempt to visually display whole complex social networks. The desire to recapture the simple visual impact of the sociogram, however, has motivated a number of researchers to investigate ways of drawing network diagrams that retain the spatial sense inherent in relational data. Unsurprisingly, perhaps, the techniques discovered have followed the methods used in cartography to represent physical landscapes on the page of a map or atlas.

The earliest and most influential visualization techniques drew on multidimensional scaling (MDS), as this was seen as a method for mapping data that retained its fundamental metrics of space and distance. Essentially similar techniques are those of principal component analysis or factor analysis. Instead of calculating distance simply by the number of lines connecting two points – "path distance" – MDS approximates to the measures of physical distance used in conventional spatial thinking. MDS techniques convert raw data on social networks into Euclidean distances. In this conversion, points are regarded as "close" to each other by virtue of their position in the overall configuration of relations. This is typically measured on the basis of a proximity measure such as the frequency of contact between two points or the intensity of a relationship between them, and these are usually given a strictly metric form by computing correlation coefficients. For example, two points with identical patterns of connection are perfectly correlated with each other, and decreasing similarity is reflected in declining closeness. Using such similarity (or dissimilarity) data, MDS procedures search for the best fit within a Euclidean space of specified dimensions. Once a solution is obtained it can be displayed on the page and rotated into an informative orientation that discloses the meaning of the dimensions that have been identified in the analysis. Non-metric MDS, using the rank order of distances rather than imputed actual distances, is particularly appropriate for much social network data and operates in very much the same way. Useful implementations of this approach are now available in the major software packages, and novel techniques such as multiple correspondence analysis are also beginning to become available.

The use of MDS and similar scaling or dimensional models provides a visual image of a network, but it also provides measures of distance, direction, and location that are not available within graph theory or algebraic approaches. This can allow a more rigorous embedding of social networks in social space and can permit intriguing hypotheses to be formed. For example, cliques and components, centrality and density, can all be mapped onto an MDS solution, and the relations among cliques or central points appear strikingly and can be measured determinately. The procedures made available within the *Pajek* program [18] have been designed specifically to allow such possibilities for large-scale networks. Graph theory and algebraic methods can be used together with the spring embedding of data through a variant of MDS to produce powerful network representations.

Particular problems of visualization occur when research is concerned with two-mode data rather than simple one-mode data. The most easily interpretable results are those that display a bipartite graph by using different symbols or colors for the two sets of data. Such graphs are a logical extension of graph theory approaches to two-mode data. Some interesting work is now being undertaken, however, using Galois lattices. Abandoning graph theoretical and spatial representations, the lattices aim to disclose the pattern of connections and their hierarchical order of "containment" from core to periphery.

One particularly striking advance in visualization techniques has been the use of models that allow the tracking of change over time. These have typically involved the adaptation of animation methods. Further advances in this area might be expected as some of the techniques discussed below begin to offer improved ways of handling temporal data on social networks.

Statistical Models for Hypothesis Testing

Much work on social networks has remained at the level of description and has failed to move towards explanatory concerns. Only rarely have researchers gone beyond a description to formulate hypotheses and test theories aimed at explaining the observed structures. One reason for this absence of theoretical work and hypothesis testing has been the weakness of the available statistical techniques for undertaking this work. While attempts have sometimes been made to use basic statistical measures of probability and significance to test hypotheses about network structure, these involve a number of difficulties. Standard statistical procedures such as significance tests, regression, and the analysis of variance all assume the independence of observations. The relational data studied by social network analysts, however, cannot be seen in this way. Relational data are, by definition, non-independent observations. Thus, novel statistical techniques have been required if methods of statistical inference are to be used. The most important work in recent years has been the generalization of Markov graphs to a larger family of models that has been undertaken by Stanley Wasserman and his colleagues [44,46,65], building on earlier work by Frank and Strauss [21]. Their $\boldsymbol{p}^*$ models – now termed exponential random graph models (ERG models or ERGM) – are designed specifically to allow the easier formulation and testing of theories. An ERGM defines a probability distribution on the set of all networks that can be constructed on a given set of points in terms of a particular parameter vector. ERGMs comprise a family of statistical models that promise a great advance in the understanding of social networks and have the potential to connect with the "small world" methods discussed below. The models are discussed in ► Social Networks, Exponential Random Graph ($\boldsymbol{p}^*$) Models for.

For any set of points it is possible to generate through simulation a set of all the possible graphs connecting them. These randomly generated graphs vary along the full range from completely unconnected to completely connected. A very large number of such graphs can exist along that range, as the number of possible graphs varies with the size of the network at an exponential rate. Thus, the number of possible configurations for a three-point graph is 64, that of a four-point graph is 1024, and the number for a five point graph is in excess of a million. An actually observed network can be treated as one realization from this set of logically possible graphs. If its probability of occurring by chance is low, then its actual occurrence may be regarded as statistically significant.

To assess this statistical significance, it is necessary to construct a probability distribution of the random graphs. Each random graph has a specific probability of occurring, depending on its particular structural properties. The aim in constructing these distributions is to see whether a particular structural property, such as a particular level of density, centralization, or clustering, is more or less likely to occur by chance than any other. These probabilities are estimated through log linear analysis from the statistical dependencies among the members of the network. The log odds ratios of the conditional probabilities of the relational ties associated with each element constructed from this dependence graph are used to produce an approximate likelihood function that can be used with Monte Carlo estimation techniques to produce maximum likelihood estimates. In this process the successive approximations constitute chains of graphs – a Markov chain – that converge towards a stationary distribution and a stable estimate of network parameters. Thus, ERGM provides a means for testing the probability that the observed network will occur with precisely the structural characteristics that it has on the basis of chance alone. This enables the researcher to highlight the statistically significant – non-chance – results apparent in the data.

Agent-Based Computational Models and Temporal Processes

As well as its descriptive focus, much social network analysis has also concentrated on the static features of social networks. This has also begun to change in recent years as more attention has been given to the dynamic processes involved in changes over time. A key advance in this direction has come from the use of models that depict the ways in which the behavior of individual agents results in global transformations of network structure. In so-called agent-based computational models, agents (whether individuals or groups) are seen as rule-following entities whose decisions to act in one way or another are consequential for the overall network by virtue of their concatenation with the action consequences of others. Therefore, a knowledge of the rules under which agents act can be used to predict broad patterns of change in network structure.

Agent-based models originated in simulation studies, where a simple and determinate set of rules can be applied to generate specific network structures (see also pp. 99ff in [25]; [40]). Applications of this idea to human social networks have tended to rely on assumptions drawn from rational choice theory, according to which individual agents are assumed to act on certain simple principles of utility maximization. However, the more complex models allow for the handling of different categories of agent, the members of each category following a different set of rules, and for a relaxation of the assumption of pure rationality by modeling rules of non-rational or ritualistic behavior. Such models are stochastic – specifying the probability of certain courses of action but not implying a complete determinism.

A particularly powerful example of such an approach is that of Tom Snijders [52,53,54] (see ▶ Network Analysis, Longitudinal Methods of). Change in network structure is regarded as a probabilistic process, describable by an objective function that measures the attractiveness to the agents of changes in their connectivity. The model sees an incremental adjustment of individual action to the changing network structure, resulting in a continuous – but often non-linear – process of network evolution. It is assumed that agents control the outgoing relations to others within the constraints on their opportunities that are set by the current network structure. However, they act "myopically" in relation to the immediate environment and the immediate consequences of their actions, having no conception of the wider consequences of their choices. At each point in time, the outcome for the overall network is a result of the intersection of the courses of action pursued by these myopic agents and so it will rarely correspond to the intentions of any one actor. At the same time, each actor has only a partial awareness of the changes that have resulted from their actions and so their next acts must be regarded as equally myopic and as likely, once again, to have unintended consequences at the network level. As a result of the continual iteration of actions, there is a co-evolution of network and behavior. Complex patterns of change are likely to occur. Snijders shows that small, incremental changes can accumulate to a point of "crisis" [55], a tipping point at which a radical, non-linear transformation of network structure occurs.

Snijders' longitudinal approach is especially powerful as it explicitly takes account of global network parameters such as density, reciprocity, distance, and balance. It can also be reprogrammed to recognize a wide range of different rule systems and decision procedures. Snijders also suggests that the approach can handle a greater degree of far-sightedness in agents, though with a corresponding decline in the determinateness of the analyses that can be drawn. Current work is making important connections with the early work of Wasserman [63] and the subsequent development of ERGM procedures. The approach is implemented in the *SIENA* program and has been used in a number of simulation studies.

Small World Models and Network Dynamics

The most recent area of development in social network analysis is the investigation of small world networks inspired by a number of physicists interested in network dynamics (explored in various entries in other sections of this *Encyclopedia*). Although this has, as yet, led to relatively few empirical investigations, there is growing interest in these applications. Many advocates of the approach have failed to discover or to appreciate the amount of work already undertaken in social network analysis and have assumed a very truncated history for the approach. There are, however, some signs of a closer appreciation of social science work, and the approaches are beginning to have an impact in the mainstream of social network analysis.

The "small world" hypothesis suggests that any two people chosen at random are likely to be connected to each other by a path of relatively short length. The hypothesis was formulated by Ithiel de Sola Pool and Manfred Kochen in a working paper of 1958 that was not published for another 20 years [17]. Their ideas achieved a wide currency and in 1967 Stanley Milgram at Harvard undertook some experimental studies to test the hypothesis [38]. He gave experimental subjects the names of people initially unknown to them and asked them to get a message to them using only known persons as intermediaries. That is, the messages were to pass through friend of friends of friends until they reached their destinations. Milgram discovered that subjects and targets were typically separated by paths of distance 6, no matter what the physical distances separating them. This finding embodied the common exclamation "it's a small world" uttered when people discover a mutual connection. Milgram hypothesized that the density of links of acquaintanceship is such that a considerable amount of redundancy is built into social networks: it is level of density in a network that explains its small world characteristics.

In the late 1990s, Watts and Strogatz [68] undertook some empirical studies in the mathematics of random networks. The structural properties of random networks, produced through the random linking of one point to another, had first been studied by Paul Erdös and Alfréd Rényi [20] and had led to a number of interesting conclusions. Watts and Strogatz discovered that a particular subset of random graphs corresponded closely to those actually found in natural and social phenomena, and they demonstrated that these had the small world characteristics identified by Milgram; though they were skeptical about the precise finding of "six degrees of separation". They showed, however, that the high levels of clique and sub-graph formation that were basic to the redundancy found in real networks gave them a number of characteristic features. Crucial to the structure of these networks was the existence of well-connected points – which they termed "hubs" – that make the density and, therefore, the small world properties, possible. It is the existence of hubs that explains why the density does not need to be extremely high for small world conditions to apply. On the contrary, there is a middle range of density in which efficient communication is possible.

The physicist Albértó-Laszlo Barabási, searching for a new topic to investigate, began to look at the findings of Watts and Strogatz. Barabási's central idea was that of the "power law" or "scale free" distribution, according to which small world networks have a frequency distribution of point degrees showing a small number of well-connected points and a large number of less well-connected points. These well-connected points are the hubs that generate the small world properties. He concluded that these findings provided the basis for a completely new approach to networks [1]. As has already been noted, his claims to novelty and to the revolutionary character of the work seriously underestimated the amount of prior work undertaken on social networks and their properties. Nevertheless, he did formulate some intriguing ideas and the work subsequently taken up by Watts does offer the prospect of genuine advances in social network analysis.

Watts holds that a small world graph is one in which there are a large number of "short cuts". These are lines that connect points that would otherwise be quite distant from each other. Neither a completely connected graph nor a sparse graph have short cuts, and so small world properties occur in an intermediate range of graphs. They are locally clustered but globally sparse. It is for these graphs, he holds, that precise mathematical conclusions about structure and structural development can be drawn. He holds, for example, that relatively small changes in network connectivity, such as the addition of a small number of shortcuts, can dramatically change its properties through "phase transitions" at critical threshold points. There are considerable possibilities inherent in using these ideas alongside those from agent-based computational studies already discussed. The common thread is a concern for the investigation of longitudinal processes in which micro-level incremental changes result in non-linear macro-level transformations of structure.

Article Outline

Glossary

2-Mode matrix A (2-dimensional) matrix is said to be 2-mode if the rows and columns index different sets of entities (e. g., the rows might correspond to persons while the columns correspond to organizations). In contrast, a matrix is 1-mode if the rows and columns refer to the same set of entities, such as a city-by-city matrix of distances.

Blockmodel A blockmodel is a partitioning of the cells of a matrix into blocks that is induced by the partitioning the rows and columns into classes and sorting the matrix such that rows (and columns) that belong to the same class are next to each other. More specifically, two matrix cells x_{ij} and x_{mp} are in the same block if $\text{class}(i) = \text{class}(m)$ and $\text{class}(j) = \text{class}(p)$.

Centrality A family of concepts for characterizing the structural importance of a node's position in a network.

Graph cohesion A family of concepts characterizing the extent of connectedness of a graph, such as density (the proportion of pairs of nodes that have ties with each other), or average path distance.

Multidimensional scaling (MDS) A method of locating points in space such that Euclidean distances between the points correspond to a matrix of input similarities/distances among objects. Used to provide visual representations of 1-mode matrices such as correlation matrices or perceptual distances among objects.

Regular equivalence The definition of regular equivalence is recursive. If two nodes are regularly equivalent, then they are connected to regularly equivalent nodes. Regular equivalence is used to identify nodes that are playing the same structural role, even if they are not connected to each other.

Social network (or, in graph theory, a graph) A collection of nodes (also referred to as vertices or actors) together with a set of ties (also known as edges or links) that connect pairs of nodes. Typically used to represent social relations such as who is friends with whom, or who is the supervisor of whom.

Structural equivalence At an intuitive level, a pair of nodes is said to be structurally equivalent to the ex-

tent that they occupy identical locations in a network, meaning that they are connected to exactly the same others. Structurally equivalent nodes are identical with respect to all structural properties, such as centrality or subgroup membership.

Definition of the Subject

In social network analysis, 2-mode data refers to data recording ties between two sets of entities. In this context, the term "mode" refers to a class of entities – typically called actors, nodes or vertices – whose members have social ties with other members (in the 1-mode case) or with members of another class (in the 2-mode case). Most social network analysis is concerned with the 1-mode case, as in the analysis of friendship ties among a set of school children or advice-giving relations within an organization. The 2-mode case arises when researchers collect relations between classes of actors, such as persons and organizations, or persons and events. For example, a researcher might collect data on which students in a university belong to which campus organizations, or which employees in an organization participate in which electronic discussion forums. These kinds of data are often referred to as affiliations. Co-memberships in organizations or participation in events are typically thought of as providing opportunities for social relationships among individuals (and also as the consequences of pre-existing relationships). At the same time, ties between organizations through their members are thought to be conduits through which organizations influence each other.

Introduction

Perhaps the best known example of 2-mode network analysis is contained in the study of class and race by Davis, Gardner and Gardner (henceforth DGG) published in the 1941 book *Deep South* [6]. They followed 18 women over a nine-month period, and reported their participation in 14 events, such as a meeting of a social club, a church event, a party, and so on. Their original figure is shown in Fig. 1.

DGG used the data to investigate the extent to which social relations tended to occur within social classes.

Basic Concepts

A typical data matrix has two dimensions or *ways*, corresponding to the rows and columns of the matrix. The number of ways in a matrix X can be thought of as the number of subscripts needed to represent a particular datum, as in x_{ij}. If we stack together a number of similarly sized 2-dimensional matrices, we can think of the result as a 3-dimensional or 3-way matrix.

The *modes* of a matrix correspond to the distinct sets of entities indexed by the ways. In the DGG dataset described above, the rows correspond to women and the columns to a different class of entities, namely events.

Hence, the matrix has two modes in addition to two ways; it is 2-way, 2-mode. In contrast, a persons-by-persons matrix A, in which $a_{ij} = 1$ if person i is friends with person j, is a 2-way, 1-mode matrix, because both ways point to the same set of entities.

In a sense, what constitutes different modes is up to the researcher. If we collect romantic ties among a group of heterosexual people of both genders, we could construct a 2-mode men-by-women matrix X in which $x_{ij} = 1$ if a romantic tie was observed between man i and woman j, and $x_{ij} = 0$ otherwise. Or, one could construct a larger 1-mode person-by-person matrix B also consisting of 1s and 0s in which it just happens that 1s only occur in cells where the row and column correspond to persons of different gender. Use of the men-by-women matrix would imply that same-gender relations were impossible, whereas use of the person-by-person matrix would suggest that same-gender relations were logically possible, even if actually not observed.

Matrices recording relational information such as romantic ties can be represented as mathematical graphs as well. A graph $G(V, E)$ consists of a set of nodes or vertices V together with a set of lines or edges E that connect them. An edge is simply an unordered pair of nodes (u, v). (In directed graphs or *digraphs* we use *ordered* pairs to indicate direction of the tie.) To indicate a tie between two nodes u and v, we simply include the pair (u, v) in the set E. The number of nodes in a graph is denoted by $|V|$ or n.

A bipartite graph is a graph in which we can partition all nodes into two sets, V_1 and V_2, such that all edges include a member of V_1 and a member of V_2. The number of nodes in each vertex set is denoted n_1 and n_2, respectively.

Two-Mode Data in Social Network Analysis

Most social networks are conceived of as relations among a set of nodes, and therefore represented as a 1-mode matrix (typically of 1s and 0s) or a simple graph or digraph. For example, we might collect data on who is friendly with whom within an organization, or who injects drugs with whom in a neighborhood.

However, 2-mode data are common in social network contexts as well. Typical examples include, actor-by-event attendance (as in the DGG data), actor by group membership (such as managers sitting on corporate boards), and actor by trait possession (such as adjective checklist data), and actor by object possession (such as material style of life scales in which inventories are made of household possessions).

In many cases when 2-mode data are collected, the analytical interest is focused on one mode or the other. For example, in the DGG dataset, person-by-event attendances were collected in order to understand social relations among the women, specifically, whether women tended to have social relations primarily within their own social classes. In the interlocking directorate literature, membership of executives on corporate boards is collected mainly in order to understand how corporations are intertwined, and how the structure of this connectivity affects corporate control of society.

However, it can also occur that neither mode dominates our analytical focus and the primary interest is in the correspondence of one mode to the other. For example, a university might ask its faculty which courses they prefer to teach. Here, the objective is typically not to understand how faculty are related to each other through courses, nor how courses are related via faculty, but in the optimal assignments of persons to courses so that courses are staffed and faculty are not complaining.

Unimodal Approaches to Two-Mode Data

One approach to handling 2-mode data in social network analysis is to convert the data to 1-mode data. This is especially appropriate when the analytical interest focuses primarily on just one of the modes. Consider, for example, the case of a person by group membership matrix X in which $x_{ij} = 1$ if person i belongs to group j. Let us assume that the groups are small and everyone in a group knows everyone else. In that case, we could try to infer an acquaintance network by constructing a 1-mode matrix A such that $a_{ij} = 1$ if person i is in at least one group with person j. Better yet, we can construct a valued matrix A such that a_{ij} gives the number of groups that i and j are both members of. In other words,

$$a_{ij} = \sum_k x_{ik} x_{jk} \text{ or } A = \mathrm{XX}' \, . \tag{1}$$

We might regard a_{ij} as a proxy for the social proximity of i and j, or perhaps as a rough indicator of the potential for information flow between them. In this approach, we analyze each mode of the data separately. Figure 2 shows the values of A for the 2-mode data shown in Fig. 1.

It should be noted that A can be seen as a matrix of profile similarities or correlations among pairs of rows in X. For example, the matrix of Pearson correlations among rows of X is defined as follows:

$$r_{ij} = \frac{\frac{1}{m} \sum_k x_{ik} x_{jk} - u_i u_j}{s_i s_j} \, , \tag{2}$$

where u_i is the mean of row i and s_i is the standard deviation of row i. It is evident that the correlation r_{ij} is es-

Contingency table *T*

sentially a_{ij} corrected for the number of groups that each belongs to. This kind of correction seems eminently desirable, but of course there are many ways of doing this. For example, consider a cross-tabulation T of row i and row j, such that t_{uv} gives the number of columns k of X for which $x_{ik} = u$ and $x_{jk} = v$, as shown in Fig 3.

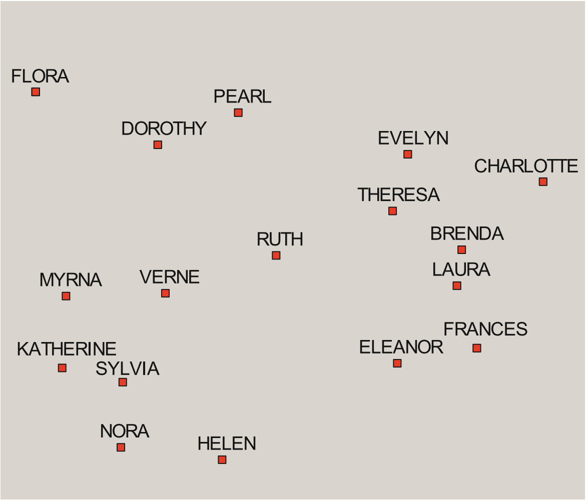
In the table, the first row marginal $(a + b)$ gives the number of groups that person i belongs to while the first column marginal gives the number of groups that person j belongs to. Note that a_{ij} of Eq. (1) corresponds to a in Fig. 3. An obvious approach is the Jaccard coefficient, which may be defined as

$$c_{ij} = \frac{a}{a+b+c} \,. \tag{3}$$

Thus, c_{ij} is essentially the cardinality of the intersection of the groups belonged to by both persons, divided by the cardinality of their union. The Jaccard coefficient is often recommended when the number of columns in X is large and the number of 1s in each row is highly limited.

An alternative specifically designed for 2-mode affiliation data is given by Bonacich [1]. It normalizes a_{ij} as follows:

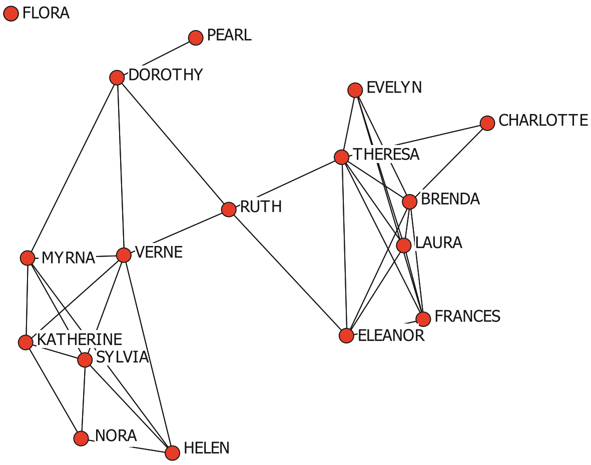
$$a^*_{ij} = \frac{a_{ij} - \sqrt{adbc}}{ad - bc} \,, \quad \text{for } ad \neq bc \,. \tag{4}$$



Social Network Analysis, Two-Mode Concepts in, Figure 4
Multidimensional scaling of Jaccard coefficients among rows of DGG matrix

Unimodal Visualization of Two-Mode Data

Given that a 2-mode matrix has been transformed into a 1-mode matrix by taking similarities among the rows (or columns), one can visualize the network using all the usual techniques for visualization of valued networks. For exam-



Social Network Analysis, Two-Mode Concepts in, Figure 5
Multidimensional scaling of Jaccard similarity coefficients, with lines indicating similarity scores greater than 0.4. Actor Olivia is obscured by Flora

ple, a standard approach is to use metric multidimensional scaling (MDS) on the matrix A, generating a map in which points corresponding to nodes (e. g., persons) appear close to each other to the extent that they share many groups. Figure 4 shows such an MDS map based on Jaccard similarities.

To highlight structure, it is common to overlay lines between pairs of nodes with a similarity score greater than a certain level. Figure 5 shows the result for similarities greater than 0.4. The diagram effectively shows the bridging role of Ruth, who, based on ethnographic evidence, was seen by DGG as a member of both groups of women.

Alternatively, one can use a standard graph layout algorithm (GLA) to draw the graph induced by dichotomizing the Jaccard similarity matrix. For example, define $(u, v) \in E$ if and only if (iff) $c_{ij} > 0.4$. Compared to multidimensional scaling representations, GLAs have the disadvantage that distances between points cannot strictly be interpreted, but this property also means that nodes need not obscure each other. Figure 6 shows the results of applying a spring-embedding [10] GLA to the dichotomized data.

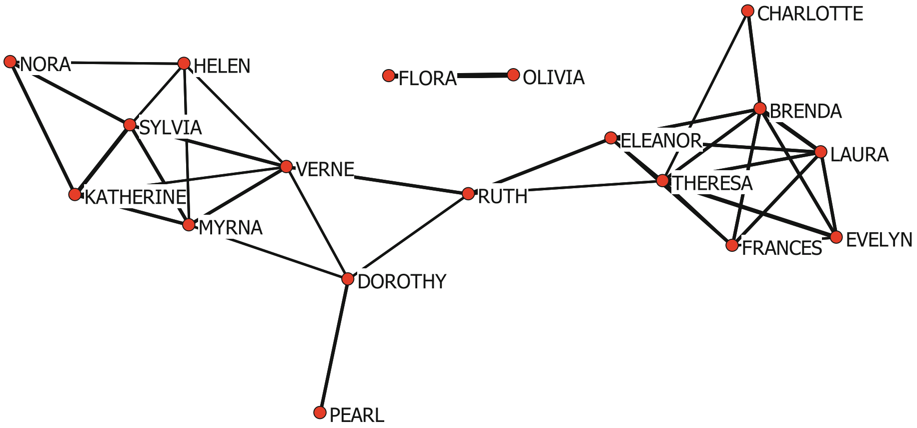
A similar analysis can be carried out on the events rather than the women. Applying Eq. (3) to the columns of the 2-mode matrix in Fig. 1 yields a matrix of Jaccard coefficients which can be visualized using the same methods used for the women. Figure 7 shows events with Jaccard overlaps greater than 0.35.

Unimodal Analysis of Two-Mode Data

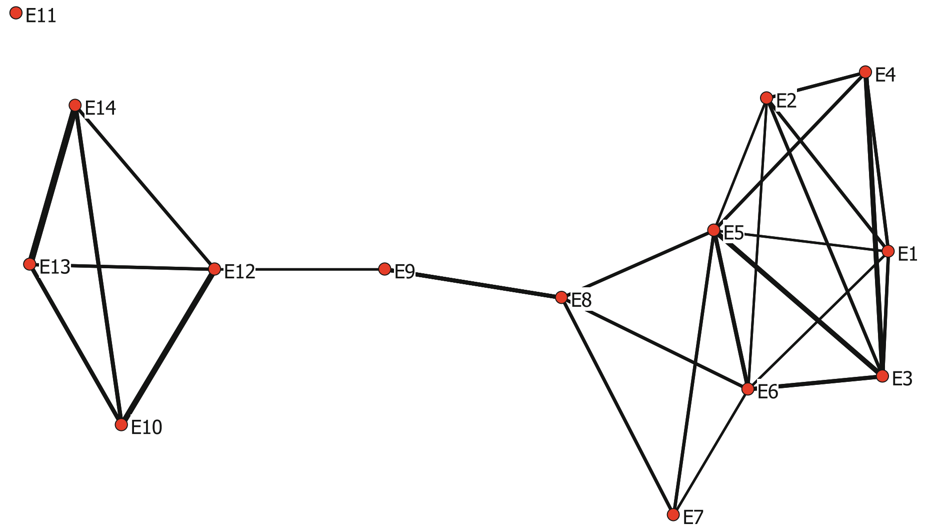
In general, analysis of 2-mode data transformed into valued 1-mode networks proceeds like any other valued network. As with visualization, this often means generating a graph from the valued data via some rule such as $(u, v) \in E$ iff $a_{ij} > q$, where q is chosen by the researcher. Typically, there is no theoretical reason for choosing any particular value of q; hence a series of different values is generally chosen and the analysis repeated for each.

There are, however, a few consequences that stem from the 2-mode origin of the data. By their very nature, many commonly used measures of similarity and dissimilarity satisfy triangle inequality laws. For example, for Euclidean distance, every triple of nodes i, j, k satisfy the following rule:

$$d_{ik} \leq d_{ij} + d_{jk} \,. \tag{5}$$



Social Network Analysis, Two-Mode Concepts in, Figure 6
Spring-embedding representation of Jaccard similarities dichotomized at > 0.4



Social Network Analysis, Two-Mode Concepts in, Figure 7
Spring-embedding representation of "ties" among events ($c_{ij} > 0.35$)

As a result, the 1-mode data (especially if not dichotomized) artifactually exhibit a certain level of transitivity that may be higher than baseline models built on simple sociometric choice data would expect. Statistics based on transitivity, such as structural holes and clustering coefficients, must similarly be interpreted with some caution in such data.

Bimodal Approaches to Two-Mode Data

Another approach to working with 2-mode data seeks to analyze both modes simultaneously. The data are seen to represent relations between two sets of nodes, forming a bipartite graph $G_B(V_1 + V_2, E)$ in which, or all u and v, $(u, v) \in E$ if and only if u and v belong to different vertex sets. In other words, all ties are between vertex sets and none are within-group. The matrix representation of such a graph can be a rectangular incidence matrix X (as in Fig. 1) or a square bipartite adjacency matrix B with $n = n_1 + n_2$ rows representing both modes, and an equal number of columns, also representing both modes. In the latter case, the original matrix X forms a submatrix of the larger adjacency matrix B in which both rows and columns index the $V_1 + V_2$ entities. The matrix B is composed of four blocks, two of which are empty, as shown in Fig. 8 Note that the original matrix X forms the top right quadrant of B, and its transpose forms the bottom left quadrant.

Bimodal Visualization of Two-Mode Data

All of the standard ways to visualize networks, such as MDS and GLAs, apply to bipartite graphs. For example, Fig. 9 shows a spring-embedding layout of the bipartite graph represented by the matrix in Fig. 8.

In the representation, two nodes are near each other roughly to the extent that the geodesic distance between them is short. Thus, events are near each other if they are attended by the same women (distance 2), and women are near each other if they attend the same events. In this example, the representation makes clear that there is a set of women on the left (Mryna, Helen, Katherine, Nora, Silvia, etc.) that attend a set of events exclusive to them (events 10 through 13), and another set of women (Evelyn, Theresa, Laura, Brenda, etc.) that have their own events (E1 through E4), and finally a set of events that both "circles" of women attend (events E6 through E9).

For small datasets, this bimodal visualization is often extremely effective for transmitting a holistic understanding of the whole dataset.

It is worth noting that there is a simple mathematical relationship between pairwise overlaps a_{ij} as defined in Eq. (1) and paths in the bipartite graph. Specifically, the number of 2-step paths between any pair of women i and j in the bipartite graph is equal to a_{ij}, the number of events they attended in common. Of course, the number of 2-step paths is simply the matrix product BB, the bipartite adjacency matrix multiplied by itself. As shown in Fig. 10, the top left block and bottom right blocks of BB are the matrices A as calculated by Eq. (1) for rows and columns respectively of X.

Bimodal Analysis of Two-Mode Data

Given a bimodal perspective, one approach to analyzing 2-mode data is to develop entirely new metrics and algo-

rithms designed specifically for 2-mode data. Such techniques take cognizance of the fact that the observed network is not just bipartite by happenstance, but could not have been any other way. In other words, taking account of the fact that the observed lack ties between certain nodes (namely, those belonging to different modes) was by design – similar to the concept of structural zeros in log-linear modeling. To date, few techniques of this kind have

Social Network Analysis, Two-Mode Concepts in, Figure 10
Matrix *BB* giving the number of paths of length 2 between all pairs of nodes

been developed, the exception being the area of 2-mode centrality measures, which has received significant attention (e. g., [2]).

Another approach is to treat the bipartite graphs as ordinary graphs and apply all the standard algorithms and techniques of social network analysis. Effectively this assumes either that the special nature of the graphs will not affect the techniques, or that we can pretend that ties within modes could have occurred and just didn't. This approach works for a small class of methods, but by no means all. For example, calculating transitivity fails because transitive triples are impossible in bipartite graphs (all ties are between modes, which means that if $a \rightarrow b$ and $b \rightarrow c$ then a and c must be members of the same class, and therefore cannot be tied, making transitivity impossible). In contrast, if we were to adapt the definition of transitivity to be based on quadruples such that a quad is transitive if $a \rightarrow b$, $b \rightarrow c$, $c \rightarrow d$ and $a \rightarrow d$, this would be an example of the first approach.

Finally, a compromise approach is to use the standard metrics and algorithms that apply to general graphs, and then either adjust the outputs via normalization or adjust the baseline expectations for the results [5,9]. In the former case, we develop normalizations that adjust the metrics (typically by dividing by theoretical bipartite maxima), and in the latter case we derive different theoretical distributions for the statistics in question. In general, we choose the former approach when statistics are bounded between 0 and 1 and can be interpreted as proportions of maximum possible values. We choose the latter approach when the statistics are unbounded and have direct interpretations (see example of cohesion below).

Bimodal Approaches to Graph Cohesion The simplest and most common measure of network cohesion is *density* – the number of edges divided by the number of pairs of nodes (using ordered pairs in the case of directed graphs and unordered pairs in the case of undirected graphs). In bipartite graphs, of course, only edges between vertex sets are possible. As a result, the maximum possible undirected ordinary density is

$$\frac{n_1 n_2}{(n_1 + n_2)(n_1 + n_2 - 1)} \,. \tag{6}$$

Thus, if density were calculated on a 2-mode network as if it were an ordinary graph, we would probably want to normalize the result by dividing by the sum above, otherwise the calculated density would appear misleadingly low. This is a case where the "compromise approach" discussed above is effective. (Of course, in terms of computation, it would be easier to simply calculate the average of the 2-mode matrix X rather than convert to bipartite form and then perform this adjustment.)

For measures of cohesion that are not expressed as fractions of maximum possible values, such as average geodesic path length, the need to renormalize is not as great, since the raw values are directly interpretable. In doing so, however, we must be careful not to compare the results with standard rules of thumb or theoretical models based on simple random graphs, as these have not assumed the bipartite restrictions.

Bimodal Approaches to Centrality Four measures of centrality are used with high frequency in social network analysis today: degree, closeness, betweenness and eigenvector. We discuss each in turn.

Degree centrality, d_i, is defined as the number of ties incident upon node i. Degree centrality is typically normalized by dividing by the maximum number of ties possible, which in a graph of n nodes is $n-1$. Hence

$$d_i^* = \frac{d_i}{n-1} \,. \tag{7}$$

However, in any (non-trivial) bipartite graph, no node can be connected to all others, since this would mean within-mode ties. Instead, for a node in V_1, the maximum number of ties it could have is n_2, whereas for a node in V_2, the maximum number of ties is n_1. Hence a natural adjustment is to provide two separate normalization formulas as follows:

$$\begin{aligned} d_i^* &= \frac{d_i}{n_2}\,, \quad \text{for } i \in V_1\,,\\ d_j^* &= \frac{d_j}{n_1}\,, \quad \text{for } j \in V_2\,. \end{aligned} \tag{8}$$

Closeness centrality is ordinarily defined as the sum of geodesic distances from a node to all others, as shown in Eq. (8), where d_{ij} is the length of the shortest path from i to j and $n = n_1 + n_2$ is the total number of nodes. The best (smallest) score possible occurs when the node has a tie to every other node, in which case the total distance to all others is $n-1$. Thus, closeness centrality is usually normalized by dividing c_i into $n-1$.

$$\begin{aligned} c_i &= \sum_j^n d_{ij}\\ c_i^* &= \frac{n-1}{c_i}\,. \end{aligned} \tag{9}$$

In the bipartite case, the maximum number of nodes that a node can be distance 1 from is the number of nodes in the other class. For other nodes in its own class, the closest it can be is two links away. Thus, the theoretical bipartite minimum value of c_i (where $i \in V_1$) is $n_2 + 2(n_1-1)$ and the minimum for c_j (where $j \in V_2$) is $n_1 + 2(n_2-1)$. Therefore, closeness centrality can be normalized in bipartite graphs as follows:

$$\begin{aligned} c_i^* &= \frac{n_2 + 2(n_1-1)}{c_i}\,, \quad \text{for } i \in V_1\,,\\ c_j^* &= \frac{n_1 + 2(n_2-1)}{c_j}\,, \quad \text{for } j \in V_2\,. \end{aligned} \tag{10}$$

Betweenness centrality refers to the sum of shares of shortest paths that pass through a given node. The betweenness of node k in an ordinary graph is defined by Eq. (11), where g_{ij} is the number of geodesic paths from node i to node j, and g_{ikj} is the number of geodesic paths from i to j that pass through k.

$$b_k = \frac{1}{2}\sum_{i\neq k}^n \sum_{j\neq k,i}^n \frac{g_{ikj}}{g_{ij}}\,. \tag{11}$$

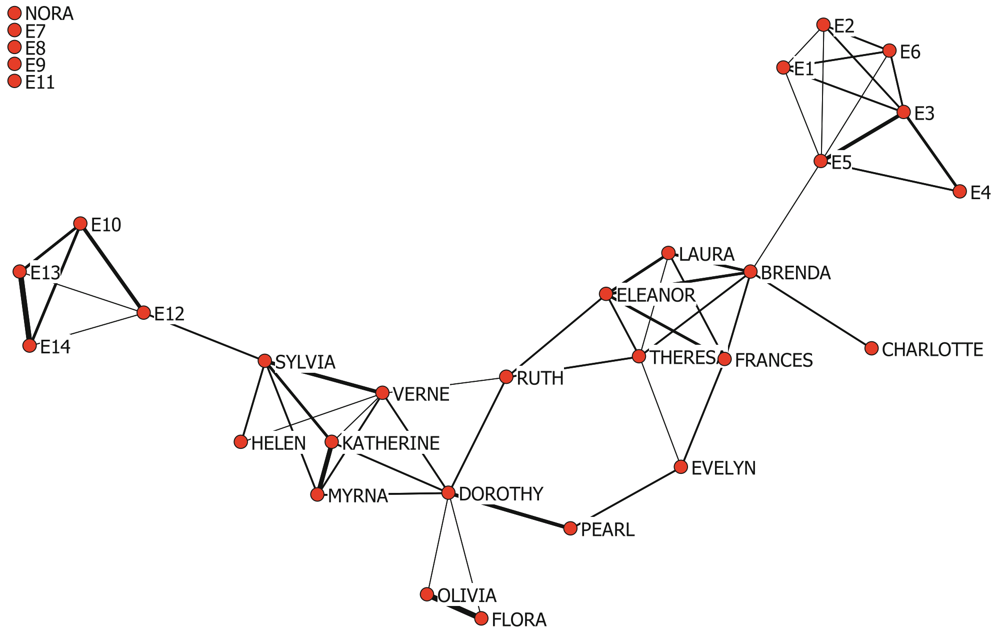
Betweenness is ordinarily normalized by dividing by $(n-1)(n-2) = n^2 - 3n + 2$, which is the maximum betweenness that any node can achieve in a graph with n nodes, which occurs for the node at the center of a star-shaped graph. This maximum is appropriate for bipartite graphs only when one mode has just one node; otherwise we must take account of the sizes of each vertex set. Eq. (12) gives the maximums for nodes in each vertex set as a function of the vertex set sizes. In the equation, x div y refers to integer division of x by y and x mod y refers to the remainder of an integer division of x by y.

$$\begin{aligned} b_{V_1\,\max} &= \tfrac{1}{2}\big[n_2^2(s+1)^2 + n_2(s+1)(2t-s-1)\\ &\qquad - t(2s-t+3)\big]\\ s &= (n_1-1) \operatorname{div} n_2\,, \quad t = (n_1-1) \mod n_2\\ b_{V_2\,\max} &= \tfrac{1}{2}\big[n_1^2(p+1)^2 + n_1(p+1)(2r-p-1)\\ &\qquad - r(2p-r+3)\big]\\ p &= (n_2-1) \operatorname{div} n_1\,, \quad r = (n_2-1) \mod n_1 \end{aligned} \tag{12}$$

Given these maxima, we can normalize standard betweenness centrality for bipartite graphs by dividing by these maxima, as shown in Eq. (13).

$$\begin{aligned} b_i^* &= \frac{b_i}{b_{V_1\,\max}}\,, \quad \text{for } i \in V_1\,,\\ b_j^* &= \frac{b_j}{b_{V_2\,\max}}\,, \quad \text{for } j \in V_2\,. \end{aligned} \tag{13}$$

Cohesive Subgroups Detecting cohesive subgroups is somewhat more difficult in bipartite graphs than in ordinary graphs. For example, one of the earliest formal definitions of a subgroup is the clique [11] which is defined



Social Network Analysis, Two-Mode Concepts in, Figure 11
Graph induced by Pearson correlations across biclique membership profiles. Edges indicate a correlation greater than 0.4

as a maximal complete subgraph – i. e., a set of nodes that is as large as possible subject to the condition that every pair is adjacent. However, in bipartite graphs, cliques are impossible, since in any connected triple, two nodes must be non-adjacent. Thus, cliques are not useful in this context. In addition, relaxations of the clique concept based on density or frequency of paths (such as k-plexes, lambda sets and ls-sets) do not work well, due to the sparse nature of bipartite graphs. For example, if we calculate k-plexes for the DGG dataset, we find huge numbers of very small groups. For $k = 2$, there are 394 2-plexes of size 3 or greater. For $k = 3$, there are 5,553 3-plexes, and for $k = 4$, there are 37,633 4-plexes of size 3 or greater.

However, other classical notions of cohesive subgroups make more sense for bipartite graphs. In particular, relaxations of the clique concept based on distance, such as n-cliques, n-clans and n-clubs have good interpretations in bipartite graphs and work well in practice. In fact, 2-cliques defined on the bipartite graph have the property of bipartite completeness, meaning that, within the bipartite subgraph induced by the 2-clique, every node of one mode has a tie with every node of the other mode, which is to say that all possible ties are present. In this sense, for bipartite graphs, 2-cliques capture the underlying idea of a clique better than cliques do. This notion has been formalized in the definition of a *biclique*, which is defined as a maximal complete bipartite subgraph. Mathematically, it is identical to a 2-clique computed on the bipartite representation.

As a practical example, a biclique analysis of the DGG dataset finds 68 bicliques, and a secondary analysis of similarities of nodes across biclique membership profiles does a good job of revealing structure, as shown in Fig. 11. In the figure, an edge is shown between two nodes if the Pearson correlation between their biclique membership profiles is greater than 0.4 (i. e., $(u, v) \in E$ iff $r_{ij} > 0.4$). The two groups are women are clearly shown, as well as the two groups of events that are associated with each of the groups of women. In addition, the separation of Flora and Olivia is clearly shown, as well as the bridging position of Ruth and Pearl.

The success of bicliques as 2-mode analogues of cliques suggests the possibility of creating 2-mode analogues for other cohesive subgroup concepts that we previously dismissed as unusable in the 2-mode context. For example, a *k-plex* is defined in ordinary network analysis as a maximal subgraph $S(V, E)$ of size n such that each member of the k-plex is adjacent to at least $n - k$ others. By analogy, for 2-mode networks we can define a (k_1, k_2)-*biplex* as a maximal bipartite subgraph $G(V_1, V_2, E)$ such that each node in V_1 is adjacent to $|V_2| - k_2$ others and each node in V_2 is adjacent is adjacent to $|V_1| - k_1$ others. Obviously, a (0,0)-biplex is a biclique. A useful feature of this relaxation of a biclique is that we can set different standards of cohesiveness for each mode of the data network, perhaps reflecting the relative sizes of the modes, or the affiliative capabilities of the nodes themselves.

Bimodal Approaches to Positions and Roles Two concepts of position and role are particularly well known in social network analysis. These are structural equivalence and regular equivalence. Generalizations to 2-mode (and higher) data were developed by Borgatti [3] and Borgatti and Everett [4] and Everett and Borgatti [7]. We consider each of these in turn.

Structural Equivalence In the best definition of structural equivalence [8], two nodes u and v are said to be structurally equivalent if there exists a graph automorphism that would be an identity except that u and v are mapped to each other. In other words, given a diagram of the graph, you could swap nodes u and v (and no other nodes) without changing the structure of the network one iota. A key implication of this definition is that structurally equivalent nodes have identical relational environments – aside from each other, they are connected and not connected to exactly the same third parties. As a result, one approach to identifying structurally equivalent nodes is to compute a similarity measure among rows and columns of the adjacency matrix defining the graph.

This approach requires no modification for the bipartite case. In fact, the unimodal analysis described in Sect. "Unimodal Approaches to Two-Mode Data" (applied to each mode in turn) is precisely the same as computing structural equivalence on the 2-mode incidence matrix (Fig. 1). In addition, for certain measures such as the Jaccard coefficient, computing structural equivalence on the bipartite adjacency matrix B of Fig. 8 gives exactly the same results as computing it on the 2-mode incidence matrix X.

Another approach to structural equivalence is known as blockmodeling. Instead of (or as a result of) measuring the extent of structural equivalence between nodes, we partition the nodes into classes such that nodes in the same class are structurally equivalent (or nearly so). Given such a partition of nodes, we can reorder and partition the corresponding rows and columns of the adjacency matrix. This in turn induces to partition of matrix cells into *matrix blocks*. A characteristic property of perfect structural equivalence partitions is that matrix blocks are necessarily homogeneous with respect to cell values, and each block will consist of all 1s or all 0s (known as 1-blocks and 0-blocks respectively). Figure 12 gives an example with three equivalence classes.

In the 2-mode case, one approach is to blockmodel the bipartite adjacency matrix B. This can be done, but the bipartite structure imposes certain constraints. For example, blocks involving within-mode ties must be 0-blocks. In addition, the best 2-block partition will almost certainly be the mode partition (except in trivial cases), and in general, all other partitions will be refinements of the mode partition (i. e., they will be nested hierarchically within the mode partition).

	A1	A2	A3	B1	B2	B3	B4	C1	C2	C3

C3	1	1	1	1	1	1	1	0	0	0

Social Network Analysis, Two-Mode Concepts in, Figure 12
Perfect structural equivalence blockmodel

A more elegant (and computationally efficient) approach is to work from the 2-mode incidence matrix X. In this case, we redefine a blockmodel to refer to a coordinated pair of partitions, one for the rows and one for the columns. We then redefine structural equivalence as follows. Given a 2-mode matrix X with modes V_1 and V_2, a 2-mode blockmodeling consists of a pair of partitions P_1 and P_2 such that (a) for all u, v in V_1, $p_1(u) = p_1(v)$ iff $x_{\text{uw}} = x_{\text{vw}}$ for all w in V_2 and (b) for all a, b in V_2, $p_2(a) = p_2(b)$ iff $x_{\text{za}} = x_{\text{zb}}$ for all z in V_1. (The notation $p(u)$ indicates the equivalence class that node u belongs to in partition P.) Restating this in words, a 2-mode structural equivalence blockmodeling is one in which row nodes in the same class if and only if they have identical rows, and column nodes are in the same class if and only if they have identical columns. An example involving 4 classes of rows and 3 classes of columns is shown in Fig. 13.

In empirical work, of course, we do not expect to obtain perfect 1-blocks and 0-blocks. Instead we seek partitions that minimize the number of errors (where we define an error as either a 1 inside a 0-block or a 0 inside a 1-block).

Regular Equivalence Two nodes are said to be *regularly equivalent* (i. e., play the same structural role) to each other to the extent that they have ties (lack of ties) to corresponding others who are themselves regularly equivalent to each other. That is, u and v are regularly equivalent

	E1	E2	E3	F1	F2	F3	F4	G1	G2	G3
A1	1	1	1	1	1	1	1	0	0	0
A2	1	1	1	1	1	1	1	0	0	0
A3	1	1	1	1	1	1	1	0	0	0

Social Network Analysis, Two-Mode Concepts in, Figure 13
A 2-mode structural equivalence blockmodel in which the row partition has 4 classes and the column partition has 3 classes

if, (a) for all x such that u has a tie to x, there exists a y that is regularly equivalent to x such that v has a tie to y, and (b) for all x such that u has an incoming tie from x, there exists a y that is regularly equivalent to x such that v has an incoming tie from y. Whereas in structural equivalence equivalent nodes are connected to the same others, in regular equivalence equivalent nodes are connected to the same types of others.

Alternatively, we can define regular equivalence in terms of a partition C of nodes into labeled classes (known as colors) such that regularly equivalent nodes are required to have the same colors in their neighborhoods. That is, for all nodes u and v,

$$C(u) = C(v) \text{ implies } C(N(u)) = C(N(v)) , \qquad (14)$$

where $C(N(u))$ is the set of distinct colors found among the nodes constituting u's immediate neighborhood.[1] Taking a blockmodeling perspective, it can readily be seen that Eq. (14) implies a blockmodel in which each matrix block is either entirely zero (a "zeroblock") or contains at least one 1 in every column and in every row (a "regular oneblock"), as illustrated in Fig. 14.

Equation (14) lends itself easily to the bipartite case. Instead of seeking a single partition of nodes, we seek a different partition for each mode. Labeling these partitions R and C, we modify our definition such that for all $u, v \in V_1$ and $x, y \in V_2$,

$$\begin{aligned} C(u) = C(v) \text{ implies } R(N(u)) = R(N(v)) , \quad \text{and} \\ R(x) = R(y) \text{ implies } C(N(x)) = C(N(y)) . \end{aligned} \qquad (15)$$

C12	0	1	0	0	0	0	0	1	0	1

Social Network Analysis, Two-Mode Concepts in, Figure 15
A 2-mode regular equivalence blockmodel

Of course, the neighbors N() of any node consist entirely of nodes belonging to the other mode. Thinking in terms of the 2-mode incidence matrix shown in Fig. 1, Eq. (15) implies that we can section the matrix into rectangular blocks such that each block is zeroblock or a regular 1-block. An example of a 2-mode regular blockmodel is shown in Fig. 15.

As with structural equivalence, in empirical work we do not expect to obtain perfect 1-blocks and 0-blocks. Instead we seek partitions induce matrix blocks that are as nearly regular as possible.

Conclusion

In this chapter we have considered methods of visualizing and analyzing 2-mode network data. An examination of the chapter suggests that four strategies are employed for handling 2-mode data. First, there is converting the data into two separate 1-mode datasets, and analyzing each separately. Second, there is using existing 1-mode methods on a bipartite representation of the 2-mode data, and essentially ignoring its special features. Third, there is using 1-mode methods but either adjusting the interpretation or

[1] For directed graphs, we require $C(N^o(u)) = C(N^o(v))$ and $C(N^i(u)) = C(N^i(v))$, where $N^o(v)$ refers to the set of nodes that v sends a tie to, and $N^i(u)$ refers to the set of nodes that v receives a tie from.

applying some kind of normalization to adjust the results. Finally, there is developing new methods designed specifically for the 2-mode case. The chapter has provided examples of all four strategies.

It is worth reminding the reader that only 2-mode data viewed in a network context has been considered here. In principle, most data dealt with by social scientists is structured as a 2-mode matrix of cases (rows) and variables (columns) and most statistical techniques assume such data. This chapter obviously does not discuss this vast pantheon of techniques, although it is clear that many would be appropriate, particularly structure-finding techniques such as factor analysis and correspondence analysis.

Future Directions

Although it would be a mistake to think of 2-mode data as an advance over 1-mode data, it is important to note that there are many cases were extending network analysis methodology to more than 2 modes is desirable. For example, we might analyze membership in organizations over time, yielding a 3-way, 3-mode data matrix of relations that is person by organization by period. Similarly, we might be interested in modeling the intellectual landscape of an academic field, representing publications as k-mode bundles of authors, journals, years, institutional affiliations and topics.

Social Networks, Algebraic Models for

PHILIPPA PATTISON
Department of Psychology, University of Melbourne, Parkville, Australia

Article Outline

Glossary

Social network A *social network* comprises a set of relationships among members of a set $N = \{1, 2, \dots, n\}$ of actors. It can be represented by an $n \times n$ binary array X recording the presence or absence of a social relationship, or *tie*, between each pair (or ordered pair) of members of $N = \{1, 2, \dots, n\}$. If there is a relationship from actor k to actor l, we write $X(k, l) = 1$; otherwise, $X(k, l) = 0$. If the relationship is a property of a pair of actors, the network is *nondirected*; if it is a property of an ordered pair, the network is termed *directed*. The directed network X may also be regarded as a *binary relation* R_X on the set N with $(k, l) \in R_X$ if and only if $X(k, l) = 1$; equivalently, it may be construed as a *directed graph* with *node set* N and *arc set* R_X, with an *arc* from node k to node l if and only if $(k, l) \in R_X$.

Affiliation network An *affiliation network* is an $n \times g$ binary array X recording the membership of each of a set N of actors in a prescribed set G of *groups*, with $X(k, l) = 1$ if actor k is a member of group l, and $X(k, l) = 0$ otherwise.

Multiple network A *multiple network* is a collection of networks for each of a set of r relations. We let $X_m(k, l) = 1$ if the tie from k to l corresponding to the relation of *type m* is present; and $X_m(k , l) = 0$ if the tie is absent. Nodes k and l are joined by a *labeled walk* with *label* $Y_1 Y_2 \dots Y_j$ if there is a sequence of nodes $k = k_0, k_1, \dots, k_j = l$, for which $Y_h(k_{h-1}, k_h) = 1$ for $h = 1, 2, \dots, j$.

Local network The *(1-)neighborhood* of a subset P of actors in a network is defined to be the set $P \cup \{l \in N\colon X_m(k,l) = 1$ for some $k \in P$ and some relation $m\}$. The *q-neighborhood* of P is then defined recursively as the 1-neighborhood of the $(q-1)$-neighborhood of P. The *q-local network* of the subset P of N is the network restricted to its q-neighborhood.

Algebra A (*partially ordered*) *algebra* is a triple $[S, F, \leq]$, where S is a nonempty set of elements (usually assumed to be finite), F is a specified set of operations, f_α, each mapping a power $S^{n(\alpha)}$ of S into S, for some non-negative finite integer $n(\alpha)$, and $\leq$ is a partial order on S. Each operation f_α is assumed to be *isotone* in each of its variables: that is, if $x_i \leq y_i$ $(x_i, y_i \in S;\ i = 1, 2, \ldots, n(\alpha))$, then $f_\alpha(x_1, x_2, \ldots, x_{n(\alpha)}) \leq f_\alpha(y_1, y_2, \ldots, y_{n(\alpha)})$. A *family of algebras* is a collection of algebras each having the same set F of operations and satisfying a specified set of postulates. Two algebras belonging to the same family are termed *similar*.

Partial algebra A *partial algebra* is a triple $[S, F, \leq]$, where S is a nonempty set of elements (usually assumed to be finite), F is a specified set of *partial* operations, f_α, each mapping some subset $T^{(\alpha)}$ of $S^{n(\alpha)}$ into S, for some non-negative finite integer $n(\alpha)$, and $\leq$ is a partial order on S. Each partial operation f_α is assumed to be *isotone* in each of its variables: that is, if $x_i \leq y_i$ $(x_i, y_i \in S;\ i = 1, 2, \ldots, n(\alpha))$, then $f_\alpha(x_1, x_2, \ldots, x_{n(\alpha)}) \leq f_\alpha(y_1, y_2, \ldots, y_{n(\alpha)})$ provided that both $(x_1, x_2, \ldots, x_{n(\alpha)})$, $(y_1, y_2, \ldots, y_{n(\alpha)}) \in T^{(\alpha)}$. A *family of partial algebras* is a collection of algebras each having the same set F of partial operations defined on the same subsets $T^{(\alpha)}$ of the power sets $S^{n(\alpha)}$.

Semigroup A *(partially ordered) semigroup* is an algebra $[S, F, \leq]$ in which F comprises a single binary operation f satisfying the *associativity* condition:

$$f(f(x,y),z) = f(x, f(y,z))\,.$$

Lattice A *lattice* L is an algebra $[S, F, \leq]$ in which F comprises two associative and commutative binary operations, $\wedge$ and $\vee$ (termed *meet* and *join*, respectively) satisfying the identities:

$$x \wedge x = x\,, \quad x \vee x = x$$

and

$$x \wedge (x \vee y) = x \vee (x \wedge y) = x\,.$$

The operations are isotone, so that $x \leq y$ is equivalent to the pair of conditions:

$$x \wedge y = x \quad \text{and} \quad x \vee y = y\,,$$

and the operations of meet and join may be interpreted as the greatest lower bound and least upper bound, respectively. A lattice L is *distributive* if the identity

$$x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$$

holds. A lattice L is *modular* if, whenever $x \leq z$, then

$$x \vee (y \wedge z) = (x \vee y) \wedge z\,.$$

Role algebra A *role algebra* is an algebra $[S, F, \leq]$ in which F comprises a single binary composition operation satisfying the condition: $s \leq t$ in S implies $su \leq tu$ in S, for any $u \in W$.

Homomorphism An (*isotone*) *homomorphism* from an algebra $A = [S, F, \leq]$ onto a similar algebra $B = [T, F, \leq]$ is a mapping $\phi\colon S \to T$ such that,

(i) for all $f_\alpha \in F$ and $x_i \in S$,

$$\phi(f_\alpha(x_1, x_2, \ldots, x_{n(\alpha)})) = f_\alpha(\phi(x_1), \phi(x_2), \ldots, \phi(x_{n(\alpha)}))\,; \quad \text{and}$$

(ii) $x \leq y$ in S implies $\phi(x) \leq \phi(y)$ in T.

The algebra B is termed a (*homomorphic*) *image* of A, and we write $B = \phi(A)$. Each homomorphism ϕ from $A = [S, F, \leq]$ onto $B = [T, F, \leq]$ has a corresponding binary relation π on S (termed here a *π-relation*) in which $(x, y) \in \pi$ if and only if $\phi(y) \leq \phi(x)$. The equivalence relation σ_π defined by $(x, y) \in \sigma_\pi$ if and only if $(x, y) \in \pi$ and $(y, x) \in \pi$ is termed a *congruence relation*.

Homomorphism lattice The *homomorphism lattice* $L(A)$ of the algebra $A = [S, F, \leq]$ is the collection of all homomorphisms of A partially ordered by the relation: $\phi_1 \leq \phi_2$ if, for all $x, y \in S$, $\phi_2(x) \leq \phi_2(y)$ implies $\phi_1(x) \leq \phi_1(y)$. The *lattice $L_\pi(A)$ of π-relations* on A, dual to $L(A)$, has the partial ordering: $\pi_1 \leq \pi_2$ if $(x, y) \in \pi_1$ implies $(x, y) \in \pi_2$, for any $x, y \in S$.

Definition of the Subject

Algebraic models have been proposed to represent structure in social networks. They are usually constructed from a set of operations and relations defined on network constituents such as paths or walks in the network, or vectors of ties directed to or from individual network members. The algebra represents the relationships among these constituents, for example, relations of ordering among all possible walks in a multiple network, or relations of overlap and ordering among profiles of group membership. To date, they have been used to represent kinship structures [6,9,48], role structures and stability in multiple networks [1,5,8,36], states of diffusion processes in networks [30], informal hierarchy [17], connectivity structures [13] and the structure of membership in affiliation networks [16,38]. In several cases, partial algebraic representations have also been proposed [35,39,40].

Algebraic models have usually been proposed as exact structural representations and, in many cases, therefore, their application to network data has been coupled with some form of prior data aggregation such as blockmodeling [5,50]; see also the entry on ▶ Positional Analysis and Blockmodeling. More rarely, algebraic construction and data aggregation have been combined into a single step [8,33].

Introduction

Algebraic models for relational structures such as networks have their foundations in anthropology and were developed for general network structures by Lorrain, White and colleagues [5,26,27]. These general network representations based on path structures in networks emerged from more specific models for path structures in kinship systems, including permutation group models for Australian aboriginal kinship systems [48]. Boyd extended this approach in an important way when he proposed that the structural evolution of kinship systems could be analyzed in terms of homomorphic mappings [6]; applications to network semigroups were described later [5,37].

Lattice representations for relational structures have a long history in mathematics [2] and applications to relational data in many domains have been developed extensively by Wille and collaborators in formal concept analysis [19,20,51]. They have also been applied to affiliation network structures [16,45,47].

The form of algebraic structure regarded as appropriate in a particular context is a matter for substantive consideration. The large majority of forms that have been proposed to date have depended upon the importance of paths or walks in the network, the symmetric or asymmetric nature of network ties, and the patterns of overlap among tie partners. A focus on one or more of these features has resulted in algebraic groups, semigroups, partially ordered semigroups, local role algebras and lattices as representations of different aspects of structure in multiple social networks and affiliation networks [5,8,14,16,29,36,48] and it is on these forms that we focus here.

Algebras from Networks

A Language for Discriminating Among Relations

We begin with a finite set $\Sigma = \{x_1, x_2, \ldots, x_r\}$ of r relational terms. We term Σ a relational *alphabet* and call each term x_i in Σ a *letter* of the alphabet. The letters $x_1, x_2, \ldots$ denote relational terms such as "friendship", "co-worker", "confidant", and so on. If $r = 1$, the set Σ simply identifies a single network relation.

In order to construct algebraic representations that are sensitive to social structural form, claims in the social network literature can be used to introduce a *free word algebra* on the alphabet Σ. The algebra is intended to provide a language for describing more complex relational terms that can be constructed from the primitive set Σ and so to provide the means for discriminating among social structural forms. The claims about appropriate ways of constructing new terms from the primitive set may be drawn from a number of sources, but one set of such claims is helpfully laid out by White [49]. White argues that there are three universal ways in which types of tie (i. e., relational terms) are discriminated. The first is in terms of patterns of overlap; the second in terms of asymmetry of relation; and the third in terms of the institutionalization of indirect ties. The overlap of two relational ties refers to their joint occurrence and can arguably be described using an *intersection* operation, $\cap$. The asymmetry of a tie can be described by the relationship between the tie and its *converse*, that is the coding of whether, for two individuals k and l, there is a tie from k to l and from l to k. The tie is *symmetric* if the tie from k to l occurs only in conjunction with the tie from l to k, and the tie is *strictly asymmetric* if a tie from k to l occurs only in the absence of a tie from l to k. We use the expression x' to denote the converse of the relational term x. Indirect ties may be described by a *composition*, or *concatenation* operation, denoted $^\circ$. If x_1 refers to the term "friendship" and x_2 to "coworker", then the concatenation $x_1{}^\circ x_2$ may be used to refer to a relation that holds between a person and his or her friend's co-workers.

We denote by F the set of operations from which our descriptive language is to be built. Unless otherwise specified, we assume here that F comprises the three operations just described; that is $F = \{\cap, {}', {}^\circ\}$. Each operation f_α in F possesses an *arity*, $n(\alpha)$, that determines the form of new terms created from Σ by f_α: in particular, f_α leads to expressions of the form $f_\alpha(y_1, y_2, \ldots, y_{n(\alpha)})$; $y_m \in \Sigma$, $m = 1, 2, \ldots, n(\alpha)$. The operations $\cap$ and $^\circ$ have arity 2, that is, they are *binary* and lead to expressions that can be written as $y_1 \cap y_2$, and $y_1{}^\circ y_2$, respectively, whereas the converse operation $'$ is *unary* (that is, it has an arity of 1) and leads to an expression that can be denoted y_1' (where $y_1, y_2 \in \Sigma$).

We describe a recursive construction of a free word algebra $W = [\Sigma, F]$ from the alphabet Σ and the set F of operations [2]. We call each letter in Σ an F-polynomial of *rank* 0. For any positive integer ρ, we define an F-polynomial of rank ρ recursively as an expression, termed a *word*, of the form $f_\alpha(u_1, \ldots, u_{n(\alpha)})$, where each u_j is an F-polynomial of rank $\leq \rho - 1$ (and at least one u_j is an F-polynomial of rank $\rho - 1$). The *(free) word algebra* $W = [\Sigma, F]$ comprises all distinct F-polynomials of finite rank (where $f_\alpha(u_1, \ldots, u_{n(\alpha)})$ and $f_\beta(v_1, \ldots, v_{n(\beta)})$ are distinct unless $\alpha = \beta$ and $u_k = v_k$ for all $k = 1, \ldots, n(\alpha)$).

It is sometimes convenient to restrict attention to the collection of words of rank no greater than some fixed integer ρ. So we also define $W_\rho = [\Sigma, F]_\rho$ as the subset of the free word algebra $W = [\Sigma, F]$ comprising words of rank $\leq \rho$.

For example, suppose that F comprises the operations $\{\cap, ', ^\circ\}$ and that $\Sigma = \{x, y\}$. Then the elements of rank 0 in the word algebra $W = [\Sigma, F]$ are $\{x, y\}$; the elements of rank 1 are $\{x \cap x, x \cap y, y \cap x, y \cap y, x', y', x^\circ x, x^\circ y, y^\circ x, y^\circ y\}$; elements of rank 3 include $x \cap x \cap x, x \cap (x^\circ x), (x^\circ x) \cap x, x \cap x', x' \cap x,$ etc; and so on. In this case, the free word algebra $W = [\Sigma, F]$ comprises all composite relational terms that can be constructed from the primitive terms x and y using the intersection, converse and concatenation operations.

The free word algebra simply provides a language that permits certain forms of discrimination among types of tie to be encoded. It makes no structural assumptions whatever, although we might anticipate from the intended interpretation of the terms in F that certain terms in W will not need to be discriminated. For instance, we might suppose that: the intersection operation can be assumed to be *idempotent* ($x \cap x = x$, for all $x \in W$), *commutative* ($x \cap y = y \cap x$, for all $x, y \in W$) and *associative* ($(x \cap y) \cap z = x \cap (y \cap z)$, for all $x, y, z \in W$); that the converse operation satisfies $x'' = x$, for all $x \in W$; and that the concatenation operation is also associative. Rather than impose such postulates at this abstract level, though, we move directly to the evaluation of the terms in W for an empirical realization of a (multiple) network.

Algebras for Multiple Networks

The language provided by the free algebra $W = [\Sigma, F]$ can be used to determine all possible discriminations among ties that our structural claims suggest as appropriate. To describe the structural forms to which observed network ties give rise, each of the derived relations for an observed multiple network can be computed. There is a straightforward correspondence between the words u in $W = [\Sigma, F]$ expressed in terms of letters in Σ and operations in F, on the one hand, and Boolean matrix manipulations of the binary constituents in the multiple network, on the other. The correspondence is achieved by replacing:

- the relational term x_m by the array X_m;
- the intersection operation $\cap$ by Boolean intersection of arrays (i. e., element-wise Boolean multiplication, denoted $\bullet$); and
- the composition operation $^\circ$ by Boolean matrix multiplication.

Boolean intersection, transposition and composition are defined for $n \times n$ binary arrays Y_1 and Y_2 by:

- $Y_1 \bullet Y_2(k, l) = Y_1(k, l) Y_2(k, l)$;
- $Y_1'(k, l) = Y_1(l, k)$; and
- $Y_1 Y_2(k, l) = Y_1(k, 1) Y_2(1, l) + Y_1(k, 2) Y_2(2, l) + \cdots + Y_1(k, n) Y_2(n, l)$.

The term $u \in W$ then corresponds to an $n \times n$ Boolean array, denoted X_u, with $X_u(k, l) = 1$ if and only if there is a relational tie described by the word u from k to l. We also define a partial order on the set of relations $\{X_u : u \in W\}$ by:

$$X_u \leq X_v \quad \text{if and only if} \quad X_u(k, l) \leq X_v(k, l) \quad \text{for all } k,\ l \in N\ .$$

Suppose that we evaluate X_u for all $u \in W$. We define a generalized version of the *Axiom of Quality* by setting $u \leq v$ in W whenever $X_u \leq X_v$ [5].

Defining an induced partition θ on W by $(u, v) \in \theta$ if and only if $u \leq v$ and $v \leq u$ and letting $S = W/\theta$ be the set of associated classes with the induced partial order:

$$s \leq t \text{ in } S \quad \text{if } u \in s\ ,\ v \in t \text{ and } u \leq v \text{ in } W\ ,$$

we can then define a general (partially ordered) algebraic structure on S.

A (*partially ordered*) *algebra* is a triple $[S, F, \leq]$, where S is a nonempty set of elements (usually assumed to be finite), F is a specified set of operations, f_α, each mapping a power $S^{n(\alpha)}$ of S into S, for some non-negative finite integer $n(\alpha)$, and $\leq$ is a partial order on S. Each operation f_α is assumed to be *isotone* in each of its variables: that is, if $x_i \leq y_i$ ($x_i, y_i \in S$; $i = 1, 2, \ldots, n(\alpha)$), then $f_\alpha(x_1, x_2, \ldots, x_{n(\alpha)}) \leq f_\alpha(y_1, y_2, \ldots, y_{n(\alpha)})$. A *family of algebras* is a collection of algebras each having the same set F of operations and satisfying a specified set of postulates. Two algebras belonging to the same family are termed *similar*.

For $F = \{\circ\}$, the algebra $[S, F, \leq]$ is a *partially ordered semigroup* [36].

The Semigroup of a Multiple Network

For multiple networks, a composite relation constructed as the concatenation of observed relations records the presence of a particular form of *labelled walk*. Specifically, actor k is connected to actor l by a walk with label u if and only if $X_u(k, l) = 1$. If $X_u \leq X_v$, two actors who are joined by a walk with label u are also necessarily joined by a walk with label v.

An algorithm for constructing the semigroup of a multiple network $[S, \{\circ\}, \leq]$ is as follows:

(S1) Let $W_1 = \{X_1, X_2, \ldots, X_r\}$ and set $i = 1$.
(S2) Construct the networks with edge sets WZ for each $W \in W_i$ and each $Z \in W_1$. Place WZ in W_{i+1} if $WZ \neq Y$, for any $Y \in W_j$, $j = 1, 2, \ldots, i+1$; otherwise, $WZ = Y$ for some $Y \in W_j$ $(j = 1, 2, \ldots, i+1)$ is an *equation* in the semigroup S.
(S3) If $W_{i+1} = \emptyset$, stop and compute the partial order among elements in $W_1 \cup W_2 \cup \ldots$; otherwise, set i to i+1 and return to step S2.

The equations $WZ = Y$ may be recorded in a *right multiplication table* in which Y appears as the table entry corresponding to the row labelled W and the column labelled Z. The partial ordering on S is constructed from the collection of networks in $W_1, W_2, \ldots$.

Lattices from Networks

Lattice representations for networks arise in two important ways. In the first, elements of the lattices are elements of $S = W/\theta$ for $F \supseteq \{\cap, \circ\}$. The meet of two elements is their intersection, and their join is the least relation in S which is greater than or equal to both of them. Indeed, the algebra $[S, F, \leq]$ is both a lattice and a partially ordered semigroup in this case.

In the second type of lattice construction, the elements correspond to rows or columns of an affiliation network. Since the affiliation array provides an explicit representation of the co-constitution of groups by actors and actors by groups, the lattice structures to which it gives rise can be used to analyze the duality of actors and groups [10,15,16,31,33,38,47].

A lattice denoted $L(X)$ is generated by the rows of a matrix X under the intersection operation; it is termed the *Galois* or *concept lattice* of X [20]. In $L(X)$, the meet of two elements is equal to their intersection, while their join is the minimal element in the lattice which is greater than or equal to both of them. A lattice can also be constructed from the rows of the matrix X under the union operation. In this lattice, termed the *Zareckii lattice* by Boyd, the join of two vectors is equal to their union, and their meet is the maximal vector which is less than or equal to both of them [8].

To construct the Galois lattice, one simply needs to compute all distinct intersections among rows of X, add the vector $[1\ 1 \ldots\ 1]$ and compute the partial order among the resulting set of row vectors.

Role Algebras from Networks

Role algebras have been proposed as local network analogues of the semigroup representation of relational structure in an entire social network. The representation has been presented in several slightly different forms but each is derived from an original formulation proposed by Mandel [11,29,53,54].

Denote by $k * X_u$ the vector $[X_u(k, 1), X_u(k, 2), \ldots, X_u(k, n)]$ for $u \in W$. The vector indicates whether there is a relationship of type u from actor k to each other actor in the network. As before, we can envisage evaluating $k * X_u$ for all $u \in W$. We then define a k-centered version of the *Axiom of Quality* by setting

$$u \leq v \text{ in } W \quad \text{whenever} \quad k * X_u \leq k * X_v$$

and an induced partition θ on W by $(u, v) \in \pi$ if and only if $u \leq v$ and $v \leq u$. Also as before, we let $S = W/\theta$ denote the set of associated classes with the induced partial order:

$$s \leq t \text{ in } S \quad \text{if } u \in s\,,\ v \in t \text{ and } u \leq v \text{ in } W\,.$$

The algebra $[S, F, \leq]$ is termed a *role algebra*.

The local role algebra for actor k may be constructed as follows.

(RA1) Let $W_1 = \{X_1, X_2, \ldots, X_r\}$ and set $i = 1$.
(RA2) Construct the vectors $k * WZ$ for each $W \in W_i$ and each $Z \in W_1$. Place WZ in W_{i+1} if $k * WZ \neq k * Y$, for any $Y \in W_j$, $j = 1, 2, \ldots, i + 1$; otherwise, $k * WZ = k * Y$ for some $Y \in W_j$ $(j = 1, 2, \ldots, i + 1)$ and $WZ = Y$ is an *equation* in the role algebra.
(RA3) If $W_{i+1} = \emptyset$, stop and compute the partial order among elements in $W_1 \cup W_2 \cup \ldots$; otherwise, set i to i+1 and return to step RA2.

Partial Algebras

To achieve algebraic closure, it may be necessary to compute relations corresponding to words of high rank in W and, in the case of some representations at least, it can be argued that some restriction on these repeated operations should be imposed. Mandel, for instance, made such an argument for the composition operation in social networks; he claimed that short network paths are likely to be more salient to the members of the network than longer ones [29]. These considerations can be formalized with the introduction of partial algebraic structures, whose elements are subject to rank restrictions on some or all of the operations used to construct the algebra.

Let $W_\rho = [\Sigma, F]_\rho$ be the subset of the free word algebra $W = [\Sigma, F]$ comprising words of rank $\leq \rho$. Define a partial order on the elements of W_ρ by the generalized Axiom of Quality:

$$u \leq v \text{ in } W_\rho \quad \text{whenever} \quad X_u \leq X_v \, .$$

The relation $\leq$ is clearly both *reflexive* ($u \leq u$ for all u) and *transitive* ($u \leq v$ and $v \leq w$ implies $u \leq w$ for any u, v, w), that is, a *quasi-order*. Further, each operation f_α is *isotone* in each of its variables whenever the result of the operation is contained in W_ρ; that is, if $x_i \leq y_i$ ($x_i, y_i \in W_\rho$; $i = 1, 2, \ldots, n(\alpha)$), then $f_\alpha(x_1, x_2, \ldots, x_{n(\alpha)}) \leq f_\alpha(y_1, y_2, \ldots, y_{n(\alpha)})$, provided that both $f_\alpha(x_1, x_2, \ldots, x_{n(\alpha)}), f_\alpha(y_1, y_2, \ldots, y_{n(\alpha)}) \in W_\rho$. Thus it follows that the partial ordering $\leq$ on W_ρ gives rise to a *partial* algebra in the following sense.

A *partial algebra* is a triple $[S, F, \leq]$, where S is a nonempty set of elements (usually assumed to be finite), F is a specified set of *partial* operations, f_α, each mapping some subset $T^{(\alpha)}$ of $S^{n(\alpha)}$ into S, for some non-negative finite integer $n(\alpha)$, and $\leq$ is a partial order on S. Each partial operation f_α is assumed to be *isotone* in each of its variables: that is, if $x_i \leq y_i$ ($x_i, y_i \in S$; $i = 1, 2, \ldots, n(\alpha)$), then $f_\alpha(x_1, x_2, \ldots, x_{n(\alpha)}) \leq f_\alpha(y_1, y_2, \ldots, y_{n(\alpha)})$ provided that both $(x_1, x_2, \ldots, x_{n(\alpha)}), (y_1, y_2, \ldots, y_{n(\alpha)}) \in T^{(\alpha)}$. A *family of partial algebras* is a collection of algebras each having the same set F of partial operations defined on the same subsets $T^{(\alpha)}$ of the power sets $S^{n(\alpha)}$.

Partial semigroup algebras may be constructed from labelled walks in a multiple network of some maximum length ρ [40]. For role algebras, the partial role algebra for a node k derived from W_ρ is the role algebra associated with the ρ-local neighborhood of k [39].

Algebraic Structure

In some cases, it is possible to analyze the structural properties of algebraic representations of networks.

The Semigroup of a (Single) Network Under Composition

We first consider the semigroup for a single network array X. We say that there is a *walk* from actor k to actor l if $X(k, l) = 1$. There is a walk of *length* p from k to l if there is a sequence of actors $k = k_0, k_1, \ldots, k_p = l$ such that $X(k_{i-1}, k_i) = 1$, for $i = 1, 2, \ldots, p$. It is readily seen that $X^p(k, l) = 1$ if and only if there is a walk of length p from k to l. The sequence $X,\ X^2, \ldots$ generated by the composition operation is therefore a sequence recording the presence of walks of different lengths between all pairs of network actors. The semigroup structure of this sequence therefore describes relations of equality and ordering among walks in the network.

The sequence can be described with the help of the following definition. Let p be the least integer such that

$$X^p = X^q \quad \text{for some} \quad q > p \, .$$

Also let $q = p + d$ ($d \geq 1$) be the least integer satisfying this relation. The integers p and d are termed the *index* and *period* of the network, respectively. It can readily be seen that the sequence has the form

$$X, \ldots, X^{p-1}, X^p, \ldots, X^{p+d-1}, X^p, \ldots, X^{p+d-1}, \ldots \, .$$

The set $\{X, X^2, \ldots, X^{p+d-1}\}$ defines a semigroup S of which $G = \{X^p, \ldots, X^{p+d-1}\}$ is a group (defined below).

It is natural to ask what is the relationship between properties of a network and its index and period.

For a strongly connected network X (that is, a network in which there is a walk of some length from each actor to each other actor), the period d is the greatest common denominator of all integers m such that m is the length of a cycle in X (that is, a walk with the same initial and final node). If X has more than one strong component, its period is the least common multiple of the periods of those strong components [24].

A network X with index 1 and period 1 is termed *idempotent*; for a network of index p and period 1, the network X^p is idempotent. It may be shown that every idempotent network is a pseudo-order, defined as follows [43]. Let Z be a quasi-order on N and let $e_Z = Z \cap Z'$. An actor $k \in N$ is termed *Z-strict* if there is no distinct actor $l \neq k$ such that $Z(k, l) = 1$. The subset H of N is *Z-permissible* if each of its actors is Z-strict and there are no pairs $k, l \in N$ such that k covers l or l covers k (recall that k covers l if $Z(k, j) = 1$ and $Z(j, l) = 1$ implies $j = k$ or $j = l$). Define the relation Z_H by

$$Z_H(k, l) = 1 \quad \text{iff} \quad k = l \text{ and } k \in H \, .$$

Then a network X is a *pseudo-order* if

$$X = Z \backslash Z_H$$

for some quasi-order Z and Z-permissible subset H of N.

Structure of Multiple Network Semigroups

In some cases, networks define semigroups with certain structural features.

An element s in a semigroup S possesses a (generalized) *inverse* if there exists some $t \in S$ such that $sts = s$ and $tst = t$. The element t is termed the inverse of s. If every $s \in S$ possesses an inverse, then S is termed an *inverse semigroup*. If, in addition, S possesses an *identity* element, that is, an element e such that for any $s \in S$, there exists some $t \in S$ such that $ts = e$, then S is a *group*. The element t is termed a *(group-)inverse* of s. An element s in a semigroup S is *regular* if there exists some $t \in S$ such that $sts = s$. The semigroup S is *regular* if each of its elements is regular.

It is clear from these definitions that any group is also an inverse semigroup and that any inverse semigroup is also regular. The results below describe some of the conditions under which mutiple networks give rise to regular semigroups, inverse semigroups and groups.

We first describe the conditions under which S is a group [28,42]. Let X be a network relation having a group-inverse Y, that is, a relation Y such that $XY' = I$ where I is the identity relation (for which $I(k,l) = 1$ if $k = l$; $I(k,l) = 0$ otherwise). Then it follows that (i) $XX' = I = X'X$ and $Y = X$ (that is, X' is a two-sided group-inverse for X and is unique); and (ii) X is a permutation relation (that is a relation in which, for each node k, there is exactly one node l for which $X(k,l) = 1$ and exactly one node j for which $X(j,k) = 1$). Hence if each relation X_i of a multiple network is a permutation relation and X'_i is included in S for each i, then the semigroup S is a group.

An important class of social relations which are constructed as permutation relations are "marriage class systems". These systems were proposed by White as models for kinship relations in certain Australian aboriginal tribes [48]. In such systems, persons are uniquely and permanently assigned to a *clan* and clans are related to one another by marriage and descent rules which can be represented as permutation relations. The marriage relation specifies the clan containing the wives of the male members of each clan, while the descent relation identifies the clan containing the children of male members of each clan. It follows that marriage class systems give rise to groups that represent the kinship structures of the societies concerned.

Another structure arising in the description of kinship systems is the inverse semigroup [9]. One can verify whether a network semigroup is an inverse semigroup by determining whether each of its elements has an inverse in S. The following is a characterization of conditions under which a relation possesses an inverse [24].

A network relation X has a *Thierrin–Vagner inverse* if there exists a relation Y satisfying $XYX = X$ and $YXY = Y$. Clearly, X has a Thierrin–Vagner inverse if and only if X possesses an inverse in S. If X is a regular element of S, so that $XYX = X$ for some Y in S, then YXY is a Thierrin–Vagner inverse for X. Thus determining whether X is regular will reveal whether X has an inverse. The regularity of X can be ascertained as follows.

The network relation Y is a *subinverse* of X if $XYX \leq X$. The set of subinverses of X is closed under union (that is, if Y and Z are subinverses of X then so is the relation $Y \cup Z$); hence there is a largest subinverse X^* for any relation X. The largest subinverse X^* of a relation X can be calculated from X according to $X^* = (X^T X^c X^T)^c$ where X^c denotes the complement of X. It therefore follows that a network X is regular if and only if $X \leq X(X^T X^c X^T)^c X$, and that the largest Thierrin–Vagner inverse of a regular relation X is $X^* X X^*$ [24,44].

The Algebraic Structure of Local Role Algebras

Less is known of the general algebraic properties of local role algebras. It is easily seen, however, that any orderings among relations present in the semigroup of a multiple network are also present in the local role algebra of each actor in the network. As a result, a number of the algebraic properties of local role algebras are inherited from the "parent" network semigroup. For example, if $s \leq t$ in the partially ordered semigroup S constructed from the composition operation, then $s \leq t$ in the local role algebra of every node in the network. Indeed, the converse is readily seen to also hold, so that $s \leq t$ in S if and only if $s \leq t$ in the local role algebra of every node in the network.

Algebraic Analysis

In order to describe an algebraic representation, general procedures for analyzing finite algebraic representations into simpler, independent components have been developed [20,36,37,39]. These procedures have been applied to the decomposition of lattice representations [20], partially ordered semigroups and local role algebras [34,35,36]. The procedures extract maximally independent components of a given algebraic representation and lead to a detailed structural analysis.

The account of these procedures for decomposing a finite algebra into simpler components is based on definitions adapted from [2,18]. Clearly, any decomposition procedure depends on the synthesis rules by which the components are assumed to be combined to produce the algebra. Two important synthesis rules are the direct and subdirect product.

Let $A_1 = [S_1, F, \leq]$, $A_2 = [S_2, F, \leq]$, $\ldots, A_q = [S_q, F, \leq]$ be a collection of similar algebras. The *direct product* $A_1 \times A_2 \times \cdots \times A_q$ of $A_1, A_2, \ldots, A_q$ is the algebra comprising the set $S_1 \times S_2 \times \cdots \times S_q$ and the operations $f_\alpha \in F$ given by

$$f_\alpha([x_1, x_2, \ldots, x_q], \ldots, [z_1, z_2, \ldots, z_q]) \\ = [f_\alpha(x_1, \ldots, z_1), \ldots, f_\alpha(x_q, \ldots, z_q)]\ .$$

The partial order for $A_1 \times A_2 \times \cdots \times A_q$ is given by

$$[x_1, x_2, \ldots, x_q] \leq [z_1, z_2, \ldots, z_q]$$

if and only if

$$x_1 \leq z_1, x_2 \leq z_2\,, \ldots, \text{ and } x_q \leq z_q\ .$$

An algebra $B = [T, F, \leq]$ is a *subalgebra* of $A = [S, F, \leq]$ if T is a subset of S (possibly empty) which is closed under the operations of F (that is, $f_\alpha(x_1, x_2, \ldots, x_{n(\alpha)}) \in T$, for any $x_1, x_2, \ldots, x_{n(\alpha)} \in T$, and any $f_\alpha \in F$); in addition, $x \leq y$ in B if and only if $x \leq y$ in A, for any $x, y \in T$. A subalgebra $C = [S, F, \leq]$ of a direct product $A_1 \times A_2 \times \cdots \times A_q$ of similar algebras $A_i = [S_i, F, \leq]\,(i = 1, 2, \ldots, q)$ is a *subdirect product* of $A_1, A_2, \ldots, A_q$ if for each $x_i \in S_i$, there exists an element $c \in S$ having x_i as its component in A_i.

In the case of both the direct and subdirect product of algebras, the operations in the composite algebra are performed as the conjunction of their independent operation in the component algebras. The difference between the two constructions lies in the set on which these operations are defined. For the direct product, the appropriate set is the full Cartesian product of elements from each component algebra; in the subdirect product case, the appropriate set is simply a subset of the full Cartesian product with the additional condition that each element in each component algebra appears in *some* element of the subset.

Some well-known theorems in universal algebra establish that the existence and nature of direct and subdirect representations of an algebra are determined by the lattice of homomorphisms of the algebra, or, equivalently, by a lattice of relations on the algebra associated with its homomorphisms.

An (*isotone*) *homomorphism* from an algebra $A = [S, F, \leq]$ onto a similar algebra $B = [T, F, \leq]$ is a mapping $\phi\colon S \to T$ such that,

(i) for all $f_\alpha \in F$ and $x_i \in S$,

$$\phi(f_\alpha(x_1, x_2, \ldots, x_{n(\alpha)})) \\ = f_\alpha(\phi(x_1), \phi(x_2), \ldots, \phi(x_{n(\alpha)}))\,; \quad \text{and}$$

(ii) $x \leq y$ in S implies $\phi(x) \leq \phi(y)$ in T.

The algebra B is termed a (*homomorphic*) *image* of A, and we write $B = \phi(A)$.

Further, each homomorphism ϕ from $A = [S, F, \leq]$ onto $B = [T, F, \leq]$ has a corresponding binary relation π on S (termed here a π*-relation*) in which $(x, y) \in \pi$ if and only if $\phi(y) \leq \phi(x)$; it may readily be established that π is transitive and reflexive (and hence a quasi-order) and that the equivalence relation σ_π defined by $(x, y) \in \sigma_\pi$ if and only if $(x, y) \in \pi$ and $(y, x) \in \pi$ has the substitution property, namely:

$$(x_1, y_1), (x_2, y_2), \ldots, (x_{n(\alpha)}, y_{n(\alpha)}) \in \sigma_\pi$$

implies

$$(f_\alpha(x_1, x_2, \ldots, x_{n(\alpha)}),\ f_\alpha(y_1, y_2, \ldots, y_{n(\alpha)})) \in \sigma_\pi\ .$$

The relation σ_π is termed a *congruence relation*. The collection of π-relations may be partially ordered by: $\pi_1 \leq \pi_2$ if $(x, y) \in \pi_1$ implies $(x, y) \in \pi_2$, for any $x, y \in S$. Under this partial ordering, the relations π form a lattice $L_\pi(A)$, the *lattice of* π*-relations* on A.

The conditions under which an algebra A may be represented as a direct or subdirect product of similar algebras $A_1, A_2, \ldots, A_r$ (that is, possesses *direct* or *subdirect representations*) can be described as follows.

Let $X = \{\pi_1, \pi_2, \ldots, \pi_q\}$ be a set of π relations in $L_\pi(A)$ for which

$$\pi_1 \wedge \pi_2 \wedge \cdots \wedge \pi_q = \pi_{\min}\,,$$

where $\pi_{\min}$ is the minimal element of $L_\pi(A)$. Then A may be represented as a subdirect product of the algebras $\phi_1(A), \phi_2(A), \ldots, \phi_q(A)$, where $\phi_i(A)$ is the image of A under the homomorphism ϕ_i corresponding to the relation π_i $(i = 1, 2, \ldots, q)$. If, in addition, for all i,

(a) $\pi_1 \wedge \pi_2 \wedge \cdots \wedge \pi_{i-1}$ and π_i are *permutable* (i. e., $(\pi_1 \wedge \pi_2 \wedge \cdots \wedge \pi_{i-1})\pi_i = \pi_i(\pi_1 \wedge \pi_2 \wedge \cdots \wedge \pi_{i-1})$); and

(b) $(\pi_1 \wedge \pi_2 \wedge \cdots \wedge \pi_{i-1}) \vee \pi_i = \pi_{\max}$, where $\pi_{\max}$ is the maximal element of $L_\pi(A)$, then A may be represented as the direct product of the algebras $\phi_1(A), \phi_2(A), \ldots, \phi_q(A)$ [2].

An algebra which possesses no nontrivial representation as the direct product of similar algebras is termed *directly irreducible*, while an algebra which cannot be expressed as a nontrivial subdirect product of similar algebras is *subdirectly irreducible*. Pattison and Bartlett advocated the use of subdirect representations, but sought to restrict attention to a small set of such representations rather than to the (possibly large) class of all subdirect representations of the algebra [37]; see also [7]. Their restriction entailed (a) identifying all *irredundant* subdirect representations of an algebra, and then (b) defining a partial ordering on the irredundant representations and selecting only minimal members of the resulting partially ordered set. The resulting set of minimal, irredundant subdirect representations were termed the factorizations of the algebra.

More formally, an element x of a lattice L is *meet-irreducible* if $x = x_1 \wedge x_2$ implies $x = x_1$ or $x = x_2$. A subset of lattice elements $X = \{x_1, x_2, \ldots, x_r\}$ is *irredundant* if

a) each x_i is meet-irreducible; and
b) $x_1 \wedge \cdots \wedge x_{i-1} \wedge x_{i+1} \wedge \cdots \wedge x_q, \neq x_{\min}$, for each $i = 1, 2, \ldots, q$; where $x_{\min}$ is the minimal element of the lattice L.

The collection of all irredundant subsets of a lattice L may be partially ordered by the relation:

$X \leq Y$ iff, for each $j = 1, 2, \ldots, p$, there exists some i $(i = 1, 2, \ldots, q)$ such that $y_j \leq x_i$ in L, where $X = \{x_1, x_2, \ldots, x_q\}$ and $Y = \{y_1, y_2, \ldots, y_p\}$.

A *factorization* of an algebra A is then the subdirect representation corresponding to any minimal, irredundant subset of elements of $L_\pi(A)$ whose meet is the minimal relation $\pi_{\min}$.

An Algorithm for Factorization

A general algorithm for constructing the set of all factorizations of an algebra has also been developed [37]. The algorithm operates on a subset of relations in the lattice $L_\pi(A)$ and conducts a reasonably efficient search for subsets of π relations which satisfy the conditions of the factorization definition. In particular, the algorithm constructs the set of factorizations of an algebra A from the atoms of its lattice $L_\pi(A)$ of π-relations and their maximal meet-complements.

An *atom* of a lattice L is an element that covers $x_{\min}$. A *meet-complement* of an element $x \in L$ is an element x^* such that $x^* > x_{\min}$ and $x \wedge x^* = x_{\min}$. A meet-complement x^* of x is *maximal* if x has no other meet-complement z such that $z > x^*$.

Let $Z = \{z_1, z_2, \ldots, z_a\}$ be the set of atoms of $L_\pi(A)$. Define the collection of sets of the form $\{z_1^*, z_2^*, \ldots, z_a^*\}$ where z_i^* is a maximal meet-complement of z_i. Then it can be shown that any factorization of A is a subset of such a set [36]. This result is the basis for the algorithm for finding factorizations. Under certain circumstances, we can write down an explicit expression for π-relations in the factorization of A.

Let A be an algebra with π-relation lattice $L_\pi(A)$. Let π_{ab} be the least π-relation in which $a \geq b$ for elements $a, b \in A$; we term π_{ab} the π-relation generated by the ordering $a \geq b$.

Let z be an atom of $L_\pi(A)$; define the relation $\pi(z) = \{(a, b) : \pi_{ab} \wedge z = \pi_{\min}\}$. If z has a unique maximal meet-complement, then $\pi(z)$ is a π-relation and is a unique maximal meet-complement of z. Conversely, if $\pi(z)$ is a π-relation, then it is the unique maximal meet-complement of z. Further, if $Z = \{z_1, z_2, \ldots, z_a\}$ is the set of atoms of $L_\pi(A)$ and if, for each $z_i \in Z$, z_i has a unique maximal meet-complement $\pi(z_i)$, then the factorization of A is unique and corresponds to the π-relations $\{\pi(z_1), \pi(z_2), \ldots, \pi(z_a)\}$ [36]. In other words, if the factorization is unique, it can be identified immediately from the maximal meet-complements of the atoms of $L_\pi(A)$.

Under some circumstances, we can make more general claims about the uniqueness of factorizations. Not surprisingly, the structure of the lattice $L_\pi(A)$ plays a major part. It is known, for instance, that if the lattice $L_\pi(A)$ is distributive, then A possesses a unique irredundant subdirect representation, and hence a unique factorization. In particular, since the lattice of π-relations for a lattice is necessarily distributive, any finite lattice has a unique factorization. If the lattice $L_\pi(A)$ is modular, then any irredundant subdirect representation of A has the same number of components [2].

Factorization for Partial Algebras

Analogous decompositions can be described for partial algebras. An (*isotone*) *homomorphism* from a partial algebra $A = [S, F, \leq]$ onto a similar partial algebra $B = [T, F, \leq]$ is a mapping $\phi \colon S \rightarrow T$ such that,

(i) for all $f_\alpha \in F$ and $x_i \in S$,

$$\begin{aligned}\phi(f_\alpha(x_1, x_2, \ldots, x_{n(\alpha)}))\\ = f_\alpha(\phi(x_1), \phi(x_2), \ldots, \phi(x_{n(\alpha)}))\end{aligned}$$

whenever the operations on both sides of the expression are defined; and

(ii) $x \leq y$ in S implies $\phi(x) \leq \phi(y)$ in T.

The algebra B is termed a (*homomorphic*) *image* of A, and we write $B = \phi(A)$.

Further, each homomorphism ϕ from $A = [S, F, \leq]$ onto $B = [T, F, \leq]$ has a corresponding binary relation π on S (termed here a π*-relation*) in which $(x, y) \in \pi$ if and only if $\phi(y) \leq \phi(x)$; it may readily be established that π is transitive and reflexive (so that π is a quasi-order). Further, the equivalence relation σ_π defined by $(x, y) \in \sigma_\pi$ if and only if $(x, y) \in \pi$ and $(y, x) \in \pi$ has the substitution property, namely:

$$(x_1, y_1), (x_2, y_2), \ldots, (x_{n(\alpha)}, y_{n(\alpha)}) \in \sigma_\pi$$

implies

$$(f_\alpha(x_1, x_2, \ldots, x_{n(\alpha)})\,,\ f_\alpha(y_1, y_2, \ldots, y_{n(\alpha)})) \in \sigma_\pi$$

whenever the latter term is defined. The relation σ_π is often termed a *congruence relation*. The collection of all π-relations form a lattice $L_\pi(A)$, the *lattice of* π*-relations* on A, under the partial ordering: $\pi_1 \leq \pi_2$ if $(x, y) \in \pi_1$ implies $(x, y) \in \pi_2$, for any $x, y \in S$.

In the case of partial algebras, it is convenient to express the algebra as an intersection of the π-relations corresponding to maximally independent homomorphic images of the algebra. Recall that the minimal element $\pi_{\min}$ of the lattice $L_\pi(A)$ corresponds to the algebra A itself. Thus, any expression of $\pi_{\min}$ in the form

$$\pi_1 \wedge \pi_2 \wedge \cdots \wedge \pi_q = \pi_{\min}$$

expresses A as the intersection of π-relations corresponding to homomorphic images of A. Any such expression that involves π-relations $\{\pi_i\,;\ i = 1, 2, \ldots, q\}$ satisfying the conditions of the factorization definition yields an expression in terms of a set of simple and maximally independent images of the algebra. Further, the same algorithm for constructing factorizations of an algebra that was described earlier may be used to find expressions of this type.

Algebraic and Network Mappings

The semigroup of a multiple network records the orderings and equations among different types of labelled paths in the network. A natural question to arise is how properties of a multiple network constrain the relational structure of its semigroup. We therefore review some general conditions under which the semigroup of one network is a homomorphic image of the semigroup of another.

We define two multiple networks to possess the same structure if their semigroups are isomorphic, that is, if the network relations are in one-to-one correspondence and they have identical right multiplication tables and partial orders.

One strategy for investigating whether networks have similar structures is to determine the conditions under which network homomorphisms induce homomorphisms of the network semigroup [4]. A *network homomorphism* from a multiple network $\{X_1, X_2, \ldots, X_r\}$ on actor set N to a multiple network $\{Y_1, Y_2, \ldots, Y_r\}$ on actor set M is a mapping ψ from N onto M such that: (a) $X_m(k, l) = 1$ implies $Y_m(\psi(k), \psi(l)) = 1$, for any k, l, m; and (b) $Y_m(i, j) = 1$ for some i, j implies that $X_m(k, l) = 1$, for some k, l such that $\psi(k) = i$ and $\psi(l) = j$. The network on M is termed the *image* of the network on N under the mapping ψ.

The mapping ψ satisfies the *structural equivalence* condition if for any m, and for any $k, l \in N$, $\psi(k) = \psi(l)$ if and only if:

- $X_m(k, j) = 1$ iff $X_m(l, j) = 1$ for any $j \in N$; and
- $X_m(j, k) = 1$ iff $X_m(j, l) = 1$ for any $j \in N$.

Lorrain and White observed that if two multiple networks are related by a network homomorphism satisfying the structural equivalence condition, then their semigroups are isomorphic and we may argue that they possess the *same* relational structure [27]. More generally, we can ask whether a homomorphism between two networks induces a homomorphism between their semigroups. It is readily seen that a homomorphism is not always guaranteed.

Network homomorphisms induced by certain blockmodels lead to semigroup homomorphisms (see the entry on ► Positional Analysis and Blockmodeling). More general conditions under which a semigroup homomorhism is guaranteed were established by Kim and Roush [25].

A network homomorphism ψ satisfies Kim and Roush's *condition* G_i if the following holds for any pair of equivalence classes ρ_1 and ρ_2 on N induced by the mapping ψ (so that $k, l \in \rho_h$ for some h iff $\psi(k) = \psi(l)$). Let the number of elements in ρ_1 and ρ_2 be n_1 and n_2, respectively. Let D be any subset of ρ_1 of i elements or, if $i > n_1$, let $D = \rho_1$. Then, for any $m = 1, 2, \ldots, r$, the set $\{l : l \in \rho_2 \text{ and } X_m(k, l) = 1 \text{ for some } k \in D\}$ has at least $\min(i, n_2)$ elements. The condition G_1 is also known as the *outdegree condition* and G_n is also termed the *indegree condition*. A network homomorphism that satisfies both G_1 and G_n is termed *regular*.

Kim and Roush demonstrated that if ψ is a network homomorphism from one multiple network onto another that satisfies the condition G_i, then there is a homomorphism mapping the semigroup of the first onto the semigroup of the second.

A more general condition combines the condition G_i with what Pattison termed the *central representatives condition* [34]. Let ψ be a network homomorphism. Then ψ satisfies the condition G_{im} if, for each class ρ of elements of N induced by ψ,

- there exists a *central subset* C of ρ such that for any X_m
  - $X_m(k, l) = 1$ for some $k \in \rho$ implies $X_m(k^*, l) = 1$ for some $k^* \in C$, and
  - $X_m(l, k) = 1$ for some $k \in \rho$ implies $X_m(l, k^*) = 1$ for some $k^* \in C$; and
- if C^* denotes the union of central subsets C, then the central subsets C satisfy Kim and Roush's condition G_i on the network defined on C^*.

If each central subset C comprises a single actor, then the condition is equivalent to Pattison's central representatives condition, while if each central subset C comprises the whole of the equivalence class on N induced by ψ, it is equivalent to the condition G_i. Kim and Roush showed that if one network can be mapped onto another by a network homomorphism satisfying the condition G_{im}, then there is a homomorphism from the semigroup of the first to the semigroup of the second [25]. The condition G_{im} is the most general condition known that guarantees the existence of such a homomorphism.

Comparing Network Semigroups

Two network semigroups S_1 and S_2 are strictly comparable only if $S_1 \leq S_2$ or $S_2 \leq S_1$. Loosely speaking, though, they are "similar" if they share many homomorphic images. Boorman and White proposed that the largest shared homomorphic image (the so-called *joint homomorphism*) is a useful construction for comparing network semigroups [5]. Bonacich and McConaghy, on the other hand, argued that the smallest semigroup containing each of S_1 and S_2 (the *common structure semigroup*) was a more appropriate representative of common semigroup structure [3,32]. The resolution of the problem of finding a representative of common structure depends on how a semigroup is viewed [36]. If a semigroup is seen as a list of the homomorphic images that it admits, then the joint homomorphism corresponds to the list of shared features, while if it seen as a collection of semigroup equations and orderings, then the common structure semigroup serves as a representation of shared structure. The common structure semigroup of two network semigroups is the semigroup of the disjoint union of the underlying networks.

Both the joint homomorphic image and common structure semigroup constructions have been shown to be useful in particular applications, the former in identifying common reductions of the networks giving rise to identical semigroups, and the latter in identifying shared cultural forms (such as "the friend of a friend is always an associate").

Linking Algebraic and Network Homomorphisms

The factorization of an algebra identifies relatively independent components of the algebra generated by constituents of the data array under the selected operation. It is natural to ask whether this analysis induces a corresponding decomposition of the network itself. That is, if an algebra A has a homomorphic image B (such as one of the factors of A), is it possible to find one or more homorphisms of the network that is consistent with the congruence relation σ for the homomorphism and that generates the algebra B? If so, we can argue that there is an association between such a reduction of the network and the homomorphic image.

In the case of the lattice of an affiliation network, such a reduction can always be uniquely found [20]. For semigroups and role algebras, there is no guarantee that such a reduction can be found, but it is possible to identify the smallest homomorphic image of the network whose algebra contained B as a homomorphic image [34].

Examples

We illustrate a number of the algebraic constructions just described for a multiple network blockmodel and an approximation to an affiliation network.

Network Semigroup

Table 1 corresponds to a multiple network on 7 nodes with two kinds of edges, F and N. The network is a blockmodel reported by Vickers for relations of friendship and negative ties among members of a high school class in an Australian country town [46]. The questions from which the blockmodel was constructed were (a) "Who are your best friends?" and (b) "Who would you rather not have as a friend?".

The semigroup generated by the multiple network in Table 1 has the right multiplication table and partial order shown in Table 2. The process of constructing the semigroup generates the sets $W_1 = \{F, N\}$, $W_2 = \{F^2, FN, NF, N^2\}$, $W_3 = \{F^3, FNF, FN^2, NF^2, N^2F, N^3\}$, $W_4 =$

$\{FN^2F, NF^3\}$ and $W_5 = \emptyset$; equations include $F^2N = FN$, $NFN = FN^2$, and $F^4 = F^3$.

It is evident from Table 2 that the relations F and N both have index 3 and period 1. The relation F is regular, whereas the relation N is not.

Each of the equations of Table 2 specifies the empirical coincidence of potentially distinct labelled walks. The equation $F^2N = FN$, for example, indicates the those individuals nominated by one's friends as preferred nonfriends coincide with individuals so nominated by the friends of one's friends.

Role Algebra

The role algebra for block 4 in the network of Table 1 is presented in Table 3. Equations in the right multiplication table indicate equalities among labelled paths having block 4 as the source. For example, the equation $FF = F$ indicates that friendship paths of length 2 emanating from block 4 reach exactly the same set of blocks as direct friendship ties. Likewise, the equation $FN = N$ allows us to infer that, namely block 4 would prefer not to have as friends precisely those blocks so nominated by their friends. The partial order diagram indicates that block 4's friendship ties are a subset of those to whom block 4 has negative tie paths (block 4) of length 2.

The role algebra of block 4 has a unique factorization. The lattice of π-relations has two atoms and each atom possesses a unique maximal meet-complement; the atoms and their maximal meet-complements are shown in Table 4. These unique maximal meet-complements are associated with the role algebras shown in Table 5. In the first factor, both *FN* and *NF* ties from block 4 coincide with N ties, and *NNF* ties include all others. In the second factor, any path from block 4 whose last tie is labelled N coincides with an N tie.

Lattice of an Affiliation Network

The affiliation network in Table 6 is an approximation to the so-called "Southern Women" data [12,23]. The approximation was obtained by a method described in [52], and is akin to a form of dual clustering of the rows and columns of the original data array. The Galois lattice of the (approximate) affiliation array is presented in Fig. 1. In Fig. 1, known as the *line diagram* of the lattice, one element *s* is drawn above and connected to another element *t* if *s* covers *t*, (that is if $s \geq t$ and there is no element *u* distinct from *s* and *t* for which $s \geq u \geq t$) [51]. The meet of two elements is the greatest element lying below both elements and connected to them by a descending path. The join of two elements is the least element to which they are both connected by an ascending path.

18	0	0	0	0	0	0	0	$\underline{1}$	1	0	$\underline{0}$	0	0	0

The rows and columns of the affiliation array may be mapped to lattice elements in such a way that any row element (in this case, a woman) is at or above any column elements (in this case, events) with which it is affiliated; likewise, any column element (event) is at or below any affiliated row elements (women). It can be seen from Fig. 1, for example, that all women attend event e8, whereas only women W1, W2 and W3 attend events e1 and e2.

Largest homomorphic image of the lattice of Fig. 1

The lattice displayed in Fig. 2 is a maximal homomorphic image of the lattice of Fig. 1 and provides a simplification of the lattice. In this diagram, a division of the women in the network into three ordered clusters is apparent. One cluster comprises the women W1 to W6, with women W4, W5 and W6 attending only a subset of the events attended by women W1, W2 and W3. A second cluster comprises women W11 to W15, with women W11 and W15 attending only a subset of the events attended by women W12, W13 and W14. The third cluster of women comprises W7, W8, W16, W17 and W18 and is again divided into two sub-clusters, one of whom (W7) attends a subset of the events attended by the other (W8, W16, W17, W18). It is also clear from the lattice of Fig. 2 that the first two clusters of women attend a mixture of distinct events (e1 to e6 in the case of the first cluster, and e10 to e14 in the case of the second) as well as common events (e7 to e9), whereas the third cluster of women attend only those events also attended by women in the first two clusters (e7 to e9). This structural feature of the affiliation network is drawn out very clearly in the unique maximal homomorphic image of the lattice of Fig. 2, shown in Fig. 3.

Future Directions

The algebraic constructions described above provide exact and detailed representations of structural relationships

Social Networks, Algebraic Models for, Figure 3
Largest homomorphic image of the lattice of Fig. 2

among network constituents. Of course, this level of detail assumes that the relational observations comprising the network are accurate, as no allowance is made for variability or error. This is often a tenuous assumption, and two important directions for further development utilize the structural sensitivities of algebraic representations in the presence of network tie variability.

The first direction is to use statistical criteria to generate (partial) algebraic structures that summarize key structural features of a network [1,8,39,40]. Instead of the generalized Axiom of Quality introduced earlier, an *Approximate Axiom of Quality* is proposed in which $u \leq v$ in W whenever there is "sufficient evidence" that the relation $X_u \leq X_v$ holds. Such an approach can lead to a theoretically-guided and structurally-focused form of exploratory data analysis for multiple networks. Theoretical guidance comes from choice of operations in the set F, while structural focus resides in the (partial) algebra to which the approach gives rise.

The second direction is to understand how exact algebraic representations can emerge as special, so-called *degenerate*, cases of statistical models such as exponential random graph models for networks (see the entry on ▶ Social Networks, Exponential Random Graph ($\boldsymbol{p}^*$) Models for *for Networks*). An exponential random graph model defines a probability distribution on the set of all networks on a node set N as a function of some parameter vector. For any parameter vector, a subset of networks have what can be defined as minimum "energy". As the parameter vector is scaled by an increasingly large multiplier, the probability associated with any network whose energy exceeds the minimum tends to zero. The minimum energy networks can therefore be seen as highly constrained or "frozen" structural forms associated with the stochastic model [21,22,41]. The structure of these forms will often warrant algebraic analysis of the type described earlier; in addition, we can understand the non-frozen models as stochastic generalizations of these structural forms.

University of Southern California, Alhambra, USA

Article Outline

Glossary

Adoption A person's change in behavior.

Agent based models Creation of hypothetical (sometimes prototypical) network structures and the simulation of diffusion within those structures.

Homophily Tendency for people to be connected to others like themselves.

Incidence The percent of new adopters at each time period.

Internal versus external influence Internal influence posits that adoption is driven by person-to-person persuasion whereas external influence posits it is driven by sources outside the network such as mass media.

Event history analysis Transformation of data to represent person-time observations.

Network exposure The degree of behavioral adoption in each person's network neighborhood.

Network threshold The number or percent of adopters in a person's neighborhood necessary for a person to adopt the innovation.

Rate The speed of diffusion.

Prevalence The cumulative percent of adopters in the population.

Weight matrix Any N×N matrix representing potential distances or similarities that models potential pathways for adoption influence (e. g., a structural equivalence matrix derived from an adjacency matrix to model influence of structural equivalence relations on adoption).

Definition of the Subject

Diffusion of innovations is the study of how new ideas and behaviors spread within a population, both within and between communities. Diffusion research spans many disciplines since understanding how new ideas and behaviors spread is an important aspect in many different fields of study. For example, marketers are often interested in how and why people change their purchasing habits and sociologists concerned with how people come to accept new norms. The first empirical investigations date back 100 years, while contemporary studies mark the beginning to the 1943 study of diffusion of hybrid seed corn in Iowa. A subset of the hundreds of empirical diffusion studies have focused specifically on the collection and analysis of social network data combined with data on when individuals adopted selected behaviors.

Introduction

Diffusion of innovations theory attempts to explain how new ideas and practices spread within and between communities. The theory has its roots in anthropology, economics, geography, sociology, marketing, mathematics, among other disciplines [1,2,3,4], and has in some ways been adapted from epidemiology [5,6]. The premise, confirmed by empirical research, is that new ideas and practices spread through interpersonal contacts largely consisting of interpersonal communication [1,7,8,9,10,11].

In their 1943 pioneering study, Ryan and Gross [10] laid the groundwork for the diffusion paradigm by showing that, among other things, social factors rather than economic ones were important influences on adoption [11]. Hundreds of diffusion studies were conducted in the 1950s and early 1960s to examine the diffusion process in more detail across a variety of settings [1]. Many studies sought to understand how information created in government or otherwise sponsored programs could be disseminated more effectively. Diffusion research peaked in the early 1960s, but has been reinvigorated recently with the advent of more sophisticated network models and technology making it possible to study the diffusion process more explicitly.

Most diffusion studies focus on trying to understand the factors that lead some members of a population to adopt a new idea, while others do not. Further, studies try to understand why some people adopt the behavior early while others wait a substantial amount of time before accepting the new practice. For example, Ryan and Gross [10] wanted to know why some farmers purchased hybrid seed corn almost immediately upon its availability while others waited until almost all the farmers in the area purchased it before they were willing to do so. Similarly, Coleman and others [12] wanted to know why some physicians began prescribing tetracycline as soon as it was available, while others waited until most physicians prescribed it before they were willing to do so.

This chapter describes a variety of mathematical and network models used to study the diffusion of these and other innovations. The Coleman and others [12] study provided a conceptual leap from other diffusion studies by explicitly measuring who talked to whom within the community about the innovation. Rogers [13] also collected network data to study the diffusion of weed spray in Iowa in his dissertation. Burt [14] unearthed the data and made it available to the network community so that scholars could debate various models used to describe the network diffusion process. Although having data has been useful for clarifying diffusion models, the limitations of these data and this study, make it a poor choice for studying adoption behavior. Rather, scholars should have focused on collecting better data, or reanalyzing diffusion network data in which contagion was more likely.

This chapter chronicles the development of network diffusion models and indicates where such progress is being made. I first present macro models used to estimate the speed of diffusion and, with the Bass [15] model, to estimate rates of innovation and imitation. Next, spatial autocorrelation is presented which is used to estimate the degree contiguous nodes adopt innovations. Spatial autocorrelation led to the network autocorrelation model which is presented statically (cross-sectional data only) and then with one time lag. I then discuss event history analysis applications of network autocorrelation and its extension by including time-based network interaction terms. Throughout the chapter, I attempt to provide a review of recent research conducted in a variety of domains, but mostly drawn from the public health field.

Macro Models

One consistent finding of diffusion research has been that the cumulative pattern of diffusion follows a growth pattern approximated by a simple one-parameter logistic function such as:

$$y_t = b_0 + \frac{1}{1 + \mathrm{e}^{-b_1 t}} , \qquad (1)$$

where y is the proportion of adopters, b_0 the y intercept, t is time, and b_1 the rate parameter to be estimated. This simple model can be used to compare growth rates for various innovations, but is extremely limited in its applicability. A considerable improvement was advanced by Bass [15]

Social Networks, Diffusion Processes in, Table 1
Diffusion Rate Parameter Estimates and Moran's *I* Estimates for Two Data Sets

	Medical Innovation	Cameroon Tontine 1 Simulation
One Parameter Model		
Coefficient (95% Confidence Intervals)	0.23 (–.053–0.51)	0.06 (.01–0.12)
N	17	50
R^2	0.76	0.71
Two Parameter (Bass) Model		
Innovation Coefficient (95% C. I.)	–0.43(–0.83–0.03)	–0.20 (–0.30–0.09)
Imitation Coefficient (95% C. I.)	4.09 (3.05–5.12)	2.96 (2.58–3.34)
N	16	49
R^2	0.89	0.89
Moran's *I*	–.13	–.08
z-score	–6.73	–7.80

and many others [16,17,18] by creating a two parameter model:

$$y_t = b_0 + (b_1 - b_0)Y_{t-1} - b_1(Y_{t-1})^2 \,, \tag{2}$$

where y is the proportion of adopters, b_0 a rate parameter for innovation, and b_1 a rate parameter for imitation (the degree of adoption due to prior adopters). The Bass model incorporates the percentage adopters at each time point and thus makes a better estimate of the growth attributable to personal network persuasion. The mathematical model in Eq. 2 can be used to: (1) forecast expected levels of diffusion [17], (2) estimate the rate of diffusion attributed to different theoretical aspects of the diffusion processes, b_0, external influence or innovativeness, and b_1, internal influence or interpersonal persuasion [15,16,18]. This model can be used to estimate rate of disease spread from a central source such as contaminated food or from infectious spread through interpersonal contact. In the social realm, one can use the model to estimate rate of adoption from a mass media advertisement or from interpersonal influence. Rate parameter estimates from both models for two diffusion datasets are provided in Table 1. Interpretation of these estimates is highly dependent on the time scale used to measure diffusion.

These rate parameter estimates can be used as outcomes to study factors associated with diffusion at the macro-level by comparing rates between groups and/or populations. For example, parameter estimates for different countries can be compared to study factors associated with the spread of behaviors in different countries. Modeling at this macro-level, however, is imprecise at best because it assumes perfect social mixing, everyone interacting with everyone else [19,20]. These macro models do not measure whether people who are connected to one another engage in the same behaviors. Geographers have devoted considerable attention to trying to determine whether innovations spread between contiguous areas.

Spatial Autocorrelation

Rather than just estimate rate of diffusion, spatial models measure whether artifacts, diseases, farming practices, and other behaviors spread between contiguous areas [2,21,22]. Proximity data are easy to obtain and are relatively unambiguous, thus providing a network of connections based on distance. Moran's I was an early model developed to test for spatial association, geographic clustering of adoption:

$$I = \frac{N \sum_{i}^{N} \sum_{j}^{N} D_{ij}(\boldsymbol{y}_i - \bar{y})(\boldsymbol{y}_j - \bar{y})}{S \sum_{i}^{N} (\boldsymbol{y}_i - \bar{y})^2} \,, \tag{3}$$

where N is the sample size, D a distance matrix (as proximities), y indicates adoption, and S the sum of the distances in the distance matrix. Moran's I measures the degree nodes that are connected to one another deviate from the average behavior in the network similarly or differently. Moran's I is high when connected nodes (positive elements of D) are either positively or negatively different from the average score. The statistical significance of Moran's I can be calculated in two ways: via permutation methods or analytically.

To use a permutation method to calculate the significance of Moran's I assume adoption (y_i) is randomly distributed and calculate I repeatedly to get a sample of estimates based on D and the number of adopters. If Moran's I calculated is significantly different than the random sample generated, Moran's I is considered significant (z-scores can be obtained). The logic then is to calculate the degree neighbors (however defined) have similar adoption behavior compared to that expected if adoption were distributed randomly. Variance estimators for Moran's I can be found in spatial statistics textbooks [21,23] and used to calculate exact significance tests. Moran's I is useful, and has been extended considerably, yet this approach often assumes that geographic proximity equates with communication and influence, which may not be true.

The spatial autocorrelation methodology was seen as a useful approach to measuring network autocorrelation, the bias inherent in a regression model when "y" appears as both the dependent and independent variable. Erbing and Young [24] wrote an influential paper on measuring network effects and using network autocorrelation methods. Dow [25,26] demonstrated the effects of network autocorrelation on estimate errors, and Doriean and others [27] found considerable bias in the point estimates and their standard errors. Exactly how network autocorrelation applied to diffusion of innovations was not clear since spatial autocorrelation measured diffusion at the macro level, but did not show whether specific individuals were more or less likely to adopt based on their network position. Further, spatial autocorrelation did not show how network structure influenced diffusion. To do so, we turn to network models.

Network Models

Figure 1 displays two networks from a study conducted in Cameroon among women in voluntary organizations [28]. Women were asked to name their friends in the organization in an attempt to determine if friendship ties were associated with contraceptive choices (they were). The diffusion network model posits that initial contraceptive choices would be made by some women based on their innovativeness and exposure to outside sources of influence such as their cosmopoliteness, media use, or greater need for the innovation. The new idea, and its practice, then spreads through the network as users persuade nonusers to adopt either by exhortation, entreaty, enticement, or example.

These influences are captured by an exposure or contagion model (Fig. 2), each individuals likelihood of adoption increases as the proportion (or number) of users in his/her personal network increases. Personal network exposure is the proportion or number of adopters in each person's network that provide information and influence with regard to some behavior. The equation for non-random mixing, or personal network exposure is:

$$E_i = \frac{\sum w_{ij} \boldsymbol{y}_j}{\sum w_i} , \qquad (4)$$

where w is the social network weight matrix, and y is vector of adoptions. For an individual who reported five contacts, network exposure (E_i) is the proportion of those contacts that have adopted (Fig. 2). When network exposure is measured on direct contacts it captures social influence conveyed through overt transmission of information, persuasion or direct pressure. Alternatively, exposure can be calculated by transforming the social network, W, to reflect other social influence processes. For example, W can be transformed to represent the degree of structural equivalence (similarity in network position) among people in the network. Exposure calculated on this network captures social influence conveyed via comparison to equivalent others such as by social comparison or competition [14]. Exposure can also be weighted by network properties such as centrality to reflect social influence by opinion leaders.

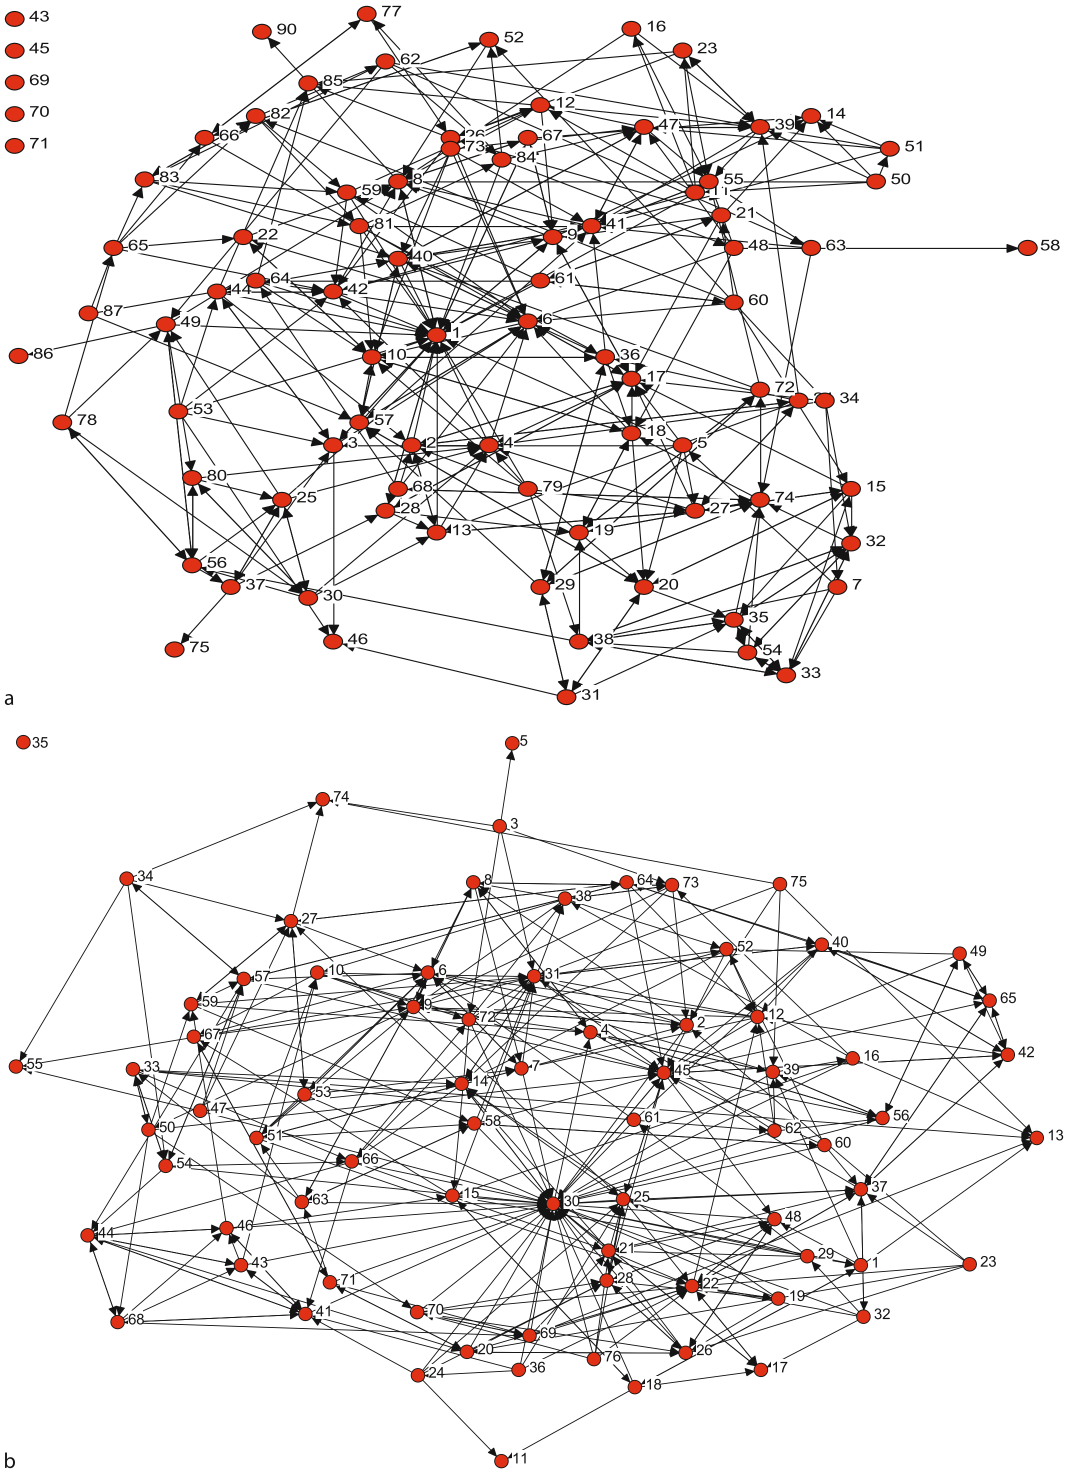
Social Networks, Diffusion Processes in, Table 2
Social network influence weightings

Relational	Positional	Central
1. Direct Ties	1. Percent Positive Matches (Tie Overlap)	1. Degree
2. Indirect Ties	2. Euclidean Distance	2. Closeness
3. Joint Participation in Groups or Events	3. Regular Equivalence	3. Betweenness
		4. Flow
		5. Integration/radiality
		6. Information
		7. Power

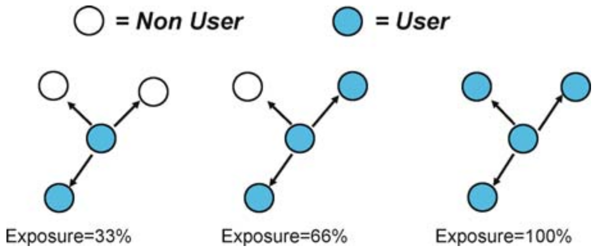
These three social influence processes are modeled with three different classes of network weight matrices (relational, positional, and central), constructed from the same social network data (Table 2). All three can be justified theoretically as sources of influence on adoption behavior and all three can be calculated various ways (there are at least 10 centrality measures). It is possible that all three operate for different people or at different times during the diffusion process.

In addition to the social influence process, a second dimension to these influence mechanisms is the weights attached to each based on social distance. For example, in relational influence models, different weights can be assigned to direct ties, ties-of-ties, and even the ties-of-ties-of-ties; in positional equivalence models, different weights can be assigned to those that are more equivalent than others [7]. A potential line of diffusion network research then is to compare different network weighting mechanisms to model and compare different social influence processes.

Diffusion was simulated through the two Cameroon networks in Fig. 1 to illustrate how network exposure and network structure influence diffusion. At each time period, adoption occurred for the non-adopter with the most nominations received, then network exposure was calculated, all nodes with exposure of 50% or higher were categorized as adopters and the process repeated. We compared diffusion in this network to that simulated in a net-



Social Networks, Diffusion Processes in, Figure 1
Networks 1 and 2 from the Cameroon Voluntary Association Study



Social Networks, Diffusion Processes in, Figure 2
Personal network exposure from direct contacts

work of the same size and density, but with links allocated randomly. Both conditions were averaged across 1000 runs. Figure 3 shows that, in Network 1, initially the diffusion trajectories are similar, but at about time 10, diffusion in the actual network accelerated.

The network accelerated diffusion because it is somewhat centralized (in-degree 21.7%) and once diffusion reaches the center of the network it can propagate rapidly. Notice that at about time 20 diffusion slowed, accelerated again at about 25, and then slowed from about time 30 to 40. These "fits and starts" are a product of the network structure: diffusion reaches pockets of inter-connectivity and spreads rapidly within these dense pockets, but slows between groups. Network 2 (Fig. 3) had more rapid and sustained diffusion because it was even more centralized (in degree, 47.2%). Note that in the spatial autocorrelation model adoptions were randomized to measure statistical significance and in this simulation, the network structure was randomized to illustrate its influence on the rate of diffusion.

Simulation assumptions regarding influences on adoption could easily be changed to achieve different outcomes. For example, when adoptions were assigned randomly, diffusion was constant in network one (and saturation lower) and similar to the random network in network two. The validity of these diffusion models rests partly on determining whether network exposure influences adoption. To that end, a number of empirical studies have been conducted to measure the degree social network exposure is associated with adoption.

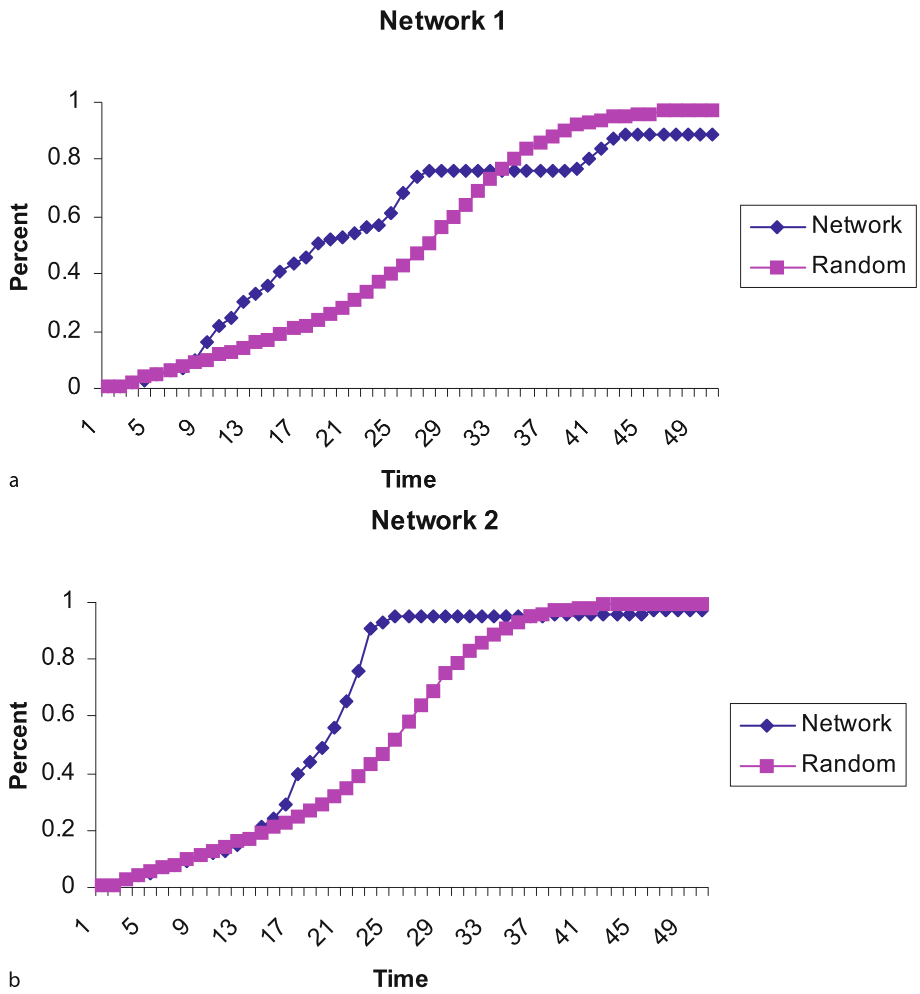
Empirical Studies

Empirical support for an association between individual own behavior and that of his/her peers can be found throughout the behavioral sciences literature. While many scholars assume adoption is associated with network exposure, few studies have traced an innovation through a network of social contacts to empirically validate this proposition. The lack of data on diffusion within an entire network stems largely from the difficulty of trying to collect data over a time period long enough for diffusion to occur. Consequently, most studies have relied on retrospective data which introduces some but not much bias [29,30]. It has also meant that several scholars have re-analyzed two studies that collected network and adoption data, (1) medical innovation study [12], reanalyzed by Burt [14], Marsden and Podolny [31], Strang and Tuma [32], Valente [7,33], and Van den Bulte and Lillien [34]; (2) Korean family planning study [35], reanalyzed by Dozier [36], Valente [7,33], Montgomery and Chung [37], and Kohler [38]. Recent studies in the fields of reproductive health [39] and substance abuse [40] have provided new data, but these classics remain classic.

Because collecting complete network data can be difficult, most empirical research has been ego-centric [41,42], based on respondent reports of their behavior and that of their network peers who are not necessarily connected to one another and not interviewed. Social influence is often based on respondent reports of perceptions of peer behavior or perceptions of peer influence [43,44]. Comparison of exposure scores based on respondent perceptions with alters' reports in one study found that perceptions were more strongly related to behavior than exposure based on alter reports [28,37,45].

Sociometric studies interview members of a bounded community and attempt to gather information from everyone in the community (typically conducted in schools, organizations, and small communities) and record their time of adoption [1,12,46,47,48]. Sociometric studies are useful for understanding how an innovation flows within the community and how certain network structural variables influence the diffusion process. Sociometric data capture network influences by the alters' reports since they were also interviewed. For example, sociometric studies can determine whether structural positions such as centrality are associated with adoption and/or whether centralization is associated with more rapid diffusion [7].

A number of recent diffusion network studies have been cross-sectional and in many cases retrospective involving only one time point. For example, a study in Thailand by Entwisle and others [49] found that contraceptive choices made by early adopters contributed significantly to the contraceptive choices made by later adopters (also see [35]). Valente and others [28] collected sociometric data on contraceptive use among women in voluntary associations in Cameroon and showed that perceptions of these friends' behavior, and in particular perceptions that these friends encouraged contraceptive use, were significantly associated with behavior. In general, statistical ana-



Social Networks, Diffusion Processes in, Figure 3
Simulated diffusion in two networks, each compared to random networks of the same size and density. Network 2 is more centralized than Network 1

lyzes use the following model:

$$\log \frac{\Pr(\boldsymbol{y}_t = 1)}{(1 - \Pr(\boldsymbol{y}_t = 1))} = \alpha + \sum B_k X_k + B_{(k+1)} \omega \boldsymbol{y}_t , \quad (5)$$

where $\boldsymbol{y}$ is a binary vector of adoption behavior, α is the intercept, β_k are parameter estimates for vectors of K socio-demographic characteristics (Xs), and ω represents the social network matrix. The $\omega \boldsymbol{y}_t$ term represents the calculation of contemporaneous network exposure and this vector is usually divided by a count of the number of nominations sent (alternatively the number of nominations can be entered into the regression separately).

Significant estimates for β_{k+1} indicate contagion effects by showing that network exposure is associated with adoption. The variances for these estimates, however, are usually biased since the observations are not independent and hence the errors in prediction are not independent. One partial solution is to obtain robust estimates by controlling for clustering. Clustering is the degree that elements from the same cluster are similar compared to those of different clusters. For example, two individuals chosen at random from the same organization are more likely to be similar than two chosen at random from different organizations. Table 3 reports regression results of the Cameroon data with and without correction for clustering. Without correction, network exposure is strongly and significantly associated with adoption, but with the correction it is only marginally statistically significant (p=.04). Controlling for clustering is particularly important in network exposure models because network choices are often restricted to the cluster.

Social Networks, Diffusion Processes in, Table 3
Logistic regression on the likelihood of contraceptive behavior on controls and network exposure with and without correction for clustering (N=555; Groups=9)

	Contraceptive Method Use			
	Without Correction		With Correction	
	Adjusted		Adjusted	
	Odds Raios	P-value	Odds Raios	P-value
Age	0.97	0.001	0.97	0.010
Education	0.91	0.247	0.91	0.184
Possessions	1.39	0.000	1.39	0.000
Network Exposure	1.14	0.005	1.14	0.047

Even with clustering controlled, social influence as measured through social networks seems to be strongly associated with behavior. For example, a school-based sociometric study was conducted by Alexander and colleagues [50] using the Adolescent health data [51] to show that students with a majority of network ties who were smokers were almost two times as likely to smoke themselves with an additional two times greater likelihood of smoking for those with best friends who smoke. Clustering was controlled and the multi-level model accurately captured micro-level effects within the context of macro-level influences. The study measured the influence of peers on smoking while conditioning on the smoking rate within the school [50].

Estimating the network exposure (autocorrelation) term with a multi-level model can provide contagion estimates across settings and estimate the degree it varies between settings (i. e., communities, schools, organizations, and so on). The models are incomplete however, because there may be factors that influence both adoption and choice of social network contacts. For example, the decision to smoke and to nominate friends who smoke may both be a function of delinquency or rebellion. Hence an association between behavior and peer behavior can be spurious. Testing social influence with network methods then requires longitudinal data involving at least two time points. Boulay and Valente [52] collected data among women in three villages of Nepal and found that having discussion partners who used contraception influenced information seeking behavior and contraceptive choice. Having data from two time points allows testing of a simple dynamic model on adoption:

$$\log \frac{\Pr(\boldsymbol{y}_t = 1)}{(1 - \Pr(\boldsymbol{y}_t = 1))} = \alpha + \sum B_k X_k + B_{(k+1)} \omega_t \boldsymbol{y}_t + B_{(k+2)} \omega_{(t-1)} \boldsymbol{y}_{(t-1)}, \quad (6)$$

where y is a binary indicator of behavior, α is the intercept, β_k are parameter estimates for vectors of K socio-demographic characteristics (Xs), and ω represents the social network matrix. A positive and significant β_{k+2} indicates that respondents with high network exposure at baseline were more likely to adopt at time two. A positive and significant β_{k+1} indicates that change in network exposure is associated with change in behavior. This may indicate contagion but still may be a product of some omitted factor. Panel data collected at two time periods is adequate for most research needs, and can provide evidence of network influences on behavior. However, since there is often a considerable time between the two measures, many factors may account for simultaneous change in behavior and network exposure. To cope with this threat, data can be collected on time of adoption, expanding the micro level dynamic analysis by using event history analysis [53].

Event History Analysis

Event history analysis techniques have been developed to analyze data with a substantive number of time points, estimating coefficients with maximum likelihood estimators [32,53,54,55,56]. There are two types of event history analysis, discrete time, in which the outcome is binary, and continuous time, in which the outcome is time-to-an-event. Since diffusion occurs over time, there is an explicit time dimension in diffusion studies captured by both discrete and continuous time models. The time of adoption variable is the dependent variable and may be influenced by both time-varying and time-constant factors. Some individuals may not have adopted by the time of data collection giving rise to time-censored observations. Right censoring occurs when data are collected before the innovation has finished diffusing or does not diffuse to all members of the community or study. Left censoring occurs when the data are incomplete at the beginning of the process. For example, adoption data for the period 1993 to 2000 may have some people who adopted in 1989–1992 classified as 1992 adopters.

There are a variety of event history techniques including hazard models developed in epidemiology used to understand the hazard or risk to disease or injury over time. Hazard and/or event history analysis generally requires that the data be reshaped from simple observations to a case-time format such that there is a case in the data for each individual at each time period of study up to and including that person's time of adoption. The time-varying and time-constant independent variables are included in each case as well as a binary indicator for whether the individual adopted or not (got sick or not).

Maximum-likelihood estimation can determine whether the independent variables are associated with the dependent variable (adopt/not adopt) [57]. A study of 100 people with an average adoption time of seven translates into 700 person-time cases. Each person-time case has a variable for the network exposure at that time period plus an indicator for whether the person adopted or not (plus additional time-constant and time-varying covariates as desired). The event history model is:

$$\log \frac{\Pr(\boldsymbol{y}_t = 1)}{(1 - \Pr(\boldsymbol{y}_t = 1))} = \alpha + \sum B_j X_j + \sum B_{kt} X_{kt} + \sum B_{(k+1)} \omega \boldsymbol{y}_t \,, \tag{7}$$

where y is a binary indicator of behavior, α is the intercept, β_j are parameter estimates for vectors of J socio-demographic characteristics (X_j), and β_{kt} are parameter estimates for the matrix of time-varying socio-demographic characteristics (X_{kt}) and ω represents the social network weight matrix, and t a time indicator. Note here we have assumed a static (constant) network. Standard statistical packages allow testing of event history or survival data in a relatively straightforward manner, once the data are reformatted. Event history analysis requires the construction of exposure matrices for each time period which can be a formidable task particularly if one uses more than one network weight matrix.

Marsden and Podolny [31] used event history analysis and tested network exposure's association with adoption in the medical innovation data. Results showed that exposure was not associated with adoption in that study. Strang and Tuma [32] revisited the issue with the same data by postulating time variance in network influence, (i. e., how much lag time, if any, is there in the influence). They found evidence of contagion. Van den Bulte and Lillien [34] supplemented the medical innovation data with archival data on media promotion by pharmaceutical firms at the time of the original study and showed that network contagion effects disappear once these data are added. Their analysis demonstrates the importance of omitted variables when studying diffusion through networks. The rapid diffusion measured in the medical innovation study indicates that contagion was probably not the primary factor driving diffusion.

Event history analysis of the three classic diffusion network datasets has been conducted [58]. The analysis controlled for within village and within person covariation, and terms for time and a logistic transformation of time were included to control for macro-level effects. Terms for infection and susceptibility [32,59] were included to measure whether adoption by central individuals (high in-degree) influenced subsequent adoption, infection, and whether centrality (out-degree) influenced a person's likelihood to adopt as diffusion occurred, susceptibility. In-degree and out-degree were also included in the model. Two network exposure terms were computed, direct ties and structural equivalence. Structural equivalence was computed as in Burt's [14] measure, Euclidian distance raised to the 16th power. For this analysis, network exposure was calculated using contemporaneous measures since two of the datasets recorded adoption in one-year intervals. Two control variables representing individual characteristics were included. Analysis was conducted only on those who adopted. The following model was estimated:

$$\log(\Pr(\boldsymbol{y}_t = 1)) = \alpha + \sum \beta_{lm} X_{lm} + \sum \beta_{lmt} V_{lmt} + \sum \beta_{lmt} \omega_s \boldsymbol{y}_t + \lambda_{lm1} C_D(\boldsymbol{y}_+) + \lambda_{lm2} C_D(\boldsymbol{y}_+) \,, \tag{8}$$

where y is a binary indicator of behavior, α is the intercept, Xs are vectors or time-constant socio-demographic and network characteristics, V represents vectors of time-varying terms, in this case time and its transformation, ω_s represents the social network matrices, and λ estimates the effects of centrality degree variables multiplied by the time varying proportion of adopters in the network (infection and susceptibility). Results were mixed, but seem to indicate that both infection and susceptibility effects are present. In all three datasets, infection is positively associated with adoption indicating that as those with high in-degree adopt, the likelihood others in the network will adopt increases. In two studies, Brazilian farmers and Korean women, susceptibility is associated with adoption indicating that those with a high number of nominations sent are more likely to adopt as the innovation diffuses. Ties sent and received are marginally associated with adoption, and only for the Brazilian data is exposure, through structural equivalence, associated with adoption. These results, however, change dramatically when non-adopters are included or when a term for the average exposure at each time period is included such that infection and susceptibility effects disappear.

The event history analysis approached has also been used by Montgomery and others (2001) using ego-centric data to study network exposure's influence on contraceptive use in Ghana. Current analysis of four rounds of data over two years has shown that contraceptive use is strongly associated with use by social network peers. The Ghana field study provides some of the most conclusive evidence of the magnitude of social influence on behavior change by showing that as the number of social network contacts who use contraceptives increases, the likelihood of contraceptives use by ego also increases. Of all the variables, the network exposure variables were the most significant influences on contraceptive adoption. Another longitudinal field study in Kenya found similar results, again based on ego-centric network data [60].

Montgomery and others [61] also report preliminary analysis in which network influences are weighted by tie characteristics such as the frequency of communication. They found that adding these weights did not change the strength of peer influence. Similar results have been reported in Valente [7] and Valente and Saba, p. 109 in [43]. Consequently, it seems that the influence of social networks on behavior (contraceptive use in these cases) seems broad in nature, and are not conditioned on specific factors such as the frequency of communication between dyads or the their socio-demographic equality. These factors may play a strong, and even pervasive role in determining who is connected to whom [62], but they do not seem to determine the degree of influence social contacts provide.

Network exposure and adoption may not always be strongly correlated for a number of reasons. First, exposure may not be associated with adoption for everyone, but may be most influential during the middle stages of diffusion, when awareness is high, but uncertainty about its relative advantages is also high [63]. Exposure may have less of an effect early in the process when there are few adopters and obvious advantages to waiting; and late in the process when most people have a majority of adopters in their personal network anyway. Second, individuals may have varying thresholds to adoption such that some are innovative and others are not [19]. Valente [7,33] posited a social network threshold model in which contagion (majority rule) is a special case. Most simulation models assume majority influence on adoption decisions as was done in the beginning of this chapter. It is reasonable, however, to expect that individuals vary in the amount of network exposure needed to adopt an innovation. Disproving thresholds may not be possible, but construct validity for the concept has been demonstrated [33]. Valente and Saba [43] replicated the threshold model using ego-centric data and showed that people with a minority of network members using contraception had higher campaign recall indicating that the media campaign could substitute for interpersonal sources of influences. If thresholds vary, network exposure is needed for people to reach those thresholds, if they do not and the special case of contagion exists, network exposure will determine when individuals adopt.

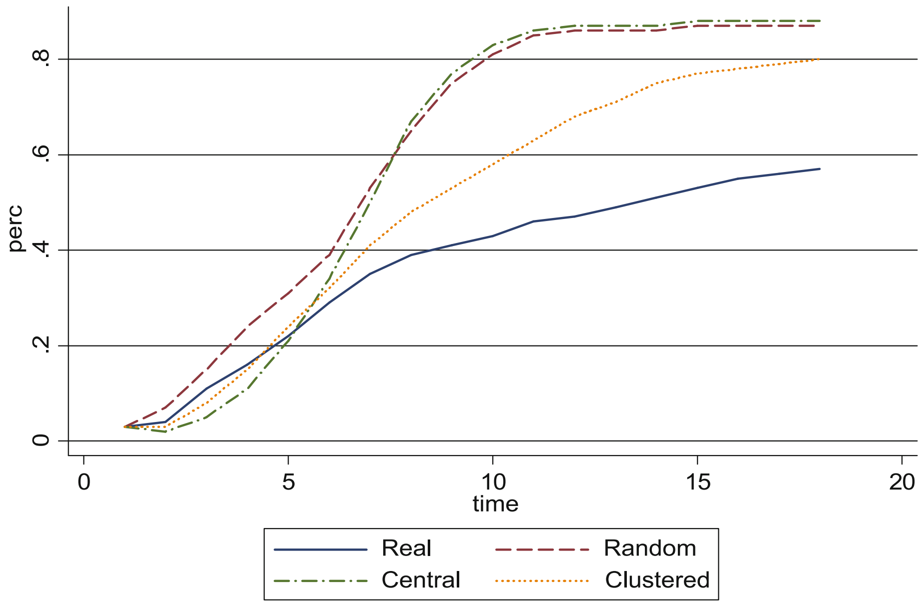
In spite of the impressive list of studies showing some support for an association between individual behavior and network exposure, and the theoretical simulations of network structure and thresholds, significant work remains to be done. Most scholars and lay people would agree that social networks influence behavior. The barriers to demonstrating this effect, however, have been challenges of data collection and agreement on appropriate statistical methodology. The most commonly analyzed dataset, Medical Innovation, is 45 years old, consists only of 125 respondents and arguably is not a diffusion study at all. The limitation of available data has forced researchers to rely on simulations and agent based modeling approaches to understand theoretical mechanisms driving diffusion.

Agent Based Models

Agent based models (ABM) are computer simulations created to understand how actors (usually though not necessarily people) behave given a set of preexisting conditions and rules for their behavior [64]. A researcher can hypothetically pose a population of people who have some degree of connectedness and some structure to those connections. Model parameters may be set that vary those structural conditions or they may be taken as fixed and other properties varied. To model the diffusion of innovations one might be interested in how network structure affects the rate of diffusion. So a simulation can be created which varies network structure and then simulates the spread of an innovation within those structures. One could also vary other properties of the diffusion by varying the number of initial adopters or the transmissibility of the innovation.

To illustrate, an empirical dataset was used to simulate theoretical network structures and potential diffusion within those structures. Data were collected among adolescents in ninth grade and they were asked to write the names of their five closest friends. A computer program was written to match the names to the roster in the school so a network could be constructed from the data. The network had 150 nodes with 327 friendship links. The agent based model had 2 parameters: (1) the initial 7% seed adopters would vary under 3 conditions: (a) randomly selected seeds, (b) the most central nodes, and (c) peripheral nodes; (2) the type of network structure would vary by 4 conditions (a) the real network, (b) a random one with the same links, (c) a centralized one, and (d) a clustered one.

A simple diffusion model was then run setting a low threshold for adoption such that at each time interval after the initial seeding those nodes connected to 15% other



Social Networks, Diffusion Processes in, Figure 4
Comparison of simulated diffusion trajectories for a real network, and 3 simulated ones based on the real network's density. The three simulated networks are random links, centralized links (centralization = 3%), and clustered links (clustering coefficient=12%). Diffusion occurs most rapidly in random and centralized networks

nodes would become adopters. The model was run for 20 time periods which was generally long enough for diffusion to occur in most situations. After a run of 20 time periods was completed, results were tabulated and then the simulation for each condition run 25 times and the results aggregated. The model was run 25 times for each condition to ensure that the results were not the product of some anomaly. It is customary in agent based models to run the simulations for hundreds or thousands to times to guarantee the results are robust.

Figure 4 shows illustrative findings by plotting the diffusion trajectories in the different conditions. The data show that simulated diffusion occurs most rapidly in the random and centralized networks. It is slowest in the real network. The network structure of real networks retards diffusion because of homophily – the tendency for people to be friends with others like themselves. This homophily tendency creates clustered networks so that diffusion gets trapped in these pockets of interconnectivity. Real networks also retard diffusion because they are symmetric (If $A \rightarrow B$ then $B \rightarrow A$) and so adoption by a pair leads to reinforcement, not more diffusion. Bridges are needed to carry the innovation across the gap between clusters and these bridges act as bottlenecks that slow diffusion.

Statistical analysis can be conducted on the data to determine the effect on diffusion. Outcomes can be the final cumulative percent of adopters (the prevalence), or the number of time periods till diffusion has reached 50%, or the rate of adoption estimated using one of the mathematical models described above. In these data we find that all 3 simulated networks have more rapid diffusion than the real network, and we find that seeding the network with central adopters accelerates diffusion while seeding it with peripheral actors slows diffusion.

Conclusions

Much progress has been made since 1943 when Ryan and Gross first laid the foundation for diffusion of innovations theory. Rogers [1] chronicled the many studies conducted since then and helped shaped a general diffusion model with wide applicability now being renewed and reinvigorated with fresh theory and analytic models. Overall, results indicate that social network influences on behavior are important and have consequences for the health and well being of populations and individuals. These new insights have shed light on important aspects of how new ideas and practices spread within and between communities.

Along with new insights have come new questions and new perspectives to be addressed. It is clear that a lack of data on time of adoption coupled with information on network relations has hampered developments. Few diffusion or behavioral studies collect information on networks, conversely few network studies record time of adoption. There are advantages to marrying these two ideas, however, and future research will hopefully try to collect both types of data.

It is also clear that our understanding of how diffusion occurs is still somewhat limited. The Medical Innovation data have often been used to demonstrate the importance of networks in adoption yet analyses by Valente [7] and by Van den Bulte and Lillien [34] have shown that contagion via social influence in this setting was unlikely. Given the number of confounding factors, and some of the data requirements, it may be prohibitively difficult to substantiate the role of social networks in innovation adoption via survey methods alone. Purposively intervening on social networks, however, may prove to be a fruitful avenue of research. If network-based interventions can be used to accelerate innovation diffusion, then a stronger case can be made for the importance of social contagion in the diffusion process.

Nonetheless, it is clear that networks are important influences on behavior since most people acknowledge that they receive information and influence via their social networks and that they model the behavior of others. What is less clear is how to capture that influence in quantitative terms that mimic the theoretical progress made in the network field. Further, verbal accounts on how people make decisions and adopt behaviors usually reveal non-linearities, chance circumstances, and whims that are not independent of networks, but not easily captured in social influence models.

The link between micro and macro levels of analysis represents an opportunity for study of diffusion processes. The opportunity lies in the fact that multi-level modeling techniques enable the separation of micro-level network exposure influences from macro-level contextual factors. Yet both are social network influences and both represent elements of the diffusion paradigm. It is hoped that by controlling for contextual effects we don't "throw the baby out with the bathwater," by eliminating the micro-level influences that provide expressions for those contextual effects.

In spite of controls for macro-level contextual effects, micro-level associations between peer network behavior, and those of respondents are still sometimes strong. Debate remains about the meaning of these associations, is it peer influence, peer selection, or further contextual effects? More rigorous studies may eventually tease this out, in the interim, better study designs and interventions will need to be created. This review has attempted to point out some of the challenges diffusion scholars face and some of the promising new directions it may take.

Scholars have turned to agent based modeling as a technique to investigate diffusion properties. Agent based models (ABM) allow the theoretical exploration of how network structure can be varied and shown to influence diffusion. ABM also enables us to study diffusion parameters such as thresholds, transmissibility, or the importance of initial adopters on diffusion speed and prevalence. Until empirical data can be gathered and analyzed ABM represent a promising approach to understanding how diffusion processes occur on networks.

Future Directions

Future developments in diffusion processes are likely to occur along two interrelated fronts. First, increasingly scholars are using network data to propose and implement social change practices [65]. These activities may involve organizational change in the business context or health promotion and treatment in the medical context. These network based interventions provide the opportunity to change networks and measure the resulting changes in performance or behavior. Thus, scholars can more definitively link changes in networks to changes in outcomes.

Second, considerable progress has been made in advancing statistical models that measure network evolution and behavioral changes that account for multiple structural influences [66]. For example, scholars can test the degree of similarity in behaviors while simultaneously estimating the influence of social network characteristics such as whether two people nominate one another or are part of a linked triad. These models (known as P* or exponential random graph models) provide a statistical estimation of concepts such as network influence, and network selection.

Melbourne, Australia

Article Outline

Exponential random graph models, also known as p^* models, constitute a family of statistical models for social networks. The importance of this modeling framework lies in its capacity to represent social structural effects commonly observed in many human social networks, including general degree-based effects as well as reciprocity and transitivity, and at the node-level, homophily and attribute-based activity and popularity effects. The models can be derived from explicit hypotheses about dependencies among network ties. They are parametrized in terms of the prevalence of small subgraphs (configurations) in the network and can be interpreted as describing the combinations of local social processes from which a given network emerges. The models are estimable from data and readily simulated. Versions of the models have been proposed for univariate and multivariate networks, valued networks, bipartite graphs and for longitudinal network data. Nodal attribute data can be incorporated in social selection models, and through an analogous framework for social influence models.

The modeling approach was first proposed in the statistical literature in the mid-1980s, building on previous work in the spatial statistics and statistical mechanics literature. In the 1990s, the models were picked up and extended by the social networks research community. In this century, with the development of effective estimation and simulation procedures, there has been a growing understanding of certain inadequacies in the original form of the models. Recently developed specifications for these models have shown a substantial improvement in fitting real social network data, to the point where for many network data sets a large number of graph features can be successfully reproduced by the fitted models.

Glossary

Alternating independent-2-paths A parameter (and statistic) in new specification models; a particular combination of *k-independent-2-path* counts into the one statistic.

Alternating k-stars A Markov parameter (and statistic) in the new specification models; a particular combination of Markov k-star counts into the one statistic; equivalent to *geometrically weighted degree counts*; useful for modeling the degree distribution.

Alternating k-triangles A parameter (and statistic) in the new specification models; a particular combination of *k-triangle* counts into the one statistic; equivalent to *weighted shared partners*.

Cyclic triad A Markov graph configuration: in a directed network, ties *ij*, *jk* and *ki* are observed among actors i, j, and k.

Degeneracy (or near-degeneracy) When a model implies that very few distinct graphs are probable, often only empty or complete graphs; degenerate models cannot be good models for social network data.

Dependence assumption Theoretical assumption about dependencies among possible network ties; determines the type of parameters in the model.

Dyad independence Assumes that dyads are independent of one another; the model includes edge and reciprocity parameters, and possibly also node or dyad attributes.

Dyad-wise shared partners A parameter (and statistic) in the higher order models; equivalent to *alternating independent 2-paths*.

Edge-wise shared partner distribution Distribution of the number of dyads who are themselves related and who have a fixed number of shared partners.

Edge-wise shared partners A parameter (and statistic) in the higher order models; equivalent to *alternating k-triangles*.

Geometrically weighted degree counts A statistic (and parameter) in the new specification models: a sum of degree counts with geometrically decreasing weights; equivalent to *alternating k-stars*.

Homogeneity assumption Assumption about which parameters to equate, to make a model identifiable.

***k*-independent-2-paths** Configurations in the higher order models; equivalent to *k*-triangles but without the base.

***k*-in-star** A Markov graph configuration: in a directed graph, *k* arcs are directed to the one actor.

***k*-out-star** A Markov graph configuration: in a directed graph, *k* arcs are expressed by the one actor.

***k*-triangle** A configuration in higher order models; in a non-directed graph, the combination of *k* triangles, each sharing the one edge (the base of the *k*-triangle).

***k*-star** A Markov graph configuration: in a non-directed graph, *k* edges are expressed by the one actor.

Markov dependence assumption Introduced by Frank and Strauss [9], proposes that, conditional on the rest of the graph, two possible ties are independent of each other unless they share an actor.

Mixed-star A Markov graph configuration: a two path in a directed graph.

Monte Carlo Markov chain maximum likelihood estimation (MCMCMLE) Method of estimation based on computer simulation; more principled than pseudolikelihood.

Network configuration A small subgraph that may be observed in the data and that is represented by parameters in the model: e. g. reciprocated ties, triangles.

Parameters Relate to specific network configurations that may be observed in the graph; a large positive parameter is interpreted as the presence of more of the configurations than might be expected from chance (given the other effects in the model); a large negative parameter signifies the relative absence of the configuration.

Partial dependence assumption Assumption for dependencies among possible ties created by the presence of other ties; permits models with higher order configurations than Markov configurations.

Pseudo-likelihood estimation An approximate method of estimation using logistic regression; does not produce reliable standard errors.

p_1 Model An early dyad independence model, including popularity and expansiveness effects.

p_2 Model Elaboration of p_1 model, where popularity and expansiveness effects are random, and independent variables may be used to predict ties.

Simple random graphs, Bernoulli graphs, Erdös–Rényi graphs Assume that edges are independent of one another and are observed with a given probability.

Social circuit dependence Two possible ties are conditionally dependent when, if observed, they would create a 4-cycle.

Transitive triad A Markov graph configuration: in a directed network, ties *ij*, *jk* and *ik* are observed among actors i, j, and k.

Triangle A Markov graph configuration: in a non-directed network, a clique of three actors, ties *ij*, *jk* and *ik* are observed among actors i, j, and k.

Definition of the Subject

Exponential random graph models, also known as p^* models, constitute a family of statistical models for social networks. These models take the form of a probability distribution of graphs:

$$\Pr(\mathbf{X} = \mathbf{x}) = (1/\kappa)\exp\{\boldsymbol{\eta}'\mathbf{g}\}\,,$$

for a set of tie indicator variables $\mathbf{X}$ on a network of fixed node size n, where $\mathbf{x}$ is a realization, with a parameter vector $\boldsymbol{\eta}$ and a vector of network statistics $\mathbf{g}$. Each value of the parameter vector corresponds to a probability distribution on the set of all graphs with n nodes.

Introduction

As noted in [34], statistical approaches to social networks have quite a long history, stretching at least back to the work of Moreno in the 1930s [24]. Yet, that history is rather sparsely scattered across various literatures and different eras and, as a result, even today we see that older techniques and approaches are reinvented and repackaged as new. The *statistical modeling* of a social network – as distinct from the use of statistically-based approaches to understanding particular properties of a social network – has a shorter and somewhat more coherent pedigree.

Criteria for a successful statistical model of a social network have been proposed by [34]: it should be possible to estimate the parameters of the model from data in a principled way, and the fitted model should be a good representation of that data; the model should provide theoretically plausible interpretations about the type of effects that might have produced the network; and using the estimated model parameters it should be possible to draw inferences about competing explanations for the data. Most, perhaps all, models for social networks fall short of completely meeting these requirements. Some models are "thought experiments", intended to illuminate but with an uncertain link to data. Some models are estimable from data but still cannot adequately represent important features of the network. Models may imply interpretations that are just not theoretically plausible in terms of social science; and some models cannot include different effects simultaneously in order to test one against the other. Of course, by definition all models are imperfect (else, they are not "models"). So these criteria direct the aim in model development, even under the knowledge that we cannot always hit the target exactly.

A major insight in the statistical modeling of social network structure has been that structural effects can be detected as some form of deviation from what would be expected as "randomness". This was in fact the original proposal of Moreno and colleagues [24] who were the first to compare observed network data to what would be expected from null distributions. More explicitly, Rapoport's biased net theory [32,33] proposed certain structural "biases" away from random tie formation, including the important notions of transitivity (later to be described as clustering), the propensity for human social networks to exhibit a high proportion of triangulated ties.

Of course, in the graph theory literature the best-known model for randomness is the *simple random graph model*, often known as the Erdös–Rényi graph [7] or uniform Bernoulli graph distribution. This model proposes that for a given number of nodes network ties are observed between pairs of nodes independently and with a fixed probability p. Properties of this model have been examined extensively, utilizing its analytic tractability. It has also been used as a null model for various sampling distributions (e. g. see the summary in [8].) For an observed network, p can be readily estimated (the maximum likelihood estimate is simply the density of the network), but unfortunately this model is not a good representation of almost any human social network. There are no structural effects here, only randomness.

For directed networks, [15] extended the Bernoulli model in the early 1980s by parametrizing structural effects for reciprocity and for differential node-level activity (out-degree) and popularity (in-degree). Possible network ties within dyads were dependent on one another, but were independent between dyads. This dyad-independence assumption permitted the model to be estimated as a straight-forward loglinear model. Holland and Leinhardt called this model p_1, the subscripted '1' implying a program of further research, with progressively enlarged dependence assumptions (within arcs, within dyads, within triads, etc.). However, Holland and Leinhardt were uncertain how to progress beyond dyads. The problem was that standard statistical estimation required some level of independence and triads, unlike dyads, overlapped. (A subsequent, more sophisticated extension, the p_2 model, also has dyadic independence at its heart, but conditional on random node-level effects, so that the random effects indirectly introduce dependencies that may extend beyond dyads [53].)

Ove Frank and his colleague, David Strauss, provided the crucial insight: in the world of complex networks, it was dependence that mattered, and assumptions involving traditional statistical independence, although helpful for fitting models, were likely to be inadequate empirically [9]. In contrast, their approach centered on *conditional* independence, whereby contingencies among network ties may transmit across the network in the sense that the presence of one network tie may affect the presence of any other, but most pairs of ties were in some sense "remote", so that the contingencies affecting a given network tie had to be transmitted through "neighboring" ties. So once one had a concept of "neighboring ties", that is, some notion of which possible ties were conditionally independent after taking into account other observed network ties, the form of a model could be specified. Approaches from spatial statistics and statistical mechanics, with notions of dependence within neighborhoods (broadly defined) could be translated in this way into social network models. Frank and Strauss proposed Markov random graph models, based on an explicit argument about conditional independence among networks ties, that could be regarded as theoretically plausible for the first time. These models incorporated reciprocity, degree-based effects and various forms of triangulation or clustering.

In the 1990s, Markov random graph models became the accepted form of exponential random graph models and they have only recently been superseded. They could be estimated through the rough and ready procedure of pseudo-likelihood [52], a not particularly sophisticated approach but enough to get the field started empirically. Wasserman and Pattison popularized these models among social networks researchers as p^* models [55] and added further generalizations, with extensions to multivariate [29] and valued networks [36]. Nodal attributes were introduced in social selection [37] and social influence models [38].

In the last decade, especially with more principled methods of estimation and simulation, it has been shown that homogeneous Markov random graph models face considerable, often insurmountable, difficulties in dealing with real network data. Data with inhomogeneities – for instance, very high degree nodes, or dense regions of multiple triangulation, both of which are not uncommon in real social networks – typically result in *degeneracy* for Markov random graph models, where no set of parameter estimates can adequately represent the data. Newer specifications have been proposed by Snijders and colleagues [48] that help considerably with these issues of degeneracy, and have the capacity to enhance our ability to model small-scale to medium-sized social networks, in some cases remarkably well. These advances are based on new theorizations of dependence among network ties, echoing the original project of Holland and Leinhardt with a notion of increasingly extended dependence assumptions.

This article begins with a presentation of notation and terminology and then discusses how dependence hypotheses lead to the general form of the model. Specific examples of dependence hypotheses, and the resulting models, are then presented: Bernoulli graph distributions; dyadic independence models; and Markov random graph models. Methods of simulation are briefly introduced before a discussion of degeneracy issues, particularly as they apply to Markov random graph models. Recently proposed dependence hypotheses are introduced, including the so-called "social circuit" dependence, leading to additional specifications for exponential random graph models that substantially improve model performance. Estimation and goodness of fit approaches are discussed before a short empirical example is presented. Extensions are briefly described followed by some concluding remarks about future directions.

Notation and Terminology

A network comprises a set of relational ties between pairs of individual *actors* (be they people or other social entities). A network can be represented as a graph G with node set $N = \{1, 2, \ldots, n\}$ representing the individuals and edge set E representing the relational ties. For the statistical models of this article, relational ties are construed as a set of binary random variables X_{ij} such that $X_{ij} = 1$ if a tie is observed from node i to node j, for $i \neq j$, and $X_{ij} = 0$, otherwise. For a nondirected network X_{ij} and X_{ji} are equivalent, whereas for a directed network the two variables are distinct. X_{ii} is undefined (or may be considered as a structural zero). A nondirected tie is an *edge* and a directed tie an *arc*. We specify x_{ij} as the observed value of the variable X_{ij} and we let $\mathbf{X}$ be the matrix of all variables with $\mathbf{x}$ being a realization (where the diagonals of the matrices are forced to be zero). $\mathbf{X}$ and $\mathbf{x}$ are necessarily symmetric for nondirected networks, but not so for directed networks. More generally, $\mathbf{x}$ may be valued but in this article we restrict attention to binary ties.

There are natural extensions to this basic notation, depending on the data structures. For instance, suppose the data is in the form of a bipartite network, with two distinct sets of nodes and ties between nodes of different types but not between nodes of the same type (e. g. such a data structure can represent people's membership of clubs). Then $\mathbf{X}$ may comprise a set of variables X_{pa} indicating the presence or absence of a tie between a node p of the first type and a node a of the second type. The data may involve *multiple* or *multivariate networks*, with r different types of relations among the one set of nodes. In that case $\mathbf{X}$ may be thought of as a three-way array of variables X_{ijr} such that $X_{ijr} = 1$ indicates that presence of a tie of type r from node i to node j. An analogous three-way array may represent network data collected for the same set of nodes at different time points such that $X_{ijt} = 1$ indicates that presence of a tie at time t from node i to node j.

Nodes themselves can have certain properties (*attributes*) that may be measured as binary, categorical or continuous variables. We denote an attribute variable with the vector $\mathbf{Y}$, where $Y_i = y_i$ indicates that for attribute Y node i has a value y_i.

Dependence Hypotheses

Following work in spatial statistics [1], Frank and Strauss introduced the notion of a *dependence graph* into social network modeling [9] in order to represent possible dependencies among network variables X_{ij}. The nodes of the dependence graph are the network variables X_{ij} and an edge between two nodes indicates dependence between the respective variables, even when the observed values for all remaining variables are known. These edges specify a *neighborhood* relationship between pairs of variables and the cliques of the dependence graph can be thought of as *local social neighborhoods* for the set of tie variables [27]. Conversely, the absence of an edge in the dependence graph indicates that two network variables are conditionally independent, and are not neighbors, so that their interaction need not be taken into account in a model based on local social neighborhoods. (A more technical discussion on dependence graphs for social network models can be found in [35]).

The previous paragraph describes one important result from the Hammersley–Clifford theorem [1], that the form of a probability distribution for a set of interacting variables relates solely to the neighborhood structure (or clique structure) of the dependence graph (with a single network variable also taken as a clique). For a given node set N, once a dependence hypothesis is specified and the dependence graph is defined, it follows *necessarily* from the Hammersley–Clifford theorem that:

$$\Pr(\mathbf{X} = \mathbf{x}) = (1/\kappa(\boldsymbol{\eta})) \exp\{\Sigma_A \eta_A g_A(\mathbf{x})\} , \qquad (1)$$

where:

(i) the summation is over all neighborhoods A;
(ii) η_A is a parameter corresponding to the neighborhood A (and there is no non-zero parameter for any set of ties that do not constitute a neighborhood);
(iii) $g_A(\mathbf{x}) = \prod_{x_{ij} \in A} x_{ij}$ is the *network statistic* corresponding to neighborhood A and indicates whether all the ties in A are observed in the network $\mathbf{x}$;
(iv) κ is a normalizing quantity, that is a function of the parameter vector $\boldsymbol{\eta}$, to ensure that (1) is a proper probability distribution.

All exponential random graph models take this general form, describing a probability distribution of graphs on n nodes. Neighborhoods A are subsets of possible ties, so they represent possible subgraphs that may or may not be observed in the network $\mathbf{x}$. There is one, and no more than one, parameter for each distinct neighborhood (although one neighborhood may be a subgraph of another and so both may have separate parameters).

The form of the model in (1) is too general to be identifiable and some homogeneity constraint needs to be imposed on what is otherwise a large number of neighborhoods A (and hence a large number of parameters). The original proposal [9] was that parameters should be equated across subsets of ties that were isomorphic to each other (that is, subgraphs that are indistinguishable once node labels are removed). With some further constraints (noted below), this assumption can produce identifiable models that can be fitted to data. (Other possible ways to constrain the number of parameters are also described below). Following the terminology first used by Moreno [24], we term these isomorphic neighborhoods as *network configurations* (although some of the network literature of the last decade has adopted the term *motif*). Counts of configurations become the sufficient statistics of the model.

Examination of the parameters for the various configurations of a fitted model can provide insight into the social processes that may underpin the network. The strength and direction of any particular parameter value will affect how frequently the corresponding configuration is observed. If the parameter is large and positive, we expect to observe the corresponding configuration to occur more frequently than if the parameter value were zero [40].

Obviously, good dependence hypotheses are necessary for this approach to work, as they crucially shape the nature of the model by defining the possible configurations.

Bernoulli Random Graph (Erdös–Rényi) Models

Suppose we hypothesize that there are no dependencies within the network, so that the dependence graph has no edges and the only neighborhoods are single tie variables X_{ij}. Then (1) becomes:

$$\Pr(\mathbf{X} = \mathbf{x}) = (1/\kappa) \exp(\Sigma_{i,j} \eta_{ij} x_{ij}) .$$

Constraining parameters to be equal for isomorphic neighborhoods here implies equating all the parameters $\eta_{ij} = \theta$, as there is only one type of neighborhood. Then we have:

$$\Pr(\mathbf{X} = \mathbf{x}) = (1/\kappa) \exp(\Sigma_{i,j} \theta x_{ij}) = (1/\kappa) \exp(\theta L(\mathbf{x})) ,$$

where $L(\mathbf{x})$ is the number of edges (arcs) in the network $\mathbf{x}$ and θ is a *density* or *edge* parameter (sometimes called a *choice* parameter in older literature). This graph distribution is equivalent to that of a distribution of simple random graphs where the probability of a tie between a pair of edges is $\exp\theta/(1 + \exp\theta)$.

The dependence assumption here is unrealistic and this model will fit few, if any, real networks, but it is often a useful null or baseline model.

Dyadic Independence Models

For directed networks, a dyadic independence hypothesis implies edges in the dependence graph between variables

X_{ij} and X_{ji}. Neighborhoods then take the form of single edges and dyadic pairs $\{X_{ij}, X_{ji}\}$. Applying constraints in the form of the one density parameter θ to all single edge neighborhoods and the one *reciprocity parameter* ρ to all dyadic neighborhoods results in the following two parameter model:

$$\Pr(\mathbf{X} = \mathbf{x}) = (1/\kappa) \exp(\theta L(\mathbf{x}) + \rho M(\mathbf{x}))\,,$$

where $L(\mathbf{x})$ is the number of arcs and $M(\mathbf{x})$ the number of mutual dyads (i. e. where $X_{ij} = X_{ji} = 1$) in the network $\mathbf{x}$. This model has the capacity to model reciprocity effects in directed networks. Slightly less sweeping homogeneity constraints result in the p_1 model [15].

The interpretation of a single parameter in an exponential random graph model is relative to other effects in the model, so that in this case, the presence of a large and positive ρ parameter is relative to the density effect. This is an advantage: in this model, for instance, we can infer that there is substantial reciprocity *given the density of the graph*. It is of little use to talk about a large reciprocity effect in absolute terms, because the number of arcs in the graph (i. e. the density) establishes the preconditions for reciprocity. In other words, graphs of very low density have very little opportunity to demonstrate reciprocity anyway, and the absence of mutual dyads in a low density graph may simply be a feature of the low density. Similarly the presence of many mutual dyads in a high density graph may simply be explained by the high density, without the need to infer a reciprocity effect. A large positive ρ, on the other hand, shows that the number of arcs in a graph are arranged in sufficiently many mutual dyads to suggest that a separate and substantial reciprocity process is required to explain the structure of this network, over and above any density effect.

Once again, the dyadic independence assumption does not do a good job of reproducing real networks, because the model has no capacity for triangulation. The model may be useful as a baseline model.

Markov Random Graphs

Frank and Strauss [9] proposed Markov dependence, by postulating that a possible tie from i to j is assumed to be contingent on any other possible tie involving i or j, even if all other ties in the network are fixed. Markov dependence implies that two possible network ties are conditionally independent unless they share a common actor. They showed that this assumption resulted in models with configurations for nondirected graphs of single edges, star-like structures and triangles (or 3-cycles). For directed graph models, configurations include directed counterparts of these as well as reciprocity (see [55] for a fuller description of directed graph parameters). Frank and Strauss termed these *Markov random graph models*.

Once homogeneity is imposed across isomorphic neighborhoods, we obtain configurations (and related parameters) for nondirected networks as depicted in Fig. 1. The resulting model is:

$$\Pr(\mathbf{X} = \mathbf{x}) = (1/\kappa) \exp(\theta L(\mathbf{x}) + \Sigma_{r=2,n-1}\sigma_r S_r(\mathbf{x}) + \tau T(\mathbf{x}))\,, \quad (2)$$

where:

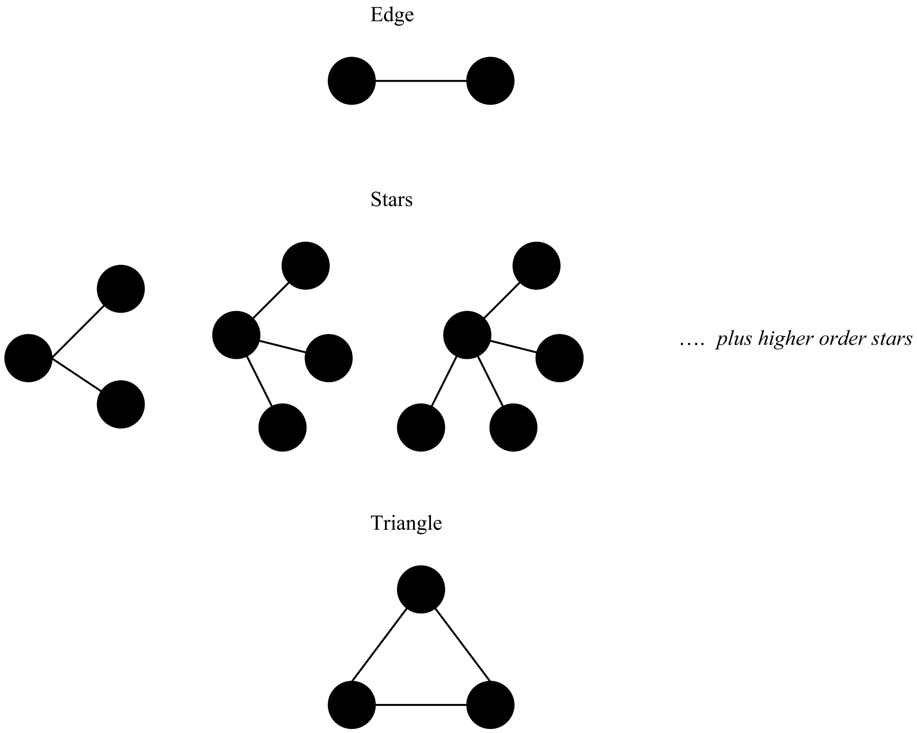
(i) θ is a density parameter, and $L(\mathbf{x})$ the number of edges in $\mathbf{x}$, as before;
(ii) σ_r is a parameter for a *star of size* r, and $S_r(\mathbf{x})$ is the number of stars of size r in $\mathbf{x}$;
(iii) a star of size r is a configuration centered on a single node i such that there are r edges emanating from i (note that stars of size larger than r contain many stars of size r, so that this is not simply a partition into nodes of different degrees, although the full set of counts $S_r(\mathbf{x})$ can be converted into the degree distribution, and vice versa);
(iv) τ is a triangle or clustering parameter and $T(\mathbf{x})$ is a count of the number of triangles in $\mathbf{x}$.

This model still has too many star parameters to be identifiable. Note that the expression $\theta L(\mathbf{x}) + \Sigma_{r=2,n-1}\sigma_r S_r(\mathbf{x})$ completely parametrizes the degree distribution (so the τ parameter can be interpreted as the strength of transitivity conditional on the degree distribution of the graph). An identifiable model can be obtained by restricting the number of star parameters to be substantially less than $n - 2$, for instance, to less than four (an alternative approach is described below). Then the model becomes:

$$\Pr(\mathbf{X} = \mathbf{x}) = (1/\kappa) \exp(\theta L(\mathbf{x}) + \sigma_2 S_2(\mathbf{x}) + \sigma_3 S_3(\mathbf{x}) + \tau T(\mathbf{x}))\,. \quad (3)$$

The parameters can be interpreted in ways that represent plausible social processes [39]:

(i) θ is a baseline propensity for social ties to form;
(ii) σ_2 represents a tendency for individuals to seek multiple partners (if it is positive);
(iii) whereas σ_3 (if negative as it often is when this model is fitted to real data) represents a ceiling effect against having too many partners; so, together the balance between σ_2 and σ_3 represents the benefits of multiple



Social Networks, Exponential Random Graph (p^*) Models for, Figure 1
Configurations for a nondirected Markov random graph model

contacts against the costs of maintaining too many contacts;

(iv) while τ represents tendencies towards clustering.

An alternative interpretation is to consider the θ, σ_2 and σ_3 parameters as controlling for the first three moments of the degree distribution, so that while model (2) in effect presents a full parametrization, model (3) provides a more parsimonious control over the degree distribution (saturated models of the degree distribution are discussed by [43] and [47], see also [11]). Of course, for any data set it is an empirical question whether the first three moments are sufficient to capture the degree distribution adequately. Below, we describe ways to investigate that question.

Extensions of this basic Markov random graph model include models for multivariate networks [29], for valued networks [36] and for affiliation networks [42] (see also [28]).

By tuning parameter values even the simple four parameter model (3) can represent many different types of networks, including small world networks, networks with long paths, and highly clustered ("caveman") networks [39]. For some parameter values, however, the models became "frozen" into certain unchanging highly structured patterns. This effect is an illustration of *degeneracy* for these models, which was a research issue given important attention in the early years of the 21st century. The upshot of this body of research was that homogeneous Markov random graph models were recognized as frequently inadequate to deal with real social network data.

Simulation and Model Degeneracy

The problems of degeneracy became apparent through a number of simulation studies. Strauss was the first to describe a rather straightforward application of standard statistical simulation techniques (e. g. Metropolis or Metropolis–Hastings algorithms) to simulate Markov random graph models for a fixed set of nodes and given set of parameter values [51]. More recent treatments and some important results are given in [13,14,17,39,45]. These methods provide a principled statistical means to produce a distribution of graphs with probabilities of each graph being observed in the distribution consistent with any particular model in the form of (1). Typically the simulation is run for a large number of iterations and a sample of graphs is extracted and examined to understand typical properties of the graphs in the distribution.

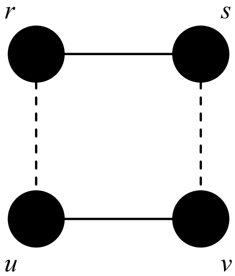
A graph distribution is termed as *near degenerate* [13,14] if it implies only a very few (possibly only one or two) distinct graphs with substantial non-zero probabilities. For instance, certain parameter values for Markov random graph models place almost all of the probability mass on either the empty or the full graph. These cannot be good models for human social networks. For certain parameter values, there may be two quite separate regions where graphs are most likely (possibly one region of low density and another of high density graphs), with the possibility of a dramatic phase transition from one region to the other (for instance, as parameter values change very slightly). Such phase transitions and other aspects of degeneracy have been studied for a variety of simple Markov random graph models by a number of authors [2,12,13,14,19,26,39,41,45,48].

Issues of degeneracy call into question whether Markov random graph models can adequately represent most network data. It would not matter if some regions of the parameter space produced degenerate models, as long as those regions applicable to empirical data were non-degenerate. Experience shows the opposite applies: for some data, Markov random graph models turn out to be well-behaved, but for many empirical networks they are degenerate. When applied to social networks with a few very high degree nodes, or with some regions of high triangulation, degeneracy frequently occurs for Markov models. Models such as (3) reflect homogeneity constraints, and they appear to have difficulty when the data presents inhomogeneity in the distribution of degrees or triangles. It is not entirely certain whether the problem with the models arises because of the Markov dependence assumption or the assumption of homogeneity. In any event, to deal more effectively with real networks, a different approach to these models seems necessary. To date, attention has been directed to revisiting the dependence assumption.

Snidjers and colleagues [48] drew two conclusions from the tendency for Markov random graph models to be degenerate when fitted to real networks with a high level of clustering: (1) the Markov dependence assumption may be too restrictive; (2) the representation of the social phenomenon of transitivity by the total number of triangles might be too simplistic. They proposed specifications that drew on both these possibilities. Before we introduce these new specifications, however, we turn to higher order network dependencies.

Social Circuit Dependence: Partial Conditional Dependence Hypotheses

There are several ways in which network dependence assumptions could be extended beyond Markov dependence [27]. One approach is of *partial conditional dependence*, whereby the presence of certain network ties *created* dependence among other possible network ties. This assumption permits the emergence of dependence structures as ties come into and go out of existence. This type of dependence can be incorporated into a version of the Hammersley–Clifford theorem and hence into exponential random graph models [27].



Social Networks, Exponential Random Graph (p^*) Models for, Figure 2
Social circuit dependence (*Broken lines* represent possible edges; *full lines* represent observed edges X_{ru} is conditionally dependent on X_{sv})

A particular hypothesis about this type of emergent dependence was used by [48] and described by [41] as *social circuit dependence*. Social circuit dependence is defined as two possible network ties being conditionally dependent if their observation would lead to a 4-cycle. This type of dependence is depicted in Fig. 2. Here $X_{rs} = X_{uv} = 1$, that is, in the network data there are observed edges between nodes r and s, and between nodes u and v. The presence of these edges leads to conditional dependence between variables X_{ru} and X_{sv} because if edges were also observed between r and u, and between s and v, a 4-cycle would result in the graph.

Interpretation of this hypothesis is discussed by [41]. Generally we would expect two distinct possible edges (r, u) and (s, v) to be conditionally independent. If, however, person r knows person s, and person u knows person v, then the presence of a tie between r and u can make the presence of a tie between s and v more likely, that is, they are conditionally dependent. It is simple to think of real social circumstances where this happens: for instance, in families the presence of a friendship between two children increases the chances of the two mothers coming to know one another; or in a business, cooperation between two bosses may lead to their employees working together; or in research, two postdoctoral researchers might discuss issues with each other because their academic mentors have been collaborators. In all of these cases, what makes the dependence come into effect is the presence of ties that constitute part of the 4-cycle. Without those ties, the dependence does not arise. So, the mothers are the mothers of the two particular children, not the mothers of entirely different children; the employees are employed by those particular bosses; and the two post-docs are supported by those two mentors.

Social Circuit Specifications

Snijders and colleagues [48] proposed three new statistics for exponential random graph models for nondirected networks: *alternating k-stars*, *alternating k-triangles*, and *alternating independent two-paths*. To derive these statistics they use: (1) social circuit dependence *in addition to* Markov dependence; and (2) a non-linear functional form combining various configurations into the one statistic.

Alternating *k*-Stars

The alternating k-star parameter uses the second idea alone and does not extend dependence beyond the class of Markov random graph models. Rather than adopt the usual practice of limiting the number of higher order stars – as for example in model (3) where the star parameters are deliberately limited to no more than 3-stars – Snijders and colleagues returned to model (2), keeping all σ_r in the model but imposing constraints among these parameter values. Specifically, the *alternating k-star assumption* proposes that for all $k \geq 2, \sigma_{(k+1)} = -\sigma_k/\lambda$ for some λ greater than 1. Then in (1) there is one parameter σ for all star effects, with an associated statistic:

$$u = \sum_{k=2}^{n-1} (-1)^k \frac{S_k}{\lambda^{k-2}} , \tag{4}$$

where the parameter σ is referred to as the *alternating k-star parameter*. As λ is greater than 1, the direct impact of higher order stars (that is, very high degree nodes) is reduced for higher k. Of course, as noted above, high degree nodes still have substantial effect in the model as they produce many 2- and 3-stars, and so on. The alternating sign helps balance these overlapping star counts for high degree nodes. In [48] λ is set at 2 but [17] show how to estimate an optimal value of λ (see also [16]). The alternating k-star parameter is equivalent to a *geometrically weighted degree parameter* that explicitly models the degree distribution but puts more weight on the numbers of nodes with lower degrees, with weights decreasing geometrically as the degrees increase [16].

The interpretation of the parameter is as follows [41, 48]. If the alternating k-star parameter is positive, then highly probable networks are likely to contain some higher degree nodes. A positive alternating k-star parameter (together with a negative density parameter) implies graphs that exhibit preference for connections between a larger number of low degree nodes and a smaller number of higher degree nodes, akin to a core-periphery structure.

Alternating *k*-Triangles

The alternating k-triangle assumption incorporates both social circuit and Markov dependence. Snijders and colleagues show that with both these dependence assumptions operating simultaneously, configurations more complex than simple triangles are possible [48]. In particular, they introduced the notion of a *k-triangle*, a combination of k individual triangles that all share one edge (the common *base* of the k triangles), as represented in Fig. 3.

Let T_k be the count of k-triangles in a graph. Then the *alternating k-triangles assumption* combines these counts into the one statistic in an analogous way as for the alternating k-stars, that is:

$$t = 3T_1 + \sum_{k=1}^{n-3} (-1)^k \frac{T_{k+1}}{\lambda^k} , \tag{5}$$

where the factor of 3 for T_1 is due to symmetry considerations in a non-directed triangle [48].

This is the *alternating k-triangle statistic* with an associated *alternating k-triangle parameter* τ. A positive k-triangle parameter indicates triangulation in the network but also tendencies for triangles themselves group together in larger higher order "clumps". A positive alternating k-triangle effect combined with a negative alternating k-star effect can produce a web of multiple smaller regions of triangulation [41,48].

[16] shows that the alternating k-triangle parameter is equivalent to the *edge-wise shared partner* (or ESP) parameter that models the distribution of shared partners of tied actors, but with weights decreasing geometrically as the number of shared partners increase.

Alternating *k*-Two-Paths

Snijders and colleagues also proposed a parameter that represents a lower order configuration for a k-triangle, namely a *k-two-path* which is a k-triangle without the base [48]. These configurations, represented in Fig. 4, describe the number of distinct two-paths between a pair of nodes. The motivation was to provide a parameter that, in conjunction with k-triangles, would distinguish between tendencies to form edges at the base, or at the sides of a k-triangle.

Social Networks, Exponential Random Graph (p^*) Models for, Figure 4
Various alternating *k*-independent 2path configurations

Again the counts of these configurations are combined into the one alternating statistic in an analogous way as in the previous two cases, to produce an alternating 2-path statistic and parameter for the model. [16] shows that this new parameter is equivalent to the *dyad-wise shared partner* (or DSP) parameter that models the distribution of shared partners of actors who may or may not be tied, but with weights decreasing geometrically as the number of shared partners increase.

The parameter can be interpreted as representing localized multiple connectivity between nodes. When this parameter is negative, together with a positive alternating *k*-triangle parameter, there is a tendency against 4-cycles in the network, unless those cycles include triangles (alternatively, the presence of many 2-paths between nodes is related to the formation of triangles).

Specifications for Directed Graphs

Counterpart statistics and parameters for directed graphs have also been proposed. We do not discuss these here but refer readers to [48].

Estimation

Pseudo-likelihood estimation [52], based on logistic regression techniques, was commonly used until more principled methods became available in recent years. Preferred methods of estimation involve simulation procedures (Monte Carlo Markov chain maximum likelihood estimation – MCMCMLE) which for these models has been discussed by a number of authors [4,5,6,17,45,47,56]. Software for Monte Carlo estimation techniques has recently become publicly available ([41] provides a review). The observed graph statistics are compared with those expected under a set of provisional parameter values, using a stochastic simulation based on those values. The goal is to find a set of parameter values whereby the observed statistics are equal to the expected statistics. Parameter values are refined until the observed and expected statistics can be equated, when the model is said to converge. If the parameter estimates never converge, the model is degenerate. Standard errors can also be estimated.

Goodness of Fit and Comparisons with Markov Models

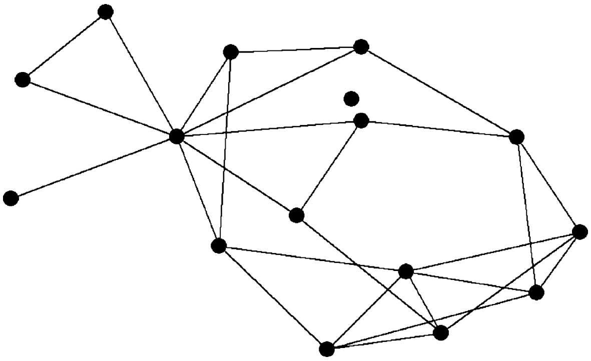
Simulation also provides an innovative means to assess how well the model can represent the data. By simulating the model from the parameter estimates, and extracting a sample of graphs it is possible to examine any graph statistic of interest (whether there is an associated parameter in the model or not). Any graph statistic for the observed graph can be compared to the distribution of such graph statistics from the simulated graphs. If the observed graph statistic is not extreme in the distribution of simulated statistics, then it is plausible that that particular feature of the observed graph could have come from the distribution of graphs implied by the model. In this way, it is possible to check which graph features the model successfully captures. This procedure is described in detail by [18] (see also [41]).

[11] provides a compelling example of how this procedure may be used to make decisions about model selection. On the basis of applying the new parametrization to a large school-based network of over 1000 nodes, [11] concludes that for this data Markov models were degenerate, but the newer parametrization had similar underlying interpretations, avoided degeneracy and was empirically validated. Other comparisons with Markov models demonstrate substantial improvements for the new parametrization in overcoming degeneracy [41].

A Simple Empirical Example

Figure 5 presents an empirical network of social relationships among 16 actors, in this case families from medieval Florence [25].

Markov models do not converge for this network. Table 1 provides parameter estimates and standard errors for models involving the social circuit parameters. The third column in the table provides a convergence statistic which indicates good convergence if it has an absolute value less than 0.1 [41]. In this case, the model exhibits excellent convergence.



Social Networks, Exponential Random Graph (p^*) Models for, Figure 5
Social relationships among 16 actors

Social Networks, Exponential Random Graph (p^*) Models for, Table 1
Parameter estimates: Florentine families network (NB: $\lambda = 2$)

Parameter	Estimate	Standard error	Convergence
Edge	−0.04	2.09	0.01
Alternating *k*-star	−1.01	0.78	0.02
Alternating *k*-triangle	0.68	0.33	0.02
Alternating *k*-2paths	0.18	0.17	0.03

A parameter may be inferred as important if its estimate in absolute terms is more than twice its standard error. So in this simple model, there is a substantial effect for alternating *k*-triangles. In Fig. 5, regions of triangulation can be seen, consistent with the alternating *k*-triangle effect, perhaps combined with the negative alternating *k*-star effect (although the reliability of that negative effect is not certain, given that the estimate is not more than twice the standard error). In sum, there is good evidence here that this network differs substantially from a simple random network, in particular, that there is substantially more triangulation in this network than would be expected in a simple random graph.

Table 2 shows the goodness of fit analysis for graph features other than those in the model. This analysis was based on extracting 1,000 sampled graphs from a simulation of 1,000,000 (after a burn-in of 100,000), using the parameter estimates in Table 1. The goodness of fit statistic takes the form of a *t*-ratio, calculated as the difference between the graph statistic and the mean from the

Social Networks, Exponential Random Graph (p^*) Models for, Table 2
Goodness of fit analysis: Florentine families network model

Graph feature	Goodness of fit
Number of 2-stars	−0.10
Number of 3-stars	−0.25
Number of triangles	−0.17
Standard deviation, degree distribution	−0.10
Skew, degree distribution	−0.12
Number of isolates	1.06
Clustering coefficient	−0.09

simulated graphs divided by the standard deviation as estimated from the sample. For graph features not in the model, the model is considered to reproduce the data well if the goodness of fit statistic is not extreme (for instance, with t-ratios of less than 2). As can be seen, on the features examined, including counts of various Markov configurations, aspects of the degree distribution, and clustering, the model reproduces the data well. There is one isolate in the data, whereas 71% of simulated graphs had no isolates, hence the rather larger goodness of fit statistic. Nevertheless, with 29% of graphs in the sample having at least one isolate, the data cannot be said to be extreme in this regard.

The clustering coefficient in the Table refers to the proportion of actual to possible triangles and is calculated as thrice the number of triangles as a ratio of the number of two-paths (the factor of three applies because there are three two-paths in any one triangle).

Table 2 does not show features of the geodesic distribution but a separate analysis reveals that the observed geodesic distribution is consistent with those from the simulated graphs: none of the geodesic quartiles of the observed graph is extreme compared to the distribution of quartiles from the simulated graphs. Overall, the model can be said to fit the data well.

Further Extensions and Future Directions

Multiple Networks

It is possible to use the same general framework as (1) when $\mathbf{X}$ is a three-way array representing multiple relations on the one set of nodes. The parametrization, however, becomes more complex. [29] showed how to develop Markov models along these lines, with these models subsequently used in some interesting empirical work, principally in organizations [22,23]. This empirical research, however, utilized pseudo-likelihood estimation and did not take into account possible model degeneracy. See also [20].

Early work on adapting the new specifications proposed by Snijders and colleagues to multiple networks has concentrated on the case of two networks, by using the alternating k-star, -triangle, and -2path parameters for effects within networks and then investigating dyadic associations between networks [57].

Bipartite Networks

Again (1) may be used as a basis for models for bipartite networks. [42] were the first to do this with Markov dependence. [28] proposed additional parameters that derived from partial conditional dependence assumptions. [54] incorporated these and other parameters, combined with an alternating combination of configuration counts analogous to those in the newer specifications, into a model for bipartite networks.

Longitudinal Networks

Perhaps the major approach to modeling network data collected at multiple time points is the actor-oriented models of Snijders and colleagues [44] which utilize a continuous time Markov chain technique. Certain specifications of actor-oriented dynamic models have exponential random graph models as their stationary distribution [44], so the links between the two approaches are quite strong. Accordingly, it is possible to develop longitudinal versions of exponential random graph models to investigate network dynamics. The conceptual difference with the actor-oriented approach is quite subtle: exponential random graph longitudinal models suppose that ties change in response to particular social neighborhoods of other ties, rather than in response to actors seeking to optimize particular structural positions. Early work along these lines, including the evolution of multiple networks, has been reported by [30]. For further discussion on the links between the actor-oriented and tie-based versions of the models, see [46].

Nodal Attributes

One of the important issues that researchers often wish to examine is whether and how nodal attributes relate to network structure. For instance, there are good empirical and theoretical grounds for expecting that people who have social relationships are more likely to be similar to each other (known as *homophily*). Conceptually, two possible processes apply: individuals may develop ties because they are similar (*social selection*) or individuals who are tied may influence each other to be similar (*social influence*).

Of course, both of these processes may occur simultaneously and it is a methodological challenge for a given set of data to disentangle the two to determine the respective strengths of selection and influence effects, respectively. Snijders and colleagues [31,49,50] have recently developed innovative methods for investigating this question for longitudinal data within actor-oriented longitudinal models.

[37] proposed social selection models within the framework of (1), having the form:

$$\Pr(\mathbf{X} = \mathbf{x}|\mathbf{Y} = \mathbf{y}) = (1/\kappa)\exp\{\Sigma_A \eta_A g_A(\mathbf{x}, \mathbf{y})\}\,, \qquad (6)$$

where **Y** is a vector of attribute variables (binary, categorical or continuous). Here the configurations A relate to combinations of nodal attributes and network subgraphs, and the network is modeled conditional on a fixed distribution of attributes. The intent of such models may be various: accounting for heterogeneity (that may otherwise cause difficulties in fitting models) as well as assessing selection, homophily, and covariate activity and popularity, while controlling for dependencies naturally occurring in the network setup.

An analogous approach to social influence models and network contagion was proposed by [38] where the patterns of attributes were modeled conditional on a fixed network:

$$\Pr(\mathbf{Y} = \mathbf{y}|\mathbf{X} = \mathbf{x}) = (1/\kappa)\exp\{\Sigma_A \eta_A g_A(\mathbf{x}, \mathbf{y})\}\,. \qquad (7)$$

Future Directions

Not only have the new specifications shown a remarkable improvement in the successful modeling of real networks, they have opened up a wide range of network modeling possibilities. The discussion of model extensions mentioned above gives some indication of current work in this area. Of course, the possibility of further improvements in model specification has not been closed. Future directions may include methods to examine very large, community-based networks, not only in terms of data collection (for instance, the development of model-based sampling methods) but also theoretical issues based on possible differences in dependence between very large scale and smaller scale structures. Model-based approaches to missing network data, perhaps within a Bayesian framework, are also in prospect [10,21].

The use of exponential random graph models in empirical research, especially in combination with multiple measures on individuals, opens a wide prospect for network statistical modeling to make a substantial contribution in many applied contexts.

Taipei, Taiwan

Article Outline

Glossary

Granulation The process of drawing a set of objects (or points) together by indiscernibility, similarity, proximity, or functionality.

Functional granulation The granulation process is functional if it is based on the attributes of the objects. It is called functional granulation because each attribute is a function from the set of objects to the set of values.

Relational granulation The granulation process is relational if it is based on the relationships between objects.

Rough set A rough set is defined by the lower and upper approximations of a concept. The lower approximation contains all elements that necessarily belong to the concept, while the upper approximation contains those that possibly belong to the concept. In rough set theory, a concept is considered a classical set.

Social network A social network is comprised of a set of actors, called the domain, and a family of relations on the domain. It is usually represented as a graph, where each node represents an actor and an edge between two nodes represents a relational tie between these two actors. An edge can be labeled with the relation it represents.

Positional equivalence Two actors are in equivalent positions if their "pattern" of relationships with other actors is the same.

Structural equivalence Two actors are structurally equivalent if they are related to the same actors.

Regular equivalence Two actors are regularly equivalent if they are equally related to equivalent actors.

Exact equivalence Two actors are exactly equivalent if they are related to the same number of equivalent actors.

Modal logic Modal logic was originally developed as a type of philosophical logic for reasoning about necessity and possibility. However, it has been extended to broadly cover a family of logics for reasoning about modalities including tense, obligation, belief, and knowledge. Semantically, it is also a powerful mathematical discipline that deals with (restricted) description languages for discussing various kinds of relational structures, where a relational structure comprises a set of elements and a collection of relations on that set.

Hybrid logic Hybrid logic is a branch of modal logic that allows direct reference to the elements in a relational structure. Traditionally, only the properties of the elements could be represented by modal logic formulas.

Definition of the Subject

Granular computing (GrC) is a problem-solving concept deeply rooted in human thinking. Hence, it has played a major role in solving many important problems throughout the history of mathematics. GrC is concerned with the processing of information granules, which are groups of objects drawn together by indiscernibility, similarity, proximity, or functionality [37]. The process of forming information granules is called granulation. If the process is based totally on the attributes of the objects, it is called *functional granulation*, since attributes are mathematical functions from the set of objects to the set of values; if, in addition, the granulation process is also based on the relationship between objects, it is called *relational granulation* [11,20].

Interestingly, social scientists have applied the techniques of relational granulation (albeit by different names) to positional analysis in social networks [7,8,10,19,35]. Social network analysis (SNA) is a methodology used extensively in social and behavioral sciences, as well as in political science, economics, organization theory, and industrial engineering [15,31,34]. Positional analysis of a social network tries to find similarities between actors in the network. While many traditional clustering methods are based on the attributes of the individual actors, SNA is more concerned with the structural similarity between the actors. In SNA, a category, called a *social role* or *social position*, is defined in terms of the similarities of the patterns of relations among the actors, rather than the attributes of the actors.

Analyzing a social position from a GrC perspective has two major advantages. On the one hand, it extends the application scope of the GrC methodology. On the other hand, we can logically transform relational granulation of social networks into functional granulation; as a result, the well-developed techniques of data table analysis can be applied to social position analysis. Thus, this is an important cross-fertilization of GrC and SNA.

Introduction

GrC encompasses a wide range of techniques in computational intelligence, such as interval computing, classification, cluster analysis, and fuzzy and rough set theories. Among them, rough set theory [26,27] is one of the most well-known methods with successful applications in data analysis and uncertainty management. The theory was first proposed by Z. Pawlak as a mathematical tool to deal with vague concepts [26]. The basic assumption of the theory is that the effective use of knowledge is based on the capability to classify objects. Thus, knowledge consists of a family of classifications of a domain of interest. A classification of a domain is represented as a partition of (or an equivalence relation on) the domain. Each equivalence class of a classification is the elementary knowledge about the classification. For example, if the domain is classified according to colors, then the elementary knowledge may include "red", "green", "blue", etc. In this sense, a classification is derivable from a set of features or attributes of objects. An important task of data analysis is to define a concept via a set of features. If the concept can be precisely defined as the objects with some specific attribute values, then it is an exact concept with respect to the given attributes. However, in practice, most concepts are vague and can not be defined precisely by a given set of attributes. In such cases, rough set theory provides an effective way to approximate the vague concepts with some exact concepts in the domain. Because of its applications in data mining, rough set theory has flourished since 1990.

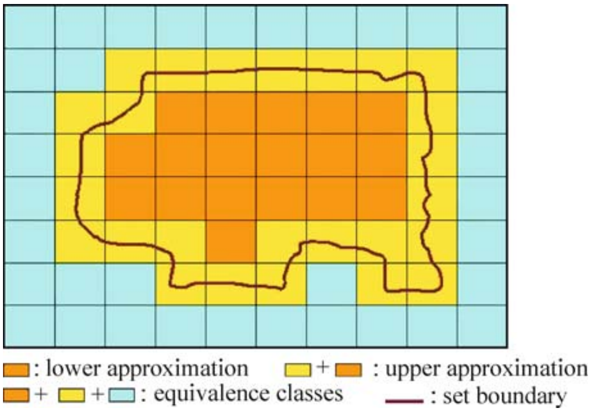
At about the time rough set theory was proposed, the pioneer of fuzzy set theory, L.A. Zadeh, emphasized the importance of information granularity in fuzzy reasoning [36]. Subsequently, T.Y. Lin proposed the term "GrC" to unify different techniques developed for processing information granules. From the GrC perspective, both classification in rough set theory and fuzzification in fuzzy set theory are types of granulation.

In rough set theory, objects are partitioned into equivalence classes based on their attribute values. While such values essentially represent functional information associated with the objects, more complicated information can be utilized in the classification of objects. In particular, relational information between objects can play an important role in the granulation process. The information is defined by general binary relations, which are extensions of the functional attributes of the objects. Geometrically, such granulation is derived from the neighborhood system of topological spaces [32], where each point/object is assigned at most one neighborhood/granule. This kind of granulation is called *relational granulation*, while granulation based on attribute values only is called *functional granulation* [11,20].

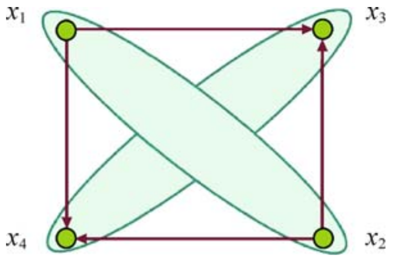
Relational granulation is especially useful for the analysis of network data because a network is a collection of relations between nodes. A concrete instance of the application of relational granulation is positional analysis of social networks. Positional analysis attempts to find actors occupying the same position in a social network based on the pattern of their relationships to other actors. Depending on the different patterns of relationships, different notions of positional equivalence have been proposed [19]. These notions can be easily regarded as instances of relational granulation. In this article, we consider three of the most important notions of positional equivalence – *structural equivalence*, *regular equivalence*, and *exact equivalence*.

Recently, it was shown that social positions based on regular equivalence can be syntactically expressed as well-formed formulas (wff) in a kind of modal logic [22]. Thus, actors occupying the same social position based on regular equivalence will satisfy the same set of modal formulas. Traditionally, modal logic has been considered the logic for reasoning about modalities, such as necessity, possibility, time, action, belief, knowledge, and obligation. However, semantically, it is essentially a language for describing relational structures [5]. A relational structure is simply a set combined with a collection of relations on that set. Thus, social networks are mathematically equivalent to relational structures. The logical characterization of social positions implies that relational granulation for positional analysis can be transformed into a functional granulation process. Indeed, since each actor in a social network may satisfy or falsify a modal formula, a modal formula can be seen as a binary attribute associated with each actor. Therefore, based on the results in [22], two actors are regularly equivalent if they have the same values with respect to all attributes defined by the language of the particular modal logic.

By extending previous results, we can find logical characterizations of different positional equivalences and transform them into a functional granulation process. Consequently, the techniques of rough set-based data analysis can also be applied to positional analysis. However, since the set of wffs of a modal logic is usually infinite, the functional granulations corresponding to positional equivalences need to consider infinite sets. To circumvent this problem, we also propose a new definition of positional equivalence, called *observational equivalence*. Let Σ be a set of wffs in a logical language that denotes the set of observable properties of the actors in a network. Two actors a and b are observationally equivalent with respect to Σ, if for each wff $\varphi \in \Sigma$, a satisfies φ iff b satisfies φ.

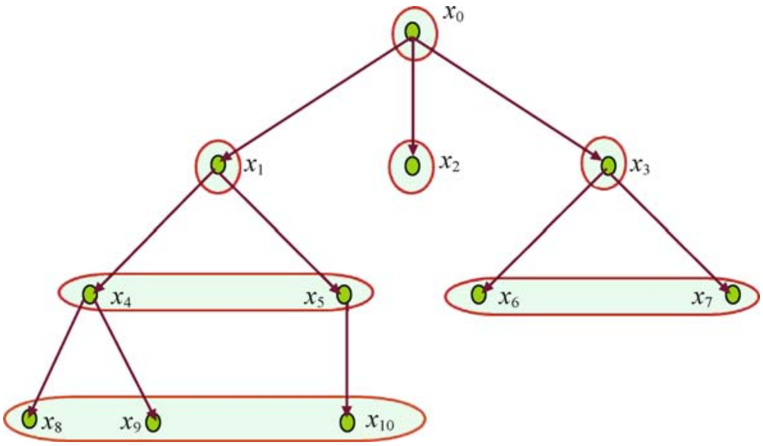


Social Networks and Granular Computing, Figure 1
A rough set: the set delimited by the *curve* (the set boundary) can not be represented exactly as a union of the basic building blocks. The *blocks* totally included in the set form the lower approximation of the set, while the *blocks* that intersect with the set (including the lower approximation) form the upper approximation of the set

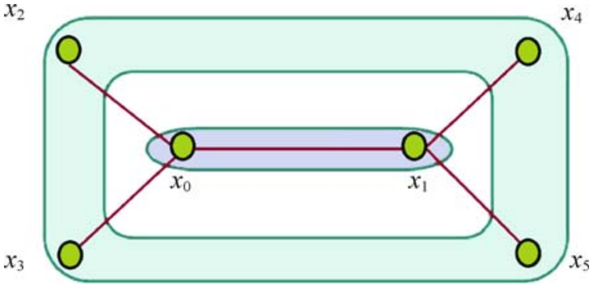


Social Networks and Granular Computing, Figure 2
Structural equivalence: the social network contains 4 actors denoted by the *nodes* and a single binary relation denoted by the *arcs*. Both the out-neighborhoods of x_1 and x_2 are $\{x_3, x_4\}$, and their common in-neighborhood is the empty set. On the other hand, both the in-neighborhoods of x_3 and x_4 are $\{x_1, x_2\}$, and their common out-neighborhood is the empty set. Thus, $x_1 \cong_s x_2$ and $x_3 \cong_s x_4$. The *green shadowed areas* indicate the equivalence classes

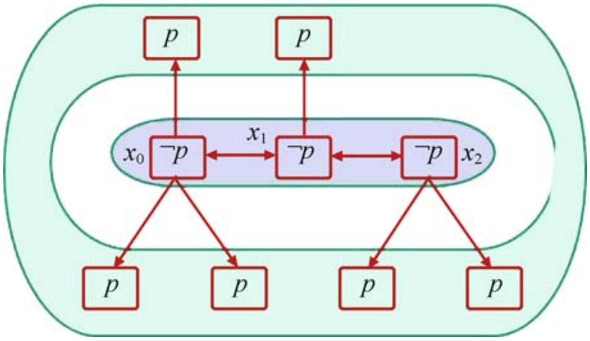
The remainder of this article is organized as follows. In Sect.“ Mathematical Preliminaries”, we introduce the background knowledge and mathematical notations of sets and relations. In Sects. “Rough Set Theory – Functional Granulation” to “Modal Logic – The Bridge”, we review rough set theory, social positional analysis, and modal logic respectively. In Sect. “From Relational Granulation to Functional Granulation”, we present the logical characterizations of three main positional equivalences and the definition of observational equivalence. Finally, in Sect. “Conclusion and Future Directions”, we present our conclusions and indicate some future research directions.



Social Networks and Granular Computing, Figure 3
Regular equivalence in a tree-structured social network: the root x_0 is discernible from other nodes because its in-neighborhood is empty, whereas all the other nodes have nonempty in-neighborhoods. Nodes x_1, x_2, x_3 are discernible from other nodes because they are the only nodes connected to x_0. Moreover, they are mutually discernible, since x_2 has no children, x_1 has children and grand-children, and x_3 has children, but not grand-children. Note that x_4 and x_5 are indiscernible, since they have the same in-neighborhood and equivalent out-neighborhoods; x_6 and x_7 are indiscernible, since they have the same in-neighborhood and both have empty out-neighborhoods; and x_8, x_9, and x_{10} are indiscernible, since they have equivalent in-neighborhoods and all have empty out-neighborhoods



Social Networks and Granular Computing, Figure 4
Exact equivalence: the social network is a undirected graph. In other words, the binary relation is symmetry. The exact equivalence partitions the nodes into two classes, $C_0 = \{x_0, x_1\}$ and $C_1 = \{x_2, x_3, x_4, x_5\}$. To verify that it is indeed an exact equivalence, we can check that both x_0 and x_1 connect to one C_0 node and two C_1 nodes, and all of x_2, x_3, x_4, and x_5 connect to one C_0 node



Social Networks and Granular Computing, Figure 5
A social network represented as a Kripke model: we assume the underlying modal language contains one propositional symbol p and one relational symbol r. Since $\{x_0, x_1, x_2\}$ is an equivalence class in the shown regular equivalence, the three nodes all satisfy the same set of PMML wffs. For example, they all satisfy $\neg p \wedge \langle r \rangle p$. However, they are not exactly equivalent, so they are distinguishable by GML wffs. For example, x_0 satisfies both $\langle r \rangle_1 p$ and $\langle r \rangle_2 p$, x_1 does not satisfy $\langle r \rangle_1 p$ or $\langle r \rangle_2 p$, and x_2 satisfies $\langle r \rangle_1 p$ but not $\langle r \rangle_2 p$

Mathematical Preliminaries

In this section, we introduce the basic knowledge about sets and relations used in this article.

Sets

A set is a collection of objects, called the elements of the set. We use capitals A, B, U, X, etc. to denote sets. The elements of a set are denoted by lower-case letters and we write $x \in U$ if x is an element of the set U. We usually use two notations to denote a set. The first one lists its elements. For example, we can write $\{x_1, x_2, \ldots, x_n\}$ for a finite set, where n is a positive integer, and $\{x_1, x_2, \ldots\}$ for an infinite set. The second notation specifies the defining property of the set. For example, we can write $\{x \mid x = 2n, n \in Z\}$ for the set of even numbers. The number of elements in a set is called its cardinality. The cardinality of U is denoted by $|U|$. A set U is called an empty set if $|U| = 0$, and a singleton if $|U| = 1$. We denote the empty set by $\emptyset$.

The basic operations on sets are defined as follows:

1. Intersection of X and Y: $X \cap Y = \{u \mid u \in X \text{ and } u \in Y\}$,
2. Union of X and Y: $X \cup Y = \{u \mid u \in X \text{ or } u \in Y\}$,
3. Cartesian product of X and Y: $X \times Y = \{(x, y) \mid x \in X \text{ and } y \in Y\}$, and
4. Difference of X by Y: $X - Y = \{u \mid u \in X \text{ and } u \notin Y\}$.

Since intersection, union, and the Cartesian product are associative (i. e., $(X \cap Y) \cap Z = X \cap (Y \cap Z)$ etc.), we can eliminate the parentheses and apply the operations to more than two sets. For example, the Cartesian product of the sets $U_1, U_2, \ldots, U_k$ is denoted by

$$U_1 \times U_2 \times \cdots \times U_k = \{(x_1, x_2, \ldots, x_k) \mid x_i \in U_i, \forall 1 \leq i \leq k\} ,$$

where each element is called a k-tuple. A 2-tuple is also called a pair. If $U_1 = U_2 = \cdots = U_k = U$, the Cartesian product is written as U^k. A set X is said to be a subset of another set Y, denoted by $X \subseteq Y$, if for all $x \in X$, it is also the case that $x \in Y$. A function f from the set X to the set Y, denoted by $f : X \to Y$, is a mapping that associates each element in X with an element in Y. The set X is called the domain of the function, and Y is called the range of f. For each $x \in X$, we write $f(x)$ for the element in Y that is associated with x by f and call it the image of x under f. Also, the image of X under f is defined as $f(X) = \{f(x) \mid x \in X\}$.

Multisets

For sets, repeat occurrences of the same elements are only counted once. Thus, the set $\{x, x\}$ is the same as the set $\{x\}$. Sometimes, the number of occurrences of an element is important. In such cases, we consider multisets (or bags). A multiset is formally defined as a pair $M = (U, m)$, where U is some set and $m : U \to N$ is a function from U to the set $N = \{0, 1, 2, 3, \ldots\}$ of natural numbers. U is called the universe and for each element $x \in U$, $m(x)$ is the multiplicity (that is, the number of occurrences) of x in M. A set can be considered as a special multiset in which $m(x) = 0$ or 1 for each x in the universe. By generalizing the notation of set membership, we can write $x \in M$ if $m(x) > 0$. The cardinality of M is defined as $|M| = \sum_{x \in U} m(x)$. Let $M_1 = (U, m_1)$ and $M_2 = (U, m_2)$ be two multisets in the same universe; then, $M_1 \subseteq M_2$ iff $m_1(x) \leq m_2(x)$ for all $x \in U$. The intersection, union, and difference between $M_1 = (U, m_1)$ and $M_2 = (U, m_2)$ are defined as follows:

1. $M_1 \cap M_2 = (U, m)$, where $m(x) = \min(m_1(x), m_2(x))$ for all $x \in U$,
2. $M_1 \cup M_2 = (U, m)$, where $m(x) = \max(m_1(x), m_2(x))$ for all $x \in U$,
3. $M_1 - M_2 = (U, m)$, where $m(x) = (m_1(x) - m_2(x)) \cdot \chi(m_1(x) - m_2(x))$ for all $x \in U$, and

$$\chi(k) = \begin{cases} 1, & \text{if } \quad k > 0, \\ 0, & \text{if } \quad k \leq 0 . \end{cases}$$

The Cartesian product of $M_1 = (U_1, m_1)$ and $M_2 = (U_2, m_2)$ is defined as $M_1 \times M_2 = (U_1 \times U_2, m)$, where $m(x, y) = m_1(x) m_2(y)$ for all $x \in U_1$ and $y \in U_2$.

Relations

In mathematics, a subset of $U_1 \times U_2 \times \cdots \times U_k$ is called a k-ary relation among the sets $U_1, U_2, \ldots, U_k$, and a subset of U^k is called a k-ary relation on U. We are particularly interested in binary relations. According to the definition, a binary relation on U is a set of pairs of elements in U. A pair (x, y) in a binary relation means that x is related to y by the relation. We use lower-case Greek letters, α, β, ρ, etc. to denote relations. The basic operations on binary relations include the three aforementioned set-theoretic operations – intersection, union, and difference, as well as converse and composition. The converse of a binary relation $\alpha \subseteq U_1 \times U_2$ is $\alpha^- \subseteq U_2 \times U_1$ such that

$$\alpha^- = \{(x, y) \mid (y, x) \in \alpha\} .$$

The composition of two binary relations $\alpha \subseteq U_1 \times U_2$ and $\beta \subseteq U_2 \times U_3$ is $\alpha\beta \subseteq U_1 \times U_3$ such that

$$\alpha\beta = \{(x, y) \mid \exists z \in U, (x, z) \in \alpha \wedge (z, y) \in \beta\} .$$

A binary relation $\rho \subseteq U^2$ is said to be reflexive if $(x, x) \in \rho$ for all $x \in U$; ρ is symmetric if for all $x, y \in U$, $(x, y) \in \rho$ implies $(y, x) \in \rho$; ρ is anti-symmetric if for all $x, y \in U$, $(x, y) \in \rho$ and $(y, x) \in \rho$ implies $x = y$; and ρ is transitive if for all $x, y, z \in U$, $(x, y) \in \rho$ and $(y, z) \in \rho$ implies $(x, z) \in \rho$. A binary relation that is reflexive, antisymmetric, and transitive is called a partial order. Let $\leq$ be a partial order on the universe U and $X \subseteq U$, then, $u \in U$ is called an upper bound (resp. lower bound) of X if for all $x \in X$, $x \leq u$ (resp. $u \leq x$). The least upper bound (resp. the greatest lower bound) of X is the upper bound (resp. lower bound) u of X such that for any upper bounds (resp. lower bounds) u' of X, $u \leq u'$ (resp. $u' \leq u$). The least upper bound (resp. the greatest lower bound) of X is called its supremum (resp. infimum), and is denoted by $\sup(X)$ (resp. $\inf(X)$). For any X (even though X is finite), $\sup(X)$ and $\inf(X)$ do not necessarily exist. If for all $x, y \in U$, $\sup(\{x, y\})$ and $\inf(\{x, y\})$ exist, then $\sup(\{x, y\})$ is called the join of x and y and denoted by $x \sqcup y$, while $\inf(\{x, y\})$ is called the meet of x and y and denoted by $x \sqcap y$. The structure $(U, \sqcap, \sqcup)$ is called a lattice. A subset $X \subseteq U$ is a sublattice of U if for any $x, y \in X$, $x \sqcap y$ and $x \sqcup y \in X$.

A binary relation that is reflexive, symmetric, and transitive is called an equivalence relation, which yields a partition of the universe. A partition of U is a class of subsets of U, $\{X_i \mid i \in I\}$ for some index set I, where $\bigcup_{i \in I} X_i = U$ and $X_i \cap X_j = \emptyset$ for any $i \neq j$. Let ρ be an equivalence relation on U, and let $x \in U$; then, the equivalence class containing x is defined as

$$[x]_\rho = \{y \in U \mid (x, y) \in \rho\} .$$

Obviously, $\{[x]_\rho \mid x \in U\}$ forms a partition of the universe. For any $X \subseteq U$, we denote $[X]_\rho$ by the set $\{[x]_\rho \mid x \in X\}$ and $[\![X]\!]_\rho$ by the multiset $([U]_\rho, m)$ such that $m([x]_\rho) = |[x]_\rho \cap X|$ for all $x \in U$.

Equivalence relations on a fixed domain are partially ordered by set-inclusion. Let ρ_1 and ρ_2 be two equivalence relations and define $\rho_1 \leq \rho_2$ iff $\rho_1 \subseteq \rho_2$; then, $\leq$ is a partial order on the set of all equivalence relations on a fixed domain. We say that ρ_1 is finer than ρ_2 or ρ_2 is coarser than ρ_1 if $\rho_1 \leq \rho_2$. Given a binary relation α, the composition of α with itself k times is denoted by α^k and the transitive closure of α is defined as $\alpha^\infty = \bigcup_{k \geq 1} \alpha^k$. Let ρ_1 and ρ_2 be two equivalence relations; then it can be shown that $\rho_1 \cap \rho_2$ and $(\rho_1 \cup \rho_2)^\infty$ are, respectively, the meet and the join of ρ_1 and ρ_2.

Rough Set Theory – Functional Granulation

The basic construct of rough set theory is the approximation space, which is a pair (U, ρ), where U is a finite set of objects (the universe) and ρ is an equivalence relation on U. From the GrC perspective, the equivalence classes of ρ are information granules of the approximation space.

In rough set theory, a concept is represented as a subset of the universe. For any concept $X \subseteq U$, we can associate the following two subsets with X,

$$\underline{\rho}X = \{x \in U \mid [x]_\rho \subseteq X\}$$
$$\overline{\rho}X = \{x \in U \mid [x]_\rho \cap X \neq \emptyset\} ,$$

where $\underline{\rho}X$ and $\overline{\rho}X$ are called the ρ-lower and ρ-upper approximation of X, respectively. From a practical viewpoint, ρ can be considered as an indiscernibility relation; thus, for a given concept X, we can only know that X contains all the elements in $\underline{\rho}X$ and does not contain any element outside $\overline{\rho}X$. In other words, the concept X cannot be defined exactly in the approximation space. The pair $(\underline{\rho}X, \overline{\rho}X)$ is considered a rough approximation of X, and any such pair is called a rough set (see Fig. 1). A concept X is called an exact concept in the approximation space if $\underline{\rho}X = X = \overline{\rho}X$; otherwise, it is called a rough concept.

Rough set theory is very useful in the analysis of data tables. A data table is a pair $S = (U, F)$, where U is a nonempty, finite set (the universe) and F is a nonempty, finite set of primitive attributes. Every $f \in F$ is a total function $f \colon U \to V_f$, where V_f denotes the possible values of f. If $E = \{f_1, \dots, f_n\} \subseteq F$, then $V_E = V_{f_1} \times \cdots \times V_{f_n}$. Thus, E is also considered a function from U to V_E. An equivalence relation $\mathrm{IND}(E)$ is associated with every subset of attributes $E \subseteq F$, and defined by

$$(x, y) \in \mathrm{IND}(E) \Leftrightarrow f(x) = f(y) \quad \forall f \in E .$$

$\mathrm{IND}(E)$ is called an indiscernibility relation. We write $\mathrm{IND}(f)$ instead of $\mathrm{IND}(\{f\})$ for all $f \in F$. It is easy to show that $\mathrm{IND}(E) = \bigcap_{f \in E} \mathrm{IND}(f)$. Since $\mathrm{IND}(E)$ is an equivalence relation, $(U, \mathrm{IND}(E))$ is an approximation space and we can define the $\mathrm{IND}(E)$-lower and $\mathrm{IND}(E)$-upper approximation of X for any $X \subseteq U$. We write $\underline{E}X$ and $\overline{E}X$ instead of $\underline{\mathrm{IND}(E)}X$ or $\overline{\mathrm{IND}(E)}X$. Obviously, exact concepts in $(U, \mathrm{IND}(E))$ are those definable using only attributes in E. In effect, the indiscernibility relation $\mathrm{IND}(E)$ granulates (or partitions) the universe according to the functions in E; thus, it results in a functional granulation of the universe.

The definitions are used in the analysis of dependency between attributes in a data table. Let us say that attribute E_2 depends on E_1, denoted by $E_1 \Rightarrow E_2$, iff $\mathrm{IND}(E_1) \subseteq \mathrm{IND}(E_2)$, i. e., any two objects in U with the same attribute values in E_1 will also have the same attribute values in E_2. It is easy to show that $E_1 \Rightarrow E_2$ iff $\underline{E_1}X = X$ for all X that are equivalence classes of $\mathrm{IND}(E_2)$. Given an attribute $f \in F$, if $F - \{f\} \Rightarrow \{f\}$, then f can be eliminated from F without influencing the definability of F. In other words, by using the set of attributes, f is redundant for classification purposes. By repeated elimination of redundant attributes, we can eventually obtain an irreducible set of attributes with the same classification capability as the original set of attributes. Such an irreducible set of attributes is called a reduct in rough set theory. Note that the definition of dependency is relative to a data table, so it does not necessarily mean that an intrinsic connection exists between the inter-dependent attributes.

Positional Analysis – Relational Granulation

Social networks are defined by actors and relations (or nodes and edges in terms of graph theory) [15]. A social network is generally defined as a relational structure $\mathfrak{N} = (A, (\alpha_i)_{i \in I})$, where A is the set of actors in the network, I is an index set, and for each $i \in I$, $\alpha_i \subseteq A^{k_i}$ is a k_i-ary relation on the domain A. If $k_i = 1$, then α_i is also called an attribute. In practice, most SNA literature considers a simplified version of social networks with only binary relations. For ease of presentation, we focus on a social network with only unary and/or binary relations. Thus, the social network considered in this article is a structure $\mathfrak{N} = (A, (P_i)_{i \in I}, (\alpha_j)_{j \in J})$, where A is a *finite set* of actors, $P_i \subseteq A$ for all $i \in I$, and $\alpha_j \subseteq A \times A$ for all $j \in J$. In terms of graph theory, $\mathfrak{N}$ is a labeled graph, where A is a set of nodes labeled with subsets of I, and each α_j denotes a set of (labeled) edges. For each $a \in A$, the out-neighborhood and in-neighborhood of a with respect to a binary relation α, denoted respectively by $N^+_\alpha(a)$ and $N^-_\alpha(a)$, are defined as follows:

$$N^+_\alpha(a) = \{b \in A \mid (a, b) \in \alpha\} ,$$
$$N^-_\alpha(a) = \{b \in A \mid (b, a) \in \alpha\} .$$

If ρ is an equivalence relation on A and a is an actor, the ρ-equivalence class of a is equal to its neighborhood, i. e., $[a]_\rho = N^+_\rho(a) = N^-_\rho(a)$. Note that the latter equality holds because of the symmetry of ρ.

Several equivalence relations have been proposed for exploring the similarity between actors' roles. The simplest definition of positional equivalence is the concept of structural equivalence proposed in [21], which states that two actors are positionally equivalent if they are related to the same individuals (see Fig. 2).

Definition 1 Let $\mathfrak{N} = (A, (P_i)_{i \in I}, (\alpha_j)_{j \in J})$ be a social network and ρ be an equivalence relation on A; then ρ is a (strong) structural equivalence with respect to $\mathfrak{N}$ if $(a, b) \in \rho$ implies

1. $a \in P_i$ iff $b \in P_i$ for all $i \in I$, and
2. $N^+_{\alpha_j}(a) = N^+_{\alpha_j}(b)$ and $N^-_{\alpha_j}(a) = N^-_{\alpha_j}(b)$ for all $j \in J$.

By the definition, there may exist more than one structural equivalence for a given network. However, it has been shown that there always exists a maximum (i. e., coarsest) structural equivalence for a network [19]. In fact, the set of all structural equivalences form a sublattice of all equivalence relations on A. Indeed, if ρ_1 and ρ_2 are structural equivalences with respect to $\mathfrak{N}$, so too are $\rho_1 \sqcap \rho_2$ and $\rho_1 \sqcup \rho_2$. Since the set of all equivalence relations on a finite domain is finite, the join of all structural equivalences is the coarsest structural equivalence with respect to a network. Let $\mathfrak{N} = (A, (P_i)_{i \in I}, (\alpha_j)_{j \in J})$ be a social network and ρ be the coarsest structural equivalence with respect to $\mathfrak{N}$; then, two actors $x, y \in A$ are said to be structurally equivalent, denoted by $x \cong_s y$, if $(x, y) \in \rho$.

Although structural equivalence is conceptually simple, it is sometimes restrictive. Regular equivalence relaxes the requirement that equivalent actors must be connected with identical actors, and suggests that actors occupy the same position if they are connected to positionally equivalent actors. Regular equivalence has been studied extensively [7,8,10,19,35], and there are several alternative definitions of the concept. We present two here. The first is based on the characterization given by Boyd and Everett [8], which states that an equivalence relation ρ is a *regular equivalence* with respect to a binary relation α if it commutes with α, i. e.

$$\alpha\rho = \rho\alpha .$$

By this definition, if ρ is a regular equivalence with respect to α and $(a, b) \in \rho$, then for each $c \in N^+_\alpha(a)(\text{resp.} N^-_\alpha(a))$, there exists $c' \in N^+_\alpha(b)(\text{resp.} N^-_\alpha(b))$ such that $(c, c') \in \rho$. The property naturally leads to an alternative definition of regular equivalence [19], which states that an equivalence relation ρ is a *regular equivalence* with respect to a binary relation α if for $a, b \in A$,

$$(a, b) \in \rho \Rightarrow [N^+_\alpha(a)]_\rho = [N^+_\alpha(b)]_\rho \quad \text{and} \quad [N^-_\alpha(a)]_\rho = [N^-_\alpha(b)]_\rho .$$

According to this definition, if a and b are regularly equivalent, then they are connected to equivalent neighborhoods (see Fig. 3). Obviously, the above definitions are equivalent. Thus, we have the following definition.

Definition 2 Let $\mathfrak{N} = (A, (P_i)_{i \in I}, (\alpha_j)_{j \in J})$ be a social network and ρ be an equivalence relation on A; then ρ is a regular equivalence with respect to $\mathfrak{N}$ if

1. $(a, b) \in \rho$ implies $a \in P_i$ iff $b \in P_i$ for all $i \in I$; and
2. ρ is a regular equivalence with respect to α_j for all $j \in J$.

Analogous to the case of structural equivalences, the join of two regular equivalences is still a regular equivalence, even though their meet is not necessarily a regular equivalence. Consequently, we can find the coarsest regular equivalence of a network. Then, two actors, x and y, are regularly equivalent, denoted by $x \cong_r y$, if (x, y) is in the coarsest regular equivalence of the network.

For regular equivalence, only the occurrence or non-occurrence of a position in the neighborhood of an actor matters. However, the number of occurrences is sometimes an important factor in positional analysis. In such cases, a number restriction can be added to the definition of regular equivalences. An equivalence relation ρ is an *exact equivalence* with respect to a binary relation α if for $a, b \in A$,

$$(a, b) \in \rho \Rightarrow [\![N_\alpha^+(a)]\!]_\rho = [\![N_\alpha^+(b)]\!]_\rho \quad \text{and} \quad [\![N_\alpha^-(a)]\!]_\rho = [\![N_\alpha^-(b)]\!]_\rho \,.$$

By replacing the set equality in the definition with the multiset equality, the number of equivalent neighbors must be the same for two actors to be considered position-equivalent (see Fig. 4).

Definition 3 Let $\mathfrak{N} = (A, (P_i)_{i \in I}, (\alpha_j)_{j \in J})$ be a social network and ρ be an equivalence relation on A; then, ρ is an exact equivalence with respect to $\mathfrak{N}$ if

1. $(a, b) \in \rho$ implies $a \in P_i$ iff $b \in P_i$ for all $i \in I$; and
2. ρ is an exact equivalence with respect to α_j for all $j \in J$.

The set of all exact equivalences also forms a lattice, but it is not a sublattice of the set of all equivalence relations [10]. Consequently, the coarsest exact equivalence for a network exists and we can define two actors x and y as exactly equivalent, denoted by $x \cong_e y$, if they belong to the coarsest exact equivalence. The partition produced by an exact equivalence is called an equitable partition or a divisor of a graph [19].

From the above definition, it is clear that all the attributes in a social network are binary. In other words, for each attribute P_i, an actor either satisfies P_i (has the value 1) or falsifies P_i (has the value 0). When a social network $\mathfrak{N} = (A, (P_i)_{i \in I}, (\alpha_j)_{j \in J})$ has the property $J = \emptyset$, it is in fact a kind of data table. In this case, all three kinds of positional equivalence are reduced to the indiscernibility relation. This means that, if information about the actors' relationship is not available, social positions are fully determined by the attributes of the actors. Thus, without relational information, functional granulation is sufficient for positional analysis. However, if relational information is available, two actors can be further differentiated by their relationship with other actors, even though all their attributes have the same values. In this sense, the definition of positional equivalence is based on the process of relational granulation.

Modal Logic – The Bridge

Modal logics were originally developed as formalizations for reasoning about modalities. The formal study started with alethic modal logics (the logics of necessity and possibility). The modalities □ (for necessity) and ◇ (for possibility) have now become standard notations in modal logic literature, and many variants of modal logic have been proposed to deal with different classes of modalities; for example, temporal logic for tense operators, deontic logic for obligation and permission, dynamic logic for actions, and epistemic logic for beliefs and knowledge. The development of these logics was motivated by philosophical enquiry as well as by technical applications in computer science, artificial intelligence, and economic game theory.

While modal logics were initially presented in the form of reasoning systems, the invention of relational semantics has been influential in the continuing development of the field [17,18]. The semantics, proposed independently by J. Hintikka, S. Kanger, and S. Kripke, and now known as Kripke semantics, show that modal logics are in fact logics for reasoning about relational structures. From this semantic perspective, standard modal logics can be regarded as fragments of first-or second-order predicate logics, whereby the necessity and possibility modalities correspond to universal and existential quantifiers, respectively. In spite of this correspondence, quantification in modal logic tends to be bounded in some way to worlds that are "relevant to" or "accessible from" the current one. Consequently, although a number of properties of modal logics follow immediately from those of their classical quantificational counterparts, the modal operators typically have less expressive power than full quantification. This results in many interesting properties not available in classical predicate logic. One of the most striking results is that semantic invariances between models are actually various forms of *bisimulation*, which preserve the local properties of worlds and their transition patterns [5]. Interestingly, it has been shown that bisimulation in Kripke models corresponds exactly to regular equivalence in social networks [22]. The implication of the results is that position-equivalent actors can be characterized by an appropriate set of modal formulas. As each modal formula can be regarded as a binary attribute, from the GrC perspective, such characterization transforms relational granulation into functional granulation.

In this section, we present three modal logics – a multimodal logic, a graded modal logic, and a hybrid logic. The presentation of a modal logic, as with any other formal logic, requires the specification of its syntax and semantics. The syntactic aspect includes the language of the logic – its alphabet and formation rules for wffs, as well as a deductive system for logical reasoning. For the purpose of this article, we need only present the language part. For the semantic aspect, we have to define the models within which the wffs can be interpreted, as well as the satisfaction of a wff in a model.

Propositional Multi-Modal Logic

We start with propositional modal logic (PML) [9]. The alphabet of PML consists of a set of propositional symbols, PV, and the logical symbols $\neg$(negation), $\wedge$(and), $\vee$(or), $\supset$(material implication), and $\Diamond$(possibility); $\neg$, $\wedge$, $\vee$, and $\supset$ are called Boolean connectives, whereas $\Diamond$ is the only primitive modality of PML. The set of wffs of PML is the smallest set containing PV that satisfies the following conditions:

- if φ is a wff, then $\neg\varphi$ and $\Diamond\varphi$ are wffs,
- if φ and ψ are wffs, then $\varphi \wedge \psi$, $\varphi \vee \psi$, and $\varphi \supset \psi$ are wffs.

As usual, we abbreviate $(\varphi \supset \psi) \wedge (\psi \supset \varphi)$ as $\varphi \equiv \psi$; $\neg \Diamond \neg\varphi$ as $\Box\varphi$; any tautology $p \vee \neg p$ as $\top$; and any contradiction $p \wedge \neg p$ as $\bot$. A Kripke model for PML is a triple $\mathfrak{M} = (W, \alpha, V)$, where W is a set of possible worlds, α is a binary relation on W, called an accessibility relation, and $V\colon W \times PV \to \{0, 1\}$ is a truth assignment for evaluating the truth value of each propositional symbol in each world. The satisfaction of a wff φ in a world w of the model $\mathfrak{M}$, denoted by $\mathfrak{M}, w \models \varphi$, is defined by the following clauses:

1. $\mathfrak{M}, w \models p$ if $V(w, p) = 1$ for each $p \in PV$;
2. $\mathfrak{M}, w \models \neg\varphi$ iff $\mathfrak{M}, w \not\models \varphi$;
3. $\mathfrak{M}, w \models \varphi \wedge \psi$ iff $\mathfrak{M}, w \models \varphi$ and $\mathfrak{M}, w \models \psi$;
4. $\mathfrak{M}, w \models \varphi \vee \psi$ iff $\mathfrak{M}, w \models \varphi$ or $\mathfrak{M}, w \models \psi$;
5. $\mathfrak{M}, w \models \varphi \supset \psi$ iff $\mathfrak{M}, w \not\models \varphi$ or $\mathfrak{M}, w \models \psi$;
6. $\mathfrak{M}, w \models \Diamond\varphi$ iff there exists $(w, u) \in \alpha$ such that $\mathfrak{M}, u \models \varphi$.

Propositional multi-modal logic (PMML) is an extension of PML that allows more than one modality [16]. PMML is particularly suitable for reasoning about relational structures that contain a number of binary relations, e. g., social networks. The alphabet of PMML consists of a set of propositional symbols PV, a set of relational symbols REL, the Boolean connectives, the relational converse symbol $^-$, and the modality-forming symbol $\langle\rangle$. The set of wffs of PMML is the smallest set containing PV that satisfies the following conditions:

- if φ is a wff, then $\neg\varphi$ is a wff;
- if φ is a wff and r is a relational symbol, then $\langle r\rangle\varphi$ and $\langle r^-\rangle\varphi$ are wffs;
- if φ and ψ are wffs, then $\varphi \wedge \psi$, $\varphi \vee \psi$, and $\varphi \supset \psi$ are wffs.

We abbreviate $\neg\langle r\rangle\neg\varphi$ and $\neg\langle r^-\rangle\neg\varphi$ as $[r]\varphi$ and $[r^-]\varphi$, respectively. A Kripke model for PMML is $\mathfrak{M} = (W, (\alpha_r)_{r \in REL}, V)$, where W and V are the same as above, and for each $r \in REL$, α_r is a binary relation on W. The satisfaction of PMML wffs is defined in the same way as that of PML wffs, except that clause 6 is replaced by

6. $\mathfrak{M}, w \models \langle r\rangle\varphi$ iff there exists $(w, u) \in \alpha_r$ such that $\mathfrak{M}, u \models \varphi$;
7. $\mathfrak{M}, w \models \langle r^-\rangle\varphi$ iff there exists $(u, w) \in \alpha_r$ such that $\mathfrak{M}, u \models \varphi$.

Note that we need the converse modalities $\langle r^-\rangle$ because all positional equivalences are defined with respect to their in-neighborhoods and out-neighborhoods. The modalities $\langle r\rangle$ allow us to access the out-neighborhood of a world, whereas $\langle r^-\rangle$ is needed to access the in-neighborhood.

Graded Modal Logic

Graded modal logic (GML) is a generalization of PMML that allows us to consider the number of worlds accessible from a given world [33]. The alphabet of GML is the same as that of PMML; however, the second formation rule of wffs is replaced by the following rule:

- if φ is a wff and r is a relational symbol, then $\langle r\rangle_n\varphi$ and $\langle r^-\rangle_n\varphi$ are wffs for each natural number n.

We also write $[r]_n\varphi$ and $[r^-]_{\varphi}$ as the abbreviations of $\neg\langle r\rangle_n\neg\varphi$ and $\neg\langle r^-\rangle_n\neg\varphi$, respectively.

The Kripke models for GML are the same as those for PMML, but clauses 6 and 7 for the conditions of satisfaction of PMML wffs are modified as follows:

6. $\mathfrak{M}, w \models \langle r\rangle_n\varphi$ iff $|\{u \in W \mid (w, u) \in \alpha_r$ and $\mathfrak{M}, u \models \varphi\}| > n$;
7. $\mathfrak{M}, w \models \langle r^-\rangle_n\varphi$ iff $|\{u \in W \mid (u, w) \in \alpha_r$ and $\mathfrak{M}, u \models \varphi\}| > n$.

According to the semantics, the modalities $\langle r\rangle_0$ and $\langle r^-\rangle_0$ in GML are respectively equivalent to $\langle r\rangle$ and $\langle r^-\rangle$ in PMML. Intuitively, $\mathfrak{M}, w \models \langle r\rangle_n\varphi$ means that φ is true in more than n worlds that are r-accessible from w, whereas $\mathfrak{M}, w \models [r]_n\varphi$ means that φ is false in no more than n worlds that are r-accessible from w. Thus, we abbreviate $\langle r\rangle_{n-1}\varphi \wedge [r]_n\neg\varphi$ (resp. $\langle r^-\rangle_{n-1}\varphi \wedge [r^-]_n\neg\varphi$) as $(r)_n\varphi$ (resp. $(r^-)_n\varphi$) to denote that there are exactly n r-accessible (resp. r^--accessible) worlds that satisfy φ.

Hybrid Logic

Hybrid logics (HL) are extensions of modal logics that include symbols to name possible worlds in models. The development of HL dates back to A. Prior's 1951 work, which had a philosophical foundation [29,30] (see [1] for a brief overview). The main idea is to use a special kind of atomic formula, called a nominal, to refer to possible worlds in models. The idea was adopted by the Sofia school in the late 80s and early 90s [14,24,25]. Subsequently, Blackburn and Seligman, who have been influential in the recent development of HL, adopted it in the late 90s [4,6].

Here, we only need the simplest hybrid logic (SHL). The alphabet of SHL is the same as that of PMML plus a set of nominals NOM that is disjoint with the set PV. The set of wffs of SHL is the smallest set containing $PV \cup NOM$ that satisfies the formation rules of PMML. The key semantic idea of HL is that each nominal must be true in exactly one possible world in any model. In other words, a nominal names a world by being true in that world and nowhere else. The idea can be easily formalized by extending PMML models with a component that assigns a nominal to a possible world. A hybrid model is then $\mathfrak{M} = (W, (\alpha_r)_{r \in REL}, V, f)$, where $(W, (\alpha_r)_{r \in REL}, V)$ is a PMML model and $f\colon NOM \to W$ is the mapping that assigns a nominal to a possible world. The satisfaction of SHL wffs is defined by clauses 1–7 for PMML, with the addition of the following clause for nominals:

8. $\mathfrak{M}, w \models i$ if $f(i) = w$ for each $i \in NOM$.

From Relational Granulation to Functional Granulation

In this section, we explain how to transform positional equivalences from relational granulation to functional granulation. Given a social network $\mathfrak{N} = (A, (P_i)_{i \in I}, (\alpha_j)_{j \in J})$, the steps are as follows:

1. For each kind of equivalence, find a corresponding modal language based on $\mathfrak{N}$. The three kinds of positional equivalence discussed earlier correspond to the following logical languages:
   (a) Structural equivalence: SHL
   (b) Regular equivalence: PMML
   (c) Exact equivalence: GML.
2. Consider $\mathfrak{N}$ as a model in the corresponding logic by a simple transformation. The set of actors is the set of possible worlds in the resultant model.
3. Find a sublanguage $\mathcal{L}$ of the corresponding logic. Prove that for any two actors x and y, $x \cong y$ iff x and y satisfy the same set of wffs in $\mathcal{L}$, where $\cong$ is $\cong_s$, $\cong_r$, or $\cong_e$ (see Fig. 5).

Structural Equivalences and Hybrid Logics

We use SHL to characterize structural equivalences. Given a social network $\mathfrak{N} = (A, (P_i)_{i \in I}, (\alpha_j)_{j \in J})$, we define an SHL language with the following alphabet:

1. $PV = \{p_i \mid i \in I\}$;
2. $REL = J$;
3. $NOM = A$.

The social network $\mathfrak{N}$ is transformed into a hybrid model $\mathfrak{M}_{\mathfrak{N}} = (A, (\alpha_j)_{j \in J}, V, id)$, where V is defined by $V(x, p_i) = 1$ iff $x \in P_i$ for all $x \in A$ and $i \in I$, and id is the identity function on A. Let us now define a sublanguage $\mathcal{H}_{\mathfrak{N}}$ of the SHL as the set of wffs $PV \cup \{\langle j \rangle a, \langle j^- \rangle a \mid j \in REL, a \in NOM\}$. We say that two actors, x and y, are $\mathcal{H}_{\mathfrak{N}}$-equivalent with respect to $\mathfrak{N}$ if for all $\varphi \in \mathcal{H}_{\mathfrak{N}}$, ($\mathfrak{M}_{\mathfrak{N}}, x \models \varphi$ iff $\mathfrak{M}_{\mathfrak{N}}, y \models \varphi$). Then, we have the following characterization theorem.

Theorem 1 *Let $\mathfrak{N} = (A, (P_i)_{i \in I}, (\alpha_j)_{j \in J})$ be a social network; then, for all $x, y \in A$, $x \cong_s y$ in $\mathfrak{N}$ iff x and y are $\mathcal{H}_{\mathfrak{N}}$-equivalent with respect to $\mathfrak{N}$.*

Proof By the satisfaction condition, ($\mathfrak{M}_{\mathfrak{N}}, x \models \langle j \rangle a$ iff $(x, a) \in \alpha_j$. Thus, x and y are $\mathcal{H}_{\mathfrak{N}}$-equivalent iff the following two conditions are satisfied

1. $x \in P_i$ iff $y \in P_i$ for all $i \in I$ (as $PV \subseteq \mathcal{H}_{\mathfrak{N}}$),
2. for all $j \in J$ and $a \in A$, $(x, a) \in \alpha_j$ iff $(y, a) \in \alpha_j$ and $(a, x) \in \alpha_j$ iff $(a, y) \in \alpha_j$ (since both $\langle j \rangle a, \langle j^- \rangle a$ and $\langle j \rangle a, \langle j^- \rangle a$ are in $\mathcal{H}_{\mathfrak{N}}$).

These two conditions are exactly the same as those in Definition 1. Since $x \cong_s y$ iff (x, y) is in the coarsest structural equivalence, $x \cong_s y$ iff these two conditions are satisfied.□

Regular Equivalences and Multimodal Logics

The first logical characterization of positional equivalences is that of regular equivalences by dynamic logic – a particular type of PMML. This is shown in [22] by the connection between regular equivalence and the well-known notion of bisimulation in modal logics. We present the result here by following the general procedure of the transformation from relational granulation to functional granulation.

Given a social network $\mathfrak{N} = (A, (P_i)_{i \in I}, (\alpha_j)_{j \in J})$, we define a PMML language with the following alphabet:

1. $PV = \{p_i \mid i \in I\}$;
2. $REL = J$.

The social network $\mathfrak{N}$ is transformed into a Kripke model $\mathfrak{M}_{\mathfrak{N}} = (A, (\alpha_j)_{j\in J}, V)$, where V is defined by $V(x, p_i) = 1$ iff $x \in P_i$ for all $x \in A$ and $i \in I$. Let $\mathcal{L}_{\mathfrak{N}}$ be the set of wffs of the PMML and $\mathcal{L}_{\mathfrak{N}}$-equivalence be defined the same as $\mathcal{H}_{\mathfrak{N}}$-equivalence.

Theorem 2 ([22]) *Let $\mathfrak{N} = (A, (P_i)_{i\in I}, (\alpha_j)_{j\in J})$ be a social network; then, for all $x, y \in A$, $x \cong_r y$ in $\mathfrak{N}$ iff x and y are $\mathcal{L}_{\mathfrak{N}}$-equivalent with respect to $\mathfrak{N}$.*

Proof It is shown in [22] that regular equivalences are exactly bisimulations, i. e., $x \cong_r y$ iff x and y are bisimular. By Theorems 2.20 and 2.24 in [5], x and y are bisimular iff they are $\mathcal{L}_{\mathfrak{N}}$-equivalent with respect to $\mathfrak{N}$. □

Exact Equivalences and Graded Modal Logics

Following the procedure used in the previous subsection, we define $\mathcal{G}_{\mathfrak{N}}$ as the set of wffs of the GML based on the given network $\mathfrak{N}$. Then, we have the following theorem.

Theorem 3 *Let $\mathfrak{N} = (A, (P_i)_{i\in I}, (\alpha_j)_{j\in J})$ be a social network; then, for all $x, y \in A$, $x \cong_e y$ in $\mathfrak{N}$ iff x and y are $\mathcal{G}_{\mathfrak{N}}$-equivalent with respect to $\mathfrak{N}$.*

Proof

1. ($\Rightarrow$): Assume that $x \cong_e y$; then, there exists an exact equivalence ρ on $\mathfrak{N}$ such that $(x, y) \in \rho$. We show that $\mathfrak{M}_{\mathfrak{N}}, x \models \varphi$ implies $\mathfrak{M}_{\mathfrak{N}}, y \models \varphi$ by induction on the complexity of φ (the proof of the converse direction is exactly the same). The case where $\varphi \in PV$ follows from condition 1 of Definition 3. The cases for Boolean connectives are straightforward by the induction hypothesis. For formulas of the form $\langle j\rangle_n\psi$ or $\langle j^-\rangle_n\psi$, we prove the case for $\langle j\rangle_n\psi$ by using the condition $[\![N^+_{\alpha_j}(x)]\!]_\rho = [\![N^+_{\alpha_j}(y)]\!]_\rho$. The case for $\langle j^-\rangle_n\psi$ is proved similarly by applying $[\![N^-_{\alpha_j}(x)]\!]_\rho = [\![N^-_{\alpha_j}(y)]\!]_\rho$. Now, if $\mathfrak{M}_{\mathfrak{N}}, x \models \langle j\rangle_n\psi$, then there exist more than n worlds in $N^+_{\alpha_j}(x)$ that satisfy ψ. Assume $u_0, u_1, \ldots, u_n$ are among these worlds. Since $[\![N^+_{\alpha_j}(x)]\!]_\rho = [\![N^+_{\alpha_j}(y)]\!]_\rho$, there exist $u'_0, u'_1, \ldots, u'_n \in N^+_{\alpha_j}(y)$ such that $(u_i, u'_i) \in \rho$ for $0 \le i \le n$. By the induction hypothesis, $\mathfrak{M}_{\mathfrak{N}}, u'_i \models \psi$ for $0 \le i \le n$; thus, $\mathfrak{M}_{\mathfrak{N}}, y \models \langle j\rangle_n\psi$.
2. ($\Leftarrow$): Let us define an equivalence relation ρ on A by

$$(x, y) \in \rho$$
$$\text{iff} \quad x \text{ and } y \text{ are } \mathcal{G}_{\mathfrak{N}}\text{-equivalent with respect to } \mathfrak{N}.$$

We prove that ρ is an exact equivalence. The first condition of Definition 3 is straightforward. For the second condition, let us assume that $(x, y) \in \rho$, $[\![N^+_{\alpha_j}(x)]\!]_\rho = ([A]_\rho, m_1)$, and $[\![N^+_{\alpha_j}(y)]\!]_\rho = ([A]_\rho, m_2)$ for some $j \in J$. Assume also that $[A]_\rho = \{[z_i]_\rho \mid 1 \le i \le k\}$. First, we consider z_1 as an example. For each $2 \le i \le k$, since $[z_1]_\rho$ is an equivalence class distinct from $[z_i]_\rho$, there exists a $\mathcal{G}_{\mathfrak{N}}$-wff ψ_i such that $\mathfrak{M}_{\mathfrak{N}}, z_i \models \psi_i$, but $\mathfrak{M}_{\mathfrak{N}}, z_1 \models \neg\psi_i$. If $m_1([z_1]_\rho) = n_1 > 0$, then there exist exactly n_1 α_j-successors of x that are $\mathcal{G}_{\mathfrak{N}}$-equivalent to z_1. Thus, $\mathfrak{M}_{\mathfrak{N}}, x \models (j)_{n_1}(\psi \wedge \bigwedge_{i=2}^k \neg\psi_i)$ for all ψ satisfied in z_1. Since $(x, y) \in \rho$, it is that $\mathfrak{M}_{\mathfrak{N}}, y \models (j)_{n_1}(\psi \wedge \bigwedge_{i=2}^k \neg\psi_i)$ for all ψ satisfied in z_1. This means there are exactly $n_1\alpha_j$-successors of y that satisfy $\bigwedge_{i=2}^k \neg\psi_i$ (by letting $\psi = \top$). Thus, these n_1 α_j-successors of y must satisfy all ψ satisfied in z_1 and be $\mathcal{G}_{\mathfrak{N}}$-equivalent to z_1. Since no other α_j-successors of y can be $\mathcal{G}_{\mathfrak{N}}$-equivalent to z_1 (otherwise there would be more than $n_1\alpha_j$-successors of y satisfying $\bigwedge_{i=2}^k \neg\psi_i$), $m_2([z_1]_\rho) = n_1$. In the same way, we can prove that if $m_2([z_1]_\rho) > 0$, then $m_1([z_1]_\rho) > 0$. Thus, $m_1([z_1]_\rho) = m_2([z_1]_\rho)$. Similarly, we can prove $m_1([z_i]_\rho) = m_2([z_i]_\rho)$ for $2 \le i \le k$. Consequently, we have $m_1 = m_2$ and $[\![N^+_{\alpha_j}(x)]\!]_\rho = [\![N^+_{\alpha_j}(y)]\!]_\rho$. The proof of $[\![N^-_{\alpha_j}(x)]\!]_\rho = [|N^-_{\alpha_j}(y)|]_\rho$ is analogous, except that the modality $(j)_{n_1}$ is replaced by $(j^-)_{n_1}$. □

Observational Equivalences

We have presented the logical characterizations of three kinds of positional equivalence. The theoretical implication of these characterizations is that positional equivalences based on relational granulation can be transformed into indiscernibility relations based on a set of binary attributes. Let $\mathfrak{N} = (A, (P_i)_{i\in I}, (\alpha_j)_{j\in J})$ be a social network and let F denote $\mathcal{H}_{\mathfrak{N}}$, $\mathcal{L}_{\mathfrak{N}}$, or $\mathcal{G}_{\mathfrak{N}}$. Then, (A, F) is a (generalized) data table such that IND(F) is the corresponding positional equivalence. However, from a practical viewpoint, since both $\mathcal{L}_{\mathfrak{N}}$ and $\mathcal{G}_{\mathfrak{N}}$ are infinite sets, it is generally difficult (if not impossible) to decide IND(F) based on such a data table representation. This motivates us to define a new kind of positional equivalence based on observations.

Let $\mathfrak{N}$ be a social network and F be a *finite* set of wffs in an appropriate logic language. Then, two actors, x and y, are *F-observationally equivalent*, denoted by $x \cong_F y$, if for any wff $\varphi \in F$, x satisfies φ iff y satisfies φ. The wffs in F denote the observable properties of the actors in the network. Due to the limited capability of the observer, the set of observable properties is usually finite. Depending on the observable properties chosen, we can focus on different parts of the social network. For example, positional analysis for a genealogical study and a political investigation may have to consider different relationships between actors. As shown by the above results, the choice of an appropriate logic language is also crucial, since it may result in different notions of positional equivalence.

A recent approach to structural equivalence that conforms with our definition of observational equivalence is reported in [28]. In that approach, a set of institutions E is given and each actor may belong to several institutions. Two actors are structurally equivalent if they belong to the same set of institutions. To avoid confusion with the structural equivalence defined in Sect. "Positional Analysis – Relational Granulation", we call the equivalence relation defined in [28] *institutional equivalence*. Note that institutional equivalence is in fact the same as structural equivalence defined in Sect. "Positional Analysis – Relational Granulation", if we consider the universe as the union of A and E and represent the network as a bipartite graph. A place (social position) is then defined as an equivalence class of actors (or equivalently, the set of institutions that those actors belong to). Here, our set of observation sentences corresponds to the set of institutions in [28]. While institutions are primitive entities, our observation sentences are formed from the social relations and attributes of actors. In fact, a wff in F can also be regarded as an intensional definition of an institution. In this sense, observational equivalence is a kind of intensionally institutional equivalence.

Conclusion and Future Directions

This article starts with an introduction to rough set theory – the basic theory of functional granulation. We then review several notions of positional equivalence in social network analysis and consider them as relational granulation from the GrC perspective. By using modal logics as a bridge, we transform the relational granulation-based positional equivalences into functional granulation. However, the transformation is mainly theoretically interesting, since the set of functional attributes used to granulate a social network may be infinite. This practical consideration motivates us to propose the notion of observational equivalence. It conforms with an alternative definition of structural equivalence, which we call institutional equivalence to avoid confusion.

More generally, both observational equivalence and institutional equivalence can be analyzed in the framework of formal concept analysis (FCA) [13]. FCA is a conceptual knowledge representation and data analysis method in which a *formal context* is defined as a triple (A, F, R), where A and F are sets of objects and attributes respectively; and $R \subseteq A \times F$ is a binary relation between A and F, called the incidence of the formal context. For $A' \subseteq A$ and $F' \subseteq F$, let us denote $R(A') = \{f \in F \mid \forall a \in A', (a, f) \in R\}$ and $R^{-}(F') = \{a \in A \mid \forall f \in F', (a, f) \in R\}$. Then, a *formal concept* is defined as a pair (A', F') such that $A' \subseteq A$, $F' \subseteq F$, $R(A') = F'$ and $R^{-}(F') = A'$. Here, we call A' the extent and F' the intent of the formal concept. The application of FCA to sociology has been proposed in [12]. In that application, the formal context (also called the Galois lattice) is used to model two-mode network data, where the set of actors is a mode of the data, the set of events is the other mode of data, and the relation between the two modes is the participation relationship between the actors and events. When we regard A as the set of actors, F as the set of observation sentences (resp. institution), and R as the satisfaction (resp. membership) relation, a formal context can be constructed out of a social network. However, a social position (or place) defined by observational or institutional equivalences may not be the extent of a formal concept. Thus, it is tempting to define a social position alternatively as a formal concept of such formal contexts. Unlike other positional analysis techniques that define a social position as an equivalence class of some positional equivalence, the extents of different formal concepts may overlap. This means that social positions may not be disjoint in such a definition. The theoretical and practical implications of such positional analysis requires further research.

Another future research direction concerns the practical computation of positional equivalences. As mentioned earlier, when a social network is transformed into a data table (A, F) for positional analysis and F is infinite, it is difficult to decide if two actors are $\mathrm{IND}(F)$-equivalent by exhaustively comparing the satisfaction of all wffs in x and y. While observational equivalence provides a practical approximation of the computation, we would like to know if precise computation is possible. To answer this question, the inference of the *most specific concept* (msc) in description logics [2] may be helpful. Description logics are a family of knowledge representation formalisms that have strong connections with modal logics [3,23]. Indeed, the description languages $\mathcal{ALC}$ and $\mathcal{ALCN}$ correspond to the sublanguages of PMML and GML respectively [3,23]. Given a network represented in a description language, the msc of an actor x, denoted by $msc(x)$, corresponds to a wff that satisfies x and implies any wffs that satisfy x. Thus, if $msc(x)$ and $msc(y)$ are logically equivalent, then x and y will satisfy the same set of wffs, i. e., $(x, y) \in \mathrm{IND}(F)$. The problem for researchers is to find logical languages that can characterize the aforementioned positional equivalences adequately and whose msc problems can be solved effectively.

In summary, we have proposed a logical approach to positional analysis in social networks from a GrC perspective. The approach facilitates a connection between more complicated relational granulation and simpler functional granulation. While there remain problems to be solved in the research programme, the approach seems promising for cross-fertilization between the fields of GrC and SNA.

Article Outline

Glossary

Adjacent A node is adjacent to another if there is an edge connecting them.

Arrow A line directed from one node to another.

Binary relation A two valued yes/no or on/off relation.

Bipartite graph A graph, $B = \langle N, E \rangle$ where N is a finite set of nodes and E is a collection of pairs of nodes in which N is partitioned into two disjoint subsets, N_1 and N_2, and no edge in E has both end points in the same subset.

Blockmodeling A procedure for clustering actors such that the actors in each cluster share similar patterns of ties both within and between clusters.

Connected Any two nodes in a graph are said to be connected if there is a path from one to the other; a graph is connected if there is a path connecting every pair of nodes.

Cycle Any path that begins and ends at the same node.

Digraph A directed graph.

Directed graph A graph $D = \langle N, A \rangle$ where N is a finite collection of nodes and A is a set of pairs linked by directed lines or arrows.

Directed line A line going from a node to another representing a non-reciprocated link.

Edge A line connecting two nodes representing a reciprocated link.

Edge labeled graph A graph in which at least two kinds of connections between nodes are identified.

Formal concept analysis A method of data analysis based on Galois lattice structure.

Galois lattice A dual structure that displays the dependencies of both objects and their properties.

Geodesic The shortest path between two nodes.

Graph A graph $G = \langle N, E \rangle$ where N is a finite set of nodes and E is a collection of pairs of nodes represented as edges.

Hyperedge An edge in a hypergraph that can enclose more than two nodes.

Hypergraph A hypergraph, $F = \langle N, H \rangle$, consists of a set of nodes N and a collection of hyperedges, H.

Indegree The indegree of a node is the number of directed lines it receives.

Irreflexive A relation in which no edge connects any node with itself.

Multidimensional scaling A search procedure designed to represent an observed set of proximities or distances in a small number of dimensions.

Node A point in a graph.

One mode matrix A data matrix in which the rows and columns both represent the same objects.

Outdegree The outdegree of a node is the number of directed lines it sends out.

Path A path is a sequence of nodes and edges beginning with a node that has an edge connecting it to the next node in the sequence and so on.

Path length The length of a path connecting two nodes is the number of edges it contains.

Permutation A reordering of the rows, columns, or rows and columns of a matrix.

Principle diagonal The set of cells in a square matrix that runs from the upper left to the lower right.

Relation A collection of ordered or unordered pairs of nodes.

Singular value decomposition an algebraic procedure that decomposes a data matrix into its "basic structure".

Sociometry An early version of social network analysis introduced by Jacob Moreno and Helen Jennings.

Spring embedder A kind of multidimensional scaling based on a model in which it is assumed that nodes are connected by springs that pull and push on them.

Symmetric A relation in which if a node a is adjacent to another, b, then b is adjacent to a.

Tree A graph is a tree if it is connected and contains no cycles.

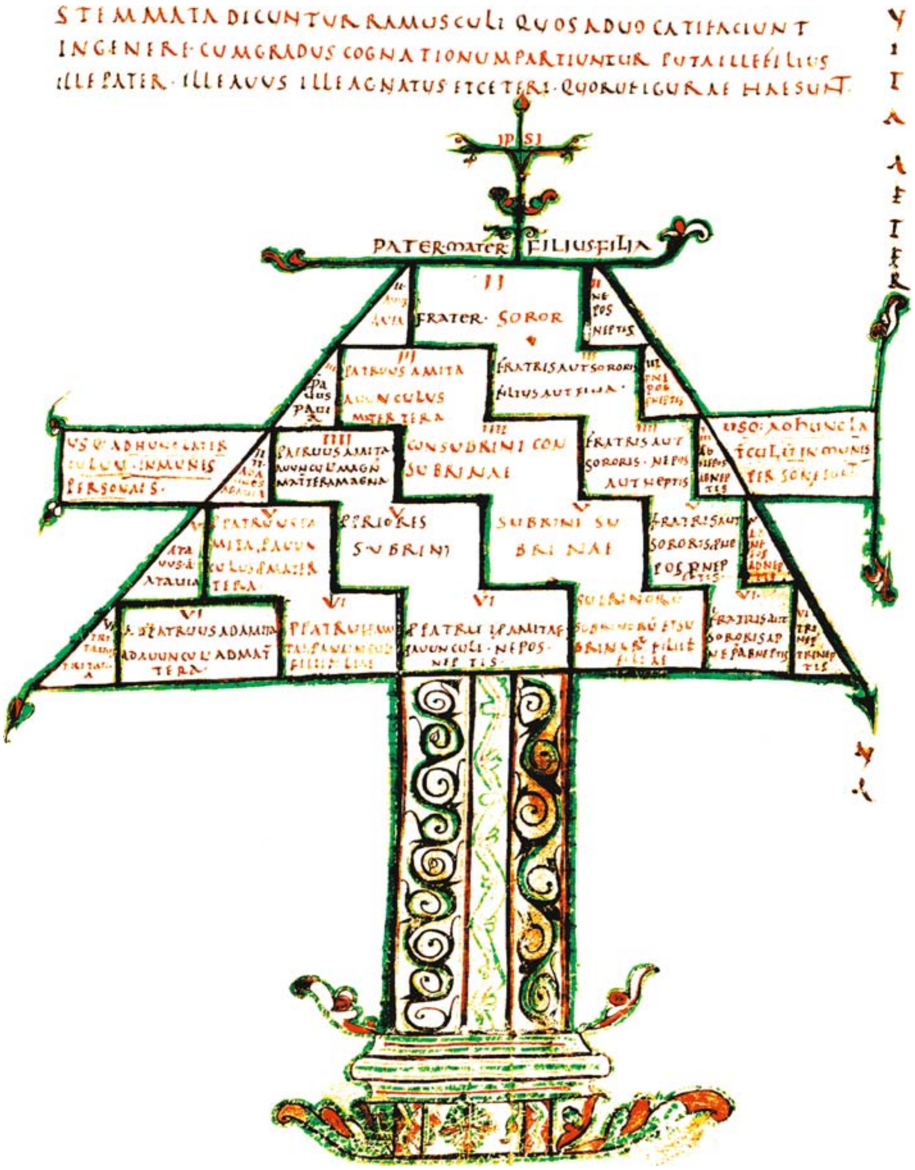
Two mode matrix A data matrix in which the rows and columns represent different objects.

Definition of the Subject

Social network visualization refers to the practice of constructing pictorial images of the connections linking social actors. The use of such images provides two benefits. It allows investigators to gain new insights into the patterning of social connections, and it helps investigators to communicate their results to others.

Introduction

Social network analysis did not emerge as a systematic field of research until early in the twentieth century [1]. But visual images of social networks were produced more than a millennium earlier. The earliest of these images that I have uncovered was produced in Spain in the middle of



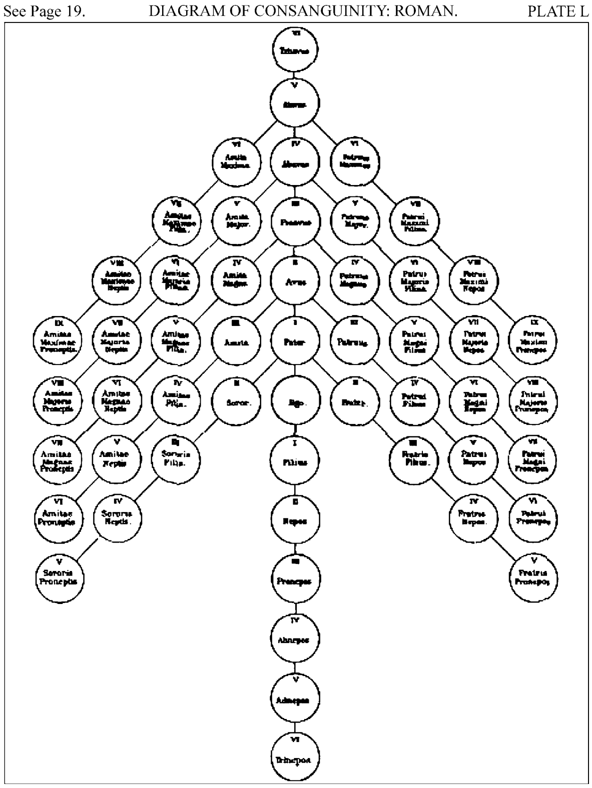
Social Network Visualization, Methods of, Figure 1
Tree of consanguinity with six degrees of relationship

the ninth century. That image is attributed to the prolific writer and Roman Catholic Saint, Isidore de Séville. It is reproduced here as Fig. 1.

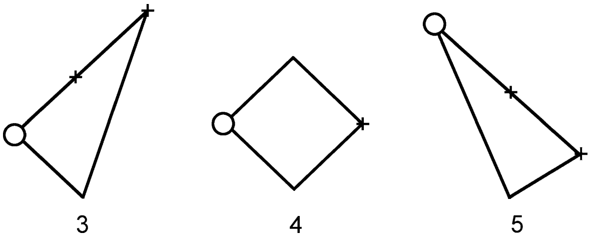
The image shown in Fig. 1 displays relationships based on genealogical descent. From the earliest times, people have been interested in kinship ties – in who is related to whom. This interest is evident in the descent lists found in the Christian bible and in the oral genealogies that were required to be memorized by Hawaiian nobles [2].

The fact that Fig. 1 takes the form of a tree shows that as early as the ninth century people saw the analogy between the branching structure of descent and that of trees. This notion was captured in a mathematical formalization in 1857 by Arthur Cayley [3]. Cayley defined a tree in mathematical graph theoretic terms. Biggs, Lloyd and Wilson (p. 38 in [4]) characterized Cayley's definition by saying that his "… use of the word 'tree' in this context is presumably derived from the diagrammatic form of these graphs, and is akin to the traditional use of the word in describing genealogical or 'family' trees."

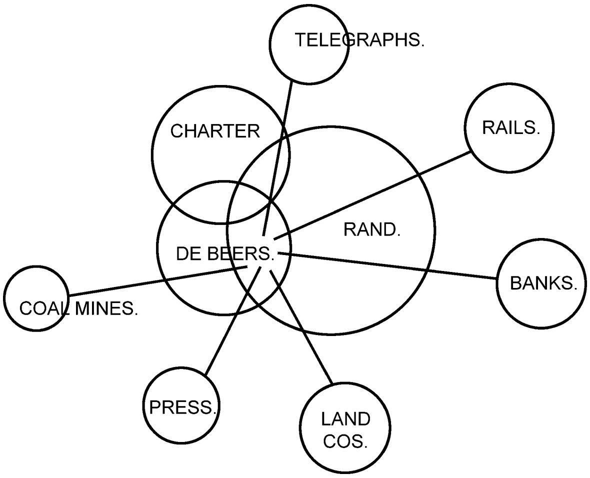
The use of trees to depict descent was, of course, continued. As time passed, however, their form became sim-



Social Network Visualization, Methods of, Figure 2
Descent in ancient Rome



Social Network Visualization, Methods of, Figure 3
Macfarlane's images of two-step marriage prohibitions



Social Network Visualization, Methods of, Figure 4
Hobson's image of corporate interlocks

plified. Lewis Henry Morgan [5] was an attorney and an anthropologist. He was interested in comparing how different peoples reckoned kinship and in 1871 he published a mammoth work containing a collection of kinship trees. Each tree depicted descent as conceived by a society somewhere in the world. Morgan's trees are quite simple. Figure 2 shows descent as it was reckoned in ancient Rome.

Twelve years later a mathematician-physicist, Alexander Macfarlane [6], produced a different kind of graphic image based still on kinship. Macfarlane set out to examine British marriage prohibitions and he represented them both algebraically and visually. His visual images depict males using plus signs (+) and females with circles (o). Earlier generations he placed higher on the page. Descent is shown by lines connecting points. A short line crossing a descent line indicates another person, of either sex, in an intermediate generation. And the lowest point is always the prohibited offspring.

The illustration shown in Fig. 3 displays all the two-step marriage relations that are prohibited by British law. The left image shows that a male may not marry his granddaughter. The middle image shows that he may not marry his sister. And the right image shows that he may not marry his grandmother. Or, put the other way, a woman may not marry her grandfather, her brother or her grandson.

Macfarlane's paper also included algebraic expressions that captured all of the same marriage prohibitions. But Sir Francis Galton [7], who attended Macfarlane's presentation, declared that his "diagrammatic form" seemed "the most distinctive and self-explanatory" of the two treatments.

Finally, in 1894, John Hobson [8] produced a visual image of a social network that was not based on kinship. He had collected two mode (corporation by director) data on interlocking corporate directorates. He reasoned that, to the degree that corporations shared directors, they could be expected to cooperate and work together.

Hobson's illustration was designed to show the interlock among, as he put it, "the small inner ring of South African finance." Corporations are depicted as circles, and interlock is shown by overlapping or by a line connecting two circles. Hobson's image is reproduced here as Fig. 4.

The important feature of this image is that it displays a connection linking more than two corporations. Hobson's data showed that three corporations, Charter, Rand and De Beers, all shared directors in common. And, at the same time, Rand and De Beers also both shared directors with coalmines, telegraphs, rails, and others. The overlaps in his image allowed him to display which companies shared with which others.

It is clear, then, that a concern with connections among social actors and the use of visual images have a long history of intimate association. It should come as no surprise therefore that images played an important part in the development of social network analysis when it did emerge as an organized field of research.

Visualization in Social Network Analysis

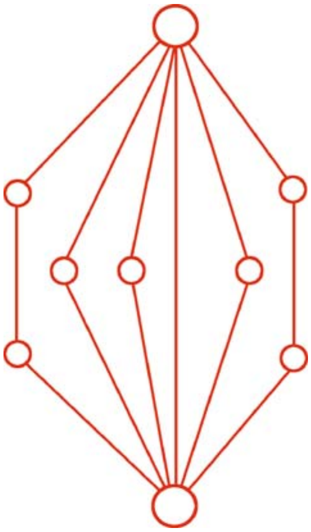
In the book cited above (p. 3 in [1]), I described the modern science of social network analysis as possessing four defining properties. They were:

1. It embodies ideas about the importance of social ties linking social actors.
2. It collects data reflecting those ties.
3. It involves the use of graphic imagery.
4. It employs mathematical and/or computational models.

Pre-network research often included one or two of those properties, but in the late 1920s each of two independent research teams came up with efforts that included all four.

One took place in the early 1930s. It involved a psychiatrist, Jacob L. Moreno, and a psychologist, Helen H. Jennings. Together, they developed an approach they called "sociometry." They reported two huge studies, both focused on examining the structure of social ties. One was conducted among prisoners at Sing Sing Prison in Ossining, New York [9] and the other among young delinquents at the New York State Training School for Girls in Hudson, New York [10].

Both Moreno–Jennings studies involved the extensive use of graphic images. The image shown in Fig. 5 was included in their report on the research at Sing Sing prison (Moreno, 1932). In that figure, individuals or other kinds of social actors are represented as points or *nodes* and links between pairs of social actors are lines or *edges* connecting pairs of nodes. In Fig. 5 Moreno was concerned with the positions of individuals and the patterning of their ties. As he put it, the individuals at the top and the bottom were "dominant" and the image showed that those dominant individuals were linked both "directly" and "indirectly".



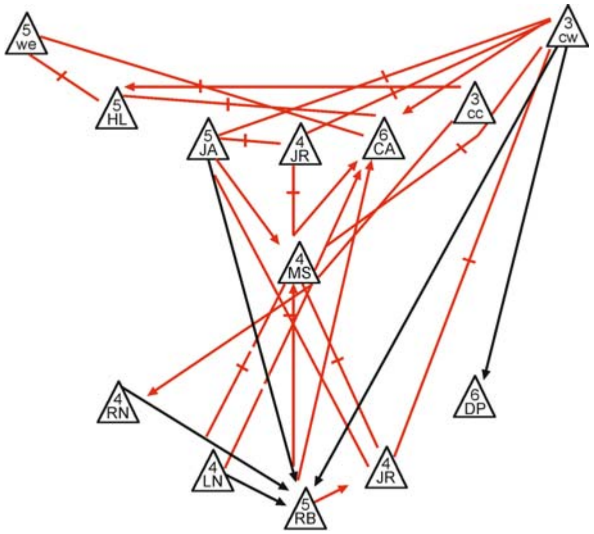
Social Network Visualization, Methods of, Figure 5
Image of a Pattern of Linkages

Most of the data collected by Moreno and Jennings involved asking individuals whom they liked or disliked. In data of that sort, choices are seldom reciprocated. So Moreno and Jennings drew lines with arrowheads to reveal who chose whom. Mutual choices were drawn without arrowheads and they also included a small line bisecting the main line connecting the two nodes.

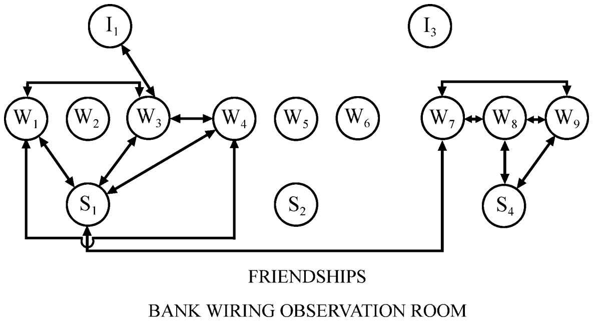
Moreno and Jennings often required subjects to report both their likes and their dislikes. By using different colors, red for likes and black for dislikes, a single image could display both. The image shown in Fig. 6 was published in the Moreno–Jennings report on the Hudson School (Moreno, 1934). It depicts positive and negative choices among 13 members of an American football team. Moreover, it contains another innovation. The various team members are placed in the drawing in approximately the same relative locations that they occupied on the football field. That arrangement shows the players' positions and permits the viewer to evaluate the impact of physical proximity on the patterning of social linkages.

Figures of the sort used by Moreno and Jennings had a major impact on the style of graphic imagery used subsequently in social network analysis. For the most part, social network analysts have represented social actors as nodes and links between actors as edges or as directed lines with arrowheads.

The second introduction of the social network approach also occurred in the early 1930s. An anthropologist, W. Lloyd Warner, and a collection of his colleagues and students at Harvard, conducted three elab-



Social Network Visualization, Methods of, Figure 6
Positive and Negative Choices in a Football Team

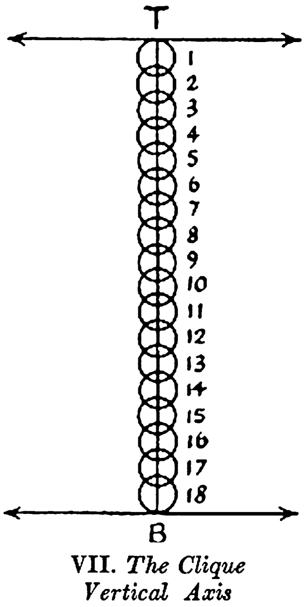


Social Network Visualization, Methods of, Figure 7
Friendships linking factory workers

orate network analytic projects. One was a study of an industrial factory, the Western Electric plant in Cicero, Illinois [11]. The other two were studies of communities: one focused on a New England town, Newburyport, Massachusetts [12], and the other on a southern town, Natchez, Mississippi [13].

The image shown in Fig. 7 was produced as part of the factory study. It displays observed friendship ties among pairs of individuals who worked together in the same workroom. It was drawn using nodes and two-headed lines instead of edges, but it is very similar to the images produced by Moreno and Jennings. In addition, as in Fig. 6 above, the impact of physical space was displayed; workers were placed in the drawing in positions that reflected the locations of their workstations.

In reporting their study of Newburyport, Warner and Lunt used the kind of drawing of overlapping circles that



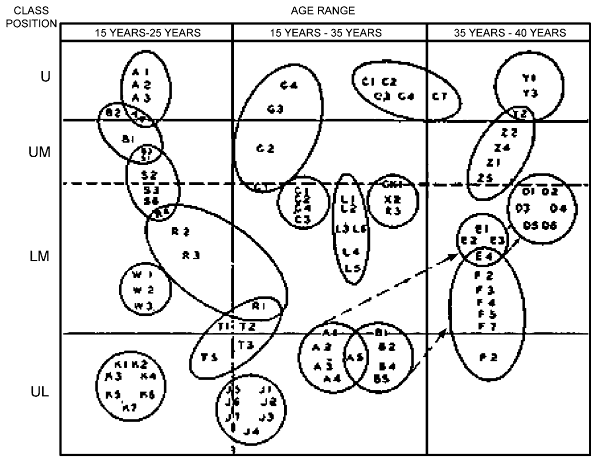
Social Network Visualization, Methods of, Figure 8
An idealized pattern of overlapping 'cliques'

Hobson had used to construct Fig. 4. But here that image was introduced, not to describe data, but to propose an idea they had about social structure. The diagram in Fig. 8 represents the investigators' idealized version of the expected structure of overlaps among subgroups in the presence of social class. The idea is that only subgroups that are close to one another in class ranking are likely to have overlapping memberships.

In their study of Natchez Davis, Gardner and Gardner [13] employed the same diagrammatic form to display two mode data reflecting on the earlier Newburyport hypothesis. Figure 9 shows subgroups of black males and their overlaps. In that image the men are arranged in terms of both social class and age. Both, it turned out, provided important bases for grouping.

Finally, in that same report, Davis, Gardner and Gardner also introduced an entirely different kind of social network image. Like Hobson, they had collected two mode data. Eighteen women were designated in the rows of their data matrix and fourteen social events were depicted in the columns. That matrix is reproduced here as Fig. 10.

The data shown in Fig. 10 were all collected during a single year. But, by examining the column headings, it is clear that Davis and his colleagues did not arrange the social events according to the dates upon which they took place. Instead, they listed both the events and the women who attended them in such a way that the arrangement itself suggests that these women were organized into two



Social stratification of a group of colored cliques: ages 15–60

Social Network Visualization, Methods of, Figure 9
Stratification, age and overlapping groups

groups. The two groups overlap, but for the most part they are distinct. Most of the women in the top half of the matrix attended the leftmost five events. And most of the women in the bottom half attended the rightmost five events. The middle four events apparently brought both groups of women together.

This arrangement of women and events was self-consciously produced by the authors. Davis, Gardner and Gardner were convinced that these women were organized into two groups and they presented their data matrix in a way that would illustrate that conclusion. The interesting thing is that these authors never commented explicitly about how they had rearranged the columns and rows in their matrix. They simply organized their display in a way that would make the point.

From the outset, then, four kinds of images have played important parts in the development of social network analysis. These first network graphics included drawings displaying (1) one mode undirected relations, (2) one mode directed relations, (3) two mode relations and (4) one or two mode data matrices. A few other kinds of network images have been used since then, but the four originals – particularly those based on one mode undirected and one mode directed relations – still dominate the field. In the next four sections we will examine the four original kinds of images and how their use has evolved in the social network context.

Images Based on One Mode Undirected Relations

Mathematically speaking, the node and edge images introduced by Moreno and Jennings in Fig. 5 are *graphs*. A graph $G = \langle N, E \rangle$ where N is a finite set of nodes and E is a collection of pairs of nodes. In graph visualizations, a pair of nodes in E is presented as a line connecting the two nodes in question. Two nodes are called *adjacent* if there is an edge directly connecting them to each other. A graph embodies a *binary* (yes/no or on/off) relation that is *irreflexive* (no node is adjacent to itself) and *symmetric* (if a node a is adjacent to another, b, then b is adjacent to a).

A *path* is a sequence of nodes and edges, beginning with a node that has an edge connecting it to the next node in the sequence. The *length* of a path between two nodes

Links in the network of a homeless woman I

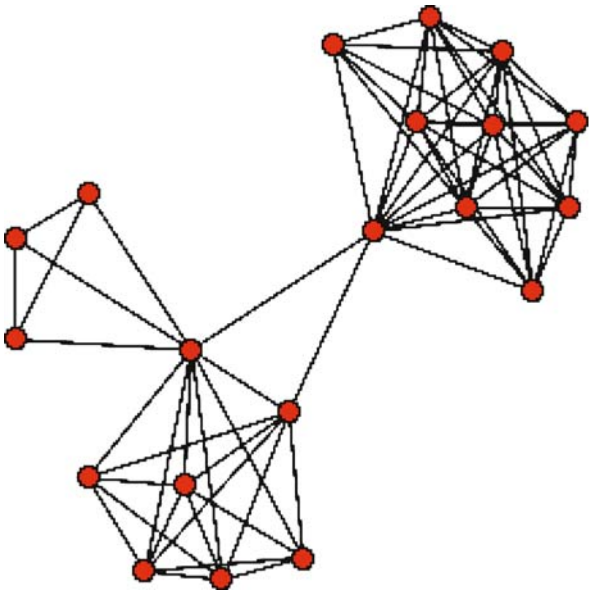
is the number of edges it contains. And the shortest path connecting two nodes is called the *geodesic*.

Any two nodes in *N* are *connected* if there is a path from one to the other. And a whole graph *G* is connected if every pair of nodes in *N* is connected. If a path begins and ends at the same node, that path is a *cycle*. Finally, a graph is a *tree* if it is both connected and it contains no cycles.

The image in Fig. 11 is a graph. It is based on data recorded by J. Clyde Mitchell [14] on the social ties among the 19 individuals involved in the personal network of a homeless woman in Britain. I used a program called NetDraw to place the nodes representing individuals in Fig. 11 in random positions. That calls attention to the importance of the locations of points in graphic displays. Given the locations of the points in Fig. 11 it is very difficult for the viewer to see anything interesting in the patterning of this woman's network.

Compare the image in Fig. 11 with that in Fig. 12. Figure 12 was also produced using NetDraw, but this time the points were placed using a *spring embedder* [16]. A spring embedder is a computer algorithm that, in effect, places a spring of unit length between every pair of adjacent nodes and a much longer spring between nodes that are not adjacent. It starts with a random placement of nodes, then the whole apparatus is set in motion and the various springs push and pull until they reach an equilibrium.

The advantage of using a spring embedder is that it does not require the investigator to make ad hoc judgments in locating nodes in a graph. It uses a standard computer algorithm to place the nodes automatically. Thus, every user will get the same result. There are several different spring embedding algorithms. And they are all examples of a more general class of computer algorithms that search for optimal locations for nodes in relatively few dimensions. This general class of search algorithms is called *multidimensional scaling* [17].



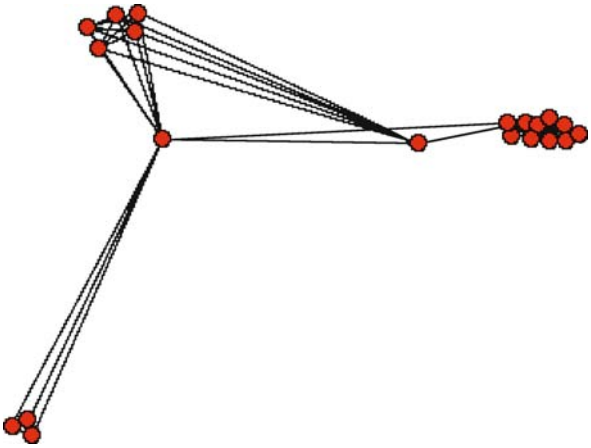
Social Network Visualization, Methods of, Figure 12
Links in the network of a homeless woman II

An alternative method for placing nodes automatically is grounded in algebra. It is called *singular value decomposition* [18]. Singular value decomposition is not search based. Instead, it uses matrix operations to produce a linear transformation of the data, and thus to position the nodes in one, two or three or more dimensions. There is no guarantee that it will always be effective, but often singular value decomposition provides very good placements of the nodes in few enough dimensions that visualization is possible [19]. A NetDraw image based on singular value decomposition of Mitchell's data is shown in Fig. 13.

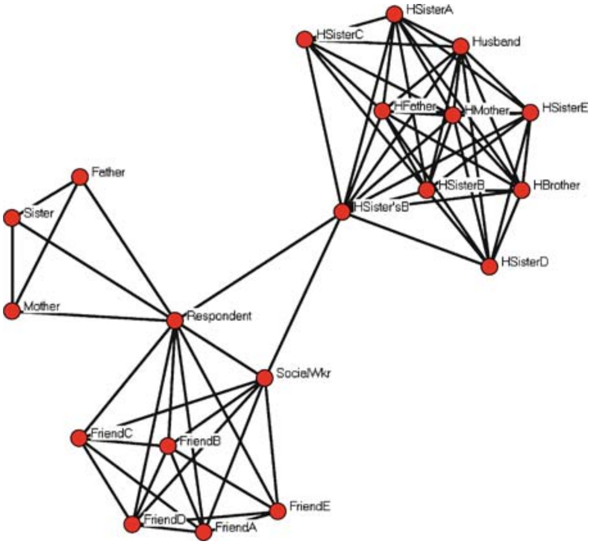
The images in Figs. 12 and 13 both show that the whole network is organized into three densely connected groups that are only loosely linked to one another. That is interesting, but it does not tell us anything about the bases for the groupings. By adding a little information, and continuing to use NetDraw, we can transform the graph of Fig. 12 into a *node labeled* graph, see Fig. 14.

Given the labels, we can identify the homeless woman, the "respondent." We can also see how her network is split up. One division includes her original family, another her friends along with her social worker, and the third contains her estranged husband and his family, her in-laws.

Mitchell's report, however, included even more details. It included estimates of the strength of the tie linking each



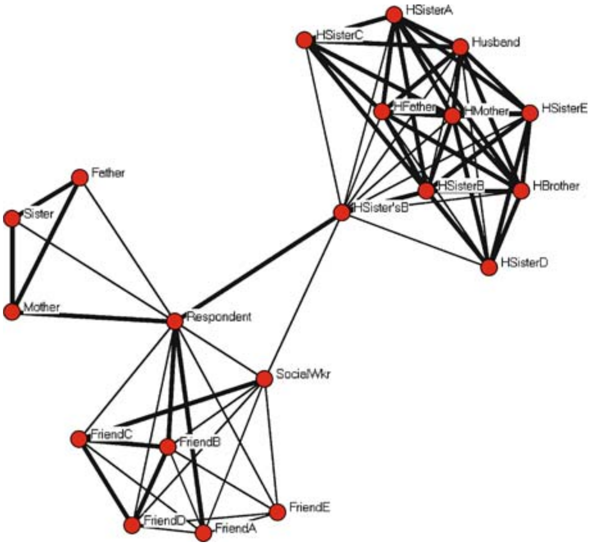
Social Network Visualization, Methods of, Figure 13
Links in the network of a homeless woman III



Social Network Visualization, Methods of, Figure 14
Links in the network of a homeless woman IV

of the pairs of individuals. He classified each tie as either strong or weak. We can embody this additional information in our NetDraw image by an adding another component to our graph. Figure 15, then, was produced using the spring embedder, it is node labeled, and, in addition, it is an *edge labeled* graph.

In Fig. 15 strong ties are indicated by wide edges. By examining their patterning, we learn that the individuals within each family are linked together mostly by strong ties, while the homeless woman's friends have fewer strong ties linking them together. This result is not surprising, but it does provide additional insight about the structural position of the woman in question. Clearly, it would be easier for either family to achieve consensus and provide support than it would be for the respondent's loosely connected collection of friends [20].



Social Network Visualization, Methods of, Figure 15
Links in the network of a homeless woman V

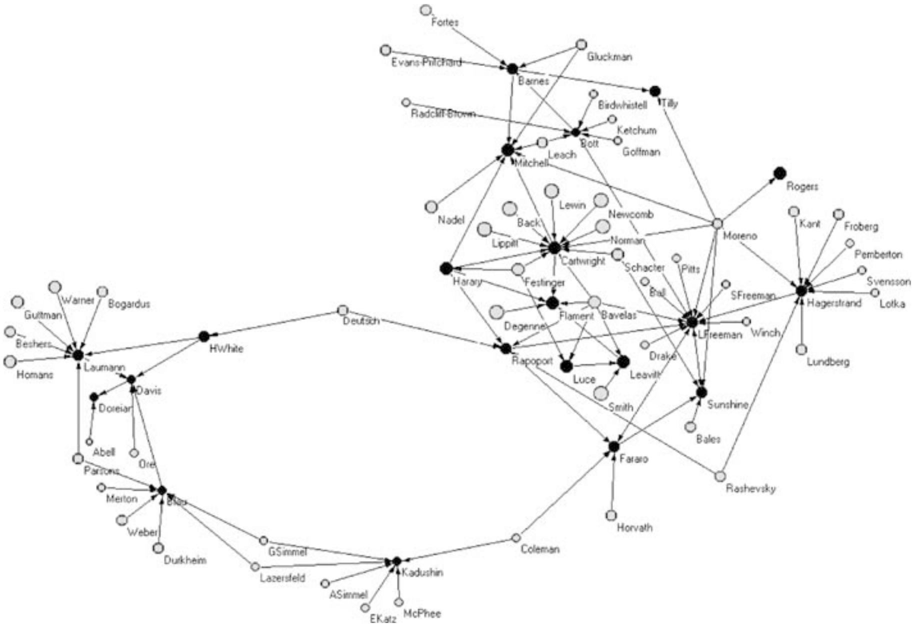
It should be clear, then, that the placement of nodes and the labeling of both nodes and edges are critical for the ability of a graph to communicate important information. Good images can provide investigators with new insights about the structural properties of the social networks they are studying. And they can, of course, help to communicate the results of social network research to outsiders.

Images Based on One Mode Directed Relations

It was obvious from the outset that these simple graphs would not permit many kinds of displays of interest to social network analysts. Even Moreno and Jennings saw the need to display the direction of choice in their sociograms. The direction of connections can be expressed using *directed graphs* or *digraphs*.

A digraph $D = \langle N, A \rangle$ where N is a finite collection of nodes and A is a set of pairs shown as *directed lines* or *arrows*. When an arrow is directed from node a to node b in a digraph, then a is the *tail* of the arrow and b is the *head*; a is the immediate *predecessor* of b and b is the immediate *successor* of a. The *outdegree* of a node is the number of arrows for which it is the tail and its *indegree* is its number for which it is the head.

In any study that involves social links that are not symmetric, digraphs provide a natural representation. Con-

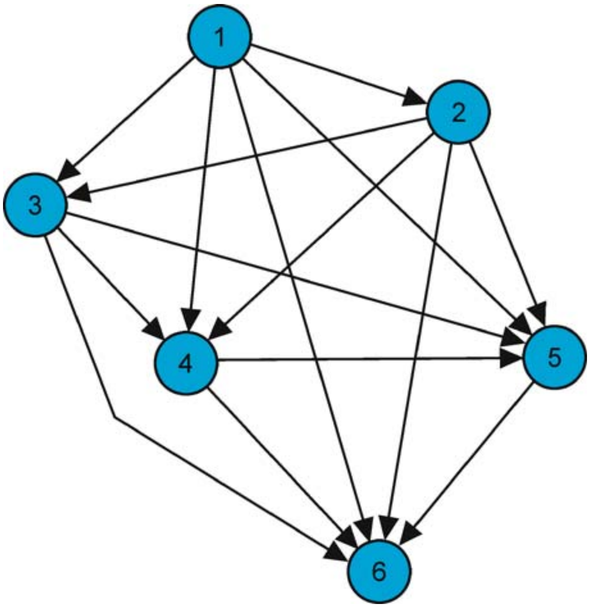


Social Network Visualization, Methods of, Figure 16
Influences on some founders of social network analysis

sider Fig. 16 that was produced by a program called Pajek [21]. In preparing a book on the development of social network analysis, I interviewed a number of the founders. Each was asked to name others who had influenced them to think in network terms. The result is a data set that obviously lacks symmetry.

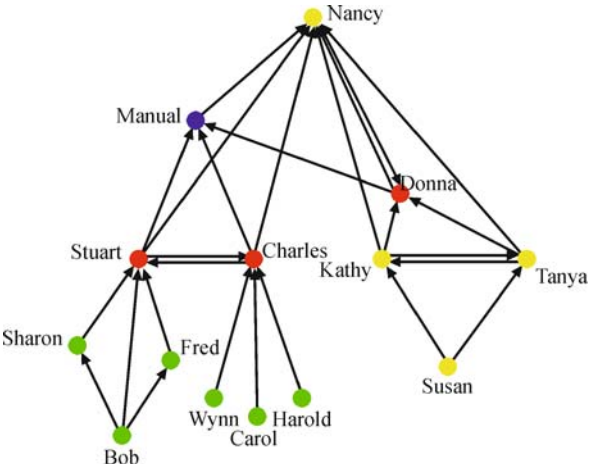
My interest, however, was with clusters, or blocs, of influentials and nominees. So I placed the nodes using a spring embedder designed by Kamada and Kawai [22]. The resulting figure shows that there seem to be two fairly well defined subgroups, one on the left and one on the right. The two groups are relatively dense but they are only loosely connected together. The people on the left are almost entirely sociologists and those on the right are mostly from other fields. And from the patterning one can suspect that there was some kind of split between these two groups.

For some kinds of data the search for clusters or groups is not appropriate. For example, when we are dealing with data that should embody some sort of ordering, digraph representations are particularly important. To illustrate how digraphs can be used to display ordering, consider the data collected by Forkman and Haskell [23]. They studied several communities, each made up of six domestic hens. In five of these communities the hens formed strict pecking orders in which the top hen pecked all the others; the second pecked all but the top, and so on. Figure 17 shows a visone [24] image of the data from one of those five communities. There the nodes are arranged, top down, in terms of their outdegrees and the pecking order is obvious.



Social Network Visualization, Methods of, Figure 17
Dominance among six hens

Often data approach, but do not achieve, a strict order. David Krackhardt [25], for example, collected data on who sought advice from whom among 14 employees in the in-



Social Network Visualization, Methods of, Figure 18
Visone image of advice seeking (from [26])

ternal auditing staff of a large company. Krackhardt's data could not be drawn with all the arrows pointing in one direction. So, in Fig. 18 he arranged the individuals in such a way that as many arrows as possible were pointing up. The viewer, then, can immediately see there is an important hierarchical element displayed by these data. From the image, it appears that Nancy is at the top of the advice chain and Bob, Wynn, Carol, Harold and Susan are at the bottom.

There is, however, an important limitation in this figure. Nancy seeks advice from Donna, Donna seeks advice from Manuel and Manuel seeks advice from Nancy. Thus, these three form a directed cycle of advice seeking. Given such a circular arrangement, no possible hierarchy among these three individuals can be established. Any order in which they were arranged would be misleading. In addition, Stuart and Charles cannot be ordered because they chose each other. The same is true for Kathy and Tanya.

The apparent ordering of nodes in Krackhardt's image was imposed by human judgment. There are computer algorithms that can automatically arrange the nodes into a hierarchical form [26]. They are, however, not as well grounded or reliable as multidimensional scaling and singular value decomposition.

Images Based on Two Mode Relations

Any time we deal with a relation that can link more than two social actors, we cannot use graphs or directed graphs. Both graphs and directed graphs can deal only with links between pairs. Two mode data, however, allow for relations that link three or more actors. So, whenever we have two mode data, like that collected by Hobson [8] or Davis, Gardner and Gardner [13] we need another way to construct images.

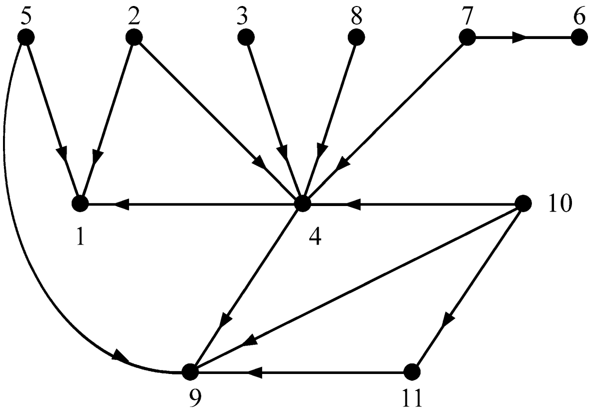
There are several ways to construct images of two mode data. I will consider three of them in the present section, hypergraphs, bipartite graphs and lattices. Then, in the next section, I will discuss the use of matrix representations for both one mode and two mode data.

Hobson [8] collected two mode data on corporations and their directors. He produced the image shown in Fig. 4 showing corporate interlocks as overlapping areas. Mathematically, images like Hobson's are *hypergraphs*. A hypergraph, $F = \langle N, H \rangle$, consists of a set of nodes N and a collection of *hyperedges*, H. While an edge in an ordinary graph connects two nodes, a hyperedge in a hypergraph may link any arbitrary subset of the nodes in N. Pictorially, hyperedges are represented as boundaries enclosing sets of nodes.

The use of hypergraphs was demonstrated in a recent report by Estrada and Rodríguez-Velázquez [27]. They began with one mode data that showed the patterning of predation among the members of eleven species in a Malaysian rain forest. Their graph, showing who preys on whom, is shown in Fig. 19.

Figure 19 shows which species preys on which other species. But if the investigator is interested, as those who study food webs often are, in defining ecological niches in terms of co-predation, Fig. 19 makes the overall pattern less than obvious. As an alternative we can build a hypergraph.

The matrix shown in Fig. 20 is based on the data in Fig. 19. It was built by considering each of the species in turn as prey. Then all of the species that share each given prey are pooled together. Species 1, 6 and 9 have no prey

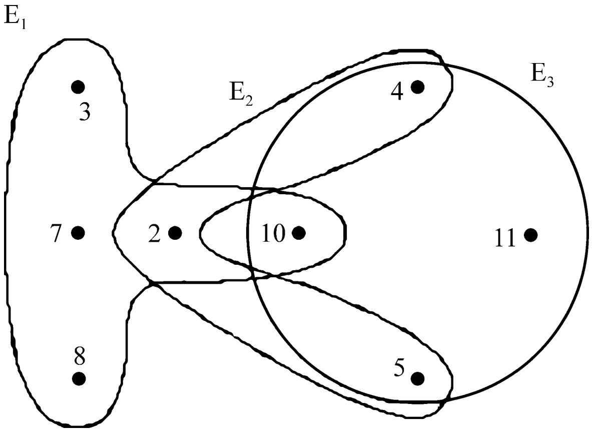


Social Network Visualization, Methods of, Figure 19
Who preys on whom in a Malaysian Rain Forest

Prey on

	4	1	9
2	1	1	0
3	1	0	0
4	0	1	1
5	0	1	1
7	1	0	0
8	1	0	0
10	1	0	1
11	0	0	1

Social Network Visualization, Methods of, Figure 20
Two mode matrix of co-predation



Social Network Visualization, Methods of, Figure 21
Hypergraph of co-predation

in the set. And species 4, 1 and 9 are the targets of co-predation. So the new matrix is two mode. It has the three targets of co-predation as columns and the eight predators as rows.

That matrix is captured visually by the hypergraph in Fig. 19. It immediately reveals that there are three niches. The one labeled E_1 includes all the species who preyed on species 4, E_2 those who preyed on species 1 and E_3 those who preyed on 9. Thus, each edge in Fig. 21 encloses a collection of species that compete directly for at least one prey.

There are, however, other ways to picture two mode data. In a more recent study of corporate interlocks, Joel Levine [29] reported data on the board memberships of seven major American corporations. Those corporations turned out to have ten directors who appeared on two or more of their boards. Levine presented his interlock data using a *bipartite graph*. A bipartite graph, $B = \langle N, E \rangle$ where N is partitioned into two disjoint subsets, N_1 and N_2, and no edge in E has both end points in the same subset. He used singular valued decomposition to place the nodes representing both corporations and board members and produced a bipartite image similar to the one displayed in Fig. 22. I prepared that figure using NetDraw. There, the corporations are shown as red circles and the board members are blue squares. Thus, both the colors and the shapes of the nodes stress the bipartite nature of the graph.

There is still another form of graphic display, one that reveals even more structural information about a two mode data set. It is based on an algebraic procedure called *Galois lattice analysis* or *formal concept analysis* [30,31,32,33]. A Galois or formal concept lattice is defined on an object by property, matrix. Let O be a set of objects and A be a set of attributes. The binary matrix $O \times A$ indicates which objects possess which attributes.

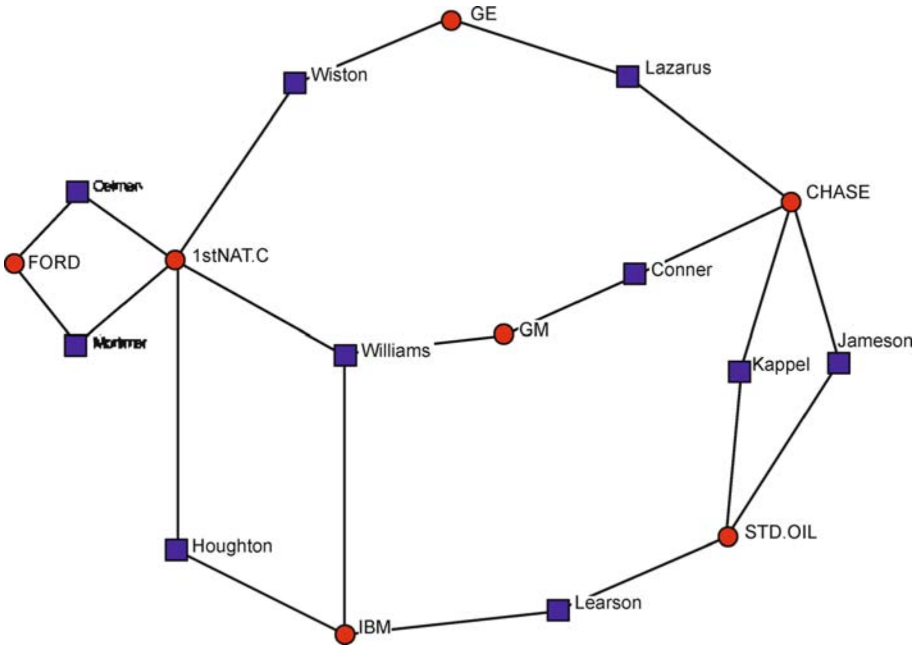
We can define a pair $\langle O_i, A_i \rangle$ such that O_i is a subset of O and A_i is a subset of A and every object in O_i has every attribute in A_i. Moreover, both O and A must be maximal. Thus, for every attribute in A that is not in A_i, there is an object in O_i that does not have that attribute. And for every object in O that is not in O_i, there is an attribute in A_i that the object lacks.

These pairs are dual and they can be partially ordered by inclusion. Given two pairs $\langle O_i, A_i \rangle$ and $\langle O_j, A_j \rangle$ we say that $\langle O_i, A_i \rangle$ is less than $\langle O_j, A_j \rangle$ when O_i is a subset of O_j or, equivalently, when A_j is a subset of A_i. Since all these pairs have unique least upper bounds and greatest lower bounds they form a dual (Galois) lattice.

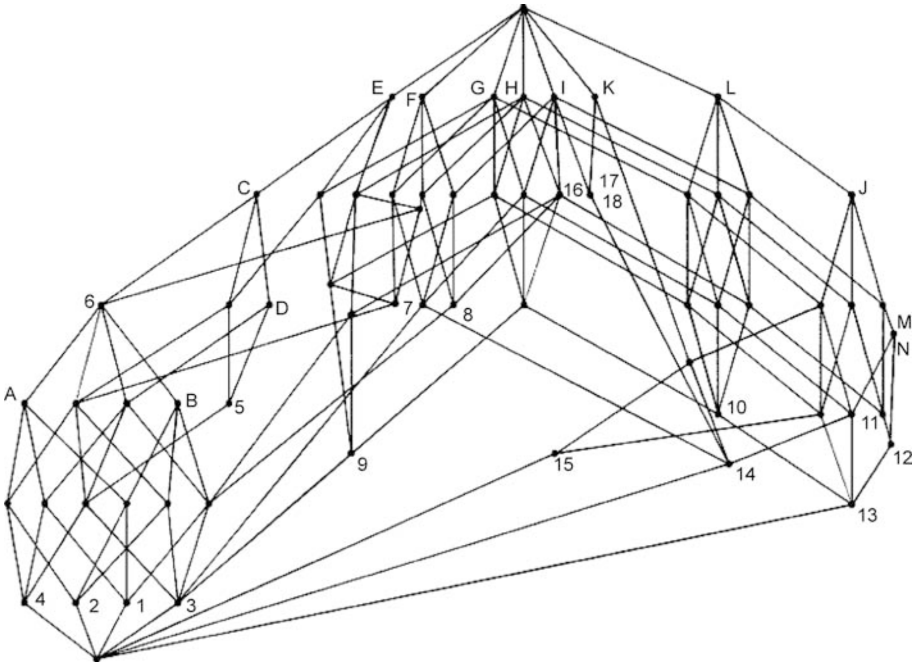
I will illustrate by considering again the woman by event data collected by Davis, Gardner and Gardner [13]. Let the women (1 through 18) be the objects and the events (A through N) be the attributes. The data, arranged into a Galois lattice by a program called GLAD, are shown in Figure into a lattice in Fig. 23.

The lattice displays the same three classes of events that define the same two groups of women that we saw in Fig. 10. But, in addition to the classes of events and groups of women, we can now see the containment structures of both events and women. To begin with, by following lines up from the bottom we can see which women attended which events. When we get to the top we hit the set of all events and, at the same time, because no woman attended all 14 events, it is also the null set of women.

The uppermost events (E–L) involved the largest sets of women. Other events are contained in the lower inter-



Social Network Visualization, Methods of, Figure 22
A NetDraw Image of Levine's interlock data as a bipartite



Social Network Visualization, Methods of, Figure 23
The Davis, Gardner and Gardner data as a Galois lattice

sections of these events. Event C, for example, is contained in E; everyone who attended C was present at E. And, at the next lower level, B and D are both contained in C. The events, then, can be seen as varying in their "openness".

At the same time, the figure shows the upward containment structure of the women in terms of their patterns of attendance. Because no event attracted all 18 women, the lowest point represents the set of all women as well as the null set of events. Then, the lowest set of women (1, 2, 3, 4, 13, 14 and 15) are the "core" attendees, so to speak. The next level contains woman 9 who never attended unless woman 3 was also present, and woman 5 whose attendance depended on that of women 4 and 3. Women 6, 7, 8, 10, 11, 12, 17 and 18 are also at this second level. In some sense, these are all secondary or peripheral participants in these events. And, finally, woman 16 turns out to be a third level participant; she was extremely peripheral. Woman 16 attended events only when secondary attendees 8–12 and core attendees 1, 3 and 13 were all present. All in all, then, the image of the Galois lattice reveals a great deal about the internal structure of attendance.

In this section I have shown three ways of visualizing two mode data. All three of them, however, share one important limitation. That limitation stems from the fact that all three of them can only be used for very small data sets. As the number of cases grows, they all produce images that become increasingly difficult to read.

The Forsyth and Katz image of sociometric choices

Images Based on One or Two Mode Data Matrices

When Davis, Davis and Gardner [13] first used matrix permutation, they did so without calling attention to the process. But since that first use a number of contributors have suggested procedures explicitly designed to rearrange the rows and columns of matrices. As time has passed, the overall tendency has been to come up with more effective procedures. And, with the introduction of computers, it has become possible to manipulate ever larger matrices. Presently, there is no end in sight.

Matrix permutations, moreover can be used with either one mode or two mode data. Five years after Davis, Gardner and Gardner introduced matrix permutation in their two mode data set, Elaine Forsyth and Leo Katz [34] explicitly proposed permuting matrices as a way to uncover and display social groups in a one mode data set. They illustrated using data from one of Moreno's [10] sociometric studies. The young women in a residence hall had each been asked to name others in their hall for whom they had positive feelings and those for whom their feelings were negative. Positive choices were recorded using plus signs and negative choices were recorded as minus signs.

Forsyth and Katz adopted a brute-force procedure that involved rearranging rows and columns and redrawing the image again and again until as many of the plus signs fell as close to the principle diagonal as possible. At that point, cohesive groups become visible as clusters of plus signs around the diagonal. Their result is shown in Fig. 24.

Obviously, the Forsyth and Katz procedure was extremely cumbersome. But Beum and Brundage [35] soon came up with a systematic iterative procedure for finding groups by rearranging the rows and columns of a one mode matrix. And, by the late 1950s, when computers emerged on the scene, Coleman and MacRae [36] developed a series of Univac programs at the Operations Analysis Laboratory at the University of Chicago that were designed to uncover the groups in large networks.

An entirely different kind matrix permutation procedure was proposed by Harrison White and his students. They introduced the idea of blockmodeling [37]. In so doing, they provided a theoretical basis for reordering network data matrices, and they developed a number of algorithms for doing so.

The aim of this new thrust was to reorder the matrix in such a way that it could be partitioned to reveal two or more collections of social actors who were *not* linked by some social relation of interest. So, instead of arraying actors along the diagonal of a matrix, White et al. sought permutations that would define zero blocks – sets of actors between which there were no social links. They used their approach to examine a great many network data sets. One example is shown in Fig. 25.

The data in Fig. 25 were collected by Sampson [38] in his study of a monastery. Sampson asked each of a collection of 18 novices to report their relationships with each of the others. Figure 25 shows an 18 by 18 matrix of their responses to a question asking the novices about which oth-

17				2		3		1										
18				3		1					2							

Social Network Visualization, Methods of, Figure 25
Sampson's data on who was a negative influence on whom

ers had negative influences on them. A response of 3 indicated a first choice. A 2 was a second choice and a 1 was a third choice. White et al. reasoned that only first and second choices represented strong responses, so they ignored the third choices and treated the entries of 1 as if they did not exist.

One of the several procedures procedure White et al. introduced was called CONCOR. CONCOR is a recursive procedure that begins by calculating correlations between the rows (or columns) of a network data matrix. Then correlations are calculated between the rows of the resulting correlation matrix. That procedure continues until it produces a matrix of correlations that uniformly displays values of +1 and −1. Those positive and negative values are used to partition the individuals into two subsets. The CONCOR procedure can be repeated using the data contained within each of the partitions. Thus, the original matrix can thus be refined to any desired degree.

White and his students used CONCOR on the data shown in Fig. 25 in an attempt to uncover blocks that contained only 0s. They could then use these zero blocks to reduce the complexity of the data matrix. That matrix produced three zero blocks. They are shown in Fig. 26.

In the reduced model in Fig. 27 each cell represents one of the blocks in Fig. 26. Thus, the 18 by 18 matrix is reduced to a 3 by 3 array. The reduction is consistent with Sampson's original ethnographic description of subgroups among the novices. Moreover, its pattern of zero blocks in the principle diagonal indicates that no block member saw any fellow block member as having a negative influence. But the members of each block saw at least some of the members of both of the other blocks as negative influences. This makes sense in the light of the ongoing conflict that Sampson described in his report.

Since that time, displays based on matrix permutations have grown in size, complexity and sophistication. One

The CONCOR reduction of the Sampson matrix

particularly striking example was produced by Richards and Seary [39]. Their data were drawn from a study of participants in a needle exchange program in Baltimore, Maryland [40]. Richards and Seary examined data on 4259 individuals who picked up and returned needles at each of four exchange sites over a 30 month period. Each cell in the matrix is a record of the number of needles picked up by the individual in that row and returned by the individual in that column. About a third of all needles fall in the principle diagonal of the matrix.

Richards and Seary used the data from the largest weak component in the data set. That component involved 100 000 needle exchanges among 36 000 individuals. Richards and Seary used their program MultiNet [41] scaled the data using a form of singular value decomposition called *correspondence analysis* [18]. They used the coordinates provided by the first Eigenvector to reorder the rows and columns of the matrix. They then colored the entries in terms of frequencies. The color scale is logarithmic: gray is 1 needle, blue 2–3, green 4–7, red 8–15, ma-

genta 16–31, yellow 32 and above. Their image is shown in Fig. 28.

Figure 28 dramatically illustrates the utility of images based on matrix permutation. It shows that there was not a single community of needle users in Baltimore. Instead, there were two distinct communities of individuals who regularly obtain, return and exchange needles with one another. These two relatively large communities were centered around two of the four needle exchange sites.

Future Directions

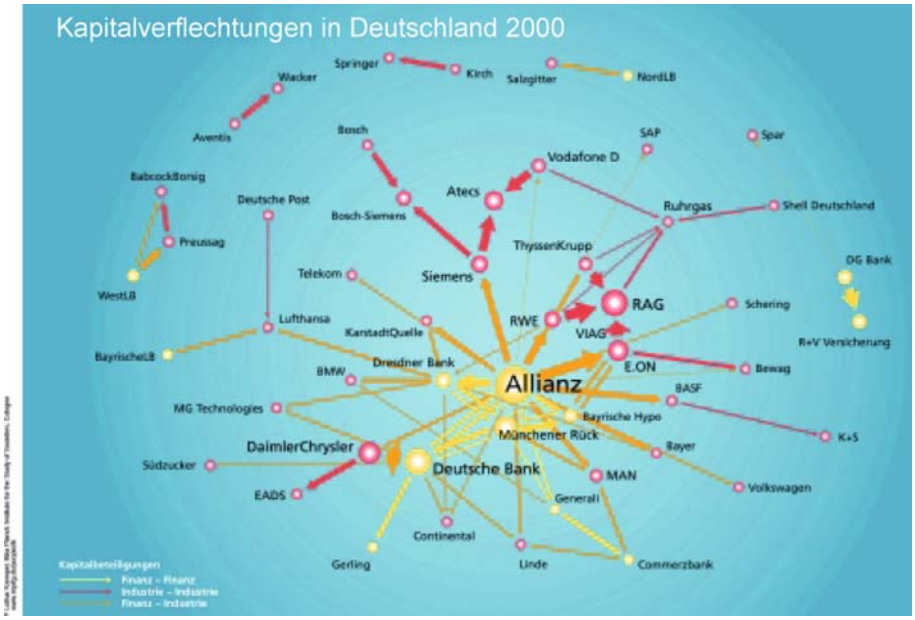
Overall, the long range the trend in visualizing social networks has been to rely on computers to do more and more of the job. First, computers used a version of singular value decomposition to locate nodes in two dimensional images [42]. Then, soon thereafter, Coleman and MacRae [35] programmed a computer both to permute rows and columns of a matrix and to print out an image of the result. And, in the early 1970s, Alba [43] wrote a program that performed calculations to place nodes and then went on to draw node and edge images of the results [44].

Since the 1970s, then, network analysts have increasingly used computers both for calculations and to draw images. And increasingly, multidimensional scaling and singular value decomposition have been used to determine locations for nodes. Moreover, when two dimensions are not enough to display network structure, three dimensional images are being produced.

When microcomputers became available it quickly became possible to produce images that gave the appearance of being three dimensional. Moreover, with the advent of color screens, color images began to be produced. Figure 29 represents data collected by Kirke [45] on social links among teenagers in a suburb of Dublin. Nodes were first located in three dimensions using multidimensional scaling. And then the virtual reality modeling language (VRML) was used to produce the appearance of three dimensions. Figure 27 was produced as a cover design for a book [46] and the colors were used simply make the image more attractive.

Colors can, however, be used to enhance the ability of an image to communicate important information. In Fig. 30 Höpner and Krempel [47] used a spring embedder and Krempel's own programs to arrange the nodes in two dimensions. The nodes represent the 100 largest German corporations in the year 2000. They used color to label both nodes and directed lines. In their image each company is represented as a node and an arrow pointing from one node to another means that the first node holds shares in the second. The size of a node indicates the number of connections to other nodes it has. Financial companies are shown as yellow nodes and industrial companies are red. Links between financial companies are yellow, those between industrial companies are red and links between financial and industrial companies are orange. Bu using color, then, his directed graph reveals a great deal of information about the organization of German industry and finance.

The image in Fig. 31 was made using a program called MAGE [48]. MAGE was written by Richardson and Richardson [49]. It is designed as a display on computer screens, and it allows the viewer to move into the picture as well as to spin and rotate it. It is useful, then, for exploring the patterning of structural data in three apparent dimensions.



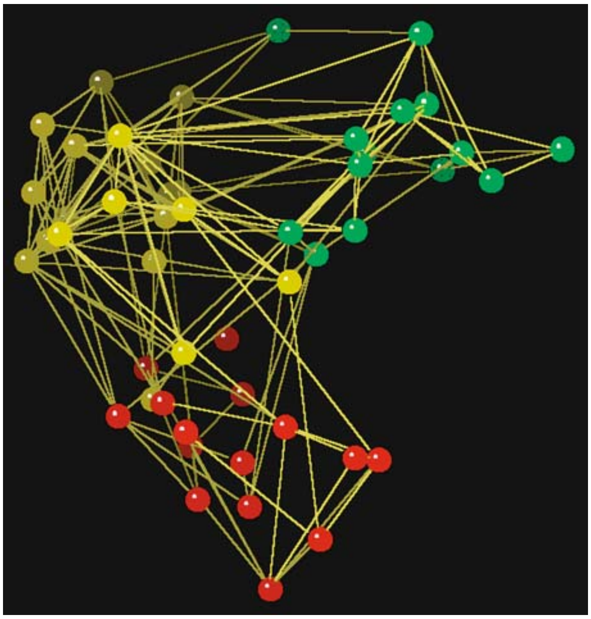
Social Network Visualization, Methods of, Figure 30
Links among German corporations in 2000

In Fig. 31 students in a university professional school program reported who their friends in their class were. Nodes were placed using a multidimensional scaling program and then they were colored according to their program in the school. It turned out that most of their friendship choices linked those that shared a program.

Richards and Seary's [50] program, Multinet, produces a wide range of graphic images. Included are images that actually can be viewed in three dimensions using *anaglyphic* glasses in which one lens is red and one is blue. Obviously, I cannot illustrate their program here, but anyone who wants to see real 3D images should explore Multinet.

The most recent development in visualizing social networks involves the production of animated graphics. As more and more process data are collected and as more process models are constructed, animated images are a natural development. A group at Stanford University has written a Java program, SoNIA [51], that makes it quite simple to produce animated node and edge and node and directed line images [52,53]. These images allow users to explore the changing structural forms generated by process data.

Overall then, in the period between Moreno's hand drawn ad hoc images and the latest animations of dynamic network processes, there has been a dramatic growth in our ability to visualize social network structure. The major contribution has come from computers. Today we can use a wide variety of readily available computer programs to both design images and to produce screen images and/or printed output.



Social Network Visualization, Methods of, Figure 31
MAGE image of friendship among classmates

But, as the job of producing images becomes easier, we must be careful not to lose our sense of why we are producing then in the first place. From the very beginning, the important point has always been that the visual images of social networks are not produced simply to be decorative. In every case, the early images were drawn in order to dramatize some feature of social structure. Moreno produced Fig. 5 to illustrate the importance of considering the number of connections in evaluating the structural position of an individual. In Fig. 6 the number of negative ties received by one of the running backs showed, as Moreno (p. 213 in [10]) put it, "It is easy to see that when 5/RB is running with the ball he is not apt to get the maximum of cooperation in interference and blocking."

Figure 7 was a pictorial statement by Warner and Lunt that when cohesive subgroups overlap, they should not be expected to bridge wide differences in social class. Figure 8, from Davis, Gardner and Gardner, demonstrated that the Warner–Lunt hypothesis was supported by data with respect to both social class and age. And, finally, Fig. 9 illustrated the presence of cohesive groups and of the variation of different individuals in their involvement in those groups. In every case each of these early authors had a point to make, and in every case the image helped to make that point. That is the key to the effective use of visual materials in social network analysis.

In future we can expect to see continued development of computer programs designed to aid in visualizing social networks. We can look forward to continued refinement of algorithms for displaying group structure that are based on multidimensional scaling, particularly spring embedding. We can anticipate better algorithms for displaying hierarchies and approximate hierarchies. We can expect to have more powerful programs for animation. And, at the same time, we can expect to be able to produce higher quality and more refined visual displays of all sorts.

Social Organizations with Complexity Theory: A Dramatically Different Lens for the Knowledge Economy

RUSS MARION
Clemson University, Clemson, USA

Article Outline

Glossary

Many of these terms are commonly understood by complexity theorists; these definitions, however, describe their meaning within the context of social organizations.

Adaptive behaviors Perturbations (creative ideas, pressures, etc.) in a system that foster some observable level of phase transition. Change leading to systemic reaction.

Adaptive tension Pressures external or internal to the organization that perturb an organization thus pressuring it toward phase transitions and structural or ideational elaboration.

Administrative leadership behaviors related to such things as strategic planning, policy making, and resource acquisition and distribution.

Agent An entity that is the smallest unit of interest in a complex dynamic. An agent could be a person, idea, task, knowledge, etc.

Aggregation Coevolutionary emergence of diverse ideas, agents, etc.

Aggregation mechanisms Macro-level complexity mechanisms. Refers to the dynamic interactions of perturbations (see initiating mechanisms), amplifications (expansion and elaboration of a perturbed state), and phase transition (nonlinear, form-shift in some part of an organization).

Coevolution A process in which "reciprocal selective pressures operate to make the evolution of ... (one agent in an interactive process) partially dependent on the evolution of (other agents)" [67]. Coevolution occurs when heterogeneous agents in a niche are interdependent such that they dynamically adjust to each others changes.

Commodity-based economy Refers to a manufacturing economy in which the major assets are physical commodities.

Complexity organizational knowledge Systemic knowledge that imbues organization with capacity for adaptive and creative responses; attributable to the strength and viability of the system's complex structures and to the viability of the relationship between the organization's complex structures and its bureaucratic structures.

Complexity mechanism Social mechanisms that underlie complexity dynamics.

Complexity theory In organizational sciences, the study of emergent dynamics in neural-like networks of adaptive, vision-oriented agents.

Conflicting constraints Conflict that emerges when the preferences of one agent challenges the preferences of another. In complex networks, conflicting constraints generate pressure to elaborate.

Dissipative structures Structures that emerge when far from equilibrium systems release excess energy in a phase transition.

Emergence The appearance of new structures or ideas from the actions of complex interactions.

Enabling behaviors Activities that foster conditions (e. g., interdependency, enabling rules, adaptive tension) in which complex dynamics can emerge.

Enabling rules Rules that govern interactions among adaptive agents in complex systems. Contrast with bureaucratic rules, which delimit the responsibilities of agents in a closed system bureaucracy.

Entanglement A dynamic relationship between the formal administrative forces and informal complexly adaptive, emergent forces of an organizational systems.

Equilibrium A stable, predictable relationship among agents and structures of a relationship. Related to thermodynamic concept of a low energy state.

Extreme event Instances of dramatic change that occur infrequently in social organizations; the US government's experience of the Katrina hurricane in New Orleans illustrates. Extreme events typically require rapid action and can be minimally responsive to top-down control.

Far from equilibrium Typically defined as a high energy state; defined here for organizational studies as an intensely complex, dynamic state driven by excess levels of pressure and perturbations.

Heterogeneity A diversity of skills, worldviews, preferences, beliefs, goals, (etc.) among interactive agents in a complex system.

Initiating mechanisms Micro-level complexity mechanisms. They include coevolutionary interaction and perturbations (an unexpected change in an interaction relationship; attributable to complex, interactive dynamic).

Interdependency Network conditions in which the actions of one agent are influenced by the actions of another.

Knowledge economy Refers to a production economy in which the major assets are the knowledge possessed by individuals and networks of individuals (organizational knowledge).

Meso theory Variously defined as theory that bridges macro and micro level theory; different levels of hierarchy; or different levels of analysis (individual, dyadic, group).

Multi-agent based modeling Agent based modeling procedure that analyzes different types of networks simultaneously (e. g., agent networks, task networks, etc.)

Organizational level From Jaques [40], the level of bureaucracy that lies between the upper echelon levels and the work production level; includes middle management.

Perturbations Events that disturb normal organizational interactions and generate pressures that can lead to phase transitions.

Phase transition Sudden, nonlinear form shifts attributable to the dissipation of accumulated pressure in complex systems. Phase transitions can occur at multiple levels of intensity.

Postmodernism In general, a rejection of scientific modernism. For organizational science, it represents a realization that organizational behaviors cannot be adequately expressed as mathematical relationships among variables. Complexity theory adds that organization is an ultimately unpredictable dynamic whose causal structure is based on interactions among complexity mechanisms.

Production level From Jaques [40], the level of bureaucracy responsible for line production.

Requisite complexity McKelvey and Boisot's [65] modification of Ashby's requisite variety; they maintain that viable organizations are at least as complex as their competition.

Requisite variety Ashby's [5] dictum that viable organizations have at least the same degree of flexibility as their competition.

Spaces between A proposal that creative ideas emerge from interactive dynamics. Creative emergence is generated when agents work to resolve tension; such tension is product of conflicting constraints, heterogeneous preferences, ideas, and knowledge, etc.

Social mechanism A process attributable to dynamic interactions among multiple people, variables, ideas, physical limitations, etc. Mechanisms describe "a set of interacting parts – an assembly of elements producing an effect not inherent in any one of them" p. 336 in [27], p. 74 in [37].

Strategic level From Jaques [40], the upper echelon level of bureaucracy; responsible for organizational strategy, policy making, resource acquisition and allocation, etc.

Swarm behavior Study of the dynamics of swarms in biology and in organizations. Scientists are finding that amazingly complex, "intelligent" behavior can emerge from complex behaviors that are structured by a few, simple enabling rules. Useful in organizations for improving such things as distribution efficiency or flexible response to environmental conditions.

System dynamics Network simulations in which relationships among agents are defined mathematically.

Top-down administration Administrative practices in which decisions are made by superiors to be carried out by subordinates.

Vision A teleological view of the future. Vision can be highly specific, or determinate, as when an organization projects future markets (such visions are more properly, goals; see Sharp Corp.'s strategy statement in this paper for an example). Vision statements appropriate for complex systems are indeterminate in that they do not preclude the future; for example, "This company will strive to enhance its competitive advantage by optimizing its flexibility."

Definition of the Subject

Complexity theory for organizations examines the influence of complex dynamics on (among many things) organizational structure, leadership, power and control, influence, and strategy. It is applicable not only to understanding but of practice in any organizational type whose primary commodity is knowledge and application of knowledge. The core outcomes of complex dynamics are creativity, adaptability, and learning. Complexity theory is particularly germane in what has come to be called, the knowledge economy.

This paper defines basic premises underlying complex dynamics in organizations, and argues in particular that organizational complexity is best understood as the interactions among complexity mechanisms (causal process attributable to dynamic interactions among multiple people, variables, ideas, etc.) rather than as the outcome of defined variables. We explore the relationship between bureaucracy and complexity, and define three levels of behavior in complex organizations: administrative, enabling, and adaptive. We apply these ideas along with complex premises underlying complexity to strategic leadership. The paper describes how complexity produces its core outcomes – creativity, adaptability, and learning – and argues that these outcomes are particularly pertinent to today's economy. It concludes with a discussion of unique research methodologies that can be used to study a process based on mechanisms rather than on variables.

Introduction

The science of complexity offers interesting solutions to some difficult challenges in organizations. These challenges affect nearly all economic sectors of society, from electronics to education, computer programming to automotives, banking, government, and the armed forces. They include hyper-competitive environments [38], globalization, unequal global distribution of wealth and production costs, rapid technological and social change, highly complex operations (e. g., the complexity of sophisticated software programming), and the changing nature of the workforce (less loyal, comfortable with electronic communication, demanding of flexible work arrangements). To address these challenges, practitioners and scholars recognize the need for radically new leadership paradigms [81], revised perspectives of organizational strategy [81], flexible structures [83], rapid adaptability [16], and decentralized problem-solving structures [25]. Complexity science is applicable to these challenges because, among other things, it focuses on flexible, interactive dynamics rather than top-down control, it offers unique descriptions of change in dynamic system, it reveals important clues about creativity, adaptability, and learning in organizations, and it shifts attention from central tendency variables to causality based on dynamic mechanisms [50,81].

Traditional thought in organization science was oriented toward efficient production and top-down coordination. It assumed that organizational behavior was intimately dependent upon structure provided by positional leaders, rational plans and goals, centralized coordination, organizational evolution, and vision [35]. It has explored the nature and impact of power [41], institutional forces [28], and charisma [23]. Traditional thought has, like complexity theory, described change but has assumed that organizational change and innovation must be planned, that effective action must be coordinated, and that organization must be structured in the board room.

By the 1990s, this "top-down" notion began losing credibility among organizational scholars and practitioners (e. g., [35]). The major culprit in this demise was the knowledge economy – the globalization, rapid change, and hyper-competitive environments described above. Top-down perspectives of organization had been oriented toward more stable, commodity based environments [9], and the emerging knowledge economy is oriented toward creativity, adaptability, and learning.

Complexity theorists in the organizational sciences seek relevant strategies for dealing with the knowledge economy. Complexity theory is useful for this because it does not merely improve traditional perspectives of doing organization but rather addresses different sets of behaviors than are typically addressed by organizational theorists. In particular, it focuses on informal interactive processes within an organization, on processes that emerge from informally interacting people and groups, and on productive relationships between informal and formal activities within an organization. It asks such questions as, "How can organizational decision making and interactive patterns be restructured and reorganized to increase flexibility" [49]? "How can leadership be re-conceptualized in a way that is effective for complex organizations" [70]? Or, "How do we re-focus organizational strategy for a knowledge economy" [58]?

In this paper, we look first at basic premises underlying the application of complexity theory to organizations, then look at how complexity can inform understanding of bureaucracy and strategic leadership. We examine the organizational outcomes of complex dynamics (hence the rational for applying this science), and conclude with a discussion of research methodologies that are useful for studying complex organizational behaviors.

Basic Premises

Studies have found that, like biological [30], economic [4], and physical [45] systems, emergent dynamics are readily observed among interacting people, or agents [20,68,69]. Interactive dynamics and emergence are common denominators in complexity studies, and while there are discipline-specific variations (organizational agents, for example, make learned, adaptive choices while weather systems react primarily to the interactions of physical properties), all are shaped by these defining dynamics. Agents interact and the interaction changes them (emergence).

Complexity organization researchers are interested in understanding how these dynamics operate in human systems. Lichtenstein and Plowman [51] have found, for example, that certain interactions among individuals and groups lead to perturbations, or pressure to elaborate. Consistent with Kauffman [43], these tensions pressure the system to adapt and to change. Perturbed, interactive systems also tend toward self-organization [57,62]. This phenomenon was first systematically observed in the 1940s and 1950s as informal groups [39] and was expanded by complexity theorists to include any situation in which ideas or people spontaneously, and without external motivation, act in some degree of synchrony with one another. Chiles et al. [20] identified dissipative structures – fluctuation, positive feedback, stabilization and recombination – in the emergence of the music industry at Branson, Missouri.

Researchers are also interested in understanding the conditions that enable emergent, self-organizing behavior in social systems [82]. *Interaction*, of course, is *sine qua non*. Schreiber, Marion, Uhl-Bien, and Carley [74], drawing from Kauffman [43], found that interactive agents must possess a requisite level of *interdependency* to enable learning outcomes (too much or too little will suppress complex dynamics; [43]). This interdependency generates *conflicting constraints*, which are important sources of perturbations in a complex system. McKelvey [64] adds that such pressure is also generated by external sources such as leadership behavior or economic pressures; he refers to this as *adaptive tension*. Uhl-Bien et al. [82] adopted this term to refer to both internal and external pressures.

Bonabeau and Meyer [10] have developed fascinating insights into the nature of swarm behavior in human organizations, and have used it to solve efficiency problems involving such things as package delivery and local surges in phone traffic [10]. Swarms are a function of a set of simple, *enabling rules*, such as "fill orders [in a distribution warehouse] until the next person in line takes over", or "drop 'digital' pheromone trails for subsequent messages to track" (in computerized instructions for phone systems).

Complex behaviors in social systems are enabled by *heterogeneity* of skills, preferences, outlooks, etc. Traditionally, organizational theorists, particularly those who study leadership, have sought to align employees to centralized goals [56]; complexity theory suggests that organizations whose employees pursue a diversity of goals (within the context of an interactive, interdependent network) will have a diversity of ideas to draw from as they seek creativity and adaptable changes.

Finally, Schreiber, Marion, Uhl-Bien, and Carley [74] found in a multi-agent based simulation that moderate levels of *vision* (or general organizational focus) are conducive to complex behaviors. High centralization of vision (in combination with high interdependency among agents) was counter-productive for complexity outcomes in their simulation, as was low levels of vision (low vision was more problematic to outcomes than was high vision).

Emergence and Phase Transitions

Emergence refers to the generation of new structures or ideas due to the actions of complex interactions. This phenomenon is important because it allows the system to rapidly produce adaptive, creative responses to environmental conditions. It occurs in social structures when heterogeneous agents or ideas act in relative synchrony with one another. The emergence of riot conditions out of the behaviors of just a few people illustrates (the emergence of a riot also illustrates that emergence is not necessarily a functional response to environmental contingencies; the notion of counter-productive emergence has been discussed by Uhl-Bien, Marion and McKelvey [82]).

One form of emergence involves the *accumulation* of different ideas or agents. Anderson [1] and Marion [55], for example, described the emergence of technology that led to the invention, in 1975, of the microcomputer. It began with disparate advances – transistors, printed boards, LEDs, etc. Engineers began using these isolated components together, as they did in the transistor radio popular in the 1960s. Accumulation took a big leap with the introduction of the handheld calculator in the late 1960s, which added such things as processors and information storage capacity. The microcomputer was the ultimate "accumulation" or emergence event.

Importantly, the components of such emergence processes accumulate because they "coevolve." Coevolution is defined by Pianka, p. 329 in [67], as a process in which "reciprocal selective pressures operate to make the evolution of either … [agent in the interactive process] partially dependent on the evolution of the other" see also McKelvey [64]. Coevolution occurs when heterogeneous agents in a niche are interdependent such that they dynamically adjust to each other's changes. It raises the important observation that an organizational species' fitness – the capacity to survive and thrive – is influenced by supporting roles from other organizational species [43].

A second form of emergence is called *phase transition*. Phase transitions are sudden, nonlinear form-shifts (changes in structure, knowledge, worldview, etc.). The sudden demise, in 1989, of the USSR illustrates this phenomenon. Phase transitions like that experienced by the USSR result from a build up of tension or pressure [32,64,71]. Haken [32], for example, illustrated phase transition in terms of slowly heated oil; eventually the heat (tension) reaches a point at which the oil precipitously transitions to a new state, observed as a gentle boil.

Phase transitions, occur at multiple levels of intensity, and a number of researchers have observed that, in complex systems, intensity of transitions plotted against their frequency describes a power law relationship ($1/f^x$); [2, 7,75]. Power law curves are steeply descending slopes that quickly bottom out into a more gently descending slope; when intensity and frequency are converted to log equivalents, the slope becomes a straight line descending left to right like a negative regression line in statistics. Power law curves describe situations in which high intensity events occur infrequently while low intensity events occur often.

This has opened a line of exploration into what are called, extreme events, or analyzes of phenomena that are highly intense but of low frequency (the 2008 Organization Science Winter Conference was devoted to this topic). Stephenson and Bonabeau [76] concluded, for example, that bottom-up, or adaptive, leadership strategies may be more effective in extreme events such as Katrina or the Twin Tower attacks of 9/11 than are top-down leadership strategies.

Far from Equilibrium

The accrued tension described by Haken generates what Prigigine [71] calls, a far from equilibrium (FFE) state. At FFE; the system will often act spontaneously to release (or dissipate) built up tension by moving to a new structural state [64].

In organizational studies, the far from equilibrium notion is unique, for organizations have traditionally been described in terms of equilibrium structures ([12]; see Maruyama [60], for a notable exception). The idea that far from equilibrium states exist suggests an equilibrium continuum for organizations that stretches from an equilibrium state to far from equilibrium conditions. Hazy and Marion [34] argue, however, that while this may be true for some physical systems, it is not true of human systems. Human systems always function in a state of change, albeit with varying degrees of complexity, and it makes no sense to juxtapose such systems against an equilibrium end point. They conclude, then, that far from equilibrium in a social system occurs when the dynamical conditions and resulting complexity of a social system are increased beyond a certain point, not when it moves away from equilibrium.

Even so, the assumption that organization exists in a state of equilibrium is common in the traditional literature on organizations. Although it has been clarified by earlier organizational theorists to be a moving equilibrium (called homeostasis) that adjusts to environmental conditions (the influential classics of this argument are [12]; and [84]), the basic premises in organizational studies have implicitly or explicitly equated organization with adapted variations of the equilibrium view from thermodynamics. Complexity theory contradicts this notion, arguing instead that adaptive systems can only survive and thrive in a state variously called far from equilibrium [64], complexity, edge of chaos [42], or Type IV order [47]. If Hazy and Marion [34] are correct, perhaps the better terms for this are those that do not imply an equilibrium state at all.

Complexity Mechanisms

Complexity is unique in organizational studies because it is oriented around social processes rather than around variables. A variable, or measure of central tendency, is static and it reveals little about the evolutionary social processes in which the variable is embedded. Complexity seeks to understand and to describe the behaviors of those social processes, or what Davis and Marquis [27] and Hedström and Swedberg [36] and others have labeled, social mechanisms.

Mechanisms are defined as commonly observed patterns of behavior [29]; they describe "a set of interacting parts – an assembly of elements producing an effect not inherent in any one of them" p. 336 in [27]; see also p. 74 in [37]. Mechanisms are processes, or dynamic interactions among agents, ideas, and structures. Elster's [29] definition proposes that certain mechanisms can be "commonly" observed across multiple phenomena (that is, they are not necessarily unique to given conditions). They illustrate by arguing that the logistic curve (emergence begins slowly, picks up speed, then levels off) is a mechanism and that it can be observed in numerous situations (Mozart's lifetime productivity, emergence of product popularity, etc.)

Uhl-Bien and Marion [81] identify two broad, interdependent categories of universal mechanisms that they call, complexity mechanisms: These are initiating mechanisms, or interactive processes that generate perturbations, or disturbances, in a system, and aggregation mechanisms, which include accumulation mechanisms (accruing of ideas or structures) and phase transitions (described earlier as nonlinear changes that generate new order). Initiating mechanisms are more micro level while aggregation mechanisms are more macro level.

Practitioners who grasp this notion of complexity mechanisms do not perceive organization in terms of average motivation or efficiency, but rather perceive organization as sets of interacting, evolving processes. They do not ask, for example, whether satisfaction will increase if leaders engage in certain specific acts, or whether high leadership scores on a transformational scale will enhance productivity. Rather they want to know how interactive, interdependent mechanisms influence the capacity of social networks within organizations to generate unpredictable but creative outcomes. These contrasting sets of illustrative questions differ in that the former are based on scientific assumptions about linear relationships among central tendencies and the latter are based on postmodern assumptions regarding complex interactions that are indeterminate in the detail but determinate in the general nature of their outcome. For example, we can predict dynamic creativity capacity but we cannot predict what that creativity will look like.

Understanding Organization with Complexity

We turn now to an examination of some specific applications of complexity to organizational theory and behavior. This discussion is framed around the relationship of complexity to bureaucracy and around strategic leadership.

Bureaucracy and Complexity

The discussion to this point has implicitly portrayed organization as an adaptive dynamic, or as a system driven exclusively by agents acting informally within complex networks to produce emergent outcomes. In reality, organizations are bureaucratic structures, and despite predictions by some of a post-bureaucratic economy [31,35,54], it is unrealistic to ignore this pervasive element of organization (as Weber [85], said, bureaucracy will be with us until the last shovel of coal is dug from the earth).

For this reason, complexity theorists Uhl-Bien et al. [82] have chosen to depict informal, complex dynamics as embedded within each of Jaques' (1989) three levels of bureaucracy: production, organizational, and strategic. They observe that, while bureaucratic functions differ at each level, the nature of complex dynamics differ only in the tasks they address. That is, complex behavior is similar across the system, whether observed in the board room or in the production divisions. Dynamic, complex behaviors are pervasive, and are universally driven by the enabling conditions described in the last section. Specific complex processes are entangled with one another and even across bureaucratic level. Further, the inter-influences across these dynamics is more horizontal than hierarchical: Dynamics on the shop floor – Jaques' [40] production level – can directly and quickly influence dynamics in the executive suite – Jaques' strategic level. Using complexity terminology, complex dynamics in organizations are, therefore, fractal in nature. From an organizational perspective, they represent a meso view of organization; that is, they describe the linkages that unite micro, or individual, level structures with macro, or organizational level, analysis [26]. Uhl-Bien and Marion [81] also argue that they are meso in that they link different hierarchical levels.

From this, Uhl-Bien, Marion, and McKelvey [82] propose three key dynamics within organizations (which they describe relative to leadership): administrative, adaptive, and enabling. *Administrative leadership* is related to traditional perspectives of leaders as those who generate organizational strategy, gather and distribute resources, and create policy. They differ from traditional perspectives in that their actions must serve to nurture the somewhat fragile, bottom-up (or adaptive) complex leadership processes (fragile in that they are somewhat sensitive to political power behaviors).

Adaptive leadership is defined as any interactive behavior that creates a perturbation which leads to a phase transition. The key elements are interaction, perturbation, and phase transition. Uhl-Bien et al. argue that change originates in the "spaces between" interacting agents (see also [52]); that is, it is the product of the push and shove that can occur between or among agents with heterogeneous skills or worldviews. Perturbations are resulting disturbances in a network (change, new ideas or perspectives, inventions, etc.) that reshape the interaction patterns in that network [81]. Phase transitions are nonlinear shifts within a network (these are described more fully below).

Enabling leadership, the third of Uhl-Bien et al. [82] types, refers to individuals who foster the enabling conditions described above (interaction, interdependency, heterogeneity, enabling rules, etc.) and who mediate the relationship between adaptive and administrative functions.

Emergence, Niche, and Strategic Leadership

The earlier discussion of emergence and phase transitions help us re-visualize the role of another strand in organization sciences: strategic leadership. Strategic leadership theorists study upper echelon behaviors of leader/agents responsible for positioning an organization in its environment. Traditional literature has perceived strategic leadership as a top-down, goal oriented process [13] in which the leader manages the organization's environment. For example, Sir Howard Stringer articulated the strategic goal of Sony Corporation at the 2006 International Consumer Electronics Show in Las Vegas, as:

> Sharpening our focus, shattering internal silos, streamlining our product offerings and growing ever more consumer-centric. We have analyzed our product lines and reorganized our corporate structure to become more nimble and better able to deliver champion products and a focused product line-up. [78].

The website for Sharp Corporation articulates both its philosophy and its business strategy in terms of expanding its market (sharp-world.com/corporate/info/philosophy/index.html). Strategic goals from other companies could be cited, but most will, like these, focus on the company's competitive position in its environment.

Given such assumptions, traditional strategic leadership literature has examined such things as the personality and decisions of top echelon leaders, relationships between the CEO and his or her board of directors, transformational leadership, and visionary leadership (see [13], for a summary).

More recent work by strategic leadership scholars is still concerned about position in the environment, but has focused not on upper echelon behavior but on the internal dynamics of organizations and how organizational flexibility contributes to organizational strategy [8]. Interestingly, Sharp has heeded this call: Stringer's articulation of their goal (above) includes a call for a "more nimble" firm. However, a review of the complexity literature has revealed little that has addressed this issue, despite the fact that it seems a natural subject for complexity analysis. One exception is an article by Marion and Uhl-Bien [58], which argues that flexible, complex structuring is key to organizational strategy. They propose that firms work to increase interaction, interdependency, and adaptive tension.

Marion and Uhl-Bien [58] also suggest that that traditional external-oriented strategic leadership has missed an important point. Much of this literature is, at least implicitly, about dominating the environment or beating the competition. Complexity theory argues that different organizations coevolve [43], and in doing so, they grow to depend upon one another. That is, coevolving systems aggregate and form a niche, or interdependent infrastructure upon which each part of the niche depends to some extent. Automobile makers depend upon fuel outlets and automotive repair shops, for instance – and vice versa. Automotive makers even depend on one another, for their competitive relationship generate pressures that foster structural and ideational elaboration and generate a heterogeneous set of creative solutions that foster even greater creativity. External strategy, then, may be about more than competition; it may also be about fostering effective infrastructure: Marion and Uhl-Bien called this, survival of the cooperative.

Complexity Outcomes: Creativity, Adaptability, Learning

From all this, we can generalize the outcomes of complex dynamics for organizations as creativity, adaptability, and learning. *Creativity* is defined as an ideational phase transition in which an outcome reasonably could not have been predicted based on preexisting conditions or paradigmatic assumptions. Described more basely, it is something that "no one saw coming." Since it is a phase transition, it can be a minor bit of creativity or a major insight.

The major creative insights, of course, capture our imagination and dramatically change our way of seeing things (e. g., Einstein's relativity or Schrödinger's cat). However, small creative events are more common and, arguably, just as important. Creative ideas exist within complex networks that enable them to coevolve and aggregate. That is, they become part of the emergence dynamic within an organization. Creative ideas and associated structures change, aggregate with other creative ideas or structures, and generate adaptive pressures that maintain or increase the complexity of a system. Without the pressures that creative ideas generate, an organization would move towards increased isomorphism and decreased complexity – they move to a state that some would mistakenly call, homeostasis.

Adaptability is enhanced when an organization increases its level of complexity. This translates into (among other things) increased heterogeneity of skills and preferences. Traditional organizational theory has assumed that everyone should be on the "same page" (e. g., "Leaders … are responsible for the dissemination of strategic organizational goals, as well as for convincing their constituents to effectively implement those goals" p. 626 in [6]). Complexity theorists argue that, although organizational agent should be united by a vision, dynamic heterogeneity enables organizations and agents to rapidly and effectively deal with environmental exigencies. Ashby [5] refers to this as "requisite variety;" he defines it by stating that it takes variety to defeat variety. McKelvey and Boisot [65] call it "requisite complexity," thus underscoring the dynamic, co-evolving nature of complex systems and their adaptive response capabilities.

Learning is defined for organizations in several ways. Many of us would define it as something that an individual does. Some organizational theorists [3,22,66], including some complexity scholars (e. g., [9]), argue that learning is best understood as an organizational process. The functioning of the brain exemplifies this logic (see [44]). Individual neurons "learn" only small pieces of an environmental event; it is only when those pieces are put together within a network of pieces that we began to make sense of that event. This, crudely, is what is meant by organizational learning. Organizational knowledge can be defined as a network of different but synchronized bits of individual knowledge. Organizational learning is related to the complex nature of those networks – that is, to its dynamic, changing capabilities. If, then, a system increases its complexity, it will increase its capacity to learn.

Still others propose that organizational learning is a function of the capacity of the network to disseminate information [15]. Like the complexity perspective of organizational knowledge in the previous paragraph, this perspective is intimately linked to the degree of complexity in the organizational network.

Methodology for Studying Complex Organizations

Before developing the methodological strategies that are useful for studying complex organizational system, it will be helpful to summarize a few of the assumptions that underlie complexity, all of which have been stated or implied in this manuscript. These assumptions guide our selection of methodological strategies in organizational studies.

1. Complexity science examines the dynamics of interactions among large numbers of adaptive agents [24].
2. Complex systems evolve dynamically and change nonlinearly (unpredictably; [21]).
3. Human systems do not exist in a state of equilibrium.
4. Complex systems are best described in terms of interactions among complexity mechanisms rather than as interaction among variables.
5. Complex dynamics are enabled rather than planned or controlled.

Traditional Methodologies in the Social Science

Perhaps the most common methodology used to study organizations involves field research strategies and regression statistical procedures. Field strategies permit researchers to draw conclusions in non-laboratory conditions. Regression techniques are based on assumptions of regular, predictable relationships among variables; if one finds such a relationship between variable A and variable B, the relationship was true yesterday and it will be true tomorrow [61]. Such relationships are predictable in that they assume that if you increase variable A, then a resulting change in variable B can be calculated.

While statistical methodology is certainly useful, it cannot deal with many of the conditions posed by complexity science. It is not suited, for example, for exploring dynamic aggregation in organizations, nor is it helpful for explaining nonlinear changes that occur at far from equilibrium states. In particular, its usefulness lapses when one seeks to understand interactions among, and outputs of, complexity mechanisms. Complexity mechanisms are a function of dynamic interactions among numerous agents, ideas, and even variables. Traditional statistical methodology is just not suited for this type of analysis. Statistical assumptions are better suited to equilibrium systems in which desired outcomes involve planning and control. Complexity science is not particularly interested in such outcomes.

A growing trend in organizational studies involves the use of qualitative strategies. Qualitative research requires careful observation of a social dynamic followed by thorough analysis of what was observed. Qualitative methodology is useful for observing dynamic activities and social mechanisms, and is rather widely used for that purpose [20,49,68,70]. Its drawbacks are that it is time and resource intensive and it does not allow one to freely experiment with, or freely change, a social mechanisms – one cannot readily play what – if games in qualitative analysis.

Methodologies for Complexity

The most widely used methodologies in complexity study in organizations are agent-based modeling (ABM), systems dynamics, and qualitative research. ABM replicates or mimics interactive dynamics among organizational agents. ABM is a simulation procedure in which individually programmed agents interact in a computer according to certain rules. Commonly used examples are NetLogo by Uri Wilinsky, Dynamic Network Analysis by Kathleen Carley, and Repast Agent Simulation Toolkit by Michael J. North. These simulations allow researchers to simulate interactions under a variety of conditions and to test the effects of various changes in those conditions. ABM has been used to explore such things as the dynamics that underlie personnel turnover [14], organizational design and performance under stress [19], and leadership as enabler of complex organizational functioning [73].

System dynamic analysis is similar to ABM in that it examines evolving relationships among agents. It differs in that those relationships are not governed by social rules as they are with ABM's, rather they're governed by mathematical defined relationships. Like ABM, it permits the researcher to experiment with various conditions. Sterman [77], for example, has used it to examine interactions among individual decisions and the effects of feedback on the decision process.

Both ABM and system dynamic computer programs permit researchers to base their simulations on data collected in real-world situations. Once that data is entered, however, the quality of the subsequent simulation is only as good as the quality of the rules or the equations that govern it. However the intent is not to predict specific outcomes; rather, the intent is to understand how dynamic relationships can affect outcomes. Carley's Dynamic Network Analysis, for example, permits a user to evaluate the effects of an evolving network on the capacity of the organization to diffuse knowledge. One can play with such things as the degree of interdependency among agents or the degree of centrality around vision (as Schreiber et al. did in their [74] study) to see how they influence the learning dynamic.

Qualitative research performs generally the same things that ABM and system dynamic analysis do, but it allows the researcher to continuously examine real life events rather than merely simulating those dynamics. The benefit is a closer description of reality; the drawbacks are that it is highly resource and time intensive (especially if one wants to obtain results as in-depth as are results available through simulations), and it does not generally permit much control over conditions that might influence outcomes. Interesting qualitive studies of complex dynamics have been conducted by such organizational theorists as Plowman, Baker et al. [68], who examined emergent conditions in an inner-city church, and Chiles, Meyer, and Hench [20], who studied the complex evolution of Branson, Missouri.

Conclusions

I believe that the best definition of complexity behavior is provided by Paul Cilliers [21]. To frame that definition, he argues that we often confuse complicated with complexity. A complicated system is one with many components interacting to perform complicated tasks, but all of those components maintain their original integrity. A jet plane, he said, is complicated: the components of the plane are unchanged by their relationship. Complex systems are composed of many interacting units, all of which are changed by that interaction such that they quickly loose their original form and function. Organizational theorists who study complex dynamics are seeking to observe and explain that dynamic [48,63]; to understand how organizations might be restructured to improve their capacity for complex outcomes [11]; to improve general leadership in organizations [51,57,80]; to restructure our understanding and implementation of strategic leadership [58], and to restructure how we think about reality, understanding, predictability, and scientific methodology [16,17,18,53,72].

Complexity is genuinely an interdisciplinary science, applicable equally to biology, physics, and the social sciences. Organizational sciences have experienced a number of cumbersome imports in the past: systems theory borrowed from biology [12], as did population ecology theory [33], and scientific management theory borrowed from mechanics [79]. Complexity theory, however, is not about biology or mechanics, it is about interaction dynamics – and this is common across multiple phenomena. It is also about change, not gradual change but change that surprises. It helps us understand how systems learn and adapt to their environment. It comes at a good time for organizational studies, and will help us adapt organizations to the dramatic, knowledge-oriented changes being experienced in world economies.

Future Directions

One is tempted to argue that organizational complexity theory represents a paradigm shift in the way we think about reality (in the Kuhnian sense; [46]), and there is considerable reason to do so. Complexity theorists, for example, acknowledges that the problems facing organizations are far too complex to be solved by rational thinking and planning, and that organizations must engage the interactive, complex capacity of all its employees to solve those problems [59]. Because of this, organizational complexity theory is probably one of the first truly postmodern theories of organization. Organizational complexity theory is premised on complexity mechanisms rather than on variables, thus the questions that emerge from this perspective are dramatically different from any that have been asked in the past (e. g., "how does level of interdependency interact with level of vision to influence temporal emergence of, and phase transitions in, organizational learning"). Complexity theory clearly separates itself from the notions of equilibrium that have so influenced 20th century organizational theory. It moves us away from the centrality of administration and focuses on the centrality of bottom-up, adaptive leadership. Its notions of leadership do not revolve around interpersonal relationships, as does most of leadership theory in the 20th century; rather, it revolves around interactive dynamics. Complexity theory proposes that organizational strategy should seek effective relationships, rather than competition, with other members of its niche. Simply put, complexity theory is a dramatically different way to understand organization.

Complexity theory has captured the attention of academics and practitioners. Important indications of this include the large number of articles on the subject that are appearing in scholarly journals (e. g., the August, 2007, edition of *The Leadership Quarterly* was a special issue on complexity leadership) and the fact that complexity-related articles are being published in top-tier journals (e. g., [11,68]); the increasing number of complexity-related grants in organizations (NSF began a complexity category for organizational scholars in 2007); and a significant surge in the number of practitioners who are seeking consultant relationships with complexity theorists.

A number of interesting research questions are emerging from the complexity paradigm. Andriani and McKelvey's work on extreme events could have significant implications for the way we approach Katrina-like tragedies in the future, for example. The work to develop methodologies such as agent based modeling can have tremendous impact on how we analyze organizational dynamics. The idea that organizational behavior is about the actions of mechanisms is beginning to sink in among scholars, and could dramatically realign the way we think about organization. Complexity leadership theory poses unique questions for the role of strategic leadership and challenges the very way we perceive leadership.

Arguably, there has not been a true paradigm shift in organization studies since Weber introduced his concept of bureaucracy [59]. At the risk of being overly optimistic, organizational complexity theory may be changing this.

Article Outline

Glossary

Agent (or software agent) A self-contained entity that has a state and that is situated (able to perceive and act) in an environment. In addition, agents are often assumed to be rational and autonomous.

Cellular automaton A mathematical structure modeling a set of cells that interact with their neighbors. Each cell has a set of neighbors and a state. All the cells update their values simultaneously at discrete time steps. The new state of a cell is determined by the current state of its neighbors according to a local function or rule.

Microlevel simulation A type of simulation in which the specific behaviors of specific individuals are explicitly modeled.

Definition of the Subject

Social phenomena simulation in the area of agent-based modeling and simulation concerns the emulation of the individual behavior of a group of social entities, typically including their cognition, actions, and interaction. Agent-based social simulation constitutes the intersection of three scientific fields, namely, agent-based computing, the social sciences, and computer simulation [6]. Agent-based computing is a research area mainly within computer science and includes, e. g., agent-based modeling, design, and programming. By the social sciences we here refer to a large set of different sciences that study the interaction among social entities, e. g., social psychology, management science, policy, and some areas of biology. Computer simulation concerns the study of different techniques for simulating phenomena on a computer, e. g., discrete-event, object-oriented, and equation-based simulation.

Introduction

Computer simulation consists of three main steps: (i) designing a model of an actual or theoretical system, (ii) executing the model on a computer, and (iii) analyzing the execution output. Already in the early days of computer development, simulation was used in different research areas to predict the behavior of complex systems. Such simulations were typically based on differential equations and focused on results at the aggregate level. These models of, for instance, predator-prey populations could result in fairly accurate models but were limited in the sense that the models excluded individual behavior and decision making, as well as interaction between individuals, and were based on homogeneous agents. The development of agent-based modeling offers a possible solution to this problem with its (seemingly) natural mapping onto interacting individuals with incomplete information and capabilities, no global control, decentralized data, asynchronous computing, and inclusion of heterogeneous agents. Agent-based simulation models also offer the possibility of studying the dynamics of the interaction processes instead of focusing on the (static) results of these processes [16,26].

Agent-based modeling can be traced back to von Neumann, who in the 1950s invented what was later termed *cellular automata*. These were used by Conway in the 1970s when he constructed the well-known *Game of Life*. It is based on very simple rules determining the life and death of the cells in a virtual world in the form of a 2-D grid. Inspired by this work, researchers developed more-refined models, often modeling the social behavior of groups of animals or artificial creatures. One example is the Boid model by Reynolds [24], which simulates coordinated animal motion such as bird flocks and fish schools. With respect to human societies, Epstein and Axtell [8] developed in the 1990s one of the first agent-based models, called Sugarscape, to explore the role of social phenomena such as seasonal migrations, pollution, sexual reproduction, combat, and transmission of disease. This work is in spirit closely related to one of the best-known and earliest examples of the use of simulation in social science, namely, the Schelling model [27], in which cellular automata were used to simulate the emergence of segregation patterns in neighborhoods based on a few simple rules expressing the preferences of the agents. Another pioneer from the 1950s worth mentioning is Barricelli [2], who to some extent used agent-based modeling for simulating biological systems.

The cellular automata models closely resemble the models used in statistical physics, which has inspired physicists to include the simulation of social phenomena in large-scale social systems in their research agenda. In this area, sometimes referred to as sociophysics, phenomena such as opinion spreading in a society and competition between languages have been studied. These models originally described the behavior of atoms and molecules, which are quite simple objects, and the macrolevel phenomena caused by their interaction (rather than by complex behavior of the individual as in the case of humans). Thus, in these models little attention is paid to individual variation and the individual decision making is rather primitively modeled. A prominent example of sociophysics is the work of Galam [10].

To sum up, we can identify two main approaches to social simulation:

- Macrolevel (or equation-based) simulation, which is typically based on mathematical models. It views the set of individuals (the population) as a structure that can be characterized by a number of variables.
- Microlevel (or agent-based) simulation, in which the specific behaviors of specific individuals are explicitly modeled. In contrast to macrolevel simulation, it views the structure as emerging from the interactions between individuals and thus exploring the standpoint that complex effects need not have complex causes.

As argued by Van Parunak et al. [21], agent-based modeling is most appropriate for domains characterized by a high degree of localization and distribution and dominated by discrete decision. Equation-based modeling, on the other hand, is most naturally applied to systems that can be modeled centrally and in which the dynamics are dominated by physical laws rather than information processing. We will here focus on agent-based models, particularly those that have a richer representation of the individual than the cellular automata and statistical physics models.

Why Simulate Social Phenomena?

Simulation of social phenomena can be done for different purposes, e. g.,

- Supporting social-theory building;
- Supporting the engineering of systems, e. g., validation, testing, etc.;
- Supporting planning, policy making, and other decision making;
- Training, in order to improve a person's skills in a certain domain.

It is possible to distinguish between four types of end users: *scientists*, who use social phenomena simulation in the research process to gain new knowledge, *policymakers*, who use it for making strategic decisions, *managers* (of systems), who use it to make operational decisions, and *other professionals*, such as architects, who use it in their daily work. We will now describe how these types of end users may use simulation of social phenomena for different purposes.

Supporting Social-Theory Building

In the context of social-theory building, agent-based simulation can be seen as an experimental method or as theories in themselves [26]. In the former case, simulations are run to test the predictions of theories, whereas in the latter case simulations in themselves are formal models of theories. Formalizing the ambiguous, natural-language-based theories of the social sciences helps to find inconsistencies and other problems, and thus contributes to theory building.

Using agent-based simulation studies as an experimental tool offers great possibilities. Many experiments with human societies are either unethical or even impossible to conduct. Experiments in silico, on the other hand, are fully possible. These can also breathe new life into the ever-present debate in sociology on the micro–macro link [1]. Agent-based models mostly focus on the emergence of macrolevel properties from the local interaction of adaptive agents that influence one another [17,26]. However, simulations in computational organization theory [4,22], for example, often try to analyze the influence of macrolevel phenomena on individuals. Using agent-based models to simulate the bidirectional relation between micro- and macrolevel concepts would provide tools to analyze the theoretical consequences of the work done by theorists such as Habermas, Giddens, and Bourdieu, to name a few [26].

Supporting the Engineering of Systems

Many new technical systems are distributed and involve complex interactions between humans and machines. The properties of agent-based simulation make it especially suitable for simulating these kinds of systems. The idea is to model the behavior of human users in terms of software agents. In particular, this seems useful in situations where it is too expensive, difficult, inconvenient, tiresome, or even impossible for real human users to test out a new technical system. Of course, also the technical system, or parts thereof, may be simulated. For instance, if the technical system includes hardware that is expensive and/or special purpose, it is natural to simulate also this part of the system when testing out the control software. An example of such a case is the testing of control systems for "intelligent buildings," where agents simulate the behavior of the people in the building [5].

Supporting Planning, Policy Making, and Other Decision Making

Here the focus is on exploring different possible future scenarios in order to choose between alternative actions. Besides this type of prediction, simulation of social phenomena may be used for analysis, i. e., to gain deeper knowledge and understanding of a certain phenomenon.

An area in which several studies of this kind have been carried out is disaster management, such as experiments concerning different roles and the efficiency of reactions to emergencies [18]. Based on individuals' observations, personal characteristics and skills, past experience and role characteristics, and social network, the agents create a plan to execute. Each agent represents a human being (acting in a particular role). The effect of adding a role (floor warden) in a fire alarm scenario upon the evacuation efficiency in an abstract environment is analyzed. In another approach, the agents are placed in an environment based on GIS (geographical information system) data, thereby tying the simulation closer to the physical reality [29]. In yet another study, real-world data were used for both the environment and the agents' internal decision-making model to analyze the effect of different insurance policies on the willingness of agents to pay for a disaster insurance policy [3].

Another application area for this type of simulation study is disease spreading. Typically, agents are used to represent human beings and the simulation model is linked to real-world geographical data. One study [32] also included agents that represent towns acting as the epicenter of disease outbreak. The town agent's behavior repertoire consisted of different containment strategies. The simulation model can be quickly adapted to local circumstances via the geographical data (given that there is data on the population as well) and is used to determine the effects of different containment strategies.

A third area where agent-based social simulation has been used to support planning and policy making is traffic and transport. An example of this is the simulation of all car travel in Switzerland during morning peak traffic [23].

Training

The main advantage of using simulation for training purposes is to be part of a real-world-like situation without real-world consequences. Especially in the military the use of simulation for training purposes is widespread. Also in medicine, where mistakes can be very expensive in terms of money and lives, the use of simulation in education is on the rise.

An early product in this area was a tool to help train police officers to manage large public gatherings such as crowds, demonstrations, and marches [31]. Another early example of agent-based simulation for training purposes is Steve [19,25]. Steve was an agent integrated with voice synthesis software and virtual reality software providing a very realistic training environment for controlling the engine room of a virtual US Navy surface ship.

An example of a more recent project is the PSI agent [15]. Whereas in most cases the simulator training is aimed at training practical skills or decision making, this work focuses on acquiring theoretical insights in the realm of psychological theory. The simulation enables students to explore psychological processes without ethical problems.

Simulating Social Phenomena

One of the first, and most simple, way of performing microlevel simulation is often called *dynamic microsimulation* [11,12]. It is used to simulate the effect of the passing of time on individuals. Data from a (preferably large) random sample from the population to be simulated is used to initially characterize the simulated individuals. Some examples of sampled features are: age, sex, employment status, income, and health status. A set of transition probabilities are used to describe how these features will change over a given time period, e. g., there is a probability that an employed person will become unemployed over the course of a year. The transition probabilities are applied to the population for each individual in turn and then repeatedly reapplied for a number of simulated time periods. Sometimes it is necessary to also model changes in the population, e. g., birth, death, and marriage. This type of simulation can be used to, e. g., predict the outcome of different social policies. However, the quality of such simulations depends on the quality of:

- the random sample, which must be representative, and
- the transition probabilities, which must be valid and complete.

In traditional microsimulation, the behavior of each individual is regarded as a "black box." The behavior is modeled in terms of probabilities and no attempt is made to justify these in terms of individual preferences, decisions, plans, etc. Also, each simulated individual is considered in isolation without regard to their interaction with others. Thus, better results may be gained if cognitive processes and communication between individuals are also simulated.

Opening the black box of individual decision making can be done in several ways. The first layer to add is often individual psychology; for instance, the so-called beliefs, desires, and intentions (BDI) model is often used. Models of individual cognition used in agent-based social simulation include the use of Soar (a computer implementation of Allen Newell's unified theory of cognition [20]), which was used in Steve (discussed in Sect. "Why Simulate Social Phenomena?").

For the simulation of social behavior the agents need to be equipped with mechanisms for reasoning at the social level (unless the social level is regarded as emerging from individual behavior and decision making). Several models have been based on theories from economics, social psychology, sociology, etc. An example of this is provided by Guye-Vuillème [13], who has developed an agent-based model for simulating human interaction in a virtual-reality environment. The model is based on sociological concepts such as roles, values, and norms and motivational theories from social psychology to simulate persons with social identities and relationships. Another example is the Consumat model [14], a metamodel combining several psychological theories on decision making in a consumer situation, used, for instance, to investigate different flood-management policies [3]. Also, nonsymbolic approaches such as neural networks have been used to model agents' decision making [18].

Future Directions

In a recent study of applications of agent-based simulation [7], it was concluded that even if agent-based simulation seems a promising approach to many problems involving the simulation of complex systems of interacting entities such as social phenomena, it seems that the full potential of the agent concept often is not utilized. For instance, most models have very primitive agent cognition, in particular if the number of agents involved is large.

Regarding future applications, Fiedrich and Burghardt [9] argue that agent-based simulation is a very promising approach to disaster management practice. In particular, agent-based social simulation in combination with sophisticated visualization techniques, such as virtual reality, in the form of "serious games," has the potential to provide very powerful training environments. In the context of military training, Stone [28] provides some interesting applications.

Further Reading

Classic books in the area of simulation of social behavior include "Growing Artificial Societies: Social Science from the Bottom Up" by Epstein and Axtell [8] and "Simulation for the Social Scientist" by Gilbert and Troitzsch [12].

Glossary

Absorbing state In a stochastic process, a state from which there is no way out. Once the system reaches the absorbing state, it stays there forever.

Complete graph A graph where every pair of vertices is connected by an edge.

Configuration space The ensemble of all allowed states (configurations) a model system can reach. Any point in configuration space represents one such state.

Graph an assembly of points (vertices), some of which are connected by lines (edges).

Hypercubic lattice A generalization of a rectangular plane mesh; a graph embedded in a space of arbitrary dimensionality d. Assuming rectangular coordinates $x_1, x_2, \ldots, x_d$, the coordinates of the vertices in a hypercubic lattice are all whole numbers.

Markov process A special type of stochastic process. In a Markov process the system changes its state randomly and, most importantly, the changes of state are independent of history. A Markov process is a memoryless system.

Random walk A stochastic process describing hops of a particle to randomly chosen neighbor sites on a lattice.

Stochastic process A sequence of random events. At each time t, which may be either discrete ($t = 1, 2$, etc.) or continuous, a new random variable is introduced representing the outcome of the process in that time. Also called a random process.

Definition of the Subject

Modeling social phenomena as if they were manifestations of mutual interactions of physical objects is the ultimate goal of the reductionist approach to reality. Both the inanimate and animate worlds, including all the behavior of humans, would be traced back to the properties of atoms and molecules. This program is absolutely unrealizable, though. On the other hand, the discipline of **sociophysics** tries to bypass the brute-force approach by developing schematically effective models which aim at describing reality at a "macroscopic", rather than microscopic, level.

For example, when one wants to model the behavior of a large assembly of humans facing the necessity of choosing between two options, it is customary to neglect all details of the behavior of the people involved and describe their states by two-value quantities, such as $s = +1$ or $s = -1$; physicists call them spins. The interactions are often expressed using a cost function, which physicists call energy. The state with lowest energy is favored, but there are also external perturbations, or noise, which prevent the system from settling in that state. Physicists call the measure of the noise the temperature. The system of interacting spins at a certain temperature then serves as a model of the particular situation in human society.

It is a non-trivial question if such approach could work and if so, why. The essential ingredient for its functioning is **universality**. This notion, borrowed from statistical physics, means, that the behavior of the system does not ultimately depend on the details of that system, but only on its generic features. In plain words, for the description of the human mind, the behavior of a driver on a highway, or of a stockbroker, it is irrelevant whether the matter is composed of quarks, strings or whatever elementary particles may be discovered. The description of the world at the "macroscopic" level is detached from "microscopic" details.

It is the task of **sociophysics** to develop suitable macroscopic models that conform to observed facts about society and, at the same time, yield themselves to the methods of theoretical physics. There are non-negligible successes in this effort, yet still many areas remain unexplored. Consequently, the subject is alive and in a state of rapid progress.

Historical Introduction

It has been nearly two hundred years since the notion of social physics was introduced by the French philosopher Auguste Comte [1] in his attempt to revolutionize all thinking under the banner of positive philosophy. He himself abandoned that term later [2], but the idea of connecting social and physical phenomena in a unified frame has been around since. Later on, it somehow degenerated into a purely descriptive science, borrowing from physics nothing more than the tendency to exactitude in measurements; a prominent name to cite in this context is the Belgian statistician Adolphe Quételet. Little use stems from twopenny analogies, advocated by some later followers of Hegelian philosophy, between phase transitions, such as boiling water, and abrupt changes, mostly violent ones, in human society. Nonetheless, you may still find these considerations, based on the "quantity turns into quality" principle, in popular-philosophy brochures.

Skipping ahead a little more than a century and half since Comte, the first modern attempt to bridge the gap between social sciences and physics was marked by a memorable conference scheduled to take place in Moscow, 1 to 5 July 1974. Scientists both from the West and from the USSR were to discuss implications of physics for other fields, including social sciences and humanities. The organizing committee included people such as Kenneth Arrow, Nobel laureate for Economy and Hans

Bethe, Nobel laureate for Physics. Among the speakers was Andrei Sakharov, the well-known dissident and Nobel laureate for Peace. However, the Communist authorities stepped in, the conference was banned, most of the Russian participants were arrested, and a majority of them were exiled. However, many of the manuscripts were smuggled from the USSR to the West, and eventually the contributions were published in a proceedings volume [3]. A small sample of it appeared in [4].

In the 1980s, a very fruitful and general concept of synergetics was developed by H. Haken and his followers. The main idea consists in spontaneous emergence of coherent structures. In addition to being illustrated by examples from several branches of physical sciences (e. g. lasers) the idea was also elaborated in the context of social phenomena [5].

About the same time, the science of complexity started to gain wider popularity (and continues to do so to this day). The Santa Fe Institute in Santa Fe, USA, pioneered this research; it was here that complex system theory began to be systematically applied to economics and, more generally, to all human social behavior. Another Physics Nobel laureate, P. W. Anderson [6], has played a prominent role in promoting this path.

To finish this historical overview, the journey returns to France, where since the early 1980s the group of Serge Galam has been busy developing genuine physical models of social phenomena, also using he term sociophysics consistently [7,8,9]. Let us stop here and turn to several selected topical problems, where physically based models may help answer social scientists' questions.

Individualism Versus Cooperation

People never earn their living alone. From the darkest prehistorical past they have joined together to form gangs, stalking and hunting their prey. Without communication within the band, our ancestors could hardly have caught a mammoth, language would never have evolved and human brain capacity would probably never have exceeded that of a lemur. In short, cooperation between humans has been decisive in shaping the world around us. A tendency to cooperation is an inherent feature of human nature.

It was not until the middle of the eighteenth century or so that a different view started to spread. In this view, people are presented as selfish profit-seekers and if any cooperation is observed, it occurs *despite* the natural tendency to maximize personal gain, or as a by-product of that tendency. Under vague names such as neo-liberalism and social Darwinism, these and related ideas pervade the current thinking on human society.

On the other hand, empirically, cooperation is much more evolved now and assumes more sophisticated and complex forms than in the old times when it was considered self-evident. To detect this more complex cooperation, however strong it may be, requires external explanation. The starting point is a zero hypothesis of non-cooperation, from which cooperation emerges by some nontrivial mechanism to be discovered.

Prisoner's Dilemma Game

Games in General *Game theory* [10,11], introduced in 1940s by John von Neumann and Oskar Morgenstern provides very fertile ground on which to model the starting assumption of selfish individuals. In this model, agents are not only utterly selfish, but also absolutely rational. In a typical setup, agents meet in pairs and each of them chooses one of S possible strategies. If the first agent adopts strategy i and the second agent strategy j, then the first one gains an amount denoted A_{ij}, while the other's gain is A_{ji}. The matrix A is called a *payoff matrix*, and various types of games are distinguished according to its properties. For example, if the gain of one agent equals the loss of the other agent, so $A_{ij} + A_{ji} = 0$ for all i and j, it is a zero-sum game. If the gain of the winning party is always smaller than the loss of the adversary, the game is a negative-sum one, so it holds that $A_{ij} + A_{ji} < 0$ for all i and j.

It is assumed that the rules of the game, quantified in the matrix A, are known to both players. Therefore, they can build their strategies on rational analysis of the payoff matrix. It may happen that one strategy gives highest gain, irrespective of the action taken by the opponent. Formally, the first player's strategy, k, is such that $A_{ij} \leq A_{kj}$ for any strategy i of the first player and any strategy j of the second player. The same may also hold for the second player. Suppose that l is her best strategy, irrespective of the action of the first player. Obviously then, the first person always plays k while the second always plays l. If either player changes his or her strategy unilaterally, he or she is instantly worse off. Such a situation, if it happens, is called Nash equilibrium, after John F. Nash, a mathematician who devoted much of his career to applications of game theory in economics [12,13].

It is vital to understand that the notion of Nash equilibrium differs fundamentally from the usual equilibrium studied in various branches of physics. Whether the problem is to find the equilibrium of solid bodies on a lever or thermodynamic equilibrium in a system of steam, water and ice, the situation is formalized by finding a unique function to be minimized (energy, for example). On the contrary, Nash equilibrium means that every player maximizes his or her own function, with state of all other players fixed [14].

Introduction to Prisoner's Dilemma Collaboration has been studied using a very simple two-player game with two strategies, called the prisoner's dilemma game. Imagine that the police have arrested two accomplices for a burglary, but do not have enough evidence to prove that they actually committed the crime. The prisoners are kept well separated and the investigator offers a deal to each of them independently. Each criminal is given a promise that if he parts company with the other and confesses to the robbery they did together, he will be rewarded. If both of them confess, they will be jailed only for a short period; if one confesses and the other does not, then the first one is released and rewarded and the other gets a severe punishment; if neither of them confesses, both are released. Each must choose without knowing the other's choice.

The strategy of collaboration (C) dictates not to confess. In fact, it would be most beneficial to both suspects, if both collaborate. However, individually it is more tempting to defect (D) and confess to the police, as it prevents the situation in which the other confesses and the individual is punished alone. If both prisoners reckon in this way, the result is that both defect and must suffer some time in prison. Hence the dilemma.

The payoff matrix of this prisoner's dilemma game is characterized by four numbers, the gain if both defect, $A_{DD} = P$, or both cooperate, $A_{CC} = R$, and the gain of the defector $A_{DC} = T$ and the collaborator $A_{CD} = S$, if one of them defects and the other does not. So,

$$A_{PD} = \begin{array}{cc} C\,D & \\ \begin{pmatrix} R\,S \\ T\,P \end{pmatrix} & \begin{matrix} C \\ D \end{matrix} \end{array} . \tag{1}$$

In order for the prisoner's dilemma to work as described above, the values must satisfy the inequalities $T > R > P > S$ and $2R > S + T$. The most studied values of the parameters are

$$T = 5\,, \quad R = 3\,, \quad P = 1\,, \quad S = 0\,. \tag{2}$$

It is easy to see that there is a single Nash equilibrium: the case in which both players defect. We arrived at this conclusion intuitively, above, and an exact check is even quicker. If the second player collaborates, the rewards of the first are R and T if he collaborates or defects, respectively; because $T > R$, defection is better. Similarly, if the second player defects, the gains for the first are S and P, and as $P > S$, it is again preferable to defect. So, defection is the optimal strategy.

Evolution of Cooperation

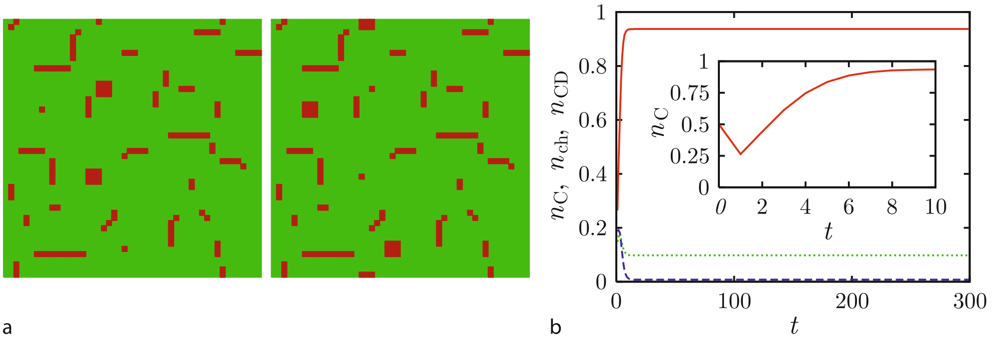
Iterated Prisoner's Dilemma The prisoner's dilemma game is rather trivial: if the players meet only once, defecting is certainly the best strategy. The Nash equilibrium excludes cooperation a priori, coinciding with the neo-liberalist view of society. What, then, is the mechanism behind the cooperation seen in reality? If there is a way for emergence of cooperation in the prisoner's dilemma game, perhaps we can see why reality sometimes follows that path.

Things become much more complex if the players face each other in an unlimited series of encounters. Robert Axelrod showed [15,16,17], in a series of computer tournaments, that complex strategies, taking into account past actions of the adversary, perform much better than simple defection. The generic and repeatedly confirmed outcome was that the strategy called Tit-For-Tat (TFT) outperformed all the rest of the strategies tried. It consists in playing cooperation at first and then repeating the last action of the other player.

Even more complicated behavior emerges if there is some level of noise. The players can make mistakes, or sometimes play at random, not obeying their usual strategies. New strategies may emerge due to mutations. Also relevant is the length of the players' memories, i. e. how many steps in the past they remember their opponents' actions. When all agents are put into a common room, where all of them they can play with all others, mixtures of strategies emerge [18,19]. The composition of the mixture depends on the length of the memory of the agents; if the memory length is unlimited, the evolution of the system proceeds indefinitely, introducing more and more complex strategies all the time.

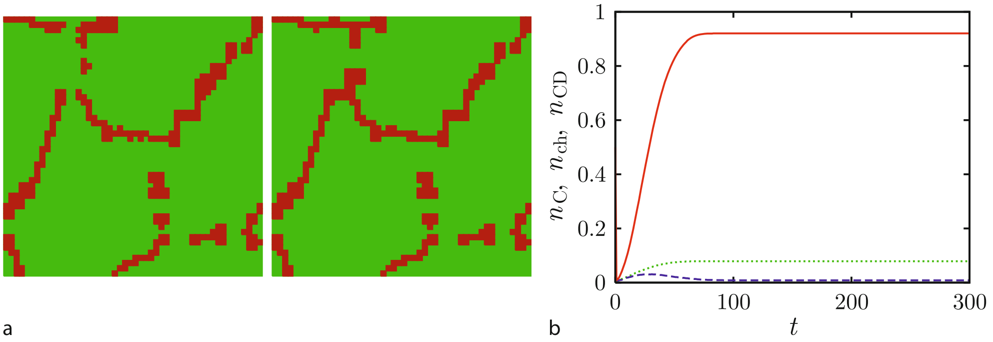
Spatial Prisoner's Dilemma The trivial prisoner's dilemma game becomes complex when the players play again and again with the same opponent. But, extending the model to cover a wider field, how it could be that among billions of people a player finds the same opponent he or she has already faced? If the two were molecules in a well-stirred container, their chance to meet repeatedly would be virtually nil. Some *compartmentalization* of the agents must be imposed, in order to apply the iterative prisoner's dilemma to a large number of players. But the influence of compartmentalization can also be studied independently, preferably in its extreme version, where immobile agents are fixed at the vertices of a network, for example a two-dimensional square lattice: that is the structure used throughout this subsection.

Agents play the usual prisoner's dilemma game with their eight neighbors. The complexity stems from their



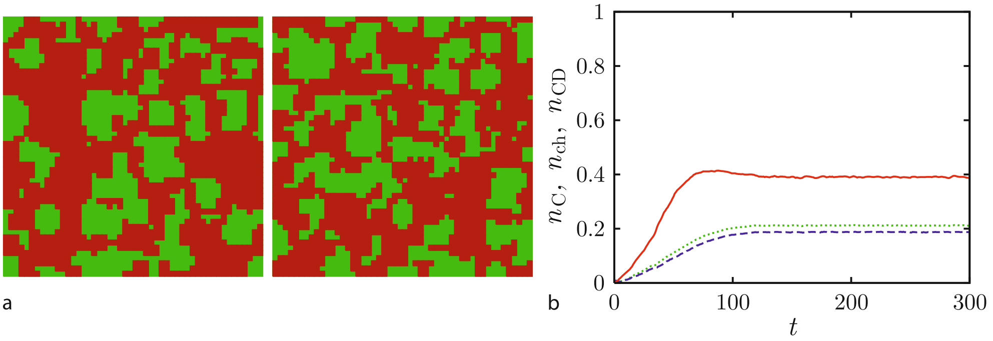
Social Processes, Physical Models of, Figure 1

Spatial prisoner's dilemma. In the *left two panels*, the configuration is drawn in times t_1, t_2, $t_1 < t_2$, on the lattice with $L = 50$. Cooperating agents are shown in *green*, the defectors in *red*. In the *right panel*, time evolution of the density of cooperators n_C (*solid line*), density of agents changing their state from one step to the next n_ch (*dashed line*), and density of interfaces n_CD (*dotted line*) are shown. System size is $L = 100$, data are averaged over 100 realizations. The incentive to defect is, $b = 1.05$. The initial condition is random spatial distribution of cooperators with density $n_\mathrm{C} = 0.5$. In the *inset*, the detail for short times is shown



Social Processes, Physical Models of, Figure 2

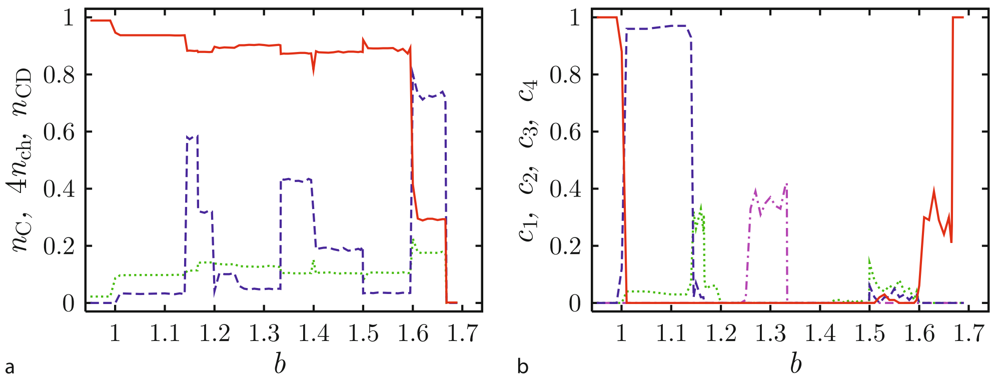
Same as Fig. 1 with $b = 1.5$



Social Processes, Physical Models of, Figure 3

Same as Fig. 1 with $b = 1.6$

ability to change their strategies from one step to the next [20]. For simplicity, let us consider only the 0-memory strategies: collaboration and defection. At each round, the agent adds her gain from the eight plays with her neighbors, who do the same in their turn. Each agent then decides upon her strategy for the next step. She looks at the gains of her neighbors and compares these numbers with her own. If any of the neighbors earns more than she, the agent adopts the current strategy of the most successful neighbor for the next step. Otherwise, the agent repeats her previous strategy. The evolution of the strategies proceeds by imitation.



Social Processes, Physical Models of, Figure 4

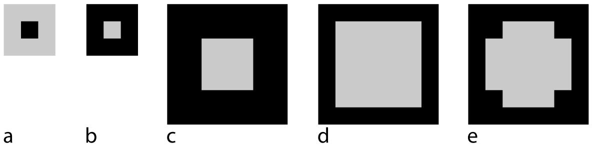
Spatial prisoner's dilemma. Various parameters of the stationary state depending on the incentive to defect *b*. All data are calculated for a lattice with $L = 100$; initial configuration is a random spatial distribution of cooperators with density $n_C = 0.5$; data are averaged over 100 realizations. The *left panel* shows the density of cooperators (*solid line*), density of sites changing their state from one step to the next (*dashed line*), and density of bonds connecting cooperators with defectors (*dotted line*). The *right panel* shows the fraction of realizations reaching static configuration (*solid line*), and fractions reaching cyclic attractors with period 2 (*dashed line*), 3 (*dot-dashed line*), and 4 (*dotted line*)

The payoff matrix can be simplified so that there is only one control parameter, the temptation to defect b. It is assumed that $T = b > 1$, $R = 1$, and $P = S = 0$. The spatial prisoner's dilemma game is then simulated, starting from a random configuration, where every agent chooses cooperation or defection with equal probability. Further evolution proceeds by deterministic parallel dynamics, as described above. In fact, the system is a cellular automaton with specific, relatively complicated, update rules. The resulting configurations are illustrated in Figs. 1 to 3. The cooperators survive in significant proportion even if the temptation for defection b is large. However, their spatial arrangement strongly depends on the value of b. Figure 1 shows the situation for the value $b = 1.05$, only slightly above the lowest limit compatible with prisoner's dilemma inequalities. Small groups of defectors survive within a large sea of cooperators. Most of the defector groups are stable or change cyclically with a short period. When the temptation is increased to $b = 1.5$, isolated islands of defectors grow into strings joined together at some places, as seen in Fig. 2. Cooperation still prevails, but only within patches encircled by defectors. The spatial structure exhibits only small variations in time. This changes when the temptation grows further. Figure 3, where $b = 1.6$, already shows more defectors than collaborators and the arrangement changes chaotically.

Systematic study of the dependence on b is summarized in Fig. 4 showing data from simulations, averaged over many realizations of the initial conditions. First, the fraction of cooperators, n_C, remains quite high, above 80%, up to about $b = 1.6$, where it drops suddenly to about 40%; only above $b = 1.7$ do the cooperators vanish. Clearly, repeated games induced by fixed spatial arrangement of the players strongly encourages cooperation. Note that the players do not follow any strategy based on observation of the past behavior of the agents. The cooperation emerges spontaneously.

Further inspection of the dependence of n_C on b reveals sudden jumps at specific values of the temptation parameter. The jumps are even more pronounced in some other parameters characterizing the stationary state, namely the concentration n_{ch} of sites changing their state from one step to the next, and the concentration of bonds (neighbor pairs) connecting a defector and a cooperator, n_{CD}, which is the measure of the density of interfaces between cooperating and defecting domains. Furthermore, some realizations end in static configurations, while other reach a cyclic attractor with short periods 2, 3, or 4. The fraction of realizations corresponding to these four types are denoted c_1, c_2, c_3, and c_4, respectively. Of course, some initial conditions may also lead to longer stationary periods or to a quasi-chaotic state with a barely identifiable periodicity. Interestingly, the quantities c_i depend on b in a very irregular fashion. For example, the period-2 states dominate in an interval from $b = 1$ to about $b = 1.14$, but are rare elsewhere. In contrast, the period-3 states occur practically only in the interval $5/4 < b < 4/3$.

To understand these features it is necessary to analyze various spatial structures produced in the dynamics [21]. For example, an isolated defector in the sea of cooperators, as shown in Fig. 5a, has 8 cooperating neighbors, so its gain is $g_D = 8p$. The neighbors themselves have 7 cooperating neighbors, resulting in gain $g_C = 7$. This means that for $p < 7/8$ the defector becomes cooperator in the next step,



Social Processes, Physical Models of, Figure 5
Several configurations of the defectors (*black*) and cooperators (*gray*) in the spatial prisoner's dilemma game on a square lattice. Their stability is discussed in the text

but for $p \geq 7/8$ it survives. Similar analysis shows that an isolated cooperator surrounded by defectors, Fig. 5b, is never stable. Indeed, the cooperator gains 0, but each of the the neighboring defectors gains p.

It is possible to proceed further to more and more complicated geometries. For example, a 2×2 square of cooperators, Fig. 5c, is much more stable than an isolated cooperator. Each of the four gains $g_C = 3$ from its three cooperating neighbors. The defecting neighbors are of two types. At the corners, they have one cooperator to exploit, so their gain is p. The defectors adjacent to the edges of the square have two cooperating neighbors, giving higher gain $g_C = 2p$. Therefore, the square persists for $p \leq 3/2$. But that is not all; the defecting neighbors see that the cooperators gain more, so they become cooperators themselves in the next step. For $p < 3/2$ the initial 2×2 square grows into a 4×4 square of cooperators, Fig. 5d, which in turn expands into 6×6 square, and so on. Cooperation spreads despite the relatively large value of the temptation to defect!

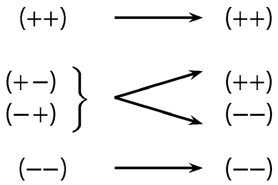
Some configurations may exhibit periodic changes. A multitude of possible generalizations can be found in the literature, either concerning update rules [22,23,24,25] or geometry of the links connecting interacting neighbors [26,27,28,29,30]. However, the general features of the spatial prisoner's dilemma game remain in force, namely the fact that repeated plays against the same agents, which are dictated by the geometry of the social network, leads naturally to coexistence of large patches of collaborators alternated with various arrangements of defectors.

To sum up, spontaneous emergence of cooperation seems to be reproduced in model situations, on condition that the game is played repeatedly. The overall picture of cooperation is typically rather complex, precluding any simplistic ideology-based conclusions.

Opinion Dynamics

Voter Model

People can make up their minds by simply looking around and picking the opinions of randomly chosen neighbors.



Social Processes, Physical Models of, Figure 6
Illustration of the dynamics of opinions in the voter model. The scheme shows how pairs of neighboring sites are updated. If the two sites have identical states, they remain unchanged. If the single-site states differ, they can become either both + or both − with equal probability. Conservation of average magnetization follows directly

That is the idea behind the stochastic process introduced in 1970s [31,32] and called the *voter model*. The voter model plays a special role among other models of opinion spreading and consensus formation, because it is exactly soluble in any spatial dimension, while showing highly non-trivial dynamics [33,34,35,36,37,38,39,40,41]. Physicists are interested in the voter model, as it can shed light on spinodal decomposition [35] and chemists use it to model catalytic reactions [36,37,42].

Definition In fact, there is a whole family of diverse voter models [43]; the exactly soluble class comprises the so-called linear voter models.

The most studied geometry is the d-dimensional hypercubic lattice Λ of linear dimension L, with periodic boundary conditions. The coordinates of the point $x \in \Lambda$ will be denoted $x_\alpha, \alpha = 1, 2, \ldots, d$.

On each lattice site there is an agent whose state can be either $+1$ or -1. These two choices can represent a person's political preferences in a two-party system, hence the name voter model. The configuration of the entire system is described by a point in the configuration space $\sigma \in S = \{-1, +1\}^\Lambda$. The state of the site $x \in \Lambda$ is denoted $\sigma(x)$.

The dynamics of the model are very simple. In each step, one site x and its neighbor y are chosen randomly. Then x adopts the state of y, so $\sigma(x)$ is replaced by $\sigma(y)$, as illustrated in Fig. 6. This scheme also demonstrates one important property of the voter model. The average opinion, which a physicist would call magnetization, defined as $m = (1/|\Lambda|) \sum_{x\in\Lambda} \sigma(x)$ is conserved after averaging all possible realizations of the process, even though in individual realizations it may fluctuate. It is also evident that the uniform states where all sites are either $+1$ or -1 never change. These two configurations are *absorbing states* of the voter model.

In one dimension the dynamics can be easily understood. The configuration is determined by the sequence of "domain walls", separating regions uniformly populated by $+1$ or -1. The configuration can change only by flipping the state of the sites beside the domain wall. Either the agent to the left of the wall adopts the state of the agent on the right side, or vice versa. In the former case the domain wall moves one step leftwards, in the latter case it jumps rightwards. Both possibilities have the same probability, so the domain wall performs a random walk. Moreover, when two domain walls meet, the region bordered by them disappears and the domain walls themselves annihilate. So, the one-dimensional voter model is exactly mapped onto the system of annihilating random walkers. This model is quite well understood [44]. Unfortunately, in any dimension larger than one such equivalence is no longer valid.

A slightly more formal description goes as follows: The voter model is a continuous-time Markov process σ_t which takes values in the configuration space $S = \{-1, +1\}^{\Lambda}$. For any $\sigma \in S$ denote as σ^x the state which is obtained from σ by flipping the state of site $x \in \Lambda$, so $\sigma^x(y) = (1 - 2\delta_{xy})\sigma(y)$. It is necessary to know the set of nearest neighbors of x on the lattice Λ. In the case of a d-dimensional hypercubic lattice, there are $2d$ neighbors obtained by shifting the point x by either $+1$ or -1 along the d Cartesian axes. Denote μth neighbor of x by x^{μ}. The transition rates describing a single flip are

$$w(\sigma, \sigma^x) = \frac{1}{2}\left[1 - \sigma(x)\frac{1}{2d}\sum_{\mu=1}^{2d}\sigma(x^{\mu})\right] \tag{3}$$

while all other transition rates are zero

$$w(\sigma, \sigma') = 0\,, \quad \text{if} \quad |\{x \in \Lambda\colon \sigma(x) \neq \sigma'(x)\}| \neq 1\,. \tag{4}$$

The dynamics proceeds according to the master equation

$$\frac{\mathrm{d}}{\mathrm{d}t}p_t(\sigma) = \sum_{x\in\Lambda}\left[w(\sigma^x, \sigma)p_t(\sigma^x) - w(\sigma, \sigma^x)p_t(\sigma)\right]\,. \tag{5}$$

Solution It is possible to directly write the equation for the average state on a single site $S(x, t) \equiv \langle\sigma_t(x)\rangle = \sum_{\sigma\in S} p_t(\sigma)\sigma(x)$, starting with the master equation (5). The result is

$$\frac{\mathrm{d}}{\mathrm{d}t}S(x, t) = \Delta_x S(x, t)\,, \tag{6}$$

where the notation $\Delta_x f(x) = -f(x) + \frac{1}{2d}\sum_{\mu=1}^{2d} f(x^{\mu})$ is used for the discrete Laplace operator on the d-dimensional hypercubic lattice. Equation (6) is in fact the discrete diffusion equation, describing the movement of a random walker over the lattice.

For two-site correlations $R(x - y, t) \equiv \langle\sigma_t(x)\sigma_t(y)\rangle$, the equation is

$$\frac{\mathrm{d}}{\mathrm{d}t}R(x, t) = 2\Delta_x R(x, t) \tag{7}$$

for $x \neq 0$. If the two points coincide, it holds trivially $R(0, t) = 1$ for all times $t \geq 0$. Technically, this is the boundary condition for the solution of the discrete diffusion Eq. (7). In this way it is possible to get closed equations for correlations of all orders.

Equation (6) can be solved by standard mathematical techniques, including Fourier and Laplace transforms. The initial condition is as follows: at the origin the state is $+1$, while all other sites are $+1$ or $+1$ with equal probability, so $S(x, 0) = \delta_{x0}$. The solution is

$$S(x, t) = \mathrm{e}^{-t}\prod_{\alpha=1}^{d} I_{x_\alpha}\left(\frac{t}{d}\right)\,, \tag{8}$$

where $I_{\nu}(z)$ is the modified Bessel function [45].

Asymptotic behavior of the Bessel function gives that, for large times, the average state of any site decays to zero as $S(x, t) \sim t^{-1/2}$, $t \to \infty$. Recall that the initial condition was $S(x, 0) = \delta_{x0}$. So, the average state of the site at the origin decays to zero monotonically, while the other sites, $x \neq 0$, exhibit first an increase in $S(x, t)$ and then decay at later times. This can be understood as propagation of a diffusive wave of $+1$'s from the origin to the rest of the lattice, eventually vanishing at large times.

More information on the dynamics is contained in the two-site correlation function $R(x, t)$. Apart from the factor 2, it obeys the same equation as $S(x, t)$. However, there is an important difference. Equation (7) holds only for $x \neq 0$ and, besides the initial condition $R(x, 0) = \delta_{0x}$, the solution must also satisfy the boundary condition $R(0, t) = 1$. Nevertheless, it is possible, again, to proceed by Fourier- and Laplace-transforming the Eq. (7). The boundary condition enters through the yet unknown function

$$n_{+-}(t) = \frac{1}{2}\left(1 - \frac{1}{2d}\sum_{\mu=1}^{2d} R(x - x^{\mu}, t)\right)\,, \tag{9}$$

which is simply the concentration of interfaces, i. e., the fraction of the bonds connecting sites with unequal state, also called *active bonds*. This quantity is an important measure of the level of activity in the system, as changes of the configuration can occur only at sites adjacent to active bonds.

Let us now separately discuss the results in dimensions $d = 1$, $d = 2$, and $d \geq 3$. In one dimension, the density of interfaces can be expressed in closed form

$$n_{+-}(t) = \frac{1}{2}\mathrm{e}^{-2t}[I_0(2t) + I_1(2t)] \,. \qquad (10)$$

For large times, the behavior is $n_{+-}(t) \simeq (4\pi t)^{-1/2}$ and $\lim_{t\to\infty} R(x,t) = 1$. This means that the activity measured by $n_{+-}(t)$ slowly decays to zero and eventually all the agents become fully correlated. Both features are signatures of complete ordering, which is the fate of the voter model in one dimension.

For $d = 2$ the situation is similar. Again, the density of interfaces decays to zero and the correlation function approaches 1 for large times. However, the evolution is much slower. The solution can be expressed in closed form using the so-called elliptic integrals, but let us mention here only the asymptotic behavior

$$n_{+-}(t) \simeq \frac{\pi}{2}\frac{1}{\ln(16t)} \,, \quad t \to \infty \,. \qquad (11)$$

The behavior changes dramatically for $d \geq 3$, because $n_{+-}(t)$ has a positive limit for $t \to \infty$. In short, the activity never ceases and the voter model never reaches a totally ordered state. Explicit calculations show that the stationary density of interfaces becomes

$$n_{+-}(\infty) = \left(2d\int_0^\infty \left[\mathrm{e}^{-t}I_0(t)\right]^d \mathrm{d}t\right)^{-1} \,. \qquad (12)$$

The asymptotic behavior of the Bessel function guarantees that the integral converges for $d > 2$ and $n_{+-}(\infty) > 0$. Numerical values for some values of d are listed in Table 1 below. One can also find how the density of interfaces approaches its asymptotic value, $n_{+-}(t) - n_{+-}(\infty) \sim t^{1-(d/2)}$.

All the above results for the voter model tacitly assume an infinitely large lattice. In practice, e. g., in numerical simulations, the system always consists of a finite number, $N = L^d$, of sites. This implies that eventually the dynamics lead to one of the two absorbing states, even for $d \geq 3$, where the *infinite* system never orders. The time needed to reach any of the absorbing states in a particular realization of the process is called *stopping time* τ_{st}. The typical scale for the stopping time, called *consensus time* $\tau(N)$, diverges in the thermodynamics limit. It is possible to show rigorously [46] that the consensus time grows like $\tau(N) \sim N^2$ in $d = 1$, $\sim N \ln N$ in $d = 2$ and $\sim N$ for $d \geq 3$. These formulae can be understood on an intuitive level, at least in one dimension, where the dynamics is equivalent to diffusion of domain walls, annihilating upon encounter. The size of homogeneous areas grows, therefore, as the mean displacement of a random walk, $\sim t^{-1/2}$. The time needed to cover the whole system of size N is therefore $\sim N^2$. A similar consideration is also feasible in higher dimensions [36].

The asymptotics of the voter model on d-dimensional hypercubic lattice are summarized in Table 1. Where the behavior is indicated by "$\sim$", the meaning is $t \to \infty$ or $x \to \infty$ or $N \to \infty$, according to the context.

Local Majority Models

Galam Model In democracy, consensus on an issue is rarely achieved by simply waiting until one of the options pervades the whole system through pairwise contact of individuals. Instead, there are various hierarchical levels of decision making, each of which comes to a conclusion based on the principle of majority. This is supposed to lead to a state in which most people are satisfied, when the opinion of the majority of those who participate in the decision process is declared a law. If there were only a single hierarchical level, namely a public referendum (Switzerland may serve as a model example), one could be quite sure that the outcome really represents the majority opinion in the society. However, as soon as there are more levels, and decisions on lower level are passed on to levels above, there is no obvious guarantee that the opinions are not distorted or even reversed. Serge Galam devised a simple model demonstrating that the distortions may not be an exception, but rather a rule [47,48,49,50,51].

The reason for breaking the society into several hierarchical levels is that the cost of communication in a too large collective is prohibitive. It is interesting that this is also the main technical obstacle hindering the introduction of secure electronic elections. One can imagine voting for a presidential candidate from one's home computer over the Internet, but to make the protocol reliable enough to ensure proper secrecy *and* resistance to any attempt at fraud on the scale of an entire nation seems to be beyond currently available technical capabilities [52].

So, the model takes it for granted that the society is organized hierarchically and, on each level, the decision is made within a small group, say, of 3 people. Within each group, majority rule tells what opinion shall be held by the representative of the group when sent to make decision on the upper level. Now, suppose there are only two possible choices, A and B and the fraction of people with opinion A on the level l is $n_A(l)$. On the basic level, $n_A(0)$ represents the concentration of A in the whole population.

Supposing that the people are not correlated in any way, the concentrations $n_A(l)$ provide full information on the system. Essentially, this is a kind of mean-field approx-

Social Processes, Physical Models of, Table 1

Table of some properties of the voter model on a hypercubic lattice in *d* spatial dimensions

						∞	1/2

imation, neglecting any social structure or network within one hierarchical level. The model of majority decisions on a complete graph, also studied in the literature [53,54], is to large extent equivalent to the Galam model.

The dynamics of the model consists in determining the fraction of A at level $n+1$ on the basis of the concentration on level n. For groups of size 3 it leads to the recurrence relation

$$n_A(l+1) = n_A^3(l) + 3\,(1-n_A(l))\,n_A^2(l)\,. \qquad (13)$$

The evolution according to this rule is depicted in Fig. 7a. There are three fixed points at values $n_{A\,\text{fix}} = 0, 1$, and $1/2$, which can be easily checked by insertion in (13). The two extreme values are stable, while the middle point is an unstable fixed point. This reminds us of physical systems with a phase transition, treated by renormalization group techniques [55]. In that formalism, the unstable fixed point corresponds to the critical value of a control parameter and the stable fixed points represent the various possible phases. Here there are two phases, populated uniformly by either all A or all B opinions, constituting total consensus on the issue.

The transition occurs at the symmetric point $n_{A\,\text{fix}} = 1/2$, where exactly half of the people have opinion A. In this sense, the decision making is "fair" because it leads to consensus according to the initial majority. However, a seemingly minor modification makes a big difference. Imagine that the groups formed at each level are composed of an even number of persons, e.g., four. The decision must be taken as to what to do if exactly half of the group pushes for decision A but the rest for B. No majority emerges and the tie must be resolved. If there is an arbitrarily small bias towards one of the choices, say, B, the recurrence relation for the concentrations of opinion A is

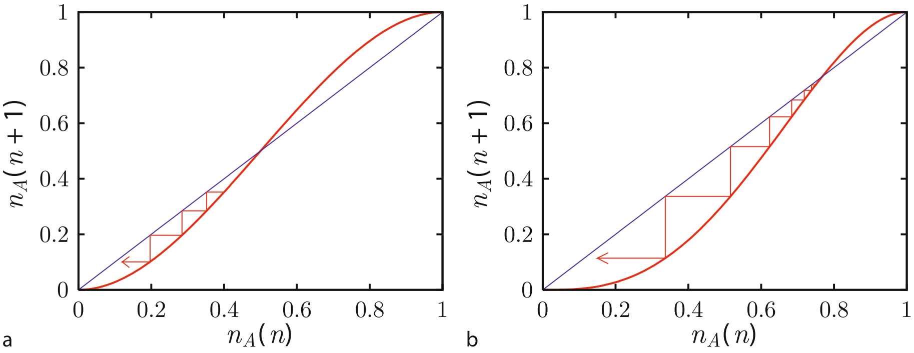
$$n_A(l+1) = n_A^4(l) + 4\,(1-n_A(l))\,n_A^3(l)\,. \qquad (14)$$

Figure 7b shows what happens. The unstable fixed point is shifted significantly to higher values of n_A, namely to

$$n_{A\,\text{fix}} = \frac{1+\sqrt{13}}{6} = 0.76759\ldots \qquad (15)$$

which means that opinion B may win even if it was initially in a minority!

The situation can be even more complicated if some of the people systematically vote against the majority, instead of following the crowd. Such agents are called *contrarians* [56,57]. For simplicity, take (again) groups of size 3. First, the majority option within the group in question is



Social Processes, Physical Models of, Figure 7

Galam model. In a, graph of the recurrence relation for groups of size 3. The *stairs* indicate how the iterations of the relation drive the system away from the unstable fixed point $n_{A\,\text{fix}} = 1/2$. In b, an analogous scheme for groups of size 4 with infinitesimal bias in favor of option *B*. Note the shift of the unstable fixed point to value $n_{A\,\text{fix}} = (1+\sqrt{13})/6$

found, then each member of the group flips her opinion with probability p_c, which is to be interpreted as the concentration of contrarians in the population. The recursion relation is modified to

$$n_A(l+1) = (1-p_c)\left[n_A^3(l) + 3\,(1-n_A(l))\,n_A^2(l)\right] + p_c\left[(1-n_A(l))^3 + 3(1-n_A(l))^2 n_A(l)\right] \tag{16}$$

and results in a shift of the stable fixed points away from the endpoints of the interval $[0,1]$. This means that total consensus is never reached; the contrarians always introduce a certain level of dissidence, but generally the final decision respects the initial majority option in the society. For $p_c < 1/6$ this picture remains valid, as there are three fixed points, with the unstable one keeping its position at $n_{A\,\mathrm{fix}} = 1/2$. However, if the concentration of contrarians rises and $p_c > 1/6$, the three fixed points coalesce to a single stable fixed point at $n_{A\,\mathrm{fix}} = 1/2$. No consensus is ever reached and the distribution of opinions tend to a precisely equilibrated state of equally represented opinions A and B. Several recent cases of popular referenda or presidential elections ending in extremely narrow victories come to mind, showing that the presence of contrarians may have palpable consequences for our lives.

A natural question is, how fast is consensus approached as one climbs higher and higher up ladder of hierarchies? It is evident that as we start closer to the unstable fixed point, it takes us more time to approach one of the stable points. To get a quantitative estimate, let us turn to the simplest case described by Eq. (13) and replace the discrete level index l by a continuous variable l which can be interpreted as time elapsed during the formation of the consensus. Thus, the differential equation

$$\frac{\mathrm{d}}{\mathrm{d}l} n_A(l) = -n_A(l)(n_A(l)-1)(2n_A(l)-1) \tag{17}$$

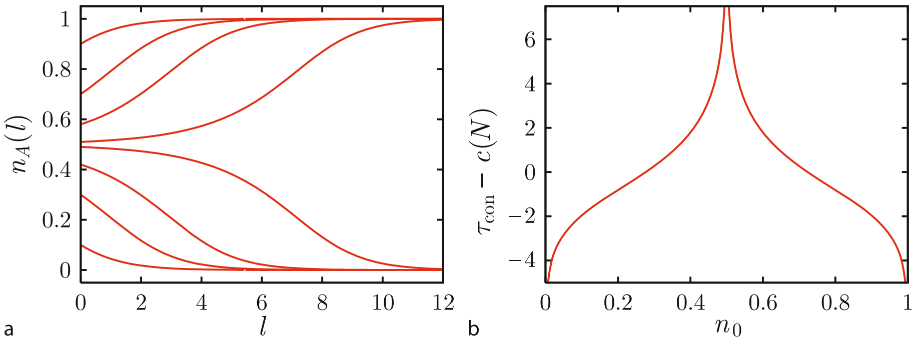
is obtained, which can be solved relatively easily. The solution for several initial conditions is shown in Fig. 8a. Of course, starting from any point $n_A(0)$ inside the interval $(0,1)$, the time to reach either of the stable fixed points 0 or 1 is infinite. However, in reality it is not necessary to reach the fixed point exactly, because the population consists of a finite number N of people, so full consensus is reached if the procedure is stopped at a distance $1/N$ from the fixed point. The time to achieve that diverges for increasing N as $\sim \ln N$, as will be seen from the explicit calculation.

To be more precise, the stopping time t_{st} as a function of the initial concentration $n_0 \equiv n_A(0) < 1/2$ can be defined by the formulae $n_A(0) = n_0$ and $n_A(t_{\mathrm{st}}(n_0)) = 1/N$, expressing the initial and final conditions, respectively. The case $n_0 > 1/2$ differs only in the final condition, which is $n_A(t_{\mathrm{st}}(n_0)) = 1 - 1/N$. Knowing the general solution of (17) the formula is

$$t_{\mathrm{st}}(n_0) = \ln\frac{n_0(1-n_0)}{(2n_0-1)^2} + \ln\frac{(N-2)^2}{N-1}\,. \tag{18}$$

Hence the already-mentioned logarithmic divergence of the stopping time for $N \to \infty$. The N-independent part of the stopping time can be seen in Fig. 8b. Note the divergence for $n_0 \to 1/2$, which can be regarded as a sign of a certain kind of dynamic phase transition.

The Galam model has potential for extensions in various directions and, indeed, it was further generalized [58,59,60,61,62,63,64,65,66,67,68]. For us, the most physically relevant question is how the dynamics change



Social Processes, Physical Models of, Figure 8

Galam model with continuous levels, for group size 3. The evolution according to Eq. (17) is shown in a, with initial concentration of opinion A equal $n_0 = 0.9, 0.7, 0.58, 0.51, 0.49, 0.42, 0.3$, and 0.1 (from *top* to *bottom*). In b, the time to reach consensus in a society of N people is shown. In this graph, $c(N) = \ln\frac{(N-2)^2}{N-1}$

if the people are distributed on a fixed lattice or network [69,70,71]. After all, the Galam model has all the attributes of a mean-field version of some more complicated model, even though it may not be obvious which one [72]. The next section will make the point more clear.

Sznajd Model Clearly, a group of people puts stronger pressure on an individual than each member of the group taken separately. Nature designed humans so that they follow the crowd. If you see two or more people sharing an opinion on certain issue, you are tempted to join. This is the basic idea behind the model invented by Katarzyna Sznajd-Weron and Józef Sznajd (the daughter and the father) [73]. In its first version, the model was defined on a one-dimensional lattice of length N. Each site is inhabited by an agent which can be in two states, denoted $+1$ and -1, as in the voter or majority-rule models. It may correspond to people choosing between two dominant brands of a certain product in the market or voting in a two-party political system. In each step of the dynamics, a pair of neighbors is chosen randomly. If they are in the same state, say, $+1$, then the two sites adjacent to the pair adopt the same opinion $+1$, propagating the consensus outwards. Conversely, if they differ in opinion, they propagate the dissensus. The rule is shown schematically in Fig. 9.

Formally, suppose the chosen pair is in state $(\sigma(x), \sigma(x+1))$, at time t. If $\sigma(x) = \sigma(x+1)$, the neighbors of the pair are updated as $\sigma_{t+1/N}(x-1) = \sigma_{t+1/N}(x+2) = \sigma(x)$, while for $\sigma(x) \neq \sigma(x+1)$ the update rule is $\sigma_{t+1/N}(x-1) = \sigma(x+1)$, $\sigma_{t+1/N}(x+2) = \sigma(x)$. Unlike the voter or majority rule model, there are three absorbing states. Besides the obvious "ferromagnetic" states of all $+1$ or all -1, there is the "antiferromagnetic" state where the sites in states $+1$ and -1 alternate regularly. Strictly speaking, there are two such states, one characterized by $+1$ at sites with odd coordinates and the other by $+1$ at even sites.

Looking at the rules more thoroughly, it is evident that the linear chain can be divided into two sublattices, one of them containing all odd coordinates x, the other all even sites. The state of the agents in one sublattice is never influenced by the agents in the other one. Moreover, the dynamics within one sublattice are a trivial modification of the voter model. The only difference is that in the voter model, one site induces change of state of one of its neighbors, while here the agent induces *both* of its neighbors adopt its state. Indeed, the update rule can be written as $\sigma_{t+1/N}(x-1) = \sigma(x+1)$, $\sigma_{t+1/N}(x+2) = \sigma(x)$, irrespective of the relation between $\sigma(x)$ and $\sigma(x+1)$ [74]. This observation simplifies the model to a large extent. Indeed, it is equivalent to two copies of the voter model evolving in parallel, where the only coupling between them comes from the fact that the sites to be updated are neighbors on the original lattice. The two voter models evolve so that the update occurs at the same place in both copies. However, the initial state of both sublattices is chosen randomly and independently and many properties, for example the concentrations of $+1$ in either of the sublattices, remain uncorrelated forever.

Restricting the study to one sublattice only, the solution follows the same way as was used successfully for the voter model. The flipping rates are analogous to (3), differing only in factor 2, originating from the fact that a site induces a change in state of its two neighbors. This factor means only a rescaling of time, so it is quite safe to neglect it. The result for the voter model can be translated directly to our case.

As a first application, let us look at the asymptotic states. The probability of reaching the state of all $+1$ is simply the concentration of $+1$ opinions in the initial state. This holds for both sublattices independently. From here, it is straightforward to deduce the probabilities P_+, P_- and P_{AF} that the system ends in absorbing states with all $+1$, all -1, and the antiferromagnetic state, respectively, as a function of the initial concentration of $+1$ opinions. Indeed, a state with all $+1$ means that both sublattices reached the uniform $+1$ state (and similarly for -1) while the antiferromagnetic state is obtained if one of the sublattices ended in a $+1$ state and the other in a -1 state. Hence

$$\begin{aligned} P_+(n_+) &= n_+^2 \\ P_-(n_+) &= (1-n_+)^2 \\ P_{AF}(n_+) &= 2(1-n_+)n_+ \,. \end{aligned} \tag{19}$$

The history of a single agent is also interesting. During its evolution, it may change its state several (including zero) times. The time elapsed between two subsequent changes of state is called *decision time* t_{dec}. It is natural to ask, what is the probability distribution of decision times of all agents? The answer relies on mapping the evolution of the voter model onto diffusive motion of domain walls. As explained in Sect. "Voter Model", the domain walls separating the regions of $+1$ and -1 opinions, evolve in time like annihilating random walkers. Selecting an agent at site x, its state flips if and only if the domain wall crosses the point x. The decision time is nothing other than the time between two successive visits of the random walker to the same position x, or, using language familiar to experts in random walks, the decision time is the time of first return of the random walk to the origin. Calculation of this quantity can be found in probability theory textbooks.

$$\text{Model of Ref. [73]}\ \left\{\begin{array}{lcl} \left.\begin{array}{lcl}(\cdot\,++\,\cdot) & \longrightarrow & (++++)\\ (\cdot\,--\,\cdot) & \longrightarrow & (----)\end{array}\right\}\ \text{Sznajd model} \\ (\cdot\,-+\,\cdot) \quad \longrightarrow \quad (-+-+) \\ (\cdot\,+-\,\cdot) \quad \longrightarrow \quad (-+-+) \end{array}\right.$$

Social Processes, Physical Models of, Figure 9
Illustration of the dynamics of opinions in the the model of Sznajd–Weron and Sznajd, as it appears in the first paper [73] and as it was modified subsequently and named the "Sznajd model". The dots replace any state of the site

The decision time distribution behaves asymptotically as a power law

$$P^{>}_{\mathrm{dec}}(t) \equiv \mathrm{Prob}\{t_{\mathrm{dec}} > t\} \sim t^{-1/2}\,, \quad t \to \infty \qquad (20)$$

and this is exactly what was found numerically in the founding work of the Sznajds.

The solution obtained by mapping to the voter model is only the beginning of the story. Things start to be exciting again as soon as the "simplification" of the dynamic rules introduced above is made, allowing only neighbor pairs with equal states to influence their neighborhood. If the two agents in the pair do not agree in their opinions, nothing happens. In the scheme shown in Fig. 9 this corresponds to taking only first two rows as allowed updates. It is this modification that has been widely studied, and common consensus has assigned it the name Sznajd model (although calling it "Sznajds' " would perhaps do more justice to the authors).

As a first step in the analysis of the Sznajd model, it is important to note that there are again three absorbing states, all $+1$, all -1 and the antiferromagnetic one. But now the antiferromagnetic state is unstable, because randomly flipping a single site results in a nucleus of three sites in the same state, which irresistibly invades the whole system. But although unstable, the existence of such an absorbing state leaves important traces in the dynamics, as will be more clear later.

The transition rates for the underlying Markov process are

$$\begin{aligned} w(\sigma, \sigma^x) = \frac{1}{8}\Big[&\sigma(x-2)\sigma(x-1) + \sigma(x+1)\sigma(x+2) \\ &- \sigma(x)\big(\sigma(x-2) + \sigma(x-1) + \sigma(x+1) \\ &+ \sigma(x+2)\big) + 2\Big]\,. \end{aligned} \qquad (21)$$

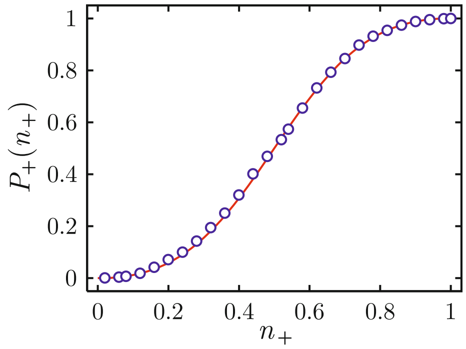
It is instructive to compare this with Eq. (3) describing voter model dynamics. The Sznajd model is a member of the family of non-linear voter models. This means that the transition rates depend non-linearly (quadratically, in fact) on the states of sites other than x.

There is a rather standard technique of approximate solution of similar systems, called the Kirkwood approximation. In our case, its use yields the probability for ending in the all $+1$ state in the form

$$P_+(n_+) = \frac{n_+^2}{(1-n_+)^2 + n_+^2}\,. \qquad (22)$$

Figure 10 compares this result with numerical simulations, showing very good agreement.

Two more questions have been asked regarding the one-dimensional Sznajd model. The first is the decision time, introduced a short while ago. It was found numerically [74] that it follows the same power law (20) as in the previous case, where it resulted from underlying linear voter dynamics. For the Sznajd model, no proof is available showing that this is the exact result, but it is possible to understand this result on an intuitive level. Although the transition rates (21) correspond to a non-linear, rather than linear, voter model, the evolution of domain walls, responsible for the behavior of the decision time, remains very similar. If the domain walls are far from each other, they again perform a random walk. Non-linearity comes into play only when the domain walls come



Social Processes, Physical Models of, Figure 10
One-dimensional Sznajd model. Probability of reaching the final configuration of all sites in state $+1$, depending on the initial concentration n_+ of $+1$ sites. The *points* are numerical simulation data extracted from [75], the *line* is the analytical result (22) obtained using the Kirkwood approximation

close together, more precisely when they are one lattice spacing apart. Then, they can no longer move freely, they can make only one step towards one another, thus annihilating each other. The dynamics is again those of a diffusion-annihilation process, but the domain walls are not independent; in addition to annihilation they interact at a short distance.

The interaction is in fact a trace of the unstable antiferromagnetic absorbing state. Two walls at distance one form a small nucleus of antiferromagnetic state, thus slowing down the dynamic with respect to free annihilating random walkers. If by chance several domain walls come so close that the distance between neighboring walls is 1, they form an antiferromagnetically ordered cluster, where the walls squeezed between another two walls from both the left and right sides cannot move at all and the dynamics is hindered even more.

However, for large times, the density of domain walls is low and the influence of such antiferromagnetic islands can be neglected. Therefore, it is no big surprise that the power-law dependence of the decision time remains unaffected, at least for large times.

The second interesting question is how many agents never changed their opinion up to certain time t, or, what is the *persistence* in the dynamics of the Sznajd model? In the voter model in one dimension, there is an exact analytical solution [44] showing that the fraction of sites which retain their initial opinion at least to time t decays as $\sim t^{-3/8}$. It may seem quite surprising that the same behavior was found numerically in the one-dimensional Sznajd model [76,77]. However, applying the same arguments as above, showing that the long-time dynamics is essentially dominated by annihilating random walks of the domain walls, it follows that it is quite plausible that the long-time behavior of the persistence is governed by the same exponent 3/8 both in the voter and the Sznajd models in one dimension.

Agents organized on a line are now understood, and it is natural to ask what changes if they are arranged in a two-dimensional mesh, like the people scattered on the surface of the Earth. For example, on a square lattice, one-dimensional dynamics can be generalized in such a way that a pair of neighboring agents is chosen, and if the two have the same state, they make all their 6 nearest neighbors share their state [78,79]. Slightly more formally, let x be a random coordinate on a square lattice with $N = L^2$ sites and $y = x^\nu$ one of the 4 neighbors of x. If $\sigma_t(x) = \sigma_t(y)$, then the configuration is updated as $\sigma_{t+1/N}(x^\mu) = \sigma_{t+1/N}(y^\mu) = \sigma_t(x)$ for all $\mu \in \{1,2,3,4\}$. Numerical simulations show an interesting difference from the one-dimensional case. The probability $P_+(n_+)$ has discontinuity at $n_+ = 1/2$, indicating a dynamical phase transition, while in one dimension the dependence is smooth. More strongly, the data suggest that $P_+(n_+) = 0$ for $n_+ < 1/2$ and $P_+(n_+) > 0$ in the opposite case $n_+ > 1/2$. This result is equally valid in any dimension larger than 1. In the limit of infinite dimension, the behavior should coincide with the mean-field approximation, which implies putting the Sznajd model on a complete graph [54]. Such a modification is analytically solvable, as we now show.

On a complete graph with N vertices, the configuration of the system is fully described by the number N_+ of agents in state $+1$ or by the magnetization $m = 2N_+/N - 1$. The evolution of the latter is governed by transition rates which in the limit $N \to \infty$ yield the Fokker–Planck equation

$$\frac{\partial}{\partial t} P_m(m,t) = -\frac{\partial}{\partial m}\left[\frac{1}{2}(1-m^2)mP_m(m,t)\right] \tag{23}$$

for the probability density $P_m(m,t)$ of the magnetization at time t. Before proceeding further, note that the average magnetization $\langle m\rangle(t) = \int mP_m(m,t)\mathrm{d}m$ satisfies the equation

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle m\rangle(t) = \frac{1}{2}\left(\langle m\rangle(t) - \langle m^3\rangle(t)\right)\ , \tag{24}$$

which has a structure similar to Eq. (17) describing the dynamics of the Galam model. Indeed, equating $m = 2n_A - 1$, identifying the level index with time, $l = t$, and making the approximation $\langle m^3\rangle = \langle m\rangle^3$, thus neglecting fluctuations, the Eqs. (17) and (24) coincide. So, the Galam and Sznajd models are solved in one shot.

It can be easily verified that the general solution of Eq. (23) has the form

$$P_m(m,t) = \frac{1}{(1-m^2)m} f\left(\mathrm{e}^{-t/2}\frac{m}{\sqrt{1-m^2}}\right) \tag{25}$$

for arbitrary function $f(y)$. The latter has to be determined from initial conditions, and assuming that at the beginning the magnetization was m_0 for all realizations of the process, it occurs that $f(m/\sqrt{1-m^2}) = (1-m^2)m\delta(m-m_0)$. Clearly, in this case the probability density consists of a single δ-function which moves, as time passes, towards one of the ends of the allowed interval for the magnetization, $m \in [-1,1]$. The dynamics is those of a pure deterministic drift and no diffusion ever smears out the evolving probability packet, as can be seen immediately from the absence of a second-derivative term in Eq. (23). Clearly, this is due to the limit of infinite system size and for finite N there is an additional diffusive term in the Fokker–Planck equation, proportional to N^{-1}.

The deterministic nature of the evolution of opinions has profound consequences. First, the initial sharp δ-function distribution of magnetization remains sharp until the end, thus justifying the neglect of fluctuations and the replacement $\langle m^3 \rangle = \langle m \rangle^3$. The fluctuations are set on only at times which diverge when $N \to \infty$ and the equivalence to the Galam model is exact in the thermodynamic limit. In a finite system of size N, the typical time t_{st} to reach the absorbing state, starting from magnetization m_0, can be estimated by requiring that drift brings the magnetization to the distance of order $\sim 1/N$ from either of the extremal points $m = \pm 1$. Expressed in terms of the initial concentration of the $+1$ opinion, $n_+ = (m_0 + 1)/2$, it is

$$t_{\mathrm{st}} \simeq \ln \left(\frac{(1 - n_+) n_+ N}{(2 n_+ - 1)^2} \right) . \qquad (26)$$

So, having clarified the close relation to the Galam model, it comes as no surprise that the Eqs. (26) and (18) coincide for large N.

For any positive initial magnetization the final state is always the uniform configuration of all agents in state $+1$, and vice versa. The probability of ending in the all $+1$ state is the step function $P_+ = \theta(n_+ - 1/2)$. This is consistent with simulations of the Sznajd model in dimensions larger than 1 and confirms the existence of a dynamical phase transition at $n_+ = 1/2$. It also shows that in a society where everybody interacts with everybody, but no person changes her opinion unless she meets at least two other people who compel her to do so, the initial majority, however narrow it is, always takes all. No chance is left to minorities. Fortunately enough, reality is more complex. The next section describes model implementations of one common "complication", that the number of choices is not limited to two but can be large, or even very large.

Bounded Confidence

Axelrod Model

Definition One of the features characteristic of the way culture is shared and propagated around the globe is that similar cultures are much more prone to mutual convergence, while incompatible lifestyles often coexist side by side without visibly influencing each other. Robert Axelrod introduced a model [80] nicely describing such a situation.

In the Axelrod model, contrary to the voter or Sznajd model, the character of each of the agents is given by more than one feature. One can think of tastes regarding food, sports, music, etc. These categories represent the features. For each feature the taste can assume various values, e. g., somebody likes eating raw vegetables, spending whole days in the fitness center and listening to Mozart in the evenings, while somebody else feeds on French fries, watches football on TV and adores the pop-star of the season. If two neighbors do not agree on any feature, they are so different that they do not influence each other. Conversely, if they find at least one feature where they share the same preference, one of them may find a second feature in which they do differ and change the preference on that second feature so that it agrees with the preference of the neighboring agent. The fact that the agents do not always interact, but do so only if they have something in common, is called *bounded confidence*.

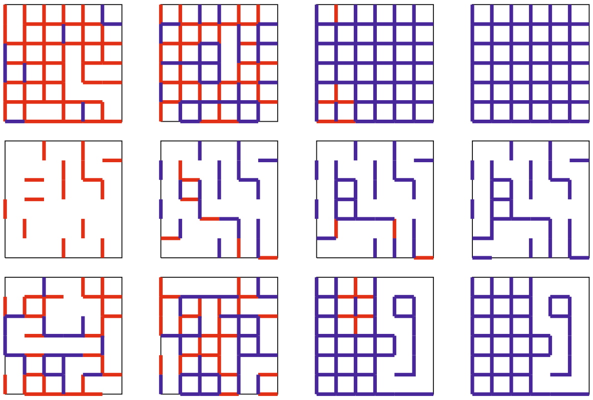
More precisely, there are $N = L^d$ agents placed again on the d-dimensional hypercubic lattice $\Lambda = \{0, 1, \ldots, L-1\}^d$ with periodic boundary conditions and endowed with $F > 1$ integers. The numbers represent the values of its F features, so the state of the agent at site $x \in \Lambda$ is described by the vector with coordinates $\sigma(x, i) \in \mathbb{Z}$, $i = 1, 2, \ldots, F$. The configuration space of the model is $\mathbb{Z}^{\Lambda \times \{1,\ldots,F\}}$ and the evolution of the configuration σ_t is a Markov process determined by transition rates

$$w(\sigma, \sigma^{x,f,a}) = \frac{1}{2d} \sum_{\mu=1}^{2d} \theta \left(A(x, x^\mu) \right) \times \left[F - A(x, x^\mu) \right]^{-1} \delta_{a, \sigma(x^\mu, f)} \, , \qquad (27)$$

where the summation goes over the set of $2d$ neighbors x^μ of the site x. We denoted here $\sigma^{x,f,a}$ the configuration which differs from σ only in feature f, so $\sigma^{x,f,a}(x, f) = a$ and $\sigma(x, f) \neq a$. The function $A(x, y) = \sum_{g=1}^{F} \delta_{\sigma(x,g), \sigma(y,g)}$ counts the number of features on which the agents at positions x and y agree, and $\theta(x)$ is the Heaviside function, $\theta(x) = 1$ for $x > 0$ and zero otherwise. The first factor after the sum in (27) accounts for the condition that the neighbors must agree in at least one feature and the second factor is here due to the fact that in each update the agent chooses randomly among $F - A(\sigma(x), \sigma(x^\mu))$ features in which she disagrees with her neighbor.

Simulations If the two factors after the sum in (27) were absent, the transition rates would depend linearly on the states of the neighbors and a generalization of the linear voter model would emerge, with all its beautiful solubility. However, the non-linearity is there and makes the model non-trivial. Lacking suitable analytical tools, it is necessary to rely on numerical simulations.

To be precise, the rules of the dynamics of the Axelrod model implemented in simulations are as follows: On



Social Processes, Physical Models of, Figure 11
Typical evolution of the Axelrod model on a square lattice with periodic boundary conditions. In each row, snapshots of the configuration in four times $t_1 < t_2 < t_3 < t_4$, from *left* to *right*, where the last configuration is the absorbing state. The active bonds are drawn in *red*, the bonds with full consensus in *blue*, the bonds with absolute disagreement are left *white*. The initial condition is drawn from $\mathbb{Z}_q$ with uniform probability. The parameters are, from *top* to *bottom*, $F = 3$ and $q = 2$; $F = 3$ and $q = 14$; $F = 2$ and $q = 2$. The frame in *light gray* around each configuration is there only for visual convenience

a lattice of size $N = L^d$, time t is discrete and proceeds in chunks of $1/N$, so from time t to $t+1$ there are as many elementary updates as there are sites. One update step consists of:

1. Choose a site x at random; randomly choose one if its neighbors x^μ. Count the number A of features in which the agent at x agrees with the chosen neighbor.
2. If $A = 0$, do nothing. If $0 < A < F$, randomly choose a feature f among those in which the agent and the neighbor differ. Then set the value of the feature f equal, $\sigma_{t+1/N}(x, f) = \sigma_t(x^\mu, f)$.

One of the principal quantities of interest will be the density of active bonds, which is a generalization of the density of interfaces investigated in the voter model. A bond connecting agents at sites x and y is called active if the agents differ in at least one feature and also agree in at least one feature, i. e., $0 < A(\sigma(x), \sigma(y)) < F$. Their fraction relative to the total number of bonds in the lattice will be denoted $n_A(t)$.

When the number of active bonds drops to zero, after the stopping time τ_{st}, evolution freezes and the system reaches one if its absorbing states. It means that all neighbors are either identical or absolutely incompatible. Clusters of agents which share the same values of all features can be identified, while the borders of such clusters are marked by bonds with no shared value. Even for the simplest case of two features $F = 2$ and the set of allowed values for these features constrained to only two elements, there are infinitely many possible absorbing states characterized by various cluster configurations. (For a finite lattice this number is of course finite, but grows very fast with the system size.) This leads to an important note: Speaking of culture, there might be a good many stable configurations and it is impossible (and improper) to discriminate as to which is the best one.

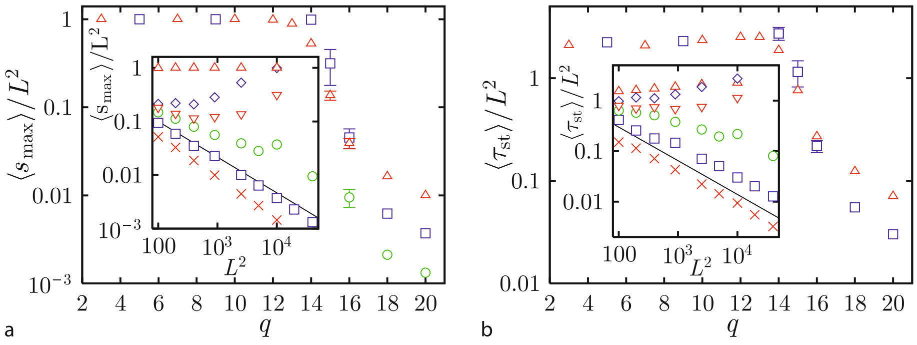
A full characterization of the set of absorbing states would be too difficult. A rough measure is the number of agents in the largest cluster $s_{\max}$, compared to the total number of agents N. When this figure is close to the total system size, it means that the absorbing state is uniform, or very close to it. If the size of the largest cluster is small, or even remains finite when $N \to \infty$, the absorbing state is "multicultural" or fragmented into many isolated islands without mutual interaction, much like the hundreds of villages in Papua-New Guinea, each of them having its own particular language.

The evolution and shape of the eventual absorbing state depends critically on the initial condition. First, note that if, at the beginning, all the values of the features belonged to certain subset $V \subset \mathbb{Z}$ of integers, all features will remain within the set V forever. The most important thing is how large the set V is. But even when V is infinite, the values can be mostly concentrated on a finite subset of V, very rarely going beyond it. A simple but reliable measure of the effective size of the set V, taking into account how often each member is actually present, is the *inverse participation ratio* (IPR). Suppose that, in the initial state, the probability of some feature of a randomly picked agent having the ith value from the set V is p_i. Then, the IPR is

$$q^{-1} = \sum_{i=1}^{|V|} p_i^2 \,. \tag{28}$$

Such a definition is motivated by a simple consideration: if set V consists of the q lowest non-negative integers, i. e., $V = \mathbb{Z}_q \equiv \{0, 1, \ldots, q-1\}$, and all members have the same probability $p_i = 1/q$, the inverse participation ratio is exactly q^{-1}. The integer q is simply the number of elements which are participating, hence the name.

Phase Transition Let us look at how the Axelrod model behaves on a two-dimensional square lattice. Recall that the linear size of the lattice is L, so there are $N = L^2$ agents. The initial condition will consist in choosing the values of all features for all agents independently from the same uniform distribution on $\mathbb{Z}_q$. The typical evolution is shown in



Social Processes, Physical Models of, Figure 12

Phase transition in Axelrod model on a square lattice of size $L \times L$, for $F = 3$, when changing the localization parameter q of the initial state. In a, relative size of the largest cluster, in b, average stopping time relative to the system size are shown. Different symbols correspond to sizes $L = 50$ (△), $L = 100$ (□), and $L = 200$ (○). In the *insets*, dependence of the corresponding quantities on the system size L^2 are shown. Symbols correspond to parameters $q = 5$ (△), 14 (◇), 15 (▽), 16 (○), 20 (□), and 30 (×). The *straight line* is the power $\sim L^{-4/3}$

Fig. 11. For larger F and q the absorbing state is very fragmented, but decreasing q it becomes totally uniform and a single cluster covers the entire lattice. On the other hand, for small F the absorbing state contains a few moderately-sized clusters.

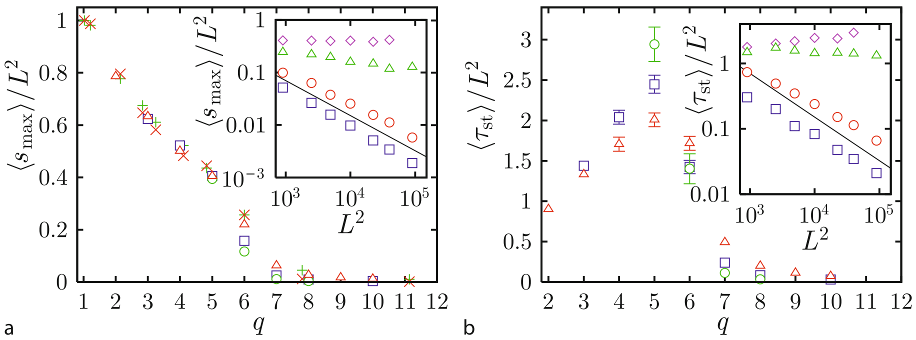
These vague observations are put on a quantitative basis in Figs. 12 and 13. Let us look first at the behavior of the average size of the largest cluster, $\langle s_{\max}\rangle$, when the parameter q is changed. The most important finding is that, at a certain value $q = q_c$, there is a phase transition separating the regime $q < q_c$, in which the maximum cluster makes up a finite fraction of the whole lattice, from the phase with $q > q_c$, where the fraction of sites within the largest cluster goes to zero for $N \to \infty$. The quantity $\langle s_{\max}\rangle/N$ can serve as an order parameter.

Another quantity which illustrates phase transition is the average stopping time, i. e., the time to reach the absorbing state. Generically, it grows with the system size as $\langle \tau_{st}\rangle \sim N^{\eta}(q)$, but below the transition it is proportional to the system size, so $\eta(q) = 1$, while for $q > q_c$ it grows more slowly, with the exponent $\eta(q) \simeq 1/3$. Interestingly, comparison of the stopping time with the size of the largest cluster leads to the conclusion that, for $F = 3$, the two quantities are roughly proportional, $\langle \tau_{st}\rangle \propto \langle s_{\max}\rangle$, both of them exhibiting a jump at the transition, suggesting that the clusters grow linearly in time until they reach the absorbing state. On the other hand, for $F = 2$, such proportionality is not observed. Instead, the average maximum cluster decreases continuously to zero when q_c is approached from below and at the same time the stopping time seems to diverge.

With discrete q, it is impossible to determine the position of the phase transition with high precision, but in practice it is possible to make some reasonable estimates, based on the dependence of $\langle s_{\max}\rangle/N$ on N, as shown in the insets. For $F = 3$ the critical value of the parameter q lies somewhere close to $q_c \simeq 15$, while for $F = 2$ the estimated value is $q_c \simeq 5$.

A more important difference between cases $F = 2$ and $F = 3$ than the numerical value of the transition point q_c is the very nature of the phase transition. It was already shown that the stopping time normalized to the system size blows up at the transition only for $F = 2$, remaining finite for $F = 3$. With fair trustworthiness it is possible to say that for $F = 2$ the transition is continuous, i. e., second-order, while for $F = 3$ the transition is clearly a first-order one. Although it may be dangerous to rely only on numerical data for the order parameter, the conclusion on the nature of the phase transition was also supported by results for the distribution of cluster sizes close to the transition. In Fig. 14a it can be seen that the probability of finding in the absorbing state a cluster of size larger than or equal to s decays as a power, i. e., $P^{>}_{\text{clust}}(s) \sim s^{1-\alpha}$, with an obvious cutoff at large s due to the finiteness of the lattice. The value of the exponent α plays critical role. For $F = 2$ the estimate is $\alpha_{F=2} \simeq 1.6$ and for $F = 3$ it is $\alpha_{F=3} \simeq 2.65$. It has been shown that the exponent does not depend on the number of features as long as $F \geq 3$ [81]. How does the distribution of cluster sizes relate to the type of the phase transition? Denoting $N_{\text{clust}}(N)$ the total number of clusters and $P_{\text{clust}}(s, N) = P^{>}_{\text{clust}}(s) - P^{>}_{\text{clust}}(s + 1)$ the fraction of clusters of size s on the lattice with N sites, the result is

$$N = N_{\text{clust}}(N) \sum_{s=1}^{N} s P_{\text{clust}}(s, N) \,. \tag{29}$$



Social Processes, Physical Models of, Figure 13

Phase transition in the Axelrod model on a square lattice of size $L \times L$, for $F = 2$, when changing the localization parameter q of the initial state. In a, relative size of the largest cluster, in b, average stopping time relative to the system size. In both panels, results for the uniform initial distribution is plotted for sizes $L = 50$ (△), 100 (□), 200 (○). In the *insets*, dependence of the corresponding quantities on the system size, for $q = 5$ (◇), 6 (△), 7 (○), and 8 (□). The *straight lines* are power laws $\sim L^{-4/3}$ In a, there are also data extracted from [81], where the initial condition was assembled from Poisson-distributed integers; sizes were $L = 50$ (+) and $L = 150$ (×)

If $P_{\rm clust}(s, N) \sim s^{-\alpha}$ and $\alpha < 2$, the sum on the right hand side diverges when $N \to \infty$. But the sum is simply the average cluster size, the quantity which plays the role of correlation length. The behavior resembles the percolation transition and the diverging correlation length is an unmistakable characteristic of a second-order phase transition.

On the other hand, if $P_{\rm clust}(s, N) \sim s^{-\alpha}$ with $\alpha > 2$, the sum converges. To keep the equality in (29) for $N \to \infty$, either the number of clusters must be proportional to the system size, or, in addition to the power-law complement, there must be an additional term in the distribution of cluster sizes, accounting for the largest cluster of size $s_{\max} \simeq N$, i. e.,

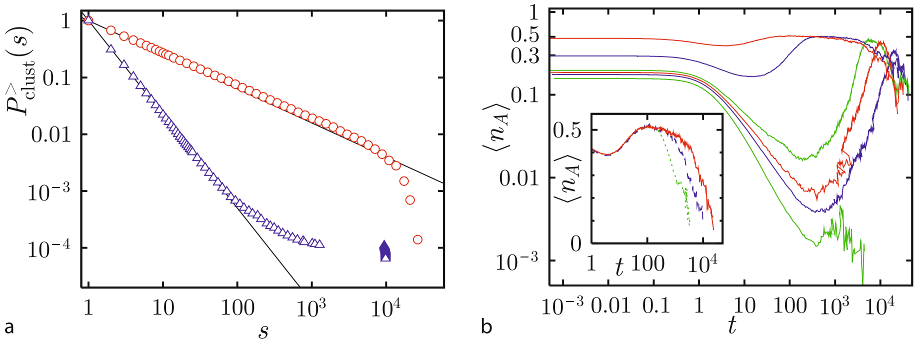
$$P_{\rm clust}(s, N) \simeq a s^{-\alpha} + b\ \ \delta_{s,s_{\max}}\ . \tag{30}$$

The former possibility occurs for $q > q_{\rm c}$ and the latter for $q < q_{\rm c}$. Indeed, the simulation data in Fig. 14a show the presence of a δ-function part in (30), with positive weight $b > 0$. Below the transition, the largest cluster spans essentially whole system, and at $q_{\rm c}$ its size drops discontinuously to a value negligible with respect to N. This is typical of first-order transitions.

These considerations are also compatible with the behavior of the stopping time as a function of q. For $F = 2$, data indicate that $\langle \tau_{\rm st}\rangle/N$ diverges as $q \to q_{\rm c}$, while for $F = 3$ it remains constant. Interpreting the stopping time as the correlation time of the dynamics, the model exhibits exactly the same behaviors commonly observed in the second- and first-order phase transitions, respectively.

To conclude, the phase transition in the Axelrod model is driven by the parameter q, measuring the localization of values in the initial condition, and belongs to the class of first-order transitions, if the number of features is at least 3, while for only 2 features the transition is continuous. Interestingly, the same dependence in terms of number of components is known in the Potts model. However, one should bear in mind that the transition in the Axelrod model has a purely dynamical origin. There is no equilibrium besides the absorbing states, so the analogy with phase transitions in equilibrium statistical physics must be taken cautiously and with certain reserve.

Although the most interesting question touches the properties of the absorbing states, it is instructive, also, to see how the system approaches them. In Fig. 14b the evolution of the average number of active bonds is shown. The averages are taken only over realizations which have not yet reached the absorbing state. Around the time $t \simeq 1$, i. e., after as many updates on the computer as there are lattice sites, the density of interfaces decreases drastically. When $q > q_{\rm c}$ it brings the system quickly to the absorbing state, while in the opposite case, $q < q_{\rm c}$, the activity rises again and n_A increases to a value close to $n_A \simeq 0.5$. Then, a very slow evolution follows. Most often, the evolution ends due to an occasional hit into an absorbing state, but this is, rather, a finite size effect, as demonstrated in the inset in Fig. 14b. When system size increases, slow evolution is increasingly prolonged. To see the behavior at these very long times is very difficult on a computer, but it seems that the density of active bonds decays very slowly to zero, resembling the logarithmic decay of the density of interfaces in the two-dimensional voter model.



Social Processes, Physical Models of, Figure 14
Axelrod model on a square lattice. In a, distribution of cluster sizes close to the transition $q \simeq q_c$, averaged over 100 realizations. The parameters are $F = 2$, $q = 5$, $L = 200$ (◯), and $F = 3$, $q = 15$, $L = 100$ (△). The *straight lines* are power laws $\sim s^{-0.6}$ and $\sim s^{-1.65}$. In the data for $F = 3$, note the the isolated points around $s \simeq 10^4 = L^2$ indicating that the distribution is composed of a power-law part plus a δ-function located close to L^2. In b, time dependence of the number of active bonds, averaged over realizations of the process. The lattice size is $L = 100$, number of features $F = 3$ and different lines correspond to $q = 5, 9, 14, 15, 16$, and 18, from *top* to *bottom*. In the *inset*, the dynamics is shown for $F = 3$, $q = 5$, and three lattice sizes, $L = 30$ (*dotted line*), 50 (*dashed line*), and 100 (*solid line*)

Bounded Confidence with Continuous Opinions

There may be a different view on consensus formation, assuming that opinions on a certain issue can vary continuously, but a discussion on that subject and possible convergence of the opinions cannot take place unless the actual opinions are close enough. If the people differ too much, they may even avoid mutual contact completely or decide to use "different means", an often-used euphemism for killing the opponent. If, on the contrary, the difference in their opinions, measured by a continuous variable, does not exceed a certain threshold, then the difference may be further diminished by discussions and peaceful persuasion. This idea is called *bounded confidence* and a kind of it is also a key ingredient of the Axelrod model.

Linear Dynamics Modeling consensus formation using continuous variables has been around for quite a long time. Let us denote F_i as the variable describing the opinion of the individual i. The simplest way to implement the convergence of opinions, introduced by DeGroot [82], is to assume that in an upcoming period, opinions are linear combinations of the current opinions of all individuals

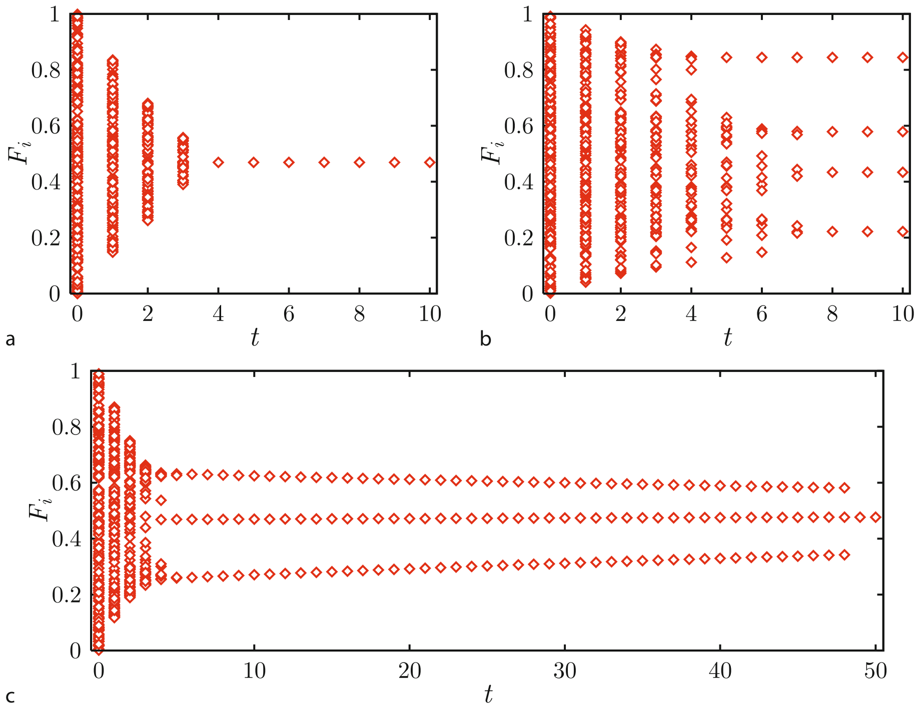
$$F_i(t+1) = \sum A_{ij} F_j(t) \,, \tag{31}$$

where A is a stochastic matrix, i. e., all its elements are non-negative, $A_{ij} \geq 0$, and the sum of all its columns is one, $\sum_i A_{ij} = 1$. This is called a *confidence matrix*. The diagonal elements are assumed to be strictly positive, $A_{ii} > 0$, which means that the individuals have at least some non-vanishing belief in their own opinions. The new values of F_i are weighted averages of previous opinions, the weights being stored in the matrix A. As such, the dynamics is very simple and is equivalent to those of a Markov chain with transition probabilities A_{ij}.

In DeGroot's model, the question of reaching a consensus or not is reduced to the study of connected components of the graph of direct interactions. When there are more of them around, each of them reaches its own consensus, independent of the others. This is quite simple. Introducing bounded confidence adds complications.

Hegselmann and Krause The new opinion of individual i takes into account others' opinions with weights A_{ij}. What if these weights are not constant, but depend on the current opinions themselves? Although some attempts in this direction have been made earlier [83], the principle of bounded confidence was first applied in the models developed by the groups of Deffuant et al. [84] and Krause and Hegselman [85,86]. Let us discuss the latter model first.

The Hegselmann–Krause (HK) model [86] considers opinion formation as a fully deterministic process, as in DeGroot's model investigated in the previous section. The new opinion of an individual is the average of current opinions of those (including the individual of concern) whose opinions lie within a fixed confidence bound $\epsilon > 0$ from the individual's own opinion.



Social Processes, Physical Models of, Figure 15
Evolution of the Hegselmann–Krause model. Each point represents one or more agents with specified value F_i. Total number of agents is $N = 200$. In a, the confidence bound is $\epsilon = 0.3$, while in b it is $\epsilon = 0.1$. c shows how the approach to consensus is slowed down when the confidence bound is close to its critical value. Here $\epsilon = 0.24$

For those pairs which do not differ more than ε in their opinions, the weights A_{ij} are uniform, so

$$A_{ij} = \begin{cases} 0 & \text{for} \quad |F_i - F_j| > \epsilon \\ \frac{1}{N_{i\epsilon}} & \text{for} \quad |F_i - F_j| \le \epsilon \,. \end{cases} \tag{32}$$

Obviously, the normalization constant is the number of individuals within the confidence bound, $N_{i\epsilon} = |\{j\colon |F_i - F_j| \le \epsilon\}|$. Note that the dependence of the confidence matrix on current opinions is very strongly non-linear. From the formal point of view, the most important thing is that the zero-pattern of the confidence matrix can also change in time. It is possible to interpret it as changing the structure of the graph of directly communicating individuals. To see if consensus is going to be reached, it is important to observe whether the graph remains connected during evolution. Clearly, once it splits into disconnected parts, it will never join together again and consensus will not be achieved.

To get an impression of how the evolution of the HK model proceeds, look at Fig. 15. For a large enough confidence bound ε, the system approaches full consensus, while lower values of ε induce several stable communicating subgroups which do not interact with each other, and the system splits into several clusters with different opinions. The number of such clusters grows as $1/\epsilon$ when the confidence bound shrinks. Numerical simulations show that the critical value ϵ_c, at which the full consensus breaks down, approaches the value about $\epsilon_c \simeq 0.2$ when the number of individuals increases. Interestingly, when the confidence bound comes close to the critical value ϵ_c, the number of steps needed to reach consensus increases, suggesting that this is indeed a kind of a dynamical phase transition. This behavior is rather robust, as it persists in various modifications of the HK model, most notably if the individuals can communicate only through a regular lattice or a random network [87,88,89,90].

Deffuant et al. Apart from the initial condition, the model of Hegselmann and Krause is fully deterministic and opinions are updated in parallel. A similar model, but with random sequential update, was introduced by G. Deffuant et al. [84].

There are, again, N individuals with opinions F_i. In each update step, two of them, say, i and j, are chosen randomly. Then, we check to see whether their opinions differ less than (or equally to) the confidence bound ε. In the positive case, their opinions are slightly shifted towards each other

$$\left.\begin{aligned} &F_i(t+1/N)\\ &\quad=(1-\mu)F_i(t)+\mu F_j(t)\\ &F_j(t+1/N)\\ &\quad=\mu F_i(t)+(1-\mu)F_j(t) \end{aligned}\right\} \text{for} \quad |F_i(t)-F_j(t)| \le \epsilon \tag{33}$$

where μ is a parameter fixing the rate of convergence.

For very large numbers of individuals, $N \to \infty$, the dynamics can be expressed in terms of the continuous distribution of opinions $P(f,t)$, which can be written formally as $\int_0^f P(f',t)\mathrm{d}f' = \lim_{N\to\infty} \frac{1}{N}\sum_j \theta(f-F_j(t))$. The following innocent-looking rate equation is obtained [91]

$$\begin{aligned} \frac{\partial}{\partial t}P(f,t) = &\int\limits_{|f_1-f_2|\le\epsilon} P(f_1,t)P(f_2,t)\\ &\times\left[\delta((1-\mu)f_1+\mu f_2-f)-\delta(f_1-f)\right]\mathrm{d}f_1\mathrm{d}f_2\,, \end{aligned} \tag{34}$$

which exhibits fairly complex behavior. Starting from the uniform initial condition $P(f,0)=1$ for $f\in[0,1]$, the configuration evolves into a stationary state composed of one or several δ-functions, each of them corresponding to one cluster of individuals sharing the same opinion.

To see this in a simple example, consider the case $\epsilon > 1$. All individuals interact with each other, so their opinions converge to a common limit $f = 1/2$. It is possible to see this when we use Eq. (34) to investigate the time evolution of the moments of the distribution. Obviously $\frac{\mathrm{d}}{\mathrm{d}t}\langle f\rangle = 0$, so the average opinion is independent of time, $\langle f\rangle = 1/2$. The dispersion from the mean $\langle f^2\rangle_\mathrm{c} = \langle f^2\rangle - \langle f\rangle^2$ obeys

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle f^2\rangle_\mathrm{c} = -2\mu(1-\mu)\langle f^2\rangle_\mathrm{c}\,, \tag{35}$$

which means that the dispersion decays exponentially to zero with rate $\mu(1-\mu)$. This confirms our intuition, noted earlier, that μ determines the speed of the evolution towards the stationary state.

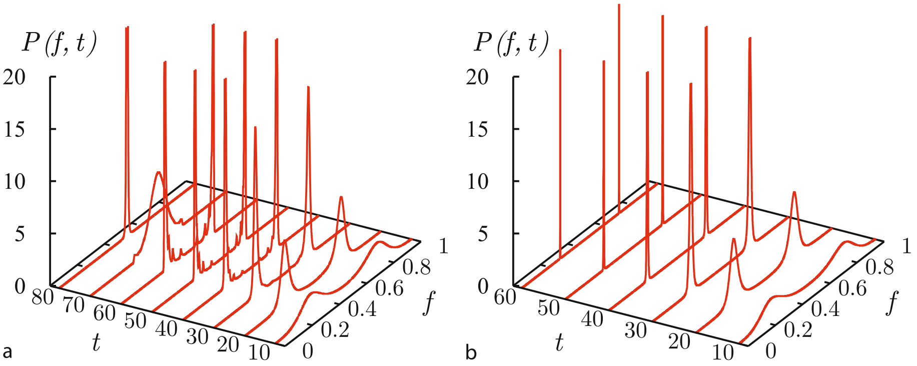
The behavior in the complementary regime of very small ε can be guessed, assuming that $P(f,t)$ does not vary too wildly at scales comparable to ε or shorter. This also means that f is assumed to be farther than ε from the extremal values 0 and 1. In this case, $P(f_{1,2},t)$ is expanded in a Taylor series and the integral on the right hand side of (34) can be performed explicitly. Finally, the following partial differential equation is obtained

$$\frac{\partial}{\partial t}P(f,t) = -\frac{\epsilon^3}{3}\mu(1-\mu)\frac{\partial^2}{\partial x^2}P^2(f,t)\,. \tag{36}$$

There is a trivial homogeneous solution $P(f,t) = C$, independent of f and t, which is, however, unstable at all length scales. To see it, it is enough to linearize (36) close to the uniform solution, $P(f,t) = C + D(f,t)$, where $|D(f,t)| \ll C$, and express the result in terms of the Fourier transform $\widetilde{D}(k,t)$ of the small perturbation. The result is $\frac{\partial}{\partial t}\widetilde{D}(k,t) = \frac{2}{3}k^2\epsilon^3 C\mu(1-\mu)\widetilde{D}(k,t)$, indicating that perturbations increase as their wavelength decreases. On the other hand, if a stationary state is reached, the structures created cannot be closer to each other than ε. This feature is lost in the derivation of Eq. (36), but nevertheless the conclusion is that, for small ε, the stationary state will be composed of regularly spaced δ-functions with period proportional to ε.

To see explicitly how the stationary state is approached for general values of the confidence bound ε, the solution of Eq. (34) should be found numerically. Examples of such evolution are shown in Fig. 16. For large enough ε, all opinions converge to the common value 1/2, as in the case $\epsilon > 1$. However, low ε produces two or more distinct peaks. Detailed analysis [91,92] reveals that a series of bifurcations occurs in the system when the confidence bound is decreased. The consensus breaks into separated groups suddenly at a critical value ϵ_{c1}, which break themselves into more groups at $\epsilon_{c2} < \epsilon_{c1}$ and so forth. The numerically found value of the first critical point is $\epsilon_{c1} = 0.269\ldots$ But how do the peaks emerge from the originally homogeneous distribution? It can be seen in Fig. 16 that they are triggered by the original inhomogeneity at the edges of the interval [0, 1]. A structure of gradually sharpening peaks propagates towards the middle of the interval, where non-linear waves from opposite endpoints meet and form the resulting pattern.

This observation can be translated into common language by saying that the ultimate fate of the opinions in the society is largely in hands of the extremists. Indeed, individuals close to the edges of the scale of possible opinions are, from the very beginning, drawn towards the middle of the interval [0, 1], i. e., close to the centrist position, while those who are farther from the edges than ε keep their opinions unchanged for some finite time. The crucial question is, how far from the extreme will the former extremists move before they settle? It may happen that they will drift so close to the midpoint that the centrists will attract them all; full consensus follows. But the extremists themselves can attract enough centrists and, instead of creating one peak at the center, two (or even more) peaks oc-



Social Processes, Physical Models of, Figure 16
Evolution of the Deffuant model with $\mu = 0.5$. In a, approach to consensus for confidence bound $\epsilon = 0.27$, slightly larger than the critical value ϵ_{c1}. In a, two peaks are formed in the distribution of opinions, for $\epsilon = 0.25$

cur. The resulting society lives with polarized (or diversified) opinions. The parameter which decides the outcome is the confidence bound ε. Higher confidence leads to an overwhelming consensus among people, while lower confidence causes the society split into several non-communicating communities.

Emergence of Social Classes

People are not equal. Not only do they differ in the color of their eyes, in their ability to play chess or to run a marathon race, but even individuals with very similar talents may find themselves very different in social status. All attempts to bring more justice into such evident disequilibrium has ended in desperate or even catastrophic failure. Perhaps the best one can do is to make the membranes separating social levels as permeable as possible, so that no one is a priori disqualified. The ubiquity of social stratification in animal as well as human collectives is certainly a phenomenon which calls for an explanation, and the fact that rabbits, dogs, apes and *Homo sapiens* exhibit similar behavior suggests some common mechanisms which may not be too complicated after all, although they produce highly complex outcomes.

Bonabeau Model

A newcomer in an animal group always has to undergo some fighting before its placement in the social ladder is commonly accepted. If, on the other hand, an individual leaves the group for some prolonged period and returns back, it has to fight again, as the previously established level has faded away. These two observations motivated Bonabeau et al. [93] to introduce a model of self-organized hierarchies [93,94,95,96,97,98].

To be clear, the hierarchies are not understood in the sense of trees with a king or a marshal on the top and lesser ranks below. Instead, it means an ordering, each individual bearing a single number called strength, indicating its position among others. When two agents meet, the stronger one has higher probability to be strengthened, while the weaker is most likely pushed down even more. The strengths of the agents who do not meet at this time relax towards zero by a fixed fraction. More formally, the configuration of the system at time t is described by the collection of strengths $F_i(t)$ of the agents $i = 1, 2, \ldots, N$. In each step, a pair of agents is chosen to fight, i and j, say, resulting in a change of the strengths by ± 1 for the winner and loser, respectively. Moreover, all strengths relax to the reference (zero) level deterministically. Thus

$$\begin{aligned} F_i\left(t+\frac{1}{N}\right) &= \left(1-\frac{\mu}{N}\right) F_i(t) + \Delta_{ij} \\ F_j\left(t+\frac{1}{N}\right) &= \left(1-\frac{\mu}{N}\right) F_j(t) - \Delta_{ij} \\ F_k\left(t+\frac{1}{N}\right) &= \left(1-\frac{\mu}{N}\right) F_k(t)\,, \quad k \neq i\,,\ k \neq j\,, \end{aligned} \tag{37}$$

with

$$\text{Prob}\left\{\Delta_{ij} = \pm 1\right\} = \frac{1}{1 + \mathrm{e}^{\mp\eta(F_i(t)-F_j(t))}}\,. \tag{38}$$

The parameter η tunes the level of randomness in the dynamics, where $\eta \to \infty$ corresponds to purely deterministic outcomes, the stronger agent always beating the weaker, while $\eta = 0$ means that the strengths are increased and decreased by mere chance.

So far, the question of which pairs of agents interact and when, has not been dealt with. The most natural choice is to place the individuals on a network, or simply on a square lattice, leaving some sites empty, and to allow the agents to diffuse along the edges of the network. When two agents happen to meet at one site, they fight. More than two agents on a site is not allowed; they behave like hard hemispheres, each site being able to accommodate one full sphere. Numerical simulations of such systems [93,94,95,96,97] show that the change in the density of agents, or, equivalently, the relaxation rate μ, induces a phase transition from a uniform state with all agents' strength close to 0 to a hierarchical state where the strengths are highly non-homogeneous. The order parameter is the dispersion of the number of fights won by the agents, i. e.,

$$\sigma = \sqrt{\frac{1}{N}\sum_{i=1}^{N}\left(w_i - \frac{1}{2}\right)^2}\,,$$

where $w_i = n_i^+/(n_i^+ + n_i^-)$ and n_i^+, n_i^- are the number of encounters won and lost by the agent i, respectively. In the homogeneous phase $\sigma = 0$ while in the hierarchical phase it has a finite value.

Mean-Field Solution

Analytical study is possible in the mean-field approximation. Indeed, if diffusion is fast enough to ensure many encounters with various agents during the typical time given by the speed of relaxation of the strengths towards zero, the spatial structure of the lattice on which the diffusion takes place becomes irrelevant. In other words, at each time step, two agents are chosen at random and allowed to fight. In this case the dynamics is much simpler, and for a large system the following deterministic evolution equations for the strengths is obtained:

$$\frac{\mathrm{d}F_i}{\mathrm{d}t} = -\mu F_i + \frac{1}{N}\sum_{j=1}^{N}\frac{\sinh\eta(F_i - F_j)}{1 + \cosh\eta(F_i - F_j)}\,. \tag{39}$$

The stochastic term decreases as $1/N$ for large N, so it is neglected here.

It can be easily seen that the average strength $\overline{F} = \frac{1}{N}\sum_i F_i$ relaxes exponentially to 0 according to $\frac{\mathrm{d}\overline{F}}{\mathrm{d}t} = -\mu\overline{F}$. So, it is sufficient to consider only stationary states with zero mean, $\overline{F} = 0$. The simplest of them, satisfying (39), is the trivial uniform state $F_i = 0$. This may be unstable, though, and its linear stability must be investigated.

Using the notation $\frac{\mathrm{d}F_i}{\mathrm{d}t} = R_i(F_1, \ldots, F_N)$ for the expression occurring in (39), the eigenvalues of the matrix $H_{ij} = \frac{\partial}{\partial F_j}R_i(0, \ldots, 0)$ should be inspected. Thus

$$H_{ij} = \left(-\mu + \frac{\eta}{2}\right)\delta_{ij} - \frac{\eta}{2N}\,. \tag{40}$$

One of the eigenvectors is uniform, $x_i = 1$, corresponding to eigenvalue $-\mu$, which is always negative. The remaining $N-1$ eigenvectors have the form $x_i = 1 - N\delta_{ik}$ for some k and they all belong to the same eigenvalue $\frac{\eta}{2} - \mu$. If the latter is positive, the uniform solution of the Eq. (39) is unstable. This happens for

$$\mu \le \mu_c \equiv \frac{\eta}{2} \tag{41}$$

and the question naturally occurs, what are the stationary configurations beyond the critical value μ_c? Not very far beyond the critical point, linear stability analysis can offer a useful hint, but it needs to be complemented by the influence of the lowest non-linear terms. Therefore, expanding the right-hand side of (39) up to the third order in the differences $F_i - F_j$, one gets for the stationary state

$$(2\mu - \eta)F_i = \frac{\eta^3}{12N}\sum_j (F_i - F_j)^3\,. \tag{42}$$

The solution is assumed in the form

$$F_i = a\delta_{ik} - b \tag{43}$$

suggested by the eigenvectors of H_{ij} corresponding to unstable modes. Inserting the trial solution (43) into (42) leads to a set of equations for the parameters a and b which can be solved easily

$$a = \begin{cases} 0 & \text{for} \quad \mu > \frac{\eta}{2} \\ \pm\sqrt{\frac{12N(\eta-2\mu)}{(N-2)\eta^3}} & \text{for} \quad \mu < \frac{\eta}{2} \end{cases} \tag{44}$$

$$(2\mu - \eta)b = -\frac{1}{12N}\eta^3 a^3\,. \tag{45}$$

Hence, the order parameter σ is deduced. Note that in the stationary state, the fraction w_i of fights won by the agent i should be balanced by a relaxation of the strength. Indeed, $2w_i - 1$ is the average increase of the strength of agent i in one step, which should be equal to μF_i. So, $\sigma = \mu\sqrt{\sum_i F_i^2/N/2}$ and inserting the result (45) yields

$$\sigma = \begin{cases} 0 & \text{for} \quad \mu > \frac{\eta}{2} \\ \frac{\mu}{\eta}\sqrt{\frac{3}{N}\left(1 - \frac{2\mu}{\eta}\right)} & \text{for} \quad \mu < \frac{\eta}{2}\,, \\ & \mu \to \frac{\eta}{2} \quad \text{and} \quad N \gg 1\,. \end{cases} \tag{46}$$

How can this solution be interpreted? One may compare it to a situation in a society with one master and many servants, a single emperor while all the rest are servants, equal to each other in their subordination. This looks nice, but it follows from the formulae (45) that this "realistic" solution always comes together with a mirror image of itself, a society of a single servant subject to many equal masters. This is an absurd situation, revealing something artificial in the Bonabeau model itself. Indeed, the dynamics is invariant with respect to inversion of all strengths, $F_i \to -F_i$, because no a priori advantage of being stronger was explicitly introduced. The only thing which was assumed was that the strong grow stronger and the weak grow weaker.

Now let us turn back to mathematical aspects of the model. It can be shown that a solution of type (43) exists for any value of μ and η, with only the complication that the equations for a and b become transcendental, thus analytically insoluble. This would be too simple, though. In fact, it is easy to find a stable solution in the limit $\eta \to \infty$, with μ kept finite, and see that it differs completely from (43). The expression within the sum in (39) becomes the sign function of the difference $F_i - F_j$ and the set of equations for the stationary state becomes

$$\mu F_i = \frac{1}{N} \operatorname{sign}(F_i - F_j) \tag{47}$$

and reordering the agents so that their strengths make an increasing sequence $F_1 < F_2 < \ldots < F_N$ one gets

$$F_i = \frac{1}{\mu N}(2i - N - 1)\,, \tag{48}$$

a society organized as a regular ladder of ranks. The order parameter corresponding to such a state,

$$\sigma = \frac{1}{3}\left(1 - \frac{1}{N^2}\right) \tag{49}$$

approaches a non-zero limit for $N \to \infty$, contrary to the configuration of (43) which is appropriate only in close proximity to the critical point, and whose order parameter decreases as $N^{-1/2}$, as can be seen from (44).

Despite the obvious criticism that the essential mirror symmetry $F_i \to -F_i$ is unrealistic and leads to unacceptable solutions, the Bonabeau model manifests quite well the basic idea of how the various social classes emerge. Within this framework, hierarchies are due to dynamical instabilities of the uniform state. The same general mechanism is also (at least partially) responsible for the stratification of human society. Any departure from the mean, be it positive or negative, is amplified. Any accidental misfortune sends one almost invariably even deeper. That is the whole mystery.

Future Directions

The prospects of physical modeling of social behavior are larger than what is presented here. The study of the emergence of cooperation within the framework of spatial and repeated prisoner's dilemma game is one of the classics. It may be, and has been, generalized in various ways. For example, one may wonder what happens if the agents could move through the lattice, or along the edges of the general graph representing the structure of the society. Indeed, people do not sit on the same lattice point forever. It turns out that, depending on the average velocity of the agents' movement, there is a phase transition. Less mobile agents form a phase with a macroscopic fraction of collaborators, while beyond a certain level of mobility the collaborators vanish.

Bounded confidence models pose some subtle and still unsolved problems. One of them concerns how the final state depends on the number of agents, or, stated differently, on the granularity of the distribution of opinions on the opinion axis. If the number of agents were arbitrarily large, the density could be arbitrarily small and it could happen that between any two agents there might be other agents which may mediate ultimate consensus. If that were true, the splitting of society into disparate groups would be the effect of limited size. The conclusion sounds somewhat paradoxical: small societies are more likely to be divided into non-communicating sub-cultures, while large societies turn to be more homogeneous. Another question naturally follows: how small must a social group be to allow disparate opinions to coexist? Implications for multicultural studies are evident.

The dynamics of social strata are relatively less explored and the state of the problem presented here must be considered as preliminary. The societies sketched in these models do not possess any internal structure, which would either stabilize or slow-down the emergence of stratification. Surely there is much space for future work here.

Some important areas were not covered at all, for example the whole family of physically based models of the birth and competition of languages [41,99]. Some social phenomena also closely touch economics, but these are covered by other articles in this Encyclopedia.

Article Outline

Glossary

Social process A social process in the current context can be defined as any series of events occurring where several human beings enter into interaction. The definition may be extended to processes in which social animals are involved.

Model A model in the current context is defined as the representation of some part of the real world, which is called a target system, where this representation is done in terms of some language, be it natural language or some formal graphic and/or computer-executable language. It represents real-world entities with nouns in natural language or objects in typical programming languages, properties of these entities with adjectives in natural language or instance variables in typical programming language, actions of these entities with verbs in natural language or methods and procedures in programming languages, and relations between such entities with relations between nouns or objects in the respective languages.

Simulation Simulation is the execution of a formal model of some process described in a programming language on a computer.

Agent An agent in the current context is usually defined as a piece of software that has some autonomy, i. e. operates without other parts of a larger computer program having direct control of its internal state and actions, that can communicate with other agents in some kind of language, i. e. without direct access to other agents' inner state, that can perceive its environment and can react on it, and that can also take the initiative, i. e. can act without a stimulus from outside and display goal-directed behavior.

System A system in the current context is a mathematical structure consisting of a set of components (composition) belonging to the system, another set of things of the same kind not belonging to the system (forming the environment of the system) and a set of relations defined on the set of things forming both composition and environment and containing at least one relation that changes the history of the involved things [6]. In other contexts, "system" may have other connotations.

Definition of the Subject

The simulation of social processes has been a topic of both the social sciences and computer science for more than five decades and goes back to the first applications of computers. This is, among others, due to the fact that the first developers of computers were not only mathematicians and people from electric engineering, but also economists and even political scientists. As one can read in biographies of Herbert A. Simon, a political scientist, [61] and John von Neumann, a mathematician and game theorist, [49] persons like these were fascinated by the idea that beyond mathematical analysis computer applications could be made fruitful for the understanding of social processes.

Whereas cross-sectional analysis in the social sciences had been supported by statistical methods even earlier, any longitudinal analysis of societies needed more advanced methods of analysis than statistics can provide.

Simulation of social processes comes in different forms, as this entry will deal with in much more detail. One usually distinguishes between pure macro-level simulations where one is only interested in what happens on one level, usually a nation, a society, or an organization and where only one entity – the whole system – is represented, from different kinds of multi-level simulations where at least a system and its components or elements are represented together with the interactions between levels and interactions among the components.

Simulation of social processes has several distinct aims. On one hand, and this is usually the primary, but most primitive aim, one is interested in the prediction of processes (this is often done before the process is properly understood and often leads to predictions that can only be invalidated by empirical research performed after the prediction). On the other hand, one is first interested to understand what is going on in a social process (i. e. to communicate to oneself what one believes are the ingredients of a social process), to make this communicable to others in order to be able to discuss one's understanding with colleagues, and to experiment with the model in order to find out whether the executable simulation model behaves like the target system it represents. Simulation thus plays a similar role as earlier kinds of models, e. g. a mathematical model in physics, which were qualified by Max Planck [48] as "a system of terms and sentences, the so-called physicist's world view, which he endows to the best of his knowledge in order that it – put in place of the real world – should send him – if ever possible – the same message as the real world would send". And a computer program written for simulation is just "a system of terms and sentences" that – even literally – is able to send messages to its user.

Introduction

This entry is organized as follows. The next section tries to give an overview of social processes that have so far been modelled for the purpose of simulation. As one will see, there is a very wide range of social processes that have been simulated with quite different simulation tools and approaches. And this section will, of course, give a more detailed definition what a social process is, and it will shortly deal with some system theories (unfortunately there are very different ones under the same name) and analyze how their adherents have used simulation to analyze what they described as systems.

Section "Microanalytical Simulation" and Sect. "Multilevel Simulation" will deal with two classical approaches to social simulation. The two classical approaches are those of system dynamics and of microanalytical simulation. Both of them have a history of more than 50 years (their learned societies celebrated their 50th anniversaries in August 2007) and have found a wide audience, with system dynamics still being an approach used from ecology to management sciences, modelling ecosystems as well as the planet as a whole, but also firms and markets, and with microanalytical simulation still being an approach used to predict consequences of tax and transfer reforms and the age structure of future generations. While system dynamics is a purely one-level, one-of-a-kind approach as it always represents exactly one undivided real-world system in terms of its properties, thus hiding its components, microanalytical simulation represents a large number of non-interacting men and women and/or households that react on the stimuli given by the experimenter who is only interested in the aggregate statistics which in turn never respond to the behavior of the micro-entities. Thus, in both of these classical approaches an important feature of social processes is in a way missing, as both of them do not actually represent interactions between human beings and, moreover, do not represent interactions between individual and group or individual and society.

Section "Multi-Agent Simulation" will deal with several contemporary approaches that have not yet made their way into the ministries or the boards of enterprises (with a few important exceptions that will be discussed). Common to all of these disparate approaches is the attempt at representing processes in which interactions among individuals and between levels play a major role. Interactions can occur in topological neighborhoods (as for instance in cellular automata) or in networks (as in many agent-based or multi-agent simulations), sometimes neither neighborhood nor network topology is represented, and models restrict themselves to the micro-macro interaction. Approaches of this type most often try to represent cognitive processes beside social processes, as at least in social systems of human beings much of the interaction is controlled by cognitive processes in the minds of participants. And it is still an open question whether a valid representation of human social system can do without taking account of cognitive processes, as it is an open question whether taking only cognitive processes into account leads to an explanation of social processes ("mind is not enough" [8], but "society is not enough" seems also to be true).

Social Processes and Social Systems

Talking about social processes makes it necessary first to define what a process is. Following Bunge [5] a process is a sequence of states a thing had or has or will have over time. It can be written as a time series whose elements denote the state of a thing at a certain point of time, the sequence of states being ordered with respect to time. Thus a process can be represented with a sequence of vectors, each vector representing the state of the thing at a certain time, and each element of each vector representing one of the properties of the thing that describe its state at this time.

When talking about social processes, what was called "thing" in the preceding paragraph (and thus following Bunge [5]) will always be a system composed of human beings (and perhaps containing several levels of subsystems) where the state of the system can and should be described both on the system level and on the component level (and perhaps on the levels defined by different subsystems). Although system dynamics describes the state of the system only on this upper level and neglects any subsystems and components, and although microanalytic simulation describes the state of the system only on the level of either households or individual (but usually not on both) and not on the aggregate level (this is done only for calculating results), both of these approaches describe social processes but in an incomplete manner.

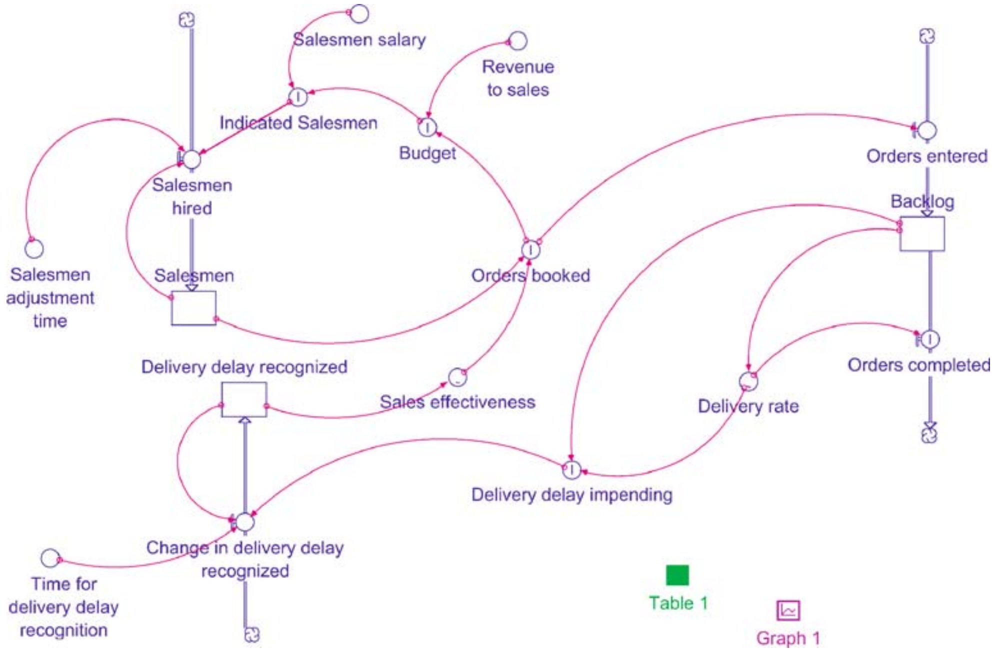
But it will not be sufficient just to describe a social process (as if videotaping it and looking at the video frame after frame), instead it is necessary for understanding and explaining why the process developed the way it developed to construct a model as a means that can create the next frame from the former frames, thus (re-) constructing the laws the process obeys. For simple things such as those elementary physics deals with this law was often represented with a differential equation, one of the classical means of modelling processes. For social systems, this representation is only rarely if ever appropriate, as the calculus does not easily lend itself to describe a population and its members at the same time. This is why system dynamics sets the members of a population (members of an organization, citizens of a country) aside and concentrates on the relatively few properties of the system as a whole, which is also done in some of the classic system theories – for Rapoport (pp. 8–9 in [52]), for instance, "the simplest mathematical description of a system – a model of a spring balance" is the "equation $L = L_0 + kW$ where L is the length of the stretched spring, W the suspended weight, L_0 the 'natural' length of the spring (when $W = 0$), and k a constant that represents the 'stretchability' of the spring." This is exactly the same view on a system as the one taken by system dynamics, where only the variable and constants attributes of the system seem to be interesting, but not the interactions between the parts of a system.

At least from the time of Coleman, but certainly even earlier, e. g. in Durckheim [14], social processes have been superficially represented with the so-called "Coleman boat" or "Coleman bath-tub", a figure [9] that mirrors the notion that processes on the level of, say, society, can be observed on this level, but it is clear that it is not society that "acts", but whatever happens on the level of society is performed by the actions of individual human beings that are in a way under the control of the society and at the same time making up society. In Coleman's example, there is an observable process in which protestant religious doctrine seems to have led to capitalism. This "single proposition breaks into three: one with an independent variable characterizing the society and a dependent variable characterizing the individual; a second with both independent and dependent variable characterizing the individual; and a third with the independent variable characterizing the individual and the dependent variable characterizing the society. Thus the proposition begins and ends in the macro level, but in between it dips to the level of the individual" [8]. The original macro proposition is usually represented with the deck of a boat, while the first of the three new proposition forms its stern, the second is the keel and the third is the bow of the boat. Thus, protestant religious doctrine introduced in a population (wherever this doctrine might originate) influences the value system of individuals, and the changed value system modifies their economic behavior; finally this economic behavior of the individuals modifies the characteristics of the population as a whole (and this latter process is often called "emergence").

The first of these inter-level processes is meanwhile known as "immergence", a term coined by Castelfranchi [7] for the process by which – in Colemans's example – an individual becomes aware of a doctrine ("cognitive emergence") and decides to act according to this doctrine; this process was already described by Durckheim [14] when he talks about "sociological phenomena [that] penetrate into us by force or at the very least by bearing down more or less heavily upon us". The other process, by which individuals change the state of the system (population, organization, ...) qualitatively is often called "emergence".

System Dynamics

As superficially mentioned in earlier sections, system dynamics is a tool for modelling processes in social systems on a macro level. The approach originated in the 1950s, when Jay W. Forrester made his first steps in representing social processes in terms of differential equations (as others had done before him, e. g. Herbert A. Simon [59,60]) and found it necessary to include non-differentiable functions into his models. This was how the programming language DYNAMO was first invented, meanwhile superseded by more modern attempts at designing modelling languages with graphical user interfaces, a functional, i. e. declarative programming language, in which the programmer does not (have to) describe how the computer should perform its calculations, but only



Social Processes, Simulation Models of, Figure 1

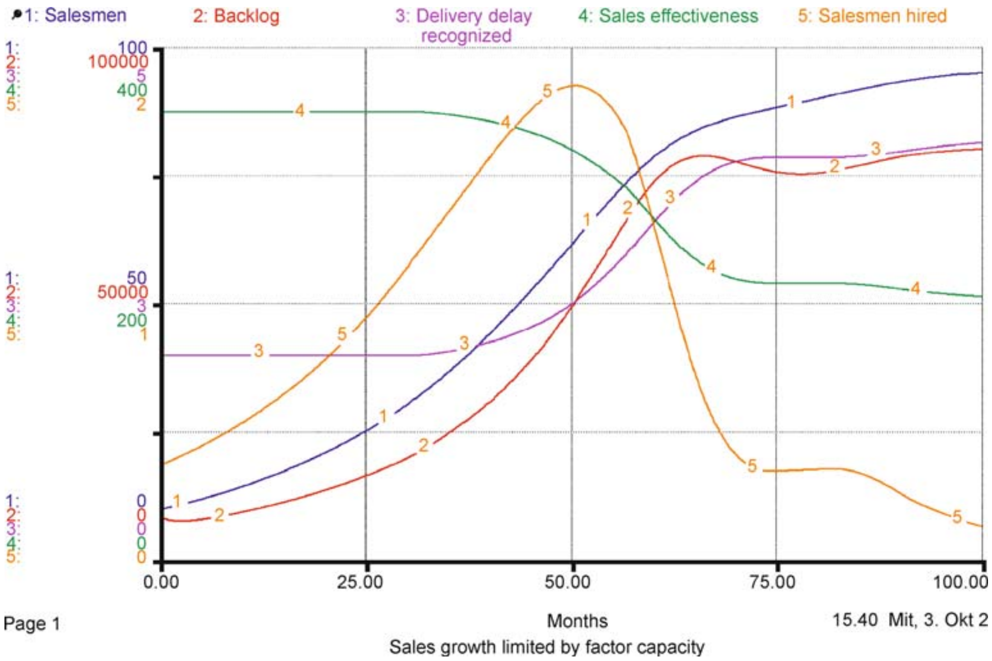
which invariants should hold over time. An invariant in this sense is an equation that holds true even when the states of a thing or system change (for instance, even if the size of population is changing over time, its growth rate could be constant for a long period, such that for all times the equation $\text{size}(t+1) = \text{size}(t) + \text{growthrate} * \text{size}(t)$ holds). System dynamics is of course much more sophisticated, but the equation in the preceding sentence is a typical representative of equations in system dynamics models. The first step in modelling is usually a graphical model showing the dependencies and feedbacks between the attributes of the modelled macro system. These attributes come in several different kinds, the two main kinds of variables being levels and rates. Levels are state variables, usually describing something like material stocks (inventory of a warehouse, size of a population etc.), whereas rates are state change variables, usually describing the material flow into a stock and from a stock per time unit. Beside these, auxiliary variables serve as abbreviations, and constants can be defined.

Among the target systems modelled with the help of system dynamics and the respective tools, there are agglomerations [18], industrial enterprises [16], ecosystems [2] as well as the world as a whole [19,42,43].

A relatively simple example of system dynamics modelling can be found in [17] where a firm with its "sales growth and saturation" is modelled and simulated. The only properties of this firm considered are the current salesperson staff, the backlog of unprocessed orders and the delivery delay recognized. These "level variables" are connected to each other via several "rate variables" – salespersons hired, change in delivery delay recognized, orders entered and orders completed – and several "auxiliary variables" – sales effectiveness, orders booked, budget, indicated salespersons, delivery rate, delivery delay impending – and a few constants – salespersons adjustment time, revenue to sales and time for delivery delay recognition. A STELLA representation of the model makes the idea behind the model sufficiently clear (see Fig. 1).

The simulation of this model shows the time series in several variables of this fictitious firm: The model starts with 10 salespersons and a high budget (stemming from a large number of orders), thus more salespersons are hired who bring more and more orders, more than can be processed such that the backlog quickly increases and the sales effectiveness decreases after some time. This is the signal for hiring less new salespersons, but the delivery delay cannot be decreased in the long run, as a still rising number of salespersons continue to bring more orders.

The graph in Fig. 2 shows some of the drawbacks of the approach: at any time (except at the start) the number of salespersons is a non-integer number, and at any time the number of newly hired persons is also a non-integer



Social Processes, Simulation Models of, Figure 2
Graphical output of the sales growth STELLA model

number ranging from 0.13 to 1.85 whereas, of course, in a real firm, persons would be hired on a full-time or half-time base, but numbers such as 0.13 or 1.85 would be quite unlikely.

At the other end of the range of applications, the world models of the early 1970 can be placed, which became very famous as the Club of Rome funded and published them. Their objective was to predict the consequences of the world population growth for the use of resources and the pollution. Forrester's version [19] is replicated in a NetLogo 4.0 reimplementation shown in Fig. 3. This model has only five level variables – population, resources, pollution, capital investment (in industry) and capital investment in agriculture – which are linked together by nine rate variables and a large number of auxiliary variables and constants. The growth of the world population, for instance, is determined by two rate variables that contain the numbers of births and deaths, respectively, per time unit, and these in turn are determined by natural birth and death rates (biological constants, as it were) and several multipliers, auxiliary variables that transport the influences of causes such as pollution, food availability etc.; resources is another level variable, and this one is only determined by one rate variable, namely the decrease in resources per time unit, as Forrester (and also his successors in Meadows's research group) did not foresee that new resources might be discovered that were not known at the beginning of the simulation run (1900) or at the time when the simulation model was designed (1970).

The output of the model (see Fig. 4) shows what was predicted in the 1970s: a continued increase in the world population up to 8.6 billion in 2040, a decrease in available resources from 900 billion units (whatever these mean) in 1900 to 445 billion in 2040, and an increase in pollution from 200 million to 20 billion units (of another kind) in about 2050 – a result that was discussed worldwide in the 1970 (and perhaps this discussion was the reason why the predictions did not come out true 40 years later – although Meadows in [43] seems to have believed that his predictions were validated by the two decades after [42] appeared.

It is one of the big advantages of system dynamics models that they are easy to understand, easy to develop and to maintain and that they deliver plausible predictions that can easily be validated (or invalidated) against empirical data, though only after several decades. One of their important drawbacks is that the estimation of their input parameters is difficult if not impossible. Take as an example the estimation of a function between the pollution ratio and the pollution dependent death-rate multiplier (the pollution ratio is the actual pollution divided by the "pollution standard", which is defined as 3.6 billion pollution units – approximately the pollution in 1975). In Forrester's world model this function is programmed as

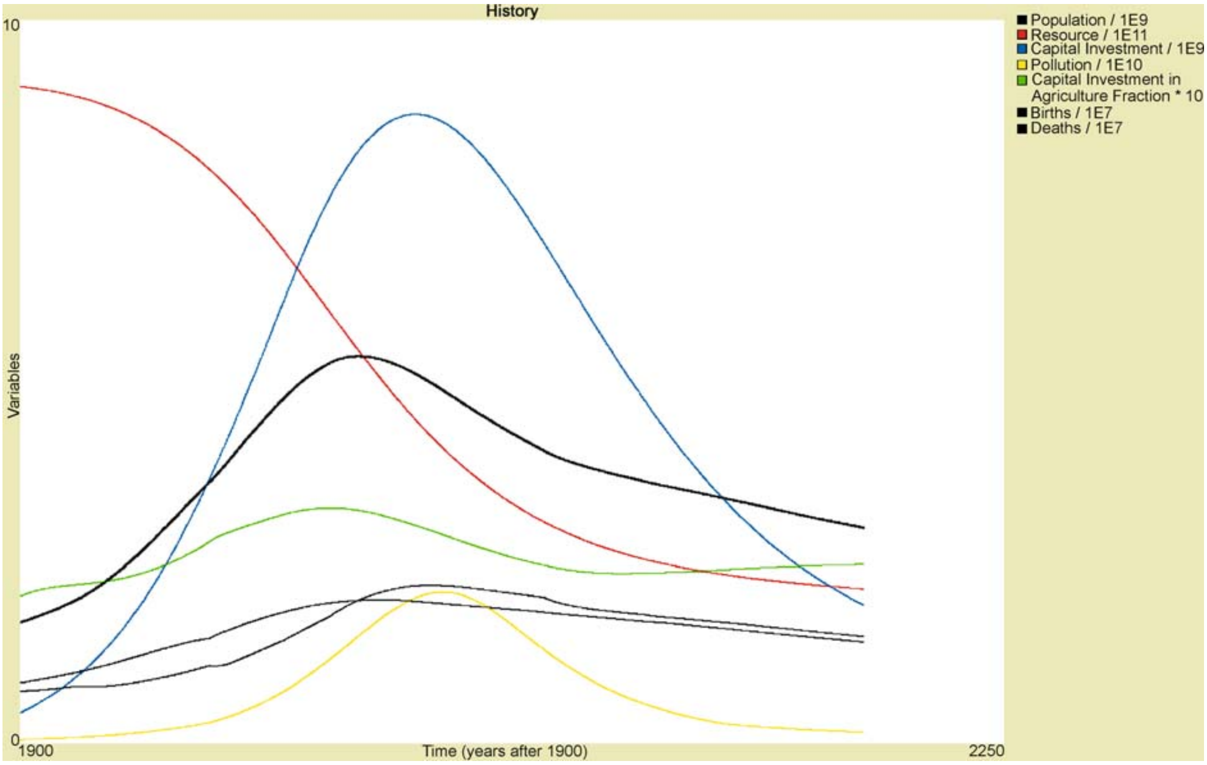
a table function (see Fig. 5), but in many cases it is quite questionable how the form of such a function was estimated.

In [42], the estimation of parameters for many functions between auxiliary variables is explained. The strategy of estimating the parameters of these functions is in most cases the same: it is usually the result of a nonlinear regression between – to take the preceding example – the pollution rate and the death rate pollution multiplier estimated from as many countries of the world as data could be found from, thus believing that synchronously found data from various places in the world were representative of data for the world as a whole collected at different points of time.

Microanalytical Simulation

Microanalytical simulation [22,47] has its origin in the necessity of predicting tax income and tax loads as well as the cost of social transfer. Every modern state needs information on how much taxes must be levied on its citizens in order to perform all the tasks of the state and how much social security contributions must be levied in order to pay retirement income, and it needs to know how many children will enter and leave the school system, how many students will enter and leave universities, how many people will enter the labor force at what time of their life and leave it at the time of their retirement, and, lastly, how many people will have near relatives who might be ready and willing to nurse them when they are in need. Whereas the age structure can be estimated even with difference equations, thus with system dynamics techniques, at least the last of the mentioned questions (which takes kinship networks into account) can only be answered on the micro level.

Microanalytical simulation always starts with a large representative sample of the target population. The sampling units are usually households (of which all members are interviewed), and the attributes sampled are at least age, gender, marital, educational and socio-economic status as well as the links to other members of the same household. This sample is then updated for every time step (usually one year) to answer the questions mentioned above for some time in the future.



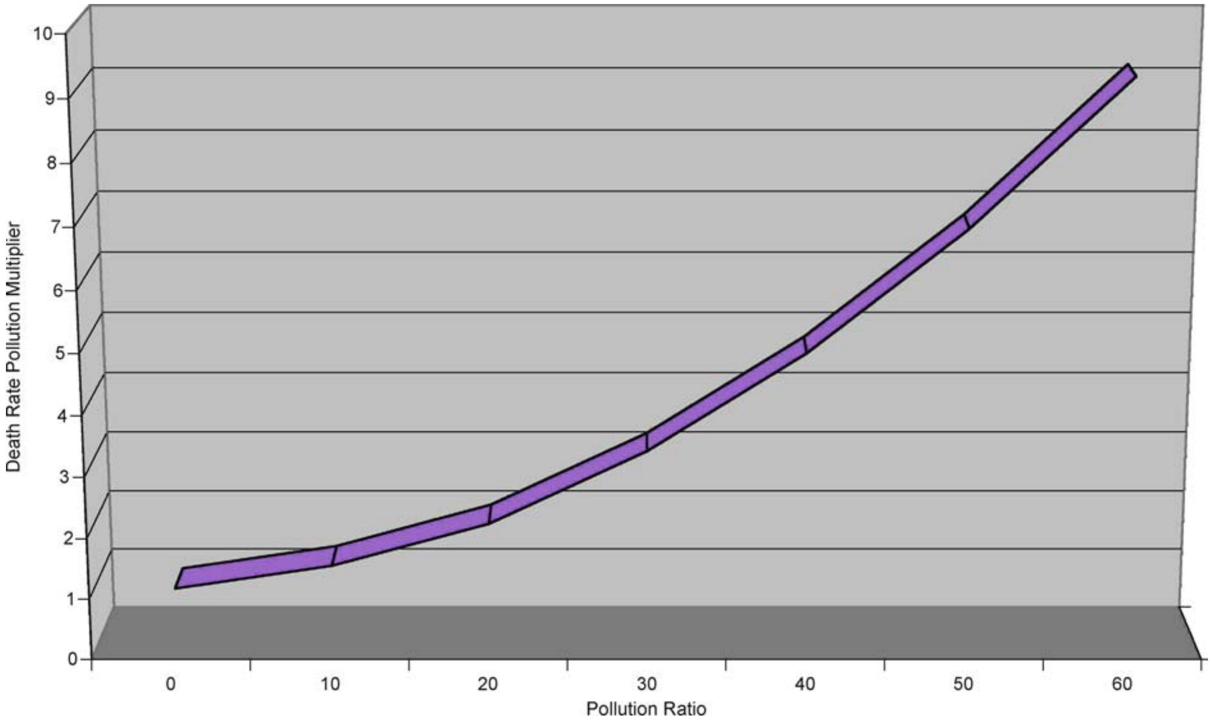
Social Processes, Simulation Models of, Figure 4
Some time series of Forrester's WORLD2 model, from a NetLogo 4.0 implementation

Microanalytical simulation has two easily distinguishable variants. They are usually labelled "static microsimulation" and "dynamic microsimulation". The former is static in so far as the attributes of the sample individuals are not changed over time, only the weights of the individual are updated in order to be representative for some macro variables where the information about the composition are taken from other (demographic or econometric) models. This static simulation is used only for short-time predictions, for instance for estimating tax loads due to revised tax regulation. Dynamic microsimulation changes all individual attributes according to known or estimated probabilities of state changes (for instance age-dependent birth, death, marriage and divorce rates or frequencies of transitions within the educational system and from the educational system into the labor force). For every time step, every micro entity has to be updated, and its link to other micro entities has to be revised, too. As compared to static microsimulation, this variant has the advantage that all state changes are endogenous and, more important, that state transition probabilities can be disaggregated to small sectors of the target and sample population (for instance, assuming different probabilities of giving birth to a first, second, third etc. child for women of different age groups, of different educational and socio-economic state), given that sufficient evidence for estimating such probabilities is available.

Early microanalytic simulation models were always programmed in general purpose programming languages from scratch, without using any particular tools. Their results were only partially published as research was mostly done for state agencies who were not always interested in having all the details of models published. Only recently, toolboxes such as UMDBS [56] and CoMicS [31] became available which lend themselves to be used in academic research and teaching, the more so as in many countries data sets of large representative samples and even panels have become available to the academic public for more than a decade now.

Multilevel Simulation

Multilevel and multi-agent simulations, different as they may be, always had their focus on interactions either among agents of the same kind or between agents of different levels or both. With levels, these approaches under-



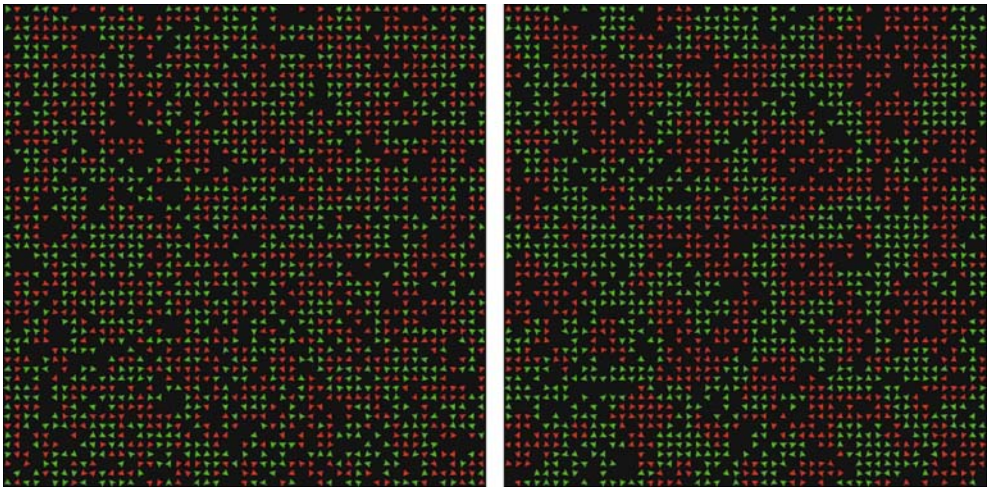
Social Processes, Simulation Models of, Figure 5
How system dynamics defines functions between its variables: the dependence of the death rate multiplier on the pollution ratio

stand different kinds of systems, where the elements of the systems of one kind are systems of the other kind [6]. To give an example: From the biologist's point of view, human beings are systems of one kind (composed of different kinds of tissues, or of cells, etc.), and on the other hand they can be seen as elements of systems called human groups, or populations, or societies etc. And what multilevel simulations are interested in is the interaction between, for instance, the group and an individual, between the macro and the micro level, thus focusing on the stern and bow of the "Coleman boat" [9]. Multi-agent simulation models are usually less focused on the inter-level interaction and more on the inter-agent interaction, but they, too, are usually interested in detecting properties emerging on the macro level.

More often than not, the label "multi1-agent simulation" is used for models in which the micro entities display only very simple behavior, have only very few states and do not communicate with other micro entities (in any reasonable sense of the word "communicate"), have no memory and make no decision. To distinguish these from multi-agent models proper (see the next section), they will here be labelled as "multilevel" models.

A first, quite well-known example may illustrate this. Thomas Schelling [57,58] designed a model in which (rather primitive) agents have to decide whether they move from one neighborhood into another, in which they can expect to be happier. Their happiness depends on the composition of their neighborhood, given that agents differ only with respect to one dichotomous property (say, their native language) – they are the happier, the more people in their neighborhood speak the same language, and there is a threshold where happiness turns into unhappiness. The world in Schelling's model is represented with a cellular automaton (see the chapter on cellular automata in this Encyclopaedia), and the neighborhood consists of the eight cells around an agent, which may be empty or inhabited by another agent. The central agent is happy if the language distribution in its neighborhood is such that a certain percentage of its neighbors speak the same language. In each time step, every agent scans its neighborhood and decides whether to move or stay, if it decides to move it tries to find another cell where the neighborhood is more attractive than in its original cell. One realization [67] of this model is shown in the two parts of Fig. 6.

It shows that the random distribution of red and green agents soon changes into a distribution with clearly distinguishable red and green clusters, part of which are even separated by uninhabited zones. The threshold between



Social Processes, Simulation Models of, Figure 6

Schelling's segregation model (*left:* initialization, *right:* state of the macro level when all individuals are happy with their neighborhoods)

happiness and unhappiness in this example is 30 per cent, i. e. an agent moves only if more than 70 per cent in its neighborhood are different from itself. Although these agents are quite tolerant with respect to strangers, clusters occur; and these clusters are larger and better separated when the tolerance threshold is higher. One should note here that the Schelling model takes only local interactions between agents into account; there is no interaction between levels if only in so far as the structure of the macro level changes due to the individual interactions, but it does not feedback into the micro level as the agents are not capable of recognizing what happens on the macro level.

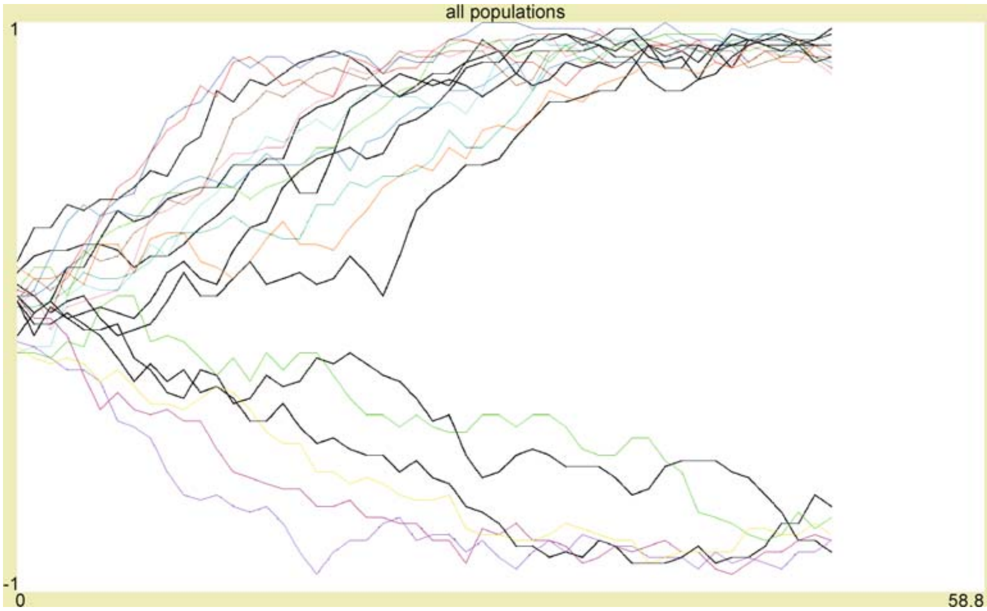
Another early approach to multilevel modelling of social processes is mainly interested in the interactions between the levels. It was originally developed by Hermann Haken [21], a German physicist who tried to apply the methods with which he had done research in laser physics to other disciplines, including sociology, and extended by his colleagues Wolfgang Weidlich and Günter Haag [66]. This approach, called synergetics by Haken, is currently better known as sociophysics or econophysics. Although the micro level entities are often also called agents by several authors, they are only particles as they only react on something like social forces or fields that are modelled in a manner very similar to the description of gravitational, electrostatic and electromagnetic forces and fields.

The original work by Weidlich and Haag [66] describes populations consisting of a large number of individuals where the individuals usually have only one discrete state variable which is either binary or can take only very few values, and the state change of the individuals depends on the macro state which is in turn determined by the individual state changes. The simplest example may make this clear: Imagine a population whose members have to decide between two options (yes and no) and whose decision depends on the perceived current majority in such a way that the probability of switching from no to yes is the higher, the larger the current yes majority is and the other way round. Then under certain assumptions of modelling the exact function between the current yes majority and the individual transition probabilities, the population as a whole shows some interesting behavior. In the example the two individual transition probabilities have the following form:

$$\mu_{\text{yes}\leftarrow\text{no}} = \nu \exp(\pi + \kappa x)$$

$$\mu_{\text{no}\leftarrow\text{yes}} = \nu \exp[-(\pi + \kappa x)] \,,$$

where ν is a flexibility parameter, π is a preference parameter, and κ is a coupling parameter, whereas x describes the current state of the population ($x = -1$ means "all no", $x = +1$ means "all yes"). The flexibility parameter only determines how likely any change between options is; the preference parameter determines whether changes from yes to no are generally more likely than those from no to yes (if it is negative) or the other way round (if it is positive); and the coupling parameter determines the strength of the influence the population exerts on the individual. It goes without saying that any individual change changes the state of the population. Figure 7 shows a typical outcome of a simulation of this very abstract social process. Each of the curves represents the history of the state of one out of twenty populations (all of them with a vanishing preference parameter and a coupling parameter of 1.4);



Social Processes, Simulation Models of, Figure 7
History of 20 populations whose members change their state with a probability that depends on the state of the population

some of the curves show that their populations soon develop into populations with a very high yes majority while others become populations with a high no probability, but none of them is ever entirely homogeneous. A more concrete social process that is likely to behave similarly is the distribution of two alternative goods that are not easily compatible, e. g. computer operating systems or videotape machines; here one could expect a high coupling as being with the majority makes the exchange of programs or videos easier. A low coupling constant results in an outcome where all populations are more or less evenly split in yes and no members – which in reality could be the case when the two alternative goods are easily compatible or substitutable, e. g. cigarette brands.

Extensions of this model were proposed by Lumsden and Wilson [41] who replaced the exponential function in the formula for the individual transition probabilities with other types of functions, to explain the co-evolution between "genes, mind, and culture". Other extensions, already given in [66], deal with several populations interacting with each other, the individual transition probabilities not only depending on the state of the members' own population, but also on the state of other populations, for instance modelling migration behavior of two populations between two regions.

Helbing [26] extended the models of his teachers, Wolfgang Weidlich and Günter Haag, in a way that he described as "quantitative sociodynamics". Much like his teachers he used closed solutions wherever possible to analyze the abstract social processes that he formalized, at the same time extending the focus not only to interactions between levels but also to interactions between individuals [24,25] which he also used to model the behavior of traffic participants, mainly pedestrians [24,27]. Here again, individual human beings are modelled as particles in a field and not endowed with the familiar human capabilities of decision making. In Helbing's pedestrian models (e. g. [27]) the pedestrians are just particles moving in a "social field", a term originally coined by Lewin [38], according to whose theory "behavioral changes are guided by so-called social fields or social forces, which has later on been put into mathematical terms" (p. 625 in [27]). These particle-pedestrians are accelerated at any time by a force which is determined by their desired directions and speeds and a repulsive force which keeps them apart from each other and from obstacles. Although the comparison between simulation results and video recordings of real pedestrian behavior shows nearly no qualitative difference, the particle-pedestrian are far from the definition of agents that is used by other authors who describe their simulations as multi-agent models.

Another kind of "social field" models was used to analyze attitude formation processes in an artificial society where the attitudes were not binary or categorical, but continuous. Models like these were inspired by Anthony Downs's early theory on party affiliation [13]. Downs assumed that voters moved in a continuous attitude space (one-dimensional, from left to right) and were attracted or repelled by parties, and he believed that under certain circumstances a polarization of the electorate would emerge with high frequencies on the left and right wings and low frequencies in the middle, but he never formalized this theory. Several different formalizations were published in the sequel which tried to explain polarization without the interference of parties. One of these formalizations was inspired by empirical data which – for some German elections in the past – showed such a polarization in terms of a bi- or multimodal frequency distribution of voters over their attitude space which emerged during election campaigns and vanished shortly after the election [63]. The simulation runs started with a sample of a large numbers of model entities which obeyed an approximate bivariate normal distribution at the beginning (samples are never perfectly normal) entities then tried to move according to a function which was composed of the gradient of the frequency density distribution and some random effect. These movements changed the frequency density distribution, which in turn changed the gradient. In most simulation runs the frequency density functions became bimodal or multimodal after some time. Another representative of models inspired by Downs was presented by Guillaume Deffuant and is colleagues [12]. Here the simulated entities have a one-dimensional continuous attitude (much like in [63]), but additionally something like persuasive power, and as in [63], typically multimodal distributions emerge with modes both in the center but also at the ends of the attitude range, representing extremists in real electorates.

The approach in [12] is in some way similar to social impact theory developed by Bibb Latané [34] who also combined attitude and persuasive power, but let simulated entities interact on a grid, thus introducing topography and restricting interaction to near-neighbor interaction. The simulation models following his theory [35,36] show, similarly to the synergetic models, a survival of minorities, but also the clusters observed in Schelling's migration models (although the simulated entities in the social impact theory do not move in topological space).

Multi-Agent Simulation

An example that can easily be compared to the pedestrian models is the riot behavior model of Wander Jager and colleagues [29]. Here, agents belong to two different subpopulations (party 1, party 2) which can be imagined as the fans of two competing football clubs. Besides moving in a two-dimensional space, they can decide to fight or withdraw. In a version with police as a third subpopulation, the agents of this kind have additional behavioral options. Which action an agent takes does not depend on anything like a social field (at least not in the sense of Helbing, but perhaps in the sense of Lewin), but on their perceptions of the behavior of other agents in their neighborhood. These agents follow more or less the definition of agents that was given by Wooldridge and Jenkins [69] and which is currently the most often cited definition of agents:

An agent is a piece of software that

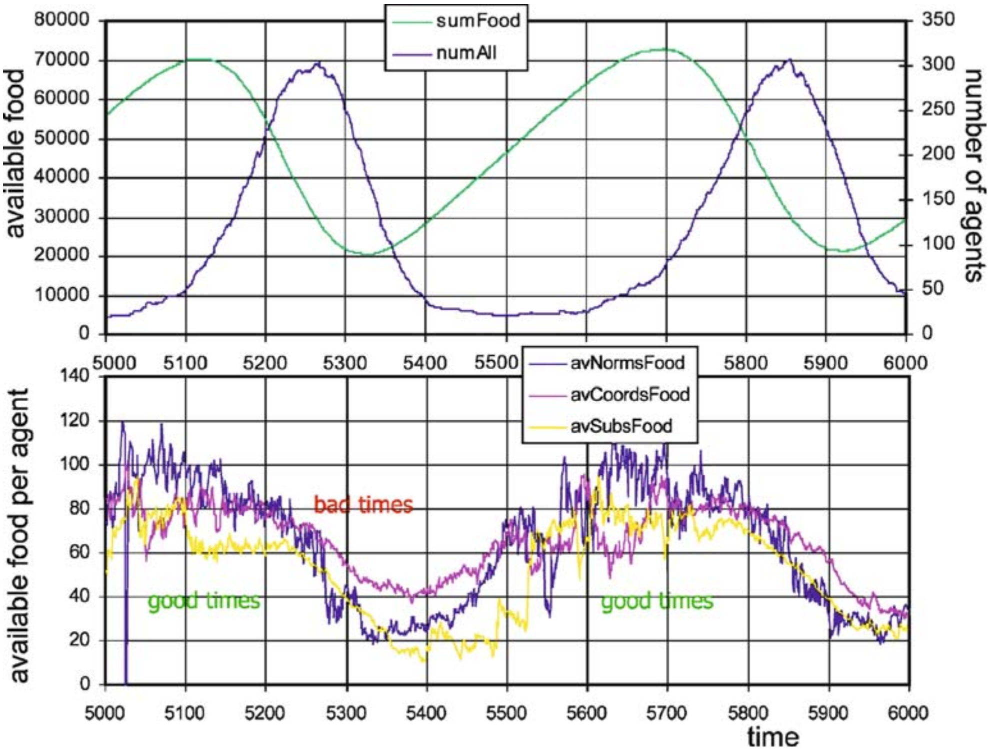
- has some autonomy, i. e. operates without other parts of a larger computer program having direct control of its internal state and actions,
- can communicate with other agents in some kind of language, i. e. without direct access to other agents' inner state,
- can perceive its environment and can react on it, and
- can also take the initiative, i. e. can act without a stimulus from outside and display goal-directed behavior.

This results in several requirements: In order to be able to take the initiative (to be pro-active), agents must have goals (descriptions of desired and possible states of their neighborhood or surroundings, including themselves) and must be able to compare their perceived state of their environment to their goals. According to the outcome of such a comparison, they must decide between several possible actions which they have to evaluate, and moreover they must be able to design a plan (i. e. a course of possible actions) if there is no action that leads them directly to their goal. Another requirement can be that agents communicate with other agents, for instance asking them for their help when only co-operation enables them to achieve their goals.

Among the early forerunners of multi-agent systems in the social sciences at least two can be named where processes of voter attitude changes are modelled and simulated. Although the poor computer languages of the late 1950s and early 1960s did not allow for agents in the sense of our days, any re-implementation would nowadays be a multi-agent system with several classes of agents (representing voters, candidates, media channels, as in [1] or in the Simulmatics project supporting John F. Kennedy's election campaign [11]) as they dealt with the communications among citizens, between citizens and candidates as well as between citizens and media channels and modelled their behavior and actions in a rule-based manner.

A classical example that fulfills most of the requirements raised in [69] is Epstein's and Axtell's attempt at building "Social Science from the Bottom Up" [15], an artificial world in which agents make their living on two different crops which they harvest, store, consume and barter according to their needs and the available resources. An extension of this artificial world can be found in [32]. In addition to all the features of the artificial society in [15], these agents can subordinate to others if the latter offer themselves as co-ordinators and promise their subordinates to inform them about the state of a wider environment than they can perceive individually, while the subordinates in turn provide their chieftains with their local information and pay a certain tribute from what they harvest. To be able to do all this, all agents have a long-term memory in which they store information about their world and which can guide them to places in their world that promise a rich harvest of the kind of crop they actually need. This extended model shows that a world with co-ordinators and subordinates is more sustainable than a world in which all agents try to harvest on their own; it also shows that lonely agents are best off when times are getting better, whereas subordinating pays best when times are getting worse and being a co-ordinator pays best when times are worst. Figure 8 is a part of two plots written by the simulation program: the green curve in the upper graph shows the development of food available over time, the blue one shows the number of surviving agents over time, while the three curves in the lower graph show the average "income" of the three types of agents (blue. the lonely agents, magenta: the chieftains, yellow: the subordinates) – "bad times" is when the overall available food is at its minimum, "good times" is when it is at a maximum. Among others, Fig. 8 shows that the macro behavior of the process is the same as the behavior of the well-known Lotka–Volterra model [39,65], but the classical coupled differential equations of this model or the stochastic process described in [66] would not have been able to display the additional information about the fate of the three kinds of agents.

Validating a model [64] such as the one described above is nearly impossible, as the model describes an abstract social process which is very unlikely to have ever occurred in reality. Nevertheless, this model makes a prediction that is quite similar to the prediction of another agent-based simulation [52,54]: "In a society of herdsmen and farmers in Western Africa, decisions which rest on



Social Processes, Simulation Models of, Figure 8
Development of an artificial society whose members can declare themselves co-ordinators and subordinates, respectively (graphs produced by the simulation model described in [32])

friendship networks ('friend-priority' decisions) proved to be much more effective then decisions which were made on pure cost deliberations ('cost priority' decisions)." See p. 189 in [52]. The papers quoted here are at the same time representatives of a style of modelling and simulating social processes which is known as "participative simulation" and usually used to discuss models with stakeholders who work with the simulation models and give hints at improving and amending models to adapt them better to their personal experience. This style of modelling and simulation is being used more and more often in consultancy to give stakeholders an opportunity to work with models on their own, instead having to believe what the consultant presents in the end.

Tools

Computer simulation always needs some tools to be run. In the early times of computer simulation, simulation programs were written in general purpose programming languages (like FORTRAN), but over the decades special simulation toolboxes were designed and implemented, first by researchers in fields such as organization science, production management (particularly for discrete event and queuing systems) or physics and engineering (particularly for numerical solutions of differential equations). Both of these kinds of tools were also used by social scientists, though only rarely. DYNAMO was the first simulation tool designed for and used by economists and social scientists [50], but only for system dynamics models. It was later on superseded by STELLA [53] with the same purpose, but a graphical user interface (see Figs. 1 and 2). There are several simulation tools for cellular automata (see the entry on cellular automata for more details). Multi-level simulation models are often written in general purpose programming languages (but see [44] describing a language – MIMOSE – explicitly designed for this kind of models). Multi-agent simulation proper has been developed with the help of toolboxes such as SWARM [30], RePAST [45,46], MASON [40], CORMAS [37] and NetLogo [68] (the latter was also used to produce the majority of graphics in this entry). All of these are freeware and capable of supporting most social simulation techniques (with the exception of microanalytic simulation, as this always needs a large database connected to the simulation tool). With the exception of NetLogo, which has a simulation language of its own, the actual description of agent behavior has to be done in object-oriented languages such as Smalltalk, Objective C or Java (for more detailed reviews of these toolboxes see [51,62]).

Future Directions

In a way, "agents cover all the world" [4] in that multiagent systems can be used for all simulation purposes, as agents can always be programmed in a way that they behave as continuous or discrete models, can be activated according to event scheduling or synchronously or in a round-robin manner, can use rule bases as well as stochastic state transitions, and all these kinds of agents can even be nested into each other, thus supporting a wider range of applications than any of the classical simulation approaches. This leads to a third aspect of complexity (after the complexity of domains and the complexity of time): agent-based models can encompass several different approaches, both from a technical and implementation point of view, but also from the disciplines making use of simulation (for instance, disciplines such as neurophysiology, cognitive psychology, social psychology and sociology can combine their contributions into a deeply structured simulation model).

It goes too far to say that all this would not be possible in a non-agents world (as everything is programmable in Assembler), but the examples above will have made clear that models combining aspects from even neighboring disciplines as the ones enumerated in this entry are only understandable and communicable when they come in a modular form that is typical for agent-based models – and the same applies to ecological models where disciplines from physics and biochemistry to population biology and economics would play their co-operative roles.

Although agent communication languages (see the special issue of Autonomous Agents and Multi-Agent Systems, vol. 14 no. 2) such as KQML [33] have been developed for a long time (back to 1993), it is still an open question how agents in a simulation model could develop a communication means on their own and/or extend their communication tool to be able to refer to a changing environment (see the special issue of Autonomous Agents and Multi-Agent Systems, vol. 14 no. 1). Hutchins and Hazlehurst [28] made a first step into the field of the emergence of a lexicon, but their agents were only able to agree on names of things (patterns) they saw. The NEWTIES project [20], ambitious as it is, aims at creating an artificial society that develops its own culture and will also need to define agent capabilities that allow them to develop something like a language although it is still questionable whether the experimenters will be able to understand what their artificial agents talk about. The same objective is aimed at in the current EMIL project (Emergence in the Loop [3,10]) which attempts at creating an agent society in which norms emerge as agents observe each other and draw conclusions about which behavioral feature is desirable and which is misdemeanor in the eyes of other agents – which, as in the case of language emergence, makes it necessary that agents can make abstractions and generalizations from what they observe in order that ambiguities are resolved.

This means that multi-agent models in the proper sense – where software agents model cognitive capacities of human beings – will be the aim of any future development in the simulation of social processes, although even these models will still contain features of the classical approaches, as even human beings display behavior that can be categorized as reflex acts and instinctive and which can be modelled with models borrowed from particle kinematics in which human beings are represented by stochastic automata. On the other hand it should be clear that only part of human behavior in very large groups can be explained this way, as an important part of this behavior consists in deliberate and conscious actions that are determined by cognition.

Glossary

Dynamical system A dynamical system is a set of interconnected elements that change due to their mutual influences. A change in each element depends on the nature of the influences from other elements. Due to these mutual influences, the system as a whole evolves in time. Because the state of every element is the effect of the states of all the relevant elements in the previous moment, and because the state of every element is one of the causes determining the state of the other elements in the next moment, a dynamical system is characterized by bi-directional causality.

Intrinsic dynamics In a dynamical system, the current state of the system is directly caused by the preceding state of the system. More precisely, the state of each element at a given moment is caused by the states of other elements in the previous moment and by its own previous state. This chain of cause and effect iterated over time gives rise to internally-generated or "intrinsic" dynamics.

Self-organization In a dynamical system consisting of inter-connected elements, the state of each element adjusts to the current state of other elements to which it is connected. Because of this mutual influence, higher order units develop that represent the organization of the basic elements. No higher-order agent is required for such order to emerge. Hence, the process is referred to as self-organization.

Emergence Emergence occurs when the individual elements of a dynamical system achieve organization by means of their mutual influence. The development of the higher level state is said to be emergent because this state was not inherent in the properties of the lower-level elements and because the higher-level state was not imposed on the system from forces outside the system. The higher-order properties that result from the mutual adjustment among lower-level elements provide coordination for the lower-level elements. Emergence thus provides for substantial growth in the complexity of a system's processes and properties. Because of emergence, very complex systems can often be described by very simple models.

Attractor An attractor represents a subset of a system's phase space to which the system evolves over time and which resists forces that would perturb this temporal trajectory. This subset can consist of a region of nearby states or it can represent two (or more) regions among which the system oscillates over time in a periodic, quasi-periodic, or chaotic manner. In a system governed by attractor dynamics, a relatively wide range of starting points (initial states) will eventually converge on a much smaller set of states or on a pattern of change between states defining the attractor. External influences may push the system out of the attractor, but over time the system will return to this equilibrium.

Cellular automata Cellular automata are programmable dynamical systems. In this approach, a finite set of elements is specified, each of which can adopt a finite number of discrete states. The elements are arranged in a specific spatial configuration that usually takes the form of a two-dimensional lattice or grid. The location of each element on this grid specifies the element's neighborhood. The elements evolve in discrete units of time, such that the state of an element at $t + 1$ depends on the states of the neighboring elements at time t. The dynamics of cellular automata depend on the nature of the updating rule and on the format of the grid dictating the neighborhood structure.

Definition of the Subject

The seminal insights that launched the field of social psychology over a century ago have stood the test of time. Such early scholars as James [41], Cooley [21], Mead [65], Lewin [59], and Asch [4] emphasized the multiplicity of interacting forces operating in individual minds and in social groups and the potential for sustained patterns of change resulting from such complexity. The inherent complexity and dynamism of human experience, however, proved problematic for mainstream social psychology during much of the 20th century. The canonical paradigm in this period reduced dynamics to a one-step process involving a purported cause, operationalized as an independent variable at an arbitrary time 1, and its effect, operationalized as a dependent variable that was assessed at an arbitrary time 2. The complexity of experience, with multiple variables interacting over time to generate a stream of thought or action, was difficult to investigate with available statistical techniques (e. g., correlation, regression, analysis of variance). Social psychology thus fostered an image of human experience that emphasized simplicity and stability at the expense of complexity and dynamism.

Contemporary social psychology shows signs of returning to the deep intuitions concerning human experience articulated by the field's founding fathers. The renewed appreciation for complexity and dynamism was made possible by developments in the understanding of nonlinear dynamical systems in the 1970s and 1980s, and the application of these developments to social processes within the last two decades. Computer simulations capture the complexity of social processes and document the emergence of higher-order properties from the interaction of basic elements in a mental or social system. Innovative means of collecting and analyzing time-series data provide rigorous insight into the intrinsic dynamics of mental, affective, behavioral, and interpersonal processes. And formal models enable researchers to identify the parameters that are critical for understanding the dynamism and complexity of social psychological phenomena. In short, the contemporary emphasis on complexity and dynamics provides a new paradigm for the field, one that holds promise for advancing the social psychology as a precise science while preserving the basic insights that launched the field over a century ago.

Introduction

Despite its ubiquity, dynamism is a poor candidate for theory construction. Theories are expressed in terms of invariant properties representing stable "signals" that are obscured by the "noise" associated with personal, interpersonal, and societal processes. The stream of consciousness may be an accurate depiction of subjective experience, for example, but its turbulent nature seems inconsistent with fundamental properties that transcend particular individuals and their moment-to-moment mental states. To identify regularities and invariant properties, social psychologists commonly ignore the ever-changing undercurrent of mind and action, focusing instead on those elements of thought and behavior that admit to stability and structure. Accordingly, they typically emphasize higher order units of mental and behavioral phenomena (e. g., traits, schemata, global evaluations, norms) that presumably lend stability and coherence to subjective experience. The turbulent flow of lower level elements (thoughts, feelings, movements) is effectively rendered irrelevant to "true" understanding and meaningful prediction.

The gulf between the reality of experiential turbulence and the focus on stability in theory construction is unnecessary. Dynamism and structure represent complementary aspects of experience that together provide the basis for cognitive, emotional, and behavioral accommodation. The basic notion is that the flow of lower-level elements gives rise to higher order structures, which in turn constrain the dynamics of lower-level elements. This reciprocal causal relationship between lower-level and higher-level units of experience is central to *dynamical social psychology* [74,106] a recently developed paradigm that represents an adaptation of the concepts, principles, and tools developed within dynamical systems and complexity science.

It is not feasible to describe every version of the dynamical perspective, nor every application of this general approach. This may have been possible in the

1990s [26,31,35,45,102] when the dynamical perspective was a promissory note rather than an established paradigm. Since that time, there has been a proliferation of many innovative research strategies—some providing formal models implemented in computer simulations, others offering empirical means for investigating the dynamics of personal, interpersonal, and societal processes—that have been used to investigate a wide variety of phenomena. The aim herein is to highlight the crucial elements of the dynamical perspective that find expression in otherwise distinct theories, research strategies, and topical agendas.

The first two sections (Sects. "Intrinsic Dynamics" and "Attractors in Psychological Systems") describe basic concepts from the study of nonlinear dynamical systems that are directly relevant to social psychology. Section "Dynamical Minimalism" describes dynamical minimalism [72], an approach that provides a workable entrée into the nature and expression of dynamic processes at different levels of social reality. This approach is illustrated in the next two sections with respect to two research agendas—one emphasizing the emergence of group-level properties from the self-organization of individual agents (Sect. "The Dynamics of Social Influence") the other exploring the tendency of individuals to coordinate their behavioral and mental dynamics in service of forming dyads and social groups (Sect. "Dynamics of Interpersonal Coordination"). The final section ("Future Directions") reflects on the trajectory of dynamical social psychology thus far and offers caveats concerning the relevance of this approach to the unique features of human experience.

Intrinsic Dynamics

People's mental and emotional states, overt behavior, and social relations evolve and change in the absence of external influence. The ubiquity of intrinsic dynamics is apparent at different levels of social reality, from basic intrapersonal processes to macro-level societal phenomena. At the level of the mind, the temporal pattern of cognitive and affective elements in the stream of thought [41] often provides a more accurate depiction of a person's mental make-up than do the summary aspects of the person's mental process (e. g., overall attitude, final decision) that are more often the focus of investigation [103]. For example, research has shown that simply thinking about an attitude object (e. g., another person) in the absence of external influence or new information tends to promote more extreme (polarized) evaluations of the object over time [97].

Research on social judgment has shown that internally generated thoughts and feelings about a target person often reflect elaborate but identifiable patterns of change that convey important information. A judgment that is neutral when average over time, for instance, can have very different meanings and implications, depending on the intrinsic dynamics of the judgment process [109]. When neutrality represents little variation in evaluation occurring on a relatively slow time-scale, the summary judgment might well reflect a truly neutral sentiment. If neutrality reflects oscillation between highly positive and highly negative judgments on a rapid timescale, however, the summary judgment signifies heightened involvement and ambivalence rather than neutrality per se.

Intrinsic dynamics also characterize personal action. Actions have a hierarchical structure, in that the performance of an action entails the coordinated interplay of more basic actions or sub-acts. "Going to work," for example, may involve getting dressed, leaving the house, driving a car, parking the car, and entering a building. Each of the lower-level acts, in turn, can be decomposed into yet more basic lower-level elements. "Driving," for instance, consists of starting the car, turning the steering wheel, making turns, and braking. Each level in an action hierarchy is associated with a different time scale, with increasingly lower-level acts taking place in correspondingly shorter intervals of time [69]. "Going to work" unfolds on a longer time scale than does "driving," for example, and the time scale for "driving" is longer than that for each instance of "turning the steering wheel." There is evidence that the embedded time scales in an action hierarchy often have a fractal structure [69].

The intrinsic dynamics of action, in turn, span the levels of action in an overall action hierarchy. What may appear to be a continual succession of momentary movements when defined in low-level, mechanistic terms can take on the appearance of switching between qualitatively different actions, each occurring on a longer time scale, when defined in higher-level terms. Research on action identification [107] has identified several factors that determine the level at which an action is regulated. This line of work has also demonstrated that people reliably differ in their default level of action identification across many action domains [108]. Individuals who tend to think about their actions in lower-level terms are predisposed to the emergence of higher-level action understanding. Emergence occurs when such individuals are exposed to cues (e. g., feedback from other people) that suggest higher-level meaning for the actions [114] or when they privately reflect on their actions, allowing the lower-level action elements to self-organize into a higher-level act identity that provides subjective integration for these elements [104].

Social interaction has also been investigated with respect to intrinsic dynamics. For example, research has focused on the interpersonal coordination of relatively low-level actions, such as speaking (e. g. [20,23]) and limb movement (e. g. [6,48,69,101]). In one approach, two individuals are asked to swing their legs while sitting down across from one another [6]. One person swings his or her legs in time to a metronome and the other person tries to match those movements. This research has revealed two forms of coordination: *in-phase*, with the individuals swinging their legs in unison, and *anti-phase*, with the individuals swinging their legs with the same frequency but in the opposite direction. Individuals can maintain anti-phase coordination only up to a certain frequency of movement, at which point they switch to in-phase coordination. When the frequency is subsequently decreased, at some value they are able to coordinate anti-phase again, but this tempo is significantly lower than the point at which they originally started to coordinate in-phase. Such *hysteresis* indicates that movement coordination can be analyzed as a nonlinear dynamical system [38,48]. This line of research has identified modes of coordination more complex than in-phase and anti-phase [5,87,101].

Interpersonal dynamics are not confined to the coordination of speech and motor movements, but also include the temporal coordination of higher-level actions (e. g., plans, goals) and internal states (e. g., moods, judgments). Although this topic has not been heavily researched, there is evidence that the quality of a social relationship is reflected in partners' ability to coordinate in-phase with respect to their respective higher-level actions, opinions, and feelings (e. g. [5,36,64,82,83,100]). The ebb and flow of feelings, information exchange, and action conveys deeper insight into the nature of a relationship than do global indices such as the average sentiment, the amount of information exchanged, or the summary action tendencies. Colloquially, people who feel positively about one another are said to "be in synch" or "on the same wavelength" with respect to their internal states.

At the societal level, tracking the temporal trajectory associated with the emergence of norms and public opinion provides greater insight into the society's future make-up and likely response to external threat than simply knowing what the societal norms and opinions are at a single point in time [76]. When norms and opinions develop gradually over a long period of time, for example, the society displays resistance to external threats or even to new information that might promote better economic conditions. But societal change in political and economic ideology can occur in a rapid, nonlinear manner (e. g. [75,84]), with a temporal trajectory that resembles phase transitions in physical systems [58]. Societies that undergo such nonlinear transitions are vulnerable to later rebounds of the earlier ideologies and are highly responsive to threats and new information, and they can experience a period of sustained oscillation between conflicting worldviews [75].

Attractors in Psychological Systems

Psychological systems are characterized by intrinsic dynamics, but they also demonstrate stability and resistance to change. Each day, people encounter vast amounts of information relevant to social judgment and interpersonal relations, much of which is mutually contradictory. People nonetheless manage to form and maintain coherent patterns of thought and behavior in their social lives. The partners to a romantic relationship, for example, experience a wide variety of thoughts and feelings about one another, but over time each partner's mental state tends to converge on positive sentiment toward the other. Thus, despite the ever-changing nature of intrapersonal and interpersonal experience, people's mental, emotional, and behavioral states tend to converge on relatively narrow sets of specific states or on patterns of change between specific states. These states or patterns of change are referred to as *attractors*.

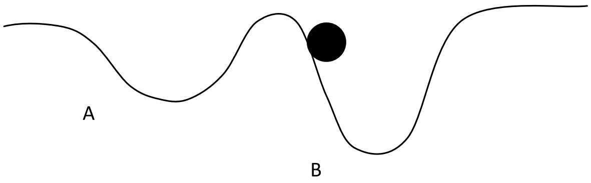
When a system is at its attractor, it tends to maintain that state despite potentially destabilizing forces and influences. An external influence may move the system to another state, but the system will return fairly quickly to one of its attractors. Several social psychological phenomena imply the existence of an attractor. For example, self-regulation is defined in terms of resistance to temptations and distractions, impulse control, and the maintenance of states representing salient personal standards and values [14,15,105]. In the same fashion, self-esteem maintenance [98], self-verification [95], and psychological reactance [8] all reflect the tendency of mental systems to converge on a particular state (e. g., a level of self-esteem) and to resist influences that threaten to dislodge the person's judgments and beliefs from that state.

Three basic types of attractors are commonly distinguished: fixed-point attractors, periodic (including multiperiodic) attractors, and deterministic chaos (cf. [25,73,89]). Each type is likely to have relevance for understanding different intrapersonal and interpersonal processes, although work designed to establish such relevance is in its nascent stage. A system can be characterized by another set of points that have the opposite effect of attractors. Termed *repellors*, they represent unstable equilibria of the system, so that the smallest departure from their exact values will result in the system rapidly escaping from the region surrounding that value. Whereas attractors may be described as states that the system "seeks" over long periods of time, repellors reflect states that the system selectively "avoids." The repellor concept has been used to describe how neural networks avoid particular memories [105].

Fixed-Point Attractors

A *fixed-point attractor* is similar to the notion of equilibrium or homeostasis [12,66]. It represents the case in which the state of the system converges to a stable value. A desired end-state or goal [14,15,104,106] for example, can be described as a fixed-point attractor. This is apparent when a person maintains a belief, an interpersonal evaluation, or an action tendency despite forces or sources of information that challenge these tendencies. Attractors, however, are not limited to goals, intentions, or other desired states. Thus, a person might display a pattern of antagonistic behavior in his or her social relations, despite efforts to avoid behaving in this manner. Similarly, a person with low self-esteem may initially embrace flattering feedback from someone, but over time the person may discount or reinterpret this feedback, displaying instead a pattern of self-evaluative thought that converges on a negative state [96]. In an inter-group context, meanwhile, warring factions may display conciliatory gestures when prompted to do so, but revert to a pattern of antagonistic thought and behavior when the outside interventions are relaxed [19]. In short, when a system's dynamics are governed by a fixed-point attractor, the system will consistently evolve to a particular state, even if this state is not hedonically pleasant, and will return to this state despite being perturbed by forces that might promote a more pleasant state.

A psychological system may have more than one attractor, with each corresponding to a distinct equilibrium. Which attractor governs a system's dynamics in a particular instance depends on the starting values of the system's evolution. The set of initial states that converge on each attractor represents the *basin of attraction* for that attractor. For a person or a group characterized by multiple fixed-point attractors, then, the process in question can display different equilibrium tendencies, each associated with a distinct basin of attraction. Within each basin, different initial states will eventually converge on the same stable value. However, even a slight change in the system's initial state will promote a large change in the system's trajectory if this change represents a state that falls just outside the original basin of attraction and within a basin for a different attractor. For example, in conflict situations there are typically two dominant responses, one corresponding to aggression and one corresponding to conciliation. Slight differences in the circumstances surrounding the conflict can thus promote dramatically different behaviors, with no option for a response that integrates the two tendencies (e. g. [19]).



A dynamical system with two fixed-point attractors (A and B)

Social Psychology, Applications of Complexity to, Figure 1
A dynamical system with two fixed-point attractors [106]

The attractor concept can be captured in a simple metaphor. Figure 1 shows a ball on a hilly landscape. The ball represents the current state of the system and the valleys (A and B) represent different fixed-point attractors. The evolution of the system toward an attractor is characterized by the ball rolling down a hill and coming to rest in the bottom of a valley. Each attractor in Fig. 1 has a basin of attraction, represented by the width of the valley. The basin of attraction for Attractor A in Fig. 1 is wider than the basin for Attractor B, which means that a wider range of states will evolve toward Attractor A. Attractors can also vary in their respective strength, which is represented by the corresponding depth of the two valleys. Attractor B, then, is stronger than Attractor A. Hence, it is more difficult for external influence to change the current state of the system when the system is within the basin of attraction for Attractor B as opposed to Attractor A.

The existence of multiple fixed-point attractors in a system captures the intuition that people may have different (even mutually contradictory) goals, self-concepts, recurring emotional states, and patterns of social behavior. Someone may have two or more standards for self-regulation, for example, with each providing for action guidance under different sets of conditions. The person's behavior may reflect an affiliation standard under one set of conditions, but reflect an achievement standard under a different set of conditions. In similar fashion, a person may have multiple self-views (e. g. [37,60,61,93]), each representing an integrated and stable way of thinking about him or herself. One self-view is likely to become salient when a specific set of self-relevant information is made salient by virtue of context or role expectations. Characteristic patterns of emotional response, meanwhile, can be viewed as distinct attractors, with each attractor reflecting an "emotional Gestalt" that provides coherence for a person's cognitive-affective dynamics under a unique set of conditions and constraints [57,99]. More generally, apparent inconsistency in personality can be viewed as the existence of multiple attractors, each associated with a different basin of attraction for thought, feeling, and action [82,86,92]. One set of conditions might promote a trajectory that evolves toward dominance and competition, for instance, whereas another might promote empathy and cooperation.

The strength of an attractor and the size of its basin of attraction are potentially independent, and different combinations of these basic properties may have unique implications for psychological processes [82,83]. Note again the two attractors in Fig. 1. Attractor A is relatively weak but has a wide basin of attraction. Thus, a relatively small force may change the state of the system (i. e., move the ball up the gradual slope), but the system is likely to return to the attractor (i. e., it will roll back into the valley) even if these changes are relatively large. In contrast, Attractor B has a narrower basin of attraction but is relatively strong. A great deal of force is required to promote even a slight impact on the system (i. e., move the ball up the steep slope), but if this effect is achieved, the system will not return to the attractor (i. e., it will escape the valley).

As an example, consider a romantic couple that has two attractors: a strong attractor associated with positive feelings and a weak attractor associated with negative feelings. Assume the couple has a wider range of attraction for positive feelings than for negative feelings. The partners are likely to evolve toward positive feelings about one another if they begin an interaction within a broad range of affective states (e. g., neutral to very positive), but they may end up feeling negative if they begin an interaction within a different (more restricted) range of affective states (e. g., mildly to highly negative). A broader range of initial states are likely to promote a communication trajectory that results in an exchange of warm sentiments as opposed to critical comments. If, however, the couple typically starts out with negative feelings, the negative attractor, despite having a narrow basin, may dictate the trajectory for feelings expressed in the couple's interactions. It is conceivable, of course, that the couple has a wider basin of attraction for negative feelings, so that anything short of a highly positive initial state will dissolve into a negatively toned exchange (see [33,34]).

Latent Attractors

A system may have multiple attractors, but when the system is at one of them, the others may not be visible to observers, or perhaps not even to the actors themselves. The existence of these potential states might not even be suspected. Such *latent attractors* may be highly important in the long run, though, because they define which states are possible for the system when conditions change. By identifying possibilities for a system that have yet to be experienced, the concept of latent attractor goes beyond the traditional notion of equilibrium (e. g. [2]). Critical changes in a system might not be reflected in the manifest state of the system, but rather in the creation or destruction of a latent attractor representing a potential state that is currently invisible.

The implications of latent attractors have been explored in the context of inter-group characterized by seemingly intractable conflict [18,19,85]. Factors such as objectification, dehumanization, and stereotyping of outgroup members are preconditions for the development of intractable conflict [17,22] but their immediate impact may not be apparent. Rather, these factors may create a latent attractor to which the system can abruptly switch in response to a provocation that is relatively minor, even trivial. By the same token, efforts at conflict resolution that seem fruitless in the short run may have the effect of creating a latent positive attractor for inter-group relations, thus establishing a potential relationship to which the groups can switch if other conditions permit. In this case, the existence of a latent positive attractor might promote a rapid de-escalation of conflict, even between groups with a long history of and seemingly intractable conflict.

Periodic Attractors

Rather than converging on a stable value, systems can display sustained rhythmic or oscillatory behavior. Such a temporal pattern is referred to as a periodic or limit-cycle attractor. Periodicity is obviously associated with many biological phenomena, such as circadian rhythms and menstrual cycles [30], but this dynamic tendency may also underlie certain psychological phenomena [32]. Moods have been shown to have a periodic structure, for example, often corresponding to a weekly cycle (e. g. [9,50,51]). Research on the intrinsic dynamics of both social judgment [109] and self-evaluation [110], meanwhile, has demonstrated that the stream of thought often oscillates between positive and negative assessments, sometimes in accordance with remarkably fast time scales. Periodic structure also characterizes human action [69] and is a feature of social interaction as well (e. g. [6,32,70]).

Distinguishing a periodic attractor from the existence of multiple fixed-point attractors can prove difficult, since the system in both cases displays movement between different states over time. The difference centers on the regularity of the movement between states and the role of external factors in producing such movement. A periodic attractor reflects a repetitive temporal pattern, such that the values of the dynamical variable repeat after a time $T, x_i(t) = (t + T)$, where T is the period of motion. The state of the system undergoes constant change even in the absence of noise or external influence. To qualify as a periodic attractor, then, a pattern of change must represent a pattern on which the system converges, and to which it returns after small perturbations. In a daily activity cycle, for example, a sleepless night might temporarily disrupt the pattern (e. g., oversleeping the next few days), but eventually the pattern will be restored.

A system with fixed-point attractors, in contrast, tends to stabilize on a particular state or set of states. Such attractors capture all trajectories within their respective basins, so a disturbance, noise, or an external influence is necessary to move the system from one stable state to another. A person with self-regulatory standards for both compromise and confrontation, for example, will display one of these tendencies as long as the action context is within the basin of attraction for that tendency. If the attractors differ in the size of their respective basins, and if contexts are avoided that attract the person's mental, emotional, or behavioral state toward the smaller basin, the person may behave for long periods of time in line with the stronger attractor. In similar fashion, a romantic couple may have fixed-point attractors for both positive and negative affective states, but whether they display periodic movement between them will depend on the starting conditions associated with their interactions. Even if the couple oscillates between positive and negative states, each state provides at least temporary stability. In periodic evolution, stability is not provided by any particular state, but rather by the pattern of changes between states.

The distinction between fixed-point and periodic attractors was observed in a study investigating the temporal trajectories of affective states on the part of bipolar depressive individuals [42]. Time-series analysis of mood and other symptoms revealed that many of these patients oscillated between a normal and a depressed state. However, patients whose temporal dynamics did not reflect fixed-point attractor tendencies were at highest risk for suicide and were hospitalized more often for their depression. These risks were low for individuals whose moods oscillated around a single attractor, even one corresponding to a depressed state, and for those whose moods switched between two distinct attractors reflecting a normal state and a depressed state. These results imply an interesting connection between attractor dynamics and self-regulatory tendencies. Self-regulation implies stabilization with respect to some states and de-stabilization of other states. The stable states reflect fixed-point attractors for a person's mental and emotional dynamics. The lack of fixed-point attractors for one's internal state signals a breakdown in the capacity for self-regulation.

Deterministic Chaos

The best known phenomena concerning nonlinear dynamical systems centers on *deterministic chaos* (cf. [89]). Many researchers and scholars, especially those from fields other than mathematics and physics, commonly discuss the primary insights from the work on nonlinear dynamics as chaos theory. When investigating a chaotic system, anything less than infinite precision in the knowledge of a system at one point in time can undermine prediction of the system's future states. This decoupling between determinism and practical predictability happens because all initial inaccuracies are amplified by the system's intrinsic dynamics, so that the inaccuracies grow exponentially over time. After some time, exponential growth assures that the size of the error will exceed the possible range of states of the system's behavior.

Chaos clearly represents a possibility in nonlinear dynamical systems [31,73], and has been demonstrated in many biological and physical phenomena. In principle, then, human thought and behavior may sometimes follow a chaotic trajectory. Despite this potential, though, unequivocal evidence for deterministic chaos in human thought and behavior remains to be documented. Human dynamics always contain some degree of randomness and human behavior is often unpredictable. It can be quite difficult, however, to determine the degree to which such unpredictability reflects deterministic chaos, the stochastic nature of the laws governing human nature, or the multitude of influences unaccounted for by measurement that can be treated as noise.

Dynamical Minimalism

In canonical social psychology, the complexity of human thought and behavior is typically assumed to reflect complex interactions among a large number of variables in the traditional approach to theory construction. The approach of *dynamical minimalism* [72], in contrast, assumes that complex properties can result from simple rules specifying the interactions among very simple elements. The emergence of complexity occurs when the elements are nonlinear and interact over time [39]. For example, complex cognitive phenomena (e. g., pattern recognition, error correction), have been observed in a simple network of binary elements, where each element reacts to the input it receives from other elements [40]. In this spirit, dynamical minimalism attempts to identify the simplest set of assumptions capable of producing a phenomenon of interest. In formal models, this is equivalent to identifying the simplest mathematical rules to express what is known about a phenomenon. The goal of dynamical minimalism, then, is to achieve parsimony in theory construction without stripping the phenomenon of its subtlety and nuance.

This approach provides a new perspective on the relation between micro and macro levels of description. Reductionism is commonly assumed in mainstream models, such that the rules observed at one level of description correspond to the rules operating at another level. In effect, the properties at a macro level of description are reduced to the properties of elements at a micro level. One might, for example, explain the relation between poverty and crime in a social system by reducing this relation to the relation between frustration and crime at the level of individuals in the society. Dynamical models, however, do not assume isomorphism among levels of description. To the contrary, the rules specifying the interaction among a system's elements are likely to generate very different rules at higher levels of system behavior (see [24] for an early appreciation of this idea).

The emergence of new properties at a macro level is illustrated in the *society of self* model of self-structure [81]. This model assumes very simple rules by which self-relevant information is integrated in forming a self-concept. Each element of information (e. g., an episodic memory, a physical feature, a self-perceived trait) adopts the prevailing valence (positive vs. negative) of related elements. This simple rule, when iterated over time, generated interesting but largely unexpected consequences at the global level of self-understanding. The self-structure became differentiated into locally coherent regions (e. g., social roles, areas of competence), each of which displayed resistance to discrepant information (e. g., negative social feedback). Global self-esteem and high self-concept certainty also emerged at the macro level from the simple rule of influence among elements at the micro level.

Emergence seems to represent a paradox for theory construction. How can knowledge of the lower-level elements provide an explanation of the higher-level properties if properties at a macro level cannot be derived from properties of the system's lower level elements? The role of computer simulations in dynamical minimalism helps to resolve this paradox. With computer models, one can specify the properties of system elements and the rules of interaction among these elements. As the elements interact in accordance with these rules over time, dynamics appear at the system level that were not assumed or programmed for the elements themselves. With computer simulation, then, a theory constructed at a basic level of psychological reality (e. g., moment-to-moment thought process, dyadic social interaction) can be tested at a higher level of psychological reality (e. g., social judgment, group norms).

Computer simulations play another important role in dynamical minimalism. The basic elements comprising a system are often uninteresting and trivial, and the interactions among them may have only minor impact on the systems' global properties. But some properties of system elements may have an important impact on the system's higher-order properties as the elements interact over time. It may not be obvious which properties are trivial and which are essential for the emergence process. Dynamical minimalism makes this distinction and thus constructs a model that incorporates only the properties that are critical for the emergence of macro level phenomena. Computer simulations enable one to systematically vary the assumptions regarding the properties of elements and their interactions, and then observe which assumptions promote meaningful changes at the macro level. Those properties that have trivial consequences at the macro level are eliminated from the model. In short, computer simulations enable one to distill the minimal set of components necessary to capture the essence of a phenomenon.

Computer simulations cannot substitute for empirical verification of a theoretical model. They are critical in identifying the properties that are central to the model and investigating the consequences of these properties for the functioning of the system in question. Knowledge of these consequences then provides the basis for framing hypotheses to be investigated in empirical research. The relationship between computer simulations and empirical research work in the other direction as well. Empirical studies can refine a model, which is then implemented in computer simulations. The results of the simulations, in turn, may generate new hypotheses to be tested in subsequent empirical research. The reciprocal feedback loops among theory, computer simulation, and empirical research is central to the approach of dynamical minimalism.

The Dynamics of Social Influence

Social influence refers to any change in an individual's thoughts, feelings, or behavior that occurs as the result of the real or imagined presence of others [3]. It is widely considered to be the core process of social experience [111] and is manifest in a wide array of phenomena, including obedience to authority, conformity, imitation and modeling, bystander intervention in emergencies, social loafing, stage fright, persuasion, and groupthink. There is evidence, however, that the essence of social influence reflects the interplay of three basic factors: the number, strength, and immediacy of the sources of influence [52]. Empirical research has shown that the magnitude and nature of social influence represents a multiplicative function of these sources.

Nowak et al. [76] modeled the dynamics of social influence using cellular automata. In this approach, each individual is represented with three properties: an opinion on a topic, a degree of persuasive strength, and a position in a social space. Individuals are commonly assumed to have one of two opinions on an issue (e. g., pro vs. con). The group consists of n individuals located on a two-dimensional grid, with each cell corresponding to an individual (see Fig. 2). The color of each cell specifies that individual's current opinion (light gray denotes pro, dark gray denotes con), whereas the height of the cell represents the individual's strength (e. g., expertise, confidence, charisma). Each individual discusses the issue with other group members ascertains the degree of support for each position. As a result of these assessments, each individual adopts the opinion that is most prevalent. The following formula expresses the strength of influence of each opinion:

$$I_i = \left(\sum_1^N \left(\frac{s_j}{d_{ij}^2} \right)^2 \right)^{1/2} ,$$

where I_i denotes total influence, s_j represents the strength of each individual, and d_{ij} represents the distance between individuals i and j. The opinions of those who are closest to the individual and have the greatest strength are weighted most heavily by the individual. An individual's own position is also considered and is weighted most heavily because of its immediacy (0 distance). Influence grows with the square root of the number of people exerting influence.

In each round of the simulations, one individual is chosen at random and influence is computed for each opinion in the group. A simple updating rule is employed: the individual changes his or her opinion to match the prevailing opinion if the resultant strength of this opinion position is greater than the strength of the individual's current position. This basic process is performed for each individual in the group. This procedure is repeated until there are no further changes in opinion. This typically involves several rounds of simulation, because an individual who had previously changed his or her position to match that of his or her neighbors may revert to the original position if the neighbors change their opinions.

Figure 2 depicts representative results of the computer simulations. In the initial configuration (Fig. 2a), there is a majority of 60% (light gray) and a minority of 40% (dark gray), with the majority and minority opinions randomly distributed in social space. The majority and minority groups have the same relative proportions of strong and weak members (tall vs. short cells). Figure 2b shows that an equilibrium is reached after six rounds of simulated discussion. Although the majority has grown (to 90%) at the expense of the minority (now 10%), the minority opinion has survived by forming clusters of like-minded people. Note that these clusters are primarily formed around strong individuals.

These two group-level outcomes—polarization and clustering—are routinely observed in computer simulations of this process [55]. Each is reminiscent of well-documented social processes. Research on group dynamics (e. g. [68]), for example, has shown that the average attitude in a group becomes polarized in the direction of the prevailing attitude as a result of group discussion. In the model, polarization reflects the greater influence of the majority opinion. In the initial (random) configuration (Fig. 2a) the average proportion of neighbors holding a particular opinion (pro or con) reflects the proportion of this opinion in the total group. The average group member, in other words, is surrounded by more majority than minority members, so more minority members are converted to the majority position than vice versa. However, some majority members are converted to the minority position because they happen to be located close to an especially strong minority member or because more minority members happen to be at this location.

Clustering is also a pervasive feature of social life, having been documented for such diverse facets of social life as attitudes, political beliefs, religions, clothing fashions, and farming techniques. It has been show, for example, that attitudes tend to cluster in residential neighborhoods [28]. When opinions are distributed randomly, the sampling of opinions through social interaction provides a realistic portrayal of the distribution of opinions in the larger society. However, when opinions are clustered, the same sampling process produces a very biased result because the opinions of one's nearby neighbors are weighted the most heavily. The prevalence of one's own opinion is therefore likely to be over-estimated. Opinions that are in the minority in global terms, then, can form a local majority. This process enables individuals with a minority opinion to maintain this opinion in the belief that it actually represents a majority position.

In the spirit of dynamical minimalism, this model focuses on the minimal set of processes responsible for the emergence of group-level properties that are invariant across diverse areas of topical interest. In so doing, it pro-

vides a platform for investigating how group-level properties emerge for different domains of social functioning. This potential has been developed in recent years. Kenrick and his colleagues, for example, have simulated the emergence of cultural norms from the mutual influence among individuals with conflicting strategies (decision-rules) pertaining to fundamental human goals (e. g. [49]). These goals, reflecting domains of adaptive functioning confronted by human groups throughout history [10,11,29], include self-protection, coalition formation, status-seeking, mate choice, relationship maintenance, and offspring care.

In their computer simulations, individuals with different decision-rules regarding a particular domain interacted with one another over time, and the group-level consequences of these interactions were observed. One series of simulations investigated how individual differences in decision-rules for cooperation versus competition affected community level propensities for such behavior. Another series explored the mutual impact of male and female mating strategies on the emergence of societal-level norms regarding mating. Clustering was observed in both cases, with an initial random configuration of decision rules giving way over time to local communities characterized by coherent norms regarding the behavior in question. In the mating simulations, for example, some communities were characterized by relatively unrestricted mating strategies (reflecting the decision-rule preferred by males), whereas other communities developed norms sanctioning restricted mating strategies (reflecting the decision-rule preferred by females).

Dynamics of Interpersonal Coordination

The dynamical account of social influence provides a concise description of how the state (e. g., attitude) of a single individual depends on the state of other individuals. Because many psychological processes reflect intrinsic dynamics, however, individuals can be conceptualized as displaying patterns of change rather than as a set of states. In this view, social influence (and social interaction generally) can be investigated as the coordination over time of individual dynamics.

The most basic form of coordination is positive correlation or in-phase relation. In social interaction, this occurs when the overt behaviors, attitudes, or emotions of one person induce similar behaviors or states in the other person at the same time (e. g. [16]). This basic form of coordination is reflected in such familiar phenomena as imitation, mimicry, and empathy [62]. Other forms of coordination can be identified, however, with counterparts in different contexts for social interaction [62,69]. Turn taking in conversation represents negative correlation or anti-phase relation between individuals in their respective talking and listening (when one person speaks, the other is silent). Negative correlation also characterizes antagonistic relationships, in that the sadness or despair of one person induces satisfaction or happiness in the other person and vice versa. More complex forms of synchronization can also be identified that reflect nonlinear relationships and higher-order interactions between the partners' respective behaviors and internal states (cf. [74,82]).

A Model of Synchronization Dynamics

This perspective provides the foundation for a recently developed model of *synchronization* [82,83], a phenomenon that characterizes coupled dynamical systems [44,91]. Because positive correlation represents the most fundamental and common form of coordination, it has provided the primary focus to date in this class of models. The Nowak et al. [82,83] model assumes that each individual attempts to achieve synchronization by adjusting his or her internal state or overt behavior in response to the state or behavior of the individual with whom he or she is interacting. Individuals in social interaction, in other words, modify their respective thoughts, feelings, or action tendencies to promote positive correlation over time in these features of experience. The synchronization of individuals' dynamics results in a higher order system with its own dynamic properties.

Coupled logistic are used to model interpersonal synchronization [74,81,82,83]. The dynamics of each individual are represented with a logistic equation, which is the simplest dynamical system capable of displaying complex (e. g., chaotic) behavior [27,89]. However, the behavior of each person not only depends on his or her preceding state but also to a certain extent on the preceding state of the other person. The coupling of individuals' dynamics is specified in the following equation:

$$x_1(t+1) = \frac{r_1 x_1(t)(1-x_1(t)) + \alpha r_2 x_2(t)(1-x_2(t))}{1+\alpha}$$
$$x_2(t+1) = \frac{r_2 x_2(t)(1-x_2(t)) + \alpha r_1 x_1(t)(1-x_1(t))}{1+\alpha} .$$

The dynamical variable (x) represents the intensity of behavior, and the control parameter, r, corresponds to internal states (e. g., personality traits, moods, values) that shape the person's pattern of behavior (i. e., changes in x over time). To the value of the dynamical variable representing one individual's behavior x_1, one adds a fraction α of the value of the dynamical variable representing the other individual's behavior x_2. The magnitude of α represents the strength of coupling and can be viewed as the degree of mutual influence characterizing the interaction. Depending on the social context, it might reflect the intensity of communication or the degree of mutual imitation. When α is 0, there is no coupling (e. g., no influence or communication) on the behavior level, whereas when α is 1, each individual's behavior is determined equally by his or her preceding behavior and the influence of the other individual. Intermediate values of α represent moderate values of coupling in the relationship.

Modeling Behavioral Synchronization

The respective control parameters of two individuals are unlikely to be identical when they first interact with one another. And the degree of influence between individuals differs across interactions and relationships. To represent this variability in social reality, Nowak, Vallacher [74] systematically varied the similarity of partners' control parameters (r), representing their internal states, and their degree of coupling (α), representing their mutual influence (e. g., communication, imitation). Each simulation began with a random value of x for each individual, drawn from a uniform distribution that varied from 0 to 1. They let the simulations run for 300 steps, allowing each system to converge on its pattern of intrinsic dynamics and both systems to synchronize. For the next 500 simulation steps, they recorded the values of x for each system and the degree of synchronization of the two systems.

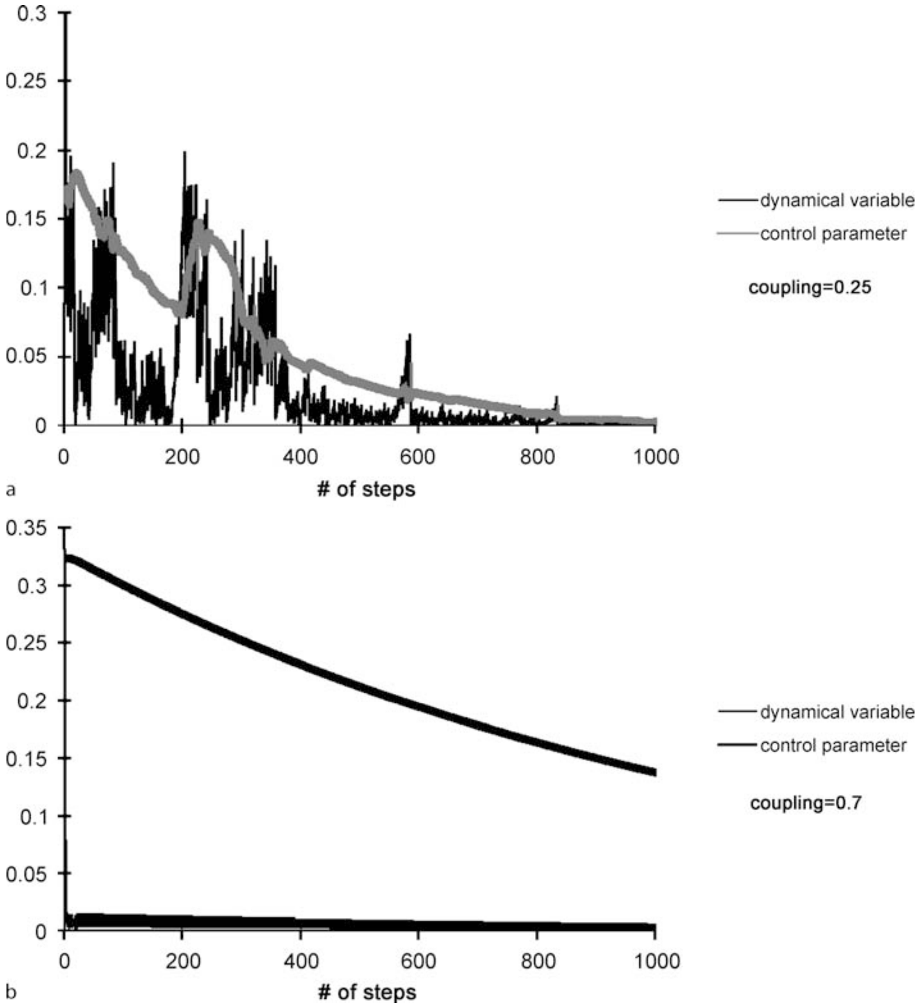
The results demonstrated that behavioral synchronization increased both with increases in α and in the similarity in r. At each degree of coupling, synchronization increased with greater similarity in partner's internal states. Likewise, at each level of similarity in internal states, synchronization increased with increased strength of coupling. These results have straightforward implications. If two people have similar control parameters (internal states), relatively little coupling (e. g., influence, communication, mutual reinforcement, monitoring) is necessary for them to achieve a high degree of synchronization in their behavior. If the partners have different internal states, on the other hand, high mutual influence is required to maintain the same level of synchronization. In a close relationship, this suggests that constant and intense communication may be a sign that the partners are not well coordinated with respect to relevant internal states (e. g., temperament, desires values). But when the partners are similar with respect to such internal states, they can devote their energy to common pursuits rather than to constant clarification, monitoring, and other forms of influence.

Modeling Internal Synchronization

Some internal parameters, such as moods and emotional states, vary considerably across time and settings. If a particular context induces a common mood or emotion (e. g., joy or sadness) in a dyad or group, interpersonal synchronization is easy to achieve. Other internal states, however, demonstrate greater stability and less likely to vary across different contexts. Attitudes, values, and personality traits, in particular, are commonly considered to be enduring (cross-situational) features of a person's psychological make-up. Yet, even these internal parameters admit to variability and even modification. The Nowak et al. [82,83] model has been used to understand and investigate the nature of such change. The core assumption is that individuals are motivated to achieve coordination in their internal parameters [13,62]. To satisfy this motive, individuals vary their internal parameters in a direction that leads to increasing synchronization. When synchronization is achieved, the value of the resultant control parameter is engraved as an attractor for that internal state. In essence, people are assumed to develop stable internal states through social synchronization (e. g. [112]).

To model this process, Nowak et al. simply assumed that the value of each individual's control parameter drifts somewhat in the direction of the value of the other individual's control parameter on each simulation step. How quickly the respective control parameters begin to match depends on the size of the initial discrepancy between them and on the rate at which they drift. This process occurs with each individual knowing the exact value of the other individual's control parameter. This is an important feature of the model, since experimental research has shown that people's internal states are often difficult to infer [43,47,71,113]. The model assumes only that each individual remembers the other individual's most recent behaviors (i. e., the most recent values of x) as well as his or her own most recent behaviors. Each individual compares his or her own behavior with that of the other individual, and then adjusts his or her internal parameter in order to promote increased similarity with the other person's behavior pattern, until a match is achieved [115]. Thus, if the other individual's behavior is more complex than the individual's own pattern of behavior, the individual slightly increases the value of his or her own control parameter. Conversely, the individual slightly decreases the value of his or her own control parameter if the other individual's behavior is less complex than his or her own. In short, interacting individuals estimate one another's internal state by monitoring the evolution of one another's behavior.

Nowak et al. [82,83] ran simulations to investigate the convergence of behavior and internal states under both relatively weak and relatively strong coupling ($\alpha = .25$ and .7, respectively). The y-axis in Fig. 3 corresponds to the magnitude of difference between the two systems in their behavior or internal states, and the x-axis corre-



Social Psychology, Applications of Complexity to, Figure 3

a Convergence of behavior and internal states under weak coupling b Convergence of behavior and internal states under strong coupling [82]

sponds to time, as reflected in the number of iterations. Consider first the results observed when the coupling was weak (Fig. 3a). The behavior of the two systems converged in a relatively slow and non-linear manner. The control parameters also showed a clear tendency towards convergence. When a match in internal states was achieved, moreover, full synchronization of behavior was also obtained. Compare these results with those observed under strong coupling (Fig. 3b). Note that although there was immediate synchronization of behavior, the control parameters failed to synchronize, even after 1000 iterations.

The differential results obtained for weak and strong coupling may have noteworthy implications for interpersonal relations. First, even for people with very different internal parameters, strong coupling tends to promote full synchronization of behavior. Once synchronization is achieved, the two people may be totally unaware that their internal states are different. This suggests that if the coupling were to be reduced in magnitude (or removed altogether), the dynamics of the two individuals would immediately diverge. Hence, people who employ very strong influence (e. g., reinforcement, monitoring) to obtain coordination of behavior may effectively hinder synchronization of their respective internal parameters. In more general terms, there may be an optimal level of influence and control over one another's behavior in interpersonal relations [111]. When influence is too weak, synchronization between individuals may fail to develop. But when influence is very strong, it can prevent the development of a relationship based on mutual understanding and empathy. Intermediate levels of mutual influence, then, may be most effective for the development of synchronization on a deep level. Stated differently, the most advantageous degree of coupling (e. g., influence) is the minimal amount necessary to achieve synchronization.

These implications are consistent with extensive research in social psychology suggesting that behavior attributed to external causes is less likely to promote psychological change than is behavior attributed to internal causes. For example, people are resistant to changing their preferences and attitudes if they believe that their behavior is in response to direct orders, rewards, threats, and other external influences [7,56]. Salient external influences, in fact, may activate mechanisms to counter the influences, creating an internal state that is opposite of the intended effect of the influence [8,111].

Future Directions

The application of complexity science to social psychology makes for an ironic discipline. The tools of complexity and dynamical systems are ideally suited to capture the subtlety and uniqueness of human experience, yet they are grounded in concepts and methods that provide meaningful integration with the natural sciences. Disciplines such as mathematics, physics, and chemistry have affirmed the significance of intrinsic dynamics, nonlinear phenomena, self-organization, and complexity. In recent years, psychologists have become increasingly cognizant that these features of systems in nature have counterparts in mental, interpersonal, and collective experience. It would be odd for a contemporary social psychologist to discount the potential for emergence or to ignore the role of computer simulations and time series in illuminating how minds, groups, and societies work.

A word of caution is in order, however. Social reality is not the same as physical reality. Unlike atoms, individuals are not interchangeable, and groups are more than self-organized ensembles of simple particles. People have values and beliefs, universal concerns and idiosyncratic tendencies, and moments of self-reflection and sudden impulse. One of the basic rules of human psychology, moreover, is the capacity for reflecting on one's operating rules and attempting to override them. People exist in a symbolically constructed world and do not respond in a reflexive way to objective reality. These unique features of human experience cannot be chalked up to the recognition that people are dynamic and complex. The task of dynamical social psychology is thus more daunting than discovering the differential equations that govern interpersonal and collective dynamics. Models derived from complexity and dynamical systems provide a foundational science for the discipline and much remains to be discovered within this new paradigm. Ultimately, though, the properties that separate us from other systems in nature must be incorporated into theoretical models. It is an ironic testament to the complexity perspective that a coherent theory of social psychology should be assembled from elements that are both universal within nature and unique to human experience.

Soft Computing, Introduction to

Janusz Kacprzyk
Systems Research Institute, Polish Academy of Sciences, Warsaw, Poland

As science progresses, scholars and researchers continue to develop models of various phenomena and problems. These models have become more and more formal, notably mathematical, and hence have relied more and more on computing.

The initial period has been characterized by computing meant as well-defined algorithmic procedures implemented by using computing architectures, tools and techniques based on traditional binary (yes – no or 0 – 1) logic. This logic has also been a basis for all kinds of approaches within the field of artificial intelligence, a field of science and technology that has been vividly developed since the mid-1900s and aimed at devising machines capable of performing human-specific tasks that require intelligence. Symbolic computation has become a main paradigm within artificial intelligence, and the role of numerical computing has been neglected to a large extent.

As promises of artificial research gurus that machines will be able to perform virtually all sophisticated human-specific tasks and practically replace humans in a short time have failed, it has become more and more evident that sticking to symbolic computations only is a mistake. Clearly, there may be tasks for which symbolic computations are adequate, but there may be tasks, presumably even more, when numerical computations are indispensable.

Even if this necessity of a synergistic use of symbolic and numerical computations in the construction of intelligent systems has become obvious, people have been, for a long time, not fully convinced that, since the human being is a crucial element in all kinds of research, analysis and construction of broadly perceived intelligent systems, computational techniques and processes involved therein should reflect human-specific features.

In our context, the main feature of the human element in computation is that natural language is the only fully natural means of articulation and communication of a human being, and natural language is plagued by inherent vagueness, ambiguity, imprecision, etc. These kinds of information imperfections are out of scope of conventional mathematical tools based on – for instance – probabilistic or statistical tools.

The necessity of developing a new framework which would differ from the traditional "hard" computing based on traditional mathematics, i. e., basically on binary logic, and the dichotomy of true and false, has been recognized quite early. However, it was Lotfi A. Zadeh from the University of California at Berkeley who first pronounced that necessity – in the context of the analysis of complex animate systems, notably human-centered – in a more comprehensive way in the early 1960s. In 1965 he introduced fuzzy sets theory, presumably the first comprehensible, yet simple and efficient calculus of imprecision. A fuzzy set is a class to which elements can belong to a degree, from full membership, through all intermediate values, to full non-membership. Clearly, this has provided a constructive means for the representation of imprecisely specified concepts, relations, reasoning schemes, etc. Zadeh then proceeded to the formulation of possibility theory, and finally based his ideas on a more direct link to natural language which has culminated in his computing with words and perceptions.

The introduction of a fuzzy set, followed by numerous applications of fuzzy logic-based tools and techniques, notably for control, ranging from the control of domestic appliances, automatic transmissions in cars, to the control of industrial installations, has certainly been very important for the proliferation of fuzzy logic, maybe even more generally for non-conventional computational tools and techniques.

As a next step, Zadeh has advocated a wider view of those new computational tools and techniques and coined the term of *soft computing*. Basically, soft computing may be viewed as a departure from conventional (hard and "precise") computing in that it is tolerant of imprecision, uncertainty, partial truth, and approximate relationships, approximately satisfied properties, etc.

The main principle underlying soft computing is to be able to exploit a tolerance for imprecision, uncertainty, partial truth, and approximation to attain tractable, robust and computationally inexpensive modeling and solution tools and techniques. A natural connection to neural computing and evolutionary computing has more recently been recognized.

It is usually assumed that the principal components of soft computing are fuzzy logic (complemented with rough sets theory which may be viewed to address related problems of imprecise information but understood and dealt with in a different way), neural computation, and evolutionary computation. These areas are sometimes complemented with machine learning and probabilistic reasoning, with the latter subsuming belief networks, chaos theory and parts of learning theory. Moreover, for a long time, rough sets have been considered to be a relevant part of soft computing.

However, it should be noticed that soft computing is not a confluence of more or less independent fields, but is meant as a synergistic combination of various methodologies and methods in which each one contributes in a synergistic and complementary way to the analysis and solution of a problem.

In this section we will present the main components of soft computing. The concepts of synergy and complementarity mentioned above will provide a pivotal perspective.

We start with a brief introduction to fuzzy sets and systems (see J. Kacprzyk, ► Fuzzy Sets Theory, Foundations of). First, we define the concept of a fuzzy set followed by the definitions of its main properties. The idea of a fuzzy relation is then introduced, and shown to be a convenient apparatus for devising approximate reasoning schemes. The concept of a linguistic variable is shown to be a basis for a natural-language-based approach to modeling and reasoning. Fuzzy arithmetic is presented making it possible to use imprecisely specified (fuzzy) numbers in models and algorithms. A universal problem of decision making is dealt with under fuzzy goals, constraints, etc., in a static and dynamic context.

Though fuzzy sets in the traditional Zadeh sense do provide a simple yet efficient means for the representation and handling of imprecision, some natural extensions of the basic concept of a fuzzy set have appeared. One of the most relevant and popular is the concept of a type 2 fuzzy set in which the degree of membership itself, which is a real number from the unit interval in the traditional fuzzy set, is now a fuzzy set defined in the unit interval. This natural extension has implied relevant extensions of fuzzy modeling and reasoning tools and techniques which are presented in detail, and potentials for applications are underlined (see R.I. John and J.M. Mendel, ▶ Fuzzy Logic, Type-2 and Uncertainty).

As in any formal model in which, as is true in virtually all cases in reality, multiple aspects, points of view and entities have to be accounted for, a proper aggregation is of a paramount importance. A comprehensive account of various aggregation operators is provided, both from a strictly mathematical point of view and from a more constructive, application oriented one (see V. Torra, ▶ Aggregation Operators and Soft Computing).

The discussion of the foundations of fuzzy logic is completed with a brief account of possibility theory initiated by Zadeh in the late 1970s as an extension of fuzzy sets theory and fuzzy logic, a mathematical theory for dealing with certain types of imperfect (uncertain) information in a way that is an alternative to probability theory. Main concepts related to possibility theory are presented, and a historical perspective is provided (see D. Dubois and H. Prade, ▶ Possibility Theory).

The comprehensive presentation of foundational concepts and properties related to fuzzy logic is then followed by sections presenting some more relevant areas which can be of use in the analysis of many systems and in the solution of many problems in diverse areas of science and technology.

First, fuzzy optimization and fuzzy mathematical programming are outlined starting with basic concepts of optimality, feasibility, etc., under fuzzy information. Then, various classes of fuzzy optimization and fuzzy mathematical programming problem classes are briefly outlined and basic solution concepts and algorithms are presented. Some examples of applications are mentioned (see W. Lodwick and E. Untiedt, ▶ Fuzzy Optimization).

The topic of statistics with imprecise data is considered next, a very interesting topic from a conceptual point of view, and practically relevant. First, a sound motivation is presented by pointing out that, in reality, much available data is imprecise, and so they cannot be used by powerful and well founded, yet too "hard" traditional statistical tools and techniques. New concepts are formulated and extensions of well known statistical means under an imprecise information are presented. Some applications are outlined (see M.A. Gil and O. Hryniewicz, ▶ Statistics with Imprecise Data).

The next papers are concerned with the two other key elements of soft computing: neural computation and evolutionary computation. To emphasize their synergy and complementarity, these tools have been presented in a hybrid context, that is as a presentation of new fields in which the confluence of fuzzy, neural and evolutionary tools yields a new quality, and results in the emergence of a new class of tools and techniques which have already changed the landscape of soft computing.

We start with the neuro-fuzzy systems, which refer to a combination of (artificial) neural networks and fuzzy logic, and may be viewed as a main, fundamental step into the development of hybrid intelligent systems (see L. Rutkowski, K. Cpałka, R. Nowicki, A. Pokropińska, R. Scherer, ▶ Neuro-fuzzy Systems). Basically, neuro-fuzzy systems try to combine transparent, human-like reasoning types of fuzzy rule-based systems with a parallel, connectionist type of neural networks. Therefore, they are universal approximators with an ability to yield interpretable IF-THEN rules, bridging the gap between accuracy and interpretability. A broad coverage of main architectures and implementations is presented.

Though neuro-fuzzy systems have been a considerable step forward towards in developing modeling tools of a better expressive power, effectiveness and efficiency, some natural extensions have been proposed that take advantage of the increasing popularity of evolutionary computation. It has been shown theoretically and experimentally that the incorporation in broadly perceived fuzzy systems, including neuron-fuzzy systems, of a learning mechanism which can make it possible to adjust the systems' structure and parameters may greatly enhance performance. The use of evolutionary computation has led in this context to the concept of an evolving fuzzy system that has been considered a promising alternative for some time (see P. Angelov, ▶ Evolving Fuzzy Systems).

The above mentioned hybridization techniques, which basically boil down to architectures and algorithms being a synergistic combination of fuzzy systems, notably fuzzy rule based systems, neural networks and evolutionary computation, in particular evolutionary learning, can be further extended when applied to real world problems which always provide much inspiration. Applications for systems modeling and control are of a universal importance for many fields of science and technology and hence are dealt with in detail (see O. Castillo and P. Melin, ► Hybrid Soft Computing Models for Systems Modeling and Control).

The chapters briefly described above have been related to fuzzy sets and some of their hybridizations by including elements of neural networks and evolutionary computation to attain some "superadditivity" of the strengths and power of the particular single tools and techniques.

Rough sets theory, introduced by the late Zdzislaw Pawlak in the early 1980s, has been for some time considered a very promising tool for dealing with imperfect information, notably in data analysis and decision making.

Basically, a rough set is a formal approximation of a conventional crisp set in that it is represented as a pair of two traditional crisp sets which constitute the lower and the upper approximation of the original. These can be viewed as sets of elements that possibly and surely belong to the original set. Rough sets theory is presented in much detail, first in a more traditional, pure setting in Pawlak's spirit. Various concepts are presented, relations between them are formulated and proved, and their possible applications are outlined, notably in the relevant areas of data mining and knowledge discovery. Some extensions of the basic concept of a rough set are also presented (see J. Peters, A. Skowron and J. Stepaniuk, ► Rough Sets: Foundations and Perspectives).

Next, a "meta-problem" in science, that is decision making, is dealt with in the context of rough sets. In addition to the basic definition of a rough set, which provides much insight into the formalization and solution of various classes of decision making problems, a novel idea of a dominance-based rough set is presented. Its use to derive new, more human consistent solution concepts in decision making and data analysis is proposed (see R. Słowiński, S. Greco and B. Matarazzo, ► Rough Sets in Decision Making).

To summarize, we have tried to present the vast and diversified area of soft computing in a comprehensive, illustrative and constructive way. The basic perspective assumed may be viewed as presenting soft computing as a significant paradigm shift in computing in that it tries to exploit the fact that the human mind, unlike the computer we have now, has a remarkable ability to store and process information which is predominantly imprecise, uncertain and granular.

We have started with some basic fundamental concepts and properties, and then have devoted much space to the presentation of what is characteristic for soft computing: a synergistic, complementary use of various tools and techniques to solve problems in an effective and efficient way. This has led to various types of hybridization in which tools from fuzzy systems, rough sets, neural networks and evolutionary computation have been employed. It seems that soft computing should play a more and more important role in the years to come, in which more and more emphasis should be put on human-consistent and human-centric tools and techniques, and on hybrid systems.

Software Architectures for Autonomy

Article Outline

Glossary

Reference architecture (RA) A reference architecture is a framework containing valuable implementation guidance for meeting the requirements of an enterprise.

Automated guided vehicle (AGV) A vehicle that can be programmed to automatically drive to designated points and perform preprogrammed functions.

JAUS The Joint Architecture for Unmanned Systems (JAUS) Reference Architecture defines a set of reusable components and their interfaces. The architecture emphasizes vehicle platform independence, mission isolation, computer hardware independence, and technology independence.

NIST 4D/RCS The acronym NIST 4D/RCS refers to the National Institute of Standards and Technology Real-time Control System. 4D/RCS describes in detail the functions and associated interfaces necessary to provide sensory processing, world modeling, knowledge management, cost/benefit analysis, and behavior generation.

Adaptive planning framework The Adaptive Planning Framework addresses dynamic situation assessment, behavior management, and decision-making. It incorporates a three-stage process of 1) understanding the current situation, 2) understanding the suitability and viability of the available behaviors in light of that situation, and 3) providing the capability to autonomously make and execute behavior-related decisions, all in real-time.

Service oriented architecture (SOA) A Service Oriented Architecture maintains a strictly enforced standardized interface among entities. A standardized messaging construct enables one entity to request a service from another entity and for that service provider to send its response.

Definition of the Subject

Developing an autonomous system, such as an autonomous ground vehicle, that can operate and maneuver in an unstructured environment is a complicated task. One of the most daunting issues facing autonomous vehicle researchers is how to best exploit sensor and other information discovered during the execution of a plan. If the system takes too long to deliberate on the possible meanings and implications of this newfound data and knowledge, the vehicle may well have progressed beyond the point where it can benefit from it. Indeed, it may now be sitting atop the unforeseen obstacle that spawned the influx of new information that was being processed.

The execution of specific autonomous behaviors is becoming reasonably well understood, such as “waypoint-following with obstacle detection”, though improvements and breakthroughs in these areas continue. However, the autonomous selection of which behavior(s) should be invoked, and in what sequence and by what method, is in need of movement in the state of the practice. Advanced ways of thinking about, organizing, and applying situational knowledge to macro-level planning and decision-making are needed by the autonomous robotics community in order to achieve the full potential of the field. This article discusses various approaches and various reference architectures that have been developed to address these problems.

Introduction

Three predominant standards are discussed in the following sections, i. e. the Joint Architecture for Unmanned Systems (JAUS) Reference Architecture, the National Institute of Standards and Technology (NIST) 4D/RCS (Real-time Control System), and the Service Oriented Architecture. A fourth architecture referred to as the Distributed Architecture for Mobile Navigation (DAMN) is also discussed although this architecture is not widely adopted. Lastly, the Adaptive Planning Framework approach that was developed at the University of Florida to address the problem of decision making is introduced.

Joint Architecture for Unmanned Systems (JAUS)

The Joint Architecture for Unmanned Systems (JAUS) Reference Architecture, Version 3.2 [18] defines a set of reusable components and their interfaces. In order to ensure that the architecture will be applicable to the entire domain of unmanned mobile systems, the following four characteristics have been considered by the JAUS Working Group in the creation of the Reference Architecture:

1. Vehicle platform independence. In order for JAUS components to be interoperable, no assumptions about the underlying vehicle or its means of propulsion are made.
2. Mission isolation. The JAUS components can typically be assembled such that a variety of missions can be supported.
3. Computer hardware independence. No assumption of or requirement of particular computer hardware is made. This allows for future adaptability and enhancement as new computer hardware becomes available.
4. Technology independence. This is similar to the computer hardware independence, but focuses more on the technical approach rather than the computer hardware. For example, many approaches could be used to determine vehicle position and orientation. No one approach, such as GPS, inertial dead reckoning, or landmark-based navigation for example, is specified.

As currently defined, JAUS Reference Architekture (RA) establishes a pre-defined set of standard, yet flexible, components that provide a menu of capabilities that can be drawn from to design an unmanned system. Components are divided into five categories:

- Command and control components
- Communications components
- Platform components
- Manipulator components
- Environmental sensor components

The RA also defines a standardized messaging construct (header and content) that enables JAUS components to exchange information in an efficient and robust fashion. The messaging approach first defines the content and usage of a standardized JAUS Header. It then prescribes the legal JAUS data types that can be incorporated into a message. Then it defines each JAUS message.

The Adaptive Planning Framework Reference Implementation was developed within such components and using such messages as defined by JAUS. Specifically, the Reference Implementation for the Adaptive Planning Framework was cast in an operational JAUS-compliant vehicle. However, the concepts and ideas that make up the Adaptive Planning Framework are not tied to nor specifically depend on JAUS. This enables other organizations to implement the framework in an alternative architecture or in future evolutions of the JAUS Reference Architecture itself.

NIST 4D/RCS

The National Institute of Standards and Technology (NIST) has been working for over two decades on establishing a standardized approach to the intelligent control of unmanned vehicle systems. The most comprehensive summary of their approach is given in NISTIR 6910, 4D/RCS: A Reference Model Architecture [27]. The 4D/RCS architecture is itself derived from NIST RCS, a domain-independent architecture developed by NIST a decade plus earlier (see [26] for a good overview of the generic RCS methodology). 4D/RCS goes on to specialize RCS to the domain of intelligent vehicle systems for military use.

4D/RCS focuses on ways to ensure that military missions involving unmanned vehicles can be analyzed, decomposed, distributed, planned, and executed in an intelligent, effective, efficient, and coordinated fashion. 4D/RCS describes in detail the functions and associated interfaces necessary to provide sensory processing, world modeling, knowledge management, cost/benefit analysis, and behavior generation. Of particular interest is its hierarchical treatment of time, providing a temporally layered set of eight planning/execution regimes (see Fig. 1). For example, it suggests that a vehicle Subsystem Planner (Level 3) ought to execute at ∼1–5 Hz with a 5 second, 50 meter planning horizon at a 40 cm grid map resolution, while a Section Planner (Level 5) might need to re-plan every 50 seconds, with a 10 minute, 5 km planning horizon at a 40 m grid map resolution.

A challenge posed by 4D/RCS is that their hierarchy of nodes calls for each node to possess a complete set of functional capabilities (i. e., World Model, Value Judgment, Behavior Generation, etc.), scaled and scoped to its level of operation in the hierarchy. The partitioning, decomposition, and distribution of the Adaptive Planning Framework Specialists and Decision Brokers across a 4D/RCS hierarchy will be a completely new research area. Of greater concern is that 4D/RCS puts a great deal of power and functionality into their World Model, including prediction and simulation.

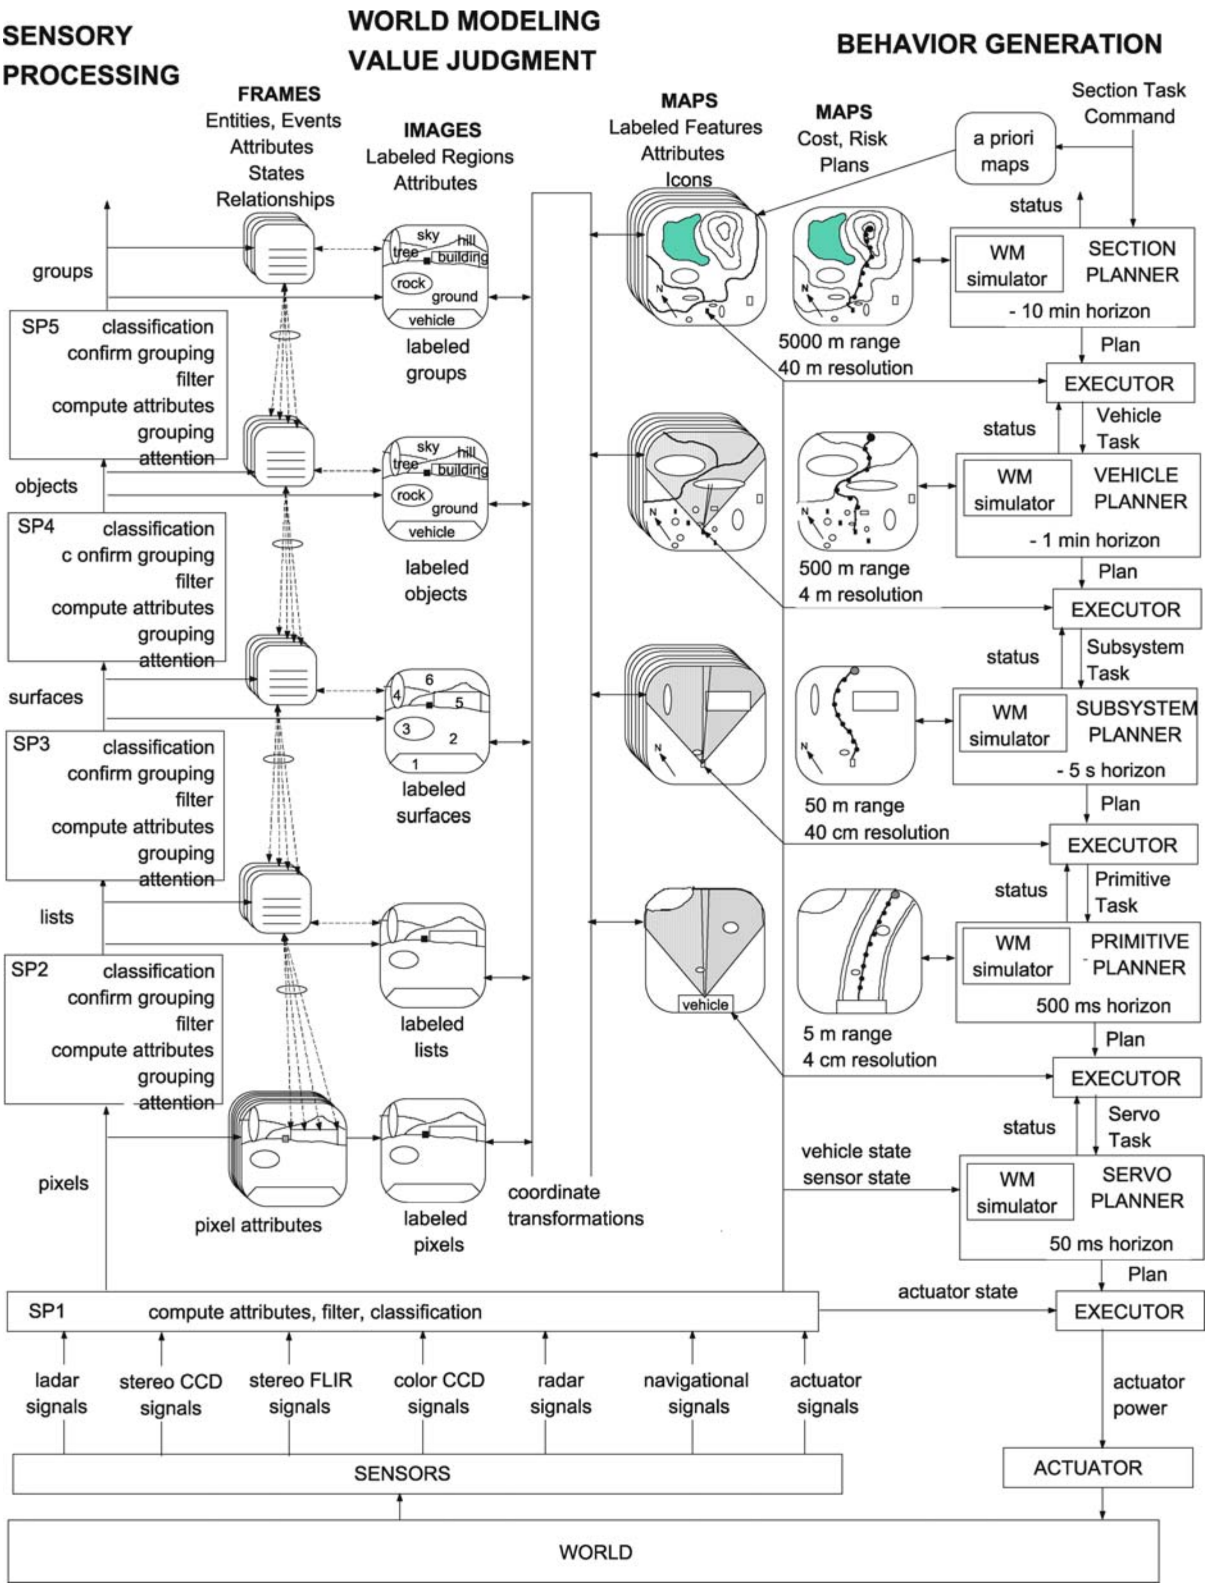
Service Oriented Architecture/ Component Oriented Architecture

Several facets of the Information Technology (IT) sector have been working to establish standards that support software interoperability across diverse organizations under the moniker of Service Oriented Architecture or SOA. SOA enables loose coupling among diverse software entities across a common network. This is accomplished by maintaining a strictly enforced standardized interface among the entities and a standardized messaging construct that enables one entity to request a service from another entity and for that service provider to send its response. This rapidly emerging standard is of interest here because the JAUS Working Group has begun a transition to a SOA-style architecture.

The most mature of these efforts is sponsored by the World Wide Web Consortium (W3C), which relies heavily upon SOA as the foundation of its Web Services initiative and, therefore, is leading the way in its maturation and adoption as a standard. Web Services extend the SOA concept to address anonymous entities that can discover one another and engage one another's services autonomously over the World Wide Web. They have published a treatise on the Web Services Architecture that includes an excellent overview of SOA in Sect. 3.1 of [45]. They go on in that section to outline some of the pitfalls of a SOA, such as network reliability and latency, lack of shared memory between service provider and consumer (i. e., everything that must be conveyed from one entity to another must be done explicitly via message content, and side effects of receipt of a message must be well understood and agreed upon), concurrency mismatches, and so on.

Industry has also taken a strong role in promoting SOA as a de facto standard. IBM (http://www-128.ibm.com/developerworks/webservices/standards/), Sun Microsystems (http://java.sun.com/developer/technicalArticles/WebServices/soa2/SOATerms.html#soaterms), and Microsoft (http://msdn.microsoft.com/architecture/soa/default.aspx?pull=/library/en-us/dnmaj/html/aj1soa.asp), to name three, have all embraced the notion.

Academia has also been active in this arena. IEEE Computer Society has formed a Technical Committee on Services Computing (http://tab.computer.org/tcsc/



Software Architectures for Autonomy, Figure 1

Excerpt from NIST PowerPoint Presentation (Source: http://www.isd.mel.nist.gov/projects/rcs/presentationhui/sld019.htm)

link.htm), and ACM has been actively including SOA topics in many of their conferences and symposiums.

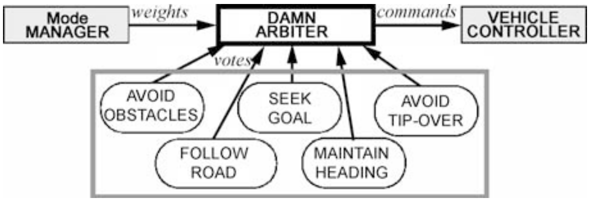
A closely related predecessor to SOA is component-based architecture (COA), which differs primarily in its stronger predisposition of what services a software entity ("component") will provide and less standardization of how components communicate with each other. In other words, COA does not worry so much about a component performing a single task (as in SOA) as long as the multiple services provided by a given component, and the interface for executing those services, are well documented. The emphasis is on providing a good platform for problem decomposition and loose coupling among components, with less emphasis on component interoperability. Aksit [1] provides an excellent compilation of articles on the topic of COA, especially Chap. 3, "Component–Based Architecting for Distributed Real-Time Systems", which, in turn, includes a detailed example of using a COA to devise a Car Navigation System (page 85). All in all, SOA can be considered a maturation, and perhaps specialization, of COA.

Distributed Architecture for Mobile Navigation

The Distributed Architecture for Mobile Navigation (DAMN) was originally published as a Ph.D. Dissertation [35] and, while not as widely adopted as the architectures discussed above, it has provided many useful insights. Even though the scope of DAMN is limited to navigation and obstacle avoidance, its distributed approach, its support of hybrid planning and implementation styles, its blend of centralized and decentralized processing, and its thoughtful treatment of salient challenges to real-time decision-making all make it worthy of elaboration here.

The basic premise behind DAMN is that centralized arbitration of distributed decision-making processes provides a reasonable and useful balance between the demands for real-time responsiveness and the challenges brought about by the asynchronous, latency-filled, heterogeneous, uncertain environment encountered by an autonomous ground vehicle. As in the other architectures discussed, DAMN provides a modular, extensible, and interoperable framework for supporting the generation and arbitration of sensor data, behaviors, and commands to the mobility platform, controllers, and actuators. This notion is shown schematically in Fig. 2, where sensor data and high-level commands have been bundled with the assortment of behaviors depicted.

The treatise goes on to present and analyze alternative structuring of the placement of arbitration (e. g., sensor vs. command vs. effect) and to explore various action selection schemes. A detailed presentation of the DAMN implementation on a CMU Navlab AGV and the experimental results achieved provides further insights into the merits and shortcomings of the architecture. Another major contribution of that research was the application of utility theory to the behavior arbitration process, as further discussed later in this article.



Software Architectures for Autonomy, Figure 2
DAMN Arbiter and Behaviors (Source: [35], page 9, Figure 1–2)

Situation Assessment

The situation assessment domain of interest to the topic of software architectures for autonomy is that of an unmanned system understanding its surroundings and status at a higher, more abstract level than that provided directly by its perception systems. In reviewing the literature, one must filter the use of the term when used in the context of the design of manned combat systems; such references often address such topics as own and enemy radars, missile tracking, and weapon lethality. Most such references are in the context of providing situational assessment for a human [16,48], such as pilot support on board a combat aircraft. Of interest here, however, is the applicability to unmanned systems, wherein the raw sensor and signal data is processed into more general situational conclusions, usually as a result of some form of inference or deduction. For clarity, the term "situation assessment" when used in this document will refer to this latter connotation. This domain is sometimes mentioned in the literature as "situational awareness" and could be referring to either of the connotations discussed above.

Work at USC [49] described the use of templates and patterns to provide situation assessment in virtual humans. They demonstrate a way to use situation assessment to improve decision-making by allowing the software system to better focus its attention (i. e., computing resources) with the goal of improved utilization of onboard resources.

Of particular interest is the work underway at NIST. They are working in several areas that address situation assessment. One has to do with incorporating situation assessment feedback to human operators of robotic devices [40]. While their emphasis is on the human-machine interface, there are insights to be gained from the situation identification and classification schemes that they developed. An even more relevant front is their work on using 4D/RCS to control on-road robotic vehicles. There are both formal papers [38] and materials and presentations available on the NIST web site (see Fig. 3) that demonstrate ways to incorporate situation assessment notions into the 4D/RCS architecture.

Weiss, Philipps and To et al. [46] present a capability that could be adapted into a Traffic Specialist. It provides situation classification and prediction for an assortment of expressway-related conditions (such as same/different lane assignment for other vehicles that are detected), and states (Such as approach rate {approach | approach with distance warning | approach with collision warning}). Similarly, [13] introduce material that could form a Collision Avoidance Specialist that could manage interactions with moving obstacles using such notions as "time to collision", "time to brake", and "time to disappear". Another area of interest is vehicle self-awareness and work such as [33] sheds light on how a Vehicle Health Specialist might be devised.

Finally, it should be noted that much of the discussion of situation assessment in the literature was secondary to a broader discussion and is, thus, of most use in providing insights into possible nomenclature and classification. References such as these are discussed in the Knowledge Representation section rather than here.

Planning and Decision Making

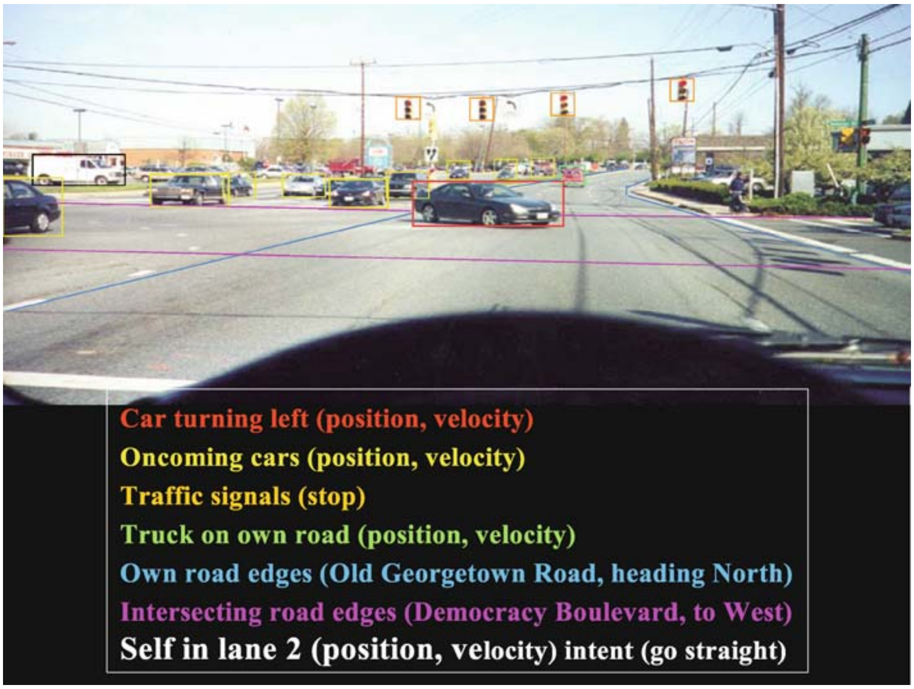
Since the scope of this topic is so broad, its treatment here will be, first of all, limited to the domain of real-time planning and decision-making on an AGV and then further organized as an assortment of "views". The notion of planning refers to the orchestration of executable behaviors to achieve a goal (e. g., find a series of waypoints that will take the vehicle to a desired goal, then drive the vehicle to those waypoints while avoiding obstacles, obeying driving rules and maintaining stability), as well as the low-level planning conducted by a given behavior (e. g., finding an obstacle-free path towards the next waypoint within the perception horizon of the vehicle). The following list of behavior primitives are but a sampling of those gleaned from the literature:

- Seek Goal
- Avoid Obstacles
- Follow Road
- Respond to Blocked Path
- Explore
- Wander
- Maintain Stability
- Seek Target/Intruder
- Intercept Target
- Mark Location

Viewed as a Sense-Plan-Act Problem

This is perhaps the most fundamental view of autonomous control of a mobile robot and one into which many autonomous robotic implementations can be cast. The notion is to neutralize uncertainties in the robot's perception of its world, its understanding of its own state, and the effects of its own actions by indirectly "closing the loop" through the continuous gathering of feedback from its environment while executing its plan [25]. Since it is anticipated that the plan itself will be divided into a sequence of steps, the idea is that the results of executing the initial steps can be observed and compared with expected results. If expectations are not being adequately met (in essence, forming an "error" signal), then the subsequent steps can be adjusted accordingly, or an entirely new plan can be published. It is presumed that the robot will have an ability to store its perception and state knowledge in some form of a world model, which can, in turn, be used by the planner.

This design style best describes the autonomous control used on the NAVIGATOR [8]. The four environmental sensors publish their findings, in the form of a traversability grid, to a sensor arbiter. Two additional pseudo-sensors each publish a traversability grid to the sensor arbiter denoting the a priori route boundary and a priori path plan. The sensor arbiter then fuses these inputs and publishes to the receding horizon planner a comprehensive traversability grid, which represents a localized view of a world model. The receding horizon planner uses an A* search algorithm and a simple vehicle model to iteratively produce viable plans that achieve a desired goal state and to choose the one that minimizes traversability cost. The goal itself is based on the a priori path plan and is replaced with a new goal once the vehicle nears it. The planning search that occurs has as its only objective the publishing of an instantaneous wrench command (steering, throttle, brake) to the vehicle's primitive driver, whose job is to execute that wrench as actuator positions. Thus, every cycle of the planner produces a new wrench command. Since every component in the chain executes at a nominal rate of 20 Hz, a new "plan" (as manifested in the instantaneous wrench command) is always being issued, thus providing a responsive behavior, with some deliberation on how that behavior is generated. Figure 4 shows a snapshot of an arbitrated traversability grid and the instantaneous plan. Red, orange, and yellow indicate lessen-



Car turning left (position, velocity)
Oncoming cars (position, velocity)
Traffic signals (stop)
Truck on own road (position, velocity)
Own road edges (Old Georgetown Road, heading North)
Intersecting road edges (Democracy Boulevard, to West)
Self in lane 2 (position, velocity) intent (go straight)

Software Architectures for Autonomy, Figure 3

Software Architectures for Autonomy, Figure 4
Example Traversability Grid taken from the NAVIGATOR while in a Cluttered Roadway

ing severity of obstacles, gray and blue indicate improving degrees of smoothness of terrain. The instantaneous plan is indicated in black.

One difference in the NAVIGATOR's implementation of the Sense-Plan-Act paradigm is that, by encapsulating the a priori plan into a pseudo-sensor whose findings compete with those of the other sensors, the conventional aspects of planning provide only "suggestions" for a preferred action, rather than forcing the vehicle onto a defined course. Although implemented quite differently, this notion is in concert with the findings of Payton, Rosenblatt and Keirsey [29], who go on to note that "In general, internalized plans should be conceived as representations that allow the raw results of search in an abstract state space to be made available as advice to continuous real-time decision-making processes".

There are many good examples of robotic systems that have implemented some fashion of the Sense-Plan-Act paradigm. Most have to do with navigation and obstacle avoidance, such as Batavia and Nourbakhsh [6]. Examples of this paradigm applied to other aspects of robotic planning and decision-making are much harder to find.

Viewed as a Subsumption Problem

The notion of empowering a mobile robot to operate without any centralized control was first introduced by Rodney Brooks as he devised a self-managing, layered control scheme dubbed the "subsumption architecture" [7]. By decomposing a robot's control system into layers of task-achieving behaviors, control is governed by the dominant layer in play at an instance in time, which, in turn, "subsumes" the behaviors of the lower level layers. For example, let "Wander" be considered a level 1 behavior and "Explore" a level 2 behavior. Since Explore is the higher level, it will self-determine whether exploring is an appropriate behavior under current circumstances. If so, then it will alter the Wander behavior to be not random, but to fulfill its wishes to visit new areas. If not, then it will allow the Wander behavior to proceed without any alteration. This notion is extrapolated across all possible behaviors. This style of planning and decision-making is often referred to as "reactive". The resultant behavior of the robot is referred to as "emergent" since it is likely that the observed behavior is some extemporaneous blend of the possible behaviors that the robot could execute.

This approach to planning and decision-making has a dedicated following and is especially appealing for multi-agent and swarm applications. For example, the subsumption architecture and reactive behavior play a major (though not exclusive) role in the design of robots at the Idaho National Lab (see www.inl.gov/adaptiverobotics).

The differences between these first two views can be captured by the relative importance placed on each of the three components of the Sense-Plan-Act view. For example, a purely reactive system does almost no local planning since every stimulus anticipated during the sensing stage has a prescribed behavioral action, thus relegating the planning stage to simply resolving action conflicts when more than one stimulus is perceived or queuing and dispensing actions when one stimulus invokes multiple actions (i. e., managing the subsumption process). Conversely, a deliberative system will have a large emphasis on the planning stage, attempting to formulate a new plan that incorporates newly sensed information along with any changes in state of the vehicle or its mission while simulating the effect of alternative actions on the quality and viability of the plan. The juxtaposition of the Sense-Plan-Act view's emphasis on deep planning through possibly time-consuming deliberation and the Subsumption view's potentially unpredictable, but fast, reaction to stimuli, explains why researchers are still seeking other, hybrid or blended, planning and decision-making styles.

Viewed as a Decision Theory Problem

Another rich area of exploration is how classical decision theory might be applied to the AGV domain. For example, Karacapilidis and Papadias [20] describe how argumentation can be automated and used to support collaborative decision-making. Their ideas for automating argumentation constructs include evaluations such as "Scintilla of Evidence", "Beyond Reasonable Doubt", and "Preponderance of Evidence".

Rauenbusch and Grosz [32] and others speak of devising explicit "Plan Trees" whose nodes encapsulate the desired action/behavior, associated constraints, and contextual applicability and whose structure models the desired decision-making outcomes. The search through the tree is conducted using some measure of cost or value such that the correct path through the tree delivers the correct series of actions/behaviors.

Hoffman and Yates [15] present a synopsis of what has become known as the "three-step decision-making process". In this paper, they report that most, if not all decisions can be modeled as a cascading set of three-step activities. One of the models specifically referenced for use in process control is 1) Situation Assessment, 2) Planning, and 3) Commitment to a course of action. Each of these steps may be expanded into another three-step decision-making process, such as deciding which situational conditions are present or relevant, or whether to keep or abandon a committed action.

A final realm under decision theory is known as Hierarchical Task Network (HTN) planning [9] provide an overview of this concept and cite the seminal works that have contributed to it on the way to introducing a formalism of HTN planning semantics. The basic premise of HTN planning is to iteratively decompose tasks until primitive tasks are reached (defined as tasks that cannot be further decomposed and that are actionable). These primitive tasks are assembled into a network of increasingly abstract tasks allowing a planning algorithm to select a high-level task, recursively expand its children until its primitive tasks are reached. Some expansions may be constrained based on the current situation, thus pruning the search when compared with an unconstrained expansion of the network. Each reachable path from the high-level tasks to the primitive tasks becomes a candidate plan. While this exploration of the HTN is taking place, the candidates are being evaluated by so-called "critics" so that any arising conflicts can be identified and the winning candidate declared. Because of its deep reasoning, HTN-based planning is not typically used for real-time applications.

Viewed as a Behavior Arbitration Problem

The concept of Behavior Arbitration was introduced as part of the Distributed Architecture for Mobile Navigation

(DAMN) [35] as a key ingredient for achieving its goal of balancing centralized and decentralized design styles. All (decentralized) behavior generators submit their control output (referred to as a "vote") and the (centralized) DAMN Arbiter fuses their votes into a single command set to the vehicle.

"Utility fusion", which uses traditional utility theory to provide an alternative to command fusion, is another concept that evolved from DAMN [36]. This notion requires each behavior generator to submit a probabilistic utility estimate along with its vote, thus enabling a "utility arbiter" to compute the Maximum Expected Utility and use it to select the optimal behavior.

Viewed as an Action Selection Problem

Action Selection is another way to view planning and decision-making on an AGV. In this view, the mobile robot is tasked with selecting the most appropriate action based on the current situation, in spite of inaccurate, incomplete, and possibly unforeseen information. For this to happen, there must exist some catalog or repository of possible actions from which to select and the criteria upon which to base a selection decision. Pirjanian [30] provides an excellent overview of ten varying approaches to the action selection problem. In this treatise, he summarizes each (including DAMN), then compares and contrasts them in terms of eight criteria, including planning vs. reactivity, synchronous vs. asynchronous, hierarchy vs. no hierarchy, and knowledge representation which all have a direct bearing on the current research.

NIST has also developed an approach to action selection via its hierarchical planning and control scheme [21, 22]. The scheme enables the system to plan at different rates at each level, with the scope of planning fixed for each level. For example, high-level goal planning might take place at a lower resolution and update rate, but would cover a larger expanse than say planning for obstacle avoidance. The plans themselves are broken into a tree or graph of subgoals and subtasks (task decomposition itself is discussed under Knowledge Representation) and the actions are selected, executed, and monitored in accordance with the defined planning levels. The planning levels are chosen to be consistent with the time, duty cycle, and range horizon parameters established in the 4D/RCS architecture. For example, AGV mobility planning is broken into four levels: Servo, Prim(itive), Autonomous Mobility, and Vehicle System. Balakirsky and Lacaze [2] elaborate how planning, in the form of Value Judgment and Behavior Generation, takes place for the Vehicle System planning level.

Viewed as an Adaptive Planning Problem

Note that in some literature, "adaptive" is used to mean that the system "learns" from its experience, thus improving its performance over time, whereas the connotation used here is that the system alters its plan based on new, situational information that has been provided by upstream knowledge and data processing. Thus, while the possibility of actually changing the a priori behaviors from which to choose through learning should not be ruled out for future generations of the Adaptive Planning Framework, it is certainly not the emphasis or the motivation for using the term "adaptive" in its moniker. The genesis of adaptive planning as used here was a search to improve the performance of (manual) military mission planning through the use of expert systems, such as the Adaptive Mission Planning System in [41]. The quest continues as military planners seek to reduce 24-month planning cycles down to a year or less for complex deployments and even less for Crisis Action Planning [14]. In fact, their definition, "Adaptive Planning is the systematic, on-demand creation and revision of executable plans, with up-to-date options, as circumstances require", could suffice for the work conducted here as long as its transition to an autonomous, real-time setting is understood.

The need to alter a plan already in progress can have a number of causes, including insufficient time for completion, ineffective results, changes in the situation, and receipt of a new objective to name a few. The Artificial Intelligence community has driven related work in this area, but application to mobile autonomous robotics has not been at the forefront. For example, [12] presents an excellent treatise of an adaptive planning architecture based on the premise that an "agent dynamically constructs explicit control plans to guide its choices among situation-triggered behaviors". To accomplish this, she identified and explored five areas where an intelligent system might require adaptive behavior, depending on the situation encountered:

1. Perception Strategy – Adapt to information requirements and resource limitations
2. Control Mode – Adapt to goal-based constraints and environmental uncertainty
3. Reasoning Tasks – Adapt to perceived and inferred conditions
4. Reasoning Methods – Adapt to available information and current performance criteria
5. Meta-Control Strategy – Adapt to dynamic configurations of demands and opportunities

As an example of more recent work that does focus on mobile robotics in a real-time setting, Hassan, Simo and Crespo [11] offer a behavior-based architecture that will adapt to temporal constraints by allowing itself to utilize more deliberative techniques when time is available, but moving towards more reactive behaviors when time is at a premium. They also introduce the notion of adjusting the quality of service that a given element might deliver based on the situation encountered. For example, this approach might allow the system to attempt to achieve its goal with a "rough" plan if a "complete" plan could not be delivered in a timely enough manner. Musliner [23] and his Adaptive Mission Planner, provides another view on how to empower an autonomous system to alter its plans based on temporal constraints and in light of changing environments, objectives, and system capabilities. That work built upon his earlier efforts to devise the Cooperative Intelligent Real-time Control Architecture (CIRCA) [24], which provides formalisms on how to represent tasks and decisions in a LISP setting. While CIRCA has not been applied in the mobile robotic domain (making its suitability to support an AGV unknown), there are insights to be gained from this work. Finally, NIST has incorporated an element of adaptive planning in their recent work on autonomous on-road driving as part of 4D/RCS. For example, Balakirsky and Scrapper [3] discuss an expert system and knowledge representation scheme that support adaptive planning for autonomous lane and speed management.

Knowledge Representation

In this section, related work on Knowledge Representation relevant to the domain of AGVs is explored. Knowledge Representation refers to the schemas and constructs used to document, standardize, normalize, and utilize the entities within the domain of interest. It must capture the semantics and meanings of the relationships among the entities, as well as their names, descriptions, attributes, and the method or reasoning mechanism for determining their current state or value.

Sources of such domain knowledge include technical documents, specifications, training manuals, etc. (many of which can be accessed via the web). Example knowledge sources include a table of Autonomous Mobility Situation Coverage Requirements from Demo III requirements analysis [34], a Functional Taxonomy chart for an AGV from a TACOM (the U. S. Army's Tank-Automotive COMmand) PowerPoint presentation [31], and by drawing analogies from human military operations as found in the Army Universal Task List [44]. Remaining knowledge gaps must be filled in by interviews of subject matter experts or perhaps empirically through experimentation.

By far, the most work in knowledge representation for intelligent vehicles has been done by NIST. Thus, this section will conclude with an extended example, demonstrating their approach to representing knowledge about situational conditions, states and events, planning, and behaviors within the 4D/RCS context.

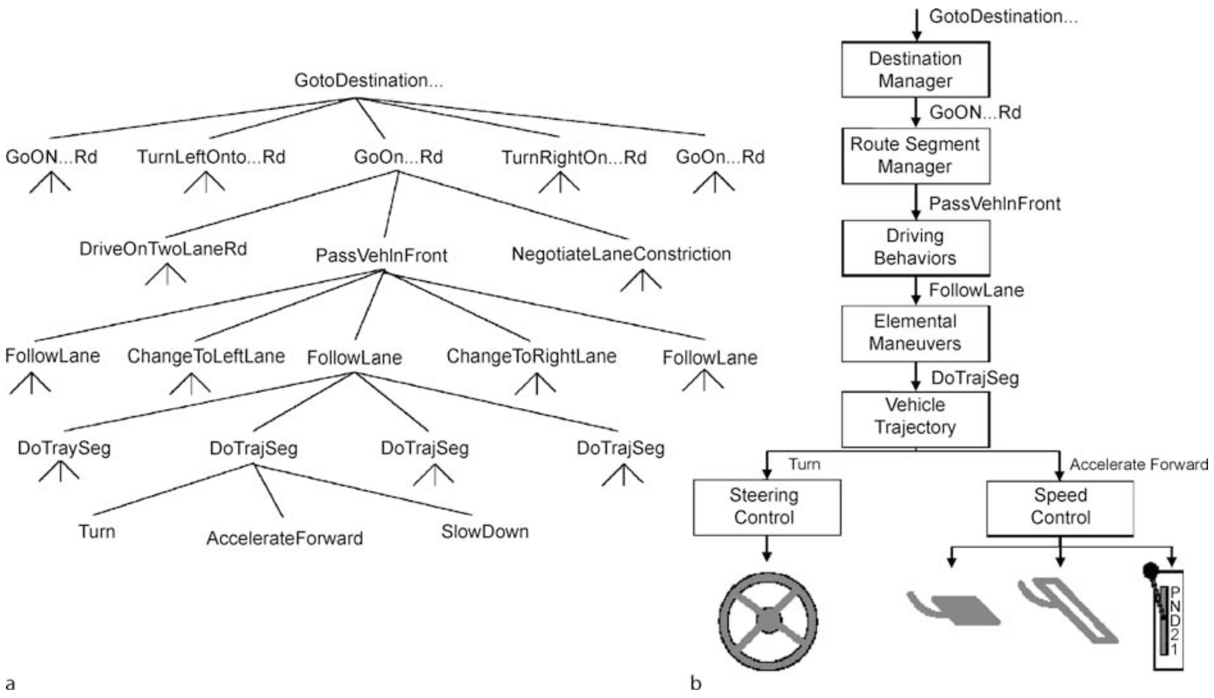
Lexicons, Taxonomies, and Ontologies

One technique for knowledge representation is to progress from a lexicon (a domain-specific dictionary of terms), to a taxonomy (a logical ordering and categorization of those terms), to an ontology (an explicit specification of those terms along with the semantics and relationships among them). One on-line dictionary defines ontology as follows:

> An explicit formal specification of how to represent the objects, concepts and other entities that are assumed to exist in some area of interest and the relationships that hold among them ... Definitions associate the names of entities in the universe of discourse (e. g. classes, relations, functions or other objects) with human-readable text describing what the names mean and formal axioms that constrain the interpretation and well-formed use of these terms ... The hierarchical structuring of knowledge about things by subcategorizing them according to their essential (or at least relevant and/or cognitive) qualities [17].

Much work is in progress attempting to build general purpose, or even "common sense" ontologies that would be useful to all domains. The most famous of these is the OpenCyc project (http://www.opencyc.org/), which, with 47,000 concepts and 306,000 assertions about them to date, is well on its way to achieving its vision to become "the world's largest and most complete general knowledge base and commonsense reasoning engine". Another initiative of interest is the DARPA Agent Markup Language (DAML) project (http://www.daml.org/), which was sponsored by DARPA to create an xml extension that provides (among other things) a rich and suitable language for the creation of general-purpose ontologies (282 distinct ontologies had been created using DAML by the time the program funding was terminated in 2006 and the work absorbed by W3C).

For the AGV domain, the scope of the knowledge that must be represented via the techniques discussed in this subsection is still quite broad. Situational knowledge spans from urban to highway to off-road environments,



Software Architectures for Autonomy, Figure 5
NIST Knowledge representation schemes for on-road driving. (Source: [4,5], Figures 3 and 4)

potential obstacles and hazards that might be present, traffic rules and driving best practices, and so on. Planning and behavior knowledge encompasses a wide variety of missions and tasks, whether they are high-level (conduct search and rescue operation), tactical (pass the vehicle), elementary (change lane), behaviors (avoid obstacles, maintain stability), planning rules and processes, and so on. Even knowledge about "self" or "ego" must be represented, such as capabilities, limitations and constraints, or current status. There is a major initiative under way at NIST, sponsored by TACOM, to develop an Intelligent Systems Ontology. Although still a work in progress, this intelligent-vehicle-specific ontology is expected to provide a standard set of domain concepts, their attributes and their interrelationships, delivered in a fashion that facilitates knowledge capture and reuse [39]. This ontology is beginning to gain traction as it makes its way into the AGV navigation planning community outside of NIST [37].

World Model Knowledge Store (WMKS)

Another dimension of knowledge representation is how data, information, and knowledge are stored. Whether it is provided a priori, or it is perceived, inferred, or received by the AGV, there must be a place and a format for storing, accessing, and analyzing it. Such data, information, and knowledge are often referred to as the "world model" and the place where they are stored as the "knowledge store". The breadth and sophistication of the world model knowledge store for a given AGV design will vary widely, depending on its degree of autonomy, the scope of its behavior, the complexity of its design, etc.

Situation Assessment findings, which must also be managed, fit into what some communities refer to as "meta-knowledge", i. e., knowledge about the knowledge. For example, while pumping out its perception data, a sensor could independently assess and report on its own confidence in its findings and its own health, and perhaps even declare that its own results should not be used right now (say, due to a camera white-out).

Although not always so, the knowledge store is usually persistent, using either a relational database or an object-oriented knowledge based system. Since much of the information stored is of a geo-spatial nature, the knowledge store often includes geo-spatial extensions for explicitly representing GIS and topographical data, polygonal objects, etc. Another consideration is whether the WMKS contents are stored in a central location, accessible by all AGV modules (sometimes referred to as a "blackboard architecture") or each module maintains a subset of the WMKS containing just the content it needs, with data, information, and knowledge marshaled among the AGV modules on an as-needed/as-requested basis (sometimes referred to as a "publish/subscribe architecture").

Knowledge Representation at NIST

NIST advocates task decomposition as a key knowledge representation technique to support the hierarchical control strategy emphasized in its 4D/RCS architecture and has published widely on various ways to accomplish it [4,5]. This technique for representing the actionable elements that could be assembled to create a plan strives to break high-level tasks (e. g., a mission objective) into distinct hierarchical levels and also to identify multiple subtasks at a given level. Figure 5a–5b shows an example of how the "GoToDestination" task is decomposed into a "planning graph" that ultimately leads to a specific wrench command to the vehicle. The system must know (or be able to infer) the state of each node in the tree along with the cost of each arc in order for the associated control module to formulate the appropriate plan. Extending the example in Fig. 2–5b, a Destination Manager has determined that staying on the current road is appropriate and a Route Segment Manager has decided that passing the vehicle in front of it is the most desirable way to reach the destination. A Driving Behaviors module knows that its own vehicle has already changed into the passing lane and has further determined that the best thing to do right now is to stay in that lane, while a low-level Elemental Maneuvers module has found a wrench that ought to produce the requested outcome. Each Manager or module manages its own situational understanding either from direct sensory input or from its own local subset of the World Model Knowledge Store. Naturally, there are other tree elements and control modules that address following distance, speed, and so on, in addition to non-mobility-related tasks, such as payload management, communications, etc.

Once a plan is devised and approved, its elements must be executed by invoking one or more actions or behaviors, or perhaps by unleashing an entire subsystem to take over low-level control of the vehicle. NIST advocates the use of State Tables to represent the action decision-making knowledge [4]. A State Table is crafted for each node in the Task Decomposition Tree containing the rules that the control module is to use for mapping node inputs (states or situations) to allowable output actions.

To trigger the appropriate and desired state response, the matching situation must be known. The NIST approach to this is to determine and store the cascading precursor situational knowledge as a collection of "world states", but, in conformance to the 4D/RCS architecture, only that subset relevant to a given module. The lane-changing example concludes with a glimpse of the dozens of situational findings that lead up to the finding of interest ("ConditionsGoodToPass").

Adaptive Planning Framework

The Adaptive Planning Framework was developed by the authors at the University of Florida in order to address the requirements of the DARPA Urban Challenge that was held in November 2007. Figure 6 shows the University of Florida Navigator vehicle on which the Adaptive Planning Framework was implemented for the DARPA Urban Challenge. In the Adaptive Planning Framework, the system is assumed to be able to operate in a finite number of behavior modes. These behavior modes govern how the vehicle operates under various driving conditions. The framework is predominantly used to make intelligent decisions pertaining to these behaviors. The framework is scalable to systems of varying complexity and size and is compatible with existing architectures such as JAUS RA-3.2, NIST 4D/RCS, and others. The Adaptive Planning Framework is composed of three principle elements tasked with assessing the situation, determining the suitability and viability of all possible solutions, and executing the most suitable of all recommended solutions.

Situation Assessment Specialist

Dynamic environment information, originating from any array of sensors is monitored and managed by the Situation Assessment Specialists. Each specialist design is tailored to the sensor or collection of sensors whose data it analyzes. These specialists can, but are not required to, "live" on the same computing node that directly receives the sensor input. While the inputs to the specialist can come from any data source, the output or "finding" must adhere to specific guidelines outlined by the framework. Findings can be in the form of conditions, state, or events. A condition may have a value of present or absent only. All conditions are by default absent and must be proven present at each iteration. A finding classified as a state can only exhibit one of many a priori states. The event category is reserved for findings whose occurrence at some point in time is of significance even after the initial finding has passed. Once the findings have been generated the information is disseminated to all other components that might need it.

An example of a situation assessment specialist would be a software component whose sole function was to determine if it is safe to move to the adjacent lane. This component would monitor sensor data and reach a Boolean

Software Architectures for Autonomy, Figure 6
Team Gator Nation NaviGATOR

conclusion that would be stored as metadata for use by other processes. A second example would be a software component whose sole function was to determine if it is 'legal' to move to an adjacent lane. Here 'legal' is defined as not crossing a yellow line or not changing lanes when approaching an intersection.

Behavior Specialist

The findings rendered by the Situation Assessment Specialists are consumed by the behavior specialists. There is a one-to-one mapping of each behavior with a behavior specialist. The role of the specialist is to monitor the findings and evaluate the suitability of its behavior under the current perceived operating conditions. As with the specialist findings, the default recommendation is unsuitable and must be proven appropriate at every iteration of the program to ensure truth of the results and operating safety. A specialist does not possess the ability to activate or deactivate its associated behavior; such authority is only given to the Decision Broker.

For the DARPA Urban Challenge problem, the vehicle was programmed with six behavior modes. The corresponding behavior specialist constantly evaluates the appropriateness of its behavior. The six behavior modes were:

1. Roadway Navigation. The Roadway Navigation behavior is the primary driving behavior deriving commands to be sent to the vehicle actuators while the objective is lane following. This behavior allows the vehicle to navigate the roadway within the lines of its desired lane and maintain a safe following distance behind any vehicles ahead.
2. Change Lane Maneuver. The change lane maneuver is used in passing situations or in cases where the vehicle must change lanes in a multi-lane road in order to pass through a mission goal point. The behavior constrains the vehicle to remain within the lane boundaries of the new lane.
3. Reverse Direction. This behavior is called whenever it is determined that the current lane is blocked and there is no alternate clear lane available for passing. It is also applicable in cases where the vehicle has entered a 'dead end' road that it must "escape" to reach a mission goal point.
4. Intersection Traversal. The intersection traversal behavior is applicable when the vehicle enters the vicinity of an intersection. This is one of the most complicated behavior modes in that the system must rely on a series of situation assessment specialists to safely navigate the intersection. This behavior mode must handle queuing, stopping at the stop line, determining right of way, and ultimately traveling through the intersection while avoiding other vehicles.
5. Open Area Navigation. Open area navigation is a behavior that is only needed in special circumstances. This behavior allows the vehicle to move towards a goal location without striking any object, while avoiding any

rough terrain. This is in effect the only behavior mode that was required in the 2005 DARPA Urban Challenge. It is useful in the Urban Challenge when the vehicle is in an open area such as a parking lot prior to performing an actual parking maneuver.

6. Parking Lot. This behavior must deal with the problems that arise in the parking lot scenario where precise motion is necessary. When the vehicle approaches the vicinity of an assigned parking space, precise path planning will be initiated to align the vehicle as required. Situation assessment specialists will be monitoring the near surroundings of the vehicle to center the vehicle in its parking space while avoiding any static or dynamic objects.

Decision Broker

At the highest level of the framework lies the Decision Broker. Its role is to monitor all Behavior Specialist recommendations. It assumes ultimate authority over how the vehicle will operate while in autonomous mode. Like the other entities within the framework, the Decision Broker can base its conclusions on not only the recommendations and findings of other specialists, but it may also look at data from any other pertinent source. The author's implementation of the Adaptive Planning Framework centralized all the Decision Broker functionality within the JAUS Subsystem Commander component. The framework architecture employs an asynchronous, iterative, forward chaining reasoning approach to decision making.

Future Directions

JAUS is migrating to the Society of Automotive Engineering (SAE) Standard AS-4, Unmanned Systems. The transition to the SAE offered opportunity to further advance the standard through the introduction of more formalized specifications and methodologies.

The AS-4A Architecture Framework subcommittee has prepared document AIR 5665, Architecture Framework for Unmanned Systems. This document describes the concepts, capabilities and interoperability concerns of unmanned systems, and lays the foundation for all subsequent Aerospace Standards to be released by AS-4.

The AS-4B Network Environment subcommittee is preparing the document AIR5645, "JAUS Transport Considerations". This document examines aspects of JAUS, aspects of communications media, and aspects of the domain of unmanned systems, explaining how these affect the design of transport mechanisms for JAUS messaging. The committee has also prepared an initial draft version of AS5669, "JAUS Transport Specification".

The AS-4C Information Modeling and Definition subcommittee has prepared a working draft of the document AS5684, JAUS Service Interface Definition Language. This specification allows for the unambiguous definition of JAUS services. AS5684 is specified using Relax NG Compact notation, a machine-readable language, allowing for the creation of various tools to aid in the unmanned system design process. The AS-4C Subcommittee has also begun work on AS5710, JAUS Service Set. AS5710 is a collection of standard unmanned system services. Each service is defined using the JAUS Service Interface Definition Language. Current work on this document includes defining a discovery service and transport service, and transitioning the JAUS Reference Architecture 3.2 components to services.

Article Outline

Glossary

Soliton A soliton is a nonlinear pulse-like wave that can exist in some nonlinear systems. The isolated wave can propagate without dispersing its energy over a large region of space; collision of two solitons leads to unchanged forms, solitons also exhibit particlelike properties.

Soliton perturbation theory The soliton perturbation theory is used to study the solitons that are governed by the various nonlinear equations in presence of the perturbation terms.

Homotopy perturbation method The homotopy perturbation method is a useful tool to the search for solitons without the requirement of presence of small perturbations. In this method, a homotopy is constructed with a homotopy parameter, p. When $p = 0$, it becomes a nonlinear wave equation such as a KdV equation with a known soliton solution; when $p = 1$, it turns out to be the original nonlinear equation. To change p from zero to unity, one must only change from a trial soliton to the solved soliton.

Variational iteration method The variational iteration method is a new method for obtaining soliton-type solutions of various nonlinear wave equations. The method begins with a soliton-type solution with some unknown parameters which can be determined after few iterations. The iteration formulation is constructed by a general Lagrange multiplier which can be identified optimally via variational theory.

Exp-function method The exp-function method is a new method for searching for both soliton-type solutions and periodic solutions of nonlinear systems. The method assumes that the solutions can be expressed in arbitrary forms of the exp-function.

Definition of the Subject

The soliton is a kind of nonlinear wave. There are many equations of mathematical physics which have solutions of the soliton type. The first observation of this kind of wave was made in 1834 by John Scott Russell [1]. In 1895, the famous KdV equation, which possesses soliton solutions, was obtained by D. J. Korteweg and H. de Vries [2], who established a mathematical basis for the study of various solitary phenomena.

From a modern perspective, the soliton is used as a constructive element to formulate the complex dynamical behavior of wave systems throughout science: from hydrodynamics to nonlinear optics, from plasmas to shock waves, from tornados to the Great Red Spot of Jupiter, from traffic flow to the Internet, from Tsunamis to turbulence [3]. More recently, solitary waves are of key importance in the quantum fields: on extremely small scales and at very high observational resolution equivalent to a very high energy, space–time resembles a stormy ocean and particles and their interactions have soliton-type solutions [4].

Introduction

The soliton was first discovered in 1834 by John Scott Russell, who observed that a canal boat stopping suddenly gave rise to a solitary wave which traveled down the canal for several miles, without breaking up or losing strength. Russell named this phenomenon the 'soliton'.

In a highly informative as well as entertaining article [1] J.S. Russell gave an engaging historical account of the important scientific observation:

> *I was observing the motion of a boat which was rapidly drawn along a narrow channel by a pair of horses, when the boat suddenly stopped – not so the mass of water in the channel which it had put in motion; it accumulated round the prow of the vessel in a state of violent agitation, then suddenly leaving it behind, rolled forward with great velocity, assuming the form of a large solitary elevation, a rounded, smooth and well-defined heap of water, which continued its course along the channel apparently without change of form or diminution of speed. I followed it on horseback, and overtook it still rolling on at*

> *a rate of some eight or nine miles an hour, preserving its original figure some thirty feet long and a foot to a foot and a half in height. Its height gradually diminished, and after a chase of one or two miles I lost it in the windings of the channel. Such, in the month of August 1834, was my first chance interview with that singular and beautiful phenomenon which I have called the Wave of Translation.*

His ideas did not earn attention until 1965 when N.J. Zabusky and M.D. Kruskal began to use a finite difference approach to the study of KdV equation [5], and various analytical methods also led to a complete understanding of Solitons, especially the inverse scattering transform proposed by Gardner, Greene, Kruskal, and Miura [6] in 1967. The significance of Russell's discovery was then fully appreciated. It was discovered that many phenomena in physics, electronics and biology can be described by the mathematical and physical theory of the 'Soliton'.

The particle-like properties of solitons [7] also caught much attention, and were proposed as models for elementary particles [8]. More recently it has been realized that some of the quantum fields which are used to describe particles and their interactions also have solutions of the soliton type [9].

Methods for Soliton Solutions

The investigation of soliton solutions of nonlinear evolution equations plays an important role in the study of nonlinear physical phenomena. There are many analytical approaches to the search for soliton solutions, such as soliton perturbation, tanh-function method, projective approach, F-expansion method, and others [10,11,12,13,14].

Soliton Perturbation

We consider the following perturbed nonlinear evolution equation [15,16]

$$u_T + N(u) = \varepsilon R(u), \quad 0 < \varepsilon \ll 1 . \tag{1}$$

When $\varepsilon = 0$, we have the un-perturbed equation

$$u_T + N(u) = 0 , \tag{2}$$

which is assumed to have a soliton solution.

When $\varepsilon \neq 0$, but $0 < \varepsilon \ll 1$, we can use perturbation theory [15,16], and look for approximate solutions of Eq. (1), which are close to the soliton solutions of Eq. (2). Using multiple time scales (a slow time τ and a fast time t, such that $\partial_T = \partial_t + \varepsilon\partial_\tau$), we assume that the soliton solution can be expressed in the form

$$u(x, T) = u_0(\xi, \tau) + \varepsilon u_1(\xi, \tau, t) + \varepsilon^2 u_2(\xi, \tau, t) + \cdots \tag{3}$$

where $\xi = x - ct$, and τ is a slow time and t is a fast time.

Substituting Eq. (3) into Eq. (1) and then equating like-powers of ε, we can obtain a series of linear equations for u_i $(i = 0, 1, 2, 3, \ldots)$.

In most cases the nonlinear term $R(u)$ in Eq. (1) plays an import role in understanding various solitary phenomena, and the coefficient ε is not limited to a "small parameter".

Variational Approach

Recently, variational theory and homotopy technology have been successfully applied to the search for soliton solutions [17,18] without requiring the small parameter assumption. Both variational and homotopy technologies can lead to an extremely simple and elementary, but rigorous, derivation of soliton solutions.

Considering the KdV equation

$$\frac{\partial u}{\partial t} - 6u\frac{\partial u}{\partial x} + \frac{\partial^3 u}{\partial x^3} = 0 , \tag{4}$$

we seek its traveling wave solutions in the following frame

$$u(x, t) = U(\xi) \quad v(x, t) = V(\xi), \quad \xi = x - ct , \tag{5}$$

where c is angular frequency. Substituting Eq. (5) into Eq. (4) yields

$$-cu' - 6uu' + u''' = 0 , \tag{6}$$

where a prime denotes the differential with respect to ξ.

Integrating Eq. (6) yields the result

$$-cu - 3u^2 + u'' = 0 . \tag{7}$$

By the semi-inverse method [19], the following variational formulation is established

$$J = \int_0^\infty \left(\frac{1}{2}cu^2 + u^3 + \frac{1}{2}\left(\frac{\mathrm{d}u}{\mathrm{d}\xi}\right)^2 \right) \mathrm{d}\xi . \tag{8}$$

The semi-inverse method is a powerful mathematical tool to the search for variational formulae for real-life physical problems.

By the Ritz method, we search for a solitary wave solution in the form

$$u = p\,\mathrm{sech}^2(q\xi) , \tag{9}$$

where p and q are constants to be further determined.

Substituting Eq. (9) into Eq. (8) results in

$$\begin{aligned} J &= \int_0^\infty \left[\frac{1}{2}cp^2 \operatorname{sech}^4(q\xi) + p^3 \operatorname{sech}^6(q\xi) \right. \\ &\qquad \left. + \frac{1}{2}(4p^2q^2 \operatorname{sech}^4(q\xi)\tanh^2(q\xi))\right] \mathrm{d}\xi \\ &= \frac{cp^2}{2q}\int_0^\infty \operatorname{sech}^4(z)\mathrm{d}z + \frac{p^3}{q}\int_0^\infty \operatorname{sech}^6(z)\mathrm{d}z \\ &\qquad + 2p^2q\int_0^\infty \left\{\operatorname{sech}^4(z)\tanh^4(z)\right\}\mathrm{d}z \\ &= \frac{cp^2}{3q} + \frac{8p^3}{15q} + \frac{4p^2q}{15}\,. \end{aligned} \tag{10}$$

Making J stationary with respect to p and q results in

$$\frac{\partial J}{\partial p} = \frac{2cp}{3q} + \frac{24p^2}{15q} + \frac{8pq}{15} = 0\,, \tag{11}$$

$$\frac{\partial J}{\partial q} = -\frac{cp^2}{3q^2} - \frac{8p^3}{15q^2} + \frac{4p^2}{15} = 0\,, \tag{12}$$

or simplifying

$$5c + 12p + 4q^2 = 0\,, \tag{13}$$

$$-5c - 8p + 4q^2 = 0\,. \tag{14}$$

From Eqs. (13) and (14), we can easily obtain the following relations:

$$p = -\frac{1}{2}c, \quad q = \sqrt{\frac{c}{4}}\,. \tag{15}$$

So the solitary wave solution can be approximated as

$$u = -\frac{c}{2}\operatorname{sech}^2\sqrt{\frac{c}{4}}\,(x - ct - \xi_0)\,, \tag{16}$$

which is the exact solitary wave solution of KdV equation (4).

The preceding analysis has the virtue of utter simplicity. The suggested variational approach can be readily applied to the search for solitary wave solutions of other nonlinear problems, and the present example can be used as paradigms for many other applications in searching for solitary wave solutions of real-life physics problems.

Variational Iteration Method

The variational iteration method [20] is an alternative approach to soliton solutions without the requirement of establishing a variational formulation for the discussed problems [17,21,22,23,24]. As an illustrating example, we consider the $K(3,1)$ equation in the form [17]:

$$u_t + u^2u_x + u_{xxx} = 0\,. \tag{17}$$

According to the variational iteration method, its iteration formulation can be constructed as follows

$$\begin{aligned} &u_{n+1}(x,t) \\ &= u_n(x,t) - \int_0^t \left\{(u_n)_t + u_n^2(u_n)_x + (u_n)_{xxx}\right\}\mathrm{d}t\,. \end{aligned} \tag{18}$$

To search for its compacton-like solution, we assume the solution has the form

$$u_0(x,t) = \frac{a\sin^2(kx + wt)}{b + c\sin^2(kx + wt)}\,, \tag{19}$$

where a, b, k, and w are unknown constants further to be determined after few iterations [17].

Homotopy Perturbation Method

The homotopy perturbation method [25] provides a simple mathematical tool for searching for soliton solutions without any small perturbation [18,26]. Considering the following nonlinear equation

$$\frac{\partial u}{\partial t} + au\frac{\partial u}{\partial x} + b\frac{\partial^3 u}{\partial x^3} + N(u) = 0, \quad a > 0,\ b > 0\,, \tag{20}$$

we can construct a homotopy in the form

$$\begin{aligned} &(1-p)\left\{\frac{\partial u}{\partial t} + 6u\frac{\partial u}{\partial x} + \frac{\partial^3 u}{\partial x^3}\right\} \\ &\quad + p\left\{\frac{\partial u}{\partial t} + au\frac{\partial u}{\partial x} + b\frac{\partial^3 u}{\partial x^3} + N(u)\right\} = 0\,. \end{aligned} \tag{21}$$

When $p = 0$, we have

$$\frac{\partial u}{\partial t} + 6u\frac{\partial u}{\partial x} + \frac{\partial^3 u}{\partial x^3} = 0\,, \tag{22}$$

a well-known KdV equation whose soliton solution is known. When $p = 1$, Eq. (21) turns out to be the original equation. According to the homotopy perturbation method, we assume

$$u = u_0 + pu_1 + p^2u_2 + \cdots \tag{23}$$

Substituting Eq. (23) into Eq. (21), and proceeding with the same process as the traditional perturbation method does, we can easily solve u_0, u_1 and other components. The solution can be expressed finally in the form

$$u = u_0 + u_1 + u_2 + \cdots \tag{24}$$

The homotopy perturbation method always stops before the second iteration, so the solution can be expressed as

$$u = u_0 + u_1 \tag{25}$$

for most cases.

Parameter-Expansion Method

The parameter-expansion method [27,28,29,30] does not require one to construct a homotopy. To illustrate its solution procedure, we re-write Eq. (20) in the form

$$\frac{\partial u}{\partial t} + au\frac{\partial u}{\partial x} + b\frac{\partial^3 u}{\partial x^3} + 1 \cdot N(u) = 0\,. \tag{26}$$

Supposing that the parameters a, b, and 1 can be expressed in the forms

$$a = a_0 + pa_1 + p^2 a_2 + \cdots \tag{27}$$

$$b = b_0 + pb_1 + p^2 b_2 + \cdots \tag{28}$$

$$1 = pc_1 + p^2 c_2 + \cdots \tag{29}$$

where p is a bookkeeping parameter, $p = 1$. Substituting Eqs. (23), (27), (28) and (29) into Eq. (26) and proceeding the same way as the perturbation method, we can easily obtain the needed solution.

Exp-function Method

The exp-function method [31,32,33] provides us with a straightforward and concise approach to obtaining generalized solitonary solutions and periodic solutions and the solution procedure, with the help of Matlab or Mathematica, is utterly simple. Consider a general nonlinear partial differential equation of the form

$$F(u, u_x, u_y, u_z, u_t, u_{xx}, u_{yy}, u_{zz}, u_{tt}, u_{xy}, u_{xt}, u_{yt}, \ldots) = 0\,. \tag{30}$$

Using a transformation

$$\eta = ax + by + cz + dt\,, \tag{31}$$

we can re-write Eq. (30) in the form of the following nonlinear ordinary differential equation:

$$G(u, u', u'', u''', \ldots) = 0\,, \tag{32}$$

where a prime denotes a derivation with respect to η.

According to the exp-function method, the traveling wave solutions can be expressed in the form

$$u(\eta) = \frac{\sum_{n=-k}^{l} a_n \exp(n\eta)}{\sum_{m=-i}^{j} b_m \exp(m\eta)}\,, \tag{33}$$

where i, j, k, and l are positive integer which could be freely chosen, a_n and b_m are unknown constants to be determined. The solution procedure is illustrated in [32].

Future Directions

It is interesting to point out the connection of catastrophe theory to loop soliton chaos, and finally to chaotic Cantorian spacetime [34,35].

El Naschie [34,35] studied the Eguchi–Hanson gravitational instanton solution and its interpretation by 't Hooft in the context of a quantum gravitational Hilbert space, as an event and a possible solitonic "extended" particle. Transferring a certain solitonic solution of Einstein's field equations in Euclidean "real" space–time to the mathematical infinitely-dimensional Hilbert space, it is possible to observe a new non-standard process by which a definite mass can be assigned to massless particles. Thus by invoking Einstein's gravity in "solitonic" gauge theory and vice versa, an alternative explanation for how massless particles acquire mass is found, which is also in harmony with the basic structure of our standard model as it stands at present [34,35].

Glossary

Soliton A soliton is a stable pulse-like wave that can exist in some nonlinear systems. The soliton, after a collision with another soliton, eventually emerges unscathed.

Compacton A compacton is a special solitary traveling wave that, unlike a soliton, does not have exponential tails.

Generalized soliton A generalized soliton is a soliton with some free parameters. Generally a generalized soliton can be expressed by exponential functions.

Compacton-like solution A compcton-like solution is a special wave solution which can be expressed by the squares of sinusoidal or cosinoidal functions.

Definition of the Subject

Soliton and compacton are two kinds of nonlinear waves. They play an indispensable and vital role in all ramifications of science and technology, and are used as constructive elements to formulate the complex dynamical behavior of wave systems throughout science: from hydrodynamics to nonlinear optics, from plasmas to shock waves, from tornados to the Great Red Spot of Jupiter, from traffic flow to Internet, from Tsunamis to turbulence. More recently, soliton and compacton are of key importance in the quantum fields and nanotechnology especially in nanohydrodynamics.

Introduction

Solitary waves were first observed by John Scott Russell in 1895, and were studied by D. J. Korteweg and H. de Vries in 1895 . Compactons are special solitons with finite wavelength. It was Philip Rosenau and his colleagues who first found compactons in 1993. Please refer to "▶ Soliton Perturbation" for detailed information.

Solitons

A soliton is a special solitary traveling wave that after a collision with another soliton eventually emerges unscathed. Solitons are solutions of partial differential equations that model phenomena like water waves or waves along a weakly anharmonic mass-spring chain.

The Korteweg–de Vries (KdV) equation is the generic model for the study of nonlinear waves in fluid dynamics, plasma and elastic media. KdV equation is one of the most fundamental equations in nature and plays a pivotal role in nonlinear phenomena. We consider the KdV equation in the form

$$\frac{\partial u}{\partial t} + 6u\frac{\partial u}{\partial x} + \frac{\partial^3 u}{\partial x^3} = 0 \,. \tag{1}$$

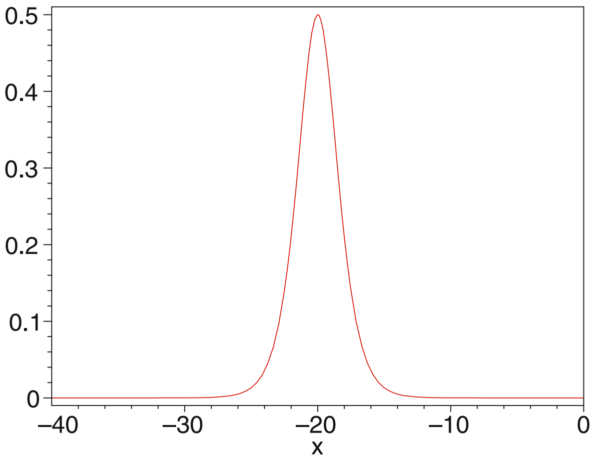
Its solitary traveling wave solution can be solved as

$$u(x,t) = \tfrac{1}{2} c \operatorname{sech}^2\left\{\tfrac{1}{2} c^{1/2}(x - ct)\right\} \,. \tag{2}$$

The bell-like solution as illustrated in Fig. 1 is called a soliton.

We re-write Eq. (2) in an equivalently form:

$$u(\xi) = p \sec h^2(q\xi) = \frac{4p}{e^{2q\xi} + e^{-2q\xi} + 2} \,. \tag{3}$$



Solitons and Compactons, Figure 1
Bell-like solitary wave

where $u(x,t) = u(\xi)$, $\xi = x - ct$, c is the wave velocity.

It is obvious that

$$\lim_{\xi\to\infty} u(\xi) = 0 \quad \text{and} \quad \lim_{\xi\to-\infty} u(\xi) = 0 \,. \tag{4}$$

The soliton has exponential tails, which are the basic character of solitary waves. The soliton obeys a superposition-like principle: solitons passing through one another emerge unmodified, see Fig. 2.

Compactons

Now consider a modified version of KdV equation in the form

$$u_t + (u^2)_x + (u^2)_{xxx} = 0 \,. \tag{5}$$

Introducing a complex variable ξ defined as $\xi = x - ct$, where c is the velocity of traveling wave, integrating once, we have

$$-cu + u^2 + (u^2)_{\xi\xi} = D \,, \tag{6}$$

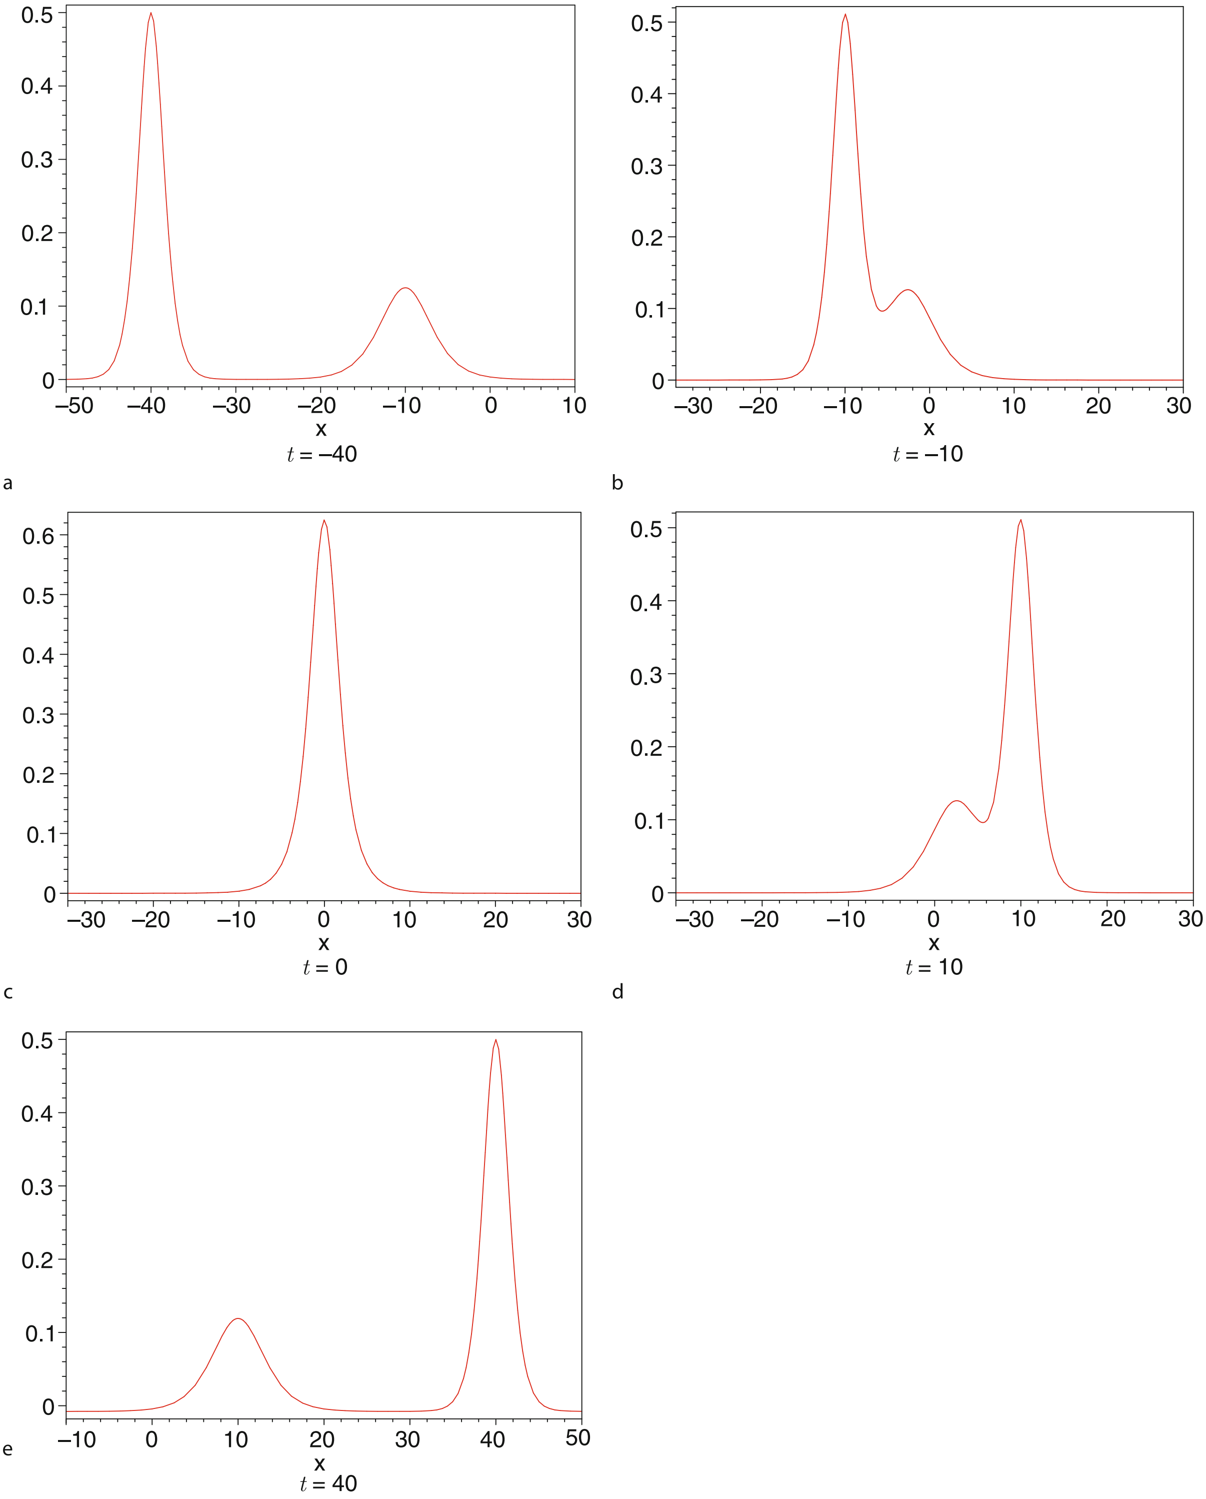
where D is an integral constant.

To avoid singular solutions, we set $D = 0$. We re-write Eq. (6) in the form

$$v_{\xi\xi} + v - cv^{1/2} = 0 \,, \tag{7}$$

where $u^2 = v$.

In case $c = 0$, we have periodic solution: $v(\xi) = A\cos\xi + B\sin\xi$. Periodic solution of nonlinear oscillators can be approximated by sinusoidal function. It helps understanding if an equation can be classified as oscillatory by direct inspection of its terms.



Solitons and Compactons, Figure 2
Collision of two solitary waves

We consider two common order differential equations whose exact solutions are important for physical understanding:

$$u'' - k^2 u = 0\,, \tag{8}$$

and

$$u'' + \omega^2 u = 0\,. \tag{9}$$

Both equations have linear terms with constant coefficients.

The crucial difference between these two very simple equations is the sign of the coefficient of u in the second term. This determines whether the solutions are exponential or oscillatory. The general solution of Eq. (8) is

$$u = Ae^{kt} + Be^{-kt}\,. \tag{10}$$

The second Eq. (9) has a positive coefficient of u, and in this case the general solution reads

$$u = A\cos\omega t + B\sin\omega t\,. \tag{11}$$

This solution describes an oscillation at the angular velocity ω.

Equation (7) behaves sometimes like an oscillator when $1 - cv^{-1/2} > 0$, i. e., $u = v^{1/2}$ has a periodic solution, we assume v can be expressed in the form

$$v = u^2 = A^2\cos^4\omega\xi\,. \tag{12}$$

Substituting Eq. (12) into Eq. (7) results in

$$\begin{aligned}12A^2\omega^2\cos^2\omega\xi - 16A^2\omega^2\cos^4\omega\xi \\ + A^2\cos^4\omega\xi - cA\cos^2\omega\xi = 0\,.\end{aligned} \tag{13}$$

We, therefore, have

$$\begin{aligned}12A^2\omega^2 - cA &= 0 \\ -16A^2\omega^2 + A^2 &= 0\,.\end{aligned} \tag{14}$$

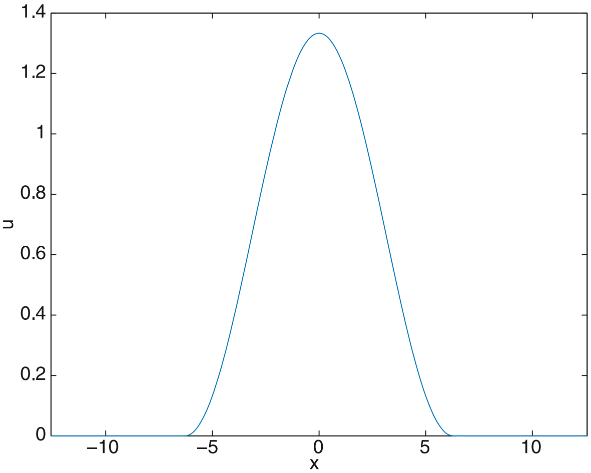
Solving the above system, Eq. (14), yields

$$\omega = \frac{1}{4}\,, \quad A = \frac{4}{3}c\,. \tag{15}$$

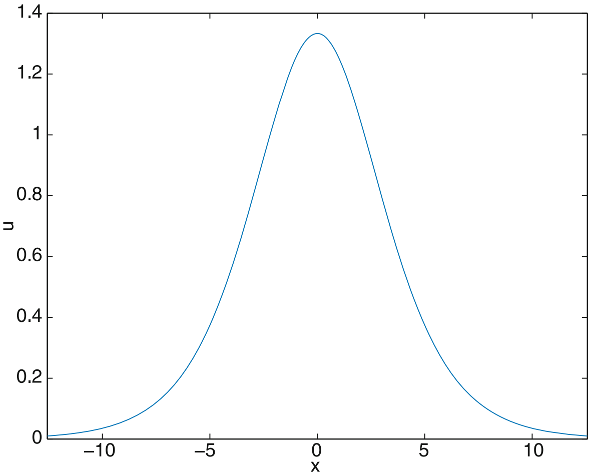
We obtain the solution in the form

$$u = v^{1/2} = \frac{4c}{3}\cos^2\left[\frac{1}{4}(x-ct)\right]\,. \tag{16}$$

By a careful inspection, v can tend to a very small value or even zero, as a result, $1 - cv^{-1/2}$ tends to negative infinite, and Eq. (7) behaves like Eq. (8) with $k \to \infty$, the exponential tails vanish completely at the edge of the bell-shape (see Fig. 3):



Solitons and Compactons, Figure 3
Compaton wave without tails



Solitons and Compactons, Figure 4
Solitary wave with two tails

$$u = \begin{cases}\frac{4c}{3}\cos^2\left[\frac{1}{4}(x-ct)\right]\,, & |x-ct| \le 2\pi \\ 0\,, & \text{otherwise.}\end{cases} \tag{17}$$

This is a compact wave. Unlike solitons (Fig. 4), compacton does not have exponential tails (Fig. 3).

Generalized Solitons and Compacton-like Solutions

Solitary solutions have tails, which can be best expressed by exponential functions. We can assume that a solitary solution can be expressed in the following general form

$$u(\eta) = \frac{\sum\limits_{n=-c}^{d} a_n \exp(n\eta)}{\sum\limits_{m=-p}^{q} b_m \exp(m\eta)}\,, \tag{18}$$

where c, d, p, and q are positive integers which are unknown to be further determined, a_n and b_m are unknown constants. The unknown constants can be easily determined using Matlab, the method is called the Exp-function method.

We consider the modified KdV equation in the form:

$$u_t + u^2 u_x + u_{xxx} = 0\,. \tag{19}$$

Using a transformation: $u(x, t) = u(\xi), \xi = kx + \omega t$, we have

$$\omega u' + ku^2 u' + k^3 u''' = 0\,, \tag{20}$$

where prime denotes the differential with respect to ξ.

We suppose that the solution of Eq. (20) can be expressed as

$$u(\xi) = \frac{a_c \exp(c\xi) + \cdots + a_{-d} \exp(-d\xi)}{b_p \exp(p\xi) + \cdots + b_{-q} \exp(-q\xi)}\,. \tag{21}$$

To determine values of c, d, p and q, we balance the linear term of highest order in Eq. (20) with the highest order nonlinear term. According to the homogeneous balance principle, we obtain the result $c = p$ and $d = q$. For simplicity, we set $c = p = 1$ and $d = q = 1$, so Eq. (21) reduces to

$$u(\xi) = \frac{a_1 \exp(\xi) + a_0 + a_{-1} \exp(-\xi)}{\exp(p\xi) + b_0 + b_{-1} \exp(-\xi)}\,. \tag{22}$$

Substituting Eq. (22) into Eq. (20), and by the help of Matlab, clearing the denominator and setting the coefficients of power terms like $\exp(j\xi), j = 1, 2, \cdots$ to zero yield a system of algebraic equations, solving the obtained system, we obtain the following exact solutions:

$$\begin{cases} a_0 = a_1 b_0 + \dfrac{3k^2 b_0}{a_1}\,, & a_{-1} = \dfrac{b_0^2\left(3k^2 + 2a_1^2\right)}{8a_1}\,, \\ b_{-1} = \dfrac{b_0^2\left(3k^2 + 2a_1^2\right)}{8a_1^2}\,, & \omega = -ka_1^2 - k^3\,, \end{cases} \tag{23}$$

where a_1 and b_0 are free parameters, which depends upon the initial conditions and/or boundary conditions. The property that stability may depend on initial/boundary conditions is characteristic only for nonlinear systems.

The relationship between wave speed and frequency is

$$\omega = -ka_1^2 - k^3\,. \tag{24}$$

Note that the value of a_1 is determined from the initial/boundary conditions, so frequency or wave speed may not independent of initial/boundary conditions.

Then, the closed form solution of Eq. (19) reads

$$\begin{aligned} &u(x, t) \\ &= \frac{\left(a_1 \exp[kx - (ka_1^2 + k^3)t] + a_1 b_0 + \frac{3k^2 b_0}{a_1} + \frac{b_0^2(3k^2+2a_1^2)}{8a_1} \exp[-kx + (ka_1^2 + k^3)t]\right)}{\left(\exp[kx - (ka_1^2 + k^3)t] + b_0 + \frac{b_0^2(3k^2+2a_1^2)}{8a_1^2} \exp[-kx + (ka_1^2 + k^3)t]\right)} \\ &= a_1 + \frac{\frac{3k^2 b_0}{8}}{\left(\exp[kx - (ka_1^2 + k^3)t] + b_0 + \frac{b_0^2(3k^2+2a_1^2)}{8a_1^2} \exp[-kx + (ka_1^2 + k^3)t]\right)}\,. \end{aligned} \tag{25}$$

Generally a_1, b_0 and k are real numbers, and the obtained solution, Eq. (25), is a generalized soliton solution.

If we choose $k = 1, a_1 = 1, b_0 = \sqrt{8/5}$, Eq. (25) becomes

$$u(x, t) = 1 + \frac{3\sqrt{1/40}}{\exp[x - 2t] + \sqrt{8/5} + \exp[-x + 2t]}\,. \tag{26}$$

The bell-like solution is illustrated in Fig. 5.

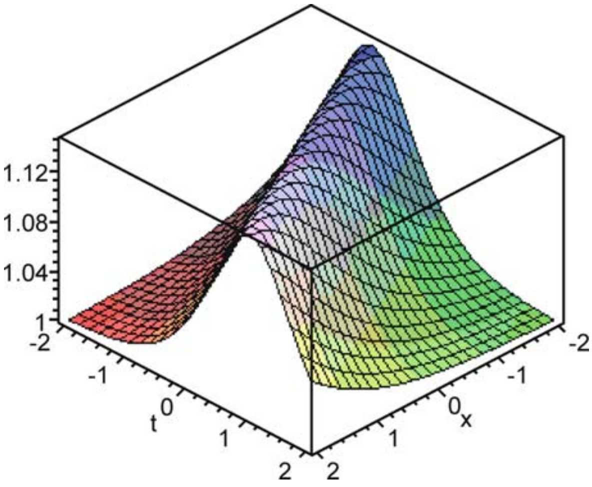
In case k is an imaginary number, the obtained solitary solution can be converted into periodic solution or compact-like solution. We write $k = iK$, Eq. (25) becomes

$$\begin{aligned} &u(x, t) = a_1 \\ &+ \frac{-\frac{3K^2 b_0}{8}}{\left((1 + p) \exp[Kx - (Ka_1^2 - K^3)t] + b_0 + i(1 - p)\frac{b_0^2(3k^2+2a_1^2)}{8a_1^2} \exp[-Kx + (Ka_1^2 - K^3)t]\right)}\,, \end{aligned} \tag{27}$$

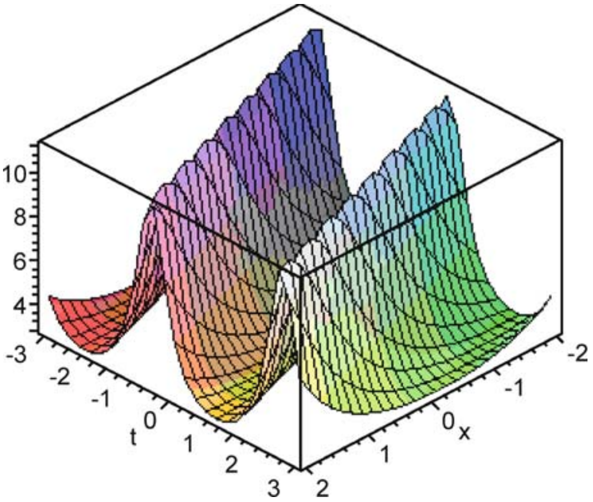
where $p = \frac{b_0^2(-3K^2+2a_1^2)}{8a_1^2}$.

If we search for a periodic solution or compact-like solution, the imaginary part in the denominator of Eq. (27) must be zero, that requires that

$$1 - p = 1 - \frac{b_0^2(-3K^2 + 2a_1^2)}{8a_1^2} = 0\,. \tag{28}$$



Solitons and Compactons, Figure 5
Propagation of a solution with respect to time



Solitons and Compactons, Figure 6
Periodic solution

Solving b_0 from Eq. (28), we obtain

$$b_0 = \pm\sqrt{\frac{8}{-3K^2 + 2a_1^2}}\,. \tag{29}$$

Substituting Eq. (29) into Eq. (27) results in a periodic solution, which reads

$$u(x,t) = a_1 + \frac{\pm 3K^2\sqrt{\frac{2}{-3K^2+2a_1^2}}}{\cos[Kx - (Ka_1^2 - K^3)t] \pm \sqrt{\frac{2}{-3K^2+2a_1^2}}} \tag{30}$$

or a generalized compact-like solution:

$$u(x,t) = \begin{cases} a_1 + \dfrac{\pm 3K^2\sqrt{\frac{2}{-3K^2+2a_1^2}}}{\left(\cos[Kx-(Ka_1^2-K^3)t] \pm \sqrt{\frac{2}{-3K^2+2a_1^2}}\right)}\,, \\ a_1 + 3K^2\,, \quad \text{otherwise} \end{cases}$$
$$\left|Kx - \left(Ka_1^2 - K^3\right)t\right| \le \frac{\pi}{2} \tag{31}$$

where a_1 and K are free parameters, and it requires that $2a_1^2 > 3K^2$. If we choose $k = 1, a_1 = 1, b_0 = \sqrt{8/5}$, Eq. (30) becomes

$$u(x,t) = 1 + \frac{3\sqrt{2}}{\cos[x - 3t] + \sqrt{2}}\,. \tag{32}$$

The periodic solution is illustrated in Fig. 6.

Now we give an heuristical explanation of why Eq. (19) behaves sometimes periodically and sometimes compaton-like.

We re-written Eq. (20) in form

$$u'' + \frac{\omega}{k^3}u + \frac{1}{3k^2}u^3 = 0. \tag{33}$$

It is a well-known Duffing equation with a periodic solution for all $\omega > 0$ and $k > 0$.

Actually in our study ω can be negative, we re-write Eq. (33) in the form

$$u'' - \frac{\omega}{k^3}u + \frac{1}{3k^2}u^3 = 0\,, \quad \omega > 0\,. \tag{34}$$

This equation, however, has not always a periodic solution. We use the parameter-expansion method to find its period and the condition to be an oscillator. In order to carry out a straightforward expansion like that in the classical perturbation method, we need to introduce a parameter, λ, because none appear explicitly in this equation. To this end, we seek an expansion in the form

$$u = u_0 + \lambda u_1 + \lambda^2 u_2 + \lambda^3 u_3 + \cdots\,. \tag{35}$$

The parameter λ is used as a bookkeeping device and is set equal to unity.

The coefficients of the linear term and nonlinear term can be, respectively, expanded in a similar way:

$$-\frac{\omega}{k^3} = \Omega^2 + m_1\lambda + m_2\lambda^2 + \ldots \tag{36}$$

$$\frac{1}{3k^2} = n_1\lambda + n_2\lambda^2 + \ldots\,, \tag{37}$$

where m_i and n_i are unknown constants to be further determined.

Interpretation of why such expansions work well is given by [1].

Substituting Eqs.(35)–(37) to (34), we have

$$\begin{aligned}&\left(u_0+\lambda u_1+\lambda^2 u_2+\dots\right)''\\+&\left(\Omega^2+m_1\lambda+m_2\lambda^2+\dots\right)\left(u_0+\lambda u_1+\lambda^2 u_2+\dots\right)\\+&\left(n_1\lambda+n_2\lambda^2+\dots\right)\cdot\left(u_0+\lambda u_1+\lambda^2 u_2+\dots\right)^3=0\end{aligned} \tag{38}$$

and equating coefficients of like powers of λ, we obtain

Coefficient of λ^0

$$u_0''+\Omega^2 u_0=0\,. \tag{39}$$

Coefficient of λ^1

$$u_1''+\Omega^2 u_1+m_1 u_0+n_0 u_0^3=0\,. \tag{40}$$

The solution of Eq. (39) is

$$u_0=A\cos\Omega t\,. \tag{41}$$

Substituting u_0 into (40) gives

$$\begin{aligned}u_1''+\Omega^2 u_1+A(m_1+\tfrac{3}{4}n_0A^2)\cos\Omega t&\\+\tfrac{1}{4}n_0A^3\cos 3\Omega t=0\,.&\end{aligned} \tag{42}$$

No secular term in u_1 requires that

$$m_1+\frac{3}{4}n_0A^2=0\quad\text{or}\quad A=0\,. \tag{43}$$

If the first-order approximate solution is searched for, then we have

$$-\frac{\omega}{k^3}=\Omega^2+m_1 \tag{44}$$

$$\frac{1}{3k^2}=n_1\,. \tag{45}$$

We finally obtain the following relationship

$$\Omega^2=-\frac{\omega}{k^3}+\frac{1}{4k^2}A^2\,. \tag{46}$$

To behave like an oscillator requires that

$$-\frac{\omega}{k^3}+\frac{1}{4k^2}A^2>0 \tag{47}$$

or

$$\frac{\omega}{k}<\frac{1}{4}A^2\,. \tag{48}$$

The amplitude A may strongly depend upon initial/boundary conditions which may determine the wave type of a nonlinear equation.

Now we approximate Eq. (34) in the form

$$u''+\frac{1}{k^2}\left(-\frac{\omega}{k}+\frac{A^2\cos^2\Omega t}{3}\right)u=0\,. \tag{49}$$

In case $|\Omega t|\to\pi/2$, the above equation behaves exponentially, resulting in a compact-like wave as discussed above.

Future Directions

It is interesting to identify the conditions for a nonlinear equation to have solitary, or periodic, or compacton-like solutions. In most open literature, many papers on soliton and compacton are focused themselves on a special solution with either a soliton or a compacton without considering the initial/boundary conditions, which might be vital important for its actual wave type.

Solitons and compactons for difference-differential equations (e. g. Lotka–Volterra-like problems) have been caught much attention due to the fact that discrete space-time may be the most radical and logical viewpoint of reality (refer to E-infinity theory detailed concept). For small scales, e. g., nano scales, the continuum assumption becomes invalid, and difference equations have to be used for space variables.

Fractional differential model is another compromise between the discrete and the continuum, and can best describe solitons and compactons.

Many interesting phenomena arise in nanohydrodynamics recently, such as remarkably excellent thermal and electric conductivity, and extremely extraordinary fast flow in nanotubes. Consider a single compacton wave along a nanotube, and its wavelength is as same as the diameter of the nanotubes, under such a case, almost no energy is lost during the transportation, resulting in extremely extraordinary fast flow in the nanotubes.

The physical understanding of the transformation $k=iK$ is also worth further studying.

Glossary

Breaking waves As waves increase in height through the shoaling process, the crest of the wave tends to speed up relative to the rest of the wave. Waves break when the speed of the crest exceeds the speed of the advance of the wave as a whole.

Crystal lattice A geometric arrangement of the points in space at which the atoms, molecules, or ions of a crystal occur.

Deep water Water sufficiently deep that surface waves are little affected by the ocean bottom. Water deeper than one-half the surface wave length is considered deepwater.

Fluxon Quantum of magnetic flux.

Freak waves Single waves which result from a local focusing of wave energy. They are of considerable danger to mariners because of their unexpected nature.

Geostrophic adjustment The process by which an unbalanced atmospheric flow field is modified to geostrophic equilibrium, generally by a mutual adjustment of the atmospheric wind and pressure fields depending on the initial horizontal scale of the disturbance.

Geostrophic equilibrium A state of motion of an inviscid fluid in which the horizontal Coriolis force exactly balances the horizontal pressure force at all points of the field.

Hydraulic jump A sudden turbulent rise in water level, such as often occurs at the foot of a spillway when the velocity of rapidly flowing water is instantaneously slowed.

Katabatic wind Most widely used in mountain meteorology to denote a downslope flow driven by cooling at the slope surface during periods of light larger-scale winds.

Lightning Lightning is a transient, high-current electric discharge.

Plasma Hot, ionized gas.

Shallow water Water depths less than or equal to one half of the wavelength of a wave.

Solitary wave Localized wave that propagates along one space direction only, with undeformed shape.

Soliton Large-amplitude pulse of permanent form whose shape and speed are not altered by collision with other solitary waves, the exact solution of a nonlinear equation.

Spillway A feature in a dam allowing excess water to pass without overtopping the dam.

Thermocline A layer in which the temperature decreases significantly (relative to the layers above and below) with depth.

Synoptic scale Used with respect to weather systems ranging in size from several hundred kilometers to several thousand kilometers.

Thunder The sound emitted by rapidly expanding gases along the channel of a lightning discharge.

Thunderstorm In general, a local storm, invariably produced by a cumulonimbus cloud and always accompanied by lightning and thunder, usually with strong gusts of wind, heavy rain, and sometimes with hail.

Tidal bore Tidal wave that propagates up a relatively shallow and sloping estuary or river, in a solitary wave form. The leading edge presents an abrupt rise in level, sometimes with continuous breaking and often immediately followed by several large undulations. The tidal bore is usually associated with high tidal range and a sharp narrowing and shoaling at the entrance. Also called pororoca (Brazilian) and mascaret (French).

Troposphere The portion of the atmosphere from the earth's surface to the tropopause, that is the lowest 10–20 km of the atmosphere.

Tsunami Long period ocean wave generated by an earthquake or a volcanic explosion.

Definition of the Subject

The interest in nonlinear physics has grown significantly over the last fifty years. Although numerous nonlinear processes had been previously identified the mathematic tools of nonlinear physics had not yet been developed. The available tools were linear, and nonlinearities were avoided or treated as perturbations of linear theories. The solitary water wave, experimentally discovered in 1834 by John Scott Russell, led to numerous discussions. This hump-shape localized wave that propagates along one space-direction with undeformed shape has spectacular stability properties. John Scott Russell carried out many experiments to obtain the properties of this wave. The theories which were based on linear approaches concluded that this kind of wave could not exist. The controversy was resolved by J. Boussinesq [5] and by Lord Rayleigh [64] who showed that if dissipation is neglected, the increase in local wave velocity associated with finite amplitude is balanced by the decrease associated with dispersion, leading to a wave of permanent form. A model equation describing the unidirectional propagation of long waves in water of relatively shallow depth with a localized solution representing a single hump as discovered by Russell was obtained by Korteweg and de Vries [42]. This equation has become very famous and is now known as the Korteweg–de Vries equation or KdV equation. These results were not considered very important when they were obtained. A remarkable numerical discovery was made by E. Fermi, J. Pasta and S. Ulam [18] as they studied the flow of incoherent energy in a solid modeled by a one-dimensional lattice of equal masses connected by nonlinear springs. The initial injected energy was not shared among all the degrees of freedom of the lattice, but returned almost entirely to the original excited mode. The explanation was given only ten years later by Zabusky and Kruskal [82] from numerical solutions of the KdV equation used to model in the continuum approximation a nonlinear atomic lattice with periodic boundary conditions. This led to the concept of solitons and ultimately to the development of integrable systems. The term soliton was chosen as it is a localized wave which propagates preserving its shape and velocity as a particle would propagate. A soliton is then a large-amplitude pulse of permanent form whose shape and speed are not altered by collision with other solitary waves, and it is the exact solution of a nonlinear equation. The mathematical features of solitons are often well developed in soliton literature since they are at the origin of very nice theoretical developments such as the powerful inverse scattering transform which solves a complex nonlinear equation through a series of linear steps. Nevertheless, the physics of solitons is very rich and it is a very actual research topic in numerous fields, for example in hydrodynamics, in optics, in electricity, in solid physics, in chemistry and in biology. Nonlinearity and dispersion are very common in macroscopic physics as well as in microscopic physics. Nonlinearity tends to localize the signals while dispersion spreads them. These two opposite effects sometimes compensate and the regime of solitons takes place. Real physical systems are only approximately described by the equations of the theory of solitons, but a remarkable feature of solitons is their very high stability relative to perturbations. The soliton concept is now firmly established. They are widely accepted as a structural basis for viewing and understanding the dynamic behavior of complex nonlinear systems.

Introduction

The first experimental observation of a solitary wave was made in August 1834 by a Scottish engineer named John Scott Russell (1808–1882). He was mounted on a horse along the Union Canal linking Edinburgh with Glasgow when he saw a rounded smooth well-defined heap detach itself from the prow of a boat brought to rest and continue its course without change of shape or diminution of speed. Scott–Russell reported his observation in the British Association Report [71] as follows:

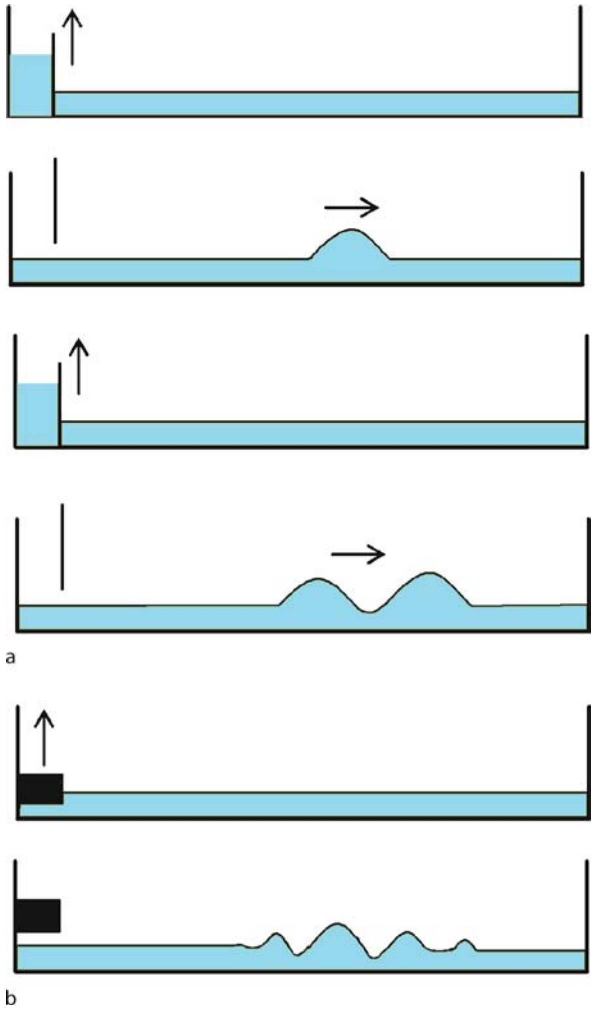
"I was observing the motion of a boat which was rapidly drawn along a narrow channel by a pair of horses, when the boat suddenly stopped—not so the mass of water in the channel which it had put in motion; it accumulated round the prow of the vessel in a state of violent agitation, then suddenly leaving it behind, rolled forward with great velocity, assuming the form of a large solitary elevation, a rounded, smooth and well-defined heap of water, which continued its course along the channel apparently without change of form or diminution of speed. I followed it on horseback, and overtook it still rolling on at a rate of some eight or nine miles an hour, preserving its original figure some thirty feet long and a foot to a foot and a half in height. Its height gradually diminished, and after a chase of one or two miles I lost it in the windings of the channel. Such, in the month of August 1834, was my first chance interview with that singular and beautiful phenomenon which I have called the Wave of Translation".

Russell wrote that this August day in 1834 was the happiest in his life. In July 1995, an international gathering of scientists witnessed a re-creation of the solitary wave observed by Russell on an aqueduct of the Union Canal. This aqueduct was named after this occasion *Scott Russell aqueduct*; the scientists were attending a conference on nonlinear waves in physics and biology at Heriot-Watt University (Edinburgh), near the canal.

Throughout his life Russell remained convinced that "his" wave that he initially called the "Wave of Translation" and later the "Great Solitary Wave" was of fundamental importance. He therefore carried out extensive experiments in wave-tanks and established the velocity formula for solitary waves:

$$V_S = \sqrt{g(d + A_S)} \tag{1}$$

where g is the acceleration due to gravity, d the undisturbed water depth and A_S the amplitude of the solitary wave. The "quasi-cycloidal" form of the wave was found to be independent of the way it was generated. Russell [69] described the induced movement of fluid particles: "By the transit of the wave the particles of the fluid are raised from their places, transferred forwards in the direction of the motion of the wave, and permanently deposited at rest in a new place at a considerable distance from their original position". He also deduced from his numerous experiments that two solitary waves can cross



Solitons: Historical and Physical Introduction, Figure 1
Schematic view of Scott Russell's experiments

each other "without change of any kind". Figure 1 shows a schematic view of his experiments in tanks, adapted from Remoissenet [65]. An initial elevation of water may induce one or two solitary waves depending on the relation between its height and length (Fig. 1a); the case where an initial depression does not evolve into solitary waves but leads to an oscillatory wave train of gradually increasing length and decreasing amplitude is shown in Fig. 1b.

In Sect. "Historical Discovery of Solitons", the historical discovery of solitons is presented. The physical concept of solitons and the associated applications are described in Sect. "Physical Properties of Solitons and Associated Applications". In Sect. "Mathematical Methods Suitable for the Study of Solitons", the mathematical methods suitable for the study of solitons are considered. Finally, Sect. "Future Directions" is devoted to future directions.

Historical Discovery of Solitons

After Russell had carried out his observation of the solitary wave in August 1834, he was put in charge by the Union Canal Company of determining the efficiency of canals for the transport of steam-driven barges. He worked on the resistance of boats towed through water of finite depth. A resistance proportional to the square of the velocity V_b of the boat was predicted by the theory at that time. Convinced of the imperfection of this theory, Russell performed numerous experiments in the summers of 1834 and 1835 [12]. Several boats were towed in canals of various depths at velocities ranging from 3 to 15 miles per hour. The resistance was measured by a dynamometer. Resistance curves such as the one depicted in Fig. 2 were obtained, with a resistance local maximum R_m for a boat velocity V_{cr} and a growing deviation from the theoretical curve for increasing values of boat velocity. The critical velocity V_{cr} was found to depend on the water depth. Russell noticed that this critical velocity was the same as the velocity of the solitary wave for the given water depth d, and gave a qualitative explanation for the diminution of flow resistance for increasing values of the boat velocity just above the critical velocity V_{cr}. For this description, he considered the variation of the shape of the water surface around the moving boat with the velocity. For velocities smaller than the critical value, the water level is raised around the prow where a wave of displacement is generated, leading to an inclination of the boat. The resulting effect is an augmentation of the section of immersion and of the corresponding flow resistance. When the velocity of the boat reaches the critical value, the wave of displacement has the velocity of a solitary wave and the vessel travels on this solitary wave. For velocities greater than the critical value, the boat stays on the wave summit leading to a smaller flow resistance. Russell [70] tried a quantitative explanation of this process, but this paper contained several errors. However, Russell was a very fine observer; he was far ahead of his time in considering the fundamental importance of solitary waves. He mentioned [70] that "a large or high wave had a greater velocity than a small one. When a small wave preceded a large one, the latter invariably overtook the other, and when the large wave was before the less, their mutual distance invariably became greater". He showed that the shape of solitary waves depends on their height, the width of the wave decreasing for increasing values of height. It is also fascinating that Russell had observed the collision properties of solitary waves [8]. Nevertheless, the observations of Russell induced numerous critical comments. Airy [2] wrote in his treatise "Tides and Waves": "We are not disposed to recognize this wave (discovered by Scott

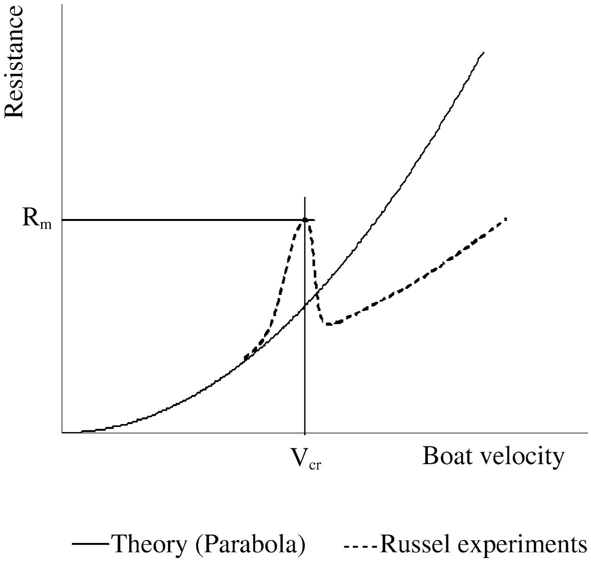
Russell) as deserving the epithets "great" or "primary", and we conceive that ever since it was known that the theory of shallow waves of great length was contained in the equation $\partial^2 X/\partial t^2 = gd\partial^2 X/\partial x^2$ the theory of the solitary wave has been perfectly well known". In the equation quoted by Airy, t is the time and x is the horizontal coordinate of a fluid particle. The wave velocity in shallow water at the first order of approximation, when the ratio H/d between the wave height H and the water depth may be neglected is $V_0 = \sqrt{gd}$, as found by Lagrange in 1786; this velocity differs from the formulation proposed by Russell for solitary waves (Eq. (1)). Airy mentioned further: "Some experiments were made by Mr. Russell on what he calls a negative wave. But (we know not why) he appears not to have been satisfied with these experiments and had omitted them in his abstract. All of the theorems of our IVth section, without exception, apply to these as well as to positive waves, the sign of the coefficient only being changed". Also, according to Airy [2] and Lamb [46], long waves could not propagate in a canal of rectangular section without changing their shape. The controversy arose because the dispersion is neglected by the nonlinear shallow water theory. Stokes [73] considered Russell results and tried to obtain them analytically; however, his linear or weakly nonlinear approach did not permit him to retrieve the results of Russell, which made him doubtful about them. In order to distinguish his "great wave" from other waves, Russell [71] introduced four orders of waves:

1. Waves of translation. These waves involve mass transfer. The solitary waves observed by Russell are included in this order.
2. Oscillatory waves. These are the waves which can be the most often observed; they do not involve mass transfer.
3. Capillary waves. The surface tension effects are important for those waves.
4. Corpuscular waves. Those waves are rapid successions of solitary waves.

Russell was most concerned with the first order, but he also carried out experiments with waves of the second and third order. The fourth order (corpuscular waves) suggested by Russell had been seriously criticized, and the manuscripts he submitted on this order were never published due to ignorance of mechanics principles.

The great difficulties encountered by Russell to prove the importance of his findings strongly disappointed him. Tired of discussions, he stopped his work on solitary waves and started to build large steam ships with great success. A detailed biography of Russell may be found in [16].

A French mathematician, Joseph Boussinesq, knew of the existence of Russell's observations, and also of detailed experiments performed by Bazin [3] in the long branch of the canal de Bourgogne close to Dijon (France), which confirmed Russell's observations. Boussinesq tried to obtain a solution of Euler's equations compatible with Russell's and Bazin's results. He developed the horizontal and vertical velocity components of fluid velocity in a rectangular channel in power of the distance from the bed. Including nonlinear terms which had been neglected by Lagrange, Boussinesq [5] obtained a solution with the properties of the solitary wave observed by Russell. In particular, the shape of the wave was found to be given by:



Solitons: Historical and Physical Introduction, Figure 2
Resistance as a function of towing velocity according to Russell

$$\eta = A_S \operatorname{sech}^2 \left[\sqrt{\frac{3A_S}{4d^3}} (x - V_S t) \right] \tag{2}$$

where η is the free surface displacement and $\operatorname{sech} x = 1/\cosh x$; the velocity of the wave V_S is given by Eq. (1). The article of Boussinesq [5] had been almost ignored in England, and five years after its publication Lord Rayleigh [64] independently obtained the solitary wave profile. Following Rayleigh's work and including the effects of surface tension, the Amsterdam professor of mathematics Diederik Johannes Korteweg and his doctoral student Gustav de Vries derived a model equation [42] which describes the unidirectional propagation of long waves in water of relatively shallow depth. This famous equation is now known as the Korteweg–de Vries equation or KdV equation, and it has the following form:

$$\frac{\partial \eta}{\partial t} + V_0 \frac{\partial \eta}{\partial x} + \frac{3}{2}\frac{V_0}{d}\eta\frac{\partial \eta}{\partial x} + \frac{1}{6}V_0 d^2 \frac{\partial^3 \eta}{\partial x^3} = 0\,. \tag{3}$$

Korteweg and de Vries showed that this nonlinear wave equation has a localized solution which represents a single hump of positive elevation corresponding to the solitary wave observed by Scott Russell. The KdV equation had been in fact formulated in 1877 by Boussinesq in an impressive paper [6], but this author did not use directly this formulation. Russell's experiments had found their theory and one could think that many scientists would rapidly extend the results of this theory. However, the KdV equation had a quiet life for many decades.

In the early 1950s, the physicists Enrico Fermi, John Pasta and Stan Ulam could use one of the first computers, the "Maniac" to work on systems without closed analytic solutions. In particular, they studied the way a crystal evolves towards the thermal equilibrium through the numerical simulation of the dynamics of a one-dimensional lattice consisting of N equal masses (atoms) connected by nonlinear springs. The problem is described by the Hamiltonian

$$H = \sum_{i=0}^{N-1} \frac{1}{2} p_i^2 + \sum_{i=0}^{N-1} \frac{1}{2} K (x_{i+1} - x_i)^2 + \frac{K\alpha}{3} \sum_{i=0}^{N-1} (x_{i+1} - x_i)^3 \quad (4)$$

where x_i is the atom i displacement, p_i the corresponding momentum, K the constant of the quadratic potential, and $\alpha (\ll 1)$ a coefficient of nonlinear interaction. The boundary condition $x_0 = x_N = 0$ is assumed. Considering a normal mode decomposition

$$A_k = \sqrt{\frac{2}{N}} \sum_{i=0}^{N-1} x_i \sin(ik\pi/N)\,, \quad (5)$$

the Hamiltonian (Eq. (4)) may be written in the following way

$$H = \frac{1}{2} \sum_k \left(\dot{A}_k^2 + \omega_k^2 A_k^2 \right) + \alpha \sum_{k,l,m} c_{klm} A_k A_l A_m \quad (6)$$

where the pulsations ω_k are given by $\omega_k^2 = 4K \sin^2(k\pi/2N)$, and c_{klm} are constants. When the masses have very small displacements from the equilibrium positions, the dynamics of the lattice may be described by a superposition of normal modes. It was supposed that if only one mode (the fundamental mode $k = 1$ in the circumstances) is excited in a crystal lattice, nonlinear interactions would lead to energy equipartition or thermal equilibrium. This was suggested by the results at the beginning of the calculations since the modes $2, 3, \ldots$ were successively excited. However, after 157 fundamental periods, almost all the energy returned to the fundamental mode. Furthermore, the energy returned almost periodically to the original excited mode leading to a near recurrence process, now known as the FPU paradox. Fermi et al. [18] did not get the expected result and the modeled crystal lattice did not approach energy equipartition. This remarkable discovery is at the origin of the comprehension of the concept of the soliton and of the developments of "numerical experiments". Fermi died just after this work; this had a rather inhibitory effect on the significance of this result and no paper was published after the preprint "Studies of nonlinear problems" [18]. The results were communicated to the scientific community by Ulam through several conferences. Complementary studies [20,39] confirmed that the introduction of nonlinearity in a system does not guarantee the equipartition of energy. In 1960, the KdV equation was rederived by Gardner and Morikawa who worked on collisionless hydromagnetic waves. These authors attracted the attention of Zabrusky and Kruskal on the KdV equation, and the FPU paradox was solved a few years later in terms of solitons [82]. Zabrusky and Kruskal considered the following motion equations corresponding to the Hamiltonian (Eq. (4))

$$\ddot{x}_i = K(x_{i+1} + x_{i-1} - 2x_i) + K\alpha \left[(x_{i+1} - x_i)^2 - (x_i - x_{i-1})^2 \right]. \quad (7)$$

Taking into account that the recurrence occurs before the excitation of high-order modes, these authors carried out an asymptotic analysis in the continuum approximation and obtained an equation including dispersive and nonlinear terms which correspond to the KdV equation. This equation, obtained in a totally different physical context as the one to explain the observations of Scott Russell, is at the origin of the explanation of the FPU paradox. As depicted in Fig. 3, the numerical experiments of Zabrusky and Kruskal showed that the initial sinusoidal condition evolves into steep fronts and then into a finite number of short pulses which are solitons. These solitons travel around the lattice with velocities depending on their amplitude; they collide preserving their individual shapes and velocities with only a small change in their phases. As time increases, there is an instant at which the solitons collide at the same point, and the initial state comes close to recurrence. The recurrence period calculated by Zabrusky and Kruskal closely approximates the actual FPU recurrence period, showing that the KdV equation is a suitable approximation of the FPU system. The system had to be considered as totally nonlinear to be solved, and the linear normal modes of the system could not be considered. The pulse-like waves were called solitons by Zabrusky and

Kruskal to indicate the remarkable quasi-particle properties of these very stable solitary waves. They were at first called solitrons to introduce them into the family of particle names such as electron and neutron, but the name solitron was a trade mark, and was therefore not suitable. The concept of solitons has spread over numerous branches of physics, such as optical physics, biological physics, astronomy, particle physics, condensed matter, fluid dynamics, ferromagnetism. The numerical experiments of Zabrusky and Kruskal led to the development of integrable systems. Taniuti and Wei [76] and Su and Gardner [74] have shown that a large class of nonlinear evolution equations may be reduced to consideration of the KdV equation which may be regarded as a very important canonical form. A famous method, the so-called Inverse Scattering Transform (IST) was proposed by Gardner et al. [24] to integrate the KdV equation. This procedure may be considered as the nonlinear analogue of the Fourier transform method suitable to linear dispersive systems.

Physical Properties of Solitons and Associated Applications

Properties of Solitons

Let us consider the KdV equation (Eq. (3)). Introducing the variable $X = x - V_0 t$, this equation may be written in the following way

$$\frac{1}{V_0}\frac{\partial \eta}{\partial t} + \frac{3}{2d}\eta\frac{\partial \eta}{\partial X} + \frac{d^2}{6}\frac{\partial^3 \eta}{\partial X^3} = 0\,. \tag{8}$$

Using the dimensionless variables $\phi = \eta/d$, $\xi = X/X_0$ and $\tau = t/t_0$ where X_0 and t_0 are respectively a typical length and time, the KdV equation may be formulated in its standard form:

$$\frac{\partial \phi}{\partial \tau} + 6\phi\frac{\partial \phi}{\partial \xi} + \frac{\partial^3 \phi}{\partial \xi^3} = 0\,. \tag{9}$$

This equation has many solutions, as all nonlinear equations. Among these solutions, there are the spatially localized solutions:

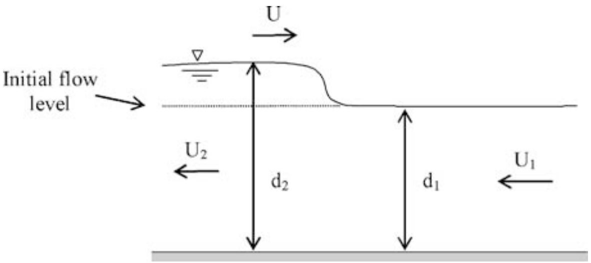
$$\phi = A\,\mathrm{sech}^2\left[\sqrt{\frac{A}{2}}(\xi - 2A\tau)\right], \tag{10}$$

where A is a positive constant. These solutions quantitatively correspond to the observations of Scott Russell. In particular, the width of the soliton decreases for increasing values of its amplitude, as depicted in Fig. 4. In dimensional variables and in a fixed referential, the corresponding solution is given by Eq. (2).

The KdV equation appears widely in physics, each time that waves propagate in a weakly nonlinear and weakly dispersive medium. The nonlinear term $\phi(\partial\phi/\partial\xi)$ in this equation causes the steepness of the wave form. In a dispersive medium, the Fourier components of a pulse propagate at different velocities, inducing a spreading of the pulse. The dispersive term $\partial^3\phi/\partial\xi^3$in the KdV equation makes the wave form spread. The soliton solution of the KdV equation results from the balance of nonlinearity and dispersion. This balance is generally very stable, which explains the numerous applications of the theory of solitons, even if the real physical situations (where friction and defects take place) are only approximately described by the soliton equations, and in particular by the KdV equation. It would be strictly speaking more appropriate to use the terminology quasi-soliton in physics; however, bearing in mind that the word soliton has a quite ideal connotation in the context of systems with exact solutions, we will use the word soliton. The conservation of the shape and of the velocity of the soliton after a collision is a manifestation of stability. The high stability of solitons relative to perturbations, combined with the fact that they can spontaneously emerge in a physical system in which energy is supplied, lead to numerous applications of solitons in macroscopic and microscopic physics. Nevertheless, a soliton may sometimes vanish. For example, this is the case when such a wave propagates in a media where the water depth decreases during the wave propagation. The dispersive effect progressively decreases when the nonlinear effect increases, leading to the wave breaking as waves on a beach. The vanishing of a soliton may also result from energy dissipation. Marin et al. [52] have shown that sand ripples may form when solitons propagate in shallow water over a sandy bed, and that a strong interaction between the free surface and the bed occurs. This interaction leads to a decrease of the soliton amplitude, which may result under certain circumstances in the disappearance of the soliton. Let us now consider some of the most typical soliton applications.

Solitons in Fluid Mechanics

In the hydrodynamic field, a very nice case where solitons take place is the tidal bore, also called hydraulic jump in translation, and known as the mascaret in France. A tidal bore is a positive wave of translation which can occur in a river with a gently slopping bottom and a broad funnel-shaped estuary, where a difference of more than six meters between high and low water takes place [50]. The tidal bore appears as a single wave or a series of waves which propagate upstream. At a given instant, it is localized at the upstream extremity of the flood tide propagation in the inter-tidal zone. The flow direction is towards the sea before the tidal bore arrival, and may be in the opposite direction after its occurrence. Such bores are distributed widely throughout the world. The most powerful can be seen in the Amazon river in South America, where it is called pororoca, which means gigantic noise. An approximately 5 m-high wave propagates with a velocity of about 30 m/s, and surfers take advantage of this exceptional wave to organize competitions. In England, bores may be contemplated on several rivers, the most famous occurring in the Severn river, near Bristol. In France, bores take place mainly in the Mont Saint-Michel bay, in the Gironde, Dordogne and Garonne rivers. The mascaret of the Seine river almost disappeared between 1960 and 1970 because of the construction of dikes and the dredging works which had been carried out in order for large boats to reach the city of Rouen. Increasing the water depth induces a decrease of the nonlinear effects which become insufficient to balance the dispersion. In Canada, several bores are observed in Fundy bay. In Asia, an important bore occurs in the Qiantang river, while the one in the river Pungue in Africa can propagate upstream over more than 80 km. Two types of bores may be observed: the breaking bore and the undulated bore, depending on the value of the Froude number F_r defined by $F_r = (U_1 + U)/\sqrt{gd_1}$, where U_1 is the flow velocity at the depth d_1 before the passage of the bore and U the bore velocity (Fig. 5). In Fig. 5, d_2 depicts the water depth after the passage of the bore and U_2 the flow velocity at the depth d_2. For a value of F_r lower than about 1.5, the bore is undulated, and for a value of F_r greater than 1.5, the breaking bore occurs. Most of the bores are undulated bores. The tidal bore is a very important turbulent phenomenon for the inter-tidal zone of a river, inducing a significant mixing of waters and complex motions of sediment on the river bed [14]. River bores have been known for many centuries but only qualitative observations were carried out. Quantitative measurements came much later, mainly because solitons are inherently nonlinear when only linear processes were considered.



Solitons: Historical and Physical Introduction, Figure 5
Sketch of the propagation of a positive wave of translation

Long waves such as tsunamis often behave like solitary waves [48]. In particular, the run-up and shoreward inundation are often simulated using solitary waves [49]. The tsunamis may be described by the KdV equation. The theory of very long shallow water waves is valid since the tsunamis have a wavelength which is generally greater than 100 km and they propagate in oceans whose mean depth is about 4000 m. Their propagation velocity is greater than $V_0 = \sqrt{gd}$, that is greater than approximately 700 km/h. When they approach a coast, their velocity decreases and their height increases to satisfy the equation of energy conservation, and they finally break inducing often very significant damages on the shore. Most tsunamis have a seismic origin, such as the dramatic one which occurred in the Indian Ocean on 26 December 2004 and which led to the death of more than 220 000 people. These solitons may also result from a quick arrival in the sea of volcanic products, through a similar process to that in Scott Russell's experiments depicted in Fig. 1. This was the case for the tsunami generated in 1883 by the eruption of Krakatau in Indonesia, when approximately 36 000 people died. The inundation phase for a tsunami highly depends on the bottom bathymetry. The breaking can be progressive and structural damages are mainly caused by inundation [13]. The breaking can also be explosive and induce the formation of a plunging jet. When the breaking takes place in very shallow water, the tsunami amplitude becomes so high that an undulation appears on the long wave, which develops into a progressive bore [10]. This turbulent front is of the same type as the wave which occurs when a dam breaks, and the water can rise very rapidly, typically from 0 to 3 meters in 1.5 minutes. The event of December 2004 has shown that the available models are not able to predict accurately the wave run-up heights under severe conditions.

Helal and El-Eissa [37] presented the connection between shallow water waves and the KdV equation. More recently, Mei and Li [55] considered the propagation of long waves over a randomly rough seabed. These authors have shown analytically and numerically that, assuming a randomness height to mean depth ratio comparable to the one of mean depth to the characteristic wavelength, disorder causes diffusion, leading to spatial attenuation of the wave amplitude. Mei and Li [55] proposed a modified KdV equation which includes terms representing the effects of disorder on amplitude attenuation. After a propagation over a region of finite length, the transmitted wave is a pulse which disintegrates into several small solitons of vanishing energy.

Hydrodynamic solitons may also be observed in deep water. Stokes showed in 1847 through the use of a small amplitude expansion of a sinusoidal wave, that periodic waves of finite amplitude are possible in deep water. The Stokes waves are unstable to infinitesimal modulation perturbations [4]. Zakharov and Shabat [83] were the first to show that an initial wave packet may evolve into a number of envelope solitons and a dispersive tail, the envelope solitons consisting of a carrier wave modulated by an envelope signal. This was experimentally verified by Yuen and Lake [81], by carrying out detailed experiments in deep water in a wave tank. The stability properties of envelope solitons were also considered. The freak waves, also called rogue waves, extreme or giant waves, may also have soliton-like shape. These waves appear surprisingly in the sea ("wave from nowhere") in deep or shallow water, and can cause severe damages to ships and fixed ocean structures. They are characterized by their brief occurrence in space and time, resulting from a local focusing of wave energy [19]. The main features of their physical processes may be obtained performing numerical simulations in the framework of classical nonlinear evolution equations, such as the KdV equation [41].

Oceanographers have also observed internal solitary waves in many regions around the world's oceans [61]. Most of the observed solitons propagate at the interface between the thermocline and the deep sea [56]. They are mainly excited by tidal flows over bottom topography [25], and they contribute to significant vertical mixing. Brandt et al. [7] developed a rotationless Boussinesq-like model for the generation and propagation of internal waves; the results of the simulations are in good agreement with large solitary waves recorded with airborne Radar images. Michallet and Barthélemy [56] carried out experiments in a 3-m-long flume to study interfacial long-waves in a two-immiscible-fluid system involving water and petrol. The comparison between the experiments and nonlinear theories shows that the KdV solitary waves match the experiments for small amplitude waves for all layer thickness ratios. When the crest is close to the critical level, that is approximately located at mid-depth, the large amplitude waves are well predicted by a modified KdV equation including both quadratic and cubic nonlinear terms (KdV-mKdV equation). However, only very few laboratory or field measurements of internal solitary waves are available, due to the prohibitive cost of obtaining precise measurements in the field and to the difficulty of generating and measuring these waves in the laboratory.

Blood pressure pulses may be considered as solitons [63]. There is a balance between the nonlinearity due to the blood flow and the dispersion connected to the elasticity of the artery. Previous studies [32,33,80] have shown that the dynamics of weakly nonlinear pressure waves in a thin nonlinear elastic tube filled with an incompressible fluid may be governed by the KdV equation. A Boussinesq-like equation was obtained by Paquerot and Remoissenet [62] to describe the blood pressure propagation in large arteries, in the limit of an ideal fluid and for slowly varying arterial parameters.

Several methods have been tested to generate hydrodynamic solitons in a flume; the method used by Scott Russell has been described in Sect. "Introduction" (Fig. 1). Hammack and Segur [29] showed experimentally and theoretically that from any net positive volume of water above the still water level, at least one solitary wave will emerge followed by a train of dispersive waves. Maxworthy [54] and Weidman and Maxworthy [79] pushed the liquid in the horizontal direction by a single displacement of a piston. The generation of solitary waves using a piston-type wave maker has been studied in detail by Goring [26]. Guizien and Barthélemy [28] have proposed an experimental procedure to generate solitary waves in a flume using a piston type wave maker from Rayleigh's (1876) solitary wave solution. The advantage of this method is that solitary waves are rapidly established with very little loss of amplitude in the initial stage of the propagation of the solitary waves. The generation of solitons using a wave flume in resonant mode, without an absorbing beach, has been considered by Marin et al. [52]. Surface waves are produced in shallow water by an oscillating paddle at one end of the flume; a near-perfect reflection takes place at the other end. The frequency of the oscillating paddle was chosen close to the resonant frequency of the mode whose wavelength is equal to the flume length. For small values of the amplitude of displacement of the oscillating paddle, only standing harmonic waves are generated in the flume. For values of this amplitude greater than a critical value, pulses propagating from one end of the channel to the other end are excited on the background of the standing harmonic wave. From one to four pulses propagating in each direction of the flume could be generated over the time period of the flow, depending on the frequency and the amplitude of horizontal displacement of the oscillating paddle. These pulses were identified as solitons (one pulse) and bound states of solitons (several pulses). The generation of solitons in the flume results from the excitation of high harmonics. The spatiotemporal properties of solitons generated in this way were studied in detail by Ezersky et al. [17]. Space-time diagrams have been constructed to highlight the spatiotemporal dynamics of nonlinear fields for two solitons colliding in the resonator. Period doublings and the multistability of the nonlinear waves, i. e. the occurrence of different regimes for the same values of the control parameters but under different initial conditions, have been shown. It is important to keep in mind that the solitary waves correspond to the limit of cnoidal waves of period tending to infinity. The velocity of cnoidal waves V_{cn} is known to depend on the so-called elliptic parameter m and is given by the formula [11]

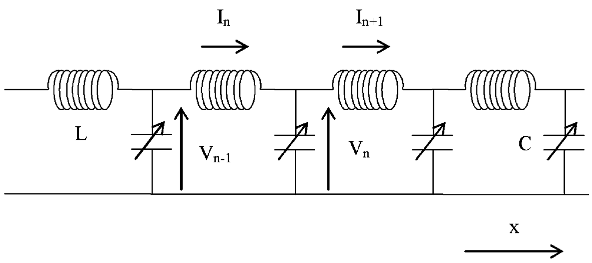
$$V_{\mathrm{cn}} = \left[1 - \frac{A_{\mathrm{S}}}{2d} + \frac{A_{\mathrm{S}}}{md}\left(1 - \frac{3E(m)}{2K(m)}\right)\right]\sqrt{gd} \qquad (11)$$

where $K(m)$ and $E(m)$ are complete elliptic functions of the first and second kind. The parameter m, which depends on the wave amplitude to width ratio, is responsible for the shape of the wave with $m = 0$ corresponding to the harmonic wave, and $m = 1$ to the soliton. Strictly speaking, the waves generated in a flume used in resonant mode are not exactly solitons, but cnoidal waves with an elliptic parameter very close to 1; the value of this parameter was found to be 0.9996 for the tests carried out by Ezersky et al. [17]. The shapes of pulses are almost indistinguishable for $m = 1$ and $m = 0.9996$, but the pulse repetition rates differ appreciably, the period tending to infinity as $m \to 1$.

Atmospheric solitons also exist, such as the Morning Glory Cloud of the Gulf of Carpentaria in northern Australia, which can be seen as a spectacular propagating roll cloud. Atmospheric solitons are horizontally propagating nonlinear internal gravity waves that can travel over large distances with minimal change in form [68]. The solitary waves that have been observed in the atmosphere can be divided into two classes: those that propagate in a fairly shallow stratified layer near the ground and those that occupy the entire troposphere. The generation mechanisms appear to be quite different for these two classes of waves. The waves that occupy the lower part of the troposphere mainly involve a gravity current such as a thunderstorm outflow, a katabatic wind, a sea breeze front, or a downslope windstorm, interacting with a low-level stable layer. The motion of the gravity current produces perturbations that are trapped in the low-level stable layer and eventually evolve over time into a series of solitary waves. For the tropospheric scale waves, they are very probably generated by synoptic scale features such as large-scale convective systems and geostrophic adjustments. For the two types of atmospheric solitons, there must exist some feature in the atmosphere that serves to prevent the wave energy from propagating away in the vertical direction. These trapping mechanisms are either deep layers of the atmosphere with very low values of the buoyancy frequency, or critical layers. The KdV equation, eventually enhanced with higher-order nonlinearity, gives a reasonable agreement with the observations [68].

Solitons in Nonlinear Transmission Lines

In another area of physics, transmission lines with nonlinear elements are found to propagate in a soliton mode. Nonlinear electrical transmission lines are simple experimental devices to observe and consider quantitatively the propagation and properties of solitons. The propagation of these waves is used for picosecond impulse generation and broadband millimeter-wave frequency multiplication [66]. Let us consider the elementary LC network depicted in Fig. 6, with linear inductors L and nonlinear capacitors C. The differential capacitance $C(V_n)$ is supposed to depend nonlinearly on the voltage across the nth



Solitons: Historical and Physical Introduction, Figure 6
Elementary circuit of an electrical network with linear inductance's *L* and nonlinear capacitance's *C*

capacitor V_n:

$$C(V_n) = \frac{\mathrm{d}Q_n(V_n)}{\mathrm{d}V_n} \tag{12}$$

where $Q_n(V_n)$ is the charge stored in the nth capacitor. Following Kirchhoff's law, we have:

$$V_{n-1} - V_n = \frac{\mathrm{d}\phi_n}{\mathrm{d}t}\,, \quad I_n - I_{n+1} = \frac{\mathrm{d}Q_n}{\mathrm{d}t} \tag{13}$$

where the magnetic flux ϕ_n is related to the current I_n by the relation: $\phi_n = LI_n$. Using Eqs. (12) and (13), it is easy to obtain:

$$\frac{\mathrm{d}^2 Q_n}{\mathrm{d}t^2} = \frac{1}{L}(V_{n+1} + V_{n-1} - 2V_n)\,, \quad n = 1, 2, \ldots \tag{14}$$

Assuming the following capacitance-voltage relation,

$$C(V_n) = C_0(1 - 2aV_n) \tag{15}$$

where a is a small nonlinear coefficient, we find:

$$\begin{aligned} &LC_0\frac{\mathrm{d}^2 V_n}{\mathrm{d}t^2} - LC_0 a\frac{\mathrm{d}^2 V_n^2}{\mathrm{d}t^2} \\ &\qquad = (V_{n+1} + V_{n-1} - 2V_n)\,, \quad n = 1, 2, \ldots \end{aligned} \tag{16}$$

The system (Eq. 16) of nonlinear equations cannot be solved analytically. The continuum limit is used to get approximate solutions; setting the position $x = n\delta$ where δ is a hypothetical cellule length, we get

$$\frac{\partial^2 V}{\partial t^2} - \frac{\delta^2}{LC_0}\frac{\partial^2 V}{\partial x^2} = \frac{\delta^4}{12LC_0}\frac{\partial V}{\partial x^4} + a\frac{\partial^2 V^2}{\partial t^2}\,. \tag{17}$$

This weakly dispersive and nonlinear wave equation describes waves that can travel both to the left and to the right; the dispersive nature is due to the discreteness of the electrical network. A localized wave solution of the Eq. (17) that does not change its shape as it propagates with constant velocity v may be found [65]:

$$V = \frac{3(v^2 - v_0^2)}{2av^2}\operatorname{sech}^2\left(\frac{\sqrt{3(v^2 - v_0^2)}}{v_0}\left(n - \frac{v}{\delta}t\right)\right) \tag{18}$$

where $v_0 = \delta/\sqrt{LC}$. This solitary wave solution represents a pulse with amplitude

$$V_m = \frac{3}{2a}\frac{v^2 - v_0^2}{v^2} \tag{19}$$

which depends on the velocity v. The width L_w at half height of this pulse is given by

$$L_w = 1.76\frac{v_0}{\sqrt{3(v^2 - v_0^2)}}\,. \tag{20}$$

The waveforms of this solitary wave and of the KdV soliton are similar, and the width L_w depends on the amplitude V_m:

$$V_m L_w^2 = C^t \tag{21}$$

where C^t is a constant.

Solitons in Plasmas

Solitons may propagate in plasmas; this has received much attention because of a possible relevance to final state configurations in fusion devices. The combination of dispersion and nonlinearity in plasmas may be described by the KdV equation. A direct analogy between the equations for shallow water and those for plasmas has been mentioned by Gardner and Morikawa [23]. However, the KdV equation is not always adapted to the excitations which can be generated in plasmas by electromagnetic waves, since wave packets are often produced instead of pulses characterizing the solutions of the KdV equation. Another type of soliton equation is then more suitable, the nonlinear Schrödinger equation (NLS); this second class of soliton equation will be considered in Subsect. "Solitons in Optical Fibers".

Solitons in a Chain of Pendulums

Hydrodynamic solitons, solitons in nonlinear transmission lines are nontopological solitons, because the system returns to its initial state after the passage of the wave. There is also another type of soliton, the kink solitons which are topological solitons, since the structure of the system is sometimes modified after the passage of the wave. A mechanical system consisting of a chain of pendulums, each pendulum being elastically connected to its neighbors by springs, is a typical example for which topological solitons can merge. It is easy to show that this mechanical system may be described by the following equation:

$$\frac{\partial^2\theta}{\partial t^2} - c_0^2\frac{\partial^2\theta}{\partial x^2} + \omega_0^2 \sin\theta = 0 \tag{22}$$

where θ is the angle of rotation of the pendulums, x is the axis along which the pendulums are distributed, $c_0^2 = l_1^2\beta/I_i$, l_1 being the distance between two pendulums, β the torque constant of a section of spring between two pendulums, I_i the moment of inertia of a single pendulum of mass m and length l_2, and $\omega_0^2 = mgl_2/I_i$. The first term in Eq. (22) represents the inertial effects of the pendulums, the second term corresponds to the restoring torque due to the coupling between pendulums, and the third term represents the gravitational torque. The Eq. (22) is called the Sine–Gordon (SG) equation [47]; it can be totally integrated and admits exact solitons solutions. It has become a very famous equation containing dispersion and nonlinearity which is used to model various phenomena in physics. It constitutes the third class of nonlinear equation leading to solitons.

Fluxons in a Josephson Tunnel Junction

Solitons arise also in a Josephson tunnel junction, which is a junction between two superconductors. These junctions are very attractive for information processing and storage [78]. The physical quantity of interest in the long Josephson junction is a quantum of magnetic flux, or a fluxon, which has a soliton behavior. The relevant nonlinear equation which describes the physical processes is the Sine–Gordon equation. This equation is particularly suitable in solid physics.

Solitons in Optical Fibers

One of the fundamental applications of solitons concerns optical fibers. In optical fiber communication using linear pulses, dispersion and losses in the fiber limit the information capacity which can be transported and the distance of transmission. Hasegawa and Tappert [31] first proposed to balance the dispersive effect by nonlinearity using soliton-based communications. The Kerr effect, in other words the nonlinear change of the refractive index of the fiber material, is used and an initial optical pulse may form a nonlinear stable pulse, an optical soliton, which is in fact an envelope soliton. Hasegawa and Tappert proposed the previously mentioned nonlinear Schrödinger equation for the description of solitons propagating in optical fibers. The first observations of these solitons were made in 1980 by Mollenauer, Stolen, and Gordon [58]. In real media, the light intensity of the soliton decreases due to losses in the fiber, and suitable reshaping of the pulse is required. Numerous theoretical and experimental studies on nonlinear guided waves have been carried out, because of their wide range of applications [30,43]. Inserting an optical fiber in a laser cavity, a "soliton laser" may be obtained, a femtosecond laser which is now in use. A real revolution in international communications is taking place at present, based on optical soliton technology. It is anecdotal that a fiber-optic cable linking Edinburgh and Glasgow now runs beneath the path from which John Scott Russell made his initial observations, and along the aqueduct which now bears his name.

The NLS equation may be obtained from the Sine–Gordon equation. Previously considered systems as water waves on the free surface or chains of pendulums have also weak amplitude solutions, plane waves which have the form:

$$\theta = \psi\, e^{i(qx-\omega t)} + \text{c.c.} \tag{23}$$

where ψ is the wave amplitude, q is the wave number, ω is the pulsation and c.c. denotes the complex conjugate of a complex number. When the wave amplitude is sufficiently increased for the nonlinearity to take place, modulation can spontaneously arise because harmonics are generated by the nonlinearity. The initial wave may split in waves packets whose properties correspond to the ones of solitons. These solitons consisting of a carrier wave which is modulated by an envelope signal are called envelope solitons. It can be shown [63] that the evolution of the envelope ψ is described by the NLS equation:

$$i\frac{\partial\psi}{\partial t} + P\frac{\partial^2\psi}{\partial x^2} + Q\,|\psi|^2\,\psi = 0 \tag{24}$$

where P and Q are coefficients which depend on the physical problem, as the significance of the variables t and x. The NLS equation is formally similar to the Schrödinger equation of quantum mechanics:

$$i\hbar\frac{\partial\psi}{\partial t} + \frac{\hbar^2}{2m}\frac{\partial^2\psi}{\partial x^2} - U\psi = 0\,. \tag{25}$$

The potential U in Eq. (25) is proportional to the absolute square of the wave envelope ψ, m is the mass of the quasi-particle and $\hbar = h/2\pi$ where h is the Planck constant. The potential represents the self-trapping of the wave energy.

Solitons in Solid Physics

Solitons are involved in the atomic structure of matter. At the beginning of the twentieth century, a central question in solid state physics was how a plastic deformation of a metal takes place in the corresponding crystal lattice. This problem induced numerous discussions, and it was suggested that if one atom in the lattice is pulled away, a neighbor atom follows the one which had been moved, jumping into the new hole, that is the new free lattice space. Then, a dislocation runs through the crystal. This proposition was improved in 1939 by Frenkel and Kontorova [22] who developed a model where not only each atom moves alone over one lattice distance, but also many atoms form a dislocation line generating a wave of translation. The process of traveling of the dislocation line through the crystal was assumed to occur without losses of energy. This is equivalent to Russell's solitary wave of translation which travels over long distance without change of form and velocity. This led Frenkel and Kontorova to make an analogy between the dislocation line and the soliton, and they obtained the one-soliton solution of the Sine–Gordon equation.

The solitons permit us to interpret properties of dielectric materials. In other respects, magnetic materials are interesting examples to experimentally verify in a very accurate way the theory of solitons at the atomic scale [57]. The concept of soliton in polymer physics constitutes a very nice case of an interdisciplinary approach. Their occurrence was suggested in 1988 by theoretician physicists [34]. Many studies have since then been carried out, in chemistry and experimental physics. Alan J. Heeger, Alan G. MacDiarmid and Hideki Shirakawa received the Nobel prize in chemistry in October 2000 for their works on the electric conduction of conductive plastics which is performed by solitons.

Solitons in Biology

Interest in the physical modeling of biological processes has grown significantly since the beginning of the 1990s. Nonlinear localization phenomena have been recently shown in systems very close to biological systems [15]. The notion of the soliton is now used to explain the dynamics of biological macromolecules such as proteins and the molecule ADN; an approach to the dynamics of the molecule ADN can be obtained using the envelope solitons solution of the NLS equation [63]. Intense researches are presently being carried out on this subject. The great size of biological molecules allows collective behaviors of atom groups, which are with nonlinearity important components for the existence of solitons.

Mathematical Methods Suitable for the Study of Solitons

Solitons may appear in many fields, such as fluid mechanics, solid state physics, plasma physics, optical fibers and biology, as shown in Sect. "Physical Properties of Solitons and Associated Applications". The description of these physical systems often leads to dispersive and nonlinear equations which are not presently solvable. It is then important to refer to the great classes of soliton equations, which are idealized models for numerous systems. These great classes of soliton equations correspond to the Korteweg–de Vries equation, known as the KdV equation (Eq. (9)), the Sine–Gordon equation (SG; Eq. (22)), and the nonlinear Schrödinger equation (NLS, Eq. (24)). These three famous equations can be totally integrated. They are not completely dissociated. For instance, it is possible to obtain the NLS equation from the SG equation and from the KdV equation. The soliton solutions represent only a first approximation of the physical properties of real systems. Dissipation or a weak spatial or temporal variation of the physical parameters in real physical systems are examples of phenomena which are very common and which are not taken into account in the soliton equations. The modeling has to be adapted to the physical system and to the excitation conditions of this system. In the case of plasmas, the KdV equation is more suitable for a description of the system when intense pulses excite it, and the NLS equation is more adapted for sinusoidal perturbations.

There are two broad theoretical approaches available to obtain the solutions of the great classes of soliton equations, the analytic and the algebraic methods. Analytic approaches include the powerful inverse scattering transform (IST) [24] and the remarkable Hirota method [38]. One-soliton solutions or multi-soliton solutions can be obtained. Moreover, the IST method can predict the number of solitons that can emerge from an initial disturbance applied to a physical system [59]. This method shows how the solitons have a role in nonlinear normal modes as the Fourier modes for a linear equation [44]. There are also the Bäcklund transformation method [67], the direct linearizing transform method [1], the Painlevé analysis [45], and the method of position-like solutions [40]. The algebraic methods involve the Lie group theoretic method [60], the direct algebraic method [53], and the tangent hyperbolic method [51].

The theoretical methods cannot always be used since they need some conditions to make them applicable. Numerical methods can be applied [36]. Zabusky and Kruskal [82] were the pioneers in studying in 1965 the KdV equation numerically, by using the leapfrog method as an explicit finite difference scheme. Many methods have since then been used: a split-step Fourier method [77], the hopscotch method [27], a pseudo-spectral method [21], spectral methods (the Galerkin and Chebyshev methods) [35,72], the finite element method [75], and Fourier collocation calculations [9].

Future Directions

Solitons may occur in the macroscopic and microscopic scales of physics. This results from their very general existence conditions, the coexistence of dispersion and nonlinearity. The concept of solitons is not restricted to a specific field of physics, and the investigation of solitons remains a very active research area. We have previously mentioned (Sect. "Physical Properties of Solitons and Associated Applications") that one important application of solitons concerns optic fibers. The propagation of optical solitons through nonlinear fibers has been extensively studied; however, in real media, the dynamics of these solitons and the conditions for their generation are significantly affected by various inhomogeneities in the media. The problem of nonlinear wave propagation in the form of solitons in inhomogeneous optical fiber media is actually not well understood, despite the wide range of applications [30]. The investigation of nonlinear processes in coupled optical waveguides is another research direction for the future design of optical computers and sensor elements. Recent advances have shown that solitons have a great potential for the improvement of optical systems which demand fast and reliable data transfer. In the hydrodynamic field, the tsunamis often behave like solitary waves. The dramatic tsunami which occurred in the Indian Ocean on 26 December 2004 has clearly shown that the actual numerical models do not accurately predict the water propagation on the coastal plains. An important direction for future research is the (3D) three-dimensional simulation of tsunami breaking along a coast. The 3D simulation of the interaction of a tsunami with different beach profiles, with and without obstacles has also to be considered. This will permit the design of protecting devices and the setting up of security zones. In biology, nonlinear localization phenomena have been proved in model systems close to biological systems, but the challenge is open for biological molecules. Other important application fields for solitons concern magneto-electronics and secure communications. The formation of spatio-temporal patterns on perturbations of soliton systems are important problems to be studied in the years to come. The existence of instabilities in the solitary wave solutions of the great classes of soliton equations have to be tackled. Nonlinear excitations in systems whose spatial dimension is greater than one raise many questions. Among these questions, there are the problems of the possible stable structures, their collision properties and the effect of external forces. New applications will certainly emerge from these studies.

Article Outline

Glossary

Solitary wave A localized structure which travels with constant speed and shape in otherwise homogeneous medium.

Soliton In the classical nomenclature, a soliton is a nonlinear spatially or temporally localized entity (solitary wave, impulse, wave packet, kink, etc.) of permanent form that retains its identity and shape in interactions with other similar entities. Also frequently used term for solutions of the relevant nonlinear partial differential equations approximately describing such physical entities.

Soliton (colloquially as well as in certain domains) Used for denoting any long-lived localized structures (e. g. solitary waves, self-trapped optical beams, localized vortices) which exhibit low energy radiation and approximately keep their shape.

Soliton solution A solution, usually in closed form, of the nonlinear partial differential equations that exhibit properties of a single soliton. A multi-soliton solution exhibits properties and collective behavior of groups of solitons.

Elastic interaction A generalization of the concept of elastic collisions of ideal mechanical bodies: interaction of localized entities in which the dynamically significant properties of the counterparts such as the total energy, linear and angular momentum, and topological charge or spin are conserved. For low-dimensional and scalar solitons denotes the case in which all the properties of interacting solitons are completely restored after interaction.

Inelastic interaction Interaction of soliton-like structures that modifies one or more dynamically significant properties of the counterparts.

Phase shift A change of the position of a soliton owing to interactions with other solitons compared to the location in which it would be in the absence of other solitons.

Resonant interaction A specific form of soliton interactions leading to the fusion of two or more solitons into a new soliton. Generally associated with an infinite phase shift of the counterparts.

Definition of the Subject

The concept of solitons reflects one of the most important developments in science of the 20th century: the nonlinear description of the world. It is customary to start an introduction to solitons by recalling that it is not easy to give a comprehensive and precise definition of a soliton. Frequently, a soliton is explained as a spatially localized (solitary) wave with spectacular stability properties. Although the combination of simultaneously being a localized structure propagating while mostly keeping its shape as waves do, and surviving for a long time in realistic (that is, nonlinear) conditions, already is a fascinating property in itself, yet another key quality defines whether a particular entity is a soliton. The distinction is made based on the way in which two or more of these objects interact with each other.

The classical nomenclature associates the term soliton with (i) nonlinear and (ii) localized entities, which (iii) have a permanent form and (iv) retain their identity in interactions with other entities from the same class (e. g. Drazin and Johnson [37]; also the entry ▶ Solitons and Compactons). The fundamental property of a soliton is thus to retain its identity in nonlinear interactions. In low-dimensional systems (understood here as environments admitting solitons in one spatial dimension and line solitons in two dimensions), a soliton's amplitude, shape, and velocity are restored after each interaction, whereas in more complex systems this request embraces all dynamically significant qualities. In other words, a structure is a soliton if and only if its *interactions* are *fully elastic*. Thus, the interaction of solitons is always an intrinsic topic whenever solitons are considered.

In the nonlinear world, *linear superposition* does not hold and *nonlinear interaction* takes place. Mathematically, classes of entities are called linear, whenever any linear combination of entities belongs to the same class. Among structures corresponding to the solutions of certain equations, exclusively those that satisfy linear equations are denoted as linear ones. Any linear combination of solutions of a linear equation also solves this equation. The principle of linear superposition is that the resultant structure is simply the sum of the parties and it implies that the individual linear wave shapes are perfectly restored after meeting with each other.

The property of elasticity of soliton interactions has a fundamentally different nature, because, as a rule, a linear superposition of soliton solutions is not a solution of the governing nonlinear equation. This property distinguishes nonlinear *solitary* traveling waves (that is, spatially or temporally localized pulses, whereas the relevant single-wave solution of the underlying equation may be completely stable) from *solitons*, which may be observed and analyzed as separate entities but which always express property (iv) should similar entities appear in the system.

The propagation and interaction of both solitons and solitary waves in realistic conditions (that is, in the presence of dissipation, external fields, and inhomogeneities of the medium) frequently results in a certain loss of energy (usually in the form of radiation of relatively short waves); in certain cases collapse or fission of the structure, or a net exchange of energy between the waves occurs. Even if a solitary wave travels without radiation losses in an ideal environment, it may only be called a soliton if neither radiation loss nor net energy exchange occurs when it meets a similar structure; otherwise a perfect re-emerging of each soliton after the interaction would be impossible. More generally, no net changes of any dynamically or topologically significant quantities are permitted in elastic collisions. Only changes of certain dynamically less significant properties such as the exact location (phase) of the solitons are common in elastic interaction. Solitary waves or structures possessing a selection of properties of solitons are sometimes called quasi-solitons.

Although the first evidence of solitons was extracted from observations in nature, the theory of solitons and their interactions has been developed very much in terms of the mathematical theory of the relevant nonlinear partial differential equations (PDEs) of the motion. The definitions of solitons and their interactions are commonly formulated in terms of solutions to such equations. It is even customary to speak of solitary waves and solitons, and of their interactions, having in mind the relevant exact solutions to these equations. Therefore, in mathematical terms, a soliton – either a solitary wave or a more complex entity – is a solution of a nonlinear PDE that elastically interacts with other similar solutions. In the contemporary nomenclature it is also customary to associate solitons and their interactions with numerical (multi-soliton) solutions to these equations.

Interactions between solitons are the most fascinating features of soliton phenomena. The most instructive quality of soliton interactions is the universality of many of their features that exists in spite of the extremely diverse physical origins of the counterparts. The presentation of the basic conceptual ideas involving soliton interactions, a discussion of several particular cases of such interactions and an overview of observations of the relevant phenomena in natural conditions are mostly limited to effects occurring in the elastic interactions of one-dimensional and line solitons, in which the solitons behave very much like ideal mechanical bodies and which serve as the kernel of the classical concept of solitons and their interactions. Some spectacular features of nearly elastic interactions in higher dimensions are interpreted in terms of generalizations of the classical elastic interactions. Finally, a selection of practical applications of specific features of soliton interactions is again discussed from the viewpoint of line solitons.

Introduction: Key Equations, Milestones, and Methods

Integrable Equations

The quality of some nonlinear PDEs to admit soliton solutions is associated with the property of integrability. Integrable equations usually admit an infinite number of integrals (constants) of motion. Many nonintegrable equations possess localized shape-preserving traveling wave solutions that resemble solitons. However, only integrable equations have the universal property of possessing exact multi-soliton solutions that reflect perfectly elastic interactions between individual solitons. Thus, the integrability of the underlying equation is a primary constituent of the classical soliton interactions. Arnold [10] defines, for example, a soliton as a solitary wave (solution) of an integrable PDE having additional stability and robustness features which are inherited directly from the integrability of this PDE. Nonlinear interactions even between the greatly different (but physically relevant) solutions of integrable equations are also elastic.

Among the variety of integrable PDEs that admit multi-soliton solutions, examples related to the Korteweg–de Vries (KdV) equation, the (focusing) nonlinear Schrödinger (NLS) equation, the integrable Boussinesq equation, the sine-Gordon (SG), and the Kadomtsev–Petviashvili (KP) equation will be used below. Below we shall refer to the listed equations as the classical soliton equations. Since the KdV and the KP equations represent a large number of different physical systems and their solutions can be easily visualized in terms of the easily accessible environment of shallow-water waves, solutions to and results from studies of these equations will be largely used for illustrations of the explanations below.

The rapid development of the theory of solitons has led to the discovery of many integrable equations which show multi-soliton solutions and describe soliton interactions (see, e. g. Arnold [10] and the entry ► Partial Differential Equations that Lead to Solitons). A number of analytical methods have been developed to obtain the (multi-) soliton solutions of integrable equations, starting from the late 1960s. A major tool is the *Inverse Scattering Transform* (IST), first developed by Gardner, Green, Kruskal and Miura [47,50] for the KdV equation. The method consists of associating to the evolution equation a Sturm–Liouville problem. In the case of the KdV equation the Sturm–Liouville equation is just the time independent Schrödinger equation of quantum mechanics, where the potential is the wave function of the KdV equation. The single- and multi-soliton solutions are associated with the discrete spectrum of eigenvalues. A generalization of the Inverse Scattering Transform, known as the *AKNS method* (named after Ablowitz, Kaup, Newell and Segur [2] who developed the method), applies to a large class of integral equations. See the entry ► Inverse Scattering Transform and the Theory of Solitons for detailed information.

At the same time, Hirota [62] found that soliton solutions can be obtained by reducing, through a suitable transformation, the evolution equation to a *bilinear form*. Using some properties of the bilinear operator, it is possible to find the multi-soliton solution of an integrable equation. The proof of integrability of a particular PDE is usually nontrivial. The experience with the Hirota method, applied to a variety of nonlinear wave equations, is that exact multi-soliton solutions are found in many cases when it is not known if the equation is integrable. It is natural to expect that the existence of such solutions reflects the integrability in some sense; however, no proof of this conjecture is known at this time.

Mathematically speaking, it is always possible to build an integrable equation representing certain features of an observed phenomenon. Nevertheless, only a few of these equations can be properly derived, normally using asymptotic expansions, from the corresponding primitive equations describing physical phenomena. Even the classical soliton equations only approximately describe the natural phenomena. A more exact description of the natural processes requires the introduction of additional contributions to these equations. Such contributions usually destroy the property of integrability and lead to nonelasticity of interactions of soliton-like entities. Consequently, most of the times solitons are just a good approximation of solitary waves in nature. This limitation is to some extent balanced by the fact that in many cases integrable soliton-admitting equations adequately represent the basic features of physical phenomena even far beyond their formal scope of validity. In spite of such intrinsic limitations, the tools developed in soliton theory have allowed researchers to reach a very deep understanding of some physical phenomena which would have hardly been explained by other means.

Milestones

Several milestones of the solitons' history (▶ Solitons: Historical and Physical Introduction) are particularly significant to soliton interactions. Already the famous first observations in 1834 of shallow-water solitons [132] implicitly involved certain effects created through soliton interactions. The observed wave ahead of a ship probably had a straight crest, as the one reproduced in 1995 in the Union Canal near Edinburgh (see, e. g. p. 11 in [34]). It is a remarkable feature of ship-induced solitons in relatively narrow and shallow channels that a straight-crested upstream soliton exists ahead of a two-dimensional (2D) disturbance, whereas the solitons generated ahead of a ship sailing in wider shallow water areas have curved crests. The straight crest of the Russell's soliton and of her sister structures are thus not intrinsically one-dimensional (1D) structured solitons. They are formed owing to a specific mechanism of soliton interactions as described below. The KP equation, allowing a simple but adequate description of the crest-straightening phenomenon, was derived even later than the word soliton was coined.

A substantial step towards the concept of solitons was made in the mid-1950s by Fermi, Pasta and Ulam [40] who numerically analyzed the evolution of phonons in an anharmonic lattice. From the mathematical point of view this problem can be described by a discretization of the KdV equation. Surprisingly at the time, the process did not lead to an energy equipartition among the modes, although nonlinearity generally tends to create such an equipartition. Instead, a sort of recurrence, an early evidence of the elastic soliton interactions, was observed.

The basic features of soliton interactions were first demonstrated for media described by the KdV equation [64,174]. The evolution of a sinusoidal initial wave with periodic boundary conditions gives rise to an ensemble of solitary waves that move with different speeds and gradually overtake each other. Originally eight of them were mentioned; later revisitations increased the count to nine [106]. The difference in the number of solitons is not principal since small-amplitude solitons only become evident through additional phase shifts in extremely long-term simulatons [39,133]. One surprise of the system was that after a very long time the whole profile reappears. The other, conceptually much more striking effect, was the persistence of the waves: after a certain phase of interaction with each other, they continued thereafter as if there had been no interaction at all. This persistence, which reflects the essence of the soliton interactions, led Zabusky and Kruskal to invent the name "soliton".

Solitons and new features of their interactions were later discovered in a large number of different physical systems. The universal principle generalizing the physical forces affecting the birth of all solitons is that the propagating disturbance (a pulse in a fiber, a wave-packet on a water surface, a self-focusing optical beam, a localized vortex, or a vortex dipole, etc.) is captured in a potential well jointly induced by its motion and by virtue of the nonlinearity of the underlying system. The solitons can thus be interpreted as the bound states of the relevant potential wells, and soliton interactions – as interactions between the bound states of a jointly induced potential well, or between bound states of different wells located at close proximity. This concept of potential well becomes vividly evident in the inverse scattering theory due to the conservation of the eigenvalues of the underlying spectral problem. This universality explains why, in spite of the immense diversity of the solitons and the underlying physical systems, the interactions (collisions) between solitons in all of these systems follow the same principles.

Classical Soliton-Admitting Equations and Appearance of Solitons

The particular appearance of soliton interactions may vary a lot, depending on the physical system and the nature of the solitons. The Russell soliton is an example of nontopological solitons that often become evident in the form of traveling waves and that cannot exist in rest. On the contrary, single topological solitons (that interpolate between two different states of the system which have the same energy) may exist in rest.

A localized entity consists of an infinite number of Fourier harmonics and generally experiences (linear) spreading or wave radiation. A localized entity of permanent form therefore may only appear if the spreading effects are balanced by a certain restoring force that evidently can only be of a nonlinear nature. In other words, all solitons correspond to a certain balance between spreading and nonlinear effects, the latter becoming evident, for example, as nonlinear steepening of the wave shape in the KdV system, or focusing of diffractive structure in nonlinear optics.

The physical meaning of spreading depends on the particular system. Dispersion is responsible for the spreading of pulses in all media in which the group velocity depends on the wave properties. The classical examples of dispersive solitons are surface [132], internal [33] and Rossby solitons [128] in geophysical systems. Similar structures occur in a large variety of environments such as drift solitons or ion-acoustic solitons in plasma [169], or solitons in optical fibers [60].

Many examples of dispersive solitons and their interactions occur in the framework of the KdV equation and its generalizations. It is a characteristic equation governing weakly nonlinear, spatially one-dimensional (1D) waves whose phase speed attains a simple maximum for infinitely long waves

$$\tilde{\eta}_t + \frac{3c_0}{2h}\tilde{\eta}\tilde{\eta}_x + \frac{c_0 h^2}{6}\tilde{\eta}_{xxx} = 0\,,$$

$$\text{in nondimensional variables}\quad \eta_t + 6\eta\eta_x + \eta_{xxx} = 0\,, \tag{1}$$

where η is the relative water surface elevation in the shallow water environment (Fig. 1), h is the still water depth, and c_0 is the maximum phase speed (celerity) of linear waves at this depth. Its generalization to the case of solitons propagating in slightly different directions

$$(\eta_t + 6\eta\eta_x + \eta_{xxx})_x + 3\eta_{yy} = 0\,, \tag{2}$$

was derived by Kadomtsev and Petviashvili [66]. Named the KP equation after them, it describes features of a so-called weakly 2D environment (also called 1.5-dimensional systems). The nondimensional (x, y, t, η) and physical variables $(\tilde{x},\ \tilde{y},\ \tilde{t},\ \tilde{\eta})$ in Eq. (2) are related as follows: $x = \sqrt{\varepsilon}(\tilde{x} - \tilde{t}\sqrt{gh})\big/h$, $y = \varepsilon\tilde{y}\big/h$, $t = \sqrt{\varepsilon^3 gh}\,\tilde{t}/h$, $\eta = 3\tilde{\eta}\big/(2\varepsilon h) + O(\varepsilon)$ whereas $\varepsilon = |\tilde{\eta}_{\max}|\big/h \ll 1$.

Since the KdV equation only admits nontopological elevation solitons, the KdV/KP framework misses several basic features of soliton interactions, such as collisions of solitons with different topological charge and interactions of solitons of different type. These classes of dispersive solitons are represented by the sine-Gordon (SG) equation

$$\theta_{tt} - c_0^2\theta_{xx} + \omega_0^2 \sin\theta = 0\,, \tag{3}$$

where θ in many applications has the meaning of a certain 2π-periodic angle and ω_0 is the minimum angular frequency of linear waves. This equation, with its name stemming from a play of words regarding its form which is similar to the Klein–Gordon equation, arose already in the 19th century in studies of certain surfaces. It grew greatly in importance when it was realized that it led to kink and antikink solutions with the collisional properties of solitons [116]. Its major field of application is solid state physics, yet it also appears in a number of other physical environments such as the propagation of fluxons in Josephson junctions (a junction between two superconductors), the motion of rigid pendulums attached to a stretched wire, and dislocations in crystals. Its kink solutions (Fig. 1)

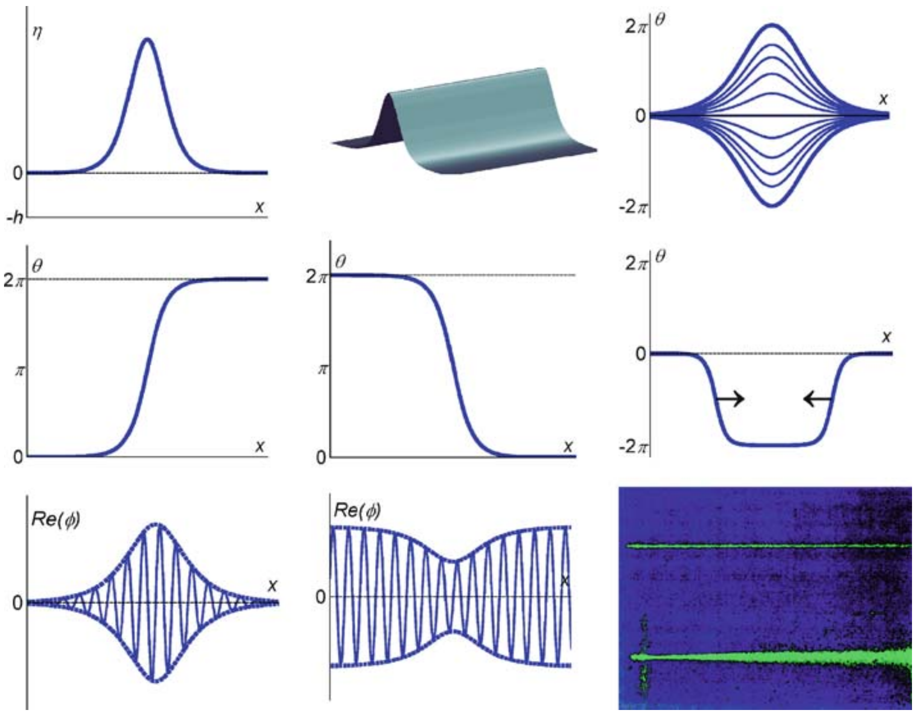
$$\theta_S = 4\arctan\exp\left(\pm\frac{\omega_0}{c_0}\frac{x - vt - x_0}{\sqrt{1 - v^2/c_0^2}}\right)\,, \tag{4}$$

where x_0 is the initial position of the single soliton at the x-axis and $v < c_0$ is the speed of translation of the soliton, represent so-called topological solitons that interpolate between two different states of the system, which have the same energy and may exist in rest (e. g. a frozen (anti)kink, $v = 0$). The SG equation is a simple model admitting breather solitons and soliton pairs with different topological charges. The bulk topological charge is an invariant of the system. In a more complex manner the topological charge becomes evident in the theory of optical spatial solitons, where it can be interpreted in terms of spin of elementary particles. The kink and antikink solutions also represent the possibility of the existence of solitons and antisolitons. Both attractive and repulsive interactions can be vividly demonstrated in this framework and, after all, interactions of physically meaningful solitons of different types are possible.

Another key equation for dispersive waves is the nonlinear Schrödinger (NLS) equation that has a nondimensional form

$$i\psi_t + p\psi_{xx} + q|\psi|\psi^2 = 0 \tag{5}$$

and only has soliton solutions in the focusing case $pq > 0$. This is a universal equation describing the evolution of complex wave envelopes ψ in a dispersive weakly nonlinear medium. It applies, among other phenomena, to



Solitons Interactions, Figure 1

A selection of solitons. The *bottom right* image is from [152]. Optical spatial solitons and their interactions: Universality and diversity. Reprinted with permission from AAAS

deep water waves. The studies of its soliton solutions and their interactions also date back to the 1960s [175,176]. Its major application in the context of soliton interactions is nonlinear optics, where its different versions describe the propagation and interactions of both dispersive solitons (e. g. envelope solitons in optical fibers) and diffractive optical spatial solitons.

The basic reason for the existence of optical solitons is that the optical properties (refractive index or absorption) of some materials are modified by the presence of light. This feature introduces nonlinearity into the system and alters the propagation of optical pulses either in space or in time. A dispersive optical soliton is formed when the linear dispersion effects are balanced by a sort of lensing (of short light pulses of permanent form that are called temporal solitons in the optical nomenclature) in an appropriate material (for example, an optical fiber). They were predicted by Hasegawa and Tappert [60] and first observed by Mollenauer et al. [97]. The basic properties of their interactions [59] are analogous to those occurring for KdV or SG solitons. There is continuous interest for their studies because of their applications, e. g. in long-distance optical communication systems.

The generic example of diffractive solitons, evolution and interactions of a part of which are described by the NLS equation in two space dimensions, are optical spatial solitons. The natural tendency to broaden in space owing to the diffraction of optical beams (Fig. 1) can be balanced, for example, due to the optical Kerr effect that consists of a local refractive index change induced by light. As a first approximation, this change is assumed to take place instantaneously and to be proportional to the local intensity of light. In the focusing case (when an increase of the intensity of light causes an increase in the refractive index), the light-induced lensing can make an optical beam stable with respect to perturbations in both its width and intensity. The resulting beam in a 2D or 3D medium is an example of a diffractive soliton. Interaction of such beams occurs owing to overlapping of the modified regions of the medium. Usually such an interaction is local and has a long range only under specific conditions [129].

The first studies suggesting the existence of such solitons in nonlinear optical Kerr media date back to the 1960s [11,27]. In some cases (such as the 1D Kerr solitons in a planar medium) they are classical solitons and described by a fully integrable equation (the NLS equation in two space dimensions [176]). Self-trapped light beams and more complex structures in a 2D and 3D medium attracted the attention of researchers starting from the 1980s, when the appropriate materials were found [13].

In multi-dimensional media, both diffraction and dispersion affect the propagation of solitary waves. A classical example of a diffractive-dispersive system is the motion of short-crested waves on the water surface. Most of the analysis of soliton interactions in this system has been made for effectively 1D solitons with infinitely long crests (so-called *plane* or *line solitons*); the effects of diffraction being implicitly neglected in their propagation and interactions. A practically realized example of diffractive-dispersive solitons are short pulses of incoherent (or white) light that is self-trapped both in the direction of its propagation and in the transversal direction(s), and that propagate changing neither their shape nor their length [94].

Extended Definitions

The classical nomenclature of low-dimensional solitons and their interactions was formulated several decades ago, and it is not surprising that many later discoveries have led to attempts to extend its content. A part of the extensions add several consistent features (such as the conservation of linear and angular momentum, and topological charge or spin during the soliton interactions); however, in several schools substantial generalizations of the term soliton and of the interpretation of the soliton interactions have been introduced. The only component of the classical nomenclature kept in all the interpretations is the essential role of nonlinearity. Since it is virtually impossible to reflect all the extensions, mostly the material and results following the classical definition are presented below.

The solitons are commonly interpreted as a subset of traveling solitary waves. The classical nomenclature favors structures that are stationary in a proper coordinate system; yet it does not exclude the resting topological solitons (e. g. single-kink solutions to the sine-Gordon equation).

A principal extension of the classical definition of solitons that caused quite a serious discussion in the 1970s [101] consists of accounting for the *resonant interactions*. They may result in the fusion of several solitons into a new soliton or, equivalently, in the decay of solitons into counterparts [177]. Although the number of solitons is not conserved, all the parties of the resonant system are solitons at the limit of exact resonance and no energy radiation occurs. It is commonly accepted now as a variation (or a limiting case) of elastic interactions.

The classical soliton interactions preserve the shape of the solitons. The shape is understood in a wide sense; e. g. the shape of the envelope of the NLS solitons is preserved as well as the time-dependent shape of breathers that have an internal oscillation. This quality, which is universal for all scalar solitons, has a more general interpretation in the case of *vector* (composite) *solitons*. For example, the otherwise elastic interactions of Manakov vector solitons exhibit a shape-changing nature [125] in an integrable system consisting of two coupled NLS equations [82]. This property has a paramount practical importance and bright perspectives e. g. in optical soliton-based computations ([155], see also entry ▶ Optical Computing), being one of the key options of practical applications of specific features of soliton interactions.

An obvious reason for a wider view on soliton interactions is that the relatively simple integrable equations admitting soliton solutions stem from certain asymptotic expansions and only approximately describe the processes in nature. A more exact representation of the physical processes through inclusion of higher order terms of those expansions generally destroys the integrability of these equations. In many cases, though, the perturbing terms are small. The influence of a small dissipative perturbation is usually obvious: it brakes the moving solitons and/or damps the oscillating solitons. Such structures are sometimes called dissipative solitons although such a name is somewhat self-contradicting. Effects due to conservative (Hamiltonian) perturbations are much richer in content. Usually they do not destroy or brake solitons, but they may, e. g., render otherwise elastic soliton interactions to inelastic ones owing to extra wave radiation. A well-known example of the effect of perturbations is dissipation-induced annihilation of a kink-antikink pair in a perturbed sine-Gordon equation that otherwise would lead to a breather [114]. A monumental survey of the relevant problems is presented in [77]; see also entry ▶ Soliton Perturbation.

Since none of the physical and numerical environments perfectly matches the governing equations, solitary waves both in realistic conditions and in numerical simulations always are approximations to solitons. In numerical experiments practically ideal solitons can be represented and errors basically occur due to purely computational inaccuracies. Laboratory experiments with solitons encounter problems with perfect excitation of even single solitons and moreover with controlling their interaction properties; however the relevant results are of fundamental importance in establishing the adequacy, the limits and the practical applicability of the properties of solitons and their interactions.

In the theory of elementary particles frequently a soliton is defined merely as a localized solution (resp. entity) of permanent form and the constraint of its survival in collisions is released (e. g. Rebbi [127]). A popular and deep example is the quantum field theory, where e. g. the Yang–Mills field equations admit solutions localized in space (which represent very heavy elementary particles), and also solutions, localized in time as well as in space (instantons). This position has certain support by the conjecture that the classical soliton equations can be interpreted as reductions of self-dual Yang–Mills equations and thus the classical solitons form a subset of the above solutions.

A similar position is also widely adopted in studies of optical beams and vortices. A large part of such beams are described by nonintegrable equations [135] and thus lie beyond the classical soliton nomenclature. Many features of their behavior and interactions, however, demonstrate a striking similarity with that of classical solitons, and exhibit universal properties [152], resembling the similar universality of the classical solitons interactions. Soliton-like beams organized by different nonlinear effects were mostly called solitary waves until the mid-1990s. The modern nonlinear optics nomenclature treats all self-trapped optical beams as solitons [136] although their interactions are not always elastic. A selection of results of studies of their interactions that give a flavor of the richness of soliton interaction phenomena in 3D media is presented below.

The constraint of energy conservation both in the motion and the interactions of the solitons is frequently disregarded in studies of long-lived structures which exhibit reasonable radiation [42] but that still survive in certain collisions. On the other hand, other highly interesting solitary structures such as (Rossby) dipole modons [83,84] do not radiate energy but only survive under certain conditions. A certain amount of results and concepts in this domain is presented to highlight the overlapping of the properties of soliton interactions and interactions of other long-living structures.

Elastic Interactions of One-Dimensional and Line Solitons

The term soliton was originally introduced for nonlinear disturbances, the interaction of which resembles the collision of particles and is fully elastic (Table 1), so that the number of solitons is always conserved and their amplitudes are fully restored afterwards. In low-dimensional cases such as those described by the KdV equation, the amplitudes, directions and propagation velocities of each soliton always recover their initial values (Fig. 2). The shape of each soliton is prescribed by the structure of (single-) soliton solutions to this equation and, as the simplest evidence of the recurrence of the system, it is not surprising that the shape is perfectly restored as well.

Three phases of the interactions of solitons can be distinguished either in time or in space (Fig. 2). First, well-defined, clearly separated solitons approach each other. In the second (interaction) phase, they usually lose their identity and merge into a composite structure. After a while, the solitons emerge again. The appearance of the composite structure depends on the particular physical system; as a rule it is neither a linear superposition of (properly shifted) counterparts nor a new soliton. Therefore solitons survive the collision event, even though they completely merge for a while. The variety of the composites range from the complete vanishing of the counterparts (e. g. kink-antikink collision in the SG equation) over certain interactions of KdV solitons, in which the individual identities are almost conserved and two humps are always visible, to a fourfold elevation of the water surface in a resonant interaction of the KP solitons.

In some environments, one cannot say whether the solitons propagate through each other as waves do or collide as particles do. Both interpretations have a solid ground. The interaction of unidirectional KdV solitons resembles the collision of two particles whereas, e. g. in head-on interactions of Rossby dipole solitons[84] the identity of both counterparts can be continuously tracked and the interaction process resembles a sort of complex overtaking.

Attraction and Repulsion

Another feature of soliton interactions resembling collisions of real massive and/or electrically charged particles that exert certain forces on each other is that soliton interactions may show an *attractive* or *repulsive* nature. This feature can be demonstrated in the framework of the kink-antikink solution of the sine-Gordon equation

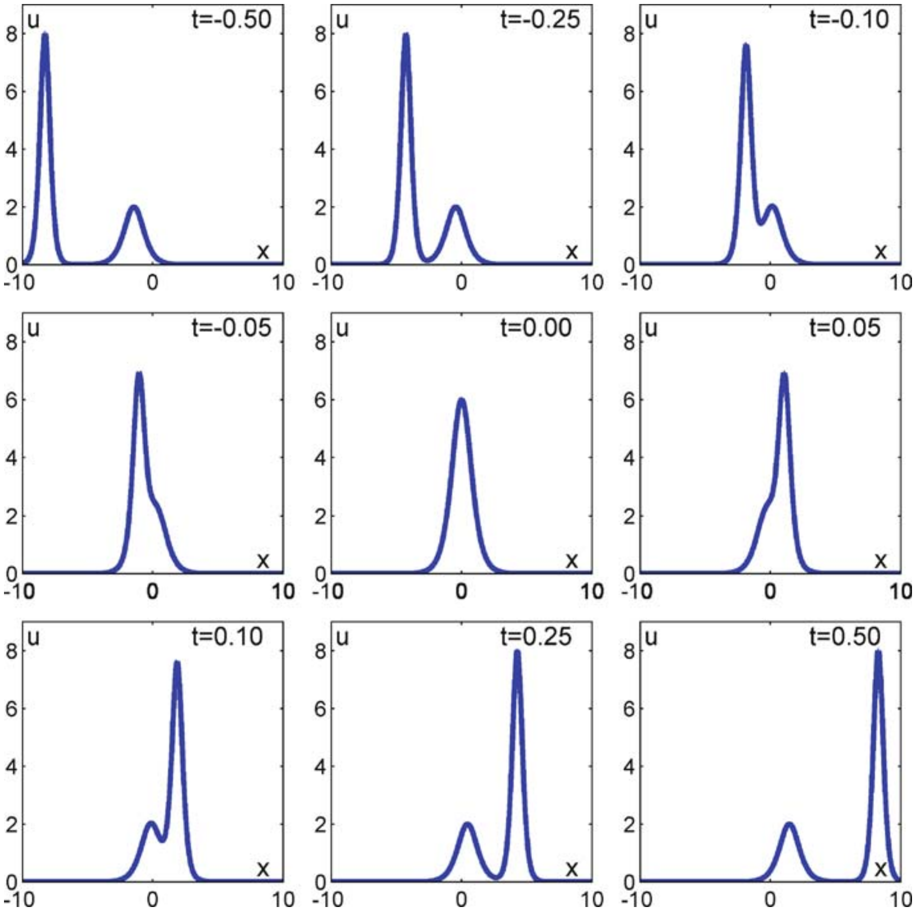
$$\theta_{SA} = 4 \arctan \frac{c_0 \sinh v t \xi}{v \cosh x \xi}, \quad \text{where} \quad \xi = \frac{\omega_0}{c_0} \frac{1}{\sqrt{1 - v^2/c_0^2}} \tag{6}$$

and that only exists if $v > 0$. The motion of the counterparts speeds up when they move towards each other, and slows down when they move apart after passing each other. If one examines the positions of the centers of the counterparts of this solution, the sequences of their positions in the vicinity of their meeting point are not the same

Solitons Interactions, Table 1

Properties of solitons in elastic interactions of 1D and line solitons. Analogous rules hold for angular momentum and spin in elastic collisions in higher dimensions

Property	1D interactions and nonresonant interactions of line solitons	Exceptions in resonant interactions
Number of solitons	Conserved except in a short phase of interaction	Changed
Energy	Restored after interactions for each soliton	Merging possible; total energy conserved.
Amplitude Shape (steepness)	Substantial local changes may occur in the interaction region; restored after interactions	Durable changes may occur
Phase or location	Finite phase shifts commonly occur; yet no phase shifts in certain environments. The total phase shift is exactly equal to the sum of partial shifts that would result from separate collisions with each of the solitons	Infinite phase shifts
Geometry	Substantial changes in the interaction region, restored after interaction	Durable changes may occur
Propagation direction, linear momentum	Conserved for each soliton	Conservation of bulk linear momentum
Topological charge	Conserved for each soliton	



Solitons Interactions, Figure 2

Temporal evolution of KdV solitons described by the two-soliton solution $u(x,t) = 12 \times (3 + 4\cosh(2x - 8t) + \cosh(4x - 64t))/([3\cosh(x - 28t) + \cosh(3x - 36t)]^2)$ [37]. The amplitudes of the counterparts are $u_{1\,\max} = 8$ and $u_{2\,\max} = 2$. Notice the gradual decrease of the taller soliton when it catches the shorter, and its gradual increase when it moves further ahead of the shorter one, and the relatively small amplitude $\tilde{u} = 6$ of the composite structure

as they would be if they had been alone in the system, or far from the other counterpart.

If the solitons were massive or charged particles, one would say that an attractive force exists between them which decreases as their separation increases. On the contrary, the speed of two kinks as well as two antikinks approaching each other slows down as their separation decreases, which is characteristic for repulsive interaction. Another classical reflection of "forces" between solitons is the effect of attraction or repulsion of (envelope) solitons in optical fibers [53].

In two dimensions, the attractive interactions of two obliquely interacting line solitons become evident as an attraction of the relevant wave crests. In the case of optical spatial solitons the attraction affects their centroids. For repulsive interactions the opposite holds. The relevant effects are vividly demonstrated in the framework of the KP equation for the description of drift vortex solitons in environment, otherwise described by the Hasegawa–Mima equation [158]. This environment is equivalent to the one described by the Charney–Obukhov equation for large-scale motions in geophysical hydrodynamics admitting Rossby waves and solitons.

Transient Amplitude Changes, Durable Phase Shifts and Recurrence Patterns

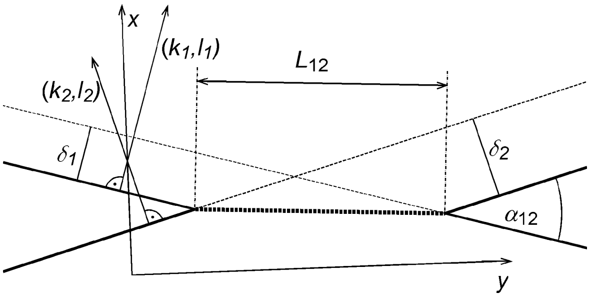
Already the first study of solitons [174] revealed some other universal aspects of soliton interactions. First, certain durable phase shifts may occur, the magnitude of which depends on the interaction details. For example, during the collision presented in Fig. 2, the taller soliton is shifted forward by an amount $\Delta x_1 = \frac{1}{2}\log 3$ and the shorter one backwards by $\Delta x_2 = \log 3$ compared to the case when the solitons are alone in the system. The above-discussed "forces", if present in the system, may be interpreted as the cause of the phase shifts.

The total phase shift of a soliton induced by elastic collisions with any number of solitons is exactly equal to the sum of (partial) shifts that would result from separate collisions with each of the solitons involved. This property is commonly referred to as the *absence of many-particle effects*.

In the case of line solitons the phase shifts become evident in the form of durable shifts of the counterparts during the interaction (Fig. 3). In the negative phase shift case the solitons are delayed compared to their position in the absence of interactions, whereas in the positive phase shift case they seem to be accelerated.

Second, the amplitudes of the interacting solitons may gradually change as they approach to each other (Fig. 2). The amplitude of the composite structure is generally not equal to the sum of amplitudes of the interacting solitons. In interactions of a small number of KdV solitons running along an infinite medium, the behavior of each counterpart and its influence on the partners can always be identified from the shape of the elevation since after some time the solitons become separated enough to detect all of them and their perfectly restored properties in the limit of infinite separation.

More insight into the properties of the soliton interaction is provided by long-term simulations of ensembles of solitons excited from a periodical signal (Fig. 4). The total number of interacting parties is infinite then, the solitons are tightly packed and such a separation not necessarily occurs. In some cases the presence of several shorter solitons can only be identified through their contributions



Solitons Interactions, Figure 3

to the phase shifts of the partners since they are seldom visually identifiable; such solitons are called hidden solitons [39].

The trajectories of the (crests of the) counterparts may show quite a complex pattern and may exhibit both simple recurrence (at which the initial system is approximately restored) as well as super-recurrence (understood as a nearly perfect restoration of the initial system over longer times).

Practically periodical in time rhombus-like patterns (suggesting that interactions of quite a small number of solitons govern the properties of the system) optionally occur in cases when a super-recurrence is possible (Fig. 5), whereas in other cases these patterns show gradual variation also over extremely long times. There seems to exist a critical value d^* in the range $-1.8 < \log \mathrm{d}^* < -1.9$ of the dispersion parameter d in the KdV equation (presented in the form $\eta_t + \eta\eta_x + \mathrm{d}\eta_{xxx} = 0$), which distinguishes if a super-recurrence exist. If $\mathrm{d} < \mathrm{d}^*$, no super-recurrence can be detected even within extremely long calculation times [39,134].

Durable Local Amplitude Changes in Oblique Interactions of Line Solitons

The interaction of unidirectional KdV solitons does not create any large changes in the wave amplitudes ([37], see also ▶ Korteweg–de Vries Equation (KdV), History, Exact *N*-Soliton Solutions and Further Properties of the). However, amplitude amplification may occur under certain conditions when line solitons propagating in slightly different directions meet each other. Extensive evidence comes from coastal engineering, where it was known already a long time ago that ocean waves approaching breakwaters and seawalls under a certain angle caused unexpectedly large overtopping. This phenomenon was systematically studied already in the 1950s [117], well before the word soliton was coined.

When a shallow-water wave is obliquely launched along an ideally reflecting wall, the reflection does not necessarily follow the rules of geometrical optics. For a certain range of incidence angles, the crests of the approaching and the reflected wave fuse together near the wall and the process resembles the *Mach reflection*. The common crest, an analogue of the *Mach stem*, is generally unsteady and gradually lengthens for sine waves [15] and Stokes waves [173]. This type of reflection also occurs during perfect reflection of random [89] and solitary waves of different nature [45,92,93,115,159].

For a certain set of parameters of the approaching KdV soliton, the resulting structure is equivalent to half of the pattern created by two interacting KP solitons of equal amplitude (Fig. 3). The prominent feature of both the (Mach) reflection and oblique interactions of shallow-water solitons is that the height of the common crest may considerably exceed the sum of the heights of the interacting solitons. For interacting waves with equal amplitudes the hump can be up to four times as high as the incoming waves. Originally established in the context of the reflection of Boussinesq solitons ([92,93]; named Mach reflection by Melville 1980 [91]), the amplitude amplification in a certain region occurs in all oblique attractive interactions of line KP solitons (that is, in interactions with a negative phase shift). Since the interaction pattern is stationary in an appropriately moving coordinate system for a range of the parameters of the interacting solitons, it may lead to durable local changes of the amplitude of the resulting pattern of elevation.

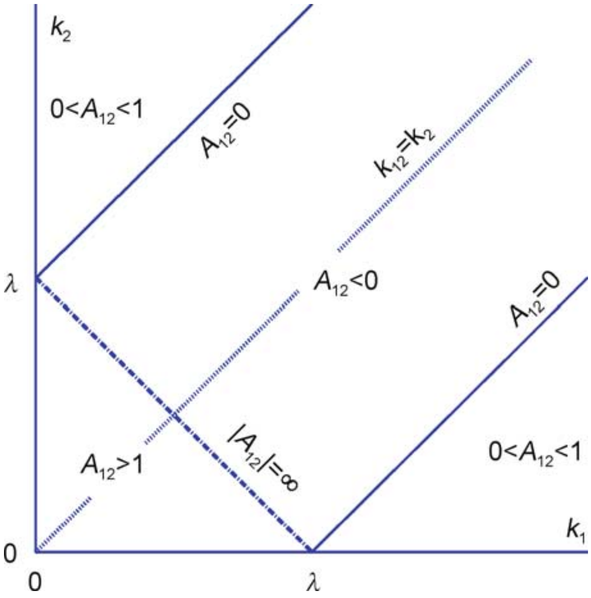
Resonance

While the theory of integrable systems requires that the 1D solitons retain their identity in interactions, collisions of solitons in multiple dimensions may lead to the formation of new solitons. The phenomenon called *resonant interaction* leads to the emergence of new structures that combine the energy of the counterparts and to modifications of the number of solitons and of some of their geometrical features.

This possibility was first recognized by Newell and Redekopp [101] in the context of the KP and NLS equations. Miles [93] gives an early answer to their question about the practical consequences of this phenomenon in terms of an essential increase of the wave amplitude occurring during the resonant Mach reflection. Originally named "breakdown of the Zakharov–Shabat theory of integrable systems with more than one spatial dimension", it highlights the more complex nature of soliton interactions in more than one dimension, where large phase shifts are possible.

Remarkably, the resonance conditions $\boldsymbol{\kappa}_\infty = \boldsymbol{\kappa}_1 + \boldsymbol{\kappa}_2$, $\omega_\infty = \omega_1 + \omega_2$, where $\boldsymbol{\kappa}_i = (k_i, l_i)$, $i = 1, 2, \infty$ are the wave vectors and ω_i are the frequencies of the solutions of the corresponding linearized KP equation, are precisely the same as those for the resonant interaction of three weakly nonlinear waves. Conceptually, however, such interactions more resemble so-called double resonance, in which not only the above resonance conditions are met but also the group velocities of two or more counterparts are equal and otherwise sporadic energy exchange within the resonant triplets is replaced by much more intense interactions (e. g. [145]).

The patterns of line soliton crests (Fig. 3) suggest that only attractive interactions may result in resonance. The resonant interactions between line solitons correspond to infinitely large phase shifts and infinitely strong attraction, and lead to durable changes of the geometry of the system. In the situation depicted in Fig. 3, the resonance would lead to an infinitely long common crest and thus render the "four-arm" pattern to a "three-arm" one.



Solitons Interactions, Figure 6
Negative and positive phase shift areas for the two-soliton solution of the KP equation for fixed $l_{1,2}$. The phase shift $\Delta_{12} = -\ln A_{12}$ has a discontinuity along the line $k_1 + k_2 = \lambda$ at which $|A_{12}| = \infty$ and the resonant interactions occur. No two-soliton solution exists in the area where $A_{12} < 0$. An analogue of linear superposition occurs when $A_{12} = 0$. Adapted from [120]

In the KP framework, the resonance phenomenon is connected with the fact that its multi-soliton solutions representing the interaction of line solutions only exist for a subset of the space of parameters of the interacting solitons (Fig. 6). Resonance occurs when the parameters of the interacting solitons lie at a certain part of the border of this subset.

A new soliton born at the exact resonance may resonantly interact with yet another soliton. This mechanism has been employed in [17] to construct a family of exact solutions to the KP equation corresponding to resonance of several solitons. Such solutions consist of unequal numbers of incoming and outgoing line solitons, the parameters of which can be obtained from asymptotic analysis [16]. This class contains a variety of multisoliton solutions, many of which exhibit nontrivial spatial interaction patterns that are generally characteristic to multisoliton solutions to the KP equation [118].

Geometry of Oblique Interactions of KP Line Solitons

Patterns

A relatively simple but instructive, easily visualizable and rich-in-content model demonstrating the discussed features of interactions of line solitons is the KP equation. It admits simple explicit formulae for multi-soliton solutions and extensive analytical treatment of their geometrical properties. The two-soliton solution to the KP equation can be written as a sum $\eta = s_1 + s_2 + s_{12}$ of terms, reflecting to some extent the two interacting solitons s_1, s_2 and residue s_{12}

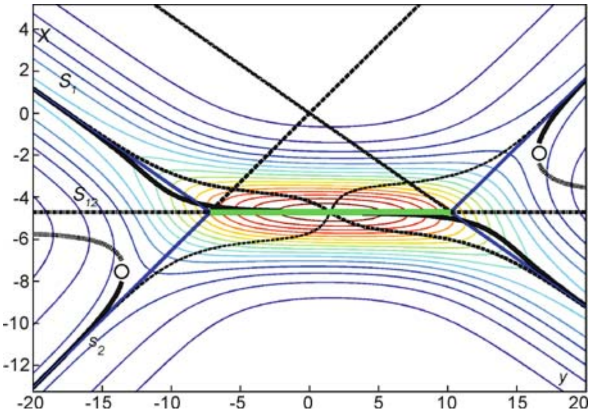
$$\begin{aligned} s_{1,2} &= \sqrt{A_{12}} k_{1,2}^2 \Theta^{-2} \cosh\left(\varphi_{2,1} x + \ln\sqrt{A_{12}}\right) , \\ s_{12} &= 2\Theta^{-2}\left[(k_1 - k_2)^2 + A_{12}(k_1 + k_2)^2\right] , \\ \Theta &= \cosh\frac{\varphi_1 - \varphi_2}{2} + \cosh\frac{\varphi_1 + \varphi_2 + \ln A_{12}}{2} . \end{aligned} \tag{7}$$

Here $\varphi_i = k_i x + l_i y + \omega_i t,\ a_i = \frac{1}{2}k_i^2,\ i = 1, 2,$ are the phases and amplitudes of the interacting solitons, the 'frequencies' ω_i satisfy the dispersion relation $k_i\omega_i + k_i^4 + 3l_i^2 = 0$ of the linearized KP equation, $A_{12} = [\lambda^2 - (k_1 - k_2)^2]/[\lambda^2 - (k_1 + k_2)^2]$ is the phase shift parameter and $\lambda = l_1 k_1^{-1} - l_2 k_2^{-1}$.

The two-soliton solution only exists in a part of the parameter space $R^{(4)}(k_1, k_2, l_1, l_2)$. An interaction may result in either the positive or the negative phase shifts $\delta_{1,2} = -\ln A_{12}/|\boldsymbol{\kappa}_{1,2}|$ of the counterparts (Fig. 6). The negative phase shift (cf. Fig. 3) can be attributed to an attractive interaction and the positive phase shift to a repulsive interaction.

The residue s_{12} (with an amplitude a_{12}) is at times considered as a virtual 2D "interaction soliton" [118], which grows into the resonant soliton at the limit of exact resonance $A_{12} \to \infty$ (cf. Fig. 7). This virtual structure can be heuristically interpreted as supported by both dispersive and diffractive effects, the latter being balanced by the oblique motion of the interacting solitons.

The patterns of both idealized (Fig. 3) and factual (Fig. 7) wave crests are symmetric with respect to a particular point called interaction center, and are stationary in a properly moving coordinate frame. If the amplitudes of the solitons are equal, the pattern is equivalent to the reflection of the incoming soliton from the wall following the motion of the interaction center. For unequal amplitude solitons the equivalence is not complete because mass and energy flux occur through such a wall.



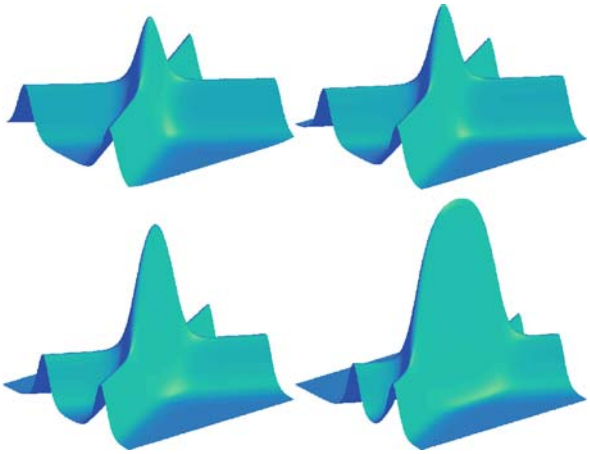
Solitons Interactions, Figure 7
Patterns of idealized (*solid/dashed straight lines*) and factual (*dashed curves*) crests of the incoming solitons s_1, s_2, the crest of the residue s_{12} (*green line*), the visible wave crests and troughs (*bold* and *bold dashed curves*, respectively), and isolines of the two-soliton solution in the case $l = l_1 = -l_2 = 0.3$, $k_1 = 0.6507$, $k_2 = 0.4599$ in normalized coordinates (x, y). The interaction center is the crossing point of all factual crests. Contour interval is $\frac{1}{4}\max(a_1, a_2) = 0.0689$. *Circles* show the common points of the troughs and crests of the two-soliton solution. Reprinted from [146]

Amplitudes

The phase shifts $\delta_{1,2}$ of the counterparts only depend on the amplitudes of the incoming solitons and the angle $\alpha_{12} = 2\arctan(\frac{1}{2}\lambda)$ between their crests. For the negative phase shift case $A_{12} > 1$ (that is typical in interactions of solitons with comparable amplitudes, Fig. 5), an interaction pattern emerges, the height of which exceeds the sum of the heights of two incoming solitons. The maximum surface elevation for equal amplitude solitons is $a_{\max} = 4a_{1,2}/(1 + A_{12}^{-1/2})$; thus, the nonlinear superposition of solitons may lead to a fourfold amplification of the surface elevation. In a highly idealized case of interactions of five solitons the maximum surface elevation may exceed the amplitude of the incoming solitons by more than an order. The largest elevation occurs if the interacting solitons are in exact resonance $A_{12} = \infty$, when solitons intersect under a physical angle $\tilde{\alpha}_{12} = 2\arctan\sqrt{3\tilde{\eta}/h}$. For unequal amplitude solitons the maximum elevation $a_{\max}$ for finite A_{12} and the amplitude of the resonant soliton a_∞ at $A_{12} = \infty$ are [46,146]

$$a_{\max} = a_{12} + 2A_{12}^{1/2}\frac{a_1 + a_2}{\left(A_{12}^{1/2} + 1\right)^2}, \quad a_\infty = \frac{(k_1 + k_2)^2}{2} . \tag{8}$$

The near-resonant high hump is particularly narrow and its front is very steep. The maximum slope of the front of the two-soliton solution may be eight times as large as



Solitons Interactions, Figure 8
Surface elevation in the vicinity of the interaction area, corresponding to the incoming solitons with equal amplitudes intersecting under different angles [120]

the slope of the incoming solitons [150]. For unequal amplitude solitons, the amplification of slope of the front of the interaction pattern is roughly proportional to the amplitude amplification. The extraordinary steepness of the front of the near-resonant hump, although intriguing, is not unexpected, because the resonant soliton is higher and therefore narrower than the incoming solitons.

The length L_{12} of the idealized common crest (Fig. 3) is $L_{12} \sim \ln A_{12}$ and therefore is modest unless the interacting solitons are near-resonant. The length of the area, where the total elevation exceeds the sum of the amplitudes of the counterparts, may be considerably longer; however it is also roughly proportional to $\ln A_{12}$ [150]. For largely different amplitudes of the interacting solitons, the amplitude amplification remains modest but the spatial extent of substantial influence of nonlinear interaction is roughly as large as if the amplitudes were equal [151]. Their near-resonant interaction becomes evident as a wave with its crest oriented and propagating differently compared with the counterparts. The described features are universal for that part of the wave vector space, in which the two-soliton solution with a negative phase shift exists. In the case of a positive phase shift (that is typical for interactions of solitons with largely different amplitudes) the highest elevation does not exceed the amplitude of the larger soliton.

Numerical simulations of the process of formation of the composite structure show that a high wave hump is formed quite fast in the interaction region and its height soon considerably exceeds the sum of the heights of the counterparts [58,124]. A high and gradually lengthening wave hump is also formed in cases when no exact two-soliton solution of the KP equations exists. The interaction in such cases is inelastic: neither the orientation of the crests nor the height of the solitons before and after interaction match each other, and a certain amount of wave radiation takes place. The described features become evident in a number of simulations of soliton interactions in different environments [105,168].

Soliton Interactions in Laboratory and Nature

Ion-Acoustic Solitons

The most productive studies of soliton interactions in the 1970s and the 1980s were performed in the framework of ion-acoustic waves. Their behavior is approximately described by the KP equation. An analytical solution describing interactions and resonance of two plane ion-acoustic solitons of small amplitude in the 3D collisionless plasma was given in [171]. This solution is wider than the two-soliton solution of the KP equation in the sense that the nearly unidirectional approximation is not used.

The first successful experiment proving that the 2D interaction of solitons has a wider spectrum of features compared with the 1D collisions is reported in [178]. A collision of two equal amplitude spherical solitons led to significant changes and to the emergence of a new 2D object. This interaction was not perfectly elastic: the solitons were not only shifted in phase but also reduced in amplitude. Soon afterwards, a near-resonant interaction of two KP solitons, with a large-amplitude wave hump of the counterparts oriented across the principal propagation direction, was observed near the interaction center, whereas the counterparts experienced clear phase shifts [43]. The amplitude amplification was found to be close to twofold the sum of the amplitudes of the incoming solitons [103].

The first adequate evidence of the nonlinear increase in amplitude during collisions of unequal amplitude KP solitons was also obtained in this framework [46]. For largely different amplitudes the measured maximum amplitudes were less than the predicted ones. A probable reason for the discrepancy is that the near-resonant wave hump occurs and covers a substantial area (equivalently, can be reliably estimated with the use of relatively large probes) only if the incoming solitons are very close to resonance. The common part of the crests of interacting solitons in the reported experiments was pretty short suggesting that the solitons were not exactly in resonance. Moreover, the complete identification of all the crests in the interactions of solitons with considerably different amplitudes is not possible because the crests are partially invisible (Fig. 7, [146]). The generic reason for experimental difficulties in this and similar experiments is the above-discussed feature that large-amplitude structures tend to mask the presence of shorter ones.

Shallow-Water and Internal Solitons

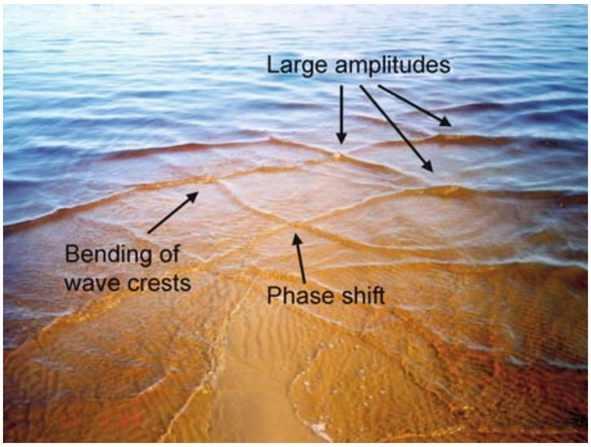
Phase shifts, formation of a common crest of the interacting soliton-like waves, and accompanying amplitude and orientation changes are commonly observable in very shallow areas (Fig. 9). A famous photo by Terry Toedtemeier (1978), in which two solitonic shallow-water waves have significant phase shifts and quite a long common crest on a beach in the US state of Oregon, has been reproduced in a number of sources (e. g. p. 24 in [34]).

Although [93] predicted up to fourfold amplification of the surface elevation, much weaker amplitude amplification was found in early experiments [91]. An amplification close to the theoretical one was detected as a by-product of studies of shallow-water channel superconductivity [25].

Russell's "great wave of translation" [132] probably had a practically straight crest, reflecting a well-known feature of the generation of solitons in relatively narrow channels: a nearly perfectly 1D upstream soliton is created also by a 2D disturbance. The KdV model, which is frequently used to describe this phenomenon, is intrinsically 1D and certainly results in straight wave crests. An analysis of the simplified problem of ship motion in the KP equation and the Boussinesq equation shows, in accordance with common experience, that the wave crests are curved [71]. In fact, the essentially 2D waves with paraboloidal crests generally emerge in front of the disturbance. Their curvature monotonously decreases as the waves propagate [85,87].

Although the sidewall of the channel is not essential for the radiation of the upstream solitons, still it plays a crucial role in the transformation of already radiated waves. The straight-crested solitons are formed in the process of the (Mach) reflection of solitons with curved crests from the sidewalls [113]. This feature can be distinguished in many numerical studies, where an initially curved soliton starts to straighten when it comes in touch with the sidewall [149]. Since the reflection of solitons, which in this case is equivalent to soliton interactions, plays the key important role in creating straight-crested waves in channels, with a certain exaggeration it can be said that Russell's soliton exists due to soliton interactions.

Probably the most common solitonic phenomenon in nature next to the shallow water waves is represented by internal solitary waves in the oceans and in the atmosphere ([56,107,111,130], see also the entry ► Non-linear Internal Waves). In many cases, the KdV equation is an appropriate model for internal waves and the effects occurring during their interactions are equivalent to those described above.



Solitons Interactions, Figure 9
Interaction patterns of solitonic surface waves in very shallow water near Kauksi resort on Lake Peipsi, Estonia. Photo and copyright by Lauri Ilison, July 2003. First published in [151]

Large-scale internal solitary waves and their groups exhibit many features unique to soliton interactions and are often called simply internal solitons. Intersecting solitary wave packets on Synthetic Aperture Radar (SAR) images frequently exhibit phase shifts while crossing each other [51], similarly to phase shifts occurring in the KP model, where the agreement between theory and experiments is quite good. Apel et al. [9] summarize advances in the descriptions and observations of internal solitons and their interactions.

The other environment for internal solitons, which provides some instructive aspects and is eligible, e. g., for the description of small-scale internal solitons in a two-layer medium, is the Benjamin–Ono (BO) equation [1]

$$\eta_t + c\eta_x + \alpha\eta\eta_x + \frac{\beta}{\pi}\frac{\partial^2}{\partial x^2} \quad P.V. \left[\int_{-\infty}^{\infty} \frac{\eta\left(x', t\right)}{x - x'} \mathrm{d}x' \right] = 0. \tag{9}$$

First, the BO solitons do not acquire a phase shift after a collision. Second, this environment demonstrates that generalization of integrable 1D soliton-admitting equations to even a weakly 2D case may lead to the loss of integrability, thus the preservation of this feature in the KP equation is not universal. The weakly 2D analogues of the BO equation [1] apparently are not integrable [9] and do not admit simple analytic multi-soliton solutions. Numerically simulated oblique interactions of weakly 2D BO solitons show that a phenomenon resembling the resonant interaction of the KP solitons and an accompanied amplitude amplification do occur but the newly generated wave in the zone of nonlinear interaction is far from the BO soliton [105,167].

Solitons at Planetary Scale

Large-scale internal waves and solitons in nature are affected by the joint influence of the Earth's rotation and sphericity, and perfect internal line solitons generally cannot exist in the ocean. The physical reason of this "antisoliton theorem" is that due to rotational dispersion, there is always a phase synchronism between a source moving at an arbitrary speed and linear perturbations in such environments. This leads to unavoidable wave radiation from a large-scale solitary internal wave [49]; however this effect is negligible for relatively small-scale solitons, the typical time scales of which in the oceans are a few tens of minutes.

The existence of nonstationary solitary waves is still possible [52]. They exhibit a phenomenon similar to the recurrence of solitons – the repeating decay and reemergence process, and formation of a nearly localized wave packet consisting of a long-wave envelope and shorter, faster solitary-like waves that propagate through the envelope [61]. The robust, long-lived structure may contain as much as 50% of the energy in the initial solitary wave. Interacting packets may either pass through one another, or merge to form a longer packet. Their further studies may reveal interesting features concerning the functioning of oceans and other large stratified water bodies. Yet in the majority of practically interesting cases such long-term behavior is masked by topographic effects that modify the internal waves much more dramatically.

Another medium of particular practical importance as well as an instructive one from the viewpoint of soliton interactions is the large-scale geophysical flow in the oceans and the atmosphere. It is frequently treated as anisotropic quasi-2D turbulence, which has the property of energy concentration in large-scale structures. Eddies in such flows are stabilized by the background rotation and also affected by the joint effect of the Earth's rotation and sphericity. The latter becomes evident through the North-South variation of the Coriolis force, the so-called (planetary) beta-effect. In this environment, large-scale vortices often maintain their coherence for surprisingly long times and show an amazing variety of interactions; perhaps the most well-known example being the Jovian Great Red Spot.

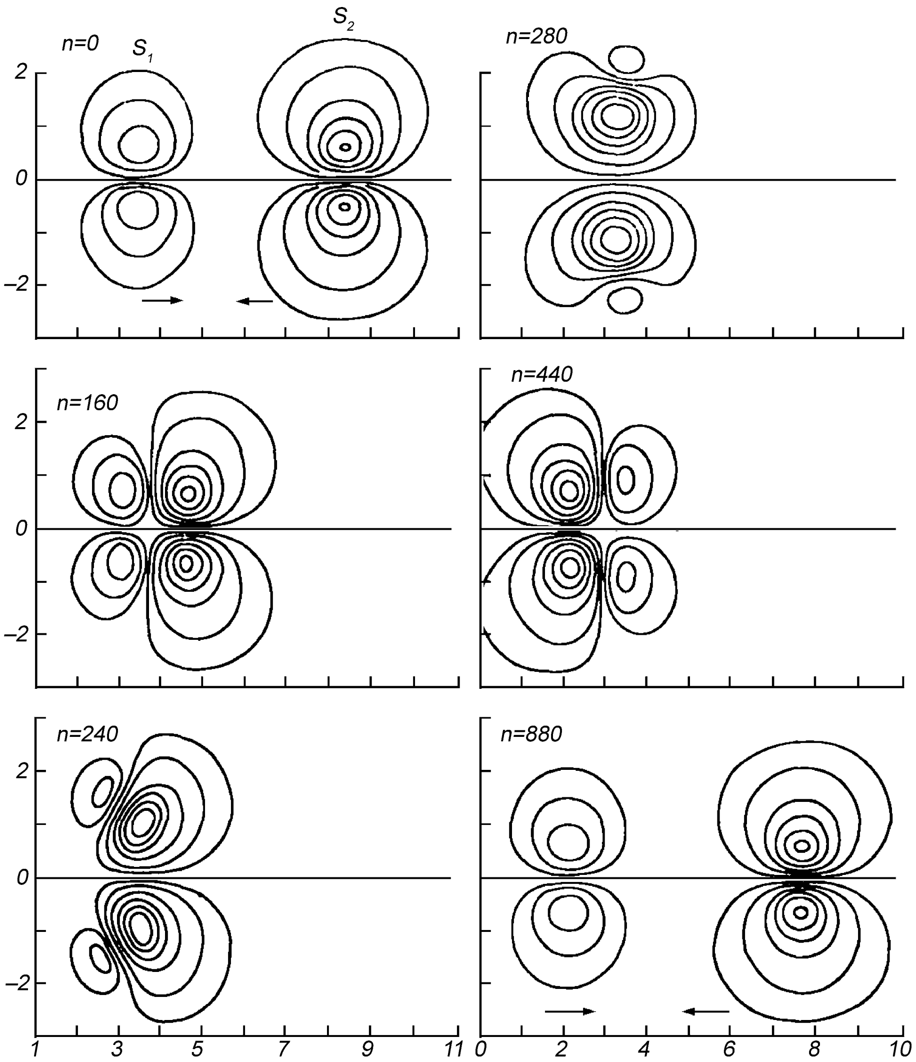
Form-preserving, uniformly translating, horizontally localized solutions (of the equations of planetary dynamics) are called modons. In nondissipative quasi-geostrophic dynamics they exhibit a variety of properties of solitons. They carry a certain amount of fluid with them, which distinguishes them from (solitary) waves that cause, if at all, a finite displacement of the medium. The word modon was coined a decade after soliton was first used [157].

The standard quasi-geostrophic models predict that the accompanying Rossby-wave radiation should cause a decay of isolated eddies. Several models explain the persistence of monopolar vortices using external features of the flow, or interactions with a background shear that suppresses the Rossby-wave radiation [19,126,144]. A number of generalizations of the quasi-geostrophic model predict that, within a certain range of parameters, a nonlinear anticyclonic vortex of a special form can exist for a long time [121,153,170] due to the mutual compensation of weak (scalar) nonlinearity and weak dispersion. Some authors call such structures (Petviashvili-type) Rossby solitons, although their collisions are not elastic.

Long-living coherent vortices and their interactions have been studied in many experiments with rapidly rotating parabolic vessels [102]. The increase of the effective gravity due to the centrifugal acceleration towards the side walls modifies the governing equations, so that the (Petviashvili-type) Rossby soliton does not exist in the paraboloidal geometry [104]; yet anticyclonic vortices have a very long lifetime [154]. Another option to study the evolution of such vortices is a tank with a sloping bottom to imitate the planetary beta-effect (e. g. [41,90], among others; for an overview of earlier studies see [63]).

The majority of interactions of solitary vortices in such an environment are inelastic. The 2D localized vortices of comparable size and intensity, and like sign attract each other and generally coalesce soon. Only practically equivalent vortices may form a quasi-stable pair rotating around each other. The vortices of different signs either repulse from each other or form a relatively stable dipole [54,55]. The simultaneous evolution of a large number of soliton-like vortices has mostly been studied theoretically or numerically (e. g. in terms of a cluster of point vortices or hetons, [57]).

The simplest stable barotropic modon in flat-bottom beta-plane dynamics is the Larichev–Reznik dipole [83]. It is a traveling dipolar vortex with a characteristic north/south antisymmetry. It propagates eastward at any speed, or westward at speeds greater than the longest-wave speed. The speed of translation is therefore out of the range of the phase speed of Rossby waves, which is the reason why this modon does not radiate waves (unlike large-scale internal solitons). The significance of such structures in everyday



Solitons Interactions, Figure 10
Head-on collision of Larichev–Reznik dipoles [67]

life and climate dynamics (where they may be responsible, e. g., for certain unusual weather events since the vortex pair may behave completely differently compared with a single cyclone or anticyclone) is far from being well understood.

A part of the numerically simulated direct head-on and overtaking collisions of Larichev–Reznik modons are elastic [84]. An instructive feature of the head-on collisions is that the identity of all four vortices can be sometimes tracked during all the interaction phase (Fig. 10). The process resembles a collision of soft particle pairs connected by an elastic chain. Their oblique collisions generally are not elastic and may lead to the formation of new dipoles, tripoles, or to the destruction of the structures.

Effects in Higher Dimensions

Optical Spatial Solitons

Starting from the mid-1980s, various optical solitary entities have become a key arena for studies of the properties and interactions of solitary structures in multiple dimensions. The interest in these studies is continuously supported by a variety of existing and emerging applications of such solitons and their interactions in communication and computation technology (see also the entry ► Optical Computing). Another reason for the rapid progress in these studies is the relative ease of their generation in suitable materials, combined with the precision of contemporary optical experiments and the possibilities of precise control over almost every parameter [136,152]. They offered a lot of the further conceptual progress of soliton interactions through making possible 3D propagation of solitary entities in laboratory conditions, albeit in many cases these entities did not match the classical nomenclature of solitons. They were called solitary waves in the field for several decades, because the governing equations are not necessarily integrable and the interactions not necessarily elastic. Still their interaction at times shows amazingly elastic nature and they are commonly called optical spatial solitons (OSS) in the modern nonlinear optics nomenclature [136].

A large number of various kinds of OSSs have been identified [76,135]. Observations of spatial Kerr solitons became possible from the mid-1980s, when so-called slab waveguides were built [3,13]. Their behavior substantially depends on the dimensions of the soliton and the waveguide. For example, the bright Kerr solitons are stable only in planar systems whereas the 2D solitons were found to collapse. Quasi-stable 2D solitons in Kerr media described by the cubic NLS in two spatial dimensions exist in the form of so-called necklace-ring beams [143].

Optical spatial solitons occurring due to the saturation of the nonlinear change in the refractive index were first demonstrated in the 1970s [18] and realized in a solid medium in the 1990s [74]. The net effect of the multiple physical effects involved in photorefractive materials is that the underlying nonlinearities are also saturable. Such solitons were also discovered in the early 1990s [137] and were found to be stable in both slab waveguides [75] and in bulk media [38].

So-called quadratic solitons (that consist of multifrequency waves coupled by means of a second-order nonlinearity) were predicted in the mid-1970s [70] and realized experimentally in the 1990s [164]. They can be thought of as vector solitons because they involve mutual self-trapping of two or more components [152]. Their interactions are similar to those occurring in other saturable nonlinear media.

Coherent and Incoherent Collisions

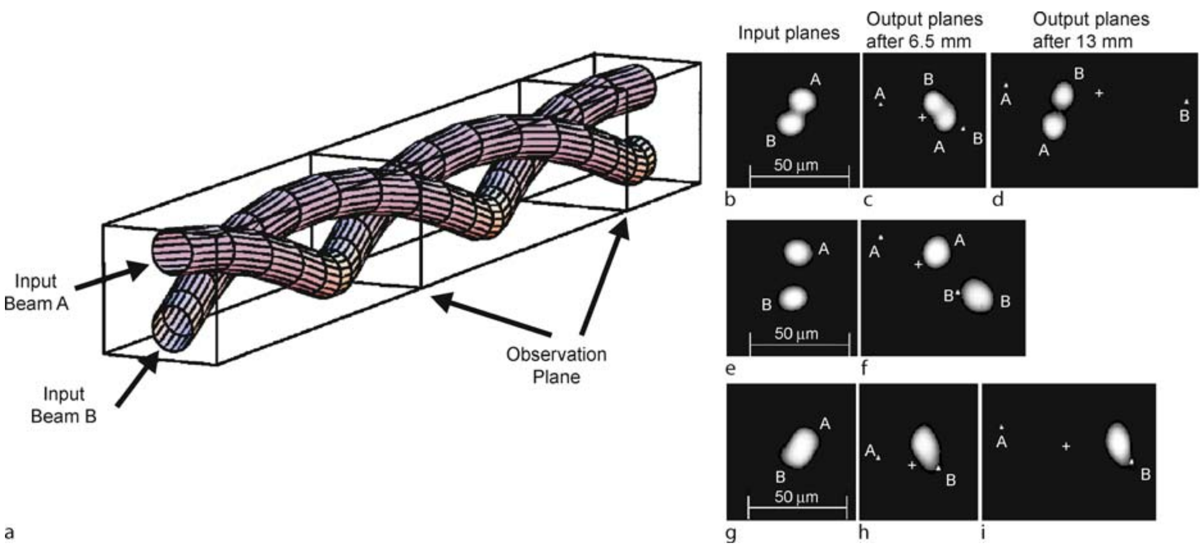
Coherent interactions of OSSs occur when the nonlinear medium responds quickly to the (interference) effects in the overlapping area of the beams. The increase of the intensity of light in the overlapping region of two parallel launched equivalent in-phase solitons in the focusing medium leads to an increase in the refractive index in that region. This in turn forces the centroid of each soliton toward it. Hence the solitons attract each other. The spatial distribution of the intensity of light resembles the temporal distribution of the amplitude of attracting interacting line solitons. In the case of antiphase beams, an opposite process occurs and such solitons exert repulsion. Coherent collisions of Kerr solitons have been demonstrated and the attraction for in-phase and the repulsion for antiphase solitons were clearly observed at the beginning of the 1990s [4,5,139]. The collision of nonequivalent coherent OSSs results in an energy exchange between the beams and in a repulsive force that makes the beams diverge.

Some reactions (e. g. photorefractive and thermal) of the optical medium are relatively slow. Solitons within which the phase varies randomly across the beam were first demonstrated in [95] and later extended to the beams of incoherent white light [94]. So-called incoherent soliton interactions occur when the response of the medium only follows the average intensity of light. Interactions of incoherent bright solitons are always attractive (Andersen and Lisak 1995).

The long-distance behavior of the counterparts in attractive interactions depends on the properties of the medium and the orientation of the beams. Pure Kerr solitons launched along nearly parallel directions result in periodic paths of the solitons' centroids. As in the case of the recurrence of the KdV solitons, Kerr solitons exactly return to their initial conditions after each cycle. Solitons launched under large enough converging angles exhibit a slight lateral deflection (which is equivalent to the phase shift of the KdV solitons). The solitons launched under large enough diverging angles never collide.

If the energy transfer were neglected, the force between the equivalent 1D Kerr solitons would vary from the maximum attractive between in-phase solitons to the maximum repulsive for antiphase solitons. This process leads to the (generally nonperiodic) energy transfer, where one soliton may gather net energy from the other. The details of the trajectories and other properties of the interacting solitons can be quite complex [152].

Interactions of 2D OSSs (e. g. in media with saturating nonlinearities) have a much larger variety of scenarios [152]; for example, interactions of incoherent photorefractive solitons may be both attractive and repulsive [156]. A number of resonance-like inelastic phenomena have been observed in which the number of solitons is not conserved. The *fusion* of two or more solitons into one structure resembles the resonance phenomenon. Here it happens owing to the gradual change of the orientation of the waveguides of attracting solitons launched under small relative angles into a new waveguide [48]. Differently from the resonance of line solitons, this happens for a certain range of initial parameters. The threshold is the maximum total internal reflection angle in the induced



Solitons Interactions, Figure 11

a The experimentally observed soliton spiraling process. The arrows indicate the initial trajectories. b, e, and g show different input conditions and c, f, and h are the outputs after 6.3 mm and d and i after 13 mm. The triangles indicate the centers of the corresponding diffracting beams. From [152]

waveguide [140,142]. For larger collision angles, the solitons interact as described above. The solitons can fuse together already on the first merging or after a certain number of oscillations of their trajectories with decreasing amplitudes and periods [12,78,160,161]. A sort of inverse of this process is the breakup (*fission*, [142]) of optical solitons into new solitons upon their interaction [163]. *Annihilation* of solitons upon collision also may occur, when three solitons collided and only two emerged from the collision process [79].

Three-Dimensional Effects

In 3D space the trajectories of interacting beam solitons do not necessarily lie on a single plane and the system possesses nonzero initial angular momentum. The trajectories of solitons that are launched along skew lines passing close to each other may bend in three dimensions. The solitons *spiraling* around each other form a double helix orbit [123], much like two celestial objects or two moving charged particles moving along nearly parallel trajectories do. The interaction generally leads to spiraling-fusion or spiraling-repulsion of the trajectories [14,160,161]. Since the mutual rotation encounters a centrifugal force (which is always repulsive), a perfect double-helix DNA-like system, an interesting class of elastic interactions, requires soliton attraction. It may be formed from identical in-phase coherent solitons; yet such a double helix is unstable with respect to perturbations of both the relative phase and amplitude of one of the solitons. This effect resembles processes occurring during the interactions of vortices of different and like sign in quasi-2D rotating fluids.

Attractive interactions of incoherent solitons have made possible the observation of spiraling solitons in saturable media [141]. The two solitons of equal power orbit periodically about each other. Such a pair conserves angular momentum and is more or less stable for a certain range of the initial orientation and distance between the beams. Although the underlying saturable nonlinearities are described by nonintegrable equations, the spiraling process does not lead to measurable energy radiation [20]. When the initial distance between the solitons is increased, they do not form a long-living interacting system. The double spiral for beams located initially very close to each other converges fast and the counterparts eventually fuse. The pair apparently has a limited lifetime. A likely reason for its fusion or off-spiraling is the potential coherence of the light in the beams.

Interactions of Vector Solitons

Vector (composite) solitons consist of two or more components (also called modes) that mutually self-trap in a nonlinear medium. The simplest vector solitons, first suggested by Manakov [88], consist of two orthogonally polarized components in a nonlinear Kerr medium in which self-phase modulation is identical to cross-phase modulation. They are described by an integrable system and interact elastically. An appropriate nonlinear material and experimental conditions for their demonstration were developed a long time after their discovery [68]. Similar solitons may exist if each field component is at a different frequency, and the frequency difference between components is much larger than the inverse of the nonlinearity relaxation time [138,166], or if the field components are incoherent with one another [22,30]. The energy exchange between the components of the interacting vector solitons takes place without radiative losses [7].

Vector solitons can also consist of different modes of their jointly induced waveguide [29,165]. These multimode solitons may possess multiple humps, may contain both bright and dark components [28,166], may have a certain internal dynamics, and were found to be stable (or weakly unstable) in large regions of their parameter space [96,109,110]. Interactions between vector solitons have, additionally to the above-discussed generic properties of solitons interactions (e. g. [86]), also some unique features. The shape transformations of colliding multimode solitons can lead to two different multimode solitons emerging from the collision process [6,69,80]. This "polarization switching" was predicted initially for Manakov solitons [125].

Composite multimode multihump solitons may carry topological charge in one of the vector components [21, 98]. This charge carried by a soliton of finite energy can be interpreted as spin of real particles. Elastic collisions of such 3D solitons should, ideally, conserve not only energy, and linear and angular momentum [122], but also the equivalent of spin. Two colliding composite solitons carrying opposite spins may form a metastable state that later decays into two or three new solitons. If the solitons interact under a certain critical angle, angular momentum is transferred from spin to orbital angular momentum. Finally, the shape transformation of the vortex component occurs at large collision angles, for which scalar solitons of all types simply go through one another unaffected or only have phase shifts [99,100]. The recent progress in optical vortices, vortex solitons, and their interactions is reviewed in [35].

Applications of Line Soliton Interactions

A generic use of soliton interactions in every case where solitary waves or topological solitons may exist, follows from the definition of a soliton. It consists of establishing if the structure is a solitonic one or not from the properties of their interactions.

The practical use of specific features of soliton interactions was started largely in parallel with the first technologies based on the use of solitons (e. g. optical soliton-based communications) more than a decade ago. The most promising is the technology of ▶ Optical Computing (see the relevant entry), which may be partially based on the interactions of vector solitons [155] and which may open completely new horizons in the architecture of computers.

Soliton Interactions on a Water Surface

Several applications based on properties of elastic soliton interactions (or changes of certain fields during such interactions) have been proposed in the framework of water waves. From the purely geometrical properties of oblique interactions of plane solitons one may extract, e. g., the water wave height. The relations for the phase shifts and for the intersection angle can be reduced to the following transcendental equation:

$$\delta_1 \sqrt{2a_1\left(1+\lambda^2/4\right)} = \pm \ln \frac{\delta_2^2\lambda^2 - 2\left(\delta_2-\delta_1\right)^2 a_1^2}{\delta_2^2\lambda^2 - 2\left(\delta_2+\delta_1\right)^2 a_1^2} \,. \quad (10)$$

If the intersection angle α_{12}, the phase shifts $\delta_{1,2}$ and their signs (or the wave propagation directions) are known, equation (10) uniquely defines the heights of the interacting solitons [118,119].

The phenomenon of drastic increase of surface elevation and slope of wave fronts described in Sect. "Geometry of Oblique Interactions of KP Line Solitons" can be attributed to formation of "freak" or "giant" waves in the ocean, the height and steepness of which are considerably larger than expected based on the classical wave statistics [73]. Their sudden appearance is a feature of paramount importance to and a generic source of danger for navigation and in coastal and offshore engineering. Interactions of envelope (Schrödinger) solitons and breather solutions of the NLS [108] in deep water are their potential source, although the model based on envelope soliton interactions underestimates the probability of large wave formation compared with the fully nonlinear model [31]. Interacting solitary wave groups that emerge from a long wave packet can produce freak wave events and may lead to a threefold increase of the wave slope [32].

The problem of extremely large-amplitude internal waves is by no means less important, as they can pose acute (currently neither well understood nor accounted for) danger for submarines, oil and gas platforms, oil risers and pipelines, and to other engineering constructions in relatively deep water. The problem of "freak" internal waves and their generation due to internal soliton interactions has only recently attracted the attention of researchers [81].

There is a clear potential in the use of the advances concerning the geometry of the line soliton interactions in studies of both internal and shallow water solitons. While phase shifts usually have no dynamical significance, unexpectedly large elevations, extreme slopes, or changes in orientation of wave crests owing to the (Mach) reflection or oblique interactions of solitonic waves frequently cause an acute danger. The particularly high (stem) waves may lead to hits by high waves arriving from an unexpected direction. They may break during propagation into shallow water and attack armor blocks from an unprotected side [89] or overtop the breakwaters in unexpected locations [172]. These effects may be particularly pronounced in the case of ship wakes that often approach seawalls or breakwaters from other directions than wind waves do [148]. The possibility of drastic steepening of the front of the near-resonant structure is immaterial in many physical systems but is a crucial component of danger from freak waves [73], since specifically steep and high waves present an acute danger (e. g. [162]). Even if the steepness of the wave front is not large in absolute terms, relatively steep and long, tsunami-like waves tend to become asymmetric and exhibit unexpectedly large runup heights [36].

The amplitude amplification, however, evidently becomes effective relatively seldom, because two or more systems of long-crested solitonic waves must approach a certain area from different directions, and extreme elevations and slopes only occur if the amplitudes of the interacting solitons, the angle between their crests and the water depth are specifically balanced. The long life-time of the resulting wave hump in favorable conditions [73] may drastically increase the probability of the occurrence of abnormally high waves.

Ship-Induced Solitons and Wave Resistance

An increasing source of solitonic waves is the fast ship traffic in relatively shallow areas. The generation of shallow-water solitons is most effective for large ships sailing at speeds roughly equal to the maximum phase speed $\sqrt{gh}$ of surface gravity waves [87]. The low decay rates and exceptional compactness of the solitonic ship wakes has led to a significant impact on the safety of people, property and craft, unusually high hydrodynamic loads in a part of the nearshore, and to a considerable remote impact of the ship traffic in shallow areas [112,147]. Such a wake has probably caused a fatal accident as far as about 10 km from the sailing line already in 1912 [149]. The interactions of ship-induced solitons may lead to dangerous waves in the vicinity of coastal fairways and harbor entrances in otherwise sheltered areas [120].

A intriguing use of soliton interactions, combining effects occurring during an elastic oblique interaction of shallow-water solitons, followed by an annihilation of solitons and forced antisolitons, has been made for reducing the wave resistance in channels [25] and for catamaran design [26]. In a channel, the bow wave reflected from a side wall is used to cancel the stern wave, whereas the bow wave of one hull of the catamaran is used to cancel the stern wave of the other hull. Its practical use is possible for ships sailing at near-critical speeds, the wake of which may consist of a single soliton. The adequate calculation of the phase shift occurring during its Mach reflection (equivalently, during the interaction of two bow solitons) is a key component in achieving a perfect annihilation of properly timed bow solitons and the sterns' waves of depression.

The use of this effect by adjusting the channel width, the water depth and the ship's speed probably is the first intentional use of the features occurring during soliton interactions in the design of a certain technology [23,24]. At the exact design conditions the reflected bow wave completely cancels the stern wave and leads to a sort of channel superconductivity [25]. The same effect may occur between two ships moving in parallel [65].

Finally, it is interesting to note that already J.S. Russell may have been aware of this possibility. He describes efforts of a spirited horse which, pulling a boat in a canal, had drawn the boat up into its own wave leading to a significant reduction in resistance. The boat owner had noted this, and the event led to 'high-speed' service on some canals in the 1820s and 1830s [131]. We shall probably never know if the decrease of wave resistance occurred due to simple crossing of the critical speed or owing to the channel superconductivity; however, even the remote possibility that the practical use of soliton interactions may have been reported even before the first report about solitons, is remarkable.

Future Directions

Although the theory of soliton interactions has been extensively developed during four decades and its basic features for low-dimensional environments have been well understood, it is still in the stage of rapid development. Its first practical applications appeared only a decade ago and there is evidently room for relevant developments in (geo)physical applications. Analysis of long-term evolution of ensembles of solitons is still a challenge and reveals ever new interesting features even in the simplest soliton-admitting systems such as the KdV equation. Although several formal procedures of building explicit multi-soliton solutions to many equations have been known since the 1970s, studies of properties of (optionally resonant) interactions of several line solitons only started at the turn of the millennium. Many fascinating features of elastic interactions of solitons of different kinds in more complex systems will obviously become evident in the nearest future. The results in this direction may largely widen understanding of the integrability of the underlying equations.

Extremely rapid progress may be expected in studies into properties of long-lived soliton-like structures, in particular, of optical spatial solitons. The classification of their nomenclature and interactions is far from being completed. This environment is the key framework for identifying the new features of soliton interactions in higher dimensions, even though interactions of such structures are not necessarily elastic.

Solitons, Introduction to

Mohamed A. Helal
Department of Mathematics, Faculty of Science,
Cairo University, Giza, Egypt

The concept of solitons reflects one of the most important developments in science at the second half of the 20th century: the nonlinear description of the world. It is not easy to give a comprehensive and precise definition of a soliton. Frequently, a *soliton* is explained as a spatially localized wave in a medium that can interact strongly with other solitons but will afterwards regain its original form.

It is a nonlinear pulse-like wave that can exist in some nonlinear systems. The soliton wave can propagate without dispersing its energy over a large region of space; collision of two solitons leads to unchanged forms, solitons also exhibit particle-like properties.

The most remarkable property of solitons is that they do not disperse and thus conserve their form during propagation and collision. ▶ Solitons Interactions.

The nonlinear science has been growing for approximately fifty years. However, numerous nonlinear processes had been previously identified, but the nonlinear mathematical tools were not developed. The available tools were linear, and nonlinearities were avoided or treated as perturbations of linear theories.

The first experimental observation of a solitary wave was made in August 1834 by a Scottish engineer named John Scott Russell (1808–1882). Scott Russell reported his observation; to the Fourteenth Meeting of the British Association for Advancement of Science, held in 1844; in a long report entitled: "Report on waves" as follows:

> "*I was observing the motion of a boat which was rapidly drawn along a narrow channel by a pair of horses, when the boat suddenly stopped – not so the mass of water in the channel which it had put in motion; it accumulated round the prow of the vessel in a state of violent agitation, then suddenly leaving it behind, rolled forward with great velocity, assuming the form of a large solitary elevation, a rounded, smooth and well-defined heap of water, which continued its course along the channel apparently without change of form or diminution of speed. I followed it on horseback, and overtook it still rolling on at a rate of some eight or nine miles an hour, preserving its original figure some thirty feet long and a foot to a foot and a half in height. Its height gradually diminished, and after a chase of one or two miles I lost it in the windings of the channel. Such, in the month of August 1834, was my first chance interview with that singular and beautiful phenomenon which I have called the Wave of Translation*".

This hump-shape localized wave that propagates along one space-direction with undeformed shape has spectacular stability properties. John Scott Russell carried out many experiments to get the properties of this wave. ▶ Solitons: Historical and Physical Introduction.

A model equation describing the unidirectional propagation of long waves in water of relatively shallow depth with a localized solution (representing a single hump as discovered by Russell) was obtained by Korteweg and de Vries. This equation has become very famous and is now known as the Korteweg–de Vries equation or KdV equation. ▶ Water Waves and the Korteweg–de Vries Equation.

There exists a certain class of nonlinear partial differential equations that leads to solitons. The Korteweg–de Vries equation, Kadomtsev–Petviashvili (KP) equation, Klein–Gordon (KG) equation, Sine–Gordon (SG) equation, nonlinear Schrodinger (NLS) equation, Korteweg–de Vries Burger's (KdVB) equation, etc… are some known equations that lie in this specific class of this NLPDE. This class of nonlinear equations has a special type of the traveling wave solutions which are either solitary waves or solitons. ▶ Partial Differential Equations that Lead to Solitons.

The Korteweg–de Vries equation is a canonical equation in nonlinear wave physics demonstrating the existence of solitons and their elastic interactions. This KdV equation attracted many authors to publish an enormous number of publications. Different analytical methods for solving this well-known equation are presented in ▶ Korteweg–de Vries Equation (KdV), Different Analytical Methods for Solving the.

One of the most famous analytical methods for solving the KdV equation is the *Inverse Scattering Transformation*. This method was first introduced by the well-known scientists Gardener, Green, Kruskal, and Miura. In 1967, Gardner et al. published a magnificent and original paper on the analytical solution to the initial value problem due to a disturbance of finite amplitude in an infinite domain. This systematic method is not easy, and needs several long steps to get the complete solution. ▶ Inverse Scattering Transform and the Theory of Solitons.

There are various algebraic and geometric characteristics that the KdV equation possesses. More significantly, a lot of physically important solutions to the KdV equation can be presented explicitly through a simple, specific form, called *the Hirota bilinear form*. More complicated types of solutions leading to N-solitons are presented in ▶ Korteweg–de Vries Equation (KdV), History, Exact *N*-Soliton Solutions and Further Properties of the.

It was suitable to search for an easier method to solve this famous and well-known nonlinear partial differential equation (KdV). Many semi-analytical methods have been developed and used to solve the KdV equation. The most popular and famous semi-analytical method that was introduced to solve this nonlinear partial differential equation (KdV), was the *Adomian Decomposition Method*. ▶ Adomian Decomposition Method Applied to Non-linear Evolution Equations in Soliton Theory.

Other semi-analytical methods like the variational iteration method (VIM), homotopy analysis method (HAM), and homotopy perturbation method (HPM) are usable to solve these types of NLPDE such as the Korteweg–de Vries equation and even the modified Korteweg–de Vries equation (mKdV). ▶ Korteweg–de Vries Equation (KdV) and Modified Korteweg–de Vries Equations (mKdV), Semi–analytical Methods for Solving the.

It is indispensable to introduce other methods to illustrate the solution of this NLPDE. The numerical technique is a powerful tool which is always needed to present and compare the results in the easiest manner. There exist different numerical tools for solving the KdV and mKdV equations, and even for any evolution equations ▶ Korteweg–de Vries Equation (KdV), Some Numerical Methods for Solving the.

In hydrodynamical problems, the motion of incompressible inviscid fluid subject to a constant vertical gravitational force (where the fluid is bounded below by an impermeable bottom and above by a free surface) with some physical assumptions lead to the shallow water model. The shallow water wave equations are usually used in oceanography and atmospheric science. The shallow water approximation theory leads to the KdV equation. This means that the soliton solution as well as the solitary waves are the straight forward solutions for many physical problems. ▶ Shallow Water Waves and Solitary Waves.

The study of the water waves in the Pacific Ocean leads directly to a special type of long gravity waves named *tsunamis*. This word is a Japanese one, which means harbor's wave.

A tsunami is essentially a long wavelength water wave train or a series of waves generated in a body of water (mostly in oceans) that vertically displaces the water column. Earthquakes, landslides, volcanic eruptions, nuclear explosions and the impact of cosmic bodies can generate tsunamis. Tsunamis, as they approach coastlines, can rise enormously and savagely attack and inundate to cause huge damage to properties and cost thousands of lives.

The theoretical study of waves in oceanography is very complicated. The simplest mathematical model includes the KdV equation. This KdV represents the governing equation that lead to tsunamis. ▶ Solitons, Tsunamis and Oceanographical Applications of.

The rapid change in water density with depth is called *Pycnocline*. This happens in open or closed seas, as well as in oceans. In the frame of shallow water approximation theory that governs the oceans, and due to the pycnocline the nonlinear internal gravity waves are presented. They arise from perturbations to hydrostatic equilibrium, where balance is maintained between the force of gravity and the buoyant restoring force. An illustrative study of nonlinear waves (that was generated inside a stratified fluid occupying a semi infinite channel of finite and constant depth by a wave maker situated in motion at the finite extremity of the channel) is presented in this section. ▶ Non-linear Internal Waves.

The soliton perturbation theory is used to study solitons that are governed by the various nonlinear equations in the presence of the perturbation terms. ▶ Soliton Perturbation.

A *compacton* is a special solitary traveling wave that, unlike a soliton, does not have exponential tails.

Another expression and terminology called *compacton-like soliton* is a special wave solution which can be expressed by the squares of sinusoidal or cosinusoidal functions.

Soliton and compacton are two kinds of nonlinear waves. They play an indispensable and vital role in all branches of science and technology, and are used as constructive elements to formulate the complex dynamical behavior of wave systems throughout science: from hydrodynamics to nonlinear optics, from plasmas to shock waves, from tornados to the Great Red Spot of Jupiter, and from tsunamis to turbulence. More recently, soliton and compacton have been of key importance in the quantum fields and nanotechnology especially in nano-hydrodynamics. ► Solitons and Compactons.

Solitons, Tsunamis and Oceanographical Applications of

Article Outline

Glossary

Soliton A class of nonlinear dispersive wave equations in (1+1) dimensions having a delicate balance between dispersion and nonlinearity admit localized solitary waves which under interaction retain their shapes and speeds asymptotically. Such waves are called solitons because of their particle like elastic collision property. The systems include Korteweg–de Vries, nonlinear Schrödinger, sine-Gordon and other nonlinear evolution equations. Certain (2+1) dimensional generalizations of these systems also admit soliton solutions of different types (plane solitons, algebraically decaying lump solitons and exponentially decaying dromions).

Shallow and deep water waves Considering surface gravity waves in an ocean of depth h, they are called shallow-water waves if $h \ll \lambda$, where λ is the wavelength (or from a practical point of view if $h < 0.07\lambda$). In the linearized case, for shallow water waves the phase speed $c = \sqrt{gh}$, where g is the acceleration due to gravity. Water waves are classified as deep (practically) if $h > 0.28\lambda$ and the corresponding wave speed is given by $c = \sqrt{g/k}$, $k = \frac{2\pi}{\lambda}$.

Tsunami Tsunami is essentially a long wavelength water wave train, or a series of waves, generated in a body of water (mostly in oceans) that vertically displaces the water column. Earthquakes, landslides, volcanic eruptions, nuclear explosions and impact of cosmic bodies can generate tsunamis. Propagation of tsunamis is in many cases in the form of shallow water waves and sometimes can be of the form of solitary waves/solitons. Tsunamis as they approach coastlines can rise enormously and savagely attack and inundate to cause devastating damage to life and property.

Internal solitons Gravity waves can exist not only as surface waves but also as waves at the interface between two fluids of different density. While solitons were first recognized on the surface of water, the commonest ones in oceans actually happen underneath, as internal oceanic waves propagating on the pycnocline (the interface between density layers). Such waves occur in many seas around the globe, prominent among them being the Andaman and Sulu seas.

Rossby solitons Rossby waves are typical examples of quasigeostrophic dynamical response of rotating fluid systems, where long waves between layers of the atmosphere as in the case of the Great Red Spot of Jupiter or in the barotropic atmosphere are formed and may be associated with solitonic structures.

Bore solitons The classic bore (also called mascaret, poroca and aeger) arises generally in funnel shaped estuaries that amplify incoming tides, tsunamis or storm surges, the rapid rise propagating upstream against the flow of the river feeding the estuary. The profile depends on the Froude number, a dimensionless ratio of intertial and gravitational effects. Slower bores can take on oscillatory profile with a leading dispersive shockwave followed by a train of solitons.

Definition of the Subject

Surface and internal gravity waves arising in various oceanographic conditions are natural sources where one can identify/observe the generation, formation and propagation of solitary waves and solitons. Unlike the standard progressive waves of linear dispersive type, solitary waves are localized structures with long wavelengths and finite energies and propagate without change of speed or form and are patently nonlinear entities. The earliest scientifically recorded observation of a solitary wave was made by John Scott Russel in August 1834 in the Union Canal connecting the Scottish cities of Glasgow and Edinburgh. The theoretical formulation of the underlying phenomenon was provided by Korteweg and de Vries in 1895 who deduced the now famous Korteweg–de Vries (KdV) equation admitting solitary wave solutions. With the insightful numerical and analytical investigations of Martin Kruskal and coworkers in the 1960s the KdV solitary waves have been shown to possess the remarkable property that under collision they pass through each other without change of shape or speed except for a phase shift and so they are solitons. Since then a large class of soliton possessing nonlinear dispersive wave equations such as the sine-Gordon, modified KdV (MKdV) and nonlinear Schrödinger (NLS) equations occurring in a wide range of physical phenomena have been identified.

Several important oceanographic phenomena which correspond to nonlinear shallow water wave or deep water wave propagation have been identified/interpreted in terms of soliton propagation. These include tsunamis, especially earthquake induced ones like the 1960 Chilean or 2004 Indian Ocean earthquakes, internal solitary waves arising in stratified stable fluids such as the ones observed in Andaman or Sulu seas, Rossby waves including the Giant Red Spot of Jupiter and tidal bores occurring in estuaries of rivers. Detailed observations/laboratory experiments and theoretical formulations based on water wave equations resulting in the nonlinear evolution equations including KdV, Benjamin–Ono, Intermediate Long Wave (ILW), Kadomtsev–Petviashivili (KP), NLS, Davey–Stewartson (DS) and other equations clearly establish the relevance of soliton description in such oceanographic events.

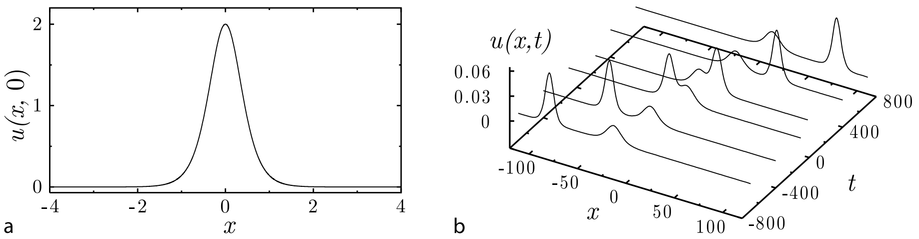
Introduction

Historically, the remarkable observation of John Scott Russel [1,2] of the solitary wave in the Union Canal connecting the cities of Edinburgh and Glasgow in the month of August 1834 may be considered as the precursor to the realization of solitons in many oceanographic phenomena. While riding on a horse back and observing the motion of boat drawn by a pair of horses which suddenly stopped but not so the mass of water it had set in motion, the wave (which he called the 'Great Wave of Translation') in the form of large solitary heap of water surged forward and travelled a long distance without *change of form or diminution of speed*. The wave observed by Scott Russel is nothing but a solitary wave having a remarkable staying power and a patently nonlinear entity. Korteweg and de Vries in 1895, starting from the basic equations of hydrodynamics and considering unidirectional shallow water wave propagation in rectangular channels, deduced [3] the now ubiquitous KdV equation as the underlying nonlinear evolution equation. It is a third order nonlinear partial differential equation in (1+1) dimensions with a delicate balance between dispersion and nonlinearity. It admits elliptic function cnoidal wave solutions and in a limiting form exact solitary wave solution of the type observed by John Scott Russel thereby vindicating his observations and putting to rest all the controversies surrounding them.

It was the many faceted numerical and analytical study of Martin Kruskal and coworkers [4,5] which firmly established by 1967 that the KdV solitary waves have the further remarkable feature that they are solitons having elastic collision property (Fig. 1).

It was proved decisively that the KdV solitary waves on collision pass through each other except for a finite phase shift, thereby retaining their forms and speeds asymptotically as in the case of particle like elastic collisions. The inverse scattering transform (IST) formalism developed for this purpose clearly shows that the KdV equation is a completely integrable infinite dimensional nonlinear Hamiltonian system and that it admits multisoliton solutions [6,7,8,9]. Since then a large class of nonlinear dispersive wave equations such as the sine-Gordon (s-G), modified Korteweg–de Vries (MKdV), NLS, etc. equations in (1+1) dimensions modeling varied physical phenomena have also been shown to be completely integrable soliton systems [6,7,8,9]. Interesting (2+1) dimensional versions of these systems such as Kadomtsev–Petviashvile (KP), Davey–Stewartson (DS) and Nizhnik–Novikov–Veselov (NNV) equations have also been shown to be integrable systems admitting basic nonlinear excitations such as line (plane) solitons, algebraically decaying lump solitons and exponentially localized dromion solutions [7,8].

It should be noted that not all solitary waves are solitons while the converse is always true. An example of a solitary wave which is not a soliton is the one which occurs in double-well $\lambda\phi^4$ wave equation which radiates energy on collision with another such wave. However even such solitary waves having finite energies are sometimes referred to as solitons in the condensed matter, particle physics and fluid dynamics literature because of their localized structure.



Solitons, Tsunamis and Oceanographical Applications of, Figure 1
KdV equation: a One soliton solution (solitary wave) at a fixed time, say $t = 0$, b Two soliton solution (depicting elastic collision)

As noted above solitary waves and solitons are abundant in oceanographic phenomena, especially involving shallow water wave and deep water wave propagations. However, these events are large scale phenomena very often difficult to measure experimentally, rely mostly on satellite and other indirect observations and so controversies and differing interpretations do exist in ascribing exact solitonic or solitary wave properties to these phenomena. Yet it is generally realized that many of these events are closely identifiable with solitonic structures. Some of these observations deserve special attention.

Tsunamis

When large scale earthquakes, especially of magnitude 8.0 in Richter scale and above, occur in seabeds at appropriate geological faults tsunamis are generated and can propagate over large distances as small amplitude and long wavelength structures when shallowness condition is satisfied. Though the tsunamis are hardly felt in the midsea, they take monstrous structures when they approach land masses due to conservation of energy. The powerful Chilean earthquake of 1960 [10] led to tsunamis which propagated for almost fifteen hours before striking Hawaii islands and a further seven hours later they struck the Japanese islands of Honshu and Hokkaido. More recently the devastating Sumatra–Andaman earthquake of 2004 in the Indian Ocean generated tsunamis which not only struck the coastlines of Asian countries including Indonesia, Thailand, India and Srilanka but propagated as far as Somalia and Kenya in Africa, killing more than a quarter million people. There is very good sense in ascribing soliton description to such tsunamis.

Internal Solitons

Peculiar striations, visible on satellite photographs of the surface of the Andaman and Sulu seas in the far east (and in many other oceans around the globe), have been interpreted as secondary phenomena accompanying the passage of “internal solitons”. These are solitary wavelike distortions of the boundary layer between the warm upper layer of sea water and cold lower depths. These internal solitons are travelling ridges of warm water, extending hundreds of meters down below the thermal boundary, and carry enormous energy. Osborne and Burch [11] investigated the underwater currents which were experienced by an oil rig in the Andaman sea, which was drilling at a depth of 3600 ft. One drilling rig was apparently spun through ninety degrees and moved one hundred feet by the passage of a soliton below.

Rossby Waves and Solitons

Rossby waves [12] are long waves between layers of the atmosphere, created by the rotation of the planet. In particular, in the atmosphere of a rotating planet, a fluid particle is endowed with a certain rotation rate, determined by its latitude. Consequently its motion in the north-south direction is constrained by the conservation of angular momentum as in the case of internal waves where gravity inhibits the vertical motion of a density stratified fluid. There is an analogy between internal waves and Rossby waves under suitable conditions. The KdV equation has been proposed as a model for the evolution of Rossby solitons [13] and NLS equation for the evolution of Rossby wave packets. The Great Red Spot of the planet of Jupiter is often associated with a Rossby soliton.

Bore Solitons

Rivers which flow to the open oceans are very often affected by tidal effects, tsunamis or storm surges. Tidal motions generate intensive water flows which can propagate upstream on tens of kilometers in the form of step-wise perturbation (hydraulic jumps) analogous to shock waves in acoustics. This phenomenon is known as a bore or mascaret (in French). Examples of such bores include the tidal bore of Seine river in France, Hooghly bore of the Ganges in India, the Amazon river bore in Brazil and Hangzhou bore in China. Bore disintegration into solitons is a possible phenomenon in such bores [14].

Besides these there are other possible oceanographic phenomena such as capillary wave solitons [15], resonant three-wave or four wave interaction solitons [16], etc., where also soliton picture is useful.

In this article we will first point out how in shallow channels the long wavelength wave propagation is described by KdV equation and its generalizations (Sect. "Shallow Water Waves and KdV Type Equations"). Then we will briefly point out how NLS family of equations arise naturally in the description of deep water waves (Sect. "Deep Water Waves and NLS Type Equations"). Based on these details, we will point how the soliton picture plays a very important role in the understanding of tsunami propagation (Sect. "Tsunamis as Solitons"), generation of internal solitons (Sect. "Internal Solitons"), formation of Rossby solitons (Sect. "Rossby Solitons") and disintegration of bores into solitons (Sect. "Bore Solitons").

Shallow Water Waves and KdV Type Equations

Kortweg and de Vries [3] considered the wave phenomenon underlying the observations of Scott Russel from first principles of fluid dynamics and deduced the KdV equation to describe the unidirectional shallow water wave propagation in one dimension.

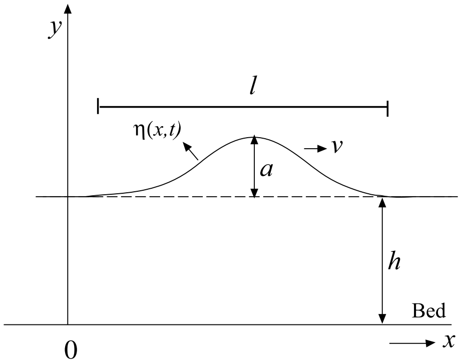
Consider the one-dimensional (x-direction) wave motion of an incompressible and inviscid fluid (water) in a shallow channel of height h, and of sufficient width with uniform cross-section leading to the formation of a solitary wave propagating under gravity. The effect of surface tension is assumed to be negligible. Let the length of the wave be l and the maximum value of its amplitude, $\eta(x,t)$, above the horizontal surface be a (see Fig. 2).

Then assuming $a \ll h$ (shallow water) and $h \ll l$ (long waves), one can introduce two natural small parameters into the problem $\epsilon = a/h$ and $\delta = h/l$. Then the analysis proceeds as follows [3,6].

Equation of Motion: KdV Equation

The fluid motion can be described by the velocity vector $\boldsymbol{V}(x,y,t) = u(x,y,t)\boldsymbol{i} + v(x,y,t)\boldsymbol{j}$, where $\boldsymbol{i}$ and $\boldsymbol{j}$ are the unit vectors along the horizontal and vertical directions, respectively. As the motion is irrotational, we have $\nabla \times \boldsymbol{V} = 0$. Consequently, we can introduce the velocity potential $\phi(x,y,t)$ by the relation $\boldsymbol{V} = \nabla\phi$.

Conservation of Density The system obviously admits the conservation law for the mass density $\rho(x,y,t)$ of the fluid, $\mathrm{d}\rho/\mathrm{d}t = \rho_t + \nabla\cdot(\rho\boldsymbol{V}) = 0$. As ρ is a constant, we have $\nabla\cdot\boldsymbol{V} = 0$. Consequently ϕ obeys the Laplace equation



Solitons, Tsunamis and Oceanographical Applications of, Figure 2
One-dimensional wave motion in a shallow channel

$$\nabla^2\phi(x,y,t) = 0\,. \tag{1}$$

Euler's Equation As the density of the fluid $\rho = \rho_0 =$ constant, using Newton's law for the rate of change of momentum, we can write $\mathrm{d}\boldsymbol{V}/\mathrm{d}t = \partial\boldsymbol{V}/\partial t + (\boldsymbol{V}\cdot\nabla)\,\boldsymbol{V} = -\frac{1}{\rho_0}\nabla p - g\boldsymbol{j}$, where $p = p(x,y,t)$ is the pressure at the point (x,y) and g is the acceleration due to gravity, which is acting vertically downwards (here $\boldsymbol{j}$ is the unit vector along the vertical direction). Since $\boldsymbol{V} = \nabla\phi$ we obtain (after one integration)

$$\phi_t + \frac{1}{2}(\nabla\phi)^2 + \frac{p}{\rho_0} + gy = 0\,. \tag{2}$$

Boundary Conditions The above two Eqs. (1) and (2) for the velocity potential $\phi(x,y,t)$ of the fluid have to be supplemented by appropriate boundary conditions, by taking into account the fact (see Fig. 2) that (a) the horizontal bed at $y = 0$ is hard and (b) the upper boundary $y = y(x,t)$ is a free surface. As a result
(a) the vertical velocity at $y = 0$ vanishes, $v(x,0,t) = 0$, which implies

$$\phi_y(x,0,t) = 0\,. \tag{3}$$

(b) As the upper boundary is free, let us specify it by $y = h + \eta(x,t)$ (see Fig. 2). Then at the point $x = x_1, y = y_1 \equiv y(x,t)$, we can write $\frac{\mathrm{d}y_1}{\mathrm{d}t} = \frac{\partial\eta}{\partial t} + \frac{\partial\eta}{\partial x}\cdot\frac{\mathrm{d}x_1}{\mathrm{d}t} = \eta_t + \eta_x u_1 = v_1$. Since $v_1 = \phi_{1y}$, $u_1 = \phi_{1x}$, we obtain

$$\phi_{1y} = \eta_t + \eta_x\phi_{1x}\,. \tag{4}$$

(c) Similarly at $y = y_1$, the pressure $p_1 = 0$. Then from (2), it follows that

$$u_{1t} + u_1 u_{1x} + v_1 v_{1x} + g\eta_x = 0\,. \tag{5}$$

Thus the motion of the surface of water wave is essentially specified by the Laplace Eq. (1) and Euler Eq. (2) along with one fixed boundary condition (3) and two *variable nonlinear* boundary conditions (4) and (5). One has to then solve the Laplace equation subject to these boundary conditions.

Taylor Expansion of $\boldsymbol{\phi(x,y,t)}$ in $\boldsymbol{y}$ Making use of the fact $\delta = h/l \ll 1$, $h \ll l$, we assume $y(= h + \eta(x,t))$ to be small to introduce the Taylor expansion

$$\phi(x,y,t) = \sum_{n=0}^{\infty} y^n \phi_n(x,t)\,. \tag{6}$$

Substituting the above series for ϕ into the Laplace Eq. (1), solving recursively for $\phi_n(x,t)$'s and making use of the boundary condition (4), $\phi_y(x,0,t) = 0$, one can show that

$$u_1 = \phi_{1x} = f - \frac{1}{2} y_1^2 f_{xx} + \text{ higher order in } \; y_1\,, \tag{7}$$

$$v_1 = \phi_{1y} = -y_1 f_x + \frac{1}{6} y_1^3 f_{xxx} + \text{ higher order in } \; y_1\,, \tag{8}$$

where $f = \partial\phi_0/\partial x$. We can then substitute these expressions into the nonlinear boundary conditions (4) and (5) to obtain equations for f and η.

Introduction of Small Parameters $\boldsymbol{\epsilon}$ and $\boldsymbol{\delta}$ So far the analysis has not taken into account fully the shallow nature of the channel $(a/h = \epsilon \ll 1)$ and the solitary nature of the wave $(a/l = a/h \cdot h/l = \epsilon\delta \ll 1$, $\epsilon \ll 1$, $\delta \ll 1)$, which are essential to realize the Scott Russel phenomenon. For this purpose one can stretch the independent and dependent variables in the above equations through appropriate scale changes, but retaining the overall form of the equations. To realize this one can introduce the natural scale changes

$$x = lx'\,, \quad \eta = a\eta', \quad t = \frac{l}{c_0} t'\,, \tag{9}$$

where c_0 is a parameter to be determined. Then in order to retain the form of (7) and (8) we require

$$\begin{aligned} u_1 &= \epsilon c_0 u_1'\,, \quad v_1 = \epsilon\delta c_0 v_1'\,, \quad f = \epsilon c_0 f', \\ y_1 &= h + \eta(x,t) = h\left(1 + \epsilon\eta'\left(x', t'\right)\right)\,. \end{aligned} \tag{10}$$

Then

$$u_1' = f' - \frac{1}{2}\delta^2\left(1 + \epsilon\eta'\right)^2 f'_{x'x'} = f' - \frac{1}{2}\delta^2 f'_{x'x'}\,, \tag{11}$$

where we have omitted terms proportional to $\delta^2\epsilon$ as small compared to terms of the order δ^2. Similarly from (8), we obtain

$$v_1' = -\left(1 + \epsilon\eta'\right) f'_{x'} + \frac{1}{6}\delta^2 f'_{x'x'x'}\,. \tag{12}$$

Now considering the nonlinear boundary condition (4) in the form $v_1 = \eta_t + \eta_x u_1$, it can be rewritten as

$$\eta'_{t'} + f'_{x'} + \epsilon\eta' f'_{x'} + \epsilon f'\eta'_{x'} - \frac{1}{6}\delta^2 f'_{x'x'x'} = 0\,. \tag{13}$$

Similarly considering the other boundary condition (5) and making use of the above transformations, it can be rewritten, after neglecting terms of the order $\epsilon^2\delta^2$, as

$$f'_{t'} + \epsilon f' f'_{x'} + \frac{ga}{\epsilon c_0^2}\eta'_{x'} - \frac{1}{2}\delta^2 f'_{x'x't'} = 0\,. \tag{14}$$

Now choosing the arbitrary parameter c_0 as $c_0^2 = gh$ so that $\eta'_{x'}$ term is of order unity, (14) becomes

$$f'_{t'} + \eta'_{x'} + \epsilon f' f'_{x'} - \frac{1}{2}\delta^2 f'_{x'x't'} = 0\,. \tag{15}$$

(Note that $c_0 = \sqrt{gh}$ is nothing but the speed of the water wave in the linearized limit). Omitting the primes for convenience, the evolution equation for the amplitude of the wave and the function related to the velocity potential reads

$$\eta_t + f_x + \epsilon\eta f_x + \epsilon f\eta_x - \frac{1}{6}\delta^2 f_{xxx} = 0\,, \tag{16}$$

$$f_t + \eta_x + \epsilon f f_x - \frac{1}{2}\delta^2 f_{xxt} = 0\,. \tag{17}$$

Note that the small parameters ϵ and δ^2 have occurred in a natural way in (16), (17).

Perturbation Analysis Since the parameters ϵ and δ^2 are small in (16), (17), we can make a perturbation expansion of f in these parameters:

$$f = f^{(0)} + \epsilon f^{(1)} + \delta^2 f^{(2)} + \text{ higher order terms}\,, \tag{18}$$

where $f^{(i)}$, $i = 0, 1, 2, \ldots$ are functions of η and its spatial derivatives. Note that the above perturbation expansion is an asymptotic expansion. Substituting this into Eqs. (16) and (17) and regrouping and comparing different powers proportional to (ϵ, δ^2) and solving them successively one can obtain (see for example [6] for further details) in a self consistent way,

$$f^{(0)} = \eta, \quad f^{(1)} = -\frac{1}{4}\eta^2, \quad f^{(2)} = \frac{1}{3}\eta_{xx}. \tag{19}$$

Using these expressions into (18) and substituting it in (16) and (17), we ultimately obtain the KdV equation in the form

$$\eta_t + \eta_x + \frac{3}{2}\epsilon\eta\eta_x + \frac{\delta^2}{6}\eta_{xxx} = 0, \tag{20}$$

describing the unidirectional propagation of long wavelength shallow water waves.

The Standard (Contemporary) Form of KdV Equation

Finally, changing to a moving frame of reference, $\xi = x - t$, $\tau = t$, and introducing the new variables $u = (3\epsilon/2\delta^2)\eta$, $\tau' = (6/\delta^2)\tau$ and redefining the variables τ' as t and ξ as x, we finally arrive at the ubiquitous form of the KdV equation as

$$u_t + 6uu_x + u_{xxx} = 0. \tag{21}$$

The Korteweg–de Vries Eq. (21) admits cnoidal wave solution and in the limiting case solitary wave solution as well. This form can be easily obtained [6,17] by looking for a wave solution of the form $u = 2f(\xi)$, $\xi = (x - ct)$, and reducing the KdV equation into a third order nonlinear ordinary differential equation of the form

$$-c\frac{\partial f}{\partial \xi} + 12f\frac{\partial f}{\partial \xi} + \frac{\partial^3 f}{\partial \xi^3} = 0. \tag{22}$$

Integrating Eq. (22) twice and rearranging, we can obtain

$$\left(\frac{\partial f}{\partial \xi}\right)^2 = -4f^3 + cf^2 - 2df - 2b \equiv P(f), \tag{23}$$

where b and d are integration constants. Calling the three real roots of the cubic equation $P(f) = 0$ as α_1, α_2 and α_3 such that

$$\left(\frac{\partial f}{\partial \xi}\right)^2 = -4(f - \alpha_1)(f - \alpha_2)(f - \alpha_3), \tag{24}$$

the solution can be expressed in terms of the Jacobian elliptic function as

$$f(\xi) = f(x - ct) = \alpha_3 - (\alpha_3 - \alpha_2)\mathrm{sn}^2 \cdot \left[\sqrt{\alpha_3 - \alpha_1}\,(x - ct), m\right], \tag{25a}$$

where

$$(\alpha_1 + \alpha_2 + \alpha_3) = \frac{c}{4}, \quad m^2 = \frac{\alpha_3 - \alpha_2}{\alpha_3 - \alpha_1}, \quad \delta = \text{constant}. \tag{25b}$$

Here m is the modulus parameter of the Jacobian elliptic function. Eq. (25a) represents in fact the so called cnoidal wave (because of its elliptic function form). In the limiting case $m = 1$, the form (25a) reduces to

$$f = \alpha_2 + (\alpha_3 - \alpha_2)\ \mathrm{sech}^2\left[\sqrt{\alpha_3 - \alpha_1}\,(x - ct)\right]. \tag{26}$$

Choosing now $\alpha_1 = 0$, $\alpha_2 = 0$, and using (25b) we have

$$f = \frac{c}{4}\ \mathrm{sech}^2\left[\frac{\sqrt{c}}{2}\,(x - ct)\right]. \tag{27}$$

Then the solitary wave solution to the KdV Eq. (21) can be written in the form

$$u(x,t) = \frac{c}{2}\mathrm{sech}^2\frac{\sqrt{c}}{2}(x - ct + \delta), \quad \delta : \text{constant} \tag{28}$$

Note that the velocity of the solitary wave is directly proportional to the amplitude: larger the wave the higher is the speed. More importantly, the KdV solitary wave is a soliton: it retains its shape and speed upon collision with another solitary wave of different amplitude, except for a phase shift, see Fig. 1 [6,7,8]. In fact for an arbitrary initial condition, the solution of the Cauchy initial value problem consists of N-number of solitons of different amplitudes in the background of small amplitude dispersive waves. All these results ultimately lead to the result that the KdV equation is a completely integrable, infinite dimensional, nonlinear Hamiltonian system. It possesses [6,7,8]

(i) a Lax pair of linear differential operators and is solvable through the so called inverse scattering transform (IST) method,
(ii) infinite number of conservation laws and associated infinite number of involutive integrals of motion,
(iii) N-soliton solution,
(iv) Hirota bilinear form,
(v) Hamiltonian structure

and a host of other interesting properties (see for example [6,7,8,9]).

KdV Related Integrable and Nonintegrable NLEEs

Depending on the actual physical situation, the derivation of the shallow water wave equation can be suitably modified to obtain other forms of nonlinear dispersive wave equations in (1+1) dimensions as well as in (2+1) dimensions relevant for the present context. Without going into the actual derivations, some of the important equations possessing solitary waves are listed below [6,7,8,9].

1. Boussinesq equation [7]

$$u_t + uu_x + g\eta_x - \frac{1}{3}h^2 u_{txx} = 0, \tag{29a}$$

$$\eta_t + [u(h+\eta)]_x = 0 \tag{29b}$$

2. Benjamin–Bona–Mahoney (BBM) equation [18]

$$u_t + u_x + uu_x - u_{xxt} = 0 \tag{30}$$

3. Camassa–Holm equation [19]

$$u_t + 2\kappa u_x + 3uu_x - u_{xxt} = 3u_x u_{xx} + uu_{xxx} \tag{31}$$

4. Kadomtsev–Petviashville (KP) equation [7]

$$(u_t + 6uu_x + u_{xxx})_x + 3\sigma^2 u_{yy} = 0 \tag{32}$$

($\sigma^2 = -1$: KP-I, $\sigma^2 = +1$: KP-II).

In the derivation of the above equations, generally the bottom of water column or fluid bed is assumed to be flat. However in realistic situations the water depth varies as a function of the horizontal coordinates. In this situation, one often encounters inhomogeneous forms of the above wave equations. Typical example is the variable coefficient KdV equation [14]:

$$u_t + f(x,t)uu_x + g(x,t)u_{xxx} = 0, \tag{33}$$

where f and g are functions of x, t. More general forms can also be deduced depending upon the actual situations, see for example [14].

Deep Water Waves and NLS Type Equations

Deep water waves are strongly dispersive in contrast to the weakly dispersive nature of the shallow water waves (in the linear limit). Various authors (see for details [8]) have shown that nonlinear Schrödinger family of equations models the evolution of a packet of surface waves in this case. There are several oceanographic situations where such waves can arise [8]:

(i) A localized storm at sea can generate a wide spectrum of waves, which then propagates away from the source region in all horizontal directions. If the propagating waves have small amplitudes and encounter no wind away from the source region, these waves can eventually sort themselves into nearly one-dimensional packets of nearly monochromatic waves. For appropriately chosen scales, the underlying evolution of each of these packets can be shown to satisfy the nonlinear Schrödinger equation and its generalizations in (2+1) dimensions.

(ii) Nearly monochromatic, nearly one-dimensional waves can cover a broad range of surface waves in the sea that results due to a steady wind of long duration and fetch. Then the generalization of the NLS equation in (2+1) dimensions can describe the waves that result in when the wind stops.

In all the above situations one looks for the solution of the equations of motion (1)-(5) but generalized in three dimensions which consists mainly in the form of a small amplitude, nearly monochromatic, nearly one-dimensional wave train. Assuming that this wave train travels in the x-direction with a mean wave number $\boldsymbol{\kappa} = (k, l)$ with a characteristic amplitude 'a' of the disturbance and a characteristic variation δk in k, one can deduce the NLS equation in (2+1) dimensions under the following conditions:

(i) small amplitudes such that $\hat{\epsilon} = \epsilon\delta \equiv \kappa a \ll 1$
(ii) slowly varying modulations, $\frac{\delta k}{\kappa} \ll 1$
(iii) nearly one dimensional waves, $\frac{|l|}{k} \ll 1$
(iv) balance of all three effects, $\frac{\delta k}{\kappa} = \frac{|l|}{k} \approx O(\hat{\epsilon})$
(v) for finite and deep water waves, $(kh)^2 \gg \hat{\epsilon}$

In the lowest order approximation (linear approximation) of water waves, the prediction is that a localized initial state will generally evolve into wave packets with a dominant wave number $\boldsymbol{\kappa}$ and corresponding frequence ω, given by the dispersion relation $\omega = (g\kappa + \sigma\kappa^3)\tanh\kappa h$, $\kappa = |\boldsymbol{\kappa}| = \sqrt{k^2 + l^2}$ within which each wave propagates with the phase speed $c = \omega/k$, while the envelope propagates with the group velocity $c_g = \mathrm{d}\omega/\mathrm{d}\kappa$. After a sufficiently long time the wave packet tends to disperse around the dominant wave number.

This tendency for dispersion can be offset by cumulative nonlinear effects. In the absence of surface tension, the outcome for unidirectional waves can be shown to be describable by the NLS equation. If the surface wave in the lowest order is $\phi \approx A\exp i(kx - \omega t)$+c.c, where ϕ is the velocity potential, then to leading order the wave amplitude evolves as

$$i(A_t + c_g A_x) + \frac{1}{2}\lambda A_{xx} + \mu|A|^2 A = 0. \tag{34}$$

The coefficients here are given by

$$\lambda = \frac{\partial^2 \omega}{\partial k^2}\,,$$
$$\mu = -\frac{\omega k^2}{16 S^4}(8C^2 S^2 + g - 2T^2) + \frac{\omega}{8C^2 S^2}\frac{(2\omega C^2 + k c_g)^2}{(gh - c_g^2)}\,, \tag{35}$$

where $C = \cosh(kh)$, $S = \sinh(kh)$, $T = \frac{S}{C}$. Equation (34) has been obtained originally by Zakharov in 1968 for deep water waves [20] and by Hasimoto and Ono for waves of finite depth in 1972 [21].

The NLS equation is also a soliton possessing integrable system and is solvable by the IST method [6,7,8,9]. For $\lambda > 0$ (focusing case), the envelope solitary (soliton) wave solution (also called bright solitons in the optical physics context) is given by

$$A(x,t) = a\, \text{sech}\gamma(x - c_g t)\exp(-i\Omega t)\,, \tag{36}$$

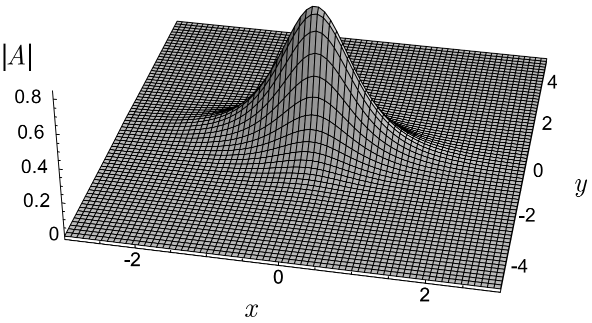
where $\mu a^2 = \lambda \gamma^2$, $\Omega = +\frac{1}{2}\mu a^2$.

When the effects of modulation in the transverse y-direction are taken into account, so that the wave amplitude is now given by $A(x,y,t)$, the NLS equation is replaced by the Benney–Roskes system [22] also popularly known as the Davey–Stewartson equations [23],

$$i(A_t + c_g A_x) + \frac{1}{2}\lambda A_{xx} + \frac{1}{2}\delta A_{yy} + \mu|A|^2 A + UA = 0\,, \tag{37a}$$

$$\alpha U_{xx} + U_{yy} + \beta(|A|^2)_{yy} = 0\,, \tag{37b}$$

where $\delta = \frac{c_g}{k}$, $\alpha = 1 - \left(\frac{c_g^2}{gh}\right)$, $gh\beta = \frac{\omega}{8C^2S^2}(2\omega C^2 + kc_g)^2$. Here $U(x,y,t)$ is the wave induced mean flow. In the deep water wave limit, $kh \to \infty$, and $U \to 0$, $\beta \to 0$ and one has the nonintegrable (2+1) dimensional NLS equation. On the other hand in the shallow water limit, one has the integrable Davey–Stewartson (DS) equations. For details see [7,8]. The DS-I equation admits algebraically decaying lump solitons and exponentially decaying dromions [24] besides the standard line solitons for appropriate choices of parameters. A typical dromion solution of DS-I equation is shown in Fig. 3.

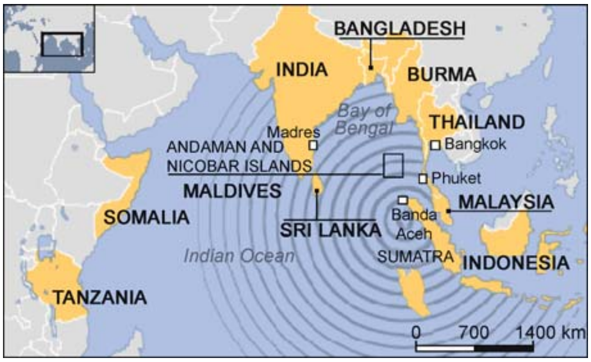


Solitons, Tsunamis and Oceanographical Applications of, Figure 3
Exponentially localized dromion solution of the Davey–Stewartson equation at a fixed time ($t = 0$) for suitable choice of parameters

Tsunamis as Solitons

The term ‘tsunami’ (tsu:harbour, nami:wave in Japanese) which was perhaps an unknown word even for scientists in countries such as India, Srilanka, Thailand, etc. till recently has become a house-hold word since that fateful morning of December 26, 2004. When a powerful earthquake of magnitude 9.1–9.3 on the Richter scale, epicentered off the coast of Sumatra, Indonesia, struck at 07:58:53, local time, described as the 2004 Indian Ocean earthquake or Sumatra–Andaman earthquake (Fig. 4), it triggered a series of devastating tsunamis as high as 30 meters that spread throughout the Indian Ocean killing about 275,000 people and inundating coastal communities across South and Southeast Asia, including parts of Indonesia, Srilanka, India and Thailand and even reaching as far as the east coast of Africa [25]. The catastrophe is considered to be one of the deadliest disasters in modern history.

Since this earthquake and consequent tsunamis, several other earthquakes of smaller and larger magnitudes keep occurring off the coast of Indonesia. Even as late as July 17, 2006 an earthquake of magnitude 7.7 on the Richter scale struck off the town of Pandering at 15.19 lo-



Solitons, Tsunamis and Oceanographical Applications of, Figure 4
26 December 2004 Indian Ocean tsunami (adapted from the website www.blogaid.org.uk with the courtesy of Andy Budd)

cal time and set off a tsunami of 2m high which had killed more than 300 people.

These tsunamis, which can become monstrous tidal waves when they approach coastline, are essentially triggered due to the sudden vertical rise of the seabed by several meters (when earthquake occurs) which displaces massive volume of water. The tsunamis behave very differently in deep water than in shallow water as pointed out below. By no means the tsunami of 2004 and later ones are exceptional; More than two hundred tsunamis have been recorded in scientific literature since ancient times. The most notable earlier one is the tsunami triggered by the powerful earthquake (9.6 magnitude) off southern Chile on May 22, 1960 [10] which traveled almost 22 hours before striking Japanese islands.

It is clear from the above events that the tsunami waves are fairly permanent and powerful ones, having the capacity to travel extraordinary distances without practically diminishing in size or speed. In this sense they seem to have considerable resemblance to shallow water nonlinear dispersive waves of KdV type, particularly solitary waves and solitons. It is then conceivable that tsunami dynamics has close connection with soliton dynamics.

Basics of Tsunami Waves

As noted above tsunami waves of the type described above are essentially triggered by massive earthquakes which lead to vertical displacement of a large volume of water. Other possible reasons also exist for the formation and propagation of tsunami waves: underwater nuclear explosion, larger meteorites falling into the sea, volcano explosions, rockslides, etc. But the most predominant cause of tsunamis appear to be large earthquakes as in the case of the Sumatra–Andaman earthquake of 2004. Then there are three major aspects associated with the tsunami dynamics [26]:

1. Generation of tsunamis
2. Propagation of tsunamis
3. Tsunami run up and inundation

There exist rather successful models to approach the generation aspects of tsunamis when they occur due to the earthquakes [27]. Using the available seismic data it is possible to reconstruct the permanent deformation of the sea bottom due to earthquakes and simple models have been developed (see for example, [28]). Similarly the tsunami run up and inundation problems [29] are extremely complex and they require detailed critical study from a practical point of view in order to save structures and lives when a tsunami strikes.

However, here we will be more concerned with the propagation of tsunami waves and their possible relation to wave propagation associated with nonlinear dispersive waves in shallow waters. In order to appreciate such a possible connection, we first look at the typical characteristic properties of tsunami waves as in the case of 2004 Indian Ocean tsunami waves or 1960 Chilean tsunamis.

The Indian Ocean Tsunami of 2004

Considering the Indian Ocean 2004 tsunami, satellite observations after a couple of hours after the earthquake establish an amplitude of approximately 60 cms in the open ocean for the waves. The estimated typical wavelength is about 200 kms [30]. The maximum water depth h is between 1 and 4 kms. Consequently, one can identify in an average sense the following small parameters (ϵ and δ^2) of roughly equal magnitude:

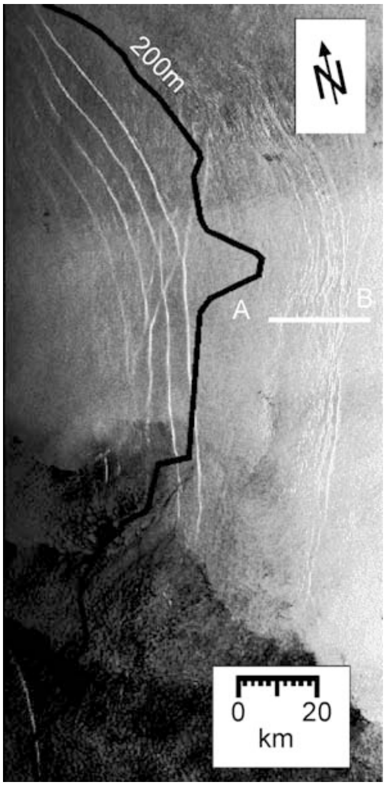
$$\epsilon = \frac{a}{h} \approx 10^{-4} \ll 1, \quad \delta^2 = \frac{h^2}{l^2} \approx 10^{-4} \ll 1 \tag{38}$$

As a consequence, it is possible that a nonlinear shallow water wave theory where dispersion (KdV equation) also plays an important role (as discussed in Sect. "Shallow Water Waves and KdV Type Equations") has considerable relevance [26]. However, we also wish to point out here that there are other points of view: Constantin and Johnson [31] estimate $\epsilon \approx 0.002$ and $\delta \approx 0.04$ and conclude that for both nonlinearity and dispersion to become significant the quantity $\delta\epsilon^{-3/2}\times$wavelength estimated as 90,000 kms is too large and shallow water equations with variable depth (without dispersion) should be used. However, it appears that these estimates can vary over a rather wide range and with suitable estimates it is possible that the range of 10,000–20,000 kms could be also possible ranges and hence taking into account the fact that both the Indian Ocean 2004 and Chilean 1960 tsunamis have traveled over 10 hours or more (in certain directions) before encountering land mass appears to allow for the possibility of nonlinear dispersive waves as relevant features for the phenomena. Segur [32] has argued that in the 2004 tsunamis, the propagation distances from the epicenter of the earthquake to India, Srilanka, or Thailand were too short for KdV dynamics to develop. In the same way one can argue that the waves that hit Somalia and Kenya in the east coast of Africa (or as in the case of Chilean earthquake see also [32]) have traveled sufficiently long distance for KdV dynamics to become important [33]. In any case one can conclude that at least for long distance tsunami propagation solitary wave and soliton picture of KdV like equations become very relevant.

Internal Solitons

For a long time seafarers passing through the Strait of Malacca on their journeys between India and the Far East have noticed that in the Andaman sea, between Nicobar islands and the north east coast of Sumatra, often bands of strongly increased surface roughness (ripplings or bands of choppy water) occur [11,34]. Similar observations have been reported in other seas around the globe from time to time. In recent times there has been considerable progress in understanding these kind of observations in terms of internal solitons in the oceans [7]. These studies have been greatly facilitated by photographs taken from satellites and space-crafts orbiting the earth, for example by synthetic aperture radar (SAR) images of ERS-1/2 satellites [34,35].

Peculiar striations of 100 km long, separated by 6 to 15 km and grouped in packets of 4 to 8, visible on satellite photographs (see Fig. 5) of the surface of the Andaman and Sulu seas in the Far East, have been interpreted as secondary phenomena accompanying the passage of 'internal solitons', which are solitary wavelike distortions of the boundary layer between warm upper layer of sea water and cold lower depths. These internal solitons are traveling edges of warm water, extending hundreds of meters down below the thermal boundary [7]. They carry enormous energy with them which is perhaps the reason for unusually strong underwater currents experienced by deep-sea drilling rigs. Thus these internal solitons are potentially hazardous to sub-sea oil and gas explorations. The ability to predict them can improve substantially the cost effectiveness and safety of offshore drilling.



Solitons, Tsunamis and Oceanographical Applications of, Figure 5

SAR image of a 200 km × 200 km large section of the Andaman Sea acquired by the ERS-2 satellite on April 15, 1996 showing sea surface manifestations of two internal solitary wave packets, see [34]. Figure reproduced from ESA website www.earth.esa.int/workshops/ers97/papers/alpers3 with the courtesy of European Space Agency and W. Alpers

A systematic study of the underwater currents experienced by an oil rig in the Andaman sea which was drilling at a depth of 3600 ft was carried out by Osborne and Burch in 1980 [11]. They spent four days measuring underwater currents and temperatures. The striations seen on satellite photographs turned out to be kilometer-wide bands of extremely choppy water, stretching from horizon to horizon, followed by about two kilometers of water "as smooth as a millpond". These bands of agitated water are called "tide rips", they arose in packets of 4 to 8, spaced about 5 to 10 km apart (they reached the research vessel at approximately hourly intervals) and this pattern was repeated with the regularity of tidal phenomenon.

As described in [7], Osborne and Burch found that the amplitude of each succeeding soliton was less than the previous one, is precisely what is expected for solitons (note that the velocity of a solitary wave solution of KdV equation increases with amplitude, vide Eq. (22)). Thus if a number of solitons are generated together, then we expect them eventually to be arranged in an ordered sequence of decreasing amplitude. From the spacing between successive waves in a packet and the rate of separation calculated from the KdV equation, Osborne and Burch were able to estimate the distance the packet had traveled from its source and thus identify possible source regions [7]. They concluded that the solitons are generated by tidal currents off northern Sumatra or between the islands of the Nicobar chain that extends beyond it and that their observations have good general agreement with the predictions for internal solitons as given by the KdV equation. Numerous recent observations and predictions of solitons in the Andaman sea have clearly established that it is a site where extraordinarily large internal solitons are encountered [34,35].

Further, Apel and Holbrook [36] undertook a detailed study of internal waves in the Sulu sea. Satellite photographs had suggested that the source of these waves was near the southern end of the Sulu sea and their research ship followed one wave packet for more than 250 miles over a period of two days – an extraordinary coherent phenomenon [7]. These internal solitons travel at speeds of about 8 kilometers per hour (5 miles per hour), with amplitude of about 100 meters and wavelength of about 1700 meters.

Similar observations elsewhere have confirmed the presence of internal solitons in oceans including the strait of Messina, the strait of Gibraltar, off the western side of Baja California, the Gulf of California, the Archipelago of La Maddalena and the Georgia strait [7]. There has also been a number of experimental studies of internal solitons in laboratory tanks in the last few decades [37]. These experiments provide detailed quantitative information usually unavailable in the field conditions, and are also an efficient tool for verifying various theoretical models.

As a theoretical formulation of internal solitons [7], consider two incompressible, immiscible fluids, with densities ρ_1 and ρ_2 and depths h_1 and h_2 respectively such that the total depth $h = h_1 + h_2$. Let the lighter fluid of height h_1 be lying over a heavier fluid of height h_2, in a constant gravitational field (Fig. 6). The lower fluid is assumed to rest on a horizontal impermeable bed, and the upper fluid is bounded by a free surface.

Then as in Sect. "Shallow Water Waves and KdV Type Equations", we denote the characteristic amplitude of wave by 'a' and the characteristic wavelength $l = k^{-1}$. Then the various nonlinear wave equations to describe the formation of internal solitons follow by suitable modification of the formulation in Sect. "Shallow Water Waves and KdV Type Equations", assuming viscous effects to be negligible. Each of these equations is completely integrable and admits soliton solutions [7].

(a) KdV equation (Eq. (21)) follows when

(i) the waves are of long wavelength $\delta = \frac{h}{l} \ll 1$,
(ii) the amplitude of the waves are small, $\epsilon = \frac{a}{h} \ll 1$, and
(iii) the two effects are comparable $\delta^2 = O(\epsilon)$

(b) Intermediate-Long-Wave (ILW) equation [38]

$$u_t + u_x + 2uu_x + Tu_{xx} = 0, \tag{39}$$

where Tu is the singular integral operator

$$(Tf)(x) = \frac{1}{2l} \fint_{-\infty}^{\infty} \coth\left\{\frac{\pi}{2l}(y-x)\right\} f(y)\mathrm{d}y \tag{40}$$

with $\fint_{-\infty}^{\infty}$ the Cauchy principal value integral is obtained under the assumption that

(a) there is a thin (upper) layer, $\epsilon = \frac{h_1}{h_2} \ll 1$,
(b) the amplitude of the waves is small, $a \ll h_1$,
(c) the above two effects balance, $\frac{a}{h_1} = O(\epsilon)$,
(d) the characteristic wavelength is comparable to the total depth of the fluid, $l = kh = O(1)$ and
(e) the waves are long waves in comparison with the thin layer, $kh_1 \ll 1$.

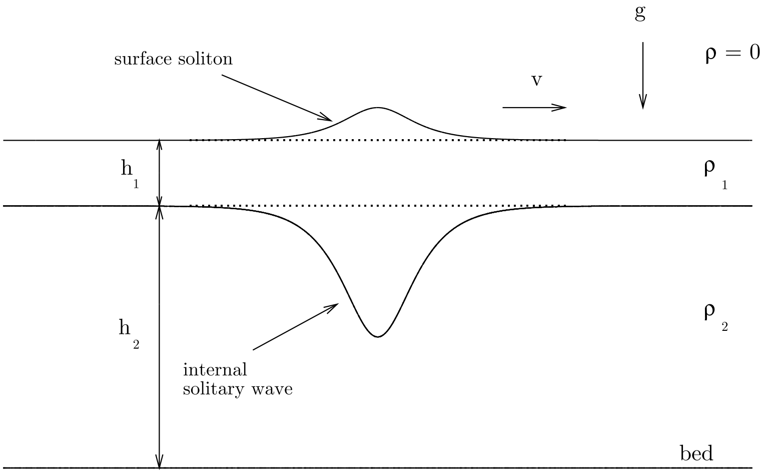
(c) Benjamin–Ono equation [39]

$$u_t + 2uu_x + Hu_{xx} = 0, \tag{41}$$

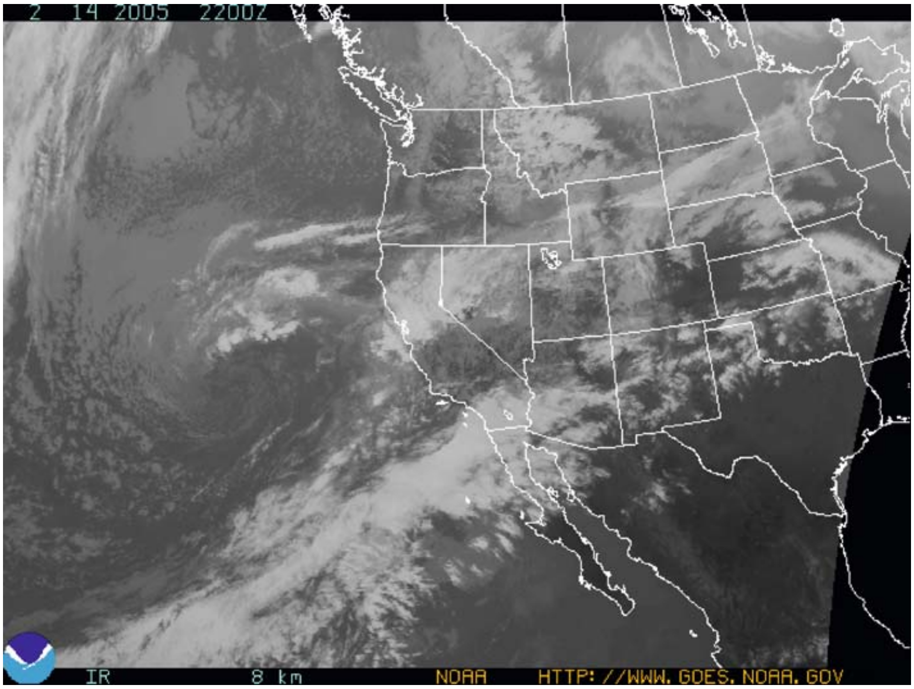
where Hu is the Hilbert transform

$$(Hf)(x) = \frac{1}{\pi} \fint_{-\infty}^{\infty} \frac{f(y)}{y-x}\mathrm{d}y, \tag{42}$$

is obtained under the assumption



Solitons, Tsunamis and Oceanographical Applications of, Figure 6
Formation of internal soliton (note that under suitable conditions small amplitude surface soliton can also be formed)



Solitons, Tsunamis and Oceanographical Applications of, Figure 7

A coupled high/low pressure systems in the form of a Rossby soliton formed off the coast of California/Washington on Valentine's Day 2005. The low pressure front hovers over Los Angeles dumping 30 inches of rain on the city in two weeks. The high pressure system lingers off the coast of Washington state providing unseasonally warm and sunny weather. This particular Rossby soliton proved exceptionally stable because of its remarkable symmetry. In an accompanying animated gif in this website one can watch the very interesting phenomenon as the jet stream splits around the soliton suctioning warm wet air from the off the coast of Mexico to Arizona, leaving behind a welcome drenching of rain. The figure and caption have been adapted from the website http://mathpost.la.asu.edu/~rubio/rossby_soliton/rs.html with the courtesy of the National Oceanic and Atmospheric Administration (NOAA) and Antonio Rubio

(a) there is a thin (upper) layer $h_1 \ll h_2$,
(b) the waves are long waves in comparison with the thin layer, $kh_1 \ll 1$,
(c) the waves are short in comparison with the total depth of the fluid, $kh \gg 1$ and
(d) the amplitude of the waves is small, $a \ll h_1$.

It may be noted that in the shallow water limit, as $\delta \to 0$, the ILW equation reduces to the KdV equation, while the Benjamin–Ono equation reduces to it in the deep water wave limit as $\delta \to \infty$. Each of these equations have their own ranges of validity and admit solitary wave and soliton solutions to represent internal solitons of the oceans.

Rossby Solitons

The atmospheric dynamics is an important subject of human concern as we live within the atmosphere and are continuously affected by the weather and its rather complex behavior. The motion of the atmosphere is intimately connected with that of the ocean with which it exchanges fluxes of momentum, heat and moisture [40]. Then the atmospheric dynamics is dominated by the rotation of the earth and the vertical density stratification of the surrounding medium, leading to newer effects. Similar effects are also present in other planetary dynamics as well.

In the atmosphere of a rotating planet, a fluid particle is endowed with a certain rotation rate (Coriolis frequency), determined by its latitude. Consequently its motion in the north-south direction is inhibited by conservation of angular momentum. The large scale atmospheric waves caused by the variation of the Coriolis frequency with latitude are called *Rossby waves*. In Sect. "Internal Solitons" we saw that KdV equation and its modifications model internal waves. Since there is a resemblance between internal waves and Rossby waves, it is expected that KdV like equations can model Rossby waves as well [8]. Under the simplest assumptions like long waves, incompressible fluid, β-plane approximations, etc. Benney [41] had derived the KdV equation as a model for Rossby waves in the presence of east-west zonal flow. Boyd [42] had shown that long, weakly nonlinear, equatorial Rossby waves are governed either by KdV or MKdV equation. Recently it has been shown by using the eight years of Topex/Poseidon altimeter observations [43] that a detailed characterization of major components of Pacific dynamics confirms the presence of equatorial Rossby solitons.

Also observational and numerical studies of propagation of nonlinear Rossby wave packets in the barotropic atmosphere by Lee and Held [44,45] have established their presence, notably in the Northern Hemisphere as storm tracks, but more clearly in the Southern Hemisphere (see Fig. 7). They also found that the wavepackets both in the real atmosphere and in the numerical models behave like the envelope solitons of the nonlinear Schrödinger equation (Fig. 7).

An interesting application of KdV equation to describe Rossby waves is the conjecture of Maxworthy and Redekopp [46] that the planet Jupiter's Great Red Spot might be a solitary Rossby wave. Photographs taken by the spacecraft Voyager of the cloud pattern show that the atmospheric motion on Jupiter is dominated by a number of east-west zonal currents, corresponding to the jet streams of the earth's atmosphere [8]. Several oval-shaped spots are also seen, including the prominent Great Red Spot in the southern hemisphere. The latter one has been seen approximately this latitude for hundreds of years and maintains its form despite interactions with other atmospheric objects. One possible explanation is that the Red Spot is a solitary wave/soliton of the KdV equation, deduced from the quasigeostrophic form of potential vorticity equation for an incompressible fluid. A second test of the model is the combined effect of interaction of the Red Spot and Hollow of the Jupiter atmosphere on the South Tropical Disturbance which occurred early in the 20th century and lasted several decades. Maxworthy and Redekopp [46] have interpreted this interaction as that of two soliton collision of KdV equation, with the required phase shift [6,7,8].

The above connection between the KdV solitary wave and the rotating planet may be seen more concretely by the following argument as detailed in [8]. One can start with the quasigeostrophic form of the potential vorticity equation for an incompressible fluid in the form

$$\left\{\left(\frac{\partial}{\partial t}+v\frac{\partial}{\partial x}\right)+\epsilon\left(\frac{\partial\psi}{\partial y}\right)\left(\frac{\partial}{\partial x}-\frac{\partial\psi}{\partial x}\frac{\partial}{\partial y}\right)\right\}$$
$$\left\{\mu^2\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial}{\partial z}\left(K^2\frac{\partial}{\partial z}\right)\right\}\psi+(\beta-U'')\frac{\partial\psi}{\partial x}=0, \tag{43}$$

where x, y and z represent the east, north and vertical directions, while the function U is related to the horizontal stream function Φ as $\Phi(x,y,z,t) = \int_{y'}^{y} U(\eta)d\eta + \epsilon\psi(x,y,z,t)$ in terms of a zonal shear flow and a perturbation. In (43), in the β-plane approximation, the Coriolis parameter is given as $f = 2\Omega\sin\theta_0 + \beta y$ and the function $K(z)$ is given by $K(z) = 2\Omega\sin\theta_0 l_2/N(z)d$, where $N(z)$ is the Brunt–Väisälä frequency and l_2 is the characteristic length scales in the north-south direction while d is the length scale in the vertical direction. Note that K compares the effects of rotation and density of variation. Then $\mu = l_2/l_1$ represents the ratio of the length scales in the north-south and east-west directions.

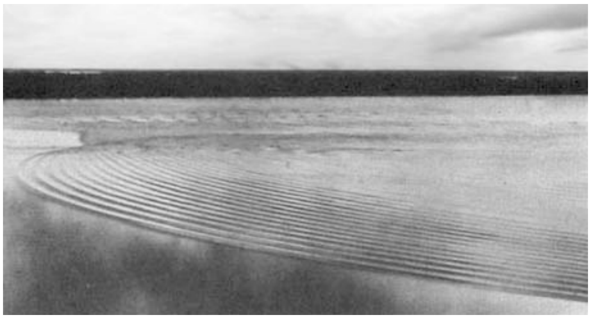
In the linear ($\epsilon \to 0$), long wave ($\mu \to 0$) limit, the potential function ψ has the form $\psi = \sum_n A_n(x - c_n t)\phi_n(y)p_n(z)$, where c_n is deduced by solving two related eigenvalue problems [8], $(K^2 p'_n)' + k_n^2 p_n = 0$, $p_n(0) = p_n(1) = 0$ and $\phi''_n - k_n^2\phi_n + [(\beta - U'')/(U - c_n)]\phi_n = 0$, $\phi_n(y_s) = \phi_n(y_N) = 0$. If the various modes are separable on a short time scale, one can then deduce an evolution equation for the individual modes, by eliminating secular terms at higher order in the expansion. Depending on the nature and existence of a stable density of stratification, which is characterized by the function $N(z)$ mentioned above, either KdV or mKdV equation can be deduced for a given mode and thereby establishing the soliton connection in the present problem.

In spite of the complexity of the phenomenon underlying Rossby solitons there is clear evidence of the significance of solitonic picture.

Bore Solitons

Rivers which flow into the open oceans are usually affected by tidal flows, tsunami or storm surge. For a typical estuary as one moves towards the mouth of the river, the depth increases and width decreases. When a tidal wave, tsunami or storm surge hits such an estuary, it can be seen as a hydraulic jump (step-wise perturbations like a shock-wave) in the water height and speed which will propagate upstream [47]. Far less dangerous but very similar is the bore (mascaret in French), a tidal wave which can propagate in a river for considerable distances.

Typical examples of bores occur in Seine river in France and the Hooghli river in West Bengal in India. A bore existed in the Seine river upto 1960 and disappeared when the river was dredged. The tide amplitude here is one of the largest in the world. The Hughli river is a branch of the Ganges that flows through Kolkata where a bore of 1m is present, essentially due to the shallowness of the river. Another interesting example is that at the time



Solitons, Tsunamis and Oceanographical Applications of, Figure 8
Tidal bore at the mouth of the Araguari River in Brazil. The bore is undular with over 20 waves visible. (Adapted from the book "Gravity Currents in the Environment and the Laboratory" by John E. Simpson, Cambridge University Press with the courtesy of D.K. Lynch, John E. Simpson and Cambridge University Press)

of the 1983 Japan sea tsunami, waves in the form of a bore ascended many rivers [48]. In some cases, bores had the form of one initial wave with a train of smaller waves and in other cases only a step with flat water surface behind was observed (Fig. 8). The Hangzhou bore in China is a tourist attraction. Other well known bores occur in the Amazon in Brazil and in Australia.

Another interesting situation where bore solitons were observed was in the International H_2O Project (IHOP), as a density current (such as cold air from thunderstorm) intrudes into a fluid of lesser density that occurs beneath a low level inversion in the atmosphere. A spectacular bore and its evolution into a beautiful amplitude-ordered train of solitary waves were observed and sampled during the early morning of 20 June 2002 by the Leandre-II abroad the P-3 aircraft. The origin of this bore was traceable to a propagating cold outflow boundary from a mesoscale convective system in extreme western Kansas [49].

In the process of propagation the bore undergoes dissipation, dispersive disintegration, enhancement due to decrease of the river width and depth, influence of nonlinear effects and so on. The profile depends on the Froude number which is a dimensionless ratio of inertial and gravitational effects. Theoretical models have been developed to study these effects based on KdV and its generalizations [14]. For example, bore disintegration into solitons in channel of constant parameters can be studied in signal coordinates in terms of the KdV like equation for the perturbation of water surface,

$$\eta_x + \frac{1}{c_0}(1-\alpha\eta)\eta_t - \beta\eta_{ttt} = 0\,, \qquad (44)$$

where $c_0 = \sqrt{gh}$, $\alpha = 3/2h$, $\beta = h^2/6c_0^3$, h being the depth of the river, with the bore represented by a Heaviside step function as the boundary condition at $x = 0$. Other effects then can be incorporated into a variable KdV equation of the form (26).

Future Directions

We have indicated a few of the most important oceanographical applications of solitons including tsunamis, internal solitons, Rossby solitons and bore solitons. There are other interesting phenomena like capillary wave solitons [15], resonant three and four wave interaction solitons [16], etc. which are also of considerable interest depending on whether the wave propagation corresponds to shallow, intermediate or deep waters. Whatever be the situation, it is clear that experimental observations as well as their theoretical formulation and understandings are highly challenging complex nonlinear evolutionary problems. The main reason is that the phenomena are essentially large scale events and detailed experimental observations require considerable planning, funding, technology and manpower. Often satellite remote sensing measurements need to be carried out as in the case of internal solitons and Rossby solitons. Events like tsunami propagation are rare and time available for making careful measurements are limited and heavily dependent on satellite imaging, warning systems and after event measurements. Consequently developing and testing theoretical models are extremely hazardous and difficult. Yet the basic modeling in terms of solitary wave/soliton possessing nonlinear dispersive wave equations such as the KdV and NLS family of equations and their generalizations present fascinating possibilities to understand these large scale complex phenomena and opens up possibilities of prediction. Further understanding of such nonlinear evolution equations, both integrable and nonintegrable systems particularly in higher dimensions, can help to understand the various phenomena clearly and provide means of predicting events like tsunamis and damages which occur due to internal solitons and bores. Detailed experimental observations can also help in this regard. It is clear that what has been understood so far is only the qualitative aspects of these phenomena and much more intensive work is needed to understand the quantitative aspects to predict them.

Glossary

Alfvén wave Transverse magnetohydrodynamic wave that propagates along the magnetic field line direction in an electrically conducting fluid.

Anomalous resistivity Nonclassical resistivity in plasma dynamics.

Astronomical unit (AU) Unit of length nearly equal to the semi-major axis of Earth's orbit around the Sun.

Auroral electrojet index (AE) Empirical index that measures magnetic perturbations in the auroral zone. It provides a gauge for the horizontal current strength in the auroral ionosphere.

Auroral zone Region where auroral activities are observed.

Castaing distribution A convolution of Gaussians with variances distributed according to a log-normal distribution.

Chaos Nonsteady, nonperiodic, complex dynamical motion.

Coarse-grained dissipation Apparent dissipation due to interactions of coherent structures.

Coarse-graining Replacement of a detailed description with a lower-resolution coarse-grained model.

Coherent structure Large scale structure of nonlinearly interacting dynamical systems.

Correlation function Ensemble average of the correlation of fluctuations.

Criticality Behavior of extended system at which scale-invariance prevails.

Crossover Transition from one critical state to another or multitudes of critical states; or, transition from one fractal state to another or multitudes of fractal states.

Current sheet Sheet-like region with strong current density usually generated by strong local magnetic shear.

Cusp Funnel shaped region dividing the sunward and tailward sides of the magnetic field lines of the Earth.

Drift Alfvén vortex Field-aligned coherent Alfvénic vortex structure that drifts across the magnetic field.

Dynamical complexity Complex stochastic behavior of numerous nonlinearly interacting coherent structures of various sizes.

Dynamical renormalization group Group generated by coarse-graining scale transformations of a nonlinear dynamical system.

Extended similarity scaling (ESS) Scale invariant property among the structure or partition functions of a fluctuating event.

Exponent relation Algebraic relation among scaling exponents.

Extreme value theory Statistical theory dealing with extreme deviations from the mean.

Flatness (kurtosis) A normalized scale dependent measure related to the fourth order moment of the scale dependent coarse-grained probability distribution. It may be evaluated by taking the ensemble average of the square of the normalized power using the wavelet transform.

Forced and/or self-organized criticality (FSOC) Organization of a dynamical system into a scale invariant critical state with or without some tuning or forcing.

Fractal Fluctuations that exhibit generalized dimension of an irrational number.

Gaussian distribution Normal distribution.

Generalized dimension Dimension of the measure of fractal characteristics of a fluctuating event based on the limiting characteristic of the logarithm of the partition function at small scales.

Helicity Extent to which the magnetic field wraps around itself.

Heliosphere Magnetic bubble containing our solar system, including the solar wind.

Hysteresis History dependence of physical system that dissipates energy.

Intermittency Random fluctuations that exhibit non-self-similar characteristics.

Irrelevant parameter Parameter that becomes irrelevant under repeated coarse-graining transformations.

Ionosphere Upper most portion of atmosphere that is ionized and connected to the magnetosphere.

Local intermittency measure, Lim Normalized power in wavelet transform that is intensity, scale and location dependent.

Low-dimensional chaos Chaotic motion characterized by a small number of parameters.

Lu/Klimas model One-dimensional dynamical model with anomalous diffusion involving hysteresis, which exhibits scale invariant stochastic processes.

Magnetic reconfiguration (and/or reconnection) Reconfiguration of magnetic topology, which may or may not involve the phenomenon of magnetic reconnection of field lines.

Magnetohydrodynamics Mathematical description of electrically conducting fluids moving within electromagnetic environments.

Magnetosphere Region of space around the Earth (or any astrophysical object), that is controlled by its magnetic field.

Magnetotail Tail region (away from the Sun) of the magnetosphere of the Earth or any object in the heliosphere.

Multifractals Fluctuations characterized by multitudes of fractal dimensions that are not linearly related.

P-model Two-scale cascade model with "p" as the parameter that characterizes the fragmentation probability of the cascading process of intermittency.

Partition function of order q qth moment-order of the segmental coarse-grained probabilities.

PDF Probability distribution function.

Plasma resonance Site at which a particular plasma propagation mode vanishes.

Rank-ordered multifractal analysis, ROMA Analysis of multifractal characteristics based on the ordering of fractal dimensions in terms of scaled sizes of the intermittent fluctuations.

Relevant parameter Parameter that becomes more and more relevant under repeated coarse-graining transformations.

Response function Ensemble average of the response of the system due to fluctuations.

Scale invariants Quantities that do not vary under coarse-graining scale transformations.

Singularity spectrum $f(\alpha)$ Continuum distribution of differential measures with singularity index α.

Self-organized criticality (SOC) Auto-organization of a dynamical system into a scale-invariant critical state without significant tuning.

Solar wind Stream of charged particles in interplanetary space ejected from the upper atmosphere of the Sun.

Space plasma Ionized medium in the space environment.

Structure function of order q qth order moment of the probability distribution function of scale-dependent, coarse-grained fluctuations. It may be evaluated in terms of the ensemble average of the qth power of the scale-dependent fluctuations.

Taylor hypothesis Hypothesis that interprets temporal fluctuations as spatial fluctuations when the transit time of the fluctuations is much less than the characteristic evolution time. Also called Taylor's "frozen-in" hypothesis.

Turbulence Chaotic stochastic flow of a continuum or discrete medium with infinite number of degrees of freedom.

Wavelet transform Transform generated by a basis set of wave-packet-like functions, which provides information of intensity, location and scale of a fluctuating quantity.

Whistler wave Right-hand polarized electromagnetic wave in a plasma with frequency well below the electron cyclotron frequency and above the ion cyclotron frequency. The high frequency whistler waves travel faster than the low frequency ones along the magnetic field lines in the plasma medium.

Definition of the Subject

Commonly called the fourth state of matter, plasmas make up 99 per cent of the Universe. They are the major constituents of the solar-terrestrial, interstellar, and intergalactic media – generally in the form of ionized gases. According to Tonks [118] who co-authored the celebrated Tonks and Langmuir [119] paper on oscillations in ionized gases, Langmuir [70] coined the terminology "plasma" to describe, in today's language, a quasineutral mixture – probably because of the likeness between the electrons and ions in an ionized medium and the red and white corpuscles in a blood plasma [99]. Recent observations, particularly in-situ measurements in the heliosphere and solar-terrestrial regions, have indicated that space plasmas commonly exhibit random, intermittent, and anisotropic fluctuating characteristics at all spatiotemporal scales while interacting with the electromagnetic environment. Such observations have led theoreticians and experimentalists alike to regard the stochastic behaviors of space plasmas as prime candidates of naturally occurring examples of dynamical complexity.

By definition, "dynamical complexity" is a phenomenon exhibited by a nonlinearly interacting dynamical system within which multitudes of different sizes of large scale "coherent structures" are formed, resulting in a complicated global nonlinear stochastic behavior for the dynamical system – vastly different from that could be surmised from the original dynamical equations.

The main purpose of this article is to demonstrate the prevalence of dynamical complexity in space plasmas and to indicate the various statistical methods of analyzing this kind of dynamical processes as well as to discuss theoretical and numerical methods that can provide the basic understanding of such processes.

Introduction

Traditionally, analyzes of space plasma processes are based on fluid or kinetic formulations. Among the fluid descriptions, the simplest is that based on the so-called one-component magnetohydrodynamic (MHD) equations, which includes the equations of motion, continuity, and energy conservation, the Ohm's law and the Maxwell equations for a single conducting fluid medium (see, e. g. [7]). Associated with such a formulation are the concepts of magnetic field lines, streamlines and other continuum variables such as velocity, electric and magnetic fields, as well as plasma, charge and current densities. The dynamical state of the system is understood in terms of a topology generally characterized by the relatively smooth or piecewise continuous variations of such entities with space and time.

Most of the observed space plasma processes, however, generally exhibit discernible turbulent fluctuations of such quantities. The standard approach to the theoretical analyzes of dynamically fluctuating states is based on the concepts of linear instabilities, nonlinear growths and interactions of the wave modes. Although the basic governing equations generally contain strong nonlinearities, one is led to believe that turbulent motions may be understood by expressing the fluctuations in Fourier modes (plane waves) and then considering the interactions among these nonlocal modes by requiring them to satisfy the "basic" equations. This procedure produced such intractable complications that have led to decades of futile search for a workable theory of "turbulence".

In reality, turbulent fluctuations in space plasmas are generally composed of the simultaneous coexistence of propagating modes and intermittent nonlinearly interacting spatiotemporal structures [32,33]. The "physics" of the bimodal state of such type of admixture of turbulent fluctuations may be understood from the point of view of the development and interactions of coherent structures arising from plasma resonance sites and the ensuring dynamical complexity resulting from such developments and interactions. In this article, we shall consider the dynamical complexity in space plasmas from such a concept. Sample results of direct numerical simulations and dynamical modeling including the calculated fluctuation probability distribution functions and local intermittency measures based on the wavelet transforms are provided to characterize the sporadic, localized, and scale-dependent nature of the intermittent turbulence. The concepts of multifractals, scale invariance and symmetry-breaking will be introduced. Observational examples demonstrating the existence of such phenomena and the associated invariance properties of intermittent space plasma turbulence will be provided.

Applications of the ideas of dynamical complexity to space plasmas were relatively recent. The first contact of these ideas with space plasmas was probably contained in a series of papers addressing the apparent low-dimensional chaotic behavior related to the dynamics of the Earth's magnetosphere [4,65,101,103,104,105]. These ideas were followed by a paper by Chang [22] that suggested the possibility of interpreting such phenomenon from the point of view of forced and/or self-organized criticality (FSOC) surmised from the method of the dynamic renormalization group (DRG). This suggestion was moti-

vated by the low-dimensional chaos papers as well as the interpretation of the observed large variability of plasma fluctuations in the Earth's magnetotail as the result of sporadic and localized current disruptions [78], Figs. 1 and 2. At approximately the same time, Lu and Hamilton [74] used the idea of self-organized criticality (SOC) of Bak et al. [3] to explain the curious scale-independent behavior of the solar flare occurrence rate on the flare sizes. Such ideas suggest that complex dynamical systems generally organize themselves into states with statistical properties describable by power laws. (A succinct tutorial review of the SOC concept may be found in Jensen [63]). An alternative viewpoint of dynamical complexity is based on the concept of multifractals [54,98] which is a generaliza-

The *XZ*-plane contains the Earth's dipole axis, and the *Y*-axis completes the right-handed coordinate system in units of Re. Reprinted from [80] with thanks to the American Geophysical Union

tion of the original ideas of fractals introduced by Mandelbrot [83]. Burlaga [12,13,14] was the first to incorporate such ideas to interpret the intermittent turbulent behavior of the solar wind. Other solar wind studies based on such a point of view followed, e. g. [16,17,18,19,20,58, 59,60,84,102]. These ideas were followed by Consolini et al. [41] and Consolini [37] in their interpretations of the observed fractal time series of the Auroral Electrojet (AE) indices.

Since then, a flurry of activities has blossomed into the current investigations of the phenomenon of complexity in space plasmas. Perhaps the most noteworthy are the connection of such phenomena with the traditional ideas of intermittent turbulence in plasmas and the development of the concept of crossovers (transitions) from one criticality to another and onto multifractals [27,28]. This article will provide simple descriptions of some of these modern ideas in conjunction with actual observational results and numerical simulations.

Due to the limitation of space, this entire article will center on the discussion of the complexity of space plasmas from the fluid description. It should be understood that situations also exist in space plasmas where the physical phenomena are related to the complexity of kinetic plasma effects, see, e. g., [33,111,115]. Since the purpose of this article is to introduce to the readers the basic concepts of – and recent developments in – the physics of dynamical complexity in space plasmas, only those primary references that touch upon these introductory ideas are included. No attempt has been made to include the hundreds of outstanding contributions that are available on the subject.

The contents of this article are structured as follows. In the next section, the concepts of plasma resonances and coherent structures are introduced. This is followed by a discourse on coarse-grained dissipation and magnetic reconfiguration. The ideas of non-Gaussian probability distributions of turbulent fluctuations, wavelet transforms and intermittency are then discussed in the two subsequent sections. Next, we introduce the basic ideas of multifractals in terms of structure functions, partition functions, singularity measures and rank-ordered multifractal spectra in Sect. "Multifractals". The concepts of scale invariants, forced and/or self-organized criticality are described in Sect. "Invariant Scaling" along with a discourse relating these ideas to multifractals. In Sect. "Dynamical Modeling – The Lu–Klimas Magnetic Field Reversal Model", we discuss the utility of dynamical models. A simple one-dimensional model, the Lu–Klimas model, is provided to illustrate the usefulness of such methods. This is followed by a brief discussion of what future details in the study and research of dynamical phenomena of complexity related to space plasmas. In addition to the primary list of references that are cited in the article, we also provide a secondary list of review articles and books in the bibliography for further in-depth study.

Plasma Resonances and Coherent Structures

Plasmas are known for their ability to form numerous types of coherent structures of varied sizes with scales that are generally much larger than those of the constituent particles (ions, electrons, neutrals) of the plasma medium. The reason behind this is closely related to the nonlinear and long range forces of the dynamical couplings among the constituent particles and species interacting within the electromagnetic environment.

Examples of coherent structures abound in the literature on theories and observations of nonlinear space plasma processes. They may appear as convective forms, nonlinear solitary structures, pseudo-equilibrium configurations, or other types of spatiotemporal entities. They may be locally generated or convected from elsewhere. Some of these structures may be more stable and long-lived; others may be less stable and relatively short-lived and sometimes partially formed. Generally, such structures are not purely laminar entities; they are likely composed of bundled fluctuations of all frequencies and scales. Due to the nature of the physics of complexity, it would be futile to attempt to evaluate and/or study the details and stabilities of each of these countless interacting structures or partially formed structures, though some basic understanding of the different types of structures would be helpful in the comprehension of the full stochastic complexity that results from their underlying nonlinear dynamics.

As an example of such coherent structures, let us consider the behavior of Alfvénic flux tubes in magnetized plasmas. We shall base our theoretical discussion by considering the plasma medium as a single, charge-neutral, conducting fluid moving in and interacting self-consistently with its electromagnetic environment. Because the plasmas in the space environment are generally highly rarefied, we can typically neglect the dissipative effects from particle collisions and assume the plasma is perfectly conducting and inviscid. The most elemental mathematical formulation for magnetized plasmas under such simplifying assumptions is the so-called ideal incompressible magnetohydrodynamics (MHD). The basic equations are the equations of continuity and motion, and the relevant Maxwell's equations where the displacement current is neglected for nonrelativistic motion.

$$\nabla \cdot \mathbf{v} = 0 \quad \text{(continuity equation for incompressible medium)} \tag{1}$$

$$\rho \mathrm{d}\mathbf{v}/\mathrm{d}t = \mathbf{j} \times \mathbf{B} - \nabla p \quad \text{(equation of motion for an inviscid medium)} \tag{2}$$

$$\nabla \cdot \mathbf{B} = 0 \text{ (Gauss' law)} \tag{3}$$

$$\partial \mathbf{B}/\partial t + \nabla \times \mathbf{E} = 0 \quad \text{(Faraday's law)} \tag{4}$$

$$\mathbf{j} = \nabla \times \mathbf{B} \quad \text{(Ampère's law neglecting the displacement current)} \tag{5}$$

where $\mathrm{d}/\mathrm{d}t = \partial/\partial t + \mathbf{v} \cdot \nabla$ is the convective derivative, ρ is the density of the medium, $\mathbf{v}$ is the velocity, $\mathbf{j}$ is the current density, $\mathbf{B}$ is the magnetic field, $\mathbf{j} \times \mathbf{B}$ is the Lorentz force, p is the fluid pressure, and $\mathbf{E}$ is the electric field. These equations are written in SI units with the vacuum permeability set equal to 1.

To complete the set of equations of such a formulation, we complement the above equations with the Ohm's law for a perfectly conducting medium:

$$\mathbf{E} + \mathbf{v} \times \mathbf{B} = 0 \tag{6}$$

These equations may be combined to form the following set of equations of motion and induction:

$$\rho \mathrm{d}\mathbf{v}/\mathrm{d}t = (\mathbf{B} \cdot \nabla)\mathbf{B} + \cdots \tag{7}$$

$$\mathrm{d}\mathbf{B}/\mathrm{d}t = (\mathbf{B} \cdot \nabla)\mathbf{v} \tag{8}$$

where the eclipses represent the gradient of the total pressure $(p + B^2/2)$. Standard arguments lead Eqs. (7) and (8) to a linearized wave equation characterizing the fundamental propagation of small fluctuations of $\mathbf{v}$ and $\mathbf{B}$. This wave equation admits the well-known Alfvén waves which are transverse waves to the magnetic field $\mathbf{B}$ and propagate along the magnetic field direction. The phase velocity v_A of the Alfvén wave is $B/\sqrt{\rho}$, i. e., proportional to the strength of the magnetic field and inversely proportional to the square root of the density ρ of the plasma. For such waves to propagate, the operators on the right hand sides of (7) and (8) must not vanish, i. e., $\mathbf{B} \cdot \nabla \rightarrow i\mathbf{k} \cdot \mathbf{B} = k_\parallel \neq 0$. Therefore, the propagation vector $\mathbf{k}$ must contain a field-aligned component $k_\parallel$. When the parallel component $k_\parallel$ of the propagation vector vanishes (i. e., at the resonance sites), the fluctuations are localized. Around these resonance sites (usually in the form of three-dimensional space curves), it may be shown that the fluctuations – which will try to propagate away as Alfvén waves – are held back by the background magnetic field and the plasmas medium, thereby forming the so-called Alfvénic coherent structures (which are actually domains of bundled stochastic fluctuations).

Coarse-Grained Helicity

We now consider such magnetized domains near the Alfvenic resonance sites. For an ideal MHD system, any physically acceptable magnetic field must satisfy the solenoidal condition (Gauss' law): $\nabla \cdot \mathbf{B} = 0$. Also, any variation of the field away from the initial value must satisfy the constraints (4) and (6), i. e., Faraday's law and Ohm's law for infinite conductivity.

It may be easily demonstrated that these constraints are equivalent to an infinite set of integral constraints involving the helicity K, such that

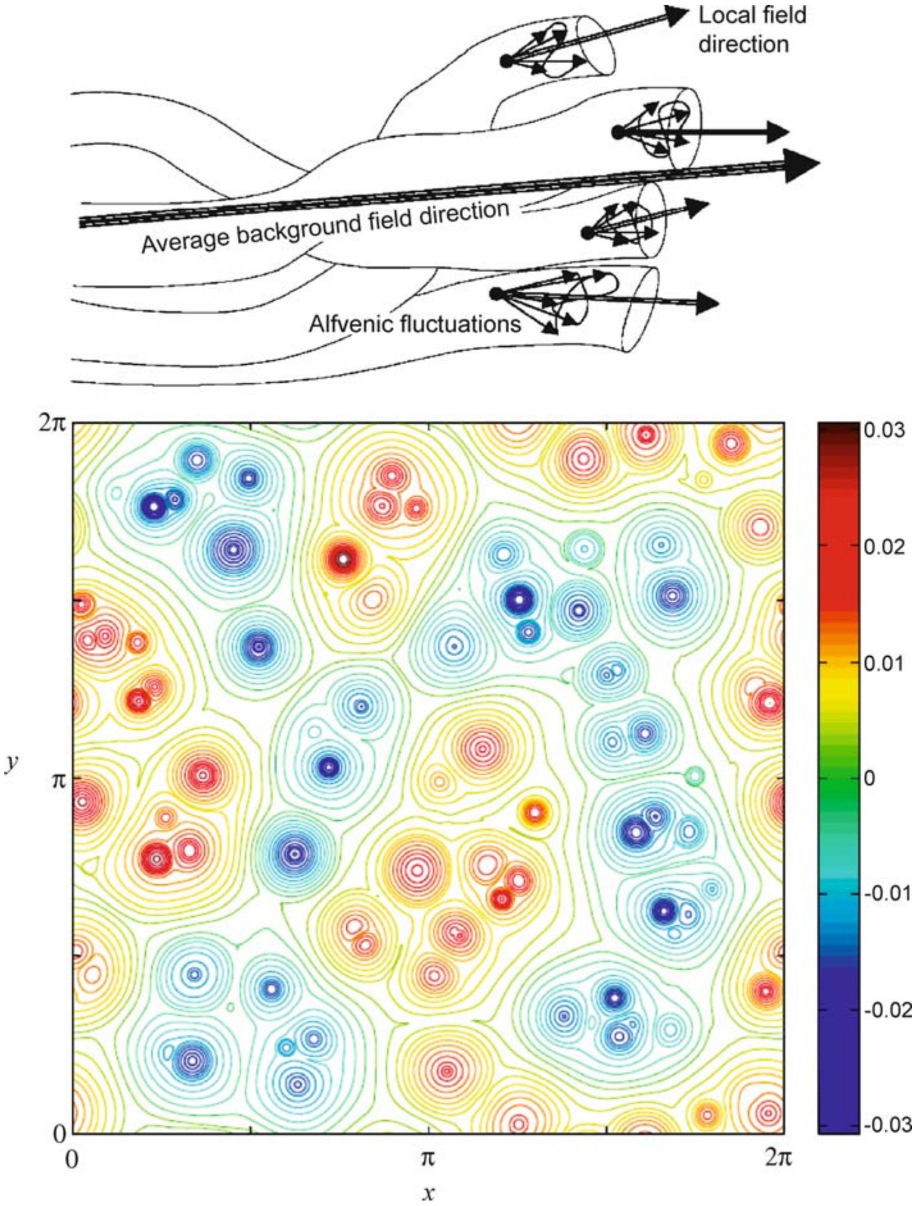
$$K = \int_V \mathbf{A} \cdot \mathbf{B} \mathrm{d}V \tag{9}$$

is an invariant for any single connected volume V enclosed by a flux surface, where $\mathbf{A} = \nabla \times \mathbf{B}$ is the vector potential.

Taylor's Conjecture

We are interested in the situation where there are domains with stochastic turbulent fluctuations within which field lines merge and mix indistinguishably. Thus, it will be difficult – in fact, unpractical – to discuss the topology of individual field lines. Nonetheless, it was suggested by Taylor [114] that when the volume integral of (9) is taken over the stochastic region, the coarse-grain averaged helicity in a relaxing state would be essentially conserved. As the domain of the stochastic region near the Alfvenic resonance site relaxes to a statistically stationary minimum energy state under the constraint of this conjecture of conservation of coarse-grained helicity, it may be shown using the variational principle that such a domain (coherent structure) will be essentially force-free in the sense that $\mathbf{j} \times \mathbf{B} = 0$ where $\mathbf{j}$ and $\mathbf{B}$ are the mean current density and magnetic field, respectively.

We are, of course, interested in dynamical states that are far from equilibrium. Thus, in visualizing the relaxed states from the point of view of this *Taylor's conjecture*, we shall consider timescales such that "nearly coherent" structures are formed. These structures actually move, mix



Space Plasmas, Dynamical Complexity in, Figure 3

***Top*: Schematics of tangled flux tubes in the solar wind. Each flux tube is characterized by a local magnetic field direction aligned approximately with the background field and the presence of Alfvénic fluctuations makes the magnetic field vector wander randomly about this direction. Moving across the tubes, strong intermittent interactions of predominantly nonpropagating (i. e., resonant) fluctuations are expected. Reprinted from [10] with permission from Elsevier. *Bottom*: 2D MHD simulation of cross-sectional view of interacting flux tubes for homogeneous intermittent turbulence. *Colors* represent current intensities and directions. Adapted from [33] with thanks to the American Institute of Physics**

and sometimes merge together while immersed in an otherwise turbulently diffusing plasma medium.

To obtain some physical insight of the geometries of these magnetic coherent structures, let us consider the special situation in the solar wind and make the reasonable assumption that the perturbed magnetic field fluctuations are much smaller than – and essentially transverse to – the mean magnetic field B_0 which will be temporarily assumed to be uniform for the current discussion [89]. Thus, let us write $\mathbf{B} = (\delta B_x, \delta B_y, B_0)$, where z is in the direction of the mean magnetic field, and (x, y) are orthogonal coordinates normal to z. The force-free condition for constant B_0 and $\nabla \cdot \mathbf{j} = 0$ then leads approximately to the scalar condition $\mathbf{B} \cdot \nabla j_z = 0$, obtained by taking the z-component of the curl of $\mathbf{j} \times \mathbf{B} = 0$. We have, then,

$$B_0 \partial j_z / \partial z = -(\delta B_x \partial / \partial x + \delta B_y \partial / \partial y) j_z \, . \tag{10}$$

For convenience, let us introduce the flux function ψ by writing $(\partial \psi / \partial y, -\partial \psi / \partial x) = (\delta B_x, \delta B_y)$ for the perturbed transverse components of the magnetic field in the (x, y) directions such that the Gauss law of magnetism, $\nabla \cdot \mathbf{B} = 0$ is satisfied. Then, j_z and ψ are governed by Eq. (10) and the Ampere's law, $\nabla \times \mathbf{B} = \mathbf{j}$.

A simple example of the flux function and axial current density satisfying the above conditions would be the class of circularly cylindrical solutions of $\psi(r)$ and $j_z(r)$, [25,26]. Generally, the solutions would be more involved because of the variabilities of the local conditions of the plasma and the three-dimensional geometry. Moreover, the dynamic coherent structures with the inclusion of plasma pressure and other modifying effects (including electron-inertia terms) would be even more complicated. However, we expect these structures to be in the form of nearly field-aligned flux tubes, Fig. 3 [10,25,26, 136,137,138]. Existence of Alfvénic flux tubes in the magnetopause and magnetotail have also been suggested by Tetreault [116,117] and Chang [23,24], respectively.

Generally, there exist various types of propagation modes (whistler modes, electromagnetic ion cyclotron waves, etc.) in magnetized plasmas. Thus, we envision a corresponding number of different types of plasma resonances and associated coherent structures that typically characterize the dynamics of the plasma medium under the influence of an electromagnetic background.

Coarse-Grained Dissipation and Magnetic Reconfiguration

When coherent Alfvénic flux tubes with the same polarity migrate toward each other, strong local magnetic shears are created, Fig. 4. Wu and Chang [136,137,138] have demonstrated that the existing sporadic nonpropagating fluctuations in the strong local shear region, particularly those close to the neutral sheet (i. e., at the location where the local magnetic field vanishes), will stay in the region and continue to interact nonlinearly. On the other hand, fluctuations away from the neutral sheet region, are nonresonant and will therefore propagate away along magnetic field lines as Alfvén waves. Combined with the magnetic shear geometry, the resonant fluctuations will induce a nonlinear instability near the neutral sheet region, which will produce more fluctuations – nonresonant and resonant. The nonresonant fluctuations will again propagate away as Alfvén waves while the resonant ones will join the other resonant fluctuations and interact nonlinearly, thereby broadening the resonance region, Fig. 5.

This combined phenomenon of "coarse-grained dissipation" depletes the energy originally contained in the coarse-grained magnetic fields near the shear region, initiating a reconfiguration of the coherent structures. In coarse-grained sense, it breaks some of the closed field lines of each of the coherent structures and then reconnects them into single closed field lines. And this process continues with the system adjusting intermittently with the surrounding environment until all free energies are exhausted, eventually leading to the formation of one single combined coherent structure with one set of coarse-grained concentric closed field lines, Fig. 6.

The final state of the resulting coherent structure will have less average energy due to the combined dissipation of Alfvénic propagation of nonresonant fluctuations and nonlinear interactions of the resonant fluctuations (i. e., resonance broadening). Such is the manifestation of continuous magnetic topological reconfiguration due to the dynamic "fluctuation-induced nonlinear instability". And this merging process may repeat over and over again among the coherent structures of the same polarity, from the largest scales to the smallest scales where kinetic effects may have to be included.

On the other hand, when coherent structures of opposite polarities approach each other due to the forcing of the surrounding plasma, they might repel each other, scatter, or induce magnetically quiescent localized regions.

Under any of the conditions of the above interaction scenarios, new fluctuations will be generated. And these new fluctuations can provide new resonance sites, thereby nucleating new coherent structures of varied sizes. This kind of tangled geometry of interacting flux tubes leading to dynamical complexity has been described by Bruno et al. [10] who first deduced their existence in the solar wind, as "cooked spaghetti", Fig. 3 (top panel), and demonstrated by Wu and Chang [136,137,138], Fig. 3 (bottom panel), Matthaeus et al. [90], Fig. 7, and others with MHD simulations. And they are the source of the observed sporadic and localized current disruptions in the Earth's magnetotail and elsewhere [75,78,82].

Topological reconfigurations of such nature occur quite frequently for the dynamical interactions of coherent structures in space plasmas and are not limited just to flux tubes; for example, Sundkvist et al. [109] and Alexandrova et al. [1] have observed intermittent interactions of drift Alfvén vortices in the cusp and magnetosheath, respec-

tively. Similarly, such enhanced intermittency at the intersection regions of whistler coherent structures has also been surmised by Consolini and Lui [40] and Consolini et al. [42] in the plasma sheet. All such intermittent interactions are quite akin to the avalanche phenomenon prevalent in sandpile models [3,35,36,62,133]. They are the origin of the various observed magnetic reconnection signatures in space plasmas.

This stochastic behavior of the interactions of the plasma coherent structures is a phenomenon of "dynamical complexity" as defined in Sect. "Definition of the Subject", which, for emphasis, is reproduced below:

"Dynamical complexity" is a phenomenon exhibited by a nonlinearly interacting dynamical system within which multitudes of different sizes of large scale "coherent structures" are formed, resulting in a complicated global nonlinear stochastic behavior for the dynamical system – vastly different from that could be surmised from the original dynamical equations.

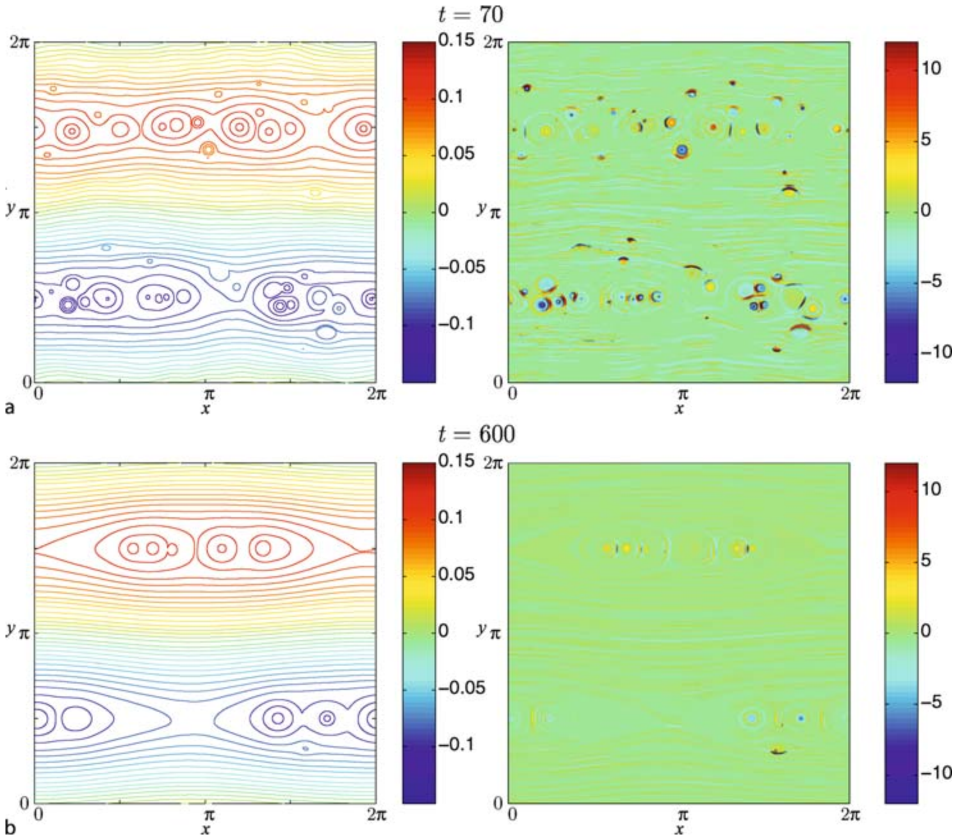
Non-Gaussian Probability Distribution Functions

The fluctuations that are induced by the interactions and mergings of coherent structures are sporadic and localized. Since the coherent structures are numerous and outsized, we expect the fluctuations within the interaction regions of these structures (resonance overlap regions) to be large and occur relatively more frequently than those that would have been expected from a medium of the original minute plasma particles (electrons, ions and neutrals). A technique useful in gauging the degree of such effects is by studying the shapes of the probability distribution functions (PDFs) of intermittent fluctuations at varying scales.

To demonstrate this, let us refer to one of the 2D MHD simulations described previously [32,33,136,137,138]. (In the following discussions, the measured fluctuations may be those of any physical property of the MHD medium. We shall choose the physical property as the strength of the magnetic field $B(x_i)$ to render the discussions more specific). Consider, for example, the spatial series of the strength of the magnetic field $B(x_i)$ for a given time t and at fixed y, with $x_i = i\delta$ where $i = 0, 1, 2, \ldots, N$, and δ is the grid size of the simulation. We can then form the coarse-grained differences

$$\delta B_i^2(\Delta) = B^2(x_i + \Delta) - B^2(x_i) \qquad (11)$$

within the interval with $\Delta = k\delta$ (k: an integer) and generate the probability distribution function $P(\delta B^2, \Delta)$. Figure 8 displays the calculated results of $P(\delta B^2, \Delta)$ for a 2D MHD simulation for the homogeneous case for several coarse-grained scales, Δ. From this figure, we note that the distribution for each scale falls nearly onto a smooth curve with the exception at the tails where scatterings from the mean are more visible. And the shapes of the PDF curves deviate more and more from that of a Gaussian at smaller and smaller scales.



Space Plasmas, Dynamical Complexity in, Figure 5
2D MHD simulation of coarse-grained dissipation in sheared magnetic field. *Left*: Contours of magnetic flux. *Right*: Corresponding current density distributions. Initially, new fluctuations are excited and the resonant fluctuations begin to interact nonlinearly near the neutral sheet region (near $y = \pi/2, 3\pi/2$). Eventually, the field lines are reconnected in the coarse-grained sense. Adapted from [137] with permission from Elsevier

Such PDFs sometimes satisfy the one-parameter scaling form:

$$P(\delta B^2, \Delta)\Delta^s = P_s(\delta B^2/\Delta^s) \tag{12}$$

where s is the parameter (or scaling exponent) such that all PDFs essentially collapse onto one master scaling function P_s. Such scaling behavior seems to be approximately satisfied for the above simulated result with $s \approx 0.335$ (Fig. 9), although closer examination reveals some discrepancies – particularly in the tail regions [33]. The more subtle nature of the scaling properties of such PDFs will be considered further in Sect. "Multifractals".

We shall now proceed to make contact with in-situ spacecraft observations. Until recently, most of the turbulence data in space came from measurements obtained by one single spacecraft. The data are then analyzed based on the Taylor hypothesis [113] which assumes that the transit time of eddies (bundled fluctuations) is much less than the characteristic evolution time. For fully developed MHD turbulence, the characteristic eddy turnover (evolution) time may be estimated:

$$t(\text{evolution}) \sim (\lambda/2\pi)/[(\delta B/B_0)v_A] \tag{13}$$

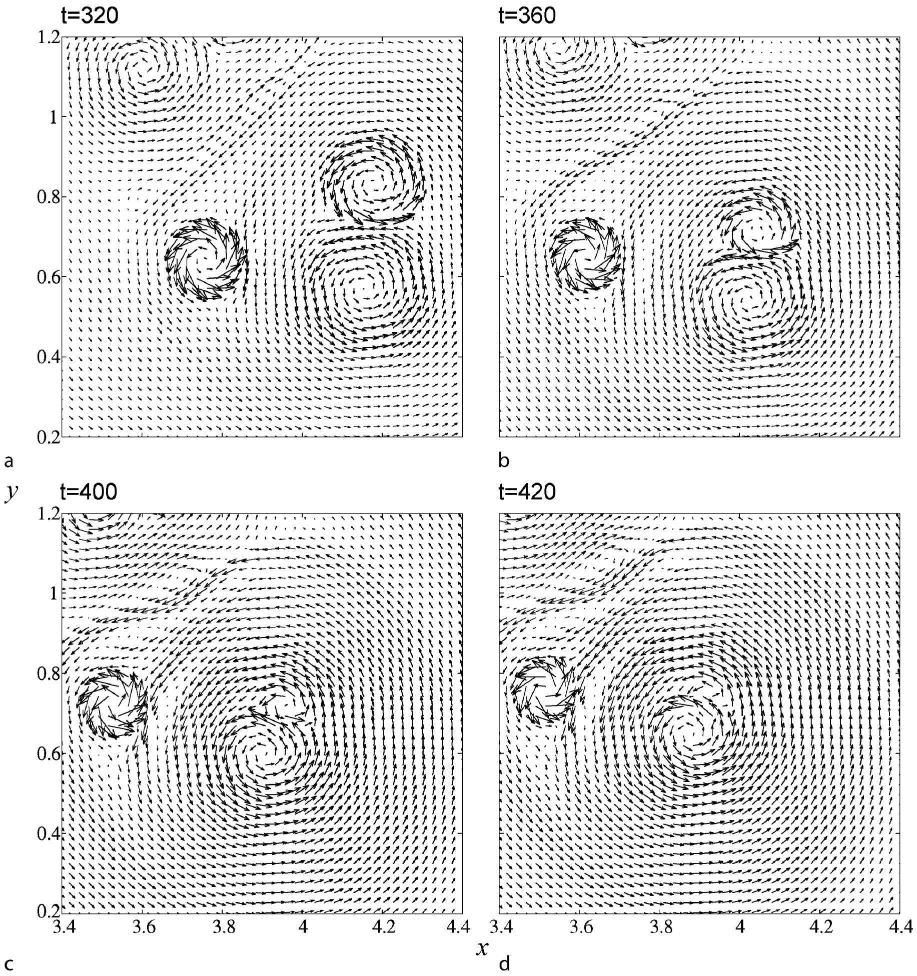
where λ is the typical size of the eddy, v_A is the Alfvén speed based on the mean magnetic field B_0 and δB is the average fluctuating magnetic field of the eddy in question. The transit time of the eddy is:

$$t(\text{transit}) \sim \lambda/v_s \tag{14}$$

where v_s is the relative streaming speed between the plasma medium and the spacecraft.

Thus, as it has been demonstrated by Matthaeus and Goldstein [88] that the requirement of $t(\text{evolution}) \gg t(\text{transit})$ becomes:

$$v_s/v_A \gg 2\pi(\delta B/B_0) \tag{15}$$



Space Plasmas, Dynamical Complexity in, Figure 6
2D MHD simulation of merging of flux tubes. *Arrows* indicate magnitudes and directions of magnetic fields. Reprinted from [137] with permission from Elsevier

As pointed out by Tu and Marsch [120], at 1 AU for solar wind observations the wind speed (which is essentially the relative speed between the plasma medium and the spacecraft since it is much larger than the spacecraft speed) is of the order of 10 times that of the ambient Alfvén speed and $\delta B/B_0 \simeq 0.5$. Therefore, condition (15) is satisfied for solar wind turbulence in that region. Because the spacecraft speed is much smaller than the solar wind speed, the data gathered by instruments aboard the spacecraft essentially sample the spatial fluctuations in the direction of the solar wind, particularly at times when the solar wind turbulence is homogeneous at large scales and fully developed. Thus, for example, the time series of such measurements of the strength of the magnetic field $B(t_i)$, where $t_i = i\delta$ with $i = 0, 1, 2, \ldots, N$ and δ is the sampling interval, may be interpreted based on the hypothesis as the spatial series of the ambient turbulence fluctuations with $x = v_s t$ (x: direction of the solar wind velocity). We can then construct the probability distribution function $P(\delta B, \tau)$ or $P(\delta B^2, \tau)$ with the coarse-grained scale $\tau = k\delta$ (k: integer) in analogy to the calculations related to the simulation results discussed above.

Non-Gaussian probability distribution functions from such statistics have been commonly observed in the solar wind for fluctuations related to the magnetic, velocity, density and other field variables, e. g. [15,47,48,56,71,72,85,107,108]. Figure 9 depicts the typical PDFs of magnetic field fluctuations obtained from such an analysis for both the slow ($\sim (400 \pm 200)$ km/s) and fast ($\sim (700 \pm 100)$ km/s) solar wind [108]. The similarities between the simulated results and results from such observations as exhibited in Fig. 9 are quite striking.

One popular empirical technique in expressing the shape of the PDFs of the observed intermittent turbulent fluctuations is the Castaing distribution. In 1990, Castaing et al. [21] suggested that the intermittent fluctuations might perhaps be viewed as an ensemble of subsets of fluctuations ξ, each subset having a normal distribution:

$$P_\sigma(\xi) = \frac{1}{\sigma\sqrt{2\pi}} \exp(-\xi^2/2\sigma^2) \tag{16}$$

where σ is the variance. The intermittency is then assumed to be due to the fluctuations of the variances that satisfy a log-normal distribution:

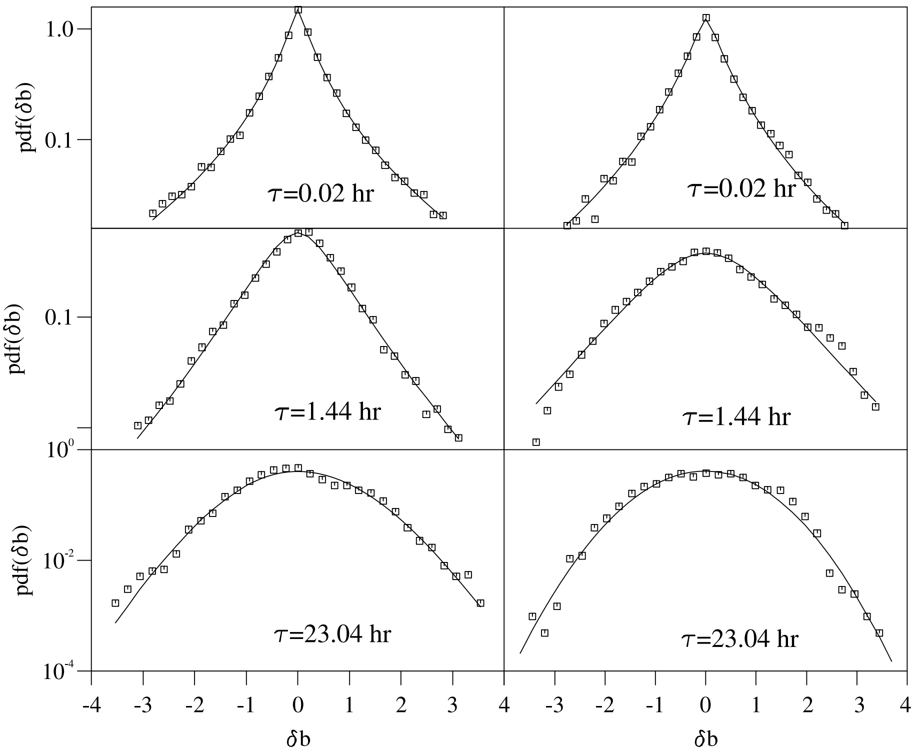
$$Q_\lambda(\sigma)\mathrm{d}\sigma = \frac{1}{\lambda\sqrt{2\pi}} \exp\left(-\frac{\ell n^2(\sigma/\sigma_0)}{2\lambda^2}\right) \mathrm{d}\ell n\sigma \tag{17}$$

where σ_0 is the most probable variance of ξ, and λ is the variance of $\ell n\sigma$. Combining (16) and (17) gives the Castaing distribution

$$\Pi_\lambda(\xi) = \frac{1}{2\pi\lambda}\int_0^{+\infty} \exp\left(-\frac{\xi^2}{2\sigma^2}\right) \exp\left(-\frac{\ell n^2(\sigma/\sigma_0)}{2\lambda^2}\right) \frac{\mathrm{d}\sigma}{\sigma^2}\,. \tag{18}$$

Such fits of data to (18) are shown as solid curves in Fig. 10. How well does such an ansatz characterize the data depends very much on the type and scale of the fluctuations [47]. Other empirical fits such as the kappa-distribution and gamma-distribution have also been suggested, but we do not have space here to enumerate and discuss these and other phenomenological models.

Similar observational results have been detected for the magnetic field and velocity fluctuations in the plasma sheet [2,134], in the cusp [44,139], for the electric field



Space Plasmas, Dynamical Complexity in, Figure 10

fluctuations in the auroral zone [111,112], as well as for fluctuations of other field variables, though caution must be exercised in interpreting some of these results as the Taylor hypothesis may or may not be satisfied in the observational regions.

Wavelet Transforms and Intermittency

Traditional procedure for analyzing fluctuations is to perform Fourier transforms of the observational, numerical or experimental data. The basis functions of the Fourier transform are sines and cosines. Each such basis function extends in space (or time) all the way from minus infinity to plus infinity. Thus, Fourier transform essentially wipes out the localized information of the intermittent fluctuations resulting from the confined interactions of the coherent structures. Therefore, for intermittent turbulence, it will be more appropriate to consider transforms whose basis functions are localized and scale dependent instead of sines and cosines. Such a transform has the generic name of "wavelet transform" [43,46]. Below, we restrict our discussions to one-dimensional wavelet transforms.

To be more specific, a wavelet transform replaces (transforms) the fluctuating spatial (or temporal) series into the coefficients of a set of basis functions that are localized in space (or time) with different scales in space (or time). The basis functions are usually chosen such that they are square-integrable and generated by a single mother wavelet, a rescalable and translatable function $\psi[(x-b)/a]$ where a is the scale and b defines the translation along x. Two of the more popular mother wavelets are the complex-valued Morlet wavelet [94] defined by

$$\psi_0(y) = \mathrm{e}^{ik\cdot y}\mathrm{e}^{-|y|^2/2} \tag{19}$$

and the Haar wavelet [52] given by

$$\psi_0(y) = \begin{cases} 1 & \text{if } y \in [0, 1/2); \\ -1 & \text{if } y \in [1/2, 1),\ \text{and} \\ 0 & \text{if } y \notin [0, 1)\,. \end{cases} \tag{20}$$

To generate the full set of functions, we simply replace the argument in (19) or (20) by $(x-b)/a$ and allow the parameters (a, b) to vary within the domain of interest.

The Morlet wavelet is appealing to the physicists because it fits in with the usual understanding of wave packets. And due to its continuous nature, the transform is amenable to analytical manipulations. One disadvantage of the Morlet wavelets is that they are not entirely orthogonal to each other. The Haar wavelet, on the other hand, is truly local and the basis functions are real and orthogonal to each other. The simple and discrete nature of the Haar wavelets renders it ideal for numerical applications. One disadvantage of the Haar wavelets is that they are not symmetrical with respect to the midpoint, thus producing slanted spectral plots. This asymmetry, however, becomes less and less noticeable for smaller and smaller scales.

To obtain the coefficients of a wavelet transform for a particular fluctuating spatial (or temporal) series $S(x)$, we evaluate the convolution integral as follows:

$$C(a,b) = (K/a)\int S(x')\psi[(x'-b)/a]\mathrm{d}x' \qquad (21)$$

where K is a normalization constant.

From $C(a,b)$, we can calculate, for example, the normalized power $\mathrm{NP}(a,b)$:

$$\mathrm{NP}(a,b) = |C(a,b)|^2 / \langle |C(a,b)^2| \rangle_x \qquad (22)$$

where $\langle \dots \rangle_x$ denotes the spatial (or temporal) average; and, here, the average is essentially the Fourier transformed power for the entirety of the fluctuations. In usual applications, only a truncated finite set of coefficients are used to perform practical calculations. The normalized power is a power spectrum of both scale and location; thus, it is sometimes called the Local Intermittency Measure, LIM. By definition, LIM is equal to 1 for the Fourier transform. Figure 11(top) is a color representation of the Local Intermittency Measure or LIM of the magnetic field intensity using the Haar transform for the 2D homogeneous MHD simulation discussed previously at a given time t and for fixed y. The scale-dependent, sporadic and localized powers of the fluctuations are vividly displayed. We note that the intermittency increases as the scale is reduced. And, the intensity can be rather strong at small scales – even when the fluctuations are strongly intermittent and localized.

Normalized power of wavelet transforms have been used to evaluate the Local Intermittency Measure LIM in the solar wind (e. g. [9,10]), for the AE index [38,39], in the magnetotail (e. g. [42,77,131]), in the cusp (e. g. [44, 139]), and in the auroral zone [112]. Figure 11 (bottom) is a color representation of the Local Intermittency Measure LIM using the Haar transform for the electrical field fluctuations in the transverse direction to the magnetic field in the auroral zone [112]. The characteristics of strong intermittency at small scales are clearly visible.

As it has been pointed out in Sect. "Non-Gaussian Probability Distribution Functions", intermittent fluctuations have non-Gaussian probability distributions especially at small scales. We may look for a quantity which provides a measure of the non-Gaussian nature of the fluctuations as a function of scale. A normalized scale dependent measure related to the fourth order moment of the coarse-grained probability distribution is called the Flatness. It indicates whether the data are more peaked or flatter relative to the Gaussian distribution. It is also called the Kurtosis. It has been suggested by Meneveau [91] that the average over space (or time) of the square of the normalized power is essentially the scale dependent Flatness of the probability distribution.

$$\text{Flatness} = \left\langle [\mathrm{NP}(a.b)]^2 \right\rangle_x \qquad (23)$$

For Gaussian probability distributions, the value of the Flatness may be shown to be equal to 3. For an intermittent event, the Flatness increases without bound at small scales. The rate at which the Flatness increases with the decrease of scale is a measure of intermittency. Figure 12(top) plots the values of the Flatness calculated as a function of scale corresponding to the fluctuations discussed above for the magnetic field fluctuations for the 2D MHD simulation for given y and fixed t. We note that the value of the Flatness becomes larger than 3 and continues to increase as the scale becomes smaller and smaller.

Flatness has been evaluated for the solar wind turbulence by Bruno et al. [10,11], Fig. 12(bottom). It is one of the tools used by Bruno et al. [10] to arrive at the conclusion that solar wind turbulence is the manifestation of interacting tangled flux tubes or "cooked spaghetti" as depicted in Fig. 3(top). Wavelet transforms have been used by various authors to evaluate Flatnesses of intermittent turbulence in other regions of space plasmas, e. g. [44,77, 112,131,139]. Other more generalized techniques of gauging the intermittency in space plasma turbulence have also been employed by Vörös [129] and Vörös et al. [130,132], which we shall not discuss here.

The normalized power and Flatness are only two tools that provide gauges of intermittency of a fluctuating series. One might ask: Are there other measures such that in their totality fully characterize the intermittency nature of the fluctuating series? This will be addressed briefly in the next section.

Multifractals

Another popular modus operandi designed to study the phenomenon of intermittency is based on the concept of multifractals. As we have seen above, turbulence in space plasmas generally encompass fluctuations of all varieties and sizes, which interact and propagate throughout the plasma medium. For illustrative purposes, let us visualize some particular fluctuations that have conventional geometrical properties in a three-dimensional Euclidean space. Because of their sporadic and localized nature, it is easy to imagine that they generally cannot fill the full three-dimensional space that they occupy at a given time. Or said in another way, the space these fluctuations occupy is only a fraction of the full three-dimensional space. Such geometrical property was popularized by Mandelbrot [83] when he coined the word "fractals" or fractal geometry.

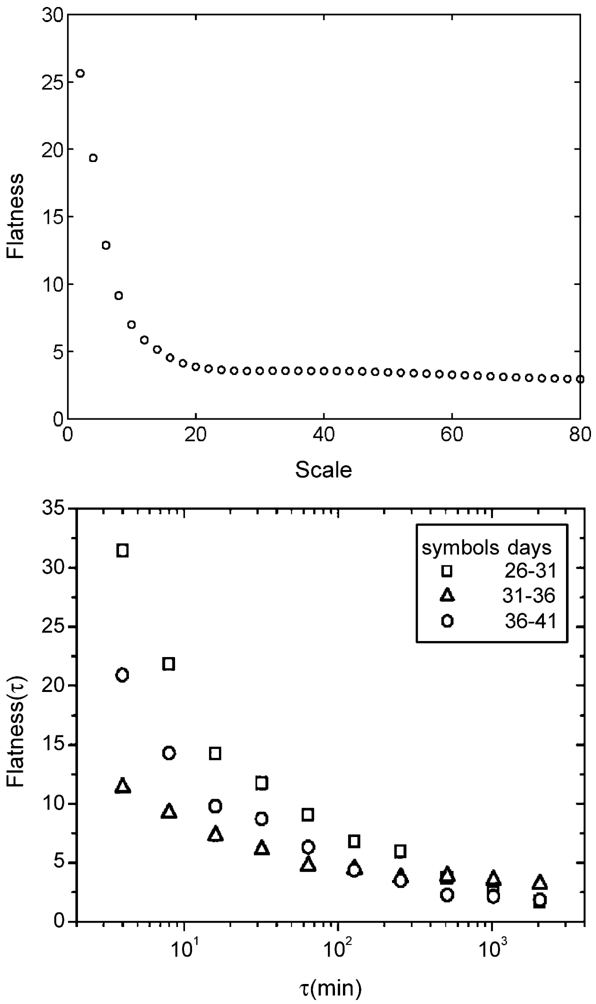
Actual fluctuations in plasma turbulence generally do not have the conventional geometrical properties. We must then devise some abstract "measure" to characterize the properties of the fluctuations and evaluate its fractal characteristics which may be interpreted with geometrical analogs. Consider, for example, the spatial series of the simulated fluctuations of the strength of the magnetic field, $B(x_i)$, along some constant value of y at time t for the two-dimensional homogeneous MHD turbulence discussed in the previous sections, where $x_i = i\delta$ with $i = 0, 1, 2, \ldots, N$ and δ is the length between grid points. From this series, we can construct a spatial series by considering, for example, the absolute value of the fluctuations due to the coarse-grained difference of the strength of the magnetic field between two spatial values $x_i + \Delta$ and x_i with $\Delta = k\delta$, some multiple of δ:

$$\delta B_i = |B(x_i + \Delta) - B(x_i)| \tag{24}$$

within the spatial interval $X = N\delta$. The simulation is statistically homogeneous over the interval X. Thus, we may calculate the ensemble average of δB_i over the interval X,

$$S_1(\delta B, \Delta) = \langle |B(x_i + \Delta) - B(x_i)| \rangle \tag{25}$$

and use it as a "measure" for the coarse-grained fluctuations of the simulated spatial series. The choice of taking



Space Plasmas, Dynamical Complexity in, Figure 12

Reprinted from [11] with thanks to the American Institute of Physics**

the ensemble average of the absolute values of the coarse-grained differences instead of the values of the raw differences is for the purpose of better statistical convergence [8, 127]. We can then plot $\log S_1(\delta B, \Delta)$ against $\log \Delta$ for different choices of Δ (or k). If the result approximates a straight line for some range of Δ for small Δ, we can then assign a fractal number $\zeta_1(\delta B)$ to the fluctuations of the strength of the magnetic field as:

$$\zeta_1(\delta B) = \mathrm{d}(\log S_1(\delta B, \Delta))/\mathrm{d}(\log \Delta) \tag{26}$$

for this range of small Δ. In other words, within this range of small Δ we may represent $S_1(\delta B, \Delta)$ as power of Δ with exponent $\zeta_1(\delta B)$. This exponent may be considered as an analog to the classical concept of dimension. It is generally an irrational number and usually cannot be surmised from simple dimensional analysis arguments; thus it is sort of a "fractal dimension" for the particular choice of "measure" described above.

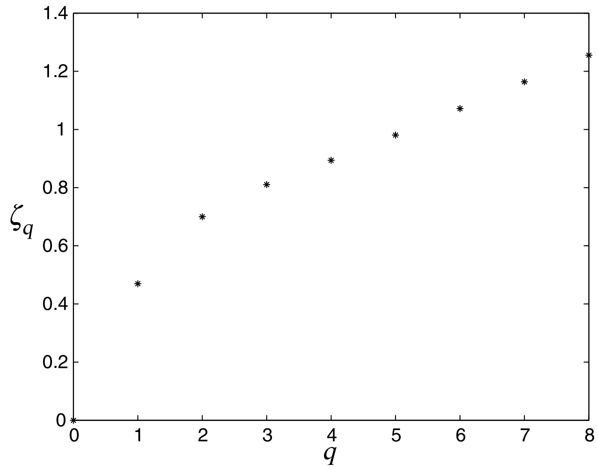
Structure Functions

It is obvious that if another choice of measure is made, the corresponding fractal number for the same spatial series will generally be different. For example, one might wish to look at higher order moments of the PDFs $P(\delta B, \Delta)$ of δB, the so-called structure functions:

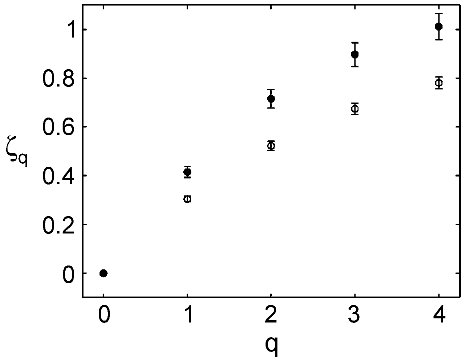
$$\begin{aligned} S_q(\delta B, \Delta) &= \int (\delta B)^q P(\delta B, \Delta)\,\mathrm{d}(\delta B) \\ &= \left\langle |B(x_i + \Delta) - B(x_i)|^q \right\rangle \end{aligned} \tag{27}$$

The motivation here is that different moments emphasize different peaks in the fluctuating series. Generally, corresponding to each ζ_q there will be a fractal exponent ζ_q for small Δ. If $\zeta_q = \zeta_1 q$, then the fractal property of the fluctuating series is fully characterized by the value of ζ_1. Such fluctuations are then said to be "monofractal" or "self-similar", i. e., the fractal characteristics for all the moment orders are similar to each other. For general intermittent turbulence, on the other hand, ζ_q would be a nonlinear function of q, or "multifractal".

In practical calculations, it has been suggested by Benzi et al. [6] for hydrodynamic turbulence studies that the correlations among the structure functions seemed to be much more apparent than those exhibited by the correlations of individual structure functions directly with coarse-grained scaling. This is particularly true for structure functions based on the absolute values of the differences of fluctuations as it is defined here [51]. This also seemed to be true for plasma turbulence studies [19,20,95, 100]. Thus, it has become very popular to first determine the relative values of the structure function exponents with respect to the structure function exponent of a particular order, and then determine the exponent for that particular order more accurately by some phenomenological, dimensional, or empirical reasoning. This procedure is called "extended similarity scaling" (ESS). Figure 13 is the result of such a statistical calculation for the fluctuations of the magnetic field strength $B(x_i)$ of the 2D homogeneous MHD simulation for given y and t. We note that the structure function exponents exhibit nonlinear, i. e., multifractal, behavior as expected for intermittent turbulence.



Space Plasmas, Dynamical Complexity in, Figure 13
Structure function exponents for the magnetic field intensity at given time *t* and for fixed *y* using ESS for a 2D MHD simulation for homogeneous intermittent turbulence. The values of the exponents at high orders are less accurate than those for the low orders due to the size limitation of the simulation box. Reprinted from [27] with thanks to the American Institute of Physics



Space Plasmas, Dynamical Complexity in, Figure 14
Structure function exponents using ESS for the time series of the strength of the magnetic field collected for extended periods during solar minimum (low solar activity) by the WIND spacecraft (*circles*) and solar maximum (high solar activity) by the ACE spacecraft (*filled circles*). Adapted from [11] with thanks to the American Institute of Physics

Calculations for structure function exponents have been carried out for magnetic and velocity fluctuations in the solar wind, e. g. [11,12,13,14,17,58,59,60,86,97,121] and elsewhere in the space environment, e. g. [57], usually by assuming the applicability of the Taylor hypothesis. We caution here again that except for most of the solar wind studies, the assumption of the Taylor hypothesis must be exercised with a critical eye. In Fig. 14, the results for such calculations for the time series of the strength of the magnetic field collected for extended periods during solar minimum (low activity) and solar maximum (high activity) by two separate spacecraft (Wind and ACE) are presented. The multifractal nature of the intermittent turbulence is apparent in both calculated results [11].

Structure function calculations may be performed conveniently for a fluctuating series for positive values of q; but will generally diverge for $q < 0$. An alternative procedure to evaluate the fractal characteristics of different moment orders is the so-called "singularity analysis" described below.

Partition Functions, Generalized Dimensions and Singularity Spectra

As we have seen in the previous discussions, turbulence in space plasmas is generally intermittent and therefore probably composed of an admixture of fluctuations of different fractal characteristics. We may attempt to extract this "multifractal" nature of the observed fluctuating time series by searching for the "dominant singular behavior" for different moment orders at small scales following the technique suggested by Parisi and Frisch [98] and Halsey et al. [54] and first applied to solar wind turbulence by Burlaga [12,13,14,15], and later for the auroral electrojet (AE) index by Consolini [41], for the high latitude geomagnetic fluctuations by Vörös [129,130], for the plasma sheet by Lui [76] and Weygand et al. [134], to the magnetospheric cusp by Yordanova et al. [139], and to the auroral electric field fluctuations by Chang et al. [34].

The basic idea here is to define an appropriate measure that is scale dependent. (Instead of referring to a spatial series such as that considered above for the numerical simulation, for variance, we consider below a generic time series based on temporal observations). To proceed, we first define an "incremental measure":

$$\delta\mu_j = \left|B(t_j+\delta) - B(t_j)\right| \tag{28}$$

where δ is the sampling interval. We now subdivide the total time interval T into $M = T/\tau$ segments with $\tau = k\delta$ and calculate the normalized scale-dependent "segmental measure"

$$\mu_i(\tau) = \sum_{j=(i-1)k+1}^{ik} \delta\mu_j/\mu \quad \text{with} \quad \mu = \sum_{j=1}^{N} \delta\mu_j \tag{29}$$

For convenience, we will generally choose M to be an integer.

The normalization of $\mu_i(\tau)$ is an attempt to represent the segmental measure as a measure of probability. This is the scale dependent measure that we seek to define. We shall assume that each such measure varies with the scale τ in a singular manner as a power law. We now form the qth moment order of the coarse-grained probabilities $\mu_i(\tau)$, traditionally called the "partition function" [54]:

$$\Gamma(q,\tau) = \sum_{i=1}^{M} \mu_i^q(\tau) \tag{30}$$

where q can be any real number. We shall now search for the dominant singular behavior of $\Gamma(q,\tau)$ as characterized by a power law in τ with exponent $\gamma(q)$ for small τ similar to that for the structure function analysis. In general, for each moment order, $\gamma(q)$ is a different number characterizing the particular fractal behavior of the subset of fluctuations, which dominates the (singular) scaling behavior of that particular moment order.

As mentioned above, Consolini et al. [41] have carried out such a singularity measure multifractal analysis for a typical time series of the auroral electrojet (AE) index, Fig. 15 (top left panel). In their calculations, the incremental measure was chosen as:

$$\delta\mu_j = \left|\phi_{\mathrm{AE}}(t_j+\delta) - \phi_{\mathrm{AE}}(t_j)\right|^2 \tag{31}$$

where $\phi_{\mathrm{AE}}(t_j)$ is the measured AE index at time t_j and δ is the sampling interval. We note from the figure that $\gamma(q)$ is indeed a nonlinear function of q, and thus, a "multifractal". There are two distinct asymptotic regimes of q ($q < -2$, and $q > +2$) for which $\gamma(q)$ varies with q nearly linearly and a nonlinear crossover region between the two asymptotes.

Henschel and Procaccia [55] suggested the concept of the so-called "generalized dimensions" for fractals. Their definition of the generalized dimension D_q is related to the partition function $\Gamma(q)$ as follows:

$$D_q = (q-1)^{-1} \lim_{\tau\to 0} \log\Gamma(q)/\log\tau = \gamma(q)/(q-1)\,. \tag{32}$$

It is called the generalized dimension because in the limit of $q \to 0$, D_0 is essentially the fractal (or similarity) dimension defined by Mandelbrot [83]. Also, it may be shown that, in the limit of $q \to 1$, D_1 corresponds to the so-called information dimension [5]. In addition, D_q's for $q \geq 2$ are the corresponding qth correlation dimensions [50]. The calculated generalized dimension D_q as a function of moment order q for the AE index is shown in Fig. 15 (top right panel). As shown by Consolini et al. [41], such a nonlinear variation may be modeled rather accurately by the so-called p-model which is a "two-scale cascade model" as follows [16,92]:

$$D_q = \log_2[p^q + (1-p)^q]^{1/(1-q)} \quad \text{with} \quad p = 0.746 \pm 0.002\,. \tag{33}$$

where p is the single fitting parameter associated with the fragmentation probability of the cascade process. This one-parameter representation of the generalized dimension for the multifractal phenomenon of the AE index reinforces the idea stated earlier that the multifractal phenomenon can be thought of as the crossover phenomenon between two invariant regions.

Another way to gauge the multifractal characteristics in terms of the partition function formalism is the method of the singularity spectrum $f(\alpha)$ [54,98]. If we associate with each segmental measure μ_i a singularity index α_i such that $\mu_i = \tau^{\alpha_i}$ where α_i is within some range between α and $\alpha + \Delta\alpha$ and pass on to the continuum limit by writing the number of differential measures whose singularity index is between α and $\alpha + \mathrm{d}\alpha$ as $\rho(\alpha)\tau^{-f(\alpha)}\mathrm{d}\alpha$, then the partition function as defined in (30) in the continuum limit is:

$$\Gamma(q,\tau) = \int \mathrm{d}\alpha' \rho(\alpha')\tau^{-f(\alpha')+q\alpha'}\,. \tag{34}$$

Since we are interested in the phenomenon for very small τ, the integral is dominated by the value of α' which makes the expression $-f(\alpha') + q\alpha'$ the smallest. Assuming $\rho(\alpha') \neq 0$ and $f(\alpha')$ smooth, the minimum is located at $\alpha' = \alpha(q)$ with

$$f'(\alpha(q)) = q \quad \text{and} \quad f''(\alpha(q)) < 0 \tag{35}$$

Therefore the partition function for very small τ is approximately

$$\Gamma(q,\tau) \sim \exp\left\{[q\alpha(q) - f(\alpha(q))]\ln\tau\right\} \tag{36}$$

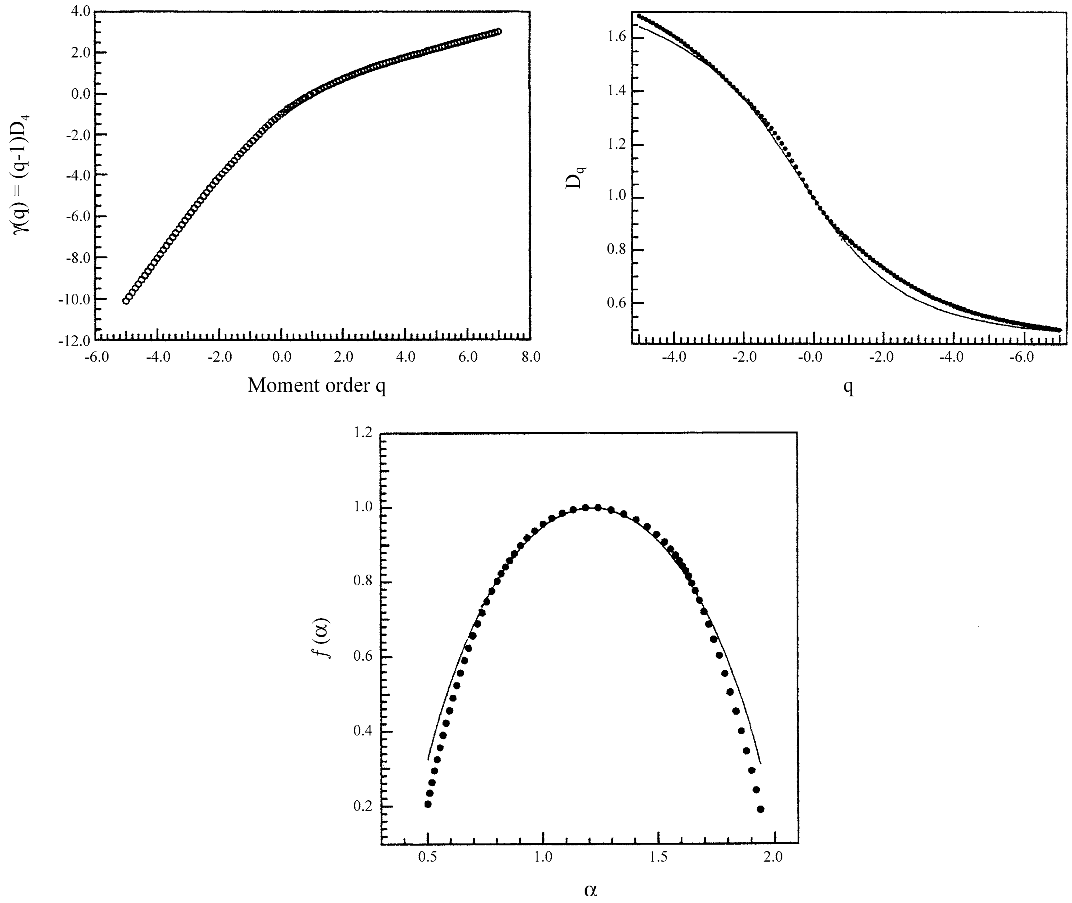
This leads immediately to the identification of

$$\gamma(q) = D_q(1-q) = [q\alpha(q) - f(\alpha(q))] \tag{37}$$

Differentiating (37) with respect to q and using the first expression of (35), we obtain

$$\alpha(q) = \gamma'(q) \equiv \mathrm{d}\gamma/\mathrm{d}q \tag{38}$$

Thus, given $\gamma(q)$, we may determine $\alpha(q)$ and then, $f(\alpha)$. Such a singularity spectrum for the AE index considered by Consolini et al. [41] is given in Fig. 15 (bottom panel). Because $\alpha(q)$ is intimately related to $\gamma(q)$ (and therefore



Space Plasmas, Dynamical Complexity in, Figure 15

***Top left*: Partition function exponent $\gamma(q)$ for a time series of the AE (auroral electrojet) index. *Top right*: Generalized dimension D_q for the same AE time series. Solid line is the best fit using the *P*-model. *Bottom*: Singularity spectrum $f(\alpha)$ for the same AE time series obtained from the Legendre transform. Adapted from [41] with thanks to the American Physical Society**

also to the partition function $\Gamma(q)$), $f(\alpha)$ sorts out the spectrum of singularities of the intermittent fluctuations, that may be mapped to the multifractal dimensions D_q as defined by (32).

In the above, we have introduced a sequence of algebraic manipulations mainly for the purpose of connecting three different popular approaches of identifying the singularity nature of the multifractal characteristics of a time (or spatial) series based on the partition function formulation. We must emphasize that these are merely different approaches of viewing fracture characteristics of intermittent fluctuations with no additional physics involved, except perhaps with the following useful thermodynamic analogy. That is, the relationship between $(\gamma(q), q)$ – or equivalently (D_q, q) – and $(f(\alpha), \alpha)$ is formally a Legendre transform. Thus, one may easily associate the relationships among such measures with the standard notion of Legendre transforms of classical thermodynamics [96]. Such a connection may become useful in identifying analogies between singularity measures of multifractals with multicriticality measures in thermodynamics.

It is interesting to note that in multifractal analyzes of space plasma turbulence in regions where intermittency are expected, similar functional dependence of $\gamma(q)$ on q as above is also generally obtained [12,13,14,15,18,34,87,134,139]. Although, we must recall that for turbulence in the plasma sheet or the auroral zone and even sometimes in the solar wind, the assumption of the validity of the Taylor hypothesis must be applied with caution.

In the previous section, it was demonstrated that intermittency characteristics of a fluctuating series could be brought out using the technique of wavelet transforms. Certain quantities, Local Intermittency Measure LIM or Normalized Power and Flatness, were introduced using the wavelet transforms to gauge the intermittency effects. Since the complete set of coefficients of the wavelet transforms essentially represents the full fluctuating event, it is reasonable to inquire if it can be used to advantage to describe the full characteristics of intermittency of a fluctuating series. The answer is a definite *yes*. For example, wavelet transforms have been used to study multifractal characteristics of time series related to intermittent turbulence in space plasmas by Yordonova et al. [139] for the magnetospheric cusp and Vörös et al. [131] for the plasma sheet.

Rank-Ordered Multifractal Analysis (ROMA)

In the above, intermittent fluctuations were analyzed using the structure function and/or partition function methods based on the statistics of the full set of fluctuations. Since most of the observed or simulated intermittent fluctuations are dominated by fluctuations with small amplitudes, the subdominant fractal characteristics of the minority fluctuations – generally of larger amplitudes – are easily masked by those characterized by the dominant population. It therefore appears useful to search for a procedure that explores the fractal nature of the subdominant fluctuations by first appropriately isolating out the minority populations and then perform statistical investigations for each of the isolated populations.

Phrasing it differently, for intermittent fluctuations exhibiting multifractal characteristics, we visualize that these fluctuations are composed of many types, each type being characterized by a particular fractal dimension. The questions to ask then are (i) what are the different fractal dimensions? and (ii) how are the various types or classes of fluctuations distributed within the turbulent medium? We answer these questions quantitatively by constructing a "rank-ordered multifractal spectrum".

Using the example of a 2D MHD simulation that was discussed in Sect. "Non-Gaussian Probability Distribution Functions", we demonstrate below how this idea may be achieved with a rank-order method that subdivides the fluctuations into groupings based on the range of the scaled-sizes of the fluctuations [28]. In the simulation, ideal compressible MHD equations expressed in conservative forms are solved numerically with 1024 × 1024 grid points in a doubly periodic (x, z) domain of length 2π in both directions using the WENO code [64] so that the total mass, energy, magnetic fluxes and momenta are conserved. The initial condition consists of random magnetic field and velocity with a constant total pressure for a high beta plasma. As discussed previously, after sufficient elapsed time, the system evolves into a set of randomly interacting multiscale coherent structures exhibiting classical aspects of intermittent fluctuations.

We recall that the PDFs $P(\delta B^2, \varDelta)$ of the square of the magnitude of the magnetic field δB^2 for such intermittent fluctuations were non-Gaussian and became more and more heavy-tailed at smaller and smaller scales (Fig. 8). An attempt to collapse the unscaled PDFs according to the one-parameter scaling formula (12) re-displayed below as (39):

$$P(\delta B^2, \delta)\delta^s = P_s(\delta B^2/\delta^s) \tag{39}$$

indicated approximate scaling with an estimated scaling exponent of $s = 0.335$ (Fig. 9). The scaling formula (39) may be interpreted from the concept of fractals. We begin the interpretation by assuming that δB^2 and P vary with δ as power laws: $\delta B^2/\delta^a = I$ and $P/\delta^b = J$, where (a, b) are the power-law (fractal) exponents and (I, J) are constants – i. e. invariants with respect to the scale δ. If the form of $P(\delta B^2, \delta)$ is invariant as the scale changes, then it has been shown that a functional relation exists between the two invariants, (I, J) [29]. Imposing the normalization condition for the PDFs, we obtain the one-parameter scaling form (39) with $s = a = -b$.

Such a phenomenon is self-similar and the PDFs collapse onto one scaled PDF $P_s(Y)$ where $Y = \delta B^2/\delta^s$ is a scale invariant. In such a case, the structure function exponents for the PDFs will satisfy the monofractal property of $\zeta_q = sq$. The scaling exponent s may be interpreted as a single fractal measure that characterizes the fluctuations of all scales through the scaling relation (39). If the PDFs are self-similar Gaussian distributions for all scales, representing random diffusion, the scaling exponent s is equal to 0.5. For other monofractal distributions, the scaling exponent may take on any positive real value.

For the current example, structure function calculations based on the full set of simulated fluctuations showed a nonlinear relation between the exponents and the moment order, indicating the phenomenon is multifractal in nature [27]. However, the physical interpretation of the multifractal nature is not easily deciphered by merely examining the curvature of the deviation from linearity.

We shall therefore attempt to perform statistical analyzes individually for subsets of the fluctuations that characterize the various fractal behaviors within the full multifractal set. Such grouping of fluctuations must depend somehow on the sizes of the fluctuations. However, the groupings cannot depend merely on the raw values of the sizes of the fluctuations because the ranges will be different for different scales. Thus, we proceed to rank-order the sizes of the fluctuations based on the ranges of the scaled variable $Y = \left|\delta B^2\right|/\varDelta^s$ where s is the scaling exponent for each grouping defined in (39). (Absolute values of the fluctuations are used to take advantage of the symmetry property of the PDFs and for the purpose of better statistical convergence.) For each chosen range we shall assume that the fluctuations of all scales will exhibit monofractal behavior satisfying the form of (39) and be characterized by an scaling exponent s. The question is then how can this procedure be accomplished.

We begin by considering a differential range of scales dY in the vicinity of some scaled size $Y = \left|\delta B^2\right| / \Delta^s$. Fluctuations whose sizes fall within such a differential range will probably exhibit monofractal behavior characterized by some scaling exponent s such that the differential structure function $\mathrm{d}S_q$ will vary with the scale as Δ^{sq}, i. e.,

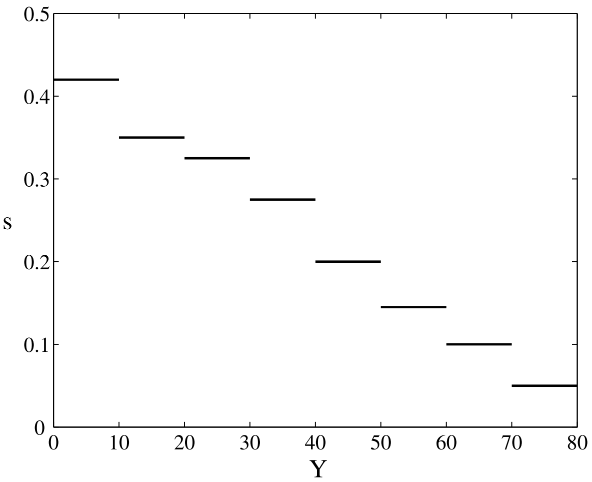
$$\mathrm{d}S_q \triangleq (|\delta B^2|)^q P(|\delta B^2|, \Delta)\,\mathrm{d}(|\delta B^2|) = \Delta^{sq} Y^q P_s(Y)\mathrm{d}Y \tag{40}$$

Given a set of PDFs $P(|\delta B^2|, \Delta)$, the corresponding multifractal spectrum $s(Y)$ may be obtained approximately (if the ansatz is valid) by integrating the functional differential expression (40) over small contiguous ranges of ΔY with the assumption that within each incremental range the scaling exponent s is essentially a constant [28]. Thus, for a generic range of ΔY within (Y_1, Y_2), we form such a range-limited structure function as follows:

$$\Delta S_q(\left|\delta B^2\right|, \Delta) = \int_{a_1}^{a_2} \left|\delta B^2\right|^q P(\left|\delta B^2\right|, \Delta)\,\mathrm{d}\left|\delta B^2\right|$$

$$\simeq \Delta^{sq} \int_{Y_1}^{Y_2} Y^q P_s(Y)\mathrm{d}Y \tag{41}$$

where $a_1 = Y_1\Delta^s$ and $a_2 = Y_2\Delta^s$. We then search the value of s such that the scaling property of the range-limited structure function that varies with s is $\Delta S_q(s) \sim \Delta^{sq}$. If such a value of s exists, then we have found one region of the multifractal spectrum of the fluctuations such that the PDFs in the range of ΔY collapses onto one scaled PDF. Performing this procedure for all contiguous ranges of ΔY produces the rank-ordered multifractal spectrum $s(Y)$ that we are looking for. The determined value of s for each grouping should be un-affected by the statistics of other subsets of fluctuations that are not within the chosen range ΔY and therefore should be quantitatively quite accurate. The physical meaning of this spectrum is that the PDFs for all time lags collapse onto one master multifractal scaled PDF. The spectrum is implicit since Y is a defined as a function of s.



Space Plasmas, Dynamical Complexity in, Figure 16
Rank-ordered multifractal spectrum, $s(Y)$. $Y = |\delta B^2|/\Delta^s; |\delta B^2|$ in units of bin size and Δ in grid spacing. The spectrum is calculated for 8 contiguous ranges of ΔY. Reproduced from [28] with thanks to the American Physical Society

Interestingly, for this particular example, there exists one and only one value of s in each range of ΔY, that satisfies the above constraint. Unlike the structure functions defined for the full range of fluctuations, the range-limited structure functions based on (41) exists also for negative real values of q (except for the range including $Y = 0$). Figure 16 displays the calculated rank-ordered spectrum $s(Y)$ based on eight contiguous ranges of ΔY [28]. It is noted that the spectrum has values of s ranging between 0.5 and 0.0. The spectrum can be refined by choosing more range intervals with smaller range sizes of ΔY, although in practice this procedure is limited by the availability of simulated data points. At $Y = 0$, the scaling exponent s appears to approach the self-similar Gaussian value of 0.5 representing random diffusion. As the value of the scaled fluctuation size Y increases the scaling exponent decreases accordingly indicating the fluctuations are becoming less and less space filling. At very large value of Y, the scaling exponent s seems to asymptotically approach the value of zero indicating the fluctuations have become extremely sparse.

Such an implicit multifractal spectrum has several advantages over the results obtainable using the conventional structure function calculations. Firstly, the utility of the spectrum is to fully collapse the unscaled PDFs. Secondly, the physical interpretation is clear. It indicates how space-filling (in terms of the value of s) are the scaled fluctuations once the value of Y is given. Thirdly, the determination of the values of the fractal nature of the grouped fluctuations is not affected by the statistics of other fluctuations that do not exhibit the same fractal characteristics. Fourthly, it provides a natural connection between the one-parameter scaling idea (39) and the multifractal behavior of intermittency.

Invariant Scaling

Forced and/or Self-Organized Criticality (FSOC)

In the above sections, we provided some convincing arguments as well as numerical and observational evidences indicating that space plasma turbulence is generally in a state of dynamic "topological complexity". By "complex" topological states we mean magnetic topologies that are not immediately deducible from the basic (e. g., MHD) equations. We also discovered that the structure/partition functions for turbulence generally scale as power laws at least at small scales. Expressed another way, we found that there were power-law scale invariants with respect to coarse-graining at small scales where intermittency prevails. Below, we shall briefly address the salient features of such "topological phase transitions" as well as the associated scale invariant properties in turbulent plasmas. (We note here that the concept of phase transitions has also been employed to address the phenomenon of complexity in space plasmas by Sitnov et al., [106] using the singular spectrum method.)

For nonlinear stochastic systems exhibiting complexity, the correlations among the fluctuations of the random dynamical fields (electric, magnetic and velocity fields, etc.) are generally very long-ranged and there exist many correlation scales (as exhibited by the various outsized plasma coherent structures). The dynamics of such systems are notoriously difficult to handle either analytically or numerically. On the other hand, since the correlations are extremely long-ranged, it is reasonable to expect that the system will exhibit some sort of invariance property under coarse-graining scale transformations. A powerful analytical technique that exploits this invariance property is the method of the dynamic renormalization group (DRG) which we shall briefly describe below. The technique is a generalization of the static renormalization group introduced by Wilson in 1972 [135] for equilibrium phase transitions. Dynamic renormalization group was originally developed as a perturbation theory by Halperin et al. [53] and first applied to hydrodynamic problems by Forster et al. [49]. A closed form exact theory of DRG was developed by Chang et al. [30]. And a review of the basic elements of this theory may be found in Sect. "Non-Gaussian Probability Distribution Functions" of a Physics Report by Chang et al. [31].

No matter how complex the stochastic behavior is for the turbulent system, we may conjecture that the system is somehow characterized by a set of dynamically evolving parameters $\{P_n\}$. We now transform the stochastic system by coarse-graining and ask how these parameters transform accordingly (subject to the rules stipulated by the underlying dynamical equations, e. g., those for the interacting flux tubes). Symbolically, we write

$$\partial\{P_n\}\partial\ell = R\{P_n\} \tag{42}$$

where R represents the coarse-graining (renormalization-group) transformation operator and ℓ *is* the coarse-graining parameter. The operator is generally very complicated for even relatively simple stochastic systems. Instead of actually delving into the mathematical formalism of DRG, we shall merely explore some of the basic concepts related to such ideas.

Forced and/or Self-organized Criticality Generally, if one starts at some initial state $\{P_n(0)\}$ and proceeds with the coarse-graining procedure following the prescription dictated by (42), the result would be a trajectory in the phase space characterized by the parameters. In analogy to nonlinear dynamics, we expect that there may be fixed points (singular points) in the phase space flow field, at which $d\{P_n\}/d\ell = 0$. At such a point, e. g., $\{P_n^*\}$, the correlation length should not be changing. However, the coarse-graining transformation requires that all length scales to change with ℓ. Therefore, to satisfy both requirements, the correlation length must be either infinite or zero at the fixed point. When it is at infinity, the state of the dynamical system would then be at a state of dynamic criticality, analogous to the state of criticality in equilibrium phase transitions.

Generally, a dynamical system will not be near a parametric state such as $\{P_n^*\}$. But, if the coarse-graining procedure (i. e., the renormalization group trajectory) leads it eventually to a point in the parametric space close to a fixed point such as $\{P_n^*\}$, then in a coarse-grained sense the stochastic system would be close to a state of dynamic criticality. We may then approximate the coarse-graining transformation (42) by linearizing the operator R. The result is a set of coupled linear differential equations characterizing the variations of the deviations of the parameters $\{P_n\}$ from $\{P_n^*\}$.

$$\mathrm{d}\{Q_n\}/\mathrm{d}\ell = R_\mathrm{L}\{Q_n\} \tag{43}$$

where $Q_n = P_n - P_n^*$ and R_L is the linearized renormalization-group matrix operator.

We assume that expression (43) may be expressed in terms of a set of eigenvalue equations:

$$\mathrm{d}\mu_i/\mathrm{d}l = \lambda_i \mu_i \qquad (44)$$

where the eigenvectors μ_i's are linear combinations of the parameters Q_n and the λ_i's are the corresponding eigenvalues. We shall assume that the eigenvectors are complete and the eigenvalues are all real. (Nondiagonalizable operator R_{L} may render the eigenvectors incomplete and lead to logarithmic corrections to the discussion below, which will not be considered here).

The solutions of (44) are simply $\mu_i = \mu_i^0 \exp \lambda_i \ell$ where $\{\mu_i^0\}$ represents some arbitrary state that is close to $\{P_n^*\}$. From this, it can be verified immediately that

$$\mu_i/\mu_j^{\lambda_i/\lambda_j} = \text{constants} \qquad (45)$$

i. e., the μ_i's form power law invariants which are independent of the coarse-graining scale transformation ℓ.

Expressing this result in words: The mathematical consequence of the linear approximation is that, close to dynamic criticality, certain linear combinations of the perturbations of the parameters that characterize the stochastic phenomenon will correlate with each other in the form of power laws. These include the (k, ω), i. e. mode number and frequency, spectra of the correlations of the various fluctuations of the dynamic field variables in space and time, etc. The fact that the dynamical (stochastic) system must initiate from some state so that the coarse-graining trajectory will carry it to the close proximity of a fixed point such as $\{P_n*\}$ means that there may need some initial tuning of the state for the system to have such behavior. For this reason, we shall refer to such dynamical systems as systems near Forced and/or Self-organized Criticality (FSOC) [22]. The phenomenon of FSOC is spatiotemporal and the invariant scaling idea permeates throughout the time-space domain. In addition, the scaling between time and space generally is not isotropic.

Such power law behavior has been detected in probability distributions related to the solar flares [74,126], Fig. 17, in the AE burst occurrences as a function of the AE burst strength [37], Fig. 18, in the global auroral UVI imagery of the statistics of size and energy dissipated by the magnetospheric system [81], in the probability distributions of spatiotemporal magnetospheric disturbances as seen in the UVI images of the nighttime ionosphere [124], in the probability distributions of durations of Bursty Bulk Flows [2], and in the magnetic field fluctuations of the Earth's magnetotail [61,93]. Similar behavior has also been obtained in numerical simulations for the distributions for solar flares [45], for dynamical models for the current sheet [66,110,122] and other applications. This invariant behavior had been called self-organized criticality (SOC) [3], i. e., tuning is generally not necessary.

An eigenvector (eigen-parameter) μ_i is "irrelevant" if the corresponding eigenvalue λ_i is less than zero because in the limit of large ℓ the value of μ_i will become negligible. The reverse is true for positive λ_i's. We shall not consider the special case of $\lambda_i = 0$ which introduces singularities of fractional powers of logarithms. If there are only a small number of relevant eigenvalues with $\lambda_i > 0$, the corresponding FSOC system has only a small number of "relevant parameters" that are needed to characterize the stochastic state, i. e., the system may appear to have low dimensionality in parameter space near criticality [22].

From Criticality to Intermittency

We now ask a deeper question: How does the invariant behavior of the structure or partition functions, which changes with moment order for intermittent turbulence amalgamate (reconcile) with the concept of criticality (SOC or FSOC) outlined above?

For systems near criticality the correlation functions are generally related to the correlation time and space as power laws. Since the structure functions are related to the spatial correlation functions [7], it is therefore not surprising that for systems near SOC/FSOC, the structure function exponents for intermittent turbulence are power law scale-invariants in coarse-graining scale transformations.

For a stochastic process that is monofractal, the structure function exponents vary with the moment order linearly. Thus a single invariant, such as $I_1 = S_1/\Delta^{\zeta_1}$ would suffice to characterize the behavior of fully developed turbulence that is self-similar. For example, it was demonstrated in Subsect. "Rank-Ordered Multifractal Analysis (ROMA)", that if the probability distributions functions (PDFs) satisfy the one-parameter scaling law of (39), the structure function exponents $\zeta_q = sq$ where s is the scaling exponent, and the PDFs collapse onto one master scaling function $P_s(\delta B^2/\Delta^s)$. This is approximately satisfied by the PDFs for the numerical simulation results discussed in Sect. "Non-Gaussian Probability Distribution Functions" [33] (Fig. 9 and re-displayed here as Fig. 19, middle panel). Similar results have been found by Hnat et al. [56] for their study of the PDFs of solar wind turbulence as seen by the WIND spacecraft and Tam et al. [112] for the electric field intensity fluctuations in the auroral zone as detected by the SIERRA rocket experiment (Fig. 19, top and bottom panels). However, it is to be noted that in all three scaling plots the deviations from the mean become larger for larger fluctuations, which are indications that multifractal characteristics will still need to be addressed. This was demonstrated in terms of the rank-ordered multifractal spectrum as discussed in Subsect. "Rank-Ordered Multifractal Analysis (ROMA)".

We note that generally – e. g., Fig. 8 – the portions of the PDFs for small fluctuations for most of the observed and simulated intermittent turbulence have shapes very close to that of a Gaussian. This is the reason why the calculated exponent s for small scaled fluctuations is close to the value of 0.5 (characteristic of self-similar random diffusion). In the numerical example considered in Subsec. "Plasma Resonances and Coherent Structures", $s \approx 0.42$ for the range of ΔY between $(0, 10)$. And the behavior of the fluctuations within this range was shown to be essentially monofractal. This would have given the value of the first structure function exponent $\zeta_1 = 0.42$ and the related power spectrum index would therefore be approximately $1 + \zeta_2 = 1 + 2\zeta_1 \approx 1.84$ (Frisch, 1995). If no attempt were made in rank-ordering and the value of s were determined for the full set of fluctuations by looking for power-law behavior of $P(0, \Delta) \sim \Delta^s$, the best value was found to be approximately 0.335. Assuming approximate monofractal scaling, this number would give a power spectrum index of approximately 1.67. Both numbers are not very different from that obtainable using classical arguments for hydrodynamic or MHD turbulence.

Most observational or numerical "critical exponents" of SOC are obtained either using first order box counting or from calculations of density, optical, and other field intensities such as electric, magnetic, velocity, and energy fields, which generally involve statistical averages over the zeroth, first, or second (i. e. low) order moments of their related PDFs and therefore each represents an approximate monofractal behavior of some sort of weighted average of the fractal values for small scaled fluctuations.

In fact, if the experimental or numerical evaluations are based on rough estimates, the values of the exponents will generally take on essentially the Gaussian – i. e., mean-field – values. And such observed "critical exponents" would satisfy the standard scaling relations. We suggest that this is the reason why recent observations [126] and numerical simulations [69] seem to indicate the coexistence of the phenomenon of SOC and multifractal signatures for intermittent turbulence. See, e. g. Figs. 17 and 20.

Thus, based on the example of rank-order procedure of the multifractal behavior of intermittent fluctuations

described in Subsect. "Rank-Ordered Multifractal Analysis (ROMA)", we suggest that power-law relations of SOC can be made more precise if the exponents are determined more meticulously using rank-ordered fluctuations. For each rank-order, particularly for the rank-order of the smallest scaled fluctuations, one can determine a corresponding set of more accurately determined "critical exponents" that satisfy the classical exponent relations.

In summary, the conventional concepts of SOC or FSOC as tested by the lower order spatiotemporal statistical averages would generally be satisfied for intermittent turbulence. However, the ideas of invariant scaling and scaling relations will need to be generalized to include the "crossover effects" for large scaled fluctuations.

Dynamical Modeling – The Lu–Klimas Magnetic Field Reversal Model

By utilizing results obtained from direct numerical simulations, investigators were able to confirm a number of the theoretical predictions of intermittent turbulence and complexity phenomena in space plasmas that could arise from the process of merging and interactions of plasma coherent structures. The system sizes of direct numerical simulations, however, are generally limited by the capabilities of the present day computers. To circumvent this limitation, an alternative approach to study the intermittency in space plasma turbulence numerically would be to mimic the coarse-grained dissipation and the development of complexity by means of dynamical modeling which, in turn, may lead to a better theoretical understanding of the fundamental underlying stochastic processes.

While there exists a number of dynamical models that mimic avalanche processes exhibiting scaling and some also intermittency, only a few have attempted to incorporate the basic physics of plasmas in their formulations. From these, we select one simple model, the Lu–Klimas fast-field annihilation model of magnetic field reversal, for further discussion and comments. The model has the basic ingredient of a diffusive equation [66]:

$$\frac{\partial B_x}{\partial t} = \frac{\partial}{\partial z}\left[D(z,t)\frac{\partial}{\partial z}\right]B_x + S(z,t)\,. \tag{46}$$

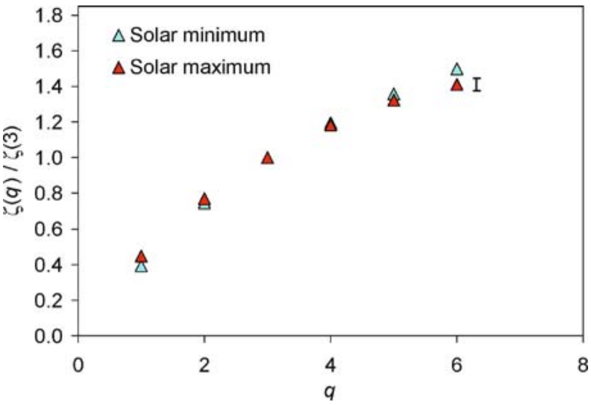
It may be obtained through the drastic reduction of the resistive MHD system in an idealized one-dimensional limit. In (46), $B_x(z,t)$ is the magnetic flux and $S(z,t)$ is a source term which could be interpreted as that characterizes the convection of the magnetic flux, although in discussions below it will be arbitrarily prescribed and assumed to be independent of time. The diffusion coefficient $D(z,t)$ is linearly proportional to an anomalous resistivity with a hysteresis characteristic as stipulated below:

$$\frac{\partial D}{\partial t} + \frac{D}{\tau} = \frac{Q(|\partial B_x/\partial z|)}{\tau} \tag{47}$$

where $Q = D_{\min}$ (low state) for $|\partial B_x/\partial z| < k$, and $Q = D_{\max} \gg D_{\min}$ (high state) for $|\partial B_x/\partial z| > \beta k$ with $\beta < 1$. Thus, Q is double-valued and dependent upon the history for $\beta k < |\partial B_x/\partial z| < k$. The value k may be thought of as a stability threshold which Klimas et al. [66] attributed to some sort of current driven instability (e. g., Lui et al. [79]). The value of Q remains in the low state ($= D_{\min}$) until the threshold is reached and switches to the high state ($= D_{\max}$). It stays at the high state until $|\partial B_x/\partial z| < \beta k$. This anomalous diffusive model is essentially that originally suggested by Lu [73], which was motivated by his studies related to the phenomena of self-organized criticality [3]; in particular, those related to the probability distributions of solar flares [74]. Unlike the Klimas' model, the source term in Lu's original formulation was assumed to be random and the boundary conditions were chosen to allow transport through the boundaries.

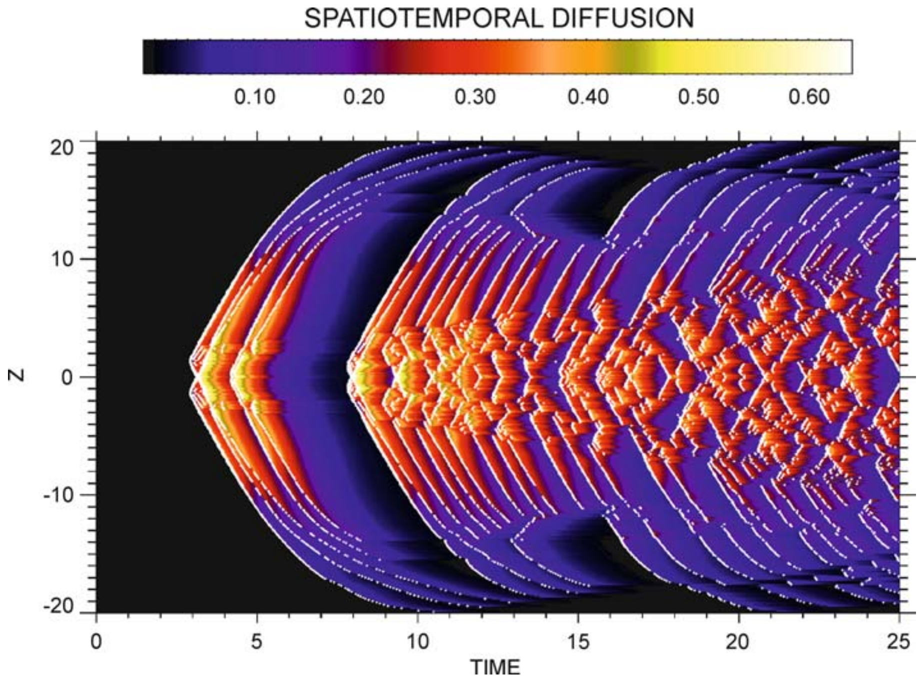
Klimas et al. [66] and Uritsky et al. [123] have studied their model numerically on a spatial interval $-L \le z \le L$ subject to the boundary conditions $\partial B_x/\partial z = 0$ at $z = \pm L$, i. e., no transport of B_x through the boundaries. They considered antisymmetric solutions with a field reversal at $z = 0$ and a time-independent source term $S(z,t) = S_0 \sin(\pi z/2L)$ which may be considered as a steady convection of B_x into the field reversal region. Setting $\tau = 1$ as the fundamental time scale and $L = 20$, they found that there exists a range of choices of parameters for which the dynamical model evolves in a sequence of quasi-periodic loading ($\mathrm{d}E/\mathrm{d}t > 0$)-unloading ($\mathrm{d}E/\mathrm{d}t < 0$) cycles where the total field energy $E(t)$ is defined by:

$$E(t) \equiv \int_{-L}^{L} \mathrm{d}z B_x^2(z,t)\,. \tag{48}$$



Space Plasmas, Dynamical Complexity in, Figure 20
Relative structure function exponents with respect to the third order exponent using ESS for flare statistics at solar maximum (high activity) and solar minimum (low activity) based on emissions detected by the EIT (extreme ultraviolet imaging telescope) aboard the SOHO spacecraft in the 195 Å wavelength. Adapted from [126] with thanks to the American Physical Society

During the loading intervals, when the system is quiet, the slow increase of $E(t)$ is the sole evolutionary feature of the system. As loading continues, the field gradient $|\mathrm{d}B_x/\mathrm{d}z|$, i. e. the current density, reaches the critical level for Q somewhere in the field distribution (usually at a pair of points symmetrically placed near $z = 0$). Subsequently a complicated process of unloading ensues, which is best understood in terms of the spatiotemporal evolution of the diffusion coefficient $D(z,t)$ as depicted in Fig. 21 during the initial stage of development of the unloading process, where the color scale of the figure indicates the intensity of the diffusion coefficient. In the figure, a white dot is placed at each point where the critical level of $|\mathrm{d}B_x/\mathrm{d}z|$ – or current density – for Q is reached and $Q(z,t) = D_{\max}$. As the instabilities spread and propagate toward both the center and the edges of the field distribution, more current sheets (i. e., sheet regions with strong current density) are excited and their topology becomes increasingly complex. The current sheets generate diffusion and the diffusion coefficient $D(z,t)$ is at a local maximum just after the passage of a current sheet at any given position. This strong localized diffusion enhances the transport of the magnetic flux toward $z = 0$ where fluxes of opposite signs meet and annihilate. This process of generation of complicated current sheet topology, transport of magnetic flux and annihilation adjusts self-consistently with the imposed source function such that there is a dynamically pseudo-stationary state. And, the loading-unloading process repeat quasi-periodically after an initial transient.



Space Plasmas, Dynamical Complexity in, Figure 21
Spatiotemporal evolution of the diffusion coefficient $D(z, t)$ for the Lu–Klimas model during the initial stage of development of an unloading process. Space Plasmas, Dynamical Complexity in, Figure 22
Avalanche size (*left*) and lifetime (*right*) distributions for the Lu–Klimas model for early (*blue*) and late (*red*) intervals during a single unloading event. Reprinted from [123] with permission from Elsevier

The above phenomenon of continued sporadic generation of unstable current sheets and the accompanying broadening of the diffusive layer during the unloading process is reminiscent of the resonance broadening phenomenon of the "apparent reconnection" process in the 2D MHD simulation result for the sheared magnetic field geometry discussed earlier. Klimas et al. [67,68,69], Uritsky et al. [125] and Uritsky and Klimas [122] have recently extended their dynamical modeling effort based on the anomalous resistivity idea with hysteresis to the 2D geometry and the similarity between their calculated results of sporadic localized reconnections and the direct 2D MHD simulation results of resonance-broadening and coarse-grained dissipation – as well as the ensuing magnetic reconfiguration process – due to the sporadic, localized merging of coherent structures is even more noticeable, even though the boundary and initial conditions as well as the presumed instabilities of both sets of calculations were quite different. The main point to note is that the phenomenon of coarse-grained dissipation in the results of direct numerical simulation is replaced in the dynamical model by the assumed anomalous resistivity with hysteresis. Thus, other than the arbitrariness of the dissipation mechanism, such type of dynamical modeling has almost achieved its purported aim; i. e., using a much simplified dissipation model, large scale simulations of complexity of space plasmas may perhaps be achieved with relatively small scale computers.

However, the existing dynamical models may be too crude to lead to quantitatively comparable results of actual observations. For example, in the Lu–Klimas model, the critical threshold was arbitrary and kept at a constant value. In addition the phenomenon of hysteresis was again quite arbitrary and the double-valuedness of Q was also triggered at arbitrary levels. In the coarse-grained dissipation scenario acquired from, for example, direct numerical simulations, there was actually no specific threshold for triggering the "fluctuation induced nonlinear instability" and the dissipation during "apparent reconnection" was due to the combination of wave (e. g., Alfvén wave) propagation and resonance broadening. The hope is that perhaps even with some of such arbitrary ad hoc assumptions in the present and/or future modeling of local dissipation, the hypothesized model(s) will still lead to some of the global features such as the scale-invariant properties that will fall in the same universality class as the actual physical phenomena.

We now proceed to discuss the invariant properties of the simulated result of the one-dimensional magnetic field reversal and annihilation model. There are at least two sets of statistics that may shed light on the scale free invariant properties of SOC for the loading-unloading events that emerge from the numerical calculations of the Lu–Klimas model. Firstly, after an initial transient, the sequence of burst-like unloading events seem to occur by clustering around an average field strength, i. e., on average, the increasing strength of the field reversal is more-or-less balanced by the annihilation of the magnetic field in the current sheet. Thus, we expect that the unloading events exhibit power law distributions in, for example, energy dissipation and burst duration. These results were essentially uncovered by Klimas et al. [66] for the special situation of very low driving rates and $D_{\min} = 0$.

We may also ask the question about the scale free invariant behavior for the complicated current sheet distributions triggered by the instabilities associated with the anomalous resistivity for a single unloading event. Such small scale fluctuations again seem to self-consistently balance between the anomalous transport and field annihilation. Thus, we may again expect certain universal SOC behavior for these small scale fluctuations. To search for such behavior, Uritsky et al. [123] defined avalanches in terms of the size and duration of contiguous unstable grid points in the spatiotemporal domain. Power law statistics of the probability distributions of avalanche size and life time emerged from the statistics of their numerical calculations, Fig. 22. And, these exponents have been demonstrated to satisfy the standard exponent relations known for SOC processes [128]. There are other statistical verifications of SOC behavior from both the 1D and 2D dynamical modeling results, which we shall not discuss here.

More interestingly, Klimas et al. [69] recently demonstrated that the velocity fluctuations of their 2D simulation of the dynamical model exhibited both SOC and multifractal characteristics very similar to those expected for intermittent MHD turbulence; thus, corroborating with some of the basic concepts of interwoven connection and crossover phenomenon between SOC/FSOC and intermittent turbulence as espoused in the previous section.

Future Directions

We have now come to perhaps the most important part of this article. As discussed in the introduction, the development of the modern concepts of dynamical complexity in space plasmas is very recent. Despite a flurry of activities, current investigations – both from the theoretical and observational points of view – have barely scratched the surface of what may be achieved and understood. For example, we need to know more about the complexity behavior of the plasmas from the kinetic point of view. We also need to know how the plasma particle distributions respond to the fluctuations of its turbulent environment. In addition, the global space environment is generally inhomogeneous with complex initial and boundary conditions. Thus we need to address processes that are statistically nonstationary and spatially inhomogeneous as well as those that evolve temporally and nonuniformly. We also need to understand how the complexity and multifractal phenomena of space plasmas influence the global dynamics of the space plasma environment.

Throughout the discourse, we have placed our emphasis of dynamical complexity in space plasmas on the basic underlying physics. We have come to realize that such fundamental ideas must come from the understanding of the complicated stochastic behavior arisen from the interactions of the multitudes of coherent structures that are prevalent in the natural development of the dynamics of space plasmas. We learned that there were various types of invariant concepts related to coarse-graining, which characterize the primary phenomena that we are attempting to study, analyze and understand. We studied a suite of statistical methodology to analyze complexity, some of which are new and some are carryovers from other fields of complexity, including hydrodynamic turbulence.

We realized that most of the so-called theories that exist today in dynamical complexity of space plasmas are mainly phenomenological concepts and generally mimic those that were prevalent before the modern developments of complexity. We know that these theories cannot carry us too far as we know that they had not advanced the true understanding of complexity phenomena in the past. For this reason, we have broken the tradition in this article and tried not to continually compare our statistically acquired results and theoretically developed understandings with the prevalent classical ideas and numerology. Such comparisons abound in the literature and generally murk the basic concepts that we are trying to convey.

We have learned that most of the phenomena of complexity in space plasmas are scale invariant concepts and yet very little theory has been developed to try to explore these invariant characteristics. We are still stuck with the dogma that we must develop our theories from the "basic elemental equations", while fully aware that the phenomena that we are trying to address generally have nothing to do with these equations directly. After all, nearly every invariant result gained from the coarse-graining concept breaks most of the symmetries and invariance properties of the basic elemental equations.

We have learned that the elemental dissipation such as classical resistivity and viscosity generally has nothing to do with the apparent dissipation that are everywhere in dynamical complexity. And yet every existing theoretical idea insists on including these almost irrelevant dissipative terms in its basic development.

We learned that intermittency generally involve large deviations from the mean and yet we insist on fitting every statistical result into neatly packed curves as if all physics and theories must result in smooth curves in parametric studies. It is time to bring in the ideas of Lebesgue measure, extreme value statistics and thermodynamics of rare events, as well as rank-ordered groupings and associated analyzes to our future developments of new theories and statistical methods

With enthusiasm, we look forward to the dawning of a new era from the future horizon when these new concepts and theoretical understandings finally establish their footings in the modern development of dynamical complexity in space plasmas.

Acknowledgments

The author is extremely grateful to Cheng–chin Wu for his unremitting collaboration and for many of the numerical results that are displayed in this article. He is indebted to Vassilis Angelopoulos, Roberto Bruno, Sandra Chapman, Abe Chian, Giuseppe Consolini, Marius Echim, Bogdan Hnat, Jack Jasperse, Charlie Kennel, Margy Kivelson, Alex Klimas, Hervé Lamy, Tony Lui, Eckart Marsch, Bill Matthaeus, John Podesta, Surja Sharma, Sunny Tam, Vadim Uritsky, Dimitri Vassiliadis, Zoltan Vöröss, Nick Watkins, Jim Weygand, and Gary Zank for cooperative research and/or useful discussions. He is very appreciative to those who kindly allowed him to quote and reprint their published results and to Rich Chang for a critical reading of the manuscript and for his helpful suggestions. The author wishes to thank the Section Editor of Chaos and Complexity in Astrophysics for this encyclopedia volume, for inviting him to contribute this article and for his careful editing and useful suggestions. He is most grateful to members of his family for their constant encouragement and particularly to his wife, Monica, for her understanding and persistent spurring. Permissions from Elsevier. Springer Science and Business Media, the American Astrophysical Society, and the Italian Society of Physics and the liberal copyright policies of the American Physical Society, the American Institute of Physics, the American Geophysical Union, and the European Geophysical Union, which allowed the author to reprint figures and illustrations from their publications, are gratefully acknowledged. This project was partially supported by the AFOSR, NASA and NSF of the US government.

Article Outline

Glossary

Spectral decomposition of a unitary representation If $\mathcal{U} = (U_a)_{a\in\mathbb{A}}$ is a continuous unitary representation of a locally compact second countable (l.c.s.c.)

Abelian group $\mathbb{A}$ in a separable Hilbert space H then a decomposition $H = \bigoplus_{i=1}^{\infty} \mathbb{A}(x_i)$ is called *spectral* if $\sigma_{x_1} \gg \sigma_{x_2} \gg \dots$ (such a sequence of measures is also called *spectral*); here $\mathbb{A}(x) := \overline{span}\{U_a x \colon a \in \mathbb{A}\}$ is called the *cyclic space* generated by $x \in H$ and σ_x stands for the spectral measure of x.

Maximal spectral type and the multiplicity function of $\mathcal{U}$ The *maximal spectral type* $\sigma_{\mathcal{U}}$ of $\mathcal{U}$ is the type of σ_{x_1} in any spectral decomposition of H; the *multiplicity function* $M_{\mathcal{U}} \colon \widehat{\mathbb{A}} \to \{1, 2, \dots\} \cup \{+\infty\}$ is defined $\sigma_{\mathcal{U}}$-a.e. and $M_{\mathcal{U}}(\chi) = \sum_{i=1}^{\infty} 1_{Y_i}(\chi)$, where $Y_1 = \widehat{\mathbb{A}}$ and $Y_i = \operatorname{supp} \mathrm{d}\sigma_{x_i}/\mathrm{d}\sigma_{x_1}$ for $i \geq 2$.

A representation $\mathcal{U}$ is said to have *simple spectrum* if H is reduced to a single cyclic space. The multiplicity is *uniform* if there is only one essential value of $M_{\mathcal{U}}$. The essential supremum of $M_{\mathcal{U}}$ is called the *maximal spectral multiplicity*. $\mathcal{U}$ is said to have *discrete spectrum* if H has an orthonormal base consisting of eigenvectors of $\mathcal{U}$; $\mathcal{U}$ has *singular* (*Haar*, *absolutely continuous*) spectrum if the maximal spectral type of $\mathcal{U}$ is singular with respect to (equivalent to, absolutely continuous with respect to) a Haar measure of $\widehat{\mathbb{A}}$.

Koopman representation of a dynamical system $\mathcal{T}$ Let $\mathbb{A}$ be a l.c.s.c. (and not compact) Abelian group and $\mathcal{T} \colon a \mapsto T_a$ a representation of $\mathbb{A}$ in the group $Aut(X, \mathcal{B}, \mu)$ of (measure-preserving) automorphisms of a standard probability Borel space $(X, \mathcal{B}, \mu)$. The *Koopman representation* $\mathcal{U} = \mathcal{U}_{\mathcal{T}}$ of $\mathcal{T}$ in $L^2(X, \mathcal{B}, \mu)$ is defined as the unitary representation $a \mapsto U_{T_a} \in U(L^2(X, \mathcal{B}, \mu))$, where $U_{T_a}(f) = f \circ T_a$.

Ergodicity, weak mixing, mild mixing, mixing and rigidity of $\mathcal{T}$ A measure-preserving $\mathbb{A}$-action $\mathcal{T} = (T_a)_{a \in \mathbb{A}}$ is called *ergodic* if $\chi_0 \equiv 1 \in \widehat{\mathbb{A}}$ is a simple eigenvalue of $\mathcal{U}_{\mathcal{T}}$. It is *weakly mixing* if $\mathcal{U}_{\mathcal{T}}$ has a continuous spectrum on the subspace $L_0^2(X, \mathcal{B}, \mu)$ of zero mean functions. $\mathcal{T}$ is said to be *rigid* if there is a sequence (a_n) going to infinity in $\mathbb{A}$ such that the sequence $(U_{T_{a_n}})$ goes to the identity in the strong (or weak) operator topology; $\mathcal{T}$ is said to be *mildly mixing* if it has no non-trivial rigid factors. We say that $\mathcal{T}$ is *mixing* if the operator equal to zero is the only limit point of $\{U_{T_a}|_{L_0^2(X, \mathcal{B}, \mu)} \colon a \in \mathbb{A}\}$ in the weak operator topology.

Spectral disjointness Two $\mathbb{A}$-actions S and $\mathcal{T}$ are called *spectrally disjoint* if the maximal spectral types of their Koopman representations $\mathcal{U}_{\mathcal{T}}$ and $\mathcal{U}_S$ on the corresponding L_0^2-spaces are mutually singular.

SCS property We say that a Borel measure σ on $\widehat{\mathbb{A}}$ satisfies the *strong convolution singularity* property (SCS property) if, for each $n \geq 1$, in the disintegration (given by the map $(\chi_1, \dots, \chi_n) \mapsto \chi_1 \cdot \ldots \cdot \chi_n$) $\sigma^{\otimes n} = \int_{\widehat{\mathbb{A}}} \nu_\chi \, d\sigma^{(n)}(\chi)$ the conditional measures ν_χ are atomic with exactly $n!$ atoms ($\sigma^{(n)}$ stands for the nth convolution $\sigma * \ldots * \sigma$). An $\mathbb{A}$-action $\mathcal{T}$ satisfies the SCS property if the maximal spectral type of $\mathcal{U}_{\mathcal{T}}$ on L_0^2 is a type of an SCS measure.

Kolmogorov group property An $\mathbb{A}$-action $\mathcal{T}$ satisfies the *Kolmogorov group property* if $\sigma_{\mathcal{U}_{\mathcal{T}}} * \sigma_{\mathcal{U}_{\mathcal{T}}} \ll \sigma_{\mathcal{U}_{\mathcal{T}}}$.

Weighted operator Let T be an ergodic automorphism of $(X, \mathcal{B}, \mu)$ and $\xi \colon X \to \mathbb{T}$ be a measurable function. The (unitary) operator $V = V_{\xi,T}$ acting on $L^2(X, \mathcal{B}, \mu)$ by the formula $V_{\xi,T}(f)(x) = \xi(x) f(Tx)$ is called a *weighted operator*.

Induced automorphism Assume that T is an automorphism of a standard probability Borel space $(X, \mathcal{B}, \mu)$. Let $A \in \mathcal{B}$, $\mu(A) > 0$. The *induced automorphism* T_A is defined on the conditional space $(A, \mathcal{B}_A, \mu_A)$, where $\mathcal{B}_A$ is the trace of $\mathcal{B}$ on A, $\mu_A(B) = \mu(B)/\mu(A)$ for $B \in \mathcal{B}_A$ and $T_A(x) = T^{k_A(x)} x$, where $k_A(x)$ is the smallest $k \geq 1$ for which $T^k x \in A$.

AT property of an automorphism An automorphism T of a standard probability Borel space $(X, \mathcal{B}, \mu)$ is called *approximatively transitive* (AT for short) if for every $\varepsilon > 0$ and every finite set $f_1, \dots, f_n$ of non-negative L^1-functions on $(X, \mathcal{B}, \mu)$ we can find $f \in L^1(X, \mathcal{B}, \mu)$ also non-negative such that $\| f_i - \sum_j \alpha_{ij} f \circ T^{n_j} \|_{L_1} < \varepsilon$ for all $i = 1, \dots, n$ (for some $\alpha_{ij} \geq 0$, $n_j \in \mathbb{N}$).

Cocycles and group extensions If T is an ergodic automorphism, G is a l.c.s.c. Abelian group and $\varphi \colon X \to G$ is measurable then the pair (T, φ) generates a *cocycle* $\varphi^{(\cdot)}(\cdot) \colon \mathbb{Z} \times X \to G$, where

$$\varphi^{(n)}(x) = \begin{cases} \varphi(x) + \ldots + \varphi(T^{n-1} x) & \text{for} \quad n > 0\,, \\ 0 & \text{for} \quad n = 0\,, \\ -(\varphi(T^n x) + \ldots + \varphi(T^{-1} x)) & \text{for} \quad n < 0\,. \end{cases}$$

(That is $(\varphi^{(n)})$ is a standard 1-cocycle in the algebraic sense for the $\mathbb{Z}$-action $n(f) = f \circ T^n$ on the group of measurable functions on X with values in G; hence the function $\varphi \colon X \to G$ itself is often called a *cocycle*.)

Assume additionally that G is compact. Using the cocycle φ we define a *group extension* T_φ on $(X \times G, \mathcal{B} \otimes \mathcal{B}(G), \mu \otimes \lambda_G)$ (λ_G stands for Haar measure of G), where $T_\varphi(x, g) = (Tx, \varphi(x) + g)$.

Special flow Given an ergodic automorphism T on a standard probability Borel space $(X, \mathcal{B}, \mu)$ and a positive integrable function $f \colon X \to \mathbb{R}^+$ we put

$$X^f = \{(x, t) \in X \times \mathbb{R} \colon 0 \leq t < f(x)\}\,,$$

$$\mathcal{B}^f = \mathcal{B} \otimes \mathcal{B}(\mathbb{R})|_{X^f}\,,$$

and define μ^f as normalized $\mu \otimes \lambda_{\mathbb{R}}|_{X^f}$. By a *special flow* we mean the $\mathbb{R}$-action $T^f = (T^f_t)_{t\in\mathbb{R}}$ under which a point $(x, s) \in X^f$ moves vertically with the unit speed, and once it reaches the graph of f, it is identified with $(Tx, 0)$.

Markov operator A linear operator $J\colon L^2(X, \mathcal{B}, \mu) \to L^2(Y, C, \nu)$ is called *Markov* if it sends non-negative functions to non-negative functions and $J1 = J^*1 = 1$.

Unitary actions on Fock spaces If H is a separable Hilbert space then by $H^{\odot n}$ we denote the subspace of n-tensors of $H^{\otimes n}$ symmetric under all permutations of coordinates, $n \geq 1$; then the Hilbert space $F(H) := \bigoplus_{n=0}^{\infty} H^{\odot n}$ is called a *symmetric Fock space*. If $V \in U(H)$ then $F(V) := \bigoplus_{n=0}^{\infty} V^{\odot n} \in U(F(H))$ where $V^{\odot n} = V^{\otimes n}|H^{\odot n}$.

Definition of the Subject

Spectral theory of dynamical systems is a study of special unitary representations, called Koopman representations (see the glossary). Invariants of such representations are called spectral invariants of measure-preserving systems. Together with the entropy, they constitute the most important invariants used in the study of measure-theoretic intrinsic properties and classification problems of dynamical systems as well as in applications. Spectral theory was originated by von Neumann, Halmos and Koopman in the 1930s. In this article we will focus on recent progresses in the spectral theory of finite measure-preserving dynamical systems.

Introduction

Throughout $\mathbb{A}$ denotes a non-compact l.c.s.c. Abelian group ($\mathbb{A}$ will be most often $\mathbb{Z}$ or $\mathbb{R}$). The assumption of second countability implies that $\mathbb{A}$ is metrizable, σ-compact and the space $C_0(\mathbb{A})$ is separable. Moreover the dual group $\widehat{\mathbb{A}}$ is also l.c.s.c. Abelian.

General Unitary Representations

We are interested in *unitary*, that is with values in the unitary group $U(H)$ of a Hilbert space H, (weakly) continuous representations $V\colon \mathbb{A} \ni a \mapsto V_a \in U(H)$ of such groups (the scalar valued maps $a \mapsto \langle V_a x, y\rangle$ are continuous for each $x, y \in H$).

Let $H = L^2(\widehat{\mathbb{A}}, \mathcal{B}(\widehat{\mathbb{A}}), \mu)$, where $\mathcal{B}(\widehat{\mathbb{A}})$ stands for the σ-algebra of Borel sets of $\widehat{\mathbb{A}}$ and $\mu \in M^+(\widehat{\mathbb{A}})$ (whenever X is a l.c.s.c. space, by $M(X)$ we denote the set of complex Borel measures on X, while $M^+(X)$ stands for the subset of positive (finite) measures). Given $a \in \mathbb{A}$, for $f \in L^2(\widehat{\mathbb{A}}, \mathcal{B}(\widehat{\mathbb{A}}), \mu)$ put

$$V^\mu_a(f)(\chi) = i(a)(\chi) \cdot f(\chi) = \chi(a) \cdot f(\chi) \quad (\chi \in \widehat{\mathbb{A}}),$$

where $i\colon \mathbb{A} \to \widehat{\widehat{\mathbb{A}}}$ is the canonical Pontriagin isomorphism of $\mathbb{A}$ with its second dual. Then $V^\mu = (V^\mu_a)_{a\in\mathbb{A}}$ is a unitary representation of $\mathbb{A}$. Since $C_0(\widehat{\mathbb{A}})$ is dense in $L^2(\widehat{\mathbb{A}}, \mu)$, the latter space is separable. Therefore also direct sums $\bigoplus_{i=1}^{\infty} V^{\mu_i}$ of such type representations will be unitary representations of $\mathbb{A}$ in separable Hilbert spaces.

Lemma 1 (Wiener Lemma) *If $F \subset L^2(\widehat{\mathbb{A}}, \mu)$ is a closed V^μ_a-invariant subspace for all $a \in \mathbb{A}$ then $F = 1_Y L^2(\widehat{\mathbb{A}}, \mathcal{B}(\widehat{\mathbb{A}}), \mu)$ for some Borel subset $Y \subset \widehat{\mathbb{A}}$.*

Notice however that since $\mathbb{A}$ is not compact (equivalently, $\widehat{\mathbb{A}}$ is not discrete), we can find μ continuous and therefore V^μ has no irreducible (non-zero) subrepresentation. From now on only unitary representations of $\mathbb{A}$ in separable Hilbert spaces will be considered and we will show how to classify them.

A function $r\colon \mathbb{A} \to \mathbb{C}$ is called *positive definite* if

$$\sum_{n,m=0}^{N} r(a_n - a_m) z_n \overline{z_m} \geq 0 \tag{1}$$

for each $N > 0$, $(a_n) \subset \mathbb{A}$ and $(z_n) \subset \mathbb{C}$. The central result about positive definite functions is the following theorem (see e. g. [173]).

Theorem 1 (Bochner–Herglotz) *Let $r\colon \mathbb{A} \to \mathbb{C}$ be continuous. Then r is positive definite if and only if there exists (a unique) $\sigma \in M^+(\widehat{\mathbb{A}})$ such that*

$$r(a) = \int_{\widehat{\mathbb{A}}} \chi(a)\, d\sigma(\chi) \quad \textit{for each} \quad a \in \mathbb{A}.$$

If now $\mathcal{U} = (U_a)_{a\in\mathbb{A}}$ is a representation of $\mathbb{A}$ in H then for each $x \in H$ the function $r(a) := \langle U_a x, x\rangle$ is continuous and satisfies (1), so it is positive definite. By the Bochner–Herglotz Theorem there exists a unique measure $\sigma_{\mathcal{U},x} = \sigma_x \in M^+(\widehat{\mathbb{A}})$ (called the *Spectral measure* of x) such that

$$\widehat{\sigma}_x(a) := \int_{\widehat{\mathbb{A}}} i(a)(\chi)\, d\sigma_x(\chi) = \langle U_a x, x\rangle$$

for each $a \in \mathbb{A}$. Since the partial map $U_a x \mapsto i(a) \in L^2(\widehat{\mathbb{A}}, \sigma_x)$ is isometric and equivariant, there exists a unique extension of it to a unitary operator

$W\colon \mathbb{A}(x) \to L^2(\widehat{\mathbb{A}}, \sigma_x)$ giving rise to an isomorphism of $\mathcal{U}|_{\mathbb{A}(x)}$ and V^{σ_x}. Then the existence of a spectral decomposition is proved by making use of separability and a choice of maximal cyclic spaces at every step of an induction procedure. Moreover, a spectral decomposition is unique in the following sense.

Theorem 2 (Spectral Theorem) *If* $H = \bigoplus_{i=1}^{\infty} \mathbb{A}(x_i) = \bigoplus_{i=1}^{\infty} \mathbb{A}(x_i')$ *are two spectral decompositions of* H *then* $\sigma_{x_i} \equiv \sigma_{x_i'}$ *for each* $i \geq 1$.

It follows that the representation $\mathcal{U}$ is entirely determined by types (the sets of equivalent measures to a given one) of a decreasing sequence of measures or, equivalently, $\mathcal{U}$ is determined by its maximal spectral type $\sigma_{\mathcal{U}}$ and its multiplicity function $M_{\mathcal{U}}$.

Notice that eigenvalues of $\mathcal{U}$ correspond to Dirac measures: $\chi \in \widehat{\mathbb{A}}$ *is an eigenvalue* (i. e. *for some* $\|x\| = 1$, $U_a(x) = \chi(a)x$ *for each* $a \in \mathbb{A}$) *if and only if* $\sigma_{\mathcal{U},x} = \delta_\chi$. Therefore $\mathcal{U}$ has a discrete spectrum if and only if the maximal spectral type of $\mathcal{U}$ is a discrete measure.

We refer the reader to [64,105,127,147,156] for presentations of spectral theory needed in the theory of dynamical systems – such presentations are usually given for $\mathbb{A} = \mathbb{Z}$ but once we have the Bochner–Herglotz Theorem and the Wiener Lemma, their extensions to the general case are straightforward.

Koopman Representations

We will consider *measure-preserving* representations of $\mathbb{A}$. It means that we fix a probability standard Borel space $(X, \mathcal{B}, \mu)$ and by $Aut(X, \mathcal{B}, \mu)$ we denote the group of automorphisms of this space, that is $T \in Aut(X, \mathcal{B}, \mu)$ if $T\colon X \to X$ is a bimeasurable (a.e.) bijection satisfying $\mu(A) = \mu(TA) = \mu(T^{-1}A)$ for each $A \in \mathcal{B}$. Consider then a representation of $\mathbb{A}$ in $Aut(X, \mathcal{B}, \mu)$ that is a group homomorphism $a \mapsto T_a \in Aut(X, \mathcal{B}, \mu)$; we write $\mathcal{T} = (T_a)_{a \in \mathbb{A}}$. Moreover, we require that the associated Koopman representation $\mathcal{U}_{\mathcal{T}}$ is continuous. Unless explicitly stated, $\mathbb{A}$-actions are assumed to be *free*, that is we assume that for μ-a.e. $x \in X$ the map $a \mapsto T_a x$ is $1-1$. In fact, since constant functions are obviously invariant for U_{T_a}, that is the trivial character 1 is always an eigenvalue of $\mathcal{U}_{\mathcal{T}}$, the Koopman representation is considered only on the subspace $L_0^2(X, \mathcal{B}, \mu)$ of zero mean functions. We will restrict our attention only to *ergodic* dynamical systems (see the glossary). It is easy to see that $\mathcal{T}$ is ergodic if and only if whenever $A \in \mathcal{B}$ and $A = T_a(A)$ (μ-a.e.) for all $a \in A$ then $\mu(A)$ equals 0 or 1. In case of ergodic Koopman representations, all eigenvalues are simple. In particular, (ergodic) Koopman representations with discrete spectra have simple spectra. The reader is referred to monographs mentioned above as well as to [26,158,177,196,204] for basic facts on the theory of dynamical systems.

The passage $\mathcal{T} \mapsto \mathcal{U}_{\mathcal{T}}$ can be seen as functorial (contravariant). In particular a measure-theoretic isomorphism of $\mathbb{A}$-systems $\mathcal{T}$ and $\mathcal{T}'$ implies spectral isomorphism of the corresponding Koopman representations; hence spectral properties are measure-theoretic invariants. Since unitary representations are completely classified, one of the main questions in the spectral theory of dynamical systems is to decide which pairs $([\sigma], M)$ can be realized by Koopman representations. The most spectacular, still unsolved, is the Banach problem concerning $([\lambda_{\mathbb{T}}], M \equiv 1)$. Another important problem is to give complete spectral classification in some classes of dynamical systems (classically, it was done in the theory of Kolmogorov and Gaussian dynamical systems). We will also see how spectral properties of dynamical systems can determine their statistical (ergodic) properties; a culmination given by the fact that a spectral isomorphism may imply measure-theoretic similitude (discrete spectrum case, Gaussian–Kronecker case). We conjecture that a dynamical system $\mathcal{T}$ either is spectrally determined or there are uncountably many pairwise non-isomorphic systems spectrally isomorphic to $\mathcal{T}$.

We could also consider Koopman representations in L^p for $1 \leq p \neq 2$. However whenever $W\colon L^p(X, \mathcal{B}, \mu) \to L^p(Y, C, \nu)$ is a surjective isometry and $W \circ U_{T_a} = U_{S_a} \circ W$ for each $a \in \mathbb{A}$ then by the Lamperti Theorem (e. g. [172]) the isometry W has to come from a nonsingular pointwise map $R\colon Y \to X$ and, by ergodicity, R "preserves" the measure ν and hence establishes a measure-theoretic isomorphism [94] (see also [127]). Thus spectral classification of such Koopman representations goes back to the measure-theoretic classification of dynamical systems, so it looks hardly interesting. This does not mean that there are no interesting dynamical questions for $p \neq 2$. Let us mention still open Thouvenot's question (formulated in the 1980s) for $\mathbb{Z}$-actions: *For every ergodic* T *acting on* $(X, \mathcal{B}, \preceq)$, *does there exist* $f \in L^1(X, \mathcal{B}, \mu)$ *such that the closed linear span of* $f \circ T^n$, $n \in \mathbb{Z}$ *equals* $L^1(X, \mathcal{B}, \mu)$?

Iwanik [79,80] proved that if T is a system with positive entropy then its L^p-multiplicity is ∞ for all $p > 1$. Moreover, Iwanik and de Sam Lazaro [85] proved that for Gaussian systems (they will be considered in Sect. "Spectral Theory of Dynamical Systems of Probabilistic Origin") the L^p-multiplicities are the same for all $p > 1$ (see also [137]).

Markov Operators, Joinings and Koopman Representations, Disjointness and Spectral Disjointness, Entropy

We would like to emphasize that spectral theory is closely related to the theory of joinings (see ► Joinings in Ergodic Theory for needed definitions). The elements ρ of the set $J(\mathcal{S},\mathcal{T})$ of joinings of two $\mathbb{A}$-actions $\mathcal{S}$ and $\mathcal{T}$ are in a 1-1 correspondence with Markov operators $J = J_\rho$ between the L^2-spaces equivariant with the corresponding Koopman representations (see the glossary and ► Joinings in Ergodic Theory). The set of ergodic self-joinings of an ergodic $\mathbb{A}$-action $\mathcal{T}$ is denoted by $J_2^e(\mathcal{T})$.

Each Koopman representation $\mathcal{U}_{\mathcal{T}}$ consists of Markov operators (indeed, U_{T_a} is clearly a Markov operator). In fact, if $U \in U(L^2(X,\mathcal{B},\mu))$ is Markov then it is of the form U_R, where $R \in Aut(X,\mathcal{B},\mu)$ [133]. This allows us to see Koopman representations as unitary Markov representations, but since a spectral isomorphism does not "preserve" the set of Markov operators, spectrally isomorphic systems can have drastically different sets of self-joinings.

We will touch here only some aspects of interactions (clearly, far from completeness) between the spectral theory and the theory of joinings.

In order to see however an example of such interactions let us recall that the simplicity of eigenvalues for ergodic systems yields a short "joining" proof of the classical isomorphism theorem of Halmos-von Neumann in the discrete spectrum case: *Assume that* $\mathcal{S} = (S_\dashv)_{\dashv\in\mathbb{A}}$ *and* $\mathcal{T} = (T_a)_{a\in\mathbb{A}}$ *are ergodic* $\mathbb{A}$*-actions on* $(X,\mathcal{B},\mu)$ *and* (Y,C,ν) *respectively. Assume that both Koopman representations have purely discrete spectrum and that their group of eigenvalues are the same. Then* $\mathcal{S}$ *and* $\mathcal{T}$ *are measure-theoretically isomorphic*. Indeed, each ergodic joining of $\mathcal{T}$ and $\mathcal{S}$ is the graph of an isomorphism of these two systems (see [127]; see also Goodson's proof in [66]). Another example of such interactions appear in the study Rokhlin's multiple mixing problem and its relation with the *pairwise independence property* (PID) for joinings of higher order. We will not deal with this subject here, referring the reader to ► Joinings in Ergodic Theory (see however Sect. "Lifting Mixing Properties").

Following [60], two $\mathbb{A}$-actions $\mathcal{S}$ and $\mathcal{T}$ are called *disjoint* provided the product measure is the only element in $J(\mathcal{S},\mathcal{T})$. It was already noticed in [72] that spectrally disjoint systems are disjoint in the Furstenberg sense; indeed, $Im(J_\rho|_{L_0^2}) = \{0\}$ since $\sigma_{\mathcal{T},J_\rho f} \ll \sigma_{\mathcal{S},f}$.

Notice that whenever we take $\rho \in J_2^e(\mathcal{T})$ we obtain a new ergodic $\mathbb{A}$-action $(T_a \times T_a)_{a\in\mathbb{A}}$ defined on the probability space $(X \times X, \rho)$. One can now ask how close spectrally to $\mathcal{T}$ is this new action? It turns out that except of the obvious fact that the marginal σ-algebras are factors, $(\mathcal{T} \times \mathcal{T}, \rho)$ can have other factors spectrally disjoint with $\mathcal{T}$: the most striking phenomenon here is a result of Smorodinsky and Thouvenot [198] (see also [29]) saying that each zero entropy system is a factor of an ergodic self-joining system of a fixed Bernoulli system (Bernoulli systems themselves have countable Haar spectrum). The situation changes if $\rho = \mu \otimes \mu$. In this case for $f, g \in L^2(X,\mathcal{B},\mu)$ the spectral measure of $f \otimes g$ is equal to $\sigma_{\mathcal{T},f} * \sigma_{\mathcal{T},g}$. A consequence of this observation is that an ergodic action $\mathcal{T} = (T_a)_{a\in\mathbb{A}}$ is weakly mixing (see the glossary) if and only if the product measure $\mu \otimes \mu$ is an ergodic self-joining of $\mathcal{T}$.

The entropy which is a basic measure-theoretic invariant does not appear when we deal with spectral properties. We will not give here any formal definition of entropy for amenable group actions referring the reader to [153]. Assume that $\mathbb{A}$ is countable and discrete. We always assume that $\mathbb{A}$ is Abelian, hence it is amenable. For each dynamical system $\mathcal{T} = (T_a)_{a\in\mathbb{A}}$ acting on $(X,\mathcal{B},\mu)$, we can find a largest invariant sub-σ field $\mathcal{P} \subset \mathcal{B}$, called the *Pinsker* σ-algebra, such that the entropy of the corresponding quotient system is zero. Generalizing the classical Rokhlin-Sinai Theorem (see also [97] for $\mathbb{Z}^d$-actions), Thouvenot (unpublished) and independently Dooley and Golodets [31] proved this theorem for groups even more general than those considered here: *The spectrum of* $\mathcal{U}_{\mathcal{T}}$ *on* $L^2(X,\mathcal{B},\mu) \ominus L^2(\mathcal{P})$ *is Haar with uniform infinite multiplicity*. This general result is quite intricate and based on methods introduced to entropy theory by Rudolph and Weiss [179] with a very surprising use of Dye's Theorem on orbital equivalence of all ergodic systems. For $\mathbb{A}$ which is not countable the same result was recently proved in [17] in case of unimodular amenable groups which are not increasing union of compact subgroups. It follows that spectral theory of dynamical systems essentially reduces to the zero entropy case.

Maximal Spectral Type of a Koopman Representation, Alexeyev's Theorem

Only few general properties of maximal spectral types of Koopman representations are known. The fact that a Koopman representation preserves the space of real functions implies that its maximal spectral type is the type of a symmetric (invariant under the map $\chi \mapsto \overline{\chi}$) measure.

Recall that the *Gelfand spectrum* $\sigma(\mathcal{U})$ of a representation $\mathcal{U} = (U_a)_{a\in\mathbb{A}}$ is defined as the of *approximative eigenvalues* of $\mathcal{U}$, that is $\sigma(\mathcal{U}) \ni \chi \in \widehat{\mathbb{A}}$ if for a sequence (x_n) bounded and bounded away from zero, $\|U_a x_n - \chi(a)x_n\| \to 0$ for each $a \in \mathbb{A}$. The spectrum is a closed subset in the topology of pointwise convergence, hence in the compact-open topology of $\widehat{\mathbb{A}}$. In case of $\mathbb{A} = \mathbb{Z}$, the above set $\sigma(U)$ is equal to $\{z \in \mathbb{C}\colon U - z \cdot Id$ is not invertible$\}$.

Assume now that $\mathbb{A}$ is countable and discrete (and Abelian). Then there exists a Fölner sequence $(B_n)_{n\geq 1}$ whose elements tile $\mathbb{A}$ [153]. Take a free and ergodic action $\mathcal{T} = (T_a)_{a\in\mathbb{A}}$ on $(X, \mathcal{B}, \mu)$. By [153] for each $\varepsilon > 0$ we can find a set $Y_n \in \mathcal{B}$ such that the sets $T_b Y_n$ are pairwise disjoint for $b \in B_n$ and $\mu(\bigcup_{b\in B_n} T_b Y_n) > 1 - \varepsilon$. For each $\chi \in \widehat{\mathbb{A}}$, by considering functions of the form $f_n = \sum_{b\in B_n} \chi(b) 1_{T_b Y_n}$ we obtain that $\chi \in \sigma(\mathcal{U}_{\mathcal{T}})$. It follows that the topological support of the maximal spectral type of the Koopman representation of a free and ergodic action is full [105,127,147]. The theory of Gaussian systems shows in particular that there are symmetric measures on the circle whose topological support is the whole circle but which cannot be maximal spectral types of Koopman representations.

An open well-known question remains whether an absolutely continuous measure ρ is the maximal spectral type of a Koopman representation if and only if ρ is equivalent to a Haar measure of $\widehat{\mathbb{A}}$ (this is unknown for $\mathbb{A} = \mathbb{Z}$).

Another interesting question was recently raised by A. Katok (private communication): *Is it true that the topological supports of all measures in a spectral sequence of a Koopman representation are full*? If the answer to this question is positive then for example the essential supremum of $M_{\mathcal{U}_{\mathcal{T}}}$ is the same on all balls of $\widehat{\mathbb{A}}$.

Notice that the fact that all spectral measures in a spectral sequence are symmetric means that $\mathcal{U}_{\mathcal{T}}$ is isomorphic to $\mathcal{U}_{\mathcal{T}^{-1}}$. A. del Junco [89] showed that generically for $\mathbb{Z}$-actions, T and its inverse are not measure-theoretically isomorphic (in fact he proved disjointness).

Let $\mathcal{T}$ be an $\mathbb{A}$-action on $(X, \mathcal{B}, \mu)$. One can ask wether a "good" function can realize the maximal spectral type of $\mathcal{U}_{\mathcal{T}}$. In particular can we find a function $f \in L^\infty(X, \mathcal{B}, \mu)$ that realizes the maximal spectral type? The answer is given in the following general theorem (see [139]).

Theorem 3 (Alexeyev's Theorem) *Assume that $\mathcal{U} = (U_a)_{a\in\mathbb{A}}$ is a unitary representation of $\mathbb{A}$ in a separable Hilbert space H. Assume that $F \subset H$ is a dense linear subspace. Assume moreover that with some F-norm $\left\vert\!\left\vert \cdot \right\vert\!\right\vert$ – stronger than the norm $\|\cdot\|$ given by the scalar product – F becomes a Fréchet space. Then, for each spectral measure σ ($\ll \sigma_{\mathcal{U}}$) there exists $y \in F$ such that $\sigma_y \gg \sigma$. In particular, there exists $y \in F$ that realizes the maximal spectral type.*

By taking $H = L^2(X, \mathcal{B}, \mu)$ and $F = L^\infty(X, \mathcal{B}, \mu)$ we obtain the positive answer to the original question. Alexeyev [14] proved the above theorem for $\mathbb{A} = \mathbb{Z}$ using analytic functions. Refining Alexeyev's original proof, Frączek [52] showed the existence of a sufficiently regular function realizing the maximal spectral type depending only on the "regularity" of the underlying probability space, e. g. when X is a compact metric space (compact manifold) then one can find a continuous (smooth) function realizing the maximal spectral type.

By the theory of systems of probabilistic origin (see Sect. "Spectral Theory of Dynamical Systems of Probabilistic Origin"), in case of simplicity of the spectrum, one can easily point out spectral measures whose types are not realized by (essentially) bounded functions. However, it is still an open question whether for each Koopman representation $\mathcal{U}_{\mathcal{T}}$ there exists a sequence $(f_i)_{i\geq 1} \subset L^\infty(X, \mathcal{B}, \mu)$ such that the sequence $(\sigma_{f_i})_{i\geq 1}$ is a spectral sequence for $\mathcal{U}_{\mathcal{T}}$. For $\mathbb{A} = \mathbb{Z}$ it is unknown whether the maximal spectral type of a Koopman representation can be realized by a characteristic function.

Spectral Theory of Weighted Operators

We now pass to the problem of possible essential values for the multiplicity function of a Koopman representation. However, one of known techniques is a use of cocycles, so before we tackle the multiplicity problem, we will go through recent results concerning spectral theory of compact group extensions automorphisms which in turn entail a study of weighted operators (see the glossary).

Assume that T is an ergodic automorphism of a standard Borel probability space $(X, \mathcal{B}, \mu)$. Let $\xi\colon X \to \mathbb{T}$ be a measurable function and let $V = V_{\xi,T}$ be the corresponding weighted operator. To see a connection of weighted operators with Koopman representations of compact group extensions consider a compact (metric) Abelian group G and a cocycle $\varphi\colon X \to G$. Then U_{T_φ} (see the glossary) acts on $L^2(X \times G, \mu \otimes \lambda_G)$. But

$$L^2(X\times G, \mu\otimes\lambda_G) = \bigoplus_{\chi\in\widehat{G}} L_\chi, \quad \text{where } L_\chi = L^2(X,\mu)\otimes\chi,$$

where L_χ is a U_{T_φ}-invariant (clearly, closed) subspace. Moreover, the map $f \otimes \chi \mapsto f$ settles a unitary isomorphism of $U_{T_\varphi}|_{L_\chi}$ with the operator $V_{\chi\circ\varphi,T}$. Therefore, spectral analysis of such Koopman representations reduces to the spectral analysis of weighted operators $V_{\chi\circ\varphi,T}$ for all $\chi \in \widehat{G}$.

Maximal Spectral Type of Weighted Operators over Rotations

The spectral analysis of weighted operators $V_{\xi,T}$ is especially well developed in case of rotations, i. e. when we additionally assume that T is an ergodic rotation on a compact monothetic group X: $Tx = x + x_0$, where x_0 is a topologically cyclic element of X (and μ will stand for Haar measure λ_x of X). In this case Helson's analysis [74] applies (see also [68,82,127,160]) leading to the following conclusions:

- The maximal spectral type $\sigma_{V_{\xi,T}}$ is either discrete or continuous.
- When $\sigma_{V_{\xi,T}}$ is continuous it is either singular or Lebesgue.
- The spectral multiplicity of $V_{\xi,T}$ is uniform.

We now pass to a description of some results in case when $Tx = x + \alpha$ is an irrational rotation on the additive circle $X = [0, 1)$. It was already noticed in the original paper by Anzai [16] that when $\xi\colon X \to \mathbb{T}$ is an affine cocycle ($\xi(x) = \exp(nx + c)$, $0 \neq n \in \mathbb{Z}$) then $V_{\xi,T}$ has a Lebesgue spectrum. It was then considered by several authors (originated by [123], see also [24,26]) to which extent this property is stable when we perturb our cocycle. Since the topological degree of affine cocyles is different from zero, when perturbing them we consider smooth perturbations by cocycles of degree zero.

Theorem 4 ([82]) *Assume that $Tx = x + \alpha$ is an irrational rotation. If $\xi\colon [0, 1) \to \mathbb{T}$ is of non-zero degree, absolutely continuous, with the derivative of bounded variation then $V_{\xi,T}$ has a Lebesgue spectrum.*

In the same paper, it is noticed that if we drop the assumption on the derivative then the maximal spectral type of $V_{\xi,T}$ is a Rajchman measure (i. e. its Fourier transform vanishes at infinity). It is still an open question, whether one can find ξ absolutely continuous with non-zero degree and such that $V_{\xi,T}$ has singular spectrum. "Below" absolute continuity, topological properties of the cocycle seem to stop playing any role – in [82] a continuous, degree 1 cocycle ξ of bounded variation is constructed such that $\xi(x) = \eta(x)/\eta(Tx)$ for a measurable $\eta\colon [0, 1) \to \mathbb{T}$ (that is ξ is a *coboundary*) and therefore $V_{\xi,T}$ has purely discrete spectrum (it is isomorphic to U_T). For other results about Lebesgue spectrum for Anzai skew products see also [24,53,81] (in [53] $\mathbb{Z}^d$-actions of rotations and so called winding numbers instead of topological degree are considered).

When the cocycle is still smooth but its degree is zero the situation drastically changes. Given an absolutely continuous function $f\colon [0, 1) \to \mathbb{R}$ M. Herman [76], using the Denjoy–Koksma inequality (see e. g. [122]), showed that $f_0^{(q_n)} \to 0$ uniformly (here $f_0 = f - \int_0^1 f \, d\lambda_{[0,1)}$ and (q_n) stands for the sequence of denominators of α). It follows that $T_{e^{2\pi i f}}$ is rigid and hence has a singular spectrum. B. Fayad [37] shows that this result is no longer true if one dimensional rotation is replaced by a multi-dimensional rotation (his counterexample is in the analytic class). See also [130] for the singularity of spectrum for functions f whose Fourier transform satisfies $o(1/|n|)$ condition or to [84], where it is shown that sufficiently small variation implies singularity of the spectrum.

A natural class of weighted operators arises when we consider Koopman operators of rotations on nil-manifolds. We only look at the particular example of such a rotation on a quotient of the Heisenberg group $(\mathbb{R}^3, *)$ (a general spectral theory of nil-actions was mainly developed by W. Parry [157]) – these actions have countable Lebesgue spectrum in the orthocomplement of the subspace of eigenfunctions) that is take the nil-manifold $\mathbb{R}^3/_*\mathbb{Z}^3$ on which we define the nil-rotation $S((x, y, z) * \mathbb{Z}^3) = (\alpha, \beta, 0)*(x, y, z)*\mathbb{Z}^3 = \big(x + \alpha, y + \beta, z + \alpha y\big)* \mathbb{Z}^3$, where α, β and 1 are rationally independent. It can be shown that S is isomorphic to the skew product defined on $[0, 1)^2 \times \mathbb{T}$ by

$$T_\varphi\colon (x, y, z) \mapsto \Big(x + \alpha, y + \beta, z \cdot e^{2\pi i\varphi(x,y)}\Big) ,$$

where $\varphi(x, y) = \alpha y - \psi(x + \alpha, y + \beta) + \psi(x, y)$ with $\psi(x, y) = x[y]$. Since nil-cocycles can be considered as a certain analog of affine cocycles for one-dimensional rotations, it would be nice to explain to what kind of perturbations the Lebesgue spectrum property is stable.

Yet another interesting problem which is related to the spectral theory of extensions given by so called *Rokhlin cocycles* (see Sect. "Rokhlin Cocycles") arises, when given $f\colon [0, 1) \to \mathbb{R}$, we want to describe spectrally the one-parameter set of weighted operators $W_c := V_{e^{2\pi i c f},T}$; here T is a fixed irrational rotation by α. As proved by quite sophisticated arguments in [84], if we take $f(x) = x$ then for all non-integer $c \in \mathbb{R}$ the spectrum of W_c is continuous and singular (see also [68] and [145] where some special α's are considered). It has been open for some time if at all one can find $f\colon [0, 1) \to \mathbb{R}$ such that for each $c \neq 0$, the operator W_c has a Lebesgue spectrum. The positive answer is given in [205]: for example if $f(x) = x^{-(2+\varepsilon)}$ ($\varepsilon > 0$) and α has bounded partial quotients then W_c has a Lebesgue spectrum for all $c \neq 0$. All functions with such a property considered in [205] are non-integrable. It would be interesting to find an integrable f with the above property.

We refer to [66] and the references therein for further results especially for transformations of the form $(x, y) \mapsto (x + \alpha, 1_{[0,\beta)}(x) + y)$ on $[0, 1) \times \mathbb{Z}/2\mathbb{Z}$. Recall however that earlier Katok and Stepin [104] used this kind of transformations to give a first counterexample to the Kolmogorov group property (see the glossary) for the spectrum.

The Multiplicity Problem for Weighted Operators over Rotations

In case of perturbations of affine cocycles, this problem was already raised by Kushnirenko [123]. Some significant results were obtained by M. Guenais. Before we state her results let us recall a useful criterion to find an upper bound for the multiplicity: *If there exist $c > 0$ and a sequence $(F_n)_{n \geq 1}$ of cyclic subspaces of H such that for each $y \in H$, $\|y\| = 1$ we have $\liminf_{n\to\infty} \|proj_{F_n} y\|^2 \geq c$, then $esssup(M_U) \leq 1/c$* which follows from a well-known lemma of Chacon [23,26,111,127]. Using this and a technique which is close to the idea of local rank one (see [44,111]) M. Guenais [69] proved a series of results on multiplicity which we now list.

Theorem 5 *Assume that $Tx = x + \alpha$ and let $\xi \colon [0, 1) \to \mathbb{T}$ be a cocycle.*

(i) If $\xi(x) = e^{2\pi icx}$ then $M_{V_{\xi,T}}$ is bounded by $|c| + 1$.
(ii) If ξ is absolutely continuous and ξ is of topological degree zero, then $V_{\xi,T}$ has a simple spectrum.
(iii) if ξ is of bounded variation, then $M_{V_{\xi,T}} \leq \max(2, 2\pi\, Var(\xi)/3)$.

Remarks on the Banach Problem

We already mentioned in Introduction the Banach problem in ergodic theory, which is simply the question whether there exists a Koopman representation for $\mathbb{A} = \mathbb{Z}$ with simple Lebesgue spectrum. In fact no example of a Koopman representation with Lebesgue spectrum of finite multiplicity is known. Helson and Parry [75] asked for the validity of a still weaker version: *Can one construct T such that U_T has a Lebesgue component in its spectrum whose multiplicity is finite*? Quite surprisingly in [75] they give a general construction yielding for each ergodic T a cocycle $\varphi \colon X \to \mathbb{Z}/2\mathbb{Z}$ such that the unitary operator U_{T_φ} has a Lebesgue spectrum in the orthocomplement of functions depending only on the X-coordinate. Then Mathew and Nadkarni [144] gave examples of cocycles over so called dyadic adding machine for which the multiplicity of the Lebesgue component was equal to 2. In [126] this was generalized to so called *Toeplitz $\mathbb{Z}/2\mathbb{Z}$-extensions* of adding machines: for each even number k we can find a two-point extension of an adding machine so that the multiplicity of the Lebesgue component is k. Moreover, it was shown that Mathew and Nadkarni's constructions from [144] in fact are close to systems arising from number theory (like the famous Rudin–Shapiro sequence, e. g. [160]), relating the result about multiplicity of the Lebesgue component to results by Kamae [96] and Queffelec [160]. Independently of [126], Ageev [8] showed that one can construct 2-point extensions of the Chacon transformation realizing (by taking powers of the extension) each even number as the multiplicity of the Lebesgue component. Contrary to all previous examples, Ageev's constructions are weakly mixing.

Still an open question remains whether for $\mathbb{A} = \mathbb{Z}$ one can find a Koopman representation with the Lebesgue component of multiplicity 1 (or even odd).

In [70], M. Guenais studies the problem of Lebesgue spectrum in the classical case of Morse sequences (see [107] as well as [124], where the problem of spectral classification in this class is studied). All dynamical sytems arising from Morse sequences have simple spectra [124]. It follows that if a Lebesgue component appears in a Morse dynamical system, it has multiplicity one. Guenais [70] using a Riesz product technique relates the Lebesgue spectrum problem with the still open problem of whether a construction of "flat" trigonometric polynomials with coefficients ±1 is possible. However, it is proved in [70] that such a construction can be carried out on some compact Abelian groups and it leads, for an Abelian countable torsion group $\mathbb{A}$, to a construction of an ergodic action of $\mathbb{A}$ with simple spectrum and a Haar component in its spectrum.

Lifting Mixing Properties

We now give one more example of interactions between spectral theory and joinings (see Introduction) that gives rise to a quick proof of the fact that r-fold mixing property of T ($r \geq 2$) lifts to a weakly mixing compact group extension T_φ (the original proof of this fact is due to D. Rudolph [175]). Indeed, to prove r-fold mixing for a mixing(=2-mixing) transformation S (acting on (Y, C, ν)) one has to prove that each weak limit of off-diagonal self-joinings (given by powers of S, see ▶ Joinings in Ergodic Theory) of order r is simply the product measure $\nu^{\otimes r}$. We need also a Furstenberg's lemma [62] about relative unique ergodicity (RUE) of compact group extensions T_φ: *If $\mu \otimes \lambda_G$ is an ergodic measure for T_φ then it is the only (ergodic) invariant measure for T_φ whose projection on the first coordinate is μ.* Now the result about lifting r-fold mixing to compact group extensions follows directly from the fact that whenever T_φ is weakly mixing, $(\mu \otimes \lambda_G)^{\otimes r}$ is an ergodic measure (this approach was shown to me by A. del Junco). In particular if T is mixing and T_φ is weakly mixing then for each $\chi \in \widehat{G} \setminus \{1\}$, the maximal spectral type of $V_{\chi\circ\varphi,T}$ is Rajchman.

See Sect. "Rokhlin Cocycles" for a generalization of the lifting result to Rokhlin cocycle extensions.

The Multiplicity Function

In this chapter only $\mathbb{A} = \mathbb{Z}$ is considered (for other groups, even for $\mathbb{R}$, much less is known; see however the case of so called *product* $\mathbb{Z}^d$*-actions* [50]). Contrary to the case of maximal spectral type, it is rather commonly believed that there are no restrictions for the set of essential values of Koopman representations.

Cocycle Approach

We will only concentrate on some results of the last twenty years. In 1983, E.A. Robinson [164] proved that for each $n \geq 1$ there exists an ergodic transformation whose maximal spectral multiplicity is n. Another important result was proved in [165] (see also [98]), where it is shown that given a finite set $M \subset \mathbb{N}$ containing 1 and closed under the least common multiple one can find (even a weakly mixing) T so that the set of essential values of the multiplicity function equals M. This result was then extended in [67] to infinite sets and finally in [125] (see also [11]) to all subsets $M \subset \mathbb{N}$ containing 1. In fact, as we have already noticed in the previous section the spectral theory for compact Abelian group extensions is reduced to a study of weighted operators and then to comparing maximal spectral types for such operators. This leads to sets of the form

$$M(G, v, H) = \Big\{\sharp(\{\chi \circ v^i : i \in \mathbb{Z}\} \cap anih(H)) : \chi \in anih(H)\Big\}$$

($H \subset G$ is a closed subgroup and v is a continuous group automorphism of G). Then an algebraic lemma has been proved in [125] saying that each set M containing 1 is of the form $M(G, v, H)$ and the techniques to construct "good" cocycles and a passage to "natural factors" yielded the following: *For each $M \subset \{1, 2, \ldots\} \subset \{\infty\}$ containing 1 there exists an ergodic automorphim such that the set of essential values for its Koopman representation equals M.* See also [166] for the case of non-Abelian group extensions.

A similar in spirit approach (that means, a passage to a family of factors) is present in a recent paper of Ageev [13] in which he first applies Katok's analysis (see [98,102]) for spectral multiplicities of the Koopman representation associated with Cartesian products $T^{\times k}$ for a generic transformation T. In a natural way this approach leads to study multiplicities of tensor products of unitary operators. Roughly, the multiplicity is computed as the number of atoms (counted modulo obvious symmetries) for conditional measures (see [98]) of a product measure over its convolution. Ageev [13] proved that for a typical automorphism T the set of the values of the multiplicity function for $U_{T^{\times k}}$ equals $\{k, k(k-1), \ldots, k!\}$ and then he just passes to "natural" factors for the Cartesian products by taking sets invariant under a fixed subgroup of permutations of coordinates. In particular, he obtains all sets of the form $\{2, 3, \ldots, n\}$ on L^2_0. He also shows that such sets of multiplicities are realizable in the category of mixing transformations.

Rokhlin's Uniform Multiplicity Problem

The Rokhlin multiplicity problem (see the recent book by Anosov [15]) was, given $n \geq 2$, to construct an ergodic transformation with uniform multiplicity n on L^2_0. A solution for $n = 2$ was independently given by Ageev [9] and Ryzhikov [188] (see also [15] and [66]) and in fact it consists in showing that for some T (actually, any T with simple spectrum for which $1/2(Id + U_T)$ is in the weak operator closure of the powers of U_T will do) the multiplicity of $T \times T$ is uniformly equal to 2 (see also Sect. "Future Directions").

In [12], Ageev proposed a new approach which consists in considering actions of "slightly non-Abelian" groups; and showing that for a "typical" action of such a group a fixed "direction" automorphism has a uniform multiplicity. Shortly after publication of [12], Danilenko [27], following Ageev's approach, considerably simplified the original proof. We will present Danilenko's arguments.

Fix $n \geq 1$. Denote $\overline{e}_i = (0, \ldots, 1, \ldots, 0) \in \mathbb{Z}^n$, $i = 1, \ldots, n$. We define an automorphism L of $\mathbb{Z}^n$ setting $L(\overline{e}_i) = \overline{e}_{i+1}$, $i = 1, \ldots, n-1$ and $L(\overline{e}_n) = \overline{e}_1$. Using L we define a semi-direct product $G\colon = \mathbb{Z}^n \rtimes \mathbb{Z}$ defining multiplication as $(u, k) \cdot (w, l) = (u + L^k w, k + l)$. Put $e_0 = (0, 1)$, $e_i = (\overline{e}_i, 0)$, $i = 1, \ldots, n$ (and $Le_i = (L\overline{e}_i, 0)$). Moreover, denote $e_{n+1} = e_0^n = (0, n)$. Notice that $e_0 \cdot e_i \cdot e_0^{-1} = Le_i$ for $i = 1, \ldots, n$ $(L(e_{n+1}) = e_{n+1})$.

Theorem 6 (Ageev, Danilenko) *For every unitary representation $\mathcal{U}$ of G in a separable Hilbert space H, for which $U_{e_1 - L^r e_1}$ has no non-trivial fixed points for $1 \leq r < n$, the essential values of the multiplicity function for $U_{e_{n+1}}$ are contained in the set of multiples of n. If, in addition, U_{e_0} has a simple spectrum, then $U_{e_{n+1}}$ has uniform multiplicity n.*

It is then a certain work to show that the assumption of the second part of the theorem is satisfied for a typical action of the group G. Using a special (C, F)-construction with all the cut-and-stack parameters explicit Danilenko [27] was also able to show that each set of the form $k \cdot M$, where $k \geq 1$ and M is an arbitrary subset of natural numbers containing 1, is realizable as the set of essential values of a Koopman representation.

Some other constructions based on the solution of the Rokhlin problem for $n = 2$ and the method of [125] are presented in [103] leading to sets different than those pointed above; these sets contain 2 as their minimum.

Rokhlin Cocycles

We consider now a certain class of extensions which should be viewed as a generalization of the concept of compact group extensions. We will focus on $\mathbb{Z}$-actions only.

Assume that T is an ergodic automorphism of $(X, \mathcal{B}, \mu)$. Let G be a l.c.s.c. Abelian group. Assume that this group acts on (Y, C, ν), that is we have a G-action $S = (S_g)_{g \in G}$ on (Y, C, ν). Let $\varphi\colon X \to G$ be a cocycle. We then define an automorphism $T_{\varphi,S}$ of the space $(X \times Y, \mathcal{B} \otimes C, \mu \otimes \nu)$ by

$$T_{\varphi,S}(x, y) = (Tx, S_{\varphi(x)}(y)).$$

Such an extension is called a *Rokhlin cocycle extension* (the map $x \mapsto S_{\varphi(x)}$ is called a *Rokhlin cocycle*). Such an operation generalizes the case of compact group extensions; indeed, when G is compact the action of G on itself by rotations preserves Haar measure. (It is quite surprising, that when only we admit G non-Abelian, then, as shown in [28], **each** ergodic extension of T has a form of a Rokhlin cocycle extension.) Ergodic and spectral properties of such extensions are examined in several papers: [63,65,129,131,132,133,167,176]. Since in these papers rather joining aspects are studied (among other things in [129] Furstenberg's RUE lemma is generalized to this new context), we will mention here only few results, mainly spectral, following [129] and [133]. We will constantly assume that G is non-compact. As $\varphi\colon X \to G$ is then a cocycle with values in a non-compact group, the theory of such cocycles is much more complicated (see e. g. [193]), and in fact the theory of Rokhlin cocycle extensions leads to interesting interactions between classical ergodic theory, the theory of cocycles and the theory of non-singular actions arising from cocycles taking values in non-compact groups – especially, the Mackey action associated to φ plays a crucial role here (see the problem of invariant measures for $T_{\varphi,S}$ in [132] and [28]); see also monographs [1,98,101,193]. Especially, two Borel subgroups of $\widehat{G}$ are important here:

$$\Sigma_\varphi = \{\chi \in \widehat{G}\colon \chi \circ \varphi = c \cdot \xi/\xi \circ T \text{ for a measurable } \xi\colon X \to \mathbb{T} \text{ and } c \in \mathbb{T}\}\,.$$

and its subgroup Λ_φ given by $c = 1$. Λ_φ turns out to be the group of L^∞-eigenvalues of the Mackey action (of G) associated to the cocycle φ. This action is the quotient action of the natural action of G (by translations on the second coordinate) on the space of ergodic components of the skew product T_φ – the Mackey action is (in general) not measure-preserving, it is however non-singular. We refer the reader to [2,78,147] for other properties of those subgroups.

Theorem 7 ([132,133])

(i) $\sigma_{T_{\varphi,S}}|_{L^2(X\times Y,\mu\otimes\nu)\ominus L^2(X,\mu)} = \int_{\widehat{G}} \sigma_{V_{\chi\circ\varphi,T}}\, d\sigma_S$.

(ii) *$T_{\varphi,S}$ is ergodic if and only if T is ergodic and $\sigma_S(\Lambda_\varphi) = 0$.*

(iii) *$T_{\varphi,S}$ is weakly mixing if and only if T is weakly mixing and S has no eigenvalues in Σ_φ.*

(iv) *if T is mixing, S is mildly mixing, φ is recurrent and not cohomologous to a cocycle with values in a compact subgroup of G then $T_{\varphi,S}$ remains mixing.*

(v) *If T is r-fold mixing, φ is recurrent and $T_{\varphi,S}$ is mildly mixing then $T_{\varphi,S}$ is also r-fold mixing.*

(vi) *If T and R are disjoint, the cocycle φ is ergodic and S is mildly mixing then $T_{\varphi,S}$ remains disjoint with R.*

Let us recall [61,195] that an $\mathbb{A}$-action $S = (S_a)_{a\in\mathbb{A}}$ is mildly mixing (see the glossary) if and only if the $\mathbb{A}$-action $(S_a \times \tau_a)_{a\in\mathbb{A}}$ remains ergodic for every properly ergodic non-singular $\mathbb{A}$-action $\tau = (\tau_a)_{a\in\mathbb{A}}$.

Coming back to Smorodinsky–Thouvenot's result about factors of ergodic self-joinings of a Bernoulli automorphism we would like to emphasize here that the disjointness result (*vi*) above was used in [132] to give an example of an automorphism which is disjoint from all weakly mixing transformations but which has an ergodic self-joining whose associated automorphism has a non-trivial weakly mixing factor. In a sense this is opposed to Smorodinsky–Thouvenot's result as here from self-joinings we produced a "more complicated" system (namely the weakly mixing factor) than the original system.

It would be interesting to develop the theory of spectral multiplicity for Rokhlin cocycle extensions as it was done in the case of compact group extensions. However a difficulty is that in the compact group extension case we deal with a countable direct sum of representations of the form

$V_{\chi\circ\varphi,T}$ while in the non-compact case we have to consider an integral of such representations.

Rank-1 and Related Systems

Although properties like mixing, weak (and mild) mixing as well as ergodicity, are clearly spectral properties, they have "good" measure-theoretic formulations (expressed by a certain behavior on sets). Simple spectrum property is another example of a spectral property, and it was a popular question in the 1980s whether simple spectrum property of a Koopman representation can be expressed in a more "measure-theoretic" way. We now recall rank-1 concept which can be seen as a notion close to Katok's and Stepin's theory of cyclic approximation [104] (see also [26]).

Assume that T is an automorphism of a standard probability Borel space $(X, \mathcal{B}, \mu)$. T is said to have *rank one* property if there exists an increasing sequence of Rokhlin towers tending to the partition into points (a *Rokhlin tower* is a family $\{F, TF, \dots, T^{n-1}F\}$ of pairwise disjoint sets, while "tending to the partition into points" means that we can approximate every set in $\mathcal{B}$ by unions of levels of towers in the sequence). Baxter [20] showed that the maximal spectral type of such a T is realized by a characteristic function. Since the cyclic space generated by the characteristic function of the base contains characteristic functions of all levels of the tower, by the definition of rank one, the increasing sequence of cyclic spaces tends to the whole L^2-space, therefore rank one property implies simplicity of the spectrum for the Koopman representation. It was a question for some time whether rank-1 is just a characterization of simplicity of the spectrum, disproved by del Junco [88]. We refer the reader to [46] as a good source for basic properties of rank-1 transformations.

Similarly to the rank one property, one can define *finite rank* automorphisms (simply by requiring that an approximation is given by a sequence of a fixed number of towers) – see e. g. [152], or even, a more general property, namely the *local rank one* property can be defined, just by requiring that the approximating sequence of single towers fills up a fixed fraction of the space (see [44,111]). Local rank one (so the more finite rank) property implies finite multiplicity [111]. Mentzen [146] showed that for each $n \geq 1$ one can construct an automorphism with simple spectrum and having rank n; in [138] there is an example of a simple spectrum automorphism which is not of local rank one. Ferenczi [45] introduced the notion of funny rank one (approximating towers are Rokhlin towers with "holes"). Funny rank one also implies simplicity of the spectrum. An example is given in [45] which is even not loosely Bernoulli (see Sect. "Inducing and Spectral Theory", we recall that local rank one property implies loose Bernoullicity [44]).

The notion of AT (see the glossary) has been introduced by Connes and Woods [25]. They proved that AT property implies zero entropy. They also proved that funny rank one automorphisms are AT. In [32] it is proved that the system induced by the classical Morse-Thue system is AT (it is an open question by S. Ferenczi whether this system has funny rank one property). A question by Dooley and Quas is whether AT implies funny rank one property. AT property implies "simplicity of the spectrum in L^1" which we already considered in Introduction (a "generic" proof of this fact is due to J.-P. Thouvenot).

A persistent question was formulated in the 1980s whether rank one itself is a spectral property. In [49] the authors maintained that this is not the case, based on an unpublished preprint of the first named author of [49] in which there was a construction of a Gaussian–Kronecker automorphism (see Sect. "Spectral Theory of Dynamical Systems of Probabilistic Origin") having rank-1 property. This latter construction turned out to be false. In fact de la Rue [181] proved that no Gaussian automorphism can be of local rank one. Therefore the question whether: *Rank one is a spectral property* remains one of the interesting open questions in that theory. Downarowicz and Kwiatkowski [33] proved that rank-1 is a spectral property in the class of systems generated by generalized Morse sequences.

One of the most beautiful theorems about rank-1 automorphisms is the following result of J. King [110] (for a different proof see [186]).

Theorem 8 (WCT) *If T is of rank one then for each element S of the centralizer $C(T)$ of T there exists a sequence (n_k) such that $U_T^{n_k} \to U_S$ strongly.*

A conjecture of J. King is that in fact for rank-1 automorphisms each indecomposable Markov operator $J = J_\rho$ ($\rho \in J_2^e(T)$) is a weak limit of powers of U_T (see [112], also [186]). To which extent the WCT remains true for actions of other groups is not clear. In [214] the WCT is proved in case of rank one flows, however the main argument seems to be based on the fact that a rank one flow has a non-zero time automorphism T_{t_0} which is of rank one, which is not true. After the proof of the WCT by Ryzhikov in [186] there is a remark that the rank one flow version of the theorem can be proved by a word for word repetition of the arguments. He also proves that if the flow $(T_t)_{t\in\mathbb{R}}$ is mixing, then T_1 does not have finite rank. On the other hand, for $\mathbb{A} = \mathbb{Z}^2$, Downarowicz and Kwiatkowski [34] gave recently a counterexample to the WCT.

Even though it looks as if rank one construction is not complicated, mixing in this class is possible; historically the first mixing constructions were given by D. Ornstein [151] in 1970, using probability type arguments for a choice of spacers. Once mixing was shown, the question arose whether absolutely continuous spectrum is also possible, as this would give automatically the positive answer to the Banach problem. However Bourgain [21], relating spectral measures of rank one automorphisms with some classical constructions of Riesz product measures, proved that a certain subclass of Ornstein's class consists of automorphisms with singular spectrum (see also [5] and [6]). Since in Ornstein's class spacers are chosen in a certain "non-constructive" way, quite a lot of attention was devoted to the rank one automorphism defined by cutting a tower at the nth step into $r_n = n$ subcolumns of equal "width" and placing i spacers over the ith subcolumn. The mixing property conjectured by M. Smorodinsky, was proved by Adams [7] (in fact Adams proved a general result on mixing of a class of staircase transformations). Spectral properties of rank-1 transformations are also studied in [114], where the authors proved that whenever $\sum_{n=1}^{\infty} r_n^{-2} = +\infty$ (r_n stands for the number of subcolumns at the nth step of the construction of a rank-1 automorphism) then the spectrum is automatically singular. H. Abdalaoui [5] gives a criterion for singularity of the spectrum of a rank one transformation; his proof uses a central limit theorem. It seems that still the question whether rank one implies singularity of the spectrum remains the most important question of this theory.

We have already seen in Sect. "Spectral Theory of Weighted Operators" that for a special class of rank one systems, namely those with discrete spectra ([87]), we have a nice theory for weighted operators. It would be extremely interesting to find a rank one automorphism with continuous spectrum for which a substitute of Helson's analysis exists.

B. Fayad [39] constructs a rank one differentiable flow, as a special flow over a two-dimensional rotation. In [40] he gives new constructions of smooth flows with singular spectra which are mixing (with a new criterion for a Rajchman measure to be singular). In [35] a certain smooth change of time for an irrational flows on the 3-torus is given, so that the corresponding flow is partially mixing and has the local rank one property.

Spectral Theory of Dynamical Systems of Probabilistic Origin

Let us just recall that when $(Y_n)_{n=-\infty}^{\infty}$ is a stationary process then its distribution μ on $\mathbb{R}^{\mathbb{Z}}$ is invariant under the shift S on $\mathbb{R}^{\mathbb{Z}}$: $S((x_n)_{n\in\mathbb{Z}}) = (y_n)_{n\in\mathbb{Z}}$, where $y_n = x_{n+1}$, $n \in \mathbb{Z}$. In this way we obtain an automorphism S defined on $(\mathbb{R}^{\mathbb{Z}}, \mathcal{B}(\mathbb{R}^{\mathbb{Z}}), \mu)$. For each automorphism T we can find $f\colon X \to \mathbb{R}$ measurable such that the smallest σ-algebra making the stationary process $(f \circ T^n)_{n\in\mathbb{Z}}$ measurable is equal to $\mathcal{B}$, therefore, for the purpose of this article, by a system of probabilistic origin we will mean (S, μ) obtained from a stationary infinitely divisible process (see e. g. [142,192]). In particular, the theory of Gaussian dynamical systems is indeed a classical part of ergodic theory (e. g. [149,150,211,212]). If $(X_n)_{n\in\mathbb{Z}}$ is a stationary real centered Gaussian process and σ denotes the *spectral measure of the process*, i. e. $\widehat{\sigma}(n) = E(X_n \cdot X_0)$, $n \in \mathbb{Z}$, then by $S = S_\sigma$ we denote the corresponding Gaussian system on the shift space (recall also that for each symmetric measure σ on $\mathbb{T}$ there is exactly one stationary real centered Gaussian process whose spectral measure is σ). Notice that if σ has an atom, then in the cyclic space generated by X_0 there exists an eigenfunction Y for S_σ – if now S_σ were ergodic, $|Y|$ would be a constant function which is not possible by the nature of elements in $\mathbb{Z}(X_0)$. In what follows we assume that σ is continuous.

It follows that U_{S_σ} restricted to $\mathbb{Z}(X_0)$ is spectrally the same as $V = V^\sigma$ acting on $L^2(\mathbb{T}, \sigma)$, and we obtain that $(U_{S_\sigma}, L^2(\mathbb{R}^{\mathbb{Z}}, \mu_\sigma))$ can be represented as the symmetric Fock space built over $H = L^2(\mathbb{T}, \sigma)$ and $U_{S_\sigma} = F(V)$ – see the glossary ($H^{\odot n}$ is called the *n-th chaos*). In other words the spectral theory of Gaussian dynamical systems is reduced to the spectral theory of special tensor products unitary operators. Classical results (see [26]) which can be obtained from this point of view are for example the following:

(A) ergodicity implies weak mixing,
(B) the multiplicity function is either 1 or is unbounded,
(C) the maximal spectral type of U_{S_σ} is equal to $\exp(\sigma)$, hence Gaussian systems enjoy the Kolmogorov group property.

However we can also look at a Gaussian system in a different way, simply by noticing that the variables $e^{2\pi i f}$ (f is a real variable), where $f \in \mathbb{Z}(X_0)$ generate $L^2(\mathbb{R}^{\mathbb{Z}}, \mu_\sigma)$. Now calculating the spectral measure of $e^{2\pi i f}$ is not difficult and we obtain easily (C). Moreover, integrals of type $\int e^{2\pi i f_0} e^{2\pi i f_1 \circ T^n} e^{2\pi i f_2 \circ T^{n+m}}\, d\mu_\sigma$ can also be calculated, whence in particular we easily obtain Leonov's theorem on the multiple mixing property of Gaussian systems [141].

One of the most beautiful parts of the theory of Gaussian systems concerns ergodic properties of S_σ when σ is concentrated on a thin Borel set. Recall that a closed subset $K \subset \mathbb{T}$ is said to be a *Kronecker set* if each $f \in C(K)$ is a uniform limit of characters (restricted to K). Each Kronecker set has no rational relations. Gaussian–Kronecker automorphisms are, by definition, those Gaussian systems for which the measure σ (always assumed to be continuous) is concentrated on $K \cup \overline{K}$, K a Kronecker set. The following theorem has been proved in [51] (see also [26]).

Theorem 9 (Foiaş–Stratila Theorem) *If T is an ergodic automorphism and f is a real-valued element of L_0^2 such that the spectral measure σ_f is concentrated on $K \cup \overline{K}$, where K is a Kronecker set, then the process $(f \circ T^n)_{n\in\mathbb{Z}}$ is Gaussian.*

This theorem is indeed striking as it gives examples of weakly mixing automorphisms which are spectrally determined (like rotations). A relative version of the Foiaş–Stratila Theorem has been proved in [129].

The Foiaş–Stratila Theorem implies that whenever a spectral measure σ is Kronecker, it has no realization of the form σ_f with f bounded. We will see however in Sect. "Future Directions" that for some automorphisms T (having the SCS property) the maximal spectral type σ_T has the property that S_{σ_T} has a simple spectrum.

Gaussian–Kronecker automorphisms are examples of automorphisms with simple spectra. In fact, whenever σ is concentrated on a set without rational relations, then S_σ has a simple spectrum (see [26]). Examples of mixing automorphisms with simple spectra are known [149], however it is still unknown (Thouvenot's question) whether the Foiaş–Stratila property may hold in the mixing class. F. Parreau [154] using independent Helson sets gave an example of mildly mixing Gaussian system with the Foiaş–Stratila property.

In [165] there is a remark that the set of finite essential values of the multiplicity function of U_{S_σ} forms a (multiplicative) subsemigroup of $\mathbb{N}$. However, it seems that there is no "written" proof of this fact.

Joining theory of a class of Gaussian system, called GAG, is developed in [136]. A Gaussian automorphism S_σ with the Gaussian space $H \subset L_0^2(\mathbb{R}^{\mathbb{Z}}, \mu_\sigma)$ is called a GAG if for each ergodic self-joining $\rho \in J_2^e(S_\sigma)$ and arbitrary $f, g \in H$ the variable

$$(\mathbb{R}^{\mathbb{Z}} \times \mathbb{R}^{\mathbb{Z}}, \rho) \ni (x, y) \mapsto f(x) + g(y)$$

is Gaussian. For GAG systems one can describe the centralizer and factors, they turn out to be objects close to the probability structure of the system. One of the crucial observations in [136] was that all Gaussian systems with simple spectrum are GAG.

It is conjectured (J.P. Thouvenot) that in the class of zero entropy Gaussian systems the PID property holds true.

For the spectral theory of classical factors of a Gaussian system see [137]; also spectrally they share basic spectral properties of Gaussian systems. Recall that historically one of the classical factors namely the σ-algebra of sets invariant for the map

$$(\ldots, x_{-1}, x_0, x_1, \ldots) \mapsto (\ldots, -x_{-1}, -x_0, -x_1, \ldots)$$

was the first example with zero entropy and countable Lebesgue spectrum (indeed, we need a singular measure σ such that $\sigma * \sigma$ is equivalent to Lebesgue measure [150]). For factors obtained as functions of a stationary process see [83].

T. de la Rue [181] proved that Gaussian systems are never of local rank-1, however his argument does not apply to classical factors. We conjecture that Gaussian systems are disjoint from rank-1 automorphisms (or even from local rank-1 systems).

We now turn the attention to Poissonian systems (see [26] for more details). Assume that $(X, \mathcal{B}, \mu)$ is a standard Borel space, where μ is infinite, σ-finite. The new configuration space $\widetilde{X}$ is taken as the set of all countable subsets $\{x_i\colon i \geq 1\}$ of X. Once a set $A \in \mathcal{B}$, of finite measure is given one can define a map $N_A\colon \widetilde{X} \to \mathbb{N}(\cup\{\infty\})$ just counting the number of elements belonging to A. The measure-theoretic structure $(\widetilde{X}, \widetilde{\mathcal{B}}, \widetilde{\mu})$ is given so that the maps N_A become random variables with Poisson distribution of parameter $\mu(A)$ and such that whenever $A_1, \ldots, A_k \subset X$ are of finite measure and are pairwise disjoint then the variables $N_{A_1}, \ldots, N_{A_k}$ are independent.

Assume now that T is an automorphism of $(X, \mathcal{B}, \mu)$. It induces a natural automorphism on the space $(\widetilde{X}, \widetilde{\mathcal{B}}, \widetilde{\mu})$ defined by $\widetilde{T}(\{x_i\colon i \geq 1\} = \{Tx_i\colon i \geq 1\}$. The automorphism $\widetilde{T}$ is called the *Poisson suspension* of T (see [26]). Such a suspension is ergodic if and only if no set of positive and finite μ-measure is T-invariant. Moreover ergodicity of $\widetilde{T}$ implies weak mixing. In fact the spectral structure of $U_{\widetilde{T}}$ is very similar to the Gaussian one: namely the first chaos equals $L^2(X, \mathcal{B}, \mu)$ (we emphasize that this is about the whole L^2 and not only L_0^2) on which $U_{\widetilde{T}}$ acts as U_T and the $L^2(\widetilde{X}, \widetilde{\mu})$ together with the action of $U_{\widetilde{T}}$ has the structure of the symmetric Fock space $F(L^2(X, \mathcal{B}, \mu))$ (see the glossary).

We refer to [22,86,168,169] for ergodic properties of systems given by symmetric α-stable stationary processes, or more generally infinitely divisible processes. Again, they share spectral properties similar to the Gaussian case: ergodicity implies weak mixing, while mixing implies mixing of all orders.

In [171], E. Roy clarifies the dynamical "status" of such systems. He uses Poisson suspension automorphisms and the Maruyama representation of an infinitely divisible process mixed with basic properties of automorphisms preserving infinite measure (see [1]) to prove that as a dynamical system, a stationary infinitely divisible process (without the Gaussian part), is a factor of the Poisson suspension over the Lévy measure of this process. In [170] a theory of ID-joinings is developed (which should be viewed as an analog of the GAG theory in the Gaussian class). Parreau and Roy [155] give an example of a Poisson suspension with a minimal possible set of ergodic self-joinings.

Many natural problems still remain open here, for example (assuming always zero entropy of the dynamical system under consideration): Are Poisson suspensions disjoint from Gaussian systems? What is the spectral structure for dynamical systems generated by symmetric α-stable process? Are such systems disjoint whenever $\alpha_1 \neq \alpha_2$? Are Poissonian systems disjoint from local rank one automorphisms (cf. [181])? In [91] it is proved that Gaussian systems are disjoint from so called simple systems (see ▶ Joinings in Ergodic Theory and [93,208]); we will come back to an extension of this result in Sect. "Future Directions". It seems that flows of probabilistic origin satisfy the Kolmogorov group property for the spectrum. One can therefore ask how different are systems satisfying the Kolmogorov group property from systems for which the convolutions of the maximal spectral type are pairwise disjoint (see also Sect. "Future Directions" and the SCS property).

We also mention here another problem which will be taken up in Sect. "Special Flows and Flows on Surfaces, Interval Exchange Transformations" – *Is it true that flows of probabilistic origin are disjoint from smooth flows on surfaces?* Recently A. Katok and A. Windsor announced that it is possible to construct a Kronecker measure so that the corresponding Gaussian system ($\mathbb{Z}$-action (!)) has a smooth representation on the torus.

Yet one more (joining) property seems to be characteristic in the class of systems of probabilistic origin, namely they satisfy so called ELF property (see [30] and ▶ Joinings in Ergodic Theory). Vershik asked whether the ELF property is spectral – however the example of a cocycle from [205] together with Theorem 7 (i) yields a certain Rokhlin extension of a rotation which is ELF and has countable Lebesgue spectrum in the orthocomplement of the eigenfunctions (see [206]); on the other hand any affine extension of that rotation is spectrally the same, while it cannot have the ELF property.

Prikhodko and Thouvenot (private communication) have constructed weakly mixing and non-mixing rank one automorphisms which enjoy the ELF property.

Inducing and Spectral Theory

Assume that T is an ergodic automorphism of a standard probability Borel space $(X, \mathcal{B}, \mu)$. Can "all" dynamics be obtained by inducing (see the glossary) from one fixed automorphism was a natural question from the very beginning of ergodic theory. Because of Abramov's formula for entropy $h(T_A) = h(T)/\mu(A)$ it is clear that positive entropy transformations cannot be obtained from inducing on a zero entropy automorphism. However here we are interested in spectral questions and thus we ask how many spectral types we obtain when we induce. It is proved in [59] that the family of $A \in \mathcal{B}$ for which T_A is mixing is dense for the (pseudo) metric $d(A_1, A_2) = \mu(A_1 \triangle A_2)$. De la Rue [182] proves the following result: *For each ergodic transformation T of a standard probability space $(X, \mathcal{B}, \mu)$ the set of $A \in \mathcal{B}$ for which the maximal spectral type of U_{T_A} is Lebesgue is dense in $\mathcal{B}$.* The multiplicity function is not determined in that paper. Recall (without giving a formal definition, see [152]) that a zero entropy automorphism is *loosely Bernoulli* (LB for short) if and only if it can be induced from an irrational rotation (see also [43,99]). The LB theory shows that not all dynamical systems can be obtained by inducing from an ergodic rotation. However an open question remained whether LB systems exhaust spectrally all Koopman representations. In a deep paper [180], de la Rue studies LB property in the class of Gaussian–Kronecker automorphisms, in particular he constructs S which is not LB. Suppose now that T is LB and for some $A \in \mathcal{B}$, U_{T_A} is isomorphic to U_S. Then by the Foiaş–Stratila Theorem, T_A is isomorphic to S, and hence T_A is not LB. However an induced automorphism from an LB automorphism is LB, a contradiction.

Special Flows and Flows on Surfaces, Interval Exchange Transformations

We now turn our attention to flows. The cases of the geodesic flow, horocycle flows on homogenous spaces of $SL(2, \mathbb{R})$ and nilflows are classical (we refer the reader to [105] with a nice description of the first two cases, while for nilflows we refer to [157]: these classes of flows on homogenous spaces have countable Lebesgue spectrum, in the third case – in the orthocomplement of the eigenspace). On the other hand the classical cyclic approximation theory of Katok and Stepin [104] (see [26]) leads to examples of smooth flows on the torus with simple continuous singular spectra.

Given an ergodic automorphism T on $(X, \mathcal{B}, \mu)$ and a positive integrable function $f: X \to \mathbb{R}^+$ consider the corresponding special flow T^f (see the glossary). Obviously, such a flow is ergodic. Special flows were introduced to ergodic theory by von Neumann in his fundamental work [148] in 1932. Also in that work he explains how to compute eigenvalues for special flows, namely: $r \in \mathbb{R}$ *is an eigenvalue of* T^f *if and only if the following functional equation*

$$e^{2\pi i r f(x)} = \frac{\xi(x)}{\xi(Tx)}$$

has a measurable solution $\xi: X \to \mathbb{T}$. We recall also that the classical Ambrose-Kakutani theorem asserts that practically each ergodic flow has a special representation ([26], see also Rudolph's theorem on special representation therein).

A classical situation when we obtain "natural" special representations is while considering smooth flows on surfaces (we refer the reader to Hasselblatt's and Katok's monograph [73]). They have transversals on which the Poincaré map is piecewise isometric, and this entails a study of interval exchange transformations (IET), see [26,108,163]. Formally, to define IET of m intervals we need a permutation π of $\{1, \ldots, m\}$ and a probability vector $\lambda = (\lambda_1, \ldots, \lambda_m)$ (with positive entries). Then we define $T = T_{\lambda,\pi}$ of $[0, 1)$ by putting

$$T_{\lambda,\pi}(x) = x + \beta_i^\pi - \beta_i \quad \text{for} \quad x \in [\beta_i, \beta_{i+1}) ,$$

where $\beta_i = \sum_{j<i} \lambda_j$, $\beta_i^\pi = \sum_{\pi j < \pi i} \beta_j$. Obviously, each IET preserves Lebesgue measure. One of possible approaches to study ergodic properties of IET is an "a.e" approach "seen" in the definition of $T_{\lambda,\pi}$. It is based on the fundamental fact that the induced transformation on a subinterval of $[0, 1)$ is also IET (see [26]). This leads to a very delicate and deep mathematics based on Rauzy induction, which is a way of inducing on special intervals, considering only irreducible permutations whose set is partitioned into orbits of some maps (any such an orbit is called a *Rauzy class*). If now $\mathcal{R}$ is a Rauzy class of permutations and λ lies in the standard simplex Δ_{m-1} then the Rauzy induction together with a natural renormalization leads to a map $\mathcal{P}: \mathcal{R} \times \Delta_{m-1} \to \mathcal{R} \times \Delta_{m-1}$. For a better understanding of the dynamics of the Rauzy map Veech [209] introduced the space of *zippered rectangles*. A zippered rectangle associated to the Rauzy class $\mathcal{R}$ is a quadruple (λ, h, a, π), where $\lambda \in \mathbb{R}^m_+$, $h \in \mathbb{R}^m_+$, $a \in \mathbb{R}^m_+$, $\pi \in \mathcal{R}$ and the vectors h and a satisfy some equations and inequalities. Every zippered rectangle (λ, h, a, π) determines a Riemann structure on a compact connected surface. Denote by $\Omega(\mathcal{R})$ the space of all zippered rectangles, corresponding to a given Rauzy class $\mathcal{R}$ and satisfying the condition $\langle \lambda, h \rangle = 1$. In [209], Veech defined a flow $(P^t)_{t\in\mathbb{R}}$ on the space $\Omega(\mathcal{R})$ putting

$$P^t(\lambda, h, a, \pi) = (e^t \lambda, e^{-t} h, e^{-t} a, \pi)$$

and extended the Rauzy map. On so called *Veech moduli space* of zippered rectangles, the flow (P^t) becomes the *Teichmüller flow* and it preserves a natural Lebesgue measure class; by passing to a transversal and projecting the measure on the space of IETs $\mathcal{R} \times \Delta_{m-1}$ Veech has proved the following fundamental theorem ([209], see also [143]) which is a generalization of the fact that Gauss measure $1/(\ln 2) 1/(1 + x) dx$ is invariant for the Gauss map which sends $t \in (0, 1)$ into the fractional part of its inverse.

Theorem 10 (Veech, Masur, 1982) *Assume that* $\mathcal{R}$ *is a Rauzy class. There exists a* σ*-finite measure* $\mu_\mathcal{R}$ *on* $\mathcal{R} \times \Delta_{m-1}$ *which is* $\mathcal{P}$*-invariant, equivalent to "Lebesgue" measure, conservative and ergodic.*

In [209] it is proved that a.e. (in the above sense) IET is then of rank one (and hence is ergodic and has a simple spectrum). He also formulated as an open problem whether we can achieve the weak mixing property a.e. This has been recently answered in positive by A. Avila and G. Forni [19] (for π which is not a rotation).

Katok [100] proved that IET have no mixing factors (in fact his proof shows more: the IET class is disjoint with the class of mixing transformations). By their nature, IET transformations are of finite rank (see [26]) so they are of finite multiplicity. They need not be of simple spectrum (see remarks in [105] pp. 88–90). It remains an open question whether an IET can have a non-singular spectrum. Joining properties in the class of exchange of 3 and more intervals are studied in [47,48]. An important question of Veech [208] whether a.e. IET is simple is still open.

When we consider a smooth flow on a surface preserving a smooth measure, whose only singularity (we assume that we have only finitely many singularities) are simple (non-degenerated) saddles then such a flow has a special representation over an interval exchange automorphism under a smooth function which has finitely many logarithmic singularities (see [73]). In the article by Arnold [18] the quasi-periodic Hamiltonian case is considered: $H: \mathbb{R}^2 \to \mathbb{R}$ satisfies $H(x+m, y+n) = H(x, y) + n\alpha_1 + m\alpha_2$, $\alpha_1/\alpha_2 \notin \mathbb{Q}$, and we then consider the following system of differential equations on $\mathbb{T}^2$

$$\frac{dx}{dt} = \frac{\partial H}{\partial y}, \quad \frac{dy}{dt} = \frac{-\partial H}{\partial x} . \tag{2}$$

As Arnold shows the dynamical system arising from the system (2) has one ergodic component which has a special representation over the irrational rotation by $\alpha := \alpha_1/\alpha_2$ under a smooth function with finitely many logarithmic singularities (all other ergodic components are periodic orbits and separatrices). By changing a speed as it is done in [57] so that critical points of the vector field in (2) become singular points, Arnold's special representation is transformed to a special flow over the same irrational rotation however under a piecewise smooth function. If the sum of jumps is not zero then in fact we come back to von Neumann's class of special flows considered in [148]. Similar classes of special flows (when the roof function is of bounded variation) are obtained from ergodic components of flows associated to billiards in convex polygones with rational angles [106]. Kochergin [115] showed that special flows over irrational rotations and under bounded variation functions are never mixing. This has been recently strengthened in [54] to the following: *If T is an irrational rotation and f is of bounded variation then the special flow T^f is spectrally disjoint from all mixing flows*. In particular all such flows have singular spectra. Moreover, in [54] it is proved that whenever the Fourier transform of the roof function f is of order $O(1/n)$ then T^f is disjoint from all mixing flows (see also [55]). In fact in the papers [54,55,56,57] the authors discuss the problem of disjointness of those special flows with all ELF-flows conjecturing that no flow of probabilistic origin has a smooth realization on a surface. In [140] the analytic case is considered leading to a "generic" result on disjointness with the ELF class generalizing the classical Shklover's result on the weak mixing property [197].

Kochergin [117] proved the absence of mixing for flows where the roof function has finitely many singularities, whenever the sum of "left logarithmic speeds" and the sum of "right logarithmic speeds" are equal – this is called a *symmetric logarithmic case*, however some Diophantine restriction is put on α.

In [128], where also the absence of mixing is considered for the symmetric logarithmic case, it was conjectured (and proved for arbitrary rotation) that a necessary condition for mixing of a special flow T^f (with arbitrary T and f) is the condition that the sequence of distributions $((f_0^{(n)})_*)_n$ tends to δ_∞ in the space of probability measures on $\overline{\mathbb{R}}$. K. Schmidt [194] proved it using the theory of cocycles and extending a result from [3] on tightness of cocycles.

A. Katok [100] proved the absence of mixing for special flows over IET when the roof function is of bounded variation (see also [187]). Katok's theorem was strengthened in [56] to the disjointness theorem with the class of mixing flows.

On the other hand there is a lot of (difficult) results pointing out classes of special flows over irrational rotations which are mixing, especially (but not only) in the class of non-symmetric logarithmic singularities: [36,38] (B. Fayad was able to give a speed of convergence to zero for Fourier coefficients), [109,119,120]. Recently mixing property has been proved in a non-symmetric case in [203] when the base transformation is a special class of IETs.

The eigenvalue problem (mainly how many frequencies can have the group of eigenvalues) for special flows over irrational rotations is studied in [41,42,71].

A. Avila and G. Forni [19] proved that a.e. translation flow on a surface (of genus at least two) is weakly mixing (which is a drastic difference with the linear flow case of the torus, where the spectrum is always discrete).

The problem of whether mixing flows indicated in this chapter are mixing of all orders is open (it is also unknown whether they have singular spectra). One of several possible approaches (proposed by B. Fayad and J.-P. Thouvenot) toward positive solution of this problem would be to show that such flows enjoy so called Ratner's property (R-property). This property may be viewed as a particular way of divergence of orbits of close points; it was shown to hold for horocycle flows by M. Ratner [162]. We refer the reader to [162] and the survey article [201] for the formal definitions and basic consequences of R-property. In particular, R-property implies "rigidity" of joinings and it also implies the PID property; hence mixing and R-property imply mixing of all orders. In [57,58] a version of R-property is shown for the class of von Neumann special flows (however α is assumed to have bounded partial quotients). This allowed one to prove there that such flows are even mildly mixing (mixing is excluded by a Kochergin's result). We conjecture that an R-property may also hold for special flows over multidimensional rotations with roof functions given by nil-cocycles which we mentioned in Sect. "Spectral Theory of Weighted Operators".

If indeed the R-property is ubiquitous in the class of smooth flows on surfaces it may also be useful to show that smooth flows on surfaces are disjoint with flows of probabilistic origin – see [91,92,135,190,202].

B. Fayad [40] gives a criterion that implies singularity of the maximal spectral type for a dynamical system on a Riemannian manifold. As an application he gives a class of smooth mixing flows (with singular spectra) on $\mathbb{T}^3$ obtained from linear flows by a time change (again this is a drastic difference with dimension two, where a smooth time change of a linear flow leads to non-mixing flows [26]).

The spectral multiplicity problem for special flows (with sufficiently regular roof functions) over irrational rotations seems to be completely untouched (except for the case of a sufficiently smooth f – the spectrum of T^f is then simple [26]). It would be nice to have examples of such flows with finite bigger than one multiplicity. In particular, is it true that the von Neumann class of special flows have finite multiplicity? This was partially solved by A. Katok (private communication) on certain subspaces in L^2, but not on the whole L^2-space.

Problem. *Given $Tx = x + \alpha$ (with α irrational) can we find $f\colon [0,1) \to \mathbb{R}^+$ sufficiently regular (e. g. with finitely many "controllable" singularities) such that T^f has a Lebesgue spectrum?*

Of course the above is related to the question whether at all one can find a smooth flow on a surface with a Lebesgue spectrum (for $\mathbb{Z}$-actions we can even see positive entropy diffeomorphisms on the torus).

We mention at the end that if we drop here (and in other problems) the assumption of regularity of f then the answers will be always positive because of the LB theory; in particular there is a section of any horocycle flow (it has the LB property [161]) such that in the corresponding special representation T^f the map T is an irrational rotation. Using a Kochergin's result [118] on cohomology (see also [98,176]) the L^1-function f is cohomologous to a positive function g which is even continuous, thus T^f is isomorphic to T^g.

Future Directions

We have already seen several cases where spectral properties interact with measure-theoretic properties of a system. Let us mention a few more cases which require further research and deeper understanding.

We recall that the weak mixing property can be understood as a property complementary to discrete spectrum (more precisely to the distality [62]), or similarly mild mixing property is complementary to rigidity. This can be phrased quite precisely by saying that T is not weakly (mildly) mixing if and only if it has a non-trivial factor with discrete spectrum (it has a non-trivial rigid factor). It has been a question for quite a long time if in a sense mixing can be "built" on the same principle. In other words we seek a certain "highly" non-mixing factor. It was quite surprising when in 2005 F. Parrreau (private communication) gave the positive answer to this problem.

Theorem 11 (Parreau) *Assume that T is an ergodic automorphism of a standard probability space $(X, \mathcal{B}, \mu)$. Assume moreover that T is not mixing. Then there exists a non-trivial factor (see below) of T which is disjoint with all mixing automorphisms.*

In fact, Parreau proved that each factor of T given by $\mathcal{B}_\infty(\rho)$ (this σ-algebra is described in [136]), where $U_T^{n_k} \to J_\rho$, is disjoint from all mixing transformations. This proof leads to some other results of the same type, for example: *Assume that T is an ergodic automorphism of a standard probability space. Assume that there exists a non-trivial automorphism S with a singular spectrum which is not disjoint with T. Then T has a non-trivial factor which is disjoint with any automorphism with a Lebesgue spectrum.*

The problem of spectral multiplicity of Cartesian products for "typical" transformation studied by Katok [98] and then its solution in [13] which we already considered in Sect. "The Multiplicity Function" lead to a study of those T for which

$$(CS) \quad \sigma^{(m)} \perp \sigma^{(n)} \text{ whenever } m \neq n\,,$$

where $\sigma = \sigma_T$ just stands for the reduced maximal spectral type of U_T (which is constantly assumed to be a continuous measure), see also Stepin's article [199].

The usefulness of the above property (CS) in ergodic theory was already shown in [90], where a spectral counterexample machinery was presented using the following observation: *If $\mathcal{A}$ is a $T^{\times\infty}$-invariant sub-σ-algebra such that the maximal spectral type on $L^2(\mathcal{A})$ is absolutely continuous with respect to σ_T then $\mathcal{A}$ is contained in one of the coordinate sub-σ-algebras $\mathcal{B}$.* Based on that in [90] it is shown how to construct two weakly isomorphic action which are not isomorphic or how to construct two non-disjoint automorphisms which have no common non-trivial factors (such constructions were previously known for so called minimal self-joining automorphisms [174]). See also [200] for extensions of those results to $\mathbb{Z}^d$-actions.

Prikhodko and Ryzhikov [159] proved that the classical Chacon transformation enjoys the (CS) property. The SCS property defined in the glossary is stronger than the (CS) condition above; the SCS property implies that the corresponding Gaussian system S_{σ_T} has a simple spectrum. Ageev [10] shows that Chacon's transformation satisfies the SCS property; moreover in [13] he shows that the SCS property is satisfied generically and he gives a construction of a rank one mixing SCS-system (see also [191]). In [134] it is proved that some special flows considered in Sect. "Special Flows and Flows on Surfaces, Interval Exchange Transformations" (including the von Neumann class, however with α having unbounded partial quotients) have the SCS property. Since the corresponding Gaussian systems have simple spectra, it would be interesting to decide whether σ_T (for an SCS-automorphism) can be concentrated on a set without rational relations. It is quite plausible that the SCS property is commonly seen for smooth flows on surfaces.

Katok and Thouvenot (private communication) considered systems called *infinitely divisible*. These are systems T on $(X, \mathcal{B}, \mu)$ which have a family of factors $\mathcal{B}_\omega$ indexed by $\omega \in \bigcup_{n=0}^{\infty}\{0,1\}^n$ ($\mathcal{B}_\varepsilon = \mathcal{B}$) such that $\mathcal{B}_{\omega 0} \perp \mathcal{B}_{\omega 1}$, $\mathcal{B}_{\omega 0} \vee \mathcal{B}_{\omega 1} = \mathcal{B}_\omega$ and for each $\eta \in \{0,1\}^{\mathbb{N}}$, $\bigcap_{n\in\mathbb{N}} \mathcal{B}_{\eta[0,n]} = \{\emptyset, X\}$. They showed (unpublished) that there are discrete spectrum transformations which are ID, and that there are rank one transformations with continuous spectra which are also ID (clearly Gaussian systems are ID). It was until recently that a relationship between ID automorphisms and systems coming from stationary ID processes was unclear. In [135] it is proved that dynamical systems coming from stationary ID processes are factors of ID automorphisms; moreover, ID automorphisms are disjoint with all systems having the SCS property. It would be nice to decide whether Koopman representations associated to ID automorphisms satisfy the Kolmogorov group property.

Article Outline

Glossary

Atomic units, a. u. The electron-charge $|e|$, and the mass m_e are taken as unity. The unit of time is fixed by setting the Plank constant $\hbar$ to unity. The Bohr radius $a_0 = \hbar^2/(m_e e^2)$ is one a.u. of length in the centimeter-gram-second(CGS) system which uses the "esu"(electrostatic unit of charge). The SI system uses the meter, kilogram, second (with the Ampere as the unit of current), $a_0 = (4\pi\varepsilon_0\hbar^2/(m_e e^2)$ where ε is the electric permittivity of the vacuum. The value of a_0 is 5.29177×10^{-9} cm. The unit of energy, the Hartree, is e^2/a_0 in the CGS system, being 27.2116 eV. In semiconductor physics, *effective atomic units* are used, with e^2/ε, replacing e^2, where ε is the dielectric constant. The band mass m_b is used instead of m_e, so that the effective Bohr radius $a_0^* = a_0(\varepsilon/m^*)$, where m^* is the effective mass. Then the effective Hartree is of the order of millivolts.

Confining potential This potential keeps the electron in a given spatial region. It is due to the physical structure of the device, the applied gate voltages etc.

Correlation energy The contribution to the total energy beyond the Hartree–Fock approximation, denoted by E_c.

Correlation hole is the depletion of electron density near an electron due to Coulomb repulsion effects.

Coupling constant is the ratio of the potential energy(PE) to the kinetic energy (KE). In a classical electron fluid, the KE (thermal energy) is T, and the PE is $1/r_s$ (atomic units), and r_s is the Wigner–Seitz radius. The coupling constant $=$ PE/KE $= \Gamma = 1/(r_s T)$. In quantum systems, the Fermi energy E_F is used instead of T for the KE, and $\Gamma = r_s$.

Classical-map hyper-netted-chain (CHNC) A method for using the classical hyper-netted-chain equation to calculate the correlation functions of quantum systems.

Effective mass is denoted by m^*, and is the band mass m_b in units of the electron mass m_e.

Exchange energy The part of the Hartree–Fock energy due to electron exchange, i. e., the "Fock" part, denoted by E_x. It is first order in the Coulomb interaction.

Fermi hole This denotes the reduction in the probability of finding a like-spin electron near another, due to Fermi statistics.

Hartree–Fock Hartree's self-consistent one-body approximation for interacting electrons is based on a product wavefunction. Fock included exchange using an antisymmetrized product. "Hartree–Fock" is the label for calculations of the energy, wavefunctions etc., where the electron moves in this mean potential generated by the electrostatics and the exchange effects. The Hartree term is zero in uniform systems.

HIGFET
Heterojunction-Insulated-Gate Field-effect Transistor.

Jellium A model "metal" where the positive ionic charges are replaced by a uniform static charge which neutralizes the free-electron charge.

MOSFET Metal-oxide semiconductor field-effect transistor.

Heterojunction A semiconductor-interface involving two dissimilar materials.

Hyper-netted-chain (HNC) A classical integral equation due to van Leeuwen, Groenveld and de Boer (1959) which non-perturbatively sums "hyper-netted-chain" diagrams, going beyond mean-field theory.

Electron gas parameter $\mathbf{r_s}$ See Wigner–Seitz radius.

Pair-correlation function Denoted by $h(\vec{r}) = g(\vec{r}) - 1$ where $g(r)$ is the pair-distribution function(PDF).

Pair-distribution function The pair-distribution function(PDF), $g(\vec{r})$, is the probability of finding a particle at the location $\vec{r}$, given a reference particle at the origin.

Plasma analogy A class of methods for approximately replacing a charged quantum fluid by an equivalent classical fluid at a finite temperature.

Pseudo-spin Discrete degrees of freedom beside the electron spin. The electrons in Si/SiO$_2$ interfaces occupy two valleys. The valley index is a pseudospin.

Quantum-Monte Carlo (QMC) In molecular dynamics (MD), Newton's equations of motion are integrated using a stochastic scheme based on the Metropolis algorithm. In QMC a trial wavefunction provides a probability measure for the Metropolis algorithm. The wavefunction is optimized in various ways, leading to "variational QMC", where the nodes of the trial wavefunction are held fixed. In "Diffusion QMC", the nodes are also relaxed.

Random-phase approximation (RPA) A time-dependent self-consistent field method where an electron with momentum $\vec{k}$ moves in an effective potential which contains the external potential and a $\vec{k}, \omega$ dependent screened potential. It reduces in the static $k \to 0$ limit to Thomas-Fermi screening, (or Debye–Hŭkel screening in classical systems). It is also called the "ring sum" or "bubble sum", and contains no exchange effects.

Subbands The electrons with the z-motion confined to a quantum well have discrete energy levels (index n). Each level carries with it a band of energies for the x, y motion. These are energy "subbands".

Singwi–Tosi–Land–Sjölander (STLS) A method due to Singwi et al. for determining the density-density correlation function of electrons (and other quantum systems) by truncating the equation of motion via an intuitive decoupling scheme involving the PDFs. STLS has been extended by Vashista, Ichimaru and others.

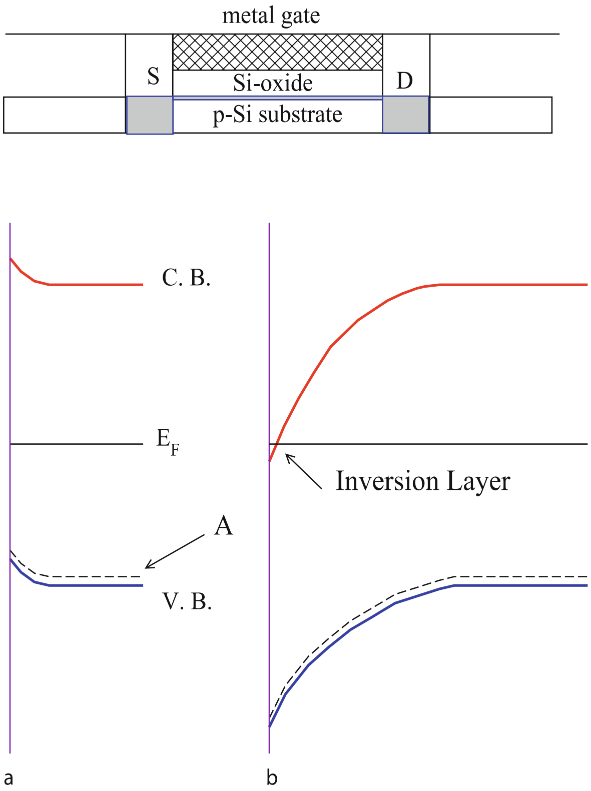
Wigner–Seitz radius In 2D this is the radius, denoted by r_s, of the circle containing, on the average, just one electron.

Definition of the Subject

Since the advent of density-functional theory (DFT), the exchange-correlation energy E_{xc} of an interacting system has become a basic quantity in many-particle theory. Here we study the E_{xc} of two-dimensional (2D) electron layers. Such layers contain electrons which move in the x and y directions, while confined in z. 2D layers are formed at insulator-semiconductor interfaces in heterojunctions, and more particularly at metal-oxide-semiconductor(MOS) interfaces. These include two types of semiconductors (e. g., GaAs and the alloyed form $Al_xGa_{1-x}As$, containing a small fraction x of Al, and written as AlGaAs for brevity). The interface region defines a "confining potential" where an electron layer may from [2]. SiO_2 is an insulator with a large bandgap, while Si can be doped in a controlled manner to behave as a conductor. The Si/SiO_2 interface supports the formation of an electron layer at the interface. The electron density n in such layers can be controlled using external potentials, and it is this which is the key to the importance of these materials systems. These structures are the basis of metal-oxide field-effect transistors (MOSFETS), ubiquitous in modern electronic devices (Fig. 1). The Si-MOSFET was developed in the 1960s, while it had been fore-shadowed as early as the 1930s in the work of Shockley and others.

Electron layers confined at the air-liquid interface of a fluid (e. g., Helium) were studied in the 1970s, but did not provide easy tunability of the density. High-mobility 2D systems in GaAs/GaAlAs heterostructures and in Si-MOSFETS ushered the more recent phase, unearthing new physics and new technologies, with the quantum Hall effect(QHE) [4], discovered in 1980, providing a classic example of fundamental physics directly leading to practical applications in metrology. Modern nanotechnology, spintronics, plasmonics etc., greatly dependent on the theory of electron layers.

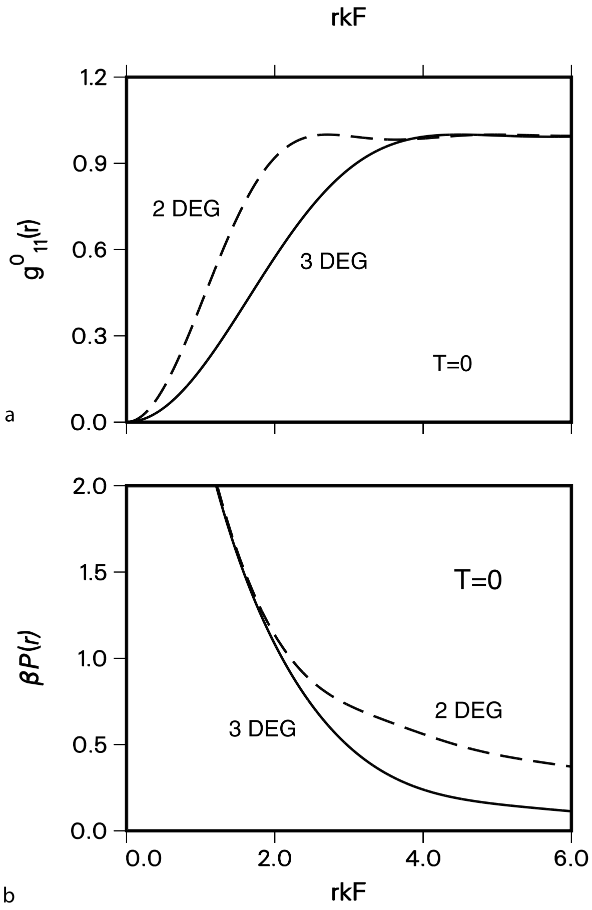
Graphite is made of 2D sheets of carbon atoms, i. e., "graphene" sheets, held together by weak inter-layer bonds The 2D electrons in graphene behave as massless Fermions with $\epsilon(\vec{k}) = \hbar v_F \vec{k}$, where v_F is the Fermi velocity. The hexagonal unit cell of graphene contains two inequivalent Carbon atoms. Thus there are two degenerate conduction bands and two valance bands, with a zero band gap located at two inequivalent points, labeled **K** and **K**′, in the hexagonal 2D-Brillouin zone of graphene. This system needs a spin index, a pseudospin index and also a band index. Graphene is a rich 2D system with novel physics (e.g, QHE) and the promise of new technological applications [9].



Spin Dependent Exchange and Correlation in Two-Dimensional Electron Layers, Figure 1

Top: A cross section of a *p*-type MOSFET. The *n*-type contacts labeled S (source) and D (drain) are made by ion-implantation into the *p*-type substrate. A voltage on the metal gate controls the current between S and D flowing in the Si/SiO_2 interface (channel region). Panel **a** shows the conduction band (c.b.), the acceptor levels (A), and the valance band (v.b.) modified by the application of negative bias to the metal gate. A sufficiently strong negative bias can produce an accumulation layer of holes. In **b** a sufficiently positive gate voltage is applied, bending the conduction band *below* the Fermi energy E_F, and creating a potential well which supports a 2D layer of electrons, known as an 'inversion layer'

The Coulomb interaction conspires to destroy the "single-particle" (i. e., "free" particle) picture of electron systems. Only the kinetic energy and the confining potential (called the "external potential") are needed in the simplest models. Mean-field (e.g, Hartree–Fock) models provide an "effective" single-particle picture. The "many-body effects", which transcend the simple picture, lead to new effects like plasmons, charge density waves, spin-polarized states, Wigner crystallization, fractional-QHE, and super-



Spin Dependent Exchange and Correlation in Two-Dimensional Electron Layers, Figure 2

***Upper panel* shows the pair-distribution function (PDF) for non-interacting parallel-spin electrons in 2D and 3D electron gases. The depletion near the origin is the "Fermi hole". The *lower panel* shows the equivalent *classical* potential (Pauli exclusion potential, in $\beta = 1/T$ units) which would create such a depletion in the PDF at the temperature T (at $T = 0$, only the product $\beta P(r)$ is meaningful). The x-axis is the electron-pair separation in reciprocal k_F units**

conductivity [18]. Many-body effects are more enhanced in low dimensional (e. g., 1D and 2D systems in comparison to 3D) systems. The Coulomb interactions force two electrons to repel each other and form a "Coulomb hole" or correlation hole, i. e., a region of low probability of approach. The energy consequence of this is the "correlation energy". Similarly, since the Pauli principle forbids the presence of two non-interacting electrons of the same spin in a common spatial eigenfunction, a "Fermi hole " is formed and leads to an exchange energy (see Fig. 2).

There is no Fermi hole for antiparallel spins, and their non-interacting PDF, i. e., $g^0_{12}(r)$ is unity for all r. When interactions are included, a Coulomb hole is formed. Hence the evaluation of E_{xc} is directly related to obtaining good PDFs.

Thus the theory of E_{xc} is of great importance in modern density-functional many-body approaches. From a technological point of view, the subject is of critical importance in the proper design of modern nano-structure devices and quantum-well lasers [16].

Introduction

We use "effective" atomic units, with the effective Bohr radius a_0^* as the unit of length. The dielectric constant ε is of the order of 10–12 for common semiconductors, while m^* may be 0.06 in GaAs and 0.19 in Si. Hence the effective Hartree is measured in meV, unlike the atomic Hartree which is 27.12 eV. Thus the properties of the material enter into the theory only via ε, m^*, and the effective Landé factor g^*, and these are usually absorbed into the effective atomic units. Since the electrons reside in the interface between two materials (say A, B),the dielectric constant ε relevant to the electron layer has to be evaluated from the individual dielectric constants of A and B. This is trivial in the case of GaAs/AlGaAs systems, since the dielectric constants are very close. This is no longer the case with Si/SiO$_2$ systems where the Si and the Si-oxide have nominal dielectric constants of 11.5 and 3.9 respectively. Then an average dielectric constant has to be used, as discussed in the appendix of [2], and in [8].

If the z-motion of an electron is restricted to a finite length a_z, as in an inversion layer, the allowed quantum states form *discrete subbands*, with energies $E(n, k_x, k_y)$:

$$E_n(k_x, k_y) = \epsilon_n + \epsilon(k_x, k_y)\,.$$

The energy of the in-plane motion, $\epsilon(k_x, k_y)$, depends on the in-plane momenta $\hbar k_x$ and $\hbar k_y$ with $\vec{k} = \vec{k}_x + \vec{k}_y$. For materials like GaAs/AlGaAs, or Si/SiO$_2$ interfaces, the in-plane energy dispersion is essentially parabolic, with

$$\epsilon(k_x, k_y) = \frac{(\hbar k_x)^2 + (\hbar k_y)^2}{2m^*}\,.$$

Here m^* is an effective mass, assumed to be the same in the x and y directions Only the lowest subband, say $n = 1$, is occupied in a 2D layer. Let ϵ_1 be the energy zero. The highest occupied state is given by the in-plane momentum $\hbar k_{\text{F}}$, known as the *Fermi momentum*. The Fermi energy (ϵ_{k_F}) has to be far below the bottom of the second subband to ensure a 2D layer. The electron density, i. e., the number of electrons n per unit area has n_1 "up-spin", and n_2 "down-spin" electrons. If $n_1 \neq n_2$ we have a *spin-polarized* electron system. The *degree of spin polarization*

ζ is:

$$\zeta = \frac{n_1 - n_2}{n_1 + n_2} \,.$$

Thus the state of a clean 2D-electron layer may be specified by n, ζ, and the temperature T. Additional pseudo-spin or valley indices are sometimes necessary.

The Fermi Energy and the Role of r_s as a Coupling Constant

When the electron-number density per a.u. of area is n, the Wigner–Seitz radius r_s is given by $r_s = 1/\sqrt{(\pi n)}$. We also have $n_1 = nx_1$, $x_1 = (1+\zeta)/2$, $n_2 = nx_2$, $x_2 = (1-\zeta)/2$. The Fermi momentum $k_{F\sigma}$ of a given spin species σ is evaluated by requiring that the sum of all occupied states of the species σ adds upto the density n_σ.

$$\int_0^{k_F} 2\pi \frac{k\mathrm{d}k}{(2\pi)^2} = n_\sigma \,.$$

This gives $k_\sigma = (4\pi n_\sigma)^{1/2}$. Since $n = n_1 + n_2$, the overall $k_F = (2\pi n)^{1/2}$, i. e., $k_F = \sqrt{2}/r_s$ and $E_F = k_F^2/2 = 1/r_s^2$.

Hence, the "coupling strength", i. e., ratio of the Coulomb energy $(1/r_s)$ to the kinetic energy $(\sim E_F)$ at $T = 0$ is clearly r_s. High density systems ($r_s < 1$) are weakly coupled, while low density systems (high r_s) are strongly correlated. When $r_s \sim 26-27$, the 2D electron system acquires a ferromagnetic ground state. At stronger coupling, $r_s \simeq 35$, a 2D Wigner crystal is formed. The strength of the 2D massless electron interactions in graphene cannot be specified by an r_s since a Bohr radius cannot be specified. Instead, the coupling constant g is taken as the ratio of a typical Coulomb energy $(1/a_0)$ to the hopping energy (t) on the Hexagonal 2D unit cell with a lattice constant of a_0.

$$g = \frac{e^2/a_0\varepsilon_0}{\hbar E_F} = \left\{e^2/a_0\varepsilon_0\right\}\left\{t\sqrt{3/2}\right\} \,.$$

If $\varepsilon_0 = 1$, then $g \simeq 2.7$. Thus, when the graphene sheet is placed on most substrates, $\varepsilon > 1$, and the electron interactions become weak, i. e., $g \leq 1$.

Fourier Transforms

The Fourier transform of 2D-functions relating their r-space forms with q-space forms is very useful. If the 2D electron system is uniform in all directions of the $x-y$ plane, i. e., isotropic, then we only need *radial* Fourier transforms. These are obtained using the relations:

$$F(\vec{r}) = \int_0^\infty F(\vec{q}) J_0(qr) q\mathrm{d}q/(2\pi)$$

$$F(\vec{q}) = \int_0^\infty F(\vec{r}) J_0(qr) 2\pi r\mathrm{d}r \,.$$

Here $J_0(qr)$ is a Bessel function [1] such that:

$$J_0(qr) = 2\int_0^\pi cos(qr\cos\theta)d\theta \,.$$

Then it is easy to show that the Coulomb interaction $1/r$ has the Fourier form $2\pi/q$. Here we assume ideally thin layers (unlike in Sect. "Graphene: 2D Two-Valley System on a Honey-Comb Lattice"). A screened Coulomb interaction $V_s(r)$, with an exponential damping is often encountered. This potential has an analytic Fourier transform and is:

$$V_s(r) = \exp(-k_s r)/r \qquad V_s(q) = 2\pi/\left\{\left(q^2 + k_s^2\right)^{1/2}\right\} \,.$$

The potential contains a "screening wavevector" k_s, and appears in what is known as "Thomas-Fermi" screening. This type of potential is also called a "Yukawa potential". The 'range' of the potential is of the order of $1/k_s$, and is known as the screening length.

The Hamiltonian of the System

The total Hamiltonian contains a contribution from a *uniform* neutralizing background of positive charge n_b which is static. In a real system, e. g., a metal, the neutralizing background is provided by the ion subsystem. Each ion has a short-ranged core-region and a Coulomb-like long-range potential which overlaps the long-range potential of the neighbours. In many metals (e. g., Sodium) the resulting overlapping positive potential is, to a very good approximation, similar to a smudged-out, structureless "jellium". In a plasma, the positive ions are dynamical but extremely heavy, and hence a jellium approximation, known as the one-component plasma (OCP) is often used. The jellium model is used in theories of electron layers as the physics then focuses entirely on electron-electron effects.

We write the electron density operator and the Coulomb interaction as:

$$n(\vec{r}) = \sum_i \delta(\vec{r} - \vec{r}_i) \,, \qquad V_{ee} = \frac{1}{2}\sum_{ij} \frac{n(\vec{r}_i)n(\vec{r}_j)}{|\vec{r}_i - \vec{r}_j|} \,.$$

The latter has a divergence when $i \to j$, with the electron interacting with "itself". We also have the terms V_{bb} and V_{be}, involving the background. For example,

$$V_{\mathrm{be}} = -\sum_{ij} n_{\mathrm{b}} \frac{n(\vec{r}_j)}{|\vec{r}_i - \vec{r}_j|}$$

where $n_{\mathrm{b}} = n$ is the uniform-background density. The background term V_{bb} has a divergent self-interaction term similar to that in V_{ee}, with (positive) sign. However, the interaction of the electron charge with the background, i. e., V_{be}, has a negative divergent term, and cancels both divergent (positive) self-interaction terms. Thus the total Hamiltonian, inclusive of the background is free of divergences. In Fourier space, the coulomb interaction is $2\pi/q$, and hence the divergence manifests in the limit $q \to 0$. This is exactly canceled by the corresponding $q \to 0$ terms in the background. Also, since the background is uniform, there are no other Fourier components. The above discussion involves the "subtraction" of divergent quantities, and can be made more rigorous using the screened Coulomb potential $V_{\mathrm{s}}(r)$, and taking the limit $k_{\mathrm{s}} \to 0$ at the end.

The electron number-density operator $n(r)$ in real space has a Fourier transform $n(q)$, defining the occupation number in the momentum state q. The expectation value of $n(r)$ is of course the constant n, which may be written as $\overline{n}$ where needed.

The momentum eigenstates of the uniform noninteracting system are the complete set of plane waves.

$$\phi_q = \phi(\vec{q}) = \mathrm{e}^{\vec{q}\cdot\vec{r}}/\Omega^{1/2}$$

Here we use a normalization volume Ω, which is sometimes set to unity, or the infinite-volume limit is taken, when the normalization becomes $1/(2\pi)^{1/2}$. The occupation number in each momentum state, for non-interacting Fermions at a temperature T, and chemical potential μ is given by:

$$n_k = \frac{1}{1 + \mathrm{e}^{\beta(\epsilon_k - \mu)}} \, .$$

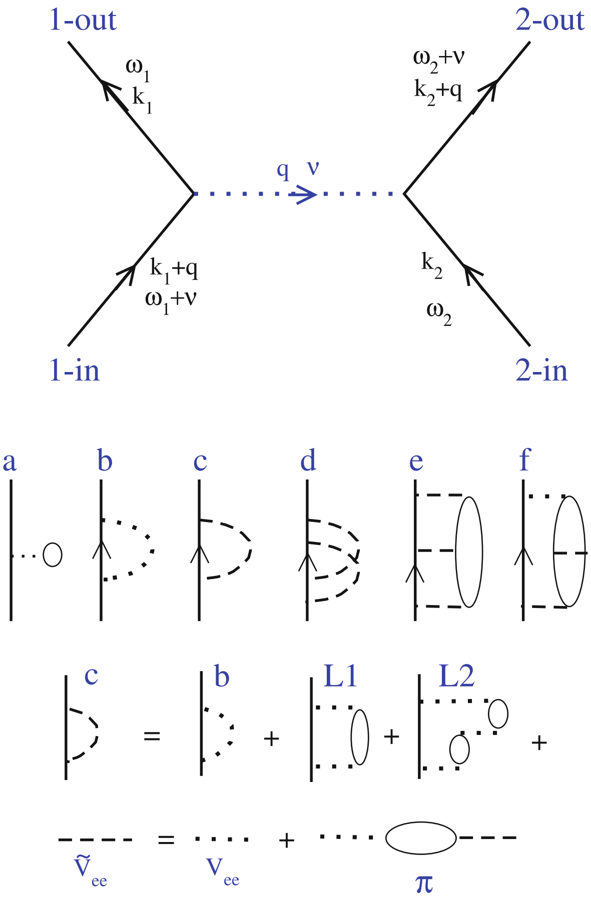
Here $\beta = 1/T$ where T is expressed in energy units. At $T = 0$, the chemical potential μ becomes the Fermi energy E_{F}, and the occupation numbers reduce to unity for energies $\epsilon_k < E_F$, and zero for higher energies. The occupation number n_k given above is really the expectation value of the operator n_k. When we need to emphasize this distinction, we write the operator as $\hat{n}_k$, and the meanvalue as $\overline{n}_k$. In a uniform system, most properties are dependent only on the modulus $|k|$ of the momentum $\vec{k}$, and we sometimes suppress the vector notation for brevity. We also introduce creation and annihilation operators a_k^+ and a_k which add an electron to a momentum state $\vec{k}$, or remove an electron from the momentum state $\vec{k}$. Thus the number operator acting on the eigenstate $|\phi_k\rangle$ is given as:

$$\hat{n}_k|\phi_k >= a_k^+ a_k|\phi_k\rangle = \overline{n}_k|\phi_k\rangle \, .$$

The total Hamiltonian of the system is:

$$H = (H^0 - \mu N) + V'_{\mathrm{ee}} \, .$$

Here we are using a thermal ensemble which allows for the definition of a chemical potential μ and a temperature T. Also, $N = \sum_{\vec{k}} \hat{n}_k$ is an operator fixing the mean



Spin Dependent Exchange and Correlation in Two-Dimensional Electron Layers, Figure 3
***Top Panel*: Feynman diagram for the bare Coulomb interaction $V_{\mathrm{ee}}(q)$ of two electrons. *Bottom panel*: a shows the exchange interaction which is first order in the bare interaction $V_{\mathrm{ee}}(q)$. b is the bare exchange, and c has the RPA "bubble sum", where $\tilde{V}_{\mathrm{ee}}(q,\nu)$ is given by an integral equation (a geometric series in this case) involving the polarization "bubble" $\pi(q,\nu)$. Contributions from diagrams like c–d are not included in the RPA propagators**

number of particles $\langle N\rangle$ in the volume Ω, given μ and T. The Coulomb interaction V'_{ee} carries a prime to indicate that a jellium background has been included to remove the divergencies at zero momentum transfer. Then we have, in momentum space:

$$H = \sum_{\vec{k}} (\epsilon_k - \mu) a_k^+ a_k + \frac{1}{2\Omega} \sum_{\vec{k}_1 \vec{k}_2 \vec{q}}{}' V_q a_{k_1}^+ a_{k_2+q}^+ a_{k_2} a_{k_1+q} .$$

The prime on the summation indicates that the case $q = 0$ is excluded, as it is exactly cancelled by the jellium background. The suffixes on the cluster of four operators are such that the total momentum of the two electrons is conserved during the interaction. That is, an electron in the initial state $\vec{k}_1 + \vec{q}$ is in the final state $\vec{k}_1$, while the second electron, in the initial state $\vec{k}_2$ is transfered to the state $\vec{k}_2 + \vec{q}$. The momentum transfer $\vec{q}$ is effected through the Coulomb interaction $V_q = 2\pi/q$. The momentum is conserved in the Coulomb collision since we are dealing with a *uniform system* (see top panel in Fig. 3).

Ideally Thin 2D Electron Layers

This system is most closely approximated in Si/SiO$_2$ systems, or in specially fabricated GaAs/GaAlAs quantum wells (HIGFETs tend to yield thick 2D electron layers and are discussed in Sect. "2D Layers with Finite Thickness"). Microscopic many-body theories have used this system as the basic "work horse". Early work used diagrammatic and other perturbation methods, or truncated equation of motion methods, like STLS, developed by Singwi and coworkers. The objective of the latter is to develop PDFs non-perturbatively, and calculate the exchange and correlation energies from an integration over the coupling constant (described below). However, the perturbation methods (restricted to the high-density regime in validity) provide basic reference results.

A Brief Outline of the Diagrammatic Method

Much of the initial work was based on a perturbation expansion of the energy or the electron propagator in powers of the Coulomb interaction $V_{\mathrm{ee}}(q)$, as in Fig. 3. In the graphs labeled a–f we look at the self-energy (i.e, the effective potential) of an electron propagating through the interacting fluid. In (a) an electron propagates forward, while the interaction with the second electron occurs with zero-momentum transfer ($q = 0$), i.e, one may imagine that the "2-out" line "falls into" the "2-in" line to from a bubble, when $\vec{k}_2 + \vec{q} = \vec{k}_2$ by momentum conservation. Such $q = 0$ terms are Hartree terms, and have already been eliminated via the static background. The graph (b) is the first-order exchange diagram (the "Fock" term). This may be pictured as the "1-out" line "falling" into the "2-in" line, exchanging electron identities. This is possible only if both electrons have the same spin. The graph (c) is the *screened exchange* diagram where the Coulomb interaction is *dynamically screened* by summing the simple polarization loops L1, L2 etc. This is known as the RPA-screened exchange, where RPA (random-phase approximation) is a name originating from methods of derivation using self-consistent equations. However, each term in such an expansion is infinite; e. g., the second-order perturbation term L1, and those beyond it (L2 etc.) are all divergent, as they involve integrals of the form $\int (2\pi/q)^n q \mathrm{d}q \ldots$, where $n \geq 2$ (there are standard "Feynman rules" for converting the graphs shown in Fig. 3 into algebraic expressions [18]; they are not needed for our purpose). The divergence arises from perturbation terms containing simple polarization loops (denoted by $\pi(q, \omega)$ in Fig. 3) connected by two or more direct interaction lines. However, although each term is infinite, the *sum* L1 + L2 + ... is finite. The bare interaction $V_{\mathrm{ee}}(q, \omega)$ gets "screened" by the polarization processes denoted by the bubble (particle- hole pairs), and gives the well-behaved (non-divergent) $\tilde{V}_{\mathrm{ee}}(q)$ which is used in the graph (c). The contributions from scattering processes shown in Fig. 3d–f, etc., are *not* included in the RPA sum.

Thus the contribution to the effective potential seen by an electron at the Fermi level can be written as

$$V_{\mathrm{eff}} = V_{\mathrm{xc}} = V_{\mathrm{x}} + V_{\mathrm{c}}$$

where V_{x} is the exchange potential, arising from the first-order diagram Fig. 3b, while V_{c} is the contribution from *all other* higher processes. Thus V_{c} in the RPA is simply the sum of contributions from L1, L2 etc. A better approximation would be a V_{c} which involves Fig. 3e–f, and all other terms. But the numerous higher terms are virtually impossible to evaluate, and their partial inclusion is problematic as various sum rules, Ward identities etc., have to be satisfied [18]. In analogy with the effective potential, we can also divide the total energy of the system (beyond the kinetic energy) as:

$$E_{\mathrm{xc}} = E_{\mathrm{x}} + E_{\mathrm{c}}; \quad \epsilon_{\mathrm{x}} = E_{\mathrm{x}}/N; \quad \epsilon_{\mathrm{c}} = E_{\mathrm{c}}/N$$

where E_{x} is the exchange energy, and E_{c} is the correlation energy. The latter by definition contains all contributions other than exchange. A large part of the spin dependence of E_{xc} is contained in E_{x}. The RPA is an evaluation of E_{c} via the series L1, L2 etc.

The Adiabatic Connection Formula

Another approach to E_{xc} is to begin with the non-interacting system and "build-up" the interacting system by increasing the value of the "coupling constant" λ from $0 \to 1$ in the scaled Coulomb potential

$$V_{\mathrm{ee}}(\lambda, r) = \lambda / r\,.$$

The usual coupling parameter r_{s} is here assumed to be merely a density parameter ($r_{\mathrm{s}} = 1/\sqrt{\pi n}$) held constant during this "charging process". As λ increases to unity, the PDFs $g_{ij}(\lambda, r)$, where i, j indicate spin species, change from the non-interacting $g^0_{ij}(r)$, Fig. 2, to the interacting from $g_{ij}(r)$. This is accompanied by the "build up" of the energies arising from the interactions. Thus the exchange-correlation energy E_{xc} appears as an integration over the coupling constant (if we are dealing with a system at a finite temperature T, then we have Helmholtz free energies F_{xc} instead of E_{xc}). Thus, if x_1, x_2 are the fractional compositions n_i/n, then the exchange-correlation energy per particle E_{xc}/N is

$$E_{\mathrm{xc}}/N = \int_0^1 \frac{\mathrm{d}\lambda}{\lambda}\frac{n}{2} \int 2\pi r \mathrm{d}r \frac{\lambda}{r} \sum_{ij} x_i x_j (g_{ij}(\lambda, r) - 1)\,. \quad (1)$$

This is known as the adiabatic connection formula [11], and is due to Pauli. Thus if the fully interacting PDF is known, the exchange-correlation energy can be obtained without the limitations of perturbation theory. The full PDF can be evaluated by (i) Quantum Monte Carlo methods (QMC), (ii) integral-equation methods developed from correlated wavefunctions using Feenberg-type analyses, (iii) classical-map hyper-netted chain (CHNC) methods, (iv) methods for specific applications as in Giorgi et al. [10] (v) SLTS methods for moderately coupled fluids.

The Exchange Energy

Note that the exchange energy alone is given by

$$E_{\mathrm{x}}/N = \frac{n}{2} \int 2\pi r \mathrm{d}r v(r) \sum_{ij} x_i x_j \left(g^0_{ij}(r) - 1\right)\,. \quad (2)$$

That is, the Fermi hole of the non-interacting PDF determines the exchange energy. This was *defined* as a contribution taken to *first order*, Fig. 3b. Since one factor of $v(r)$ is already included in Eq. (2), we can only use $g^0_{ij}(r)$ as a better form would have go beyond first order in V_{ee}. The noninteracting PDF $g^0_{ij}(r)$ can be evaluated [18] directly from the noninteracting one-body wavefunctions (plane waves):

$$\begin{aligned} h_{ij} &= g_{ij} - 1 \\ h^0_{ij}(r) &= -\delta_{ij} F_i(r) F_j(r) \\ F_i(r) &= \frac{1}{n_i} \int \frac{\mathrm{d}\vec{k}}{(2\pi)^2} f_i(k) \mathrm{e}^{i\vec{k}\cdot\vec{r}}\,. \end{aligned}$$

Here $f_i(k)$ is the Fermi occupation number for the momentum state k. At $T = 0$, $F_i(r) = 2J_1(k_i r)/(k_i r)$; $k_i = \sqrt{4\pi n_i}$ where $J_1(x)$ is a Bessel function [1], and k_i is the Fermi momentum of the spin species i. At finite temperatures, the integrations have to be done numerically.

Formulae for the Kinetic and Exchange Energies.

At zero temperature, the Hartree–Fock energy can be written in terms of the spin polarization ζ and the density parameter r_{s}. The Hartree energy E_{H} is zero.

$$E_{\mathrm{HF}} = E_0 + E_{\mathrm{H}} + E_X\,; \quad E_{\mathrm{H}} = 0 E_0/N = \frac{1+\zeta}{2r_{\mathrm{s}}^2}\,;$$

$$E_{\mathrm{x}}/N = -\frac{2\sqrt{2}}{3\pi r_{\mathrm{s}}}\left[(1+\zeta)^{3/2} + (1-\zeta)^{3/2}\right]$$

The spin-dependent energies, e. g. $E_{\mathrm{x}}(\zeta)$, may be written as:

$$\begin{aligned} E_{\mathrm{x}}(\zeta) &= E_{\mathrm{x}}(0) + (E_{\mathrm{x}}(1) - E_{\mathrm{x}}(0))P(\zeta) \\ P(\zeta) &= \frac{\zeta_+^\alpha + \zeta_-^\alpha - 2}{2^\alpha - 2}\,. \end{aligned}$$

Here $\zeta_\pm = (1 \pm \zeta)$, and $P(\zeta)$ is called the "polarization function"; $\alpha = 3/2$ in Hartree–Fock theory.

The Correlation Energy

The calculation of the correlation energy E_{c} is the heart of the many-body problem, and is the main challenge. If E_{c} were known, the total ground state energy is $E_{\mathrm{T}} = E_{\mathrm{HF}} + E_{\mathrm{c}}$. A widely used QMC evaluation was given in 1989 by Tanatar and Ceperley [23] using a variational Monte Carlo method (VMC) as well as a Greens Function Monte Carlo method. They gave parametrized forms for the unpolarized ($\zeta = 0$) and fully polarized ($\zeta = 1$) energies per electron, i. e., $\epsilon_{\mathrm{c}}(r_{\mathrm{s}})$, in the form

$$\epsilon_{\mathrm{c}}(r_{\mathrm{s}}) = a_0 \frac{1 + a_1 x}{1 + a_1 x + a_2 x^2 + a_3 x^3}$$

where $x = \sqrt{r_{\mathrm{s}}}$. The parameters have the values, $a_0 \ldots a_3 = -0.1784,\ 1.1300,\ 0.9052,\ 0.4165$ for $\zeta = 0$ and $-0.02575,\ 340.5813,\ 75.2293,\ 37.0170$ for $\zeta = 1$. No simulations were done for intermediate ζ, and hence it was often *assumed* that the exchange-like polarization function $P(\zeta)$ could be used for the correlation energy as well.

$$\epsilon_{\mathrm{c}}(\zeta) = \epsilon_{\mathrm{c}}(0) + (\epsilon_{\mathrm{c}}(1) - \epsilon_{\mathrm{c}}(0))P(\zeta)$$

A more detailed study, given by Attaccalite et al. in 2002 is currently the best available QMC form of E_{c}. These authors [3] did simulations for finite-ζ as well and proposed a parameterized form.

$$\begin{aligned}
\epsilon_{\mathrm{c}}(r_{\mathrm{s}},\zeta) &= (\mathrm{e}^{-\beta r_{\mathrm{s}}} - 1)\epsilon_x^6(r_{\mathrm{s}},\zeta)\\
&= +\epsilon_{\mathrm{c}}(r_{\mathrm{s}},0) + \alpha_1(r_{\mathrm{s}})\zeta^2 + \alpha_2\zeta^4\\
\alpha_1(r_{\mathrm{s}}) &= (1/2\left[\partial^2\epsilon_{\mathrm{c}}(r_{\mathrm{s}},\zeta)/\partial^2\zeta^2\right]_{\zeta=0}\\
\alpha_2(r_{\mathrm{s}}) &= (1/24)[\partial^4\zeta^4]_{\zeta=0}\\
\epsilon_x^6(r_{\mathrm{s}},\zeta) &= \epsilon_x(r_{\mathrm{s}},\zeta) - \{1 + (3\zeta^2)(1 + \zeta^2/16)\}
\end{aligned}$$

Here parameters α_1, α_2 are spin-stiffness constants. A short computer program for the calculation of ϵ_{c} is available [24].

CHNC Approaches

QMC procedures are computationally very demanding, and hence the development of other, simpler methods is of great interest. The accuracy of such methods can be ascertained by comparison with QMC results, and then such methods can be used in areas where QMC is prohibitive (e. g., at finite temperatures, many valley systems). In this respect, the classical-map HNC approach (CHNC) is worthy of note. In CHNC [21], the quantum fluid at $T = 0$ is replaced by a classical Coulomb fluid at a finite temperature T_{q}. The latter is chosen requiring that (i) the non-interacting classical fluid has the same $g^0_{ii}(r)$ as the quantum fluid. (ii) the correlation energy of the interacting classical fluid has the same correlation energy as the quantum fluid. The first requirement is easily met, and involves the construction of a classical potential which would give the same Fermi hole as the quantum fluid (see Fig. 2). The classical potential, $\beta V_{\mathrm{pau}}(r)$ is called the "Pauli potential" and is a universal function of rk_{F}. This potential is zero for anti-parallel spins. This procedure fixes a 'Pauli potential' but not the temperature T_{q}, since only the product $\beta \times V_{\mathrm{pau}}(r)$ is obtained. The second condition is used to determines T_{q} by evaluating $\epsilon_{\mathrm{c}}(r_{\mathrm{s}})$ using the adiabatic connection formula, for a trial value of T_{q}., and a chosen ζ, say $\zeta = 1$. Then T_{q} is adjusted till the QMC value of $\epsilon_{\mathrm{c}}(r_{\mathrm{s}}, \zeta = 1)$ is obtained. Thus a table of T_{q} for each r_{s}, i. e., $T_{\mathrm{q}}(r_{\mathrm{s}})$, is obtained. The classical PDFs needed here are easily calculated using a well established hyper-netted-chain technique. Only the ϵ_{c} value at $\zeta = 1$ is used as the input to the fit. The output is the full tabulation of the interacting $g_{ij}(r)$. It is found to be in *remarkably good agreement with the QMC generated* $g_{ij}(r)$. This is perhaps a consequence of DFT where it is asserted that the true density distribution is obtained if the true ground state energy (i.e, $E_0 + E_X + E_{\mathrm{c}}$) is captured. It is also found that this CHNC procedure yields accurate $\epsilon_{\mathrm{c}}(r_{\mathrm{s}})$ values at spin-polarizations different to the input value. The $T_q(r_{\mathrm{s}})$ function is found to be transferable to many Coulomb-fluid problems including hydrogen plasmas [6].

Fermi-Liquid Parameters

A knowledge of the correlation energy as a function of the r_{s}, ζ, and T enables an easy evaluation of Landau Fermi liquid parameters (LFLP). These are usually evaluated from complicated perturbation theory calculations whose domain of validity is, strictly speaking, restricted to small r_{s}. Three quantities are of great interest for the LFLP. These are, the inverse compressibility κ which is the density derivative of the chemical potential μ, the enhanced spin-susceptibility χ compared to the Pauli susceptibility χ_{P}, (incorporated in g^*, the effective Landé g factor), and the effective mass m^*. The latter involves the interacting and ideal specific heats C_v, C_v^0. AT finite T, the correlation energy is replaced by the correlation Free energy, $F_{\mathrm{c}}(r_{\mathrm{s}}, \zeta, T)$. This is the correction to the Helmholtz free energy beyond the Hartree–Fock approximation. If $F_{\mathrm{c}}(r_{\mathrm{s}}, \zeta, T)$ is known, a non-perturbative result becomes available for κ, m^* and g^* (for detailed, see [8]). Thus:

$$\begin{aligned}
m^* &= C_{\mathrm{v}}/C^0_{\mathrm{v}} = 1 + \frac{\left[\partial^2 F_{\mathrm{xc}}(t)/\partial t^2\right]}{\left[\partial^2 F_0(t)/\partial t^2\right]}\\
\chi_P/\chi_{\mathrm{s}} &= (m^* g^*)^{-1} = 1 + \frac{\left[\partial^2 F_{\mathrm{xc}}(\zeta)/\partial\zeta^2\right]}{\left[\partial^2 F_0(\zeta)/\partial\zeta^2\right]}\\
1/\kappa &= n^2\partial\mu/\partial n = n^2\partial^2[F_0 + F_{\mathrm{x}} + F_{\mathrm{c}}]/\partial n^2\,.
\end{aligned}$$

Calculations of the ground-state energy as a function of r_{s}, ζ, as well as the spin-susceptibility enhancement using the QMC and the CHNC methods show that the 2D fluid (which is paramagnetic $\zeta = 0$ at high densities), becomes a ferromagnetic liquid (see [3,7]) for $r_{\mathrm{s}} \simeq 26$. Thus the gain in kinetic energy due to spin-polarization is compensated by the exchange-correlation energy at sufficiently low densities. If simple perturbation methods are used for evaluating $E_{\mathrm{xc}}(r_{\mathrm{s}})$, incorrect predictions (e. g., a magnetic transition at $r_{\mathrm{s}} \sim 2$ in RPA) are obtained. The spin-susceptibility enhancement "blows up" towards infinity, as the transition is approached. These theoretical predictions have been confirmed experimentally (see [22]).

2D Layers with Finite Thickness

The assumption that the 2D layer is infinitely thin (i. e., “ideal”) is often incorrect in practice. The lowest subband of a quantum well supporting a 2D layer may have an z-extension w of 10–20 nm, with a density distribution $n(z)$. If the next subband is inaccessible to the electrons, then they are 2D systems with a finite thickness. The HIGFETS used in many experiments contain a nearly triangular potential well (see Fig. 1) and the lowest subband wavefunction is approximated by the Fang-Howard(FH) function [2] $\phi_{\mathrm{fh}}(z)$. The difficulty of modeling exchange and correlation in such systems using either the ideal-2D parametrized E_{xc} forms, or the 3D forms (to allow for the z-extension) was noted by Martin et al. [14]. In fact, new exchange-correlational functionals have to be constructed for the effective-2D potential found in thick-2D layers [5]. We denote the Coulomb potential in an infinitely thin layer by $V(r) = 1/r$, while $W(r)$ is used for the effective 2-D potential of a thick layer. The potential $W(r)$ between two electrons having coordinates $(\vec{r}_1, z_1)$ and $(\vec{r}_2, z_2)$, with $\vec{r} = \vec{r}_1 - \vec{r}_2$ is given by,

$$W(r) = \int_0^{z_m}\int_0^{z_m} \frac{\mathrm{d}z_1 \mathrm{d}z_2 n(z_1) n(z_2)}{\left[r^2 + (z_1 - z_2)^2\right]^{1/2}} . \tag{3}$$

Here z_{m} is ∞ for FH, while $z_{\mathrm{m}} = w$ for a quantum well. The potential $W(r) = (1/r)F(r)$ and the form factor $F(r)$ reflects the effect of the z-extension of the density. It has been shown that any arbitrary density distribution $n(z)$ can be replaced by a electrostatically equivalent rectangular slab of width w by choosing w such that: in the 2D plane as $n(z)$.

$$n_{\mathrm{cd}} = 1/w = \int n(z)^2 \mathrm{d}z . \tag{4}$$

The quasi-2D potential for a constant-density slab of width w is given by

$$W(r) = V(r)F(s), \quad s = r/w, \quad t = \sqrt{\left(1 + s^2\right)} \tag{5}$$

$$F(s) = 2s\left[\log\frac{1-t}{s} + 1 - t\right] . \tag{6}$$

This potential tends to $1/r$ for large r, and behaves as

$$\frac{2}{w}\left(\ln\frac{2w}{r} + \frac{r}{w} - 1\right)$$

for $r < w$. Thus the short-range behaviour is logarithmic and weaker than the Coulomb potential. The k-space form of the CDM potential is:

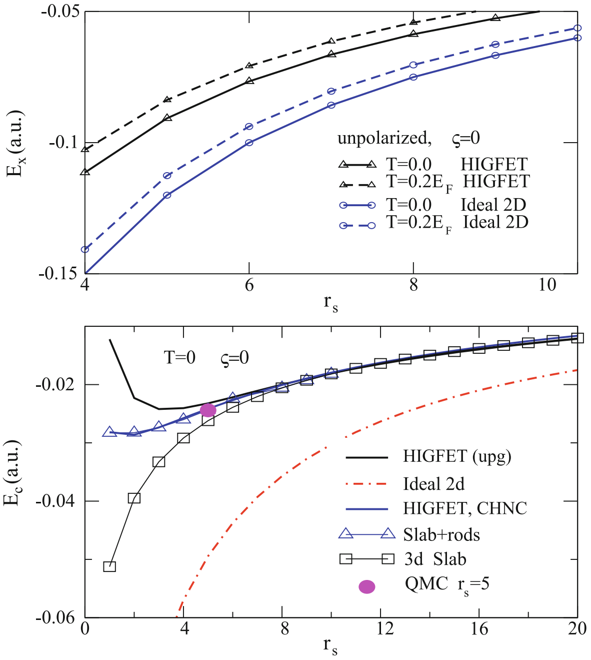
$$W(k, w) = V(k)F(p), \quad p = kw \tag{7}$$

$$F(p) = (2/p)\{(\mathrm{e}^{-p} - 1)/p + 1\} . \tag{8}$$

The form factors $F(s)$ and $F(p)$ tend to unity as $w \to 0$. The effective w in HIGFETS depends on r_{s}, i. e., in atomic units.

$$w = 16/(3b)b^3 = 33/\left(2r_{\mathrm{s}}^2\right) .$$

Using these potentials, layer-thickness dependent exchange-correlations functionals $E_{\mathrm{x}}c(r_{\mathrm{s}}, \zeta, w)$ can be evaluated using perturbation methods, or using the CHNC. The resulting xc-functionals have been given in [5], and displayed in Fig. 4. It is found that the exchange energy is reduced due to layer thickness which enters as w/r_{s}, thus



Spin Dependent Exchange and Correlation in Two-Dimensional Electron Layers, Figure 4

a The exchange energy E_{x} (Hartree a.u.) of a 2DES in a HIGFET compared to that of an ideal 2DES, at $T/E_{\mathrm{F}=0}$ and 0.2, with $\zeta = 0$. *Solid line with circles*, ideal 2D, $T = 0$, *Solid line with triangles*, HIGFET at $T = 0$. Corresponding *broken lines* are for $T = 0.2E_F$. b The correlation energy E_{c} at $T = 0$ and $\zeta = 0$, for the HIGFET layer. HIGFET(upg), *black solid line*, is the “unperturbed-g” approximation. The *deep grey dashed line*, HIGFET(CHNC), is the full calculation. This is compared with the correlation energy of a 3D slab model (*line with squares*), and the “slab+rod”model (*triangles*). For details, see [5]. The QMC datum (*blacked hatched circle*) for a HIGFET, $r_{\mathrm{s}} = 5$, is from [22]

affecting high densities and thick layers. A most interesting observation is that the transition to a ferromagnetic state which occurs at $r_s \simeq 26-27$ in ideal 2D, is pushed to higher r_s as the thickness w is increased.

Multi-Component 2D Layers

The two most important multi-component systems are 2D layers found in Si/SiO$_2$ interfaces, and in graphene monolayers.

Two-Valley System in Silicon-Silica Interfaces

Bulk Si has six equivalent valleys. However, when SiO$_2$ layers are grown on the (001) surface, with z the growth direction, the 2D layer occupies two degenerate layers in the (001) plane. This is a 4-component fluid, with two spin states and two valley states. Thus using an index $\nu = 1, 2, 3, 4$ where the first two are for spin, and the last two are for the valleys, there are 10 PDFS in the upper triangle of the matrix $g_{\nu\eta}(r)$. Only five of these are independent even for $\zeta \neq 0$. Four of these 10 are diagonal and contribute to both exchange and correlation, where as the off diagonals contribute *only* to the correlation energy E_c. This contrasts with the usual single valley system where there are two diagonals, and one off-diagonal PDF in the matrix of PDFs. Thus correlation effects dominate over exchange effects in multi-valley systems, and they show less tendency to spin-polarization effects which are driven by exchange effects. Thus there is no spontaneous spin-polarized state in the 2D-two valley system. However, the large increase in the correlation energy has been argued to be responsible for a rapid increase in the effective mass of electrons in Si MOSFETS as the density n decreases towards $\simeq 8 \times 10^{10}$ electrons/cm^2 [8,15]. However, this is found to be sensitive to slight changes in the CHNC parametrization.

Quantum Monte Carlo results of $E_{xc}(r_s)$ at $\zeta = 0, 1$ and CHNC results (at many values of ζ) are available, and are in excellent agreement with each other. If the total electron number density per unit area in the 2D layer is n in atomic units, then the overall $r_s = 1/\sqrt{\pi n}$, while the valley density, $n/2$ yields an $r_{sv} = \sqrt{2} r_s$. This r_{sv} and the corresponding k_{Fv} are used in constructing the non-interacting PDFs $g^0_{\nu\eta}$ from which the exchange energy can be calculate. Clearly, this is $2\epsilon_x(r_{sv})$, where ϵ_x is the usual one-valley formula for E_x/N .

The correlation energy cannot be completely mapped into results based on the 1-valley system. Thus E_c is determined via a coupling constant integration over the 10 PDFs, obtained from QMC or CHNC, using the adiabatic connection formula. Detailed results and numerical fits are available in [8].

Graphene: 2D Two-Valley System on a Honey-Comb Lattice

The electrons in the two-valley 2D system of Si/SiO$_2$ interfaces carry a valley index, but the single-particle wavefunctions are simple plane waves. In graphene, the two-component wavefunctions of massless fermions have a “chiral” character, since they carry phase angles ϕ_k, where $\vec{k}$ is the momentum vector in the 2D plane. The valence and conduction bands touch at the $\mathbf{K}, \mathbf{K}'$ points, and we need a band index $b = 1, -1$, to indicate the conduction and valence bands. Thus, we may have simultaneous electron and hole occupations, leading to an eight-component problem. Although the ϵ_x can be calculated explicitly, the calculation of the ϵ_c becomes very demanding. However, as the coupling constant g is independent of of the electron density, being $\simeq 2.7/\varepsilon$, the interactions are weak. Also, for pure electron doping or pure hole doping, the ϵ_c of the 4-component system in Si/SiO$_2$ at the same coupling strength as g (i.e, $r_s = g$) may be used as an estimate. Hence we focus on E_x and introduce a unit of energy $E_u = v_F k_c$ Here v_F is the Fermi velocity of the massless fermions, and k_c is a cutoff wavenumber chosen so that the number of states in the Brillouin zone is conserved, that is, if A_0 is the area per carbon atom, $k_c^2 = 4\pi(1/A_0)$. Then the exchange energy per Carbon atom can be written as:

$$E_x/E_u = -\frac{A_0 g^0/k_c}{(2\pi)^2}\frac{1}{4}\sum_{b_1,b_2,\sigma}\int_0^{2\pi} d\theta\, dk\, dp \times kp\frac{1+b_1 b_2\cos(\theta)}{|\mathbf{k}-\mathbf{p}|} n_{b_1,\sigma}(k) n_{b_2,\sigma}(p)\,. \quad (9)$$

In the above $g^0 = 2.7/\varepsilon$. A special feature, not found in the usual (non-chiral) 2D system is the occurrence of a term which depends on θ, the scattering angle. Because of this modulation of the interaction potential, the exchange energy in graphene is weaker than in a normal 2D layer with the same coupling strength. The above expressions for the exchange energy may be expressed [19] in terms of integrals over PDFs involving Bessel and Struve functions, or as elliptic elliptic integrals which depend on ζ and the fractional doping. Calculations of the total energy, (i.e, kinetic+E_{xc}) for graphene layers doped with electrons, holes or both, *do not* support a transition to a spin-polarized ground state. This is not surprising since the strength of the coulomb interaction is $\sim 2.7/\varepsilon$, i. e., weak, given that the spin transition in usual 2D systems occur for $r_s \sim 26$.

Exchange and Correlation in a Magnetic Field

Electrons respond to an external magnetic field by forming Landau Levels. If B is the magnetic field in the z-direction, then the energy spectrum is that of a harmonic oscillator, where the cyclotron frequency ω_c and the magnetic length ℓ are given by:

$$\omega_c = |e|B/(m_{bc}) \,, \quad \ell = \{\hbar c/(|e|B)\}^{1/2} \,. \tag{10}$$

Here m_b is the band mass and c is the velocity of light. The Harmonic oscillator energy levels with index η are:

$$\epsilon_\eta = (\eta + 1/2)\hbar\omega_c + \epsilon_{sb} \tag{11}$$

contains the lowest subband energy ϵ_{sb} of z-motion, and this may be taken as the zero of energy. The momentum states of the 2D system collapse into degenerate states, with each Landau level having $N_L = eBA/hc$ states, where A is the area of the system. If there are N electrons in A, the *filling factor* $\nu = N/N_L = n/(2\pi\ell^2)$. The integer part η of ν gives the number of *filled* Landau levels, while $\nu - \eta$ is the part of the highest landau level which is partially field. The filled Landau levels are like "inert shells" of atoms, while the partially filed part is polarizable and accounts for the more interesting aspects of exchange and correlation among electrons in magnetic fields. The total filling factor $\nu = \nu_1 + \nu_2$ where ν_i is for the ith spin species.

Since we are interested in ϵ_{xc}, we need the PDFs for use in Eq. (1). Thus it is convenient to work in the symmetric gauge where the eigenstates are functions of the radial distance r and the angle ϕ in the 2D plane, having radial and angular momentum quantum numbers n_r and m. Then, with $\hbar = 1$,

$$\epsilon_{n_r,m} = \{n_r + (|m| - m)/2 + 1/2\}\omega_c \,. \tag{12}$$

When the field is weak, there are a large number of Landau levels, and the usual 2D formulae for exchange and correlation can be used. This can be improved by using the summations over the density of states instead of integrations over k_x, k_y. A discussion may be found in, e. g., [4]. The high magnetic field limit, where only a few occupied Landau levels is of great importance. The integer and fractional QHE are found in this 'high-field' regime. If the number of full Landau levels of spin σ is ν_σ, the non-interacting PDF $g^0(r)$ is:

$$g^0(r) = 1 - \frac{e^{-x/2}}{\nu^2} \sum_\sigma \left[L^1_{\nu_\sigma - 1}(x^2/2)\right]^2 \tag{13}$$

where $x = r/\ell$, and $L_n{}^1$ is an associated Laguerre polynomial. The spin summation is unimportant in high fields, when the LLL is fully polarized by the field. ϵ_x can be evaluated from Eq. (2). The 2D Coulomb interaction may contain finite-layer thickness corrections. The effect of the magnetic field is totally contained in $e_{mag} = e^2/(\varepsilon\ell)$ and forms a natural energy unit for this system. The exchange energy ϵ_ν (in e_{mag} units), is $-\sqrt{\pi/8}$ at $\nu = 1$, and increases almost linearly to $2.35\epsilon_1$ at $\nu = 6$.

The correlation energy $\epsilon_c(r_s, \nu)$ of filled Landau levels can be evaluated using the adiabatic connection formula and the interacting PDFs. However, only an RPA evaluation is available, and $\epsilon_c(r_s, \nu)$ is very close to the zero. Hence the $B = 0$ value of ϵ_c is a good approximation.

The highest occupied Landau level is partially filled if $\nu_L = \nu - \eta$ is nonzero. The correlations in partially field states are clearly manifest in the high field limit when the lowest Landau level is fractionally occupied. Here ϵ_c has to be calculated from Quantum Monte Carlo simulations, or from methods based on the plasma analogy, via an ansatz for the many particle wavefunction. The case $\nu_L = 1/3$ and other "odd-integer" fractional-QHE states were elegantly explained by Laughlin [4], leading to a Nobel prize. This can be extended to other fractions within the plasma analogy to construct PDFs and obtain ϵ_c via the adiabatic connection formula [17]. Quantum simulations as well as composite-Fermion models have now largely superseded such methods. The literature on the quantum Hall effect [4] should be consulted for more details.

Exchange and Correlation at Finite Temperatures

The first-order (exchange) free energy F_x consists of F_x^i, where i denotes the two spin species. At $T = 0$ these reduce to the exchange energies:

$$E_i^x/n = \frac{8}{3\sqrt{\pi}} n_i^{1/2} \,. \tag{14}$$

Here $n_1 = n(1+\zeta)/2$, and $n_2 = n(1-\zeta)/2$. Then the exchange energy per particle at $T = 0$, i. e., the total E_x/n becomes

$$E_x/n = \left(E_1^x + E_2^x\right)/n = -\frac{8}{3\pi r_s}\left[x_1^{3/2} + x_2^{3/2}\right] \tag{15}$$

where x_1 and x_2 are the fractional compositions $(1 \pm \zeta)/2$ of the two spin species.

We define a reduced temperature $t = T/E_F$, $E_F = \pi n$, and the species-dependent reduced chemical potentials μ_i^0/T by η_i, reduced temperatures $t_1 = t/(1+\zeta)$ and $t_2 = t/(1-\zeta)$, based on the two Fermi energies E_{F1} and E_{F2} which are $E_F(1 \pm \zeta)$. Then we have:

$$F_i^x/E_i^x = \frac{3}{16} t_i^{3/2} \int_{-\infty}^{\eta_i} \frac{I^2_{-1/2}(u)\mathrm{d}u}{(\eta_i - u)^{1/2}} \,. \tag{16}$$

The $I_{-1/2}$ is the Fermi integral defined as usual:

$$I_\nu(z) = \int_0^\infty \frac{\mathrm{d}x x^\nu}{1+\mathrm{e}^{x-z}} \,. \tag{17}$$

The η_i are given by

$$\eta_i = \log(\mathrm{e}^{1/t_i} - 1) \,. \tag{18}$$

In the paramagnetic case Eq. (16) reduces to the result given by Isihara et al. [13]. For small values of t, the exchange energy is of the form,

$$E_\mathrm{x}(r_\mathrm{s}, t) = E_\mathrm{x}(r_\mathrm{s}, 0)[1 + (\pi^2/16)t^2 \log(t) - 0.56736t^2 + \ldots] \,. \tag{19}$$

The total exchange free energy is $F_\mathrm{x} = \Sigma F^x_i$.

A real-space formulation of $F_\mathrm{x} = F^x_1 + F^x_2$ using the zeroth-order PDFs fits naturally with the approach of our study. Thus

$$F_\mathrm{x}/n = n\int \frac{2\pi r\mathrm{d}r}{r}\sum_{i<j} h^0_{ij}(r) \,. \tag{20}$$

Here $h^0_{ij}(r) = g^0_{ij}(r) - 1$. In the non-interacting system at temperature T, the antiparallel h^0_{12}, viz., $g^0_{12}(r, T) - 1$, is zero while

$$h^0_{11}(\mathbf{r}) = -\frac{1}{n_i^2}\Sigma_{\mathbf{k}_1,\mathbf{k}_2} n(k_1)n(k_2)\mathrm{e}^{i(\mathbf{k}_1-\mathbf{k}_2)\cdot\mathbf{r}} \;=\; -[f(r)]^2 \,.$$

Here k, r are 2D vectors and $n(k)$ is the Fermi occupation number at the temperature T. At $T = 0$ $f(r) = 2J_1(k_i r)/k_r$ where $J_1(x)$ is a Bessel function.

The exchange free energy is a universal function $F_\mathrm{x}(t)/E_\mathrm{x}$, for arbitrary ζ. That is, the same function applies to any component, on using the reduced Fermi temperature of the spin species. The total F_x is the sum of both spin terms. A parametrized fit is:

$$F^x_i(t,\zeta)/E^x_i(\zeta) = \frac{1 + C_1 t_i + C_2 t_i^2}{1 + C_3 t_i + C_4 t_i^2}\tanh(1/\sqrt{t_i}) \,. \tag{21}$$

The fit coefficients C_i are 3.27603, 4.81484, 3.33100, 6.51436. The temperature t_i is $t/(1 \pm \zeta)$, appropriate to the spin polarization. The exchange effects in the 2DES decay more slowly with temperature than in the 3D case where a $\tanh(1/t)$ factor appears in Eq. 3.2 of [20]. The above form does not explicitly contain the low-temperature logarithmic term [12], but it reproduces the value of 0.99382 at $t = 0.05$, while the numerical integration gives 0.9939497. Similarly, at $t = 1$, 10 and 30 the fit (integral) returns 0.63839 (0.63839), 0.22999 (0.22990), and 0.13421 (0.13410) respectively.

If the 2D layer has a finite thickness, E_x is reduced. For numerical procedures and parametrized forms, the reader is referred to [5]. The correlation energy $\epsilon_\mathrm{c}(r_\mathrm{s}, \zeta, T)$ can be easily calculated using the PDFs from CHNC [7], but they have not been presented in a parametrized form.

Conclusion

An understanding of electron-exchange and correlation, i. e., many-body effects, is crucial to the design of quantum-well lasers, field-effect transistors, spintronics and other areas of nanostructure technology. We currently have excellent results for uniform electron systems at zero magnetic fields. The case of moderate magnetic fields is poorly understood. The very high-field case has progressed with our understanding of the fractional and integer quantum Hall effects.

Spin Dynamics in Disordered Solids

Fridrikh S. Dzheparov
Institute for Theoretical and Experimental Physics,
Moscow, Russia

Article Outline

Glossary

Averaging Two kinds of averaging are necessary for any observable $\hat{Q}$: a standard quantum mechanical one $Q = \langle\hat{Q}\rangle = \mathrm{Tr}(\hat{Q}\rho)$, where ρ is the density matrix, and consequent averaging over all possible positions of particles in disordered media $\langle Q\rangle_c = \langle\langle\hat{Q}\rangle\rangle_c$.

Continuum media approximationj Positions of particles forming the disordered solids can be considered as a subset (impurity sites) of crystal lattice sites, randomly distributed on the lattice with a small probability $c \ll 1$ to find a given site occupied. Many important results can be received in continuum media approximation (CMA) when prime cell volume $\Omega_c \to 0$ together with impurity concentration $c \to 0$ at a fixed value of impurity density $n = c/\Omega_c$.

Disordered solids Statically disordered media are considered, this means that constituent particles (atoms, ions and so on) do not participate in significant translational motions during the relaxation time under discussion, and therefore their positions are fixed (frozen) in the main approximation.

High-temperature approximation High-temperature approximation (HTA) in spin dynamics consists of using the simplest density matrix $\rho = 1/\,\mathrm{Tr}\,1$, corresponding to the limit of infinite temperature T of canonical Gibbs distribution $\rho_G = \exp(-H/T)/\,\mathrm{Tr}\exp(-H/T)$; here H is the Hamiltonian. Spin dynamics remains nontrivial and rich in this limit. Sometimes HTA means application of $\rho = (1 - H/T)/\,\mathrm{Tr}\,1$.

Local field See "Secular part of dipole–dipole interactions".

Local frequency The frequency $\omega_{\mathrm{loc}} = \gamma H_{\mathrm{loc}}$ of rotation of the spin in local field H_{loc}.

Secular part of dipole–dipole interactions As a rule any spin is considered as subjected to an external static magnetic field $\mathbf{H}_0 = H_0\mathbf{n}_z$ (directed along the z-axis) and local field, produced by dipole magnetic moments of surrounding spins. The Hamiltonian of the dipole–dipole interaction of spins $\mathbf{I}_i$ and $\mathbf{I}_j$ is of the form $H_d^{(0)}(i,j) = r_{ij}^{-3}((\mathbf{m}_i\mathbf{m}_j) - 3(\mathbf{n}_{ij}\mathbf{m}_i)(3\mathbf{n}_{ij}\mathbf{m}_j))$, where $\mathbf{r}_{ij} = \mathbf{n}_{ij}r_{ij} = \mathbf{r}_i - \mathbf{r}_j$, and $\mathbf{r}_i$ is the position of spin "i" having magnetic moment $\mathbf{m}_i = \hbar\gamma_i I_i$. If $H_0 \gg H_{\mathrm{loc}}$, where H_{loc} is the mean square field produced at any spin by surrounding spins (local field), then the Hamiltonian $H_d^{(0)}(i,j)$ can be substituted by the so-called secular dipole–dipole Hamiltonian $H_d(i,j) = \frac{1}{2r_{ij}^3}(1-3(\mathbf{n}_{ij}\mathbf{n}_z)^2)(\mathbf{m}_i\mathbf{m}_j - 3(\mathbf{m}_i\mathbf{n}_z)(\mathbf{m}_j\mathbf{n}_z))$. The accuracy of the substitution is not less than $\sim H_{\mathrm{loc}}/H_0$.

Spin dynamics Spin dynamics is considered as a time evolution of correlation functions directly connected with measurable quantities of paramagnetic samples.

Units As a rule $\hbar = 1$ is supposed. Part of the equations contains $\hbar$ written explicitly.

Definition of the Subject

The main specifics of the theory of spin dynamics in disordered solids result from the fact that calculation of observable values must start from the solution of the equation of motion, and then they should be averaged over random distribution of spins in the sample. Nominally any problem in statistical physics looks analogous, but the content of existing text books contains much more simple bypass methods to achieve the results. An important bypass class, determined in the preceding century, consists of problems that are equivalent to the motion of weak (or seldom) interacting (quasi)particles in translational invariant media. The basis of this solution is formed by the Boltzmann equation (devised in the 19th century) and by methods of deriving hydrodynamic equations based on this foundation [1]. Other important advancements in physical kinetics are connected with the invention of a projection technique by Nakajima–Zwanzig for deriving various master equations and with the development of effective approximations for corresponding memory functions [1,2]. Both these bypass methods produce satisfactory predictions if the system has such small parameters as, for example, the ratio of collision duration to time between collisions, or ratio of memory time to time of variation of substantial observables (the observables whereon the system evolution is projected). Similar small parameters do not exist in disordered solids after a beginning stage, or they are totally absent. Therefore, other more refined methods are necessary to predict experimental results. They are partially presented below.

Introduction

The first correct solutions of the problems of disordered media kinetics, which are directly connected with the spin dynamics, were obtained by Forster [3] and Anderson [4].

Forster's problem (in application to spin kinetics) describes the relaxation of impurity nuclei via paramagnetic impurities in the absence of nuclear spin diffusion. The evolution of the polarization $p_j(t) = \langle I_j^z(t) \rangle$ of the jth nucleus, placed at site $\mathbf{r}_j$, and having the spin I, is described by the kinetic equation

$$\dot{p}_j = -\sum\nolimits_{a=1}^{N} \nu_{aj} p_j = -\sum\nolimits_{\mathbf{r}} n_{\mathbf{r}} \nu_{\mathbf{r}j} p_j \,, \quad p_j(t=0) = 1 \,. \tag{1}$$

Here ν_{aj} is the depolarization rate under influence of the ath paramagnetic center (acceptor), N is the total number of acceptors in the sample, $\nu_{\mathbf{r}j} = \nu_{aj}(\mathbf{r}_a = \mathbf{r})$, and $n_{\mathbf{r}}$ is the occupation number of the site $\mathbf{r}$ by an acceptor ($n_{\mathbf{r}} = 1\ (0)$ if the site $\mathbf{r}$ is (not) occupied by an acceptor). Occupations of different sites will be assumed to be independent and having no dependence on $\mathbf{r}$ (with a small probability of occupation $c \ll 1$ as a rule):

$$\begin{aligned} &\langle n_{\mathbf{r}} \rangle_c = c \,, \quad \langle n_{\mathbf{r}} n_{\mathbf{x}} \rangle_c = c\delta_{\mathbf{rx}} + c^2(1 - \delta_{\mathbf{rx}}) \,, \\ &\left\langle \prod\nolimits_{j=1}^{\prime m} n_{\mathbf{r}_j} \right\rangle_c = \prod\nolimits_{j=1}^{\prime m} \langle n_{\mathbf{r}_j} \rangle_c = c^m \,. \end{aligned} \tag{2}$$

All $\mathbf{r}_j$ are different in the last relation. Coincidence in indexes can be treated using the identity $n_{\mathbf{r}}^2 = n_{\mathbf{r}}$. The problem consists of calculation of the observable polarization, averaged over all possible positions of acceptors in the sample. Ensemble averaging can be used for macroscopic samples: $p(t) = \langle p_j(t) \rangle_c$. Occupation number representation gives the simplest and general solution of the last problem [5]. Indeed

$$\begin{aligned} p(t) &= \langle p_j(t) \rangle_c = \left\langle \exp\left(-\sum\nolimits_{\mathbf{r}} n_{\mathbf{r}} \nu_{\mathbf{r}j} t\right) \right\rangle_c \\ &= \prod\nolimits_{\mathbf{r}} \langle \exp(-n_{\mathbf{r}} \nu_{\mathbf{r}j} t) \rangle_c \\ &= \prod\nolimits_{\mathbf{r}} \langle 1 + n_{\mathbf{r}} [\exp(-\nu_{\mathbf{r}j} t) - 1] \rangle_c \\ &= \prod\nolimits_{\mathbf{r}} \langle 1 + c [\exp(-\nu_{\mathbf{r}j} t) - 1] \rangle_c \\ &= \exp\left\{ \sum\nolimits_{\mathbf{r}} \ln [1 + c(\exp(-\nu_{\mathbf{r}j} t) - 1)] \right\} \,. \end{aligned} \tag{3}$$

The identity $f(n_{\mathbf{r}}) = f(0) + n_{\mathbf{r}}(f(1) - f(0))$ is applied here. It is valid for any realistic function $f(x)$. The relation (3) is exact for any c.

The typical depolarization rate is of the form $\nu_{aj} = \nu_0 r_0^6 \chi(\mathbf{n}_{aj})/r_{aj}^6$, where ν_0 scales the transport at minimal distance r_0, $\mathbf{n}_{aj} = \mathbf{r}_{aj}/r_{aj}$, $\mathbf{r}_{aj} = \mathbf{r}_a - \mathbf{r}_j$, $\chi(\mathbf{n}) = |Y_{21}(\mathbf{n})|^2$, and $Y_{lm}(\mathbf{n})$ is the spherical harmonics. Additional simplification is possible for the continuum media approximation (CMA), when $c \to 0$, but $p(0) - p(t) \neq 0$:

$$\begin{aligned} p(t, c \to 0) &= \exp\left(n \int \mathrm{d}^d r \left(\mathrm{e}^{-\nu_{\mathbf{r}j} t} - 1 \right) \right) \\ &= \exp\left(-(\beta_F t)^{d/6} \right) \,, \quad \beta_F \propto n^{6/d} \nu_0 r_0^6 \,. \end{aligned} \tag{4}$$

Here arbitrary spatial dimension d is considered, and impurity density $n = c/\Omega_{\mathrm{c}}$ is introduced together with the prime cell volume Ω_c.

The most important properties of Forster's result (4) consist of replacement of the simple exponential kinetics by a slower law, and in proportionality of β_F to transfer rate at average distance $\bar{r} = n^{-1/d}$: $\beta_F = \mathrm{const} \cdot \nu_{\mathbf{r}j}(|\mathbf{r} - \mathbf{r}_j| = \bar{r})$, where const doesn't depend on concentration.

Anderson introduced the model to calculate the EPR line form function $g(\omega) = \int_{-\infty}^{\infty} \frac{\mathrm{d}t}{2\pi} \mathrm{e}^{-i\omega t} F(t)$ and free induction decay $F(t) = \langle\langle S_+(t) S_- \rangle\rangle_c \,/\, \langle\langle S_+ S_- \rangle\rangle_c$ for the system of equivalent spins $S_j = 1/2$, randomly distributed inside a sample and having dipole–dipole interaction. The model consists of substitution of exact secular interaction

$$\begin{aligned} H &= \frac{1}{2} \sum_{ij} b_{ij} \left(S_i^z S_j^z - \frac{1}{3} \mathbf{S}_i \mathbf{S}_j \right) \\ &= \frac{1}{2} \sum_{\mathbf{r},\mathbf{q}} n_{\mathbf{q}} n_{\mathbf{r}} b_{\mathbf{rq}} \left(S_{\mathbf{r}}^z S_{\mathbf{q}}^z - \frac{1}{3} \mathbf{S}_{\mathbf{r}} \mathbf{S}_{\mathbf{q}} \right) \end{aligned} \tag{5}$$

by a simpler one, depending on spin z-components only:

$$H_A = \frac{1}{2} \sum_{\mathbf{r},\mathbf{q}} n_{\mathbf{q}} n_{\mathbf{r}} b_{\mathbf{rq}} S_{\mathbf{r}}^z S_{\mathbf{q}}^z \,, \tag{6}$$

where $S_{\mathbf{r}}^\alpha$ is the α component of spin $\mathbf{S}_{\mathbf{r}}$ placed at site $\mathbf{r}$ and $b_{\mathbf{rq}} = b_0 r_0^3 (1 - 3\cos^2 \vartheta_{\mathbf{rq}}) / |\mathbf{r} - \mathbf{q}|^3$ is the standard dipole–dipole coefficient [2] (here and below $b_{\mathbf{rr}} = 0$). It is of great importance, that free induction signals $F_2(t) = \langle S_+(t)S_-\rangle_0 / \langle S_+S_-\rangle_0$ are the same for both Hamiltonians for two spin problem, if $S_j = 1/2$. Anderson's model has an exact solution for arbitrary concentration [6]. Indeed, the equation of motion for orthogonal spin components has the solution

$$\begin{aligned} n_{\mathbf{r}} S_{\mathbf{r}}^{+}(t) &= n_r \exp(iH_A t) S_{\mathbf{r}}^{+} \exp(-iH_A t) \\ &= n_{\mathbf{r}} S_{\mathbf{r}}^{+} \exp\left(i \sum\nolimits_{\mathbf{q}} n_{\mathbf{q}} b_{\mathbf{rq}} S_{\mathbf{q}}^{z} t \right) . \end{aligned}$$

Introducing total moment of the sample $\mathbf{S} = \sum_{\mathbf{r}} n_{\mathbf{r}} \mathbf{S}_{\mathbf{r}}$, and using standard high-temperature approximation for free induction decay (FID) we have

$$\begin{aligned} F(t) = \frac{\langle\langle S_+(t)S_-\rangle\rangle_c}{\langle\langle S_+S_-\rangle\rangle_c} &= \left\langle\left\langle \exp\left(i \sum\nolimits_{\mathbf{q}} n_{\mathbf{q}} b_{\mathbf{rq}} S_{\mathbf{q}}^{z} t \right) \right\rangle\right\rangle_c \\ &= \prod\nolimits_{\mathbf{q}} \langle \cos(n_{\mathbf{q}} b_{\mathbf{qr}} t/2) \rangle_c \\ &= \prod\nolimits_{\mathbf{q}} \left(1 + c\left(\cos\left(b_{\mathbf{qr}} t/2\right) - 1\right)\right) \\ &= \exp\left(\sum\nolimits_{\mathbf{q}} \ln\left(1 + c\left(\cos(b_{\mathbf{qr}} t/2) - 1\right)\right) \right) . \end{aligned} \tag{7}$$

Applying CMA to (7) we arrive at Anderson's result:

$$\begin{aligned} F(t, c \to 0) &= \exp\left(-n \int \mathrm{d}^d q \left(1 - \cos\left(b_{\mathbf{qr}} t/2\right)\right) \right) \\ &= \exp\left(-(D_A t)^{d/3} \right) . \end{aligned} \tag{8}$$

For three-dimensional systems the model evidently has simple Lorentz form function:

$$g(\omega) = g_A(\omega) = \frac{D_A}{\pi\left(\omega^2 + D_A^2\right)} .$$

Anderson's parameter D_A, as well as β_F, is proportional to the rate of the process taken at the average distance: $D_A \propto b_{\mathbf{qr}}(|\mathbf{q} - \mathbf{r}| = \bar{r})$. Other derivations of Eq. (8) (closer to the original Anderson's treatment fulfilled for $d = 3$) can be found in [7].

Delocalization of Nuclear Polarization in a Disordered Spin System

One of the most important generalizations of the Forster process is presented by delocalization of nuclear polarization in the system of impurity nuclei, randomly distributed in a diamagnetic matrix, when host nuclei have faster phase relaxation and flip-flop transitions then impurities. Examples of such systems: nuclei ^{6}Li in the single crystal ^{7}Li^{19}F or spins ^{107}Ag in the single crystal ^{109}Ag^{19}F. The former system is of special interest, because it is accessible for direct experimental study due to unique coincidence of g-factors of stable nuclei ^{6}Li and β-active nuclei ^{8}Li (β-nuclei) [8]. The system has simple and instructive ergodic properties as well [9]. Therefore, we will consider below a specific system (consisting of ^{6}Li nuclei in a LiF single crystal with addition of one β-nucleus ^{8}Li) where nuclear polarization transfers from initially polarized ^{8}Li nucleus to the nearest nonpolarized ^{6}Li nuclei and then migrates over other ^{6}Li nuclei and might return back to the ^{8}Li.

It was shown in [10] that modern master equation treatment leads to a description of the system by following kinetic equations, which have been formulated in [5]:

$$\frac{\partial p_{i0}}{\partial t} = -\sum\nolimits_j \left(\nu_{ji} p_{i0} - \nu_{ij} p_{j0} \right) , \quad p_{i0}(t = 0) = \delta_{i0} . \tag{9}$$

Here $p_{i0} = \langle I_i^z \rangle$ is the quantum statistical average value of the z-component (polarization) of the ith nucleus of the system ^{8}Li-^{6}Li, placed at $\mathbf{r}_i$ ($i = 0$ corresponds to ^{8}Li with a spin $I_0 = I = 2$, and $i \neq 0$ to ^{6}Li with a spin $I_i = S = 1$). The rates of polarization transfer are of the form:

$$\begin{aligned} \nu_{ji} &= \xi_j \nu_{ji}^0 r_0^6 \cdot \left(\frac{1 - 3\cos^2\theta_{ji}}{r_{ji}^3} \right)^2 , \\ \nu_{ji}^0 &= \frac{\pi}{6} S(S + 1) \left(\frac{g_i g_j \beta_n^2}{\hbar r_0^3} \right)^2 g_{ij}(\omega_{ij}) . \end{aligned} \tag{10}$$

Here $\xi_j = I_j(I_j + 1)/[S(S + 1)]$, $g_0 = g_I = 0.8267$ and $g_{i \neq 0} = g_S = 0.8220$ are g-factors of ^{8}Li and ^{6}Li correspondingly, β_n is nuclear magneton, θ_{ji} is the angle between external static field H_0 and $\mathbf{r}_{ji} = \mathbf{r}_j - \mathbf{r}_i$, $r_0 = 2.01 \cdot \sqrt{2}$ Å is the minimal distance between Li nuclei, and ω_{ij} is the difference of the Larmor frequencies. The cross-relaxation form function $g_{ij}(\omega)$ was studied in [11], and it can be taken as Gaussian $g_{ij}(\omega) \approx \exp(-\omega^2/(2M))/(2\pi M)^{1/2}$ in the main approximation. Here $M = 2M_2$, where M_2 is the second moment of the ^{8}Li NMR line. As a result ν_{ij}^0 have two values only, $\nu_{ij}^0 = \nu_0$ for transfer between ^{6}Li spins (at that $\omega_{ij} = 0$), and $\nu_{i0}^0 = \nu_1$ for transfer between ^{8}Li and ^{6}Li (with $\omega_{ij} = \Delta$).

The occupation number representation of the Eq. (9) is of the form [5]

$$\frac{\partial \tilde{P}_{\mathbf{x0}}}{\partial t} = -\sum\nolimits_{\mathbf{z}} \left(n_{\mathbf{z}} \nu_{\mathbf{zx}} \tilde{P}_{\mathbf{x0}} - n_{\mathbf{x}} \nu_{\mathbf{xz}} \tilde{P}_{\mathbf{z0}} \right) \,, \qquad \tilde{P}_{\mathbf{x0}}(t=0) = n_x \delta_{\mathbf{x0}}/c \,, \quad (11)$$

where propagator $\tilde{P}_{\mathbf{x0}}$ gives polarization of the lattice site $\mathbf{x}$ when initially the site $\mathbf{0}$ was polarized, and $\nu_{\mathbf{zx}} = \nu_{ij}(\mathbf{r}_i = \mathbf{z}, \mathbf{r}_j = \mathbf{x})$. Equation (9) is a direct consequence of Eq. (11), that is evident, if we omit all empty sites for which $n_{\mathbf{x}} = 0$ and, consequently, $\tilde{P}_{\mathbf{x0}} = 0$.

The experimentally observable value is polarization of the β-nucleus, averaged over a random distribution of ^{8}Li-^{6}Li nuclei $P_{\mathbf{00}}(t) = \langle p_{00} \rangle_c = \langle \tilde{P}_{\mathbf{00}} \rangle_c$. A calculation of such a value belongs to the problems of random walks in disordered media (RWDM), which is one of the most complex modern fields of statistical physics, which defines the actuality of this kind of study. To clarify the status of the problem we note that its solution in CMA can be connected [12] with the calculation of the path integral of the form:

$$\mathcal{P}_{\mathbf{xy}}(t) = \int_{\mathbf{q}(0)=\mathbf{x}}^{\mathbf{q}(t)=\mathbf{y}} D\mathbf{p}(\tau) D\mathbf{q}(\tau) \exp\left[i \int_{\mathbf{x}}^{\mathbf{y}} \mathbf{p} \mathrm{d}\mathbf{q} + L\left[\mathbf{q}, \mathbf{p}, t\right] \right] \quad (12)$$

$$L\left[\mathbf{q}, \mathbf{p}, t\right] = n \int \mathrm{d}^3 z \left(\mathrm{e}^{-\int_0^t \mathrm{d}\tau A^z(\mathbf{q}(\tau), \mathbf{p}(\tau))} - 1 \right) \,, \quad (13)$$

where $A^z(\mathbf{q}, \mathbf{p}) = \nu_{\mathbf{zq}} \left(1 - \mathrm{e}^{-i\mathbf{p}(\mathbf{z}-\mathbf{q})} \right)$. The representation (12) is similar to, but more complex than path integrals in the famous polaron problems (PP) [12]. The main difference consists of multi-time action L in (13) instead of two-time action in PP, in strong singularity of $\nu_{\mathbf{zq}}$ instead of the less singular kernel $1/|\mathbf{z} - \mathbf{q}|$ in PP, in additional path integral over all $\mathbf{p}(\tau)$ and in strong dependence of the infinite-fold integral (12) on the exact form of approximations by the integrals with finite multiplicity.

Field and superfield path integral representations for $P_{\mathbf{xy}}(t) = \langle \tilde{P}_{\mathbf{xy}} \rangle_c$ exist as well [13]. They demonstrate the relation of the RWDM with general problems of the modern field theory. It should be noted, that Eq. (9) and corresponding propagator $P_{\mathbf{xy}}(t)$ have wide applications in many fields of physics. For example they describe (after minimal corrections, but retaining the dipole long-range action) incoherent spatial transport of the localized electronic excitations (which is of importance in optics and biophysics) [14], and with $\ln(\nu_{ij}) \propto r_{ij}$ the same equations are used in the theory of the hopping conductivity [15], where their applications are combined with percolation theory.

The prognosis of the measurements with dipole transport has been based on the relation [10]

$$P_{\mathbf{00}}(t) = F(t) = \exp\left(-\sqrt{\beta_1 t}\right) + \xi \frac{1 - \exp\left(-\sqrt{\beta_1 t}\right)}{(\mu\beta(t+\tau))^{3/2}} \cdot \left(1 + \frac{\varphi}{\sqrt{\mu\beta(t+\tau)}} \right) \,, \quad (14)$$

where $\xi = \xi_0 = I(I+1)/[S(S+1)] = 3$, Forster parameters $\beta = \frac{256}{243} \frac{r_0^6}{\Omega_\mathrm{c}^2} \pi^3 c^2 \nu_0$ and $\beta_1 = \beta \cdot \nu_1/\nu_0$, and the limit of small c is assumed (CMA). The values $\varphi = 2.09$ and $\mu\beta\tau = 5.11$ were chosen here to construct Eq. (14) as an interpolating formula between exact results [16] of the expansion of $P_{\mathbf{00}}$ in terms of c^m (which is an expansion in powers of $(\beta t)^{m/2}$ in reality) and expansion in terms of $1/(\beta t)^{m/2}$, produced by the approximative or numerical treatment of the long time asymptotics (where dipole long ranging induces exact dependence between the first and second terms [10]). The value of μ is connected with the main values D_α of the diffusion tensor: $\mu\beta = 4\pi (c/\Omega_\mathrm{c})^{2/3} (\prod_{\alpha=1}^3 D_\alpha)^{1/3}$. It should be stressed that an analytical solution for the nature of the long time asymptotics is absent up to now, but studies of realistic models [17] and modern numerical-analytical studies [13,18,19] indicate that it is of diffusion type. The diffusion tensor is calculated now with 1% uncertainty [18,19] giving $\mu = 0.71$. As a result the relation (14) holds to within $(\beta t)^{1/2}$ at small βt, and it holds to within $(\beta t)^{-2}$ at large βt.

The applicability of the Eq. (14) (having no fitting parameters) was checked at $\beta_1 t \leq 10$ in [8] and at $\beta_1 t \leq 15$ in [20]. The last experimental results [21,22] of the ITEP group indicate that at $\beta_1 t \sim 25$ some correction is necessary. It can be introduced in simplest form as

$$P_{\mathbf{00}}(t) = F(t) G(t)$$
$$G(t) = G_{\exp} = \left(1 - \frac{\left(\frac{1}{8} + \alpha\right) \beta_1 t - u(\beta_1 t)^2}{(1 + \nu\beta t)^3} \right) \,. \quad (15)$$

Here $F(t)$ is defined in (14), $\alpha = \alpha(\Delta)$ is tabulated in [10] (at that $\alpha(\Delta \to 0) = 0.013$), and fitting parameters u and ν should be determined by experimental data. The relation (15) holds to within βt at small βt, and it holds to within $(\beta t)^{-2}$ at large βt. The fitting produces $u \approx 0.06$ and $\nu \approx 0.12$ [21]. Direct numerical simulation of the $P_{\mathbf{00}}(t)$ fulfilled in [19] for a small external magnetic field corresponding to $\beta \approx \beta_1$ justified this correction and gave more precise form and values for $F(t)$ indicating that

$0.9 \le F(t) \le 2$. New experimental results [23] have been obtained for larger magnetic fields, when $\beta - \beta_1 \propto \beta_1$. More detailed numerical simulation is expected for description of the process in this region of fields. This should take into account correlations of local fields on impurity spins [11].

The numerical simulation [13,18,19] is based on the substitution of infinite disordered media by a crystal with a large disordered elementary cell, containing $N_d \sim 1000$ impurity spins, and on checking of stability of the results with regard to variation of N_d. It starts from Eq. (9) written as

$$\frac{\partial p_{i0}}{\partial t} = -\sum_j B_{ij} p_{j0} \,, \quad B_{ij} = \delta_{ij} \sum_k \nu_{ki} - \nu_{ij} \,,$$
$$p_{i0}(t=0) = \delta_{i0} \,, \tag{16}$$

and N_d impurities randomly placed in sites of a supercell, having $N = N_d/c = N_g^3$ lattice sites, and edges $\mathbf{R}_\alpha = N_g \mathbf{b}_\alpha$, where $\mathbf{b}_\alpha$ form the basis of the matrix crystal (LiF for the system ^{8}Li-^{6}Li). Then the supercell is continued periodically to cover all space. If $N_d \to \infty$, then we go back to random media. It is very important that the initial condition remains of the correct form and that it is not continued periodically. The eigenvalue problem

$$\sum_j B_{ij}\phi_j(m) = \varepsilon_m \phi_i(m) \tag{17}$$

has Bloch's solution

$$\phi_j(m) = \exp(i\mathbf{k}\mathbf{r}_j)\chi_j(\mathbf{k},\mu) \,, \quad m = \{\mathbf{k},\mu\} \,, \tag{18}$$

where $\chi_j(\mathbf{k},\mu)$ has periodical dependence on impurity position $\mathbf{r}_j$ and $\mathbf{k}$ belongs to Brillouin zone V_B formed by all $\mathbf{k}$ satisfying the condition

$$|\mathbf{k}\mathbf{R}_\alpha| \le \pi \,.$$

Therefore, we have a finite eigenproblem for $\chi_j(\mathbf{k},\mu)$:

$$\sum_{j=0}^{N_d-1} \bar{B}_{ij}(\mathbf{k})\chi_j(\mathbf{k},\mu) = \varepsilon_{\mathbf{k},\mu}\chi_j(\mathbf{k},\mu) \,, \tag{19}$$
$$\bar{B}_{ij}(\mathbf{k}) = \sum_{n\alpha} \mathrm{e}^{-i\mathbf{k}(\mathbf{r}_i - \mathbf{r}_j - \mathbf{R}(\mathbf{n}))} B_{ij}\left(\mathbf{r}_j + \mathbf{R}(\mathbf{n})\right) \,. \tag{20}$$

Here $\mathbf{R}(\mathbf{n}) = \sum_{\alpha=1}^{3} n_\alpha \mathbf{R}_\alpha$, and $B_{ij}\left(\mathbf{r}_j + \mathbf{R}(\mathbf{n})\right)$ is B_{ij} with substitution $\mathbf{r}_j \to \mathbf{r}_j + \mathbf{R}(\mathbf{n})$. As a result

$$p_{j0}(t) = \frac{1}{V_B}\int_{V_B} \mathrm{d}^3k \exp\left(i\mathbf{k}\mathbf{r}_j\right)\left(\exp\left(-\bar{B}(\mathbf{k})t\right)\right)_{j0} \,, \tag{21}$$

$$P_{\mathbf{00}}(t) = \frac{1}{V_B}\int_{V_B} \mathrm{d}^3k \left\langle\left(\exp\left(-\bar{B}(\mathbf{k})t\right)\right)_{00}\right\rangle_c \,, \tag{22}$$

$$P_{\mathbf{x0}}(t) = \frac{c}{V_B}\int_{V_B} \mathrm{d}^3k \exp\left(i\mathbf{kx}\right)\left\langle\left(\exp\left(-\bar{B}(\mathbf{k})t\right)\right)_{10}\right\rangle_c^{(\mathbf{r}_1=\mathbf{x})} \,. \tag{23}$$

Here $\langle(\exp(-\bar{B}(\mathbf{k})t))_{10}\rangle_c^{(\mathbf{r}_1=\mathbf{x})}$ means that averaging is fulfilled under condition that site $\mathbf{x}$ is occupied by an impurity spin having number 1 (the site $\mathbf{0}$ is always occupied by spin "0").

For identical impurities

$$P_{\mathbf{00}}(t) = \frac{1}{V_B N_d}\int_{V_B} \mathrm{d}^3k \left\langle \mathrm{Tr}\left\{\exp\left(-\bar{B}(\mathbf{k})t\right)\right\}\right\rangle_c \,. \tag{24}$$

The Eqs. (22–24) were applied for numerical simulation basing on modern programs of matrix diagonalization. The results for the ^{8}Li-^{6}Li system and for electrodipole transport of localized electronic excitations among identical impurities can be found in [19].

Nuclear Relaxation via Paramagnetic Impurities

Another important generalization of Forster's process is presented by nuclear relaxation via paramagnetic impurities, which is the main relaxation channel in isolators if nuclear spin $I = 1/2$. The fundamental studies [2,24,25,26] were based on calculation of the linear (in impurity concentration c) term of the time dependence of the sample magnetization $P(t) = 1 - cQ(t)$ (for 3d-systems) with following substitution $P(t) = \exp(-cQ(t))$. Analysis of two- and one-dimensional problems was absent whereas experiments are already aimed at fractal objects [27]. Therefore, new theory was constructed [28]. It produced the relation $P(t) = \exp(-cQ(t))$ as the main approximation, and the function $Q(t)$ is calculated for arbitrary $d \le 3$.

The process used to be described by the kinetic equation

$$\frac{\partial p(\mathbf{x},t)}{\partial t} = D\Delta p(\mathbf{x},t) - \sum\nolimits_{\mathbf{z}} n_{\mathbf{z}}\nu_{\mathbf{zx}} p(\mathbf{x},t) \,,$$
$$\nu_{\mathbf{zx}} = \frac{\nu_0 r_0^6}{|\mathbf{x}-\mathbf{z}|^6} = \frac{C}{|\mathbf{x}-\mathbf{z}|^6} \,, \tag{25}$$

with the initial condition $p(\mathbf{x},t) = p_0$. Here $p(\mathbf{x},t)$ is polarization of the nucleus, placed at the crystal site $\mathbf{x}$, D is spin-diffusion coefficient, and the angular dependence of $\nu_{\mathbf{zx}}$ is neglected together with the difference in eigenvalues of the diffusion tensor. The observable nuclear polarization (normalized to $\bar{p}(t=0)=1$) is

$$\bar{p}(t)=\frac{1}{\Omega}\int \mathrm{d}^d x\, p(\mathbf{x},t)=\langle 0\,|G(t)|\,0\rangle=\langle 0\,|\langle G(t)\rangle_c|\,0\rangle\,. \tag{26}$$

Here d is the space dimensionality, Ω is the crystal volume, the symbol $|0\rangle$ presents a vector having components $\langle \mathbf{x}|0\rangle = 1/\sqrt{\Omega}$, and the propagator $G_{\mathbf{xy}}(t)=\langle \mathbf{x}|G(t)|\mathbf{y}\rangle$ obey Eq. (25), but for initial condition $G_{\mathbf{xy}}(t=0)=\delta(\mathbf{x}-\mathbf{y})$.

Expansion of the observable $\bar{p}(t)$ in concentration powers [16] gives in first terms

$$\begin{aligned}\bar{p}(t)&=\langle 0\,|G(t)|\,0\rangle=\left\langle 0\left|G^{(0)}(t)\right|0\right\rangle\\&\quad+n\int \mathrm{d}^d r\left\langle 0\left|\left[G^{(1)}(t,\mathbf{r})-G^{(0)}(t)\right]\right|0\right\rangle+O(n^2)\\&=\exp\left(-M_0(t)(1+O(n^2))\right)\,,\end{aligned} \tag{27}$$

$$M_0(t)=n\int \mathrm{d}^d r\left\langle 0\left|\left[G^{(0)}(t)-G^{(1)}(t,\mathbf{r})\right]\right|0\right\rangle\,. \tag{28}$$

The propagator $G^{(0)}(t)$ corresponds to evolution in the absence of acceptors, and $G^{(1)}(t,\mathbf{r})$ is the propagator of the system, having only one acceptor, placed at $\mathbf{r}$. Then, using operator representation of Eq. (25), translational invariance, resolvent identity and spectral expansion, we have

$$\begin{aligned}M_0(\lambda)&=\int_0^\infty \mathrm{d}t\mathrm{e}^{-\lambda t}M_0(t)\\&=\frac{n\Omega}{\lambda}\left\langle 0\left|U_0\frac{1}{\lambda+A+U_0}\right|0\right\rangle\\&=\frac{n\Omega}{\lambda}\left\langle 0\left|U_0\frac{1}{(A+U_0)(\lambda+A+U_0)}U_0\right|0\right\rangle\\&=\frac{n\Omega}{\lambda}\sum_n\frac{|\langle n\,|U_0|\,0\rangle|^2}{(\lambda+E_n)\,E_n}\,.\end{aligned} \tag{29}$$

Here $A=-D\Delta$, $\langle \mathbf{x}|U_0|\mathbf{z}\rangle=\delta_{\mathbf{xz}}\nu_{\mathbf{x0}}$, and $(A+U_0)|n\rangle=E_n|n\rangle$. This representation is too complex for direct calculations, but it is useful for different asymptotical treatments (see, for example, [8]). The most important are short time and long time studies, because a satisfactory precision can be achieved with the aid of the representation

$$M_0(t)=M_F(t)+M_1(t)\,. \tag{30}$$

Here the first term

$$M_F(t)=n\int \mathrm{d}^d x\,(1-\exp(-\nu_{\mathbf{x0}}t))=(\beta_F t)^{d/s}$$

describes the initial (Forster's) part of the relaxation, while $M_1(t)$ is the long-time asymptotic expression, calculated on the basis of the representation (30) and formally continued to arbitrary positive values of t. Here we use $\nu_{\mathbf{x0}}=\nu_0 r_0^s/x^s$ to clarify some parametrical dependencies. The results, obtained for $M_1(t)$ at arbitrary $d\le 3$, are presented in detail in Ref [28]. In particular, at long time

$$\begin{aligned}M_1(t,d=1)&=4n\sqrt{\frac{Dt}{\pi}}\,,\\M_1(t,d=2)&=\frac{4\pi Dnt}{\ln\left(Dt/b^2\right)}\,,\\M_1(t,d=3)&=4\pi Dbnt\,,\end{aligned} \tag{31}$$

where $b\propto (C/D)^{1/(s-2)}$ is a "scattering length", which incorporates all dependence on the "potential" $\nu_{\mathbf{x0}}$. It is evident, that at $d=1$ the dependence on b is absent here, and for $d=2$ it is rather weak.

In order to find an argument for regrouping (27) of the concentration expansion, we represent the propagator $G(t)$ in the form

$$\begin{aligned}G(t)&=\langle\exp\left(-(A+U)t\right)\rangle_c=\exp\left(-B(t)\right)\,,\\B(t)&=At+M(t)\,,\end{aligned} \tag{32}$$

$$U=\sum\nolimits_{\mathbf{z}} n_{\mathbf{z}}U^{\mathbf{z}}\,,\quad U^{\mathbf{z}}_{\mathbf{xq}}=\delta_{\mathbf{xq}}\nu_{\mathbf{xz}}\,. \tag{33}$$

The operator $M(t)$, which is as-yet undefined, can be written in the form $M(t)=\sum_{\mathbf{z}} M_{\mathbf{z}}(t)$ similar to the form of U in (33). It can be said that the operators $M_{\mathbf{z}}(t)$ must adequately describe the effect of acceptors in the so-called effective medium that appears upon averaging over the configurations of acceptors. It is therefore natural to assume that, on average, the propagator $G(t)$ undergoes no changes if one of the sites of the effective medium is replaced by an actual one and if the result is thereupon averaged over the distribution of acceptors; that is,

$$G(t)=\left\langle\exp\left(-At-M(t)+M^z(t)-n_z U^z t\right)\right\rangle_c\,. \tag{34}$$

Relations (32)–(34) form a closed set of nonlinear operator equations. The solution, according to [28], practically coincides with $P(t)=\exp(-M_0(t))$, if $cQ(t)=M_0(t)\sim 1$ and $c\ll 1$, and corrections are important for longer time.

It should be stressed, that (1) to clarify the influence of corrections to this solution in more detail we can calculate the next ($\propto c^2$) term of the concentration expansion, and (2) there exist physical [29] and mathematical [30,31] studies, giving the law $\log\left(1/\bar{p}(t\to\infty)\right)\propto t^{d/(d+2)}$, which is expected [32] to be valid at $\bar{p}(t)\lesssim 10^{-12}$. The asymptotics can be received by methods of field theory, but up to a preexponential multiplier only [33], therefore these methods did not produce useful results for the problem of random walks in disordered media, discussed in Sect. "Delocalization of Nuclear Polarization in a Disordered Spin System", where the exponential part of the asymptotics is absent.

Resonance Line Form Function for Magnetically Diluted Solids

The line shape and the Fourier-transform-related free induction decay (FID) belong to the most important observable values in the physics of magnetic resonance. In the study of nuclear spin systems forming a crystal lattice the first ($\propto t^2$ and $\propto t^4$) terms of the expansion of FID in powers of time carry information of high importance [2]. In the theory of the line shape of disordered (magnetically diluted) electron spin systems, the first ($\propto c$ and $\propto c^2$) terms in the expansion in powers of the concentration c of paramagnetic centers play the same role [6]. The third ($\propto c^2$) term was calculated in a recent study [34] for the first time. This consideration is particularly topical in connection with the new experiments on measuring the EPR spectra of paramagnetic impurities distributed at the solid surface [35,36]. It can be expected, that modern pulse methods will produce new possibilities for measurement of FID in such magnetically disordered nuclear systems as ^{29}Si in silicon crystals for example. Some efforts in this direction can be found in the recent article [37] and in references therein.

Let the paramagnetic centers (PCs) be randomly distributed in a d-dimensional crystal lattice with the prime-cell volume Ω_c. The free induction decay in the high-temperature approximation is given by

$$G(t) = \left\langle \langle S^+(t) S^- \rangle_0 \right\rangle_c / \left\langle \langle S^+ S^- \rangle_0 \right\rangle_c \ , \tag{35}$$

where $S^\pm = \sum_{\mathbf r} n_{\mathbf r} S^\pm_{\mathbf r}$, $S^\pm_{\mathbf r} = S^x_{\mathbf r} \pm i S^y_{\mathbf r}$, $S^+(t) = \mathrm{e}^{iHt} S^+ \mathrm{e}^{-iHt}$, $n_{\mathbf r}$ is the occupation number, $\langle\cdots\rangle_0 = \mathrm{Tr}\,(\cdots)\,/\mathrm{Tr}1$, $\langle\cdots\rangle_c$ stands for the averaging over the spatial spin distributions (over occupation numbers), and H is the secular part of dipole–dipole interactions:

$$H = \frac{3}{4}\sum_{rq} n_{\mathbf r} n_{\mathbf q} A(\mathbf r, \mathbf q)\left(S^z_{\mathbf r} S^z_{\mathbf q} - \frac{a}{3}\mathbf S_{\mathbf r} \mathbf S_{\mathbf q}\right) . \tag{36}$$

Here $A(\mathbf r, \mathbf q) = \hbar\gamma^2\left(1 - 3\cos^2\vartheta_{rq}\right) / |\mathbf r - \mathbf q|^3$, γ is the gyromagnetic ratio, and ϑ_{rq} is the angle between $\mathbf r - \mathbf q$ and external static field $\mathbf H_0$. Parameter $a = 0$ in the Anderson model and $a = 1$ for pure dipole interaction. For other a values, Hamiltonian (36) corresponds to a system with the anisotropic axisymmetric g-factor. In what follows, $S = 1/2$ for all PCs. Let us expand FID in power of $n_{\mathbf x}$ and perform configurational averaging [6]. To terms $\propto O(c^3)$ one has

$$\begin{aligned} G(t) = {} & 1 + c\sum_{\mathbf r_1}(2K_{01}(t) - 1) \\ & + \frac{c^2}{2}\sum_{\mathbf r_1 \neq \mathbf r_2}(2K_{012}(t) - 2K_{01}(t) - 2K_{02}(t) + 1) \ , \end{aligned} \tag{37}$$

and, applying CMA we have up to terms $\propto O(n^3)$

$$\begin{aligned} G(t) = {} & 1 + n\int \mathrm{d}^d r_1\,(2K_{01}(t) - 1) \\ & + \frac{n^2}{2}\int \mathrm{d}^d r_1 \mathrm{d}^d r_2\,(2K_{012}(t) - 2K_{01}(t) \\ & - 2K_{02}(t) + 1) \ , \end{aligned} \tag{38}$$

where $n = c/\Omega_c$ is the d-dimensional PC density, and

$$K_{01}(t) = \left\langle \mathrm{e}^{iH_{01}t} S_0^+ \mathrm{e}^{-iH_{01}t}(S_0^- + S_1^-)\right\rangle_0 \ ,$$

$$K_{012}(t) = \left\langle \mathrm{e}^{iH_{012}t} S_0^+ \mathrm{e}^{-iH_{012}t}(S_0^- + S_1^- + S_2^-)\right\rangle_0 \ .$$

Here, according to Eq. (36),

$$H_{ij} = \tfrac{1}{2}A_{ij}(3S_i^z S_j^z - a\mathbf S_i \mathbf S_j) , \quad H_{012} = H_{01} + H_{02} + H_{12} , \tag{39}$$

with $A_{ij} = A(\mathbf r_i, \mathbf r_j)$. The interaction $A_{ij} \propto \left|\mathbf r_i - \mathbf r_j\right|^{-3}$. Therefore, substitution of integration variables $\mathbf r_i \to t^{1/3}\mathbf r_i$ excludes time from the integrands and reveals that the mth term in (38) is $\propto (nt^{d/3})^m$. That is Eq. (38) is expanded [16] in terms of dimensionless parameter

$$(D_d t)^{d/3} = n\int \mathrm{d}^d r_1\,(1 - 2K_{01}(t)) \ , \tag{40}$$

and, hence, can be represented as

$$G(t) = 1 - (D_d t)^{\frac{d}{3}} + \frac{1}{2}\xi_d(a)(D_d t)^{\frac{2d}{3}} + O\left((D_d t)^d\right) . \tag{41}$$

The functions $\xi_d(a)$ were calculated numerically basing on the Eq. (38). It was supposed, that at $d \leq 2$ all field directions are equally probable. For this case, after averaging of (41) we have

$$\bar G(t) = 1 - (\bar D_d t)^{\frac{d}{3}} + \frac{\bar\xi_d(a)}{2}(\bar D_d t)^{\frac{2d}{3}} + O\left((\bar D_d t)^d\right) , \tag{42}$$

and

$$\begin{aligned} & \bar D_d = \beta_d n^{d/3}\gamma^2\hbar \ , \quad \beta_3 = \frac{2\pi^2}{3\sqrt 3} \ , \\ & \beta_2 = 4.647 \ , \qquad \beta_1 = 6.348 \ . \end{aligned} \tag{43}$$

It should be noticed, that $\bar{D}_3 = D_3$, and D_3 coincides with Anderson's result [4].

The results are presented in the following table:

a	0	0.2	0.4	0.6	0.8	1.0	1.2	1.4	1.6
ξ_3	1	1.01	1.03	1.05	1.08	1.11	1.13	1.15	1.18
$\bar{\xi}_2$	1.027	1.07	1.11	1.15	1.19	1.22	1.25	1.27	1.29
$\bar{\xi}_1$	1.062	1.16	1.20	1.25	1.28	1.32	1.35	1.37	1.40

(44)

These relations can be used directly for analysis of the wings of experimental EPR lines [34]. But treatment of the full line or FID requires regrouping of the expansion (42) in such a way to receive a physically adopted result for all t. One of the simplest approaches [38,39,40] was generalized for this aim in [34]. It introduces the most essential properties of the disordered systems into the Anderson–Weiss–Kubo (AWK) theory [41,42], which was originally developed for the description of line narrowing by motion. The result is of the form

$$\begin{aligned} G(t) &= \exp\left(-\left(2B_d^2 \int_0^t \mathrm{d}\tau (t-\tau) F(B_d\tau)\right)^{d/6}\right) , \\ F(x) &= \exp\left(-(q_d x)^{d/3}\right) . \end{aligned} \tag{45}$$

Being approximative Eq. (45) nevertheless reproduces the structure of the expansion (41), non-negativity of the resonance line shape and parameters B_d and q_d can be defined using D_d and ξ_d, that gives

$$\begin{aligned} B_3 &= D_3 , & B_2 &= \bar{D}_2 , \\ q_3 &= 3(\xi_3 - 1) , & q_2 &= \left((10/3)(\bar{\xi}_2 - 1)\right)^{3/2} . \end{aligned} \tag{46}$$

The dimensionality $d = 1$ requires more refined treatment, because system orientations near the "magic" direction $\theta = \arccos(1/\sqrt{3})$ produce a singularity $g_1(\omega \to 0) \propto \ln(1/\omega)$.

In application to pure dipole interaction with $a = 1$ the Eqs. (46) and (44) give $q_3 = 0.33 \approx 1/3$ and $q_2 = 0.63$. Fitting of the experimental data of [35] in the region, where the sample was considered as two-dimensional gives $q_2 = q_2^{\exp} \approx 0.05$ with significant distinctions from both $q_2 = 0$, and $q_2 = 0.63$. Additional studies are necessary to clarify the nature of this deviation from pure dipole evolution.

Application of the approach to magnetically diluted nuclear spin systems (like ^{29}Si in silicon) requires one important modification connected with the fact that typical nuclear concentration $c = 0.01 \div 0.1$ is not sufficiently small to replace lattice sums by integrals in Eq. (38). Therefore, FID for such concentrations can be represented by the Eq. (45) with substitution

$$(D_d t)^{d/3} \to \varkappa(t) = c \sum_{\mathbf{r}_1} (1 - 2K_{01}(t)) . \tag{47}$$

For example, if $d = 3$ and $a = 1$, then Eqs. (45), (46) produce

$$G(t) = \exp\left(-\left(6\left(D_3 t + 3\exp(-D_3 t/3) - 3\right)\right)^{1/2}\right) . \tag{48}$$

Applying the recipe (47) we receive the representation

$$G(t) = \exp\left(-\left(6\left(\varkappa(t) + 3\exp\left(-\varkappa(t)/3\right) - 3\right)\right)^{1/2}\right) , \tag{49}$$

which is exact at small $\varkappa(t)$ up to $O(\varkappa^2(t))$ and coincides with (48) for $\varkappa(t) \gtrsim 1$.

Saturation on the Wing of a Dipole-Broadened EPR Line and Cluster Expansions

A bright demonstration of peculiarities of spin dynamics in disordered media is realized in the shape of the hole burned on the wing of the EPR line. The EPR spectrum in dipole-broadened 3d solids has the Lorentz wing, but experimentation [43] revealed that the wing of the hole falls down exponentially contrary to expectations, that a dipole broadened line should be homogeneous. To solve this contradiction a new method of cluster expansions [39,40] was invented, which gives a constructive alternative to both concentration expansion, discussed in Sect. "Resonance Line Form Function for Magnetically Diluted Solids", and spin pockets conception [44], used in [43] for interpretation of the data.

If interaction inside a pair of spins exceeds interactions with any other spin, then the spectrum of the pair is similar to a discrete one, broadened by small interactions with surrounding spins. The pair forms a two-spin cluster (2-cluster). Analogically we can define 3- and other many-spin clusters. It is sufficient for many tasks to divide all spins into three groups: 2- and 3-clusters and all other "mass" spins. Numerical analysis [39] shows, that 2- and 3-clusters contain 51(1)% and 11(1)% of all spins correspondingly, but 2-clusters define all Lorentz wings of the EPR line. Mass spins (similar to nuclear spins in a crystal) have finite heat capacity, which is defined by interaction at average distance contrary to infinite heat capacity of a full dipole–dipole reservoir, calculated in CMA. Mass spins produce fluctuating fields, which gave the main broadening of the clusters spectra. Transitions between states of the cluster take place due to interactions with other clusters and with mass spins, and they are slow. As a result saturation at the EPR line wing induce transitions between states of the 2-cluster, and the line shape of the hole is defined by interaction of the cluster with mass spins. If this interaction is estimated within the AWK model, then any mass configuration produces exponential wings of the hole $g(\Delta) \propto \exp(-\Delta/\mu)$, where Δ is detuning of the saturating field from the cluster transition frequency, and μ is defined by magnitude of the fields produced by other spins on the cluster, and by the rate of their fluctuations. After configurational averaging the wings became $\langle g(\Delta)\rangle_c \propto \Delta^{-4}$, but averaged hole shape described the transitions for small magnitude ω_1 of the saturating field only. In a general case the observable area of the hole σ should be averaged. For large ω_1 we have $\sigma \propto \ln\left(t_p\omega_1^2/\mu\right)$, where t_p is the duration of the saturating pulse. Logarithm is a slow function, therefore $\langle\sigma\rangle_c \propto \ln\left(t_p\omega_1^2/\langle\mu\rangle_c\right)$, which was observed in [43] and was interpreted as the exponential wing of Portis's pockets. The described theory produces a microscopic picture of the phenomenon and indicates that Portis's pockets have limited relation to the problem, because they are homogeneous by definition, i. e. $g(\Delta) = \langle g(\Delta)\rangle_c$, while in the cluster theory this relation isn't fulfilled.

Future Developments

Methods described in Sect. "Delocalization of Nuclear Polarization in a Disordered Spin System" are expected to be useful for understanding of studies of delocalization of relaxed excitons in different problems which can be studied by optical methods (fluorescence and multi-wave mixing) first of all. We expect that results obtained in this section will also produce a reliable basis for development of general methods of statistical physics and path integration theory in order to reproduce and clarify these results and many other problems of nonlinear field theory.

The results of Sect. "Nuclear Relaxation via Paramagnetic Impurities" create a new regular method for treatment of a wide class of problems of disordered media. The method is similar to, but, nevertheless, different from standard coherent (effective) potential approximation. We expect that the same ideas applied to the second term of the concentration expansion can produce better understanding for many related problems.

The results of Sect. "Resonance Line Form Function for Magnetically Diluted Solids" require new experimental studies for all spatial dimensions. Checking on nuclear spin systems like ^{29}Si in silicon crystals is most desirable, because the details of interaction of nuclei are known much better then for paramagnetic centers.

Cluster expansion, described in Sect. "Saturation on the Wing of a Dipole-Broadened EPR Line and Cluster Expansions" should be useful for different problems of spectral transport in disordered solids.

Article Outline

Glossary

Aharonov Bohm effect The magnetic flux enclosed in between propagating quantum mechanical waves shifts their relative phases as a result of the underlying electromagnetic vector potential. This gives rise to distinct oscillations in the magnetoconductance of a ring conductor.

Landauer–Büttiker formalism For phase-coherent quantum transport, the Landauer–Büttiker formalism relates the conductance of a device to the transmission probability of charge carriers.

Rashba- and Dresselhaus spin-orbit coupling Coupling of the spin degree of freedom to the orbital motion of charge carriers due to structural or bulk inversion asymmetry in semiconductors.

Ratchets Devices that convert unbiased fluctuations or perturbations into directed motion.

Spintronics Extension of charge-based electronics in metals or semiconductors by utilizing the spin degree of freedom of the charge carriers.

Definition of the Subject

Mesoscopic conductors are electronic systems of sizes in between nano- and micrometers, and often of reduced dimensionality. In the phase-coherent regime at low temperatures, the conductance of these devices is governed by quantum interference effects, such as the Aharonov–Bohm effect and conductance fluctuations as prominent examples. While first measurements of quantum charge transport date back to the 1980s, spin phenomena in mesoscopic transport have moved only recently into the focus of attention, as one branch of the field of spintronics. The interplay between quantum coherence with confinement-, disorder- or interaction-effects gives rise to a variety of unexpected spin phenomena in mesoscopic conductors and allows moreover to control and engineer the spin of the charge carriers: spin interference is often the basis for spin-valves, -filters, -switches or -pumps. Their underlying mechanisms may gain relevance on the way to possible future semiconductor-based spin devices.

A quantitative theoretical understanding of spin-dependent mesoscopic transport calls for developing efficient and flexible numerical algorithms, including matrix-reordering techniques within Green function approaches, which we will explain, review and employ.

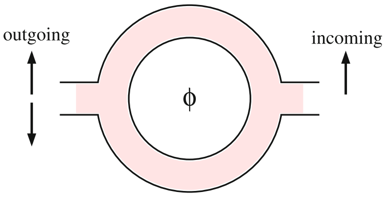
Introduction

Charge and spin transport through phase-coherent conductors of mesoscopic scales carry imprints of wave interference as predominant and characteristic features: in the simplest case of a point contact, the conductance increases stepwise with Fermi energy, reflecting the discrete number of quantized open transverse channels contributing to transport; for more complex mesoscopic systems, such as ballistic quantum dots or diffusive conductors, the conductance typically wildly fluctuates, upon varying the Fermi energy or other parameters, around its classical mean value. Among the different effects on charge transport, the Aharonov–Bohm (AB) effect represents possibly the most genuine interference phenomenon at the heart of mesoscopic physics: The magnetoconductance of a ring conductor coupled to two leads exhibits distinct sinusoidal oscillations when monitored as a function of a perpendicular magnetic field threading the ring, with a period given by the magnetic flux quantum. As the AB signal stems from interfering waves traveling through the two different arms of the ring, it requires phase coherent wave functions extending over the ring typically on micron scales [1]. Hence the AB effect is frequently being used as a tool to investigate phase coherence and dephasing mechanisms of the orbital part of the wave functions, while the spin degree of freedom was usually neglected.

With rising interest in spin-dependent transport, the interplay of the electron spin and charge degree of freedom has been exploited in a variety of spin interference devices, to be discussed below. Different types of couplings to the electron spin have been considered for spin engineering in non-magnetic conductors. On the one hand this is possible through the Zeeman coupling to an externally applied magnetic field. Non-uniform *B*-fields with spatially varying direction are being employed to achieve a tailored spin dynamics, including the possibility for guided spin evolution or triggering spin flips. On the other hand, intrinsic spin-orbit (SO) interaction proves to be relevant in spin-dependent transport. It exists in systems with bulk inversion asymmetry and/or structure inversion asymmetry, e. g. due to the vertical confinement in semiconductor heterostructures (Rashba SO coupling [2,3]).

Among the mesoscopic spin interference systems considered in the literature, ring geometries have again played an important role, opening up the field of spin-based AB physics (see [4,5] for recent accounts including overviews over the literature). This includes topics such as Berry phase-signatures in transport, both theoretically [6,7,8,9,10,11,12] and experimentally [13,14,15,16], spin-related conductance modulation [17,18,19], persistent currents [6,20], spin Hall effect [21], spin filters [22,23] and detectors [24], and spin switching mechanisms [4,10].

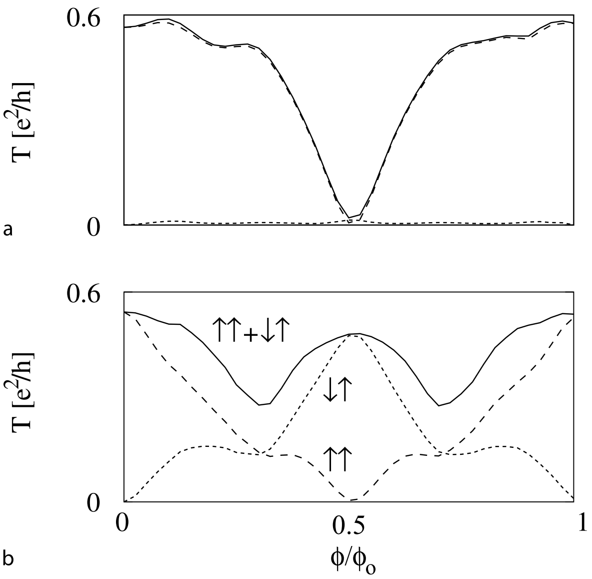
To illustrate how the spin polarization can be tuned by exploiting (orbital and spin) interference in such an AB setup, we consider as an introductory example spin switching in a two-dimensional (2D) ballistic phase-coherent ring symmetrically coupled to two single-channel leads (Fig. 1, [17]). We assume Rashba SO coupling which is relevant in conductors laterally defined on GaAs- or InAs-based two-dimensional electron gases (2DEGs). Rashba SO coupling will be defined and discussed in Sect. "Spin Filtering in Nanostructures". It can be viewed as the coupling of the spin to a fictitious in-plane magnetic field directed perpendicular to the electron momentum. Hence in a ring it points mainly in radial direction. The strength of the SO field can be tuned by an external gate voltage [25] allowing to control experimentally the spin evolution.



Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 1

Aharonov–Bohm physics with spin: Two-dimensional Aharonov–Bohm ring of mean radius r_0 used for numerical calculations of the conductance presented in Fig. 2. An additional perpendicular magnetic field B generates a flux $\phi = \pi r_0^2 B$. The *gray zone* corresponds to the region subject to a finite Rashba coupling switched adiabatically on and off in the leads (from [17])

We assume *spin-polarized* spin-up electrons entering the ring from the right (see Fig. 1). Figure 2 displays numerically computed (see Sect. "Numerical Quantum Transport") conductance traces as a function of the external magnetic flux ϕ for weak and moderate Rashba strengths. The overall conductance is presented as a solid line, and its spin-resolved components, $G^{\uparrow\uparrow}$ and $G^{\downarrow\uparrow}$, corresponding to outgoing spin-up and -down channels, are shown as dashed and dotted lines, respectively. In the weak SO coupling limit, Fig. 2a, the overall conductance (solid line) shows the usual AB oscillations of period ϕ_0 and is dominated by $G^{\uparrow\uparrow}$ (dashed line). As expected for weak spin-coupling, the spin polarization is almost conserved during transport. Interesting features appear for the case of moderate SO coupling depicted in panel (b). There, both components, $G^{\uparrow\uparrow}$ (dashed line) and $G^{\downarrow\uparrow}$ (dotted line), contribute similarly to the overall conductance (solid line). However, the spin polarization of the transmitted electrons varies as a function of the magnetic flux ϕ: $G^{\downarrow\uparrow} = 0$ at $\phi = 0$, while $G^{\uparrow\uparrow} = 0$ at $\phi = \phi_0/2$. Hence, for zero flux all transmitted carriers conserve their original (incoming) spin-orientation, while for $\phi = \phi_0/2$ the transmitted particles reverse their spin polarization. In other words: by tuning the magnetic flux from 0 to $\phi_0/2$ we can reverse the spin-polarization of transmitted particles in a controlled way. Hence the AB ring with SO coupling acts as a tunable spin-switch. This switching can be traced back to constructive or destructive AB interference [4].



Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 2
Mesoscopic Aharonov–Bohm spin interference: The conductance of spin-up polarized carriers entering a single-channel two-dimensional Aharonov–Bohm ring (see Fig. 1) is shown as a function of flux $\phi = \pi r_0^2 B$ (in units of the flux quantum $\phi_0 = hc/e$) through the ring in the presence of Rashba spin-orbit coupling. For panel a and b the scaled spin-orbit coupling strength takes the values 0.2 and 1.0, expressed as the product $\omega_R T_0/2\pi$ of the precession frequency ω_R of the spin around the effective spin-orbit magnetic field and the time T_0 for traveling of the electrons around the ring. The overall conductance (*solid line*) is split into its components $G^{\uparrow\uparrow}$ (*dashed line*) and $G^{\downarrow\uparrow}$ (*dotted line*). Note in panel b the continuous change of the spin polarization, related to $G^{\uparrow\uparrow} - G^{\downarrow\uparrow}$, with ϕ and the spin switching at $\phi = \phi_0/2$ (adapted from [17])

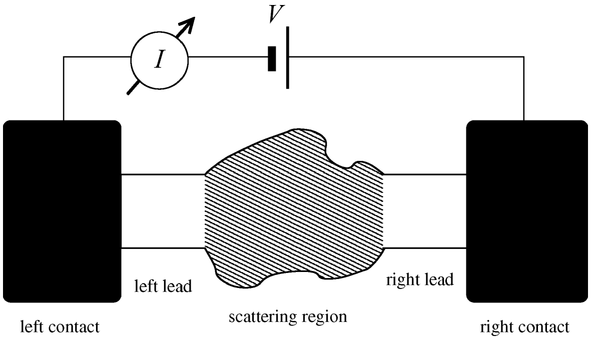
Switching a given spin polarization requires the generation of spin-polarized particles in non-magnetic mesoscopic conductors in the first place. Since spin injection from ferromagnets into a semiconductor remains problematic [26], alternative proposals have been made to achieve spin-polarized currents or spin accumulation without magnets, which we will briefly review in Sect. “Spin Filtering in Nanostructures”. Among those are the spin Hall effect [27] and, in the context of coherent mesoscopic transport, concepts for Zeeman- and SO-mediated adiabatic spin pumping and spin ratchets.

For a recent account on spin phenomena in systems of reduced dimensions see [28]; for a review on the related field of magnetization dynamics and pumping in layered magnetic heterostructures see [29].

A complete and quantitative understanding of spin phenomena in the mesoscopic realm requires computational approaches to quantum transport which also serve as reference calculations for analytical predictions usually based on model assumptions. However, also numerical approaches cannot cope with the full many-body transport problem without relying on approximations. Here we focus on mesoscopic conductors, i. e. systems with a considerable number of electrons, with strong coupling to external leads. Then, a mean-field treatment is usually justified which allows one to reduce the Hamiltonian to a single-particle problem with an effective confinement potential resulting from a combination of external and mean-field potentials.

We further consider coherent transport close to equilibrium at relatively low bias, excluding inelastic effects, such that the Landauer approach to transport is justified. However, even in this case brute-force computational approaches quickly reach their limits: Conductors at mesoscopic scales are typically characterized by extensions which are (at least in one direction) much larger than the Fermi wavelength of the charge carriers, the shortest quantum scale involved. This implies rapidly oscillating, complex and often irregular spinor wave functions extending throughout the systems which require for the quantum mechanical numerical solution either huge sets of basis functions or, in tight-binding approaches, the use of rather fine, preferentially adapted grids. The strength of the widespread tight-binding approaches for transport discussed and reviewed here lies in their flexibility and general applicability. Moreover, tight-binding transport codes can be combined with density-functional (DFT) calculations for structure and electronic properties of the nano-conductors by using the parameters computed within DFT as input. This approach is frequently applied to transport in nano- or molecular electronics.

The paper is organized as follows: In the methodological Sect. “Numerical Quantum Transport” we will first briefly summarize and provide the key relations for spin quantum transport within the Landauer framework. In Sect. “Matrix Reordering Strategies for Quantum Transport” we focus on and explain in some detail advanced computational concepts, making use of graph-theory, to implement powerful and flexible algorithms for tight-binding transport codes. The numerical strength of the codes is demonstrated for ring-type geometries showing that by efficient tight-binding implementation one can gain orders of magnitude in performance. In Sect. “Spin Filtering in Nanostructures” and “Pure Spin Current Generation” we employ these numerical schemes to address two important aspects of spin-dependent transport, namely spin filtering and generating pure spin currents. To this end we focus on laterally-confined 2D ballistic nanostructures with Rashba SO interaction. We conclude



Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 3
Schematic view of a two-point measurement setup

with an outline of future research directions in mesoscopic spin transport which we consider important.

Numerical Quantum Transport

Landauer–Büttiker Transport Theory

If the dimensions of a device get smaller than the phase coherence length l_ϕ of charge carriers, classical transport theories are not valid any more. Instead, carrier dynamics is now governed by quantum mechanics and the wave-like nature of particles becomes important. In general, the conductance/resistance of such a device does not follow Ohm's law.

Consider a two-point measurement setup as shown in Fig. 3: A scattering region is connected to large (phase-breaking) reservoirs by leads. The leads are assumed to be perfect and infinitely long to define asymptotic eigenstates $\phi_{n,\sigma}(y)\mathrm{e}^{\pm ikx}$ at energy E, where n is the quantum number of transverse confinement —also called the *channel* number —and σ is the spin index. The total scattering eigenstate $\psi_{n,\sigma}$ originating from channel n with spin σ in the left lead is, within the lead region, given by

$$\psi_{n,\sigma}(\mathbf{x}) = \begin{cases} \phi_{n,\sigma}(y)\mathrm{e}^{ikx} + \sum_m r_{m,\sigma';n,\sigma} \ \phi_{m,\sigma'}(y)\mathrm{e}^{-ikx} \\ \qquad\qquad \text{for } \mathbf{x} \text{ in left lead} \\ \sum_m t_{m,\sigma';n,\sigma} \ \phi_{m,\sigma'}(y)\mathrm{e}^{ikx} \\ \qquad\qquad \text{for } \mathbf{x} \text{ in right lead} \end{cases}, \tag{1}$$

and obeys the stationary Schrödinger equation $H\psi_{n,\sigma} = E\psi_{n,\sigma}$. The conductance G in linear response can then be calculated within the *Landauer–Büttiker* formalism [30,31,32] (for tutorials see [1,33]):

$$G = \frac{\mathrm{e}^2}{h}\sum_{n,m}\sum_{\sigma,\sigma'} T_{m,\sigma';n,\sigma} = \frac{\mathrm{e}^2}{h}\,T_{\mathrm{C}}\,, \tag{2}$$

where $T_{m,\sigma';n,\sigma} = |t_{m,\sigma';n,\sigma}|^2$ is given by the squared transmission amplitudes of the scattering states $\psi_{n,\sigma}$. The fraction e^2/h is called the conductance quantum. The *scattering matrix* $S_{m,\sigma';n,\sigma}$ is a useful definition that combines reflection and transmission amplitudes for both leads into a single matrix. In this notation the index n,σ then also contains information about the respective lead.

The problem of calculating the conductance G is thus reduced to calculating the scattering eigenstates $\psi_{n,\sigma}$. Alternatively, the scattering amplitudes $r_{m,\sigma';n,\sigma}$ and $t_{m,\sigma';n,\sigma}$ can also be derived from the retarded Greens function $G^{\mathrm{R}}(\mathbf{x},\mathbf{x}')$ of the system. The retarded Greens function for a given energy E obeys the equation

$$(E - H + \mathrm{i}\eta)\, G^{\mathrm{R}}(\mathbf{x},\mathbf{x}') = \delta(\mathbf{x}-\mathbf{x}')\,, \tag{3}$$

where H is the Hamiltonian of the system and η an infinitesimally small number. Formally this equation can be solved as

$$G^{\mathrm{R}} = (E - H + \mathrm{i}\eta)^{-1}\,. \tag{4}$$

The transmission and reflection amplitudes are then given by the *Fisher–Lee* relation [34]:

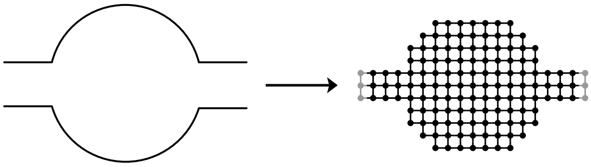
$$\begin{aligned} t_{m,\sigma';n,\sigma} &= -\mathrm{i}\hbar\sqrt{v_m v_n}\int_{C_{\mathrm{R}}}\mathrm{d}y \\ &\qquad \times \int_{C_{\mathrm{L}}}\mathrm{d}y'\phi_{m,\sigma'}(y)\, G^{\mathrm{R}}(\mathbf{x},\mathbf{x}')\,\phi_{n,\sigma}(y')\,, \end{aligned} \tag{5}$$

$$\begin{aligned} r_{m,\sigma';n,\sigma} &= \delta_{mn}\delta_{\sigma'\sigma} - \mathrm{i}\hbar\sqrt{v_m v_n}\int_{C_{\mathrm{L}}}\mathrm{d}y \\ &\qquad \times \int_{C_{\mathrm{L}}}\mathrm{d}y'\phi_{m,\sigma'}(y)\, G^{\mathrm{R}}(\mathbf{x},\mathbf{x}')\,\phi_{n,\sigma}(y')\,, \end{aligned} \tag{6}$$

where v_n denotes the velocity of channel n and the integration runs over the cross-section $C_{\mathrm{L}}(C_{\mathrm{R}})$ of the left (right) lead. Equations (5) and (6) are valid only for leads without magnetic fields and no spin-orbit interaction. Baranger and Stone [35] have extended the formalism to also account for arbitrary magnetic fields in the leads, and their description can also be applied to finite spin-orbit interaction.

Tight-binding Representation of the Hamiltonian

Except for very simple geometries, the scattering problem cannot be solved analytically. Therefore, the use of computers for a numerical solution of the scattering problem is very often the method of choice. However, the related stationary Schrödinger equation $H\psi = E\psi$ is a differential equation with continuous degrees of freedom that are difficult to treat on a computer. In general, a numerical solution is thus only attempted within a *discrete* basis set which converts the differential equation into a matrix equation.



Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 4
Discretizing a continuous region on a square grid

The method of finite differences is a very simple and yet powerful way to introduce such a discrete basis set and has been applied to the Schrödinger equation already as early as 1934 [36,37] (for an introduction see [1,33]). Here we illustrate, as an example, the application of the method for a simple one-dimensional effective mass Hamiltonian including a potential

$$H = -\frac{\hbar^2}{2m}\frac{\mathrm{d}^2}{\mathrm{d}x^2} + V(x)\,. \tag{7}$$

In the method of finite differences, space is approximated by a grid of discrete lattice points spaced equidistantly with lattice constant a. For the 2D case, usually a square grid is used as depicted in Fig. 4. Using the Taylor expansion of the wave function ψ we can write

$$\begin{aligned}\psi(x+a) &= \psi(x) + \psi'(x)a + \frac{1}{2}\psi''(x)a^2 \\ &\quad + \frac{1}{6}\psi^{(3)}(x)a^3 + \frac{1}{24}\psi^{(4)}(x)a^4 + \dots\,,\end{aligned} \tag{8}$$

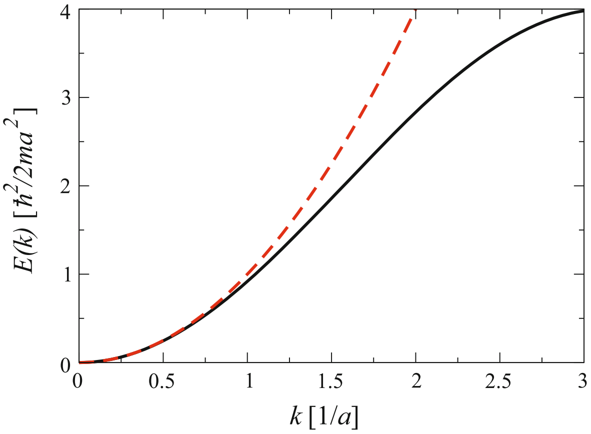
$$\begin{aligned}\psi(x-a) &= \psi(x) - \psi'(x)a + \frac{1}{2}\psi''(x)a^2 \\ &\quad - \frac{1}{6}\psi^{(3)}(x)a^3 + \frac{1}{24}\psi^{(4)}(x)a^4 + \dots\,.\end{aligned} \tag{9}$$

Adding Eq. (8) and (9), we arrive at an expression for the second derivative of the wave function in terms of values of the wave function on the grid,

$$\begin{aligned}&\frac{\mathrm{d}^2}{\mathrm{d}x^2}\psi(x) \\ &\quad = \frac{1}{a^2}\left(\psi(x+a) + \psi(x-a) - 2\psi(x)\right) + \mathcal{O}(a^2)\,,\end{aligned} \tag{10}$$

valid up to second order in the lattice spacing a. The differential equation

$$-\frac{\hbar^2}{2m}\frac{\mathrm{d}^2}{\mathrm{d}x^2}\psi(x) + V(x)\psi(x) = E\psi(x) \tag{11}$$



Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 5
Energy spectrum *E*(*k*) for the continuous Schrödinger equation (*red dashed line*) and the tight-binding approximation (*black solid line*)

is thus replaced by a set of difference equations

$$\begin{aligned}-\frac{\hbar^2}{2ma^2}\left(\psi(x_{i+1}) + \psi(x_{i-1}) - 2\psi(x_i)\right) + V(x)\psi(x_i) \\ = E\psi(x_i)\,,\end{aligned} \tag{12}$$

where $x_{i\pm1} = x_i \pm a$, yielding the tight-binding representation of the Hamiltonian:

$$\begin{aligned}H = \sum_{x_i} -\frac{\hbar^2}{2ma^2}\left(|x_i\rangle\langle x_{i+1}| + \text{h.c.}\right) \\ + \left(2\frac{\hbar^2}{2ma^2} + V(x_i)\right)|x_i\rangle\langle x_i|\,.\end{aligned} \tag{13}$$

Here, $|x_i\rangle$ denotes a state localized at grid point x_i.

In principle, the quality of the finite differences approximation can be improved up to a desired precision by reducing the lattice spacing a. However, since this leads to a larger problem size, the minimum lattice spacing achievable is set by the available computing time and memory. Thus, one must keep an eye on the validity of the finite differences approximation. In Fig. 5 we show the energy spectrum $E(k)$ for the continuous one-dimensional Schrödinger equation and the tight-binding (finite differences) approximation. The tight-binding approximation only holds for $ka \ll 1$ and $E \ll \hbar^2/(2ma^2)$, and it does not make sense to consider the whole energy spectrum given by the tight-binding band width. The method of finite differences presented here can straight-forwardly be applied to more complex Hamiltonians, including for example spin-orbit interactions [17], and will be later used to calculate transport phenomena including spin in Sect. "Spin Filtering in Nanostructures" and "Pure Spin Current Generation".

A tight-binding representation of the Hamiltonian can also be obtained by applying the finite element method [38]. Furthermore tight-binding Hamiltonians are also used in treatments beyond the effective mass approximation, such as from atomic orbitals in empirical tight-binding models [39,40,41], or from orbitals of the Kohn–Sham equations within DFT [42,43,44].

Numerical Algorithms

Within the tight-binding approximation the Hamiltonian H can be represented by a matrix, even though this matrix is still infinite as the leads are infinitely long. However, the infinite matrix problem can be reduced to a finite problem by partitioning the system into three isolated parts: left lead, scattering region, and right lead. The Hamiltonian then reads

$$H = \begin{pmatrix} H_\mathrm{L} & V_\mathrm{LS} & 0 \\ V_\mathrm{SL} & H_\mathrm{S} & V_\mathrm{SR} \\ 0 & V_\mathrm{RS} & H_\mathrm{R} \end{pmatrix}\,, \tag{14}$$

where $H_{\mathrm{L(R)}}$ is the (infinite) Hamiltonian of the left (right) lead, H_S is the Hamiltonian of the scattering region and of finite size. $V_\mathrm{SL} = V_\mathrm{LS}^{+}$ and $V_\mathrm{SR} = V_\mathrm{RS}^{+}$ represent the coupling of the left and right lead to the scattering region. Since the leads are always chosen such that asymptotic eigenstates can be defined, the Hamiltonian of the isolated leads must contain some periodicity that facilitates calculating their Greens functions $g^\mathrm{R}_\mathrm{L,R}$. This can be done analytically for simple systems [1,33], for more complex situations the Greens function can be calculated numerically either by iteration [45,46] or semianalytical formulas [40,44,47]. Introducing the retarded self-energy $\Sigma^\mathrm{R} = \sum_{i=L,R} \; V_{\mathrm{S}i}\, g^\mathrm{R}_i\, V_{i\mathrm{S}}$, [1,33] the Greens function G_S of the scattering region is given by

$$G^\mathrm{R}_\mathrm{S} = \left(E - H - \Sigma^\mathrm{R}\right)^{-1}\,, \tag{15}$$

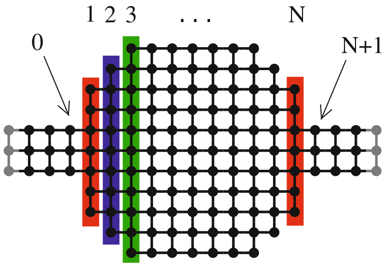
reminiscent of Eq. (4) but with an effective Hamiltonian $H + \Sigma^\mathrm{R}$.

The original infinite-dimensional problem has thus been reduced to a finite size matrix problem that can, in principle, be solved straight-forwardly on a computer. However, for any but rather small problems, the computational task of the direct inversion in Eq. (15) is prohibitive. Therefore, many algorithms make use of the *sparsity* of the Hamiltonian matrix in tight-binding representation – in particular they employ the property that this matrix can be written in block-tridiagonal form

$$H = \begin{pmatrix}
\ddots & & & & & & & & \\
H_\mathrm{L} & V_\mathrm{L} & & & & & & & \\
V_\mathrm{L}^\dagger & H_\mathrm{L} & H_{01} & & \ddots & & & & \\
 & H_{10} & H_{11} & H_{12} & & 0 & & & \\
 & & H_{21} & H_{22} & H_{23} & & \ddots & & \\
 & & & H_{32} & \ddots & & & & \\
 & \ddots & & & \ddots & H_{N-1N} & & & \\
 & & 0 & & H_{NN-1} & H_{NN} & H_{NN+1} & & \\
 & & & \ddots & & H_{N+1N} & H_\mathrm{R} & V_\mathrm{R} & \\
 & & & & & & V_\mathrm{R}^\dagger & H_\mathrm{R} & \\
 & & & & & & & & \ddots
\end{pmatrix}. \tag{16}$$

Here the index L(R) denotes the blocks in the left (right) lead, $1 \ldots N$ the blocks within the scattering region, and 0, $(N+1)$ the first block in the left (right) lead. Such a form arises naturally in the method of finite differences, when grid points are grouped into vertical slices according to their x-coordinates, as shown in Fig. 6, but also applies to any other sparse tight-binding Hamiltonians.

The block-tridiagonal form of the Hamiltonian is the foundation of several quantum transport algorithms, together with the fact that, according to Eq. (5) and (6), only the blocks $G^\mathrm{R}_{N+1\,0}$ and G^R_{00} of the Greens function G^R are needed for the calculation of transmission and reflection probabilities. The transfer matrix approach applies naturally to block-tridiagonal Hamiltonians, but becomes unstable for larger systems. However, a stabilized version has been developed by Usuki et al. [48,49]. In the dec-



Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 6

Schematic view of the recursive Greens function algorithm: the system is built up adding block by block

imation technique [50,51], the Hamiltonian of the scattering region is replaced by an effective Hamiltonian between the two leads by eliminating internal degrees of freedom. The contact block reduction method [52] calculates the full Greens function of the system using a limited set of eigenstates. The recursive Greens function (RGF) technique [53,54,55] uses Dyson's equation to build up the system's Greens function block by block. It has also been adapted to Hall geometries with four terminals [56] and to calculate non-equilibrium densities [57,58]. Furthermore, the RGF algorithm has been formulated to be suitable for parallel computing [59], and the modular recursive Greens function (MRGF) method is an extension to take advantage of special geometries, such as circles or rectangles [60,61].

Here we give a simple form of the RGF algorithm as described in [33,55]. The RGF method makes use of Dyson's equation

$$G = G_0 + G_0 V G \tag{17}$$

to add successively blocks to the system, as depicted in Fig. 7. Let $G^{\mathrm{R},(i)}$ denote the Greens function for the system containing all blocks $\geq i$. Then, at energy E, the Greens function $G^{\mathrm{R},(i)}$ is related to $G^{\mathrm{R},(i+1)}$ by

$$G^{\mathrm{R},(i)}_{i\,i} = \left(E - H_{i\,i} - H_{i\,i+1}\, G^{\mathrm{R},(i+1)}_{i+1\,i+1}\, H_{i+1\,i}\right)^{-1} \tag{18}$$

and

$$G^{\mathrm{R},(i)}_{N+1\,i} = G^{\mathrm{R},(i+1)}_{N+1\,i+1}\, H_{i+1\,i}\, G^{\mathrm{R},(i)}_{i\,i}\ . \tag{19}$$

Starting from $G^{\mathrm{R},(N+1)}_{N+1\,N+1} = g^{\mathrm{R}}_{\mathrm{R}}$, the surface Greens function of the right lead, N slices are added recursively, until $G^{\mathrm{R},(1)}$ has been calculated. The blocks of the Greens function of the full system necessary for transport are then given by

$$G^{\mathrm{R}}_{00} = \left(\left(g^{\mathrm{R}}_{\mathrm{L}}\right)^{-1} - H_{01}\, G^{\mathrm{R},(1)}_{11}\, H_{10}\right)^{-1} \tag{20}$$

and

$$G^{\mathrm{R}}_{N+1\,0} = G^{\mathrm{R},(1)}_{N+1\,1}\, H_{10}\, G^{\mathrm{R}}_{00}\ , \tag{21}$$

where $g^{\mathrm{R}}_{\mathrm{L}}$ is the surface Greens function of the left lead.

Each step of the algorithm performs inversions and matrix multiplications with matrices of size M_i. Since the computational complexity of matrix inversion and multiplications scales as ${M_i}^3$, the complexity of the RGF algorithm is $\propto \sum_{i=0}^{N+1} M_i^3$. Thus, it scales linearly with the "length" N, and cubically with the "width" M_i of the system.

While for certain geometries the RGF algorithm cannot compete with more specialized algorithms such as MRGF, it is very versatile and easily adapted to many situations, and is thus our method of choice. In the next section we will discuss matrix reordering techniques that improve the runtime of the RGF algorithm considerably and allow the treatment of arbitrary systems.

Matrix Reordering Strategies for Quantum Transport

Graph-theoretical Approaches to Matrix Reordering

As shown in the previous section, the structure of a Hamiltonian matrix H does influence the runtime of the RGF algorithm. Thus, the runtime of the algorithm can potentially be improved by reordering the matrix with a permutation P,

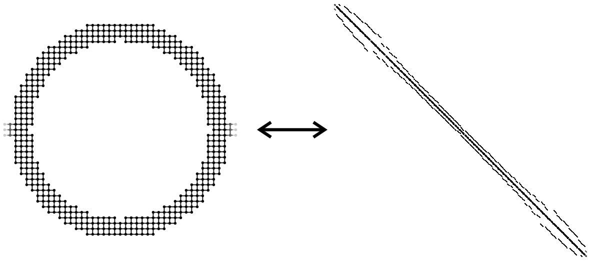
$$H' = P\, H\, P^{-1}\ . \tag{22}$$

At first glance, such an effort may seem pointless: For example, the block-tridiagonal structure naturally associated with a finite difference grid (as discussed in Sect. "Numerical Quantum Transport") leads to a sparse matrix with a small bandwidth, as shown in Fig. 8. However, as we show below, the choice of a suitable permutation P can still lead to a significant speed-up of the RGF algorithm.

For this we define a weight $w(H)$ associated with a given matrix H as

$$w(H) = \sum_{i=0}^{N+1} M_i^3 \quad \text{where } M_i \text{ is the size of block } H_{ii}\ . \tag{23}$$

Optimizing the matrix for the RGF algorithm is then equivalent to minimizing the weight $w(H)$. Since $\sum_{i=0}^{N+1} M_i = N_{\mathrm{grid}}$, where N_{grid} is the total number of grid points, $w(H)$ is minimal, if all M_i are equal, and $M_i = N_{\mathrm{grid}}/(N+2)$. Therefore, a matrix tends to have



Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 8

Example of a sparsity structure of a matrix associated with a finite difference grid. *Black dots* mark non-zero entries. The picture of the finite difference grid can also be interpreted as a graphical representation of a graph

small weight, if the number N of blocks is large, and all blocks are equally sized. The reordering problem of the matrix H is thus summarized as follows:

Matrix reordering problem: Find a reordered matrix H' such, that

1. H'_{00} and H'_{N+1N+1} are blocks given by the left and right leads (as required by the RGF algorithm),
2. H' is block-tridiagonal ($H'_{ij} \neq 0$, iff $j = i+1, i, i-1$),
3. the number N of blocks is as large as possible, and all blocks are equally sized.

These requirements define the optimization problem of reordering the matrix H. Usually, in such optimization problems finding the best solution deterministically is prohibitively expensive, and one has to resort to heuristic strategies.

In order to do that, we reformulate our matrix problem using concepts from graph theory. A *graph* G is a pair $G = (V, E)$, where V is a set of *vertices* i, and E a set of pairs of vertices $(i, j) \in V \times V$. Such a pair is called an *edge*. A graph is called *undirected*, if for every edge $(i, j) \in E$ also $(j, i) \in E$. Two vertices i and j are called *adjacent*, if $(i, j) \in E$. A graph can be visualized by drawing dots for each vertex i and lines connecting these dots for every edge (i,j). It should be noted, that all the pictures of finite difference grids shown so far can directly be interpreted as graphs . There is a natural one-to-one correspondence between graphs and the structure of sparse matrices. For a given $n \times n$ matrix H, we define a graph $G = (V, E)$ with $V = \{1, \ldots, n\}$ and $(i, j) \in E$ iff $H_{ij} \neq 0$. Thus, the symmetric zero–nonzero structure of Hermitian matrices, as considered in quantum transport, leads to associated undirected graphs. An example of such a correspondence between a graph and a matrix has already been shown in Fig. 8. With respect to matrices, graphs are also very convenient for storing and handling sparse matrix data structures on a computer.

In terms of graph theory, matrix reordering corresponds to renumbering the vertices of a graph. Since we are only interested in reordering the matrix in terms of matrix blocks (the order within a block should not matter too much), we define a *partitioning* of G as a set $\{V_i\}$ of disjoint subsets $V_i \subset V$ such that $\bigcup_i V_i = V$ and $V_i \cap V_j = \emptyset$ for $i \neq j$. Using these concepts, we can now reformulate the original matrix reordering problem into a graph partitioning problem:

Graph partitioning problem: Find a partitioning $\{V_0, \ldots, V_{N+1}\}$ of G such that:

1. V_0 and V_{N+1} contain the vertices belonging to left and right leads,
2. there are edges between V_i and V_j iff $j = i+1, i, i-1$ (block-tridiagonality),
3. the number of sets V_i is as large as possible and all sets V_i have the same cardinality. Such a partitioning with all V_i equally sized is called *balanced*.

A partitioning that meets requirement 2 is called a *level set* with levels V_i and appears commonly as an intermediate step in algorithms for bandwidth reduction of a matrix [62,63,64,65]. These algorithms seek to find a level set of minimal width, i. e. $\max_{i=0\ldots N+1} |V_i|$ as small as possible which is equivalent to requirement 3. The major difference between our graph partitioning problem and the bandwidth reduction algorithms is requirement 1: In our case the start and end blocks are given by the geometry of the system, whereas in the bandwidth reduction methods these can be chosen freely. The implications of this difference will be discussed below.

The bandwidth reduction algorithms start with the observation that a *breadth first search* (BFS) starting from any vertex in the graph creates a level set: In our situation, the BFS starts from level V_0 of the left lead. Then, successively for $i = 0, 1, 2, \ldots$, all vertices adjacent to V_i that have not been assigned to a level yet are placed in V_{i+1}. This construction ensures that each level V_i only has edges connecting to vertices in $V_{i+1,i,i-1}$ and thus ensures block-tridiagonality. The search stops, once a vertex adjacent to the right lead is encountered, and all unassigned vertices are placed into the last level V_N. The number of BFS steps determines therefore the maximum number N of blocks and is related to the minimum distance between left and right lead in the graph. However, this construction of the level set also suffers from a serious problem: Depending on the distance between the leads, the last level V_N can potentially contain a large number of vertices leading to a very unbalanced partitioning. In the bandwidth reduction methods, the first and the last vertex are chosen to have (to a good approximation) maximum distance, and thus this problem does not occur there. Hence, conventional bandwidth reduction algorithms can only be applied to quantum transport problems, if the leads are —in terms of the underlying graph —furthest apart.

In this study, we will consider two reordering algorithms: First, the Gibbs–Poole–Stockmeyer (GPS) algorithm [65], a widely used bandwidth reduction algorithm. The GPS algorithm combines the level sets originating from a BFS from both left and right lead to give an optimized level set. Due to the limitations discussed above, it can only be used efficiently for systems with leads far apart. To overcome this difficulty partly, we also propose a second algorithm, later referred to as *BFS partitioning*: The system is bisected recursively by means of a simultaneous BFS from left and right leads. In a bisection process, vertices that are closer (as given by the number of BFS steps) to the left (right) lead are placed into the left (right) level. The resulting two levels are then further bisected recursively until the final level set has been constructed. This algorithm tries to avoid an unbalanced partitioning, as every step tries to create a balanced bisection. We have found this global approach —as opposed to the local approach in the BFS —to yield balanced partitionings for systems where there are only few local minima in the weight $w(H)$. For general systems, a more sophisticated method should be used [66].

Obviously, reordering the matrix will only improve the runtime of the RGF algorithm, if the overhead of the reordering process is small compared to the actual transport calculation. Because of this reason, applying general optimization algorithms to the matrix reordering problem is not an option. Instead, heuristics designed for graph problems give much better performance. The GPS algorithm scales linearly with the number of edges $|E|$, and since in a tight-binding representation $|E| \propto N_{\text{grid}}$, its computational complexity is $\mathcal{O}(N_{\text{grid}})$, whereas the BFS partitioning algorithm scales as $\mathcal{O}(N_{\text{grid}} \log N_{\text{grid}})$. In any case, the scaling is much more favorable than that of the RGF algorithm, $\propto \sum_{i=0}^{N+1} M_i^3$, so that for systems of typical size the overhead of the reordering process becomes negligible, as we will demonstrate in the next section.

Example: Ring Geometry

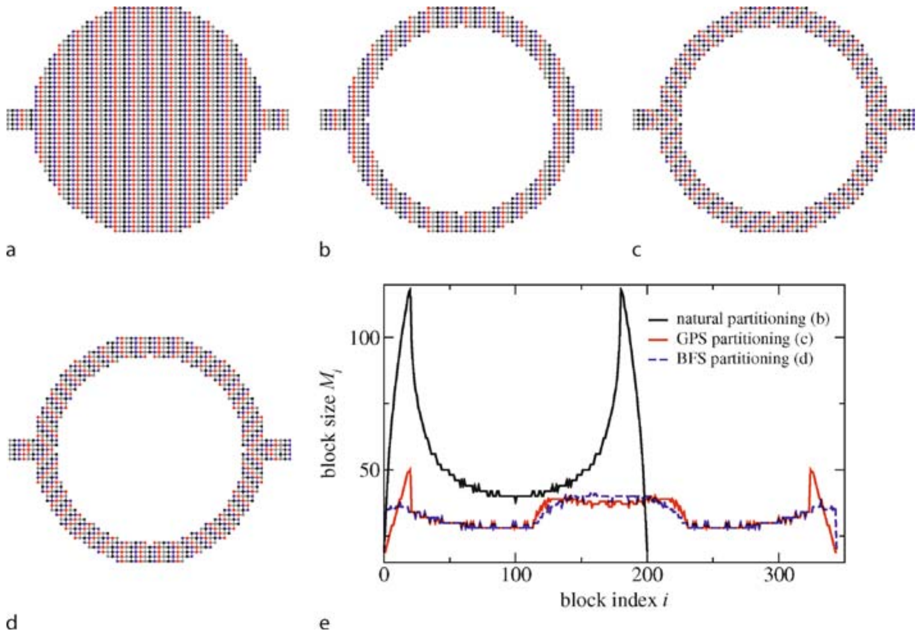
In order to demonstrate the performance of the algorithms discussed above, we consider their application to a ring geometry in finite difference approximation. The performance of the RGF algorithm after matrix reordering is compared with the performance using the ordering that arises naturally in finite difference grids as shown in Fig. 6 (in the remainder referred to as *natural partitioning*).

In Fig. 9a–d we show four different approaches for calculations in a ring geometry. A ring can be treated as a circular cavity (see Fig. 9a), with a large potential on the lattice points inside the inner ring diameter. This approach is easier to implement than a real ring but less efficient, as a large additional number of lattice points enters the calculation. However, this approach has been used frequently in the past, and therefore we also consider its performance. Transport calculations in a real ring require somewhat more bookkeeping because of the non-trivial geometry, but can be easily done describing the grid as a graph. For the circular cavity, we only consider natural partitioning, as shown in Fig. 9a, for the ring we consider natural partitioning (Fig. 9b), GPS partitioning (Fig. 9c) and BFS partitioning (Fig. 9d).

The partitionings in Fig. 9c and d are dramatically different from the natural partitioning. The levels align mainly in vertical or diagonal directions as these are the preferred directions in the square lattice. The number of levels is increased with respect to the natural partitioning, as the distance between both leads is much larger than the number of vertical slices, leading to a larger number of blocks in the block-tridiagonal matrix, as can be seen from Fig. 9e. Both GPS and BFS partitioning lead to a drastically reduced block size with respect to the natural partitioning and the result is rather balanced. Though the actual partitionings in Fig. 9c and d look quite different, with respect to minimizing the weight $w(H)$ they are equally good. The BFS partitioner conforms to the geometric structure, as it puts vertices in levels according to their distance from the leads. Except for a small number of blocks in the beginning and the end of the block-tridiagonal matrix (see Fig. 9e), the GPS partitioner leads to an equally balanced structure, although the partitioning looks quite different. The GPS partitioner works well in this case, as the leads are almost at maximum distance in this ring structure.

We now apply the recursive Greens function algorithm from Sect. "Numerical Quantum Transport" to the different partitionings. In Fig. 10a we show the runtime of the algorithm as a function of the number of lattice points in the leads, which is also the number of lattice points across the arms of the ring. Note that in all cases the runtime includes both the time spent in calculating the matrix reordering and the time spent in the actual transport calculation.

The runtime scales similarly in all cases, as this is the scaling of the RGF algorithm. Nevertheless, the runtimes of the different approaches can differ by a factor that is significant. As expected, the circular cavity is slowest, due



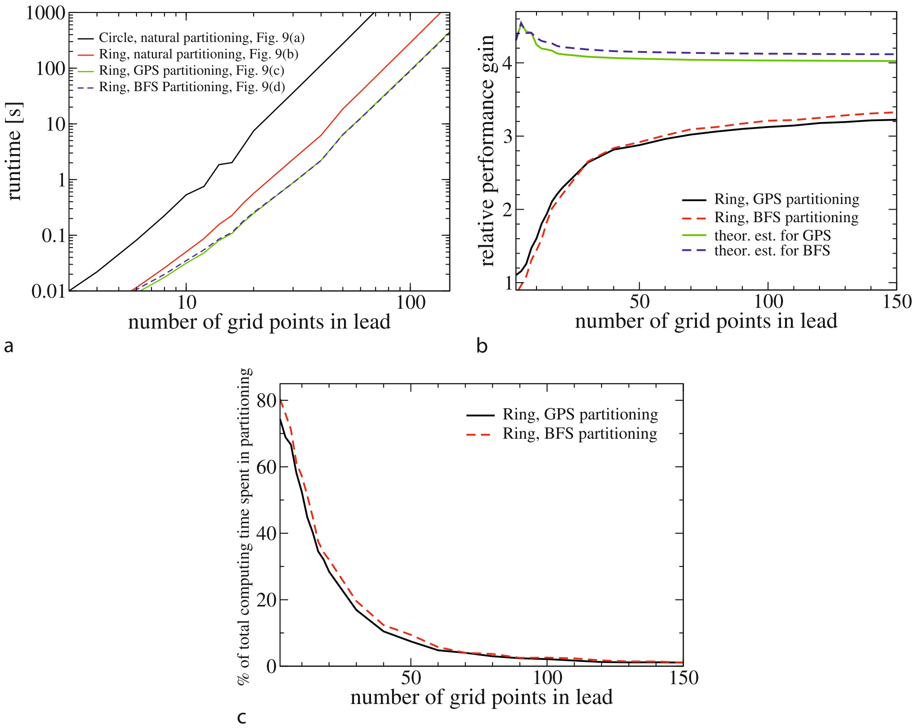
Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 9

Partitioning of the different systems considered in the performance study. a Circular cavity in natural partitioning, where the ring structure is enforced by a potential term in the middle of the cavity, b ring in natural partitioning, c ring in GPS partitioning and d ring in BFS partitioning. In a–d, vertices belonging to the same level in the partitioning are marked with the *same color*, different levels are marked in *alternating colors*. Note that, in order to reveal the partitioning structure more clearly, the grids shown here are much smaller than in a typical calculation. e Size M_i of the blocks H_{ii} in the block-tridiagonal matrix for a ring with 20 lattice points in the leads for natural, GPS and BFS partitioning (the circular cavity is not shown here)

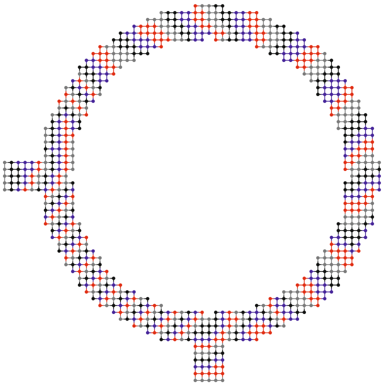
to the extra number of lattice points. GPS and BFS partitionings lead to a rather similar performance that is *significantly* better than the ring in natural partitioning. It outperforms the circular cavity even by a factor of up to 100. In the remainder, we examine the performances of the ring for different partitionings in more detail and leave out the circular cavity. In Fig. 10b we show the relative performance gain of GPS and BFS partitionings over the natural partitioning. Except for the smallest of systems that are too small to be useful in practice, the performance of GPS and BFS partitionings is better than the natural partitionings. Even for moderately sized systems the performance gain through the matrix reordering is approximately 3, with the BFS partitioner being slightly better than the GPS partitioner. In Fig. 10b we also show estimates of the performance gain calculated from the weights $w(H)$ of the different partitionings. These estimates predict a performance gain of approximately 4. For small system sizes, we see deviations from these estimates because of the overhead of the partitioning process, for larger system sizes we almost reach the estimated value. On modern computer architectures, runtime does not only depend on the number of arithmetic operations [67], and thus we do not achieve the full theoretical potential of the reordering, yet still significant improvements. In Fig. 10c we show the fraction of time spent in calculating the matrix reordering with respect to the total computation time, and as expected the overhead becomes negligible already for moderately sized systems. It should be noted that in actual calculations the partitioning is commonly only done once, and transport calculations can be done repeatedly with the same partitioning: Usually one is interested in transport properties depending on some parameters, and these generally do not change the *structure* of the Hamiltonian matrix but only the values of the respective entries. In this case, the partitioning overhead becomes even more irrelevant.

It should be emphasized, that for all the situations, the *same* transport code was used. In addition to the significant speedup through the graph techniques considered here, the abstraction of the system through graph structures allows for very generic transport codes. This is an additional strength of this approach, as the well-established RGF algorithm is thus readily applied to arbitrary systems that would require special treatment otherwise, such as a scattering region with perpendicular leads, as depicted in Fig. 11.

Of course, for any system, an algorithm designed for that special system will probably outperform generic ap-



Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 10
Performance of the partitionings (for rings, Fig. 9): a runtime of the different systems as a function of the number of lattice points in the leads, i. e. as a function of system size. The calculations were performed on a Core2Duo T5500 processor and 1GB of memory, and the runtime includes both partitioning overhead and transport calculation. b Performance gain of GPS and BFS partitionings with respect to natural partitioning and c overhead of the matrix reordering as a function of system size



Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 11
BFS partitioning of a ring with perpendicular leads. Note that in this case the two leads are closer together and thus the number of blocks is reduced. Therefore the block sizes tend to be larger than in the previous examples

proaches. However, the combination of matrix reordering and RGF algorithm can be applied to arbitrary systems and is thus probably the most versatile transport approach. In addition, all the algorithms relying on the block-tridiagonal structure of the Hamiltonian mentioned in Sect. "Numerical Quantum Transport" can benefit from these matrix reordering strategies.

Modern transport calculations tend to be more and more complex and time-consuming. For example, an electronic calculation including the electron spin typically takes $2^3 = 8$ times longer than a calculation on spinless electrons. Furthermore, calculations including disorder involve averages over many disorder configurations. Any increase in computation speed is therefore beneficial, and the added versatility through matrix reordering methods makes these techniques even more useful.

Spin Filtering in Nanostructures

In the introductory example in Sect. "Introduction" it was shown how to realize systems that work as spin switches making use of the interference of wavefunctions propagating clockwise and counterclockwise in Aharonov–Bohm rings with SO-interaction. However, several other device proposals have been put forward utilizing different concepts in order to achieve spin filtering in mesoscopic systems.

A very prominent category is transverse focusing of ballistic electrons/holes in two dimensional electron/hole gases (2DEGs/2DHGs) [68]. In materials that exhibit SO interaction the cyclotron radius of ballistic electrons/holes due to a magnetic field perpendicular to the 2DEG/2DHG depends on the spin state of the charge carriers. Therefore, it is possible to filter out either spin-up or spin-down electrons by an appropriate arrangement of quantum point contacts and a proper choice of the perpendicular magnetic field. Apart from several theoretical treatments of this topic [69,70,71], spin filtering by transverse focusing has already been experimentally verified in a GaAs-based 2DHG [72]. In related experiments, spin-polarized currents in 2DEGs/2DHGs were detected by a setup consisting of point contacts and making use of transverse focusing of the charge carriers [73]. With such a detector it was possible to confirm the presence of spin-polarized currents emitted from mesoscopic quantum dots utilizing quantum interference at high in-plane magnetic fields [74] and from quantum point contacts, which were either made spin sensitive with high in-plane magnetic fields [73] or showed a pronounced "0.7-anomaly" [75].

A further appealing approach to filter spins are three terminal structures, that act as mesoscopic Stern–Gerlach type spin filters [76]. In these devices one of the leads injects spin-unpolarized current and, after passing a region where the spin-degeneracy is lifted, oppositely-polarized output currents exit through the other two leads. This separation of up and down spins can be accomplished, e. g., by utilizing Rashba SO interaction [77,78,79].

However, three terminals are not required to create spin polarized currents. Many devices, as e. g. the AB-ring presented in Sect. "Introduction", typically rely on two terminals only, where transport through tailored geometries with SO interaction [80,81,82], magnetic fields [83,84,85,86] or a combination of both [87] can result in a significant spin filter effect.

As a representative example for the methods mentioned above, in the present section we present spin filtering due to Rashba SO interaction in quantum wires connected to two terminals. We consider a quantum wire in y-direction realized in a 2DEG in the (x, y) plane connected to two nonmagnetic leads. The Hamiltonian of the system, with spatially dependent Rashba SO interaction is given by

$$H_0 = \frac{\hat{p}^2}{2m^*} + \frac{\alpha(x)}{2\hbar}(\hat{\sigma}_x \hat{p}_y - \hat{\sigma}_y \hat{p}_x) + (\hat{\sigma}_x \hat{p}_y - \hat{\sigma}_y \hat{p}_x)\frac{\alpha(x)}{2\hbar} + V(x, y) + U_B(x, y) \, . \tag{24}$$

Here $V(x, y)$ is the lateral transverse confinement potential forming the quantum wire, while $U_B(x, y)$ is an additional electrostatic potential in the system, e. g., realized by gate voltages. Furthermore, $\hat{\sigma}_i$ denote the Pauli spin matrices, and m^* is the effective electron mass of the semiconducting material. We consider a constant Rashba SO interaction strength $(= \alpha_C)$ in the central region of the system, which is connected to two semi-infinite leads on opposite sides, where $\alpha(x)$ is chosen to be zero avoiding ambiguities in the definition of spin current that arise for leads with SO interaction [88]. In order not to introduce additional effects due to an abrupt jump in the SO coupling strength, the parameter $\alpha(x)$ is changed sufficiently smooth from zero to α_C between the leads and the central region. For the numerical calculations presented in the next two sections the Hamiltonian (24) is discretized as shown in Sect. "Numerical Quantum Transport" yielding a tight-binding Hamiltonian on a square grid.

In the rest of this section we investigate the transport properties in the linear response regime due to an infinitesimal bias voltage δU applied between the left and right contact. The charge (C) and spin (S) current in the Landauer–Büttiker formalism are then given by

$$I_{C/S} = G_{C/S} \, T_{C/S} \, \delta U \, ,$$

where $G_C = e^2/h$ and $G_S = e/4\pi$ are the conductance quanta of charge and spin respectively. Since, opposite to charge current, the spin current can be different in the right and left lead [85], here we choose to evaluate the respective currents in the right lead. Then the transmission probabilities $T_{C/S}$ at the Fermi energy are given by

$$\begin{aligned} T_C &= T_{+,+} + T_{+,-} + T_{-,+} + T_{-,-} \, , \\ T_S &= T_{+,+} + T_{+,-} - T_{-,+} - T_{-,-} \, , \end{aligned} \tag{25}$$

where $T_{\sigma,\sigma'} = \sum_{n \in R, n' \in L} |S_{n,\sigma;n',\sigma'}|^2$ is the probability for an electron, injected into the left (L) lead with spin state σ' to be transmitted to the right (R) lead and end up there in spin state σ. In the present and the following section we fix the spin quantization axis to the y-axis. The scattering matrix elements $S_{n,\sigma;n',\sigma'}$ and therefore also the spin resolved transmission probabilities $T_{\sigma,\sigma'}$ are evaluated using the recursive Greens function algorithm presented in Sect. "Numerical Quantum Transport" and "Matrix Reordering Strategies for Quantum Transport".

One general feature of Landauer transport in a quantum wire with SO interaction and non-magnetic leads is the absence of spin-polarized currents in a lead that supports only a single transversal mode. This property can be derived from the invariance of the system under the time-reversal operator $\hat{\mathcal{T}} = -\mathrm{i}\hat{C}\sigma_y$ [89], where $\hat{C}$ is the operator of complex conjugation. For a perfect quantum wire which is translationally invariant in the direction of transport all occupied transversal subbands transmit without reflection and spin polarization is not possible due to SO interaction. However, if backreflection, caused by deviations from a perfect quantum wire, is present, it is possible to observe spin-polarized currents in leads with at least two transversal channels. There the typical mechanism responsible for spin polarization is the mixing of spins from different transversal subbands due to the SO interaction.

In Eq. (24) this translational invariance in y-direction is already broken by the spatially varying SO interaction $\alpha(x)$ even if the quantum wire was perfect in y-direction otherwise, i. e. $V(x, y) = V(y)$ and $U_\mathrm{B}(x, y) = U_\mathrm{B}(y)$. However, if the region where $\alpha(x)$ is turned on/off is sufficiently long, reflection due to the change of $\alpha(x)$ is negligible.

There exist several device proposals relying on this mixing of spins from different transversal subbands due to x-dependent lateral confinement potentials $V(x,y)$ or other superimposed electrostatic potentials $U_\mathrm{B}(x, y)$. These device designs include, e. g., constrictions [80,90], lateral side pockets [81], or electrostatic barriers [82], to name only a few.

In most of those proposals, systems symmetric with respect to inversion of the x-coordinate were considered, i. e. $V(x, y) = V(-x, y)$, $U_\mathrm{B}(x, y) = U_\mathrm{B}(-x, y)$ and $\alpha(x) = \alpha(-x)$. Then the Hamiltonian (24) is left invariant upon application of the symmetry operation

$$\hat{\mathcal{P}} = -\mathrm{i}\,\hat{C}\hat{R}_x\hat{\sigma}_z\ , \tag{26}$$

where the operator $\hat{R}_x$ inverses the x-coordinate. The scattering wavefunctions inside the leads are changed by the operator $\hat{\mathcal{P}}$ in the following way: $\hat{R}_x$ exchanges the leads, i. e., a transversal mode index n is replaced by the corresponding mode index $\bar{n}$ in the other lead. The operator of complex conjugation transforms incoming (outgoing) states into outgoing (incoming) states with complex conjugated amplitude. Moreover, the combined effect of $\hat{C}\sigma_z$ is to rotate a spinor with the coordinates (θ, ϕ) on the Bloch sphere to the coordinates $(\theta, -\phi + \pi)$. Exploiting this invariance of the Hamiltonian one can derive the relation $S_{n,\sigma;n',\sigma'}(E) = S_{\bar{n}',\sigma';\bar{n},\sigma}(E)$ between the elements of the scattering matrix (see [85,89] for related expressions). This results in the equality of the spin flip transmissions $T_{+,-} = T_{-,+}$. Therefore, for those devices to be able to work as a spin filter, in view of Eq. (25) the spin conserving transmissions $T_{+,+}$ and $T_{-,-}$ need to be different.

As an example, in the following we consider Landauer transport through a Rashba SO quantum wire with a constriction. Similar calculations were carried out in [71,80] where it was shown, that this setup is able to produce a spin polarized current of sizeable quantity. It was conjectured, that the mechanism responsible for the spin polarization was the depletion of higher transversal modes of the wire and a subsequent spin dependent repopulation of those modes when traversing the constriction [80]. To experimentally observe the predicted spin polarization the use of a transverse electron focusing technique was suggested [71].

A typical grid (with lattice spacing a) used in the calculation for the symmetric point contact in a wire of width $W = 15a$ is shown in Fig. 12a, where the constriction of length $L_\mathrm{PC} = 10a$ is formed by hard-wall potentials:

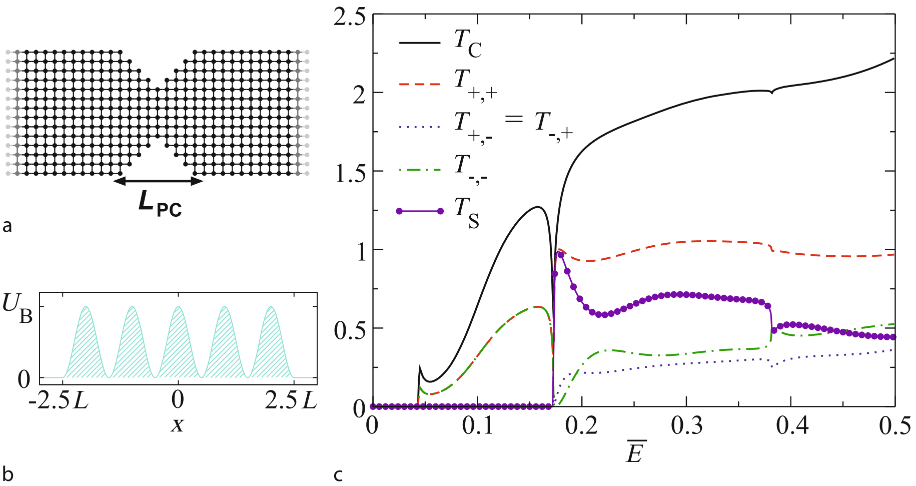
$$V(x, y) = \begin{cases} 0 & \text{for } C(x) < y < 15a - C(x) \\ \infty & \text{else} \end{cases}$$

with

$$C(x) = \begin{cases} 2.05a\left(1 - \cos\left(\frac{2\pi\left(x + \frac{L_\mathrm{PC}}{2}\right)}{L_\mathrm{PC}}\right)\right) & \text{for } |x| < \frac{L_\mathrm{PC}}{2} \\ 0 & \text{otherwise}\,. \end{cases} \tag{27}$$

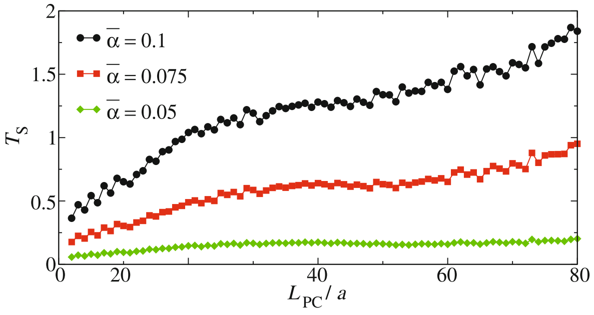
Additionally $U_\mathrm{B}(x, y)$ is set to zero. In Fig. 12c we present the relevant transmission probabilities with respect to the Fermi energy E for this system. There we observe that the total conductance T_C is reduced in comparison with that of a perfect quantum wire. In the latter case T_C exhibits sharp steps due to conductance quantization [91,92] which are washed out here due to tunneling processes through the constriction. Furthermore, for energies, where only a single transversal mode is supported in the quantum wire, the spin transmission vanishes as expected, i. e. $T_{+,+} = T_{-,-}$ for energies $\bar{E} \lesssim 0.175$. Also the relation $T_{+,-} = T_{-,+}$ is fulfilled as required by the symmetry of the setup. Finally, at energies where a new transversal mode opens up ($\bar{E}_2 \approx 0.18$, $\bar{E}_3 \approx 0.39$) dips in the transmission probabilities become apparent. Those dips can be explained by interference of localized states in the central region where $\alpha(x) = \alpha_\mathrm{C}$ and the scattering states in the quantum wire where $\alpha(x) = 0$ [93].

In order to study the influence of the adiabaticity of the constriction on the degree of spin polarization that can be extracted, in Fig. 13 we show T_S as a function of the length of the constriction L_PC for several values of α_C. For all of the curves we clearly observe an increase in spin transmission with increasing L_PC, in accordance with the mechanism suggested in [80]. There it was argued in the context of Landau–Zener transitions that the repopulation of higher transversal subbands will be more efficient for more



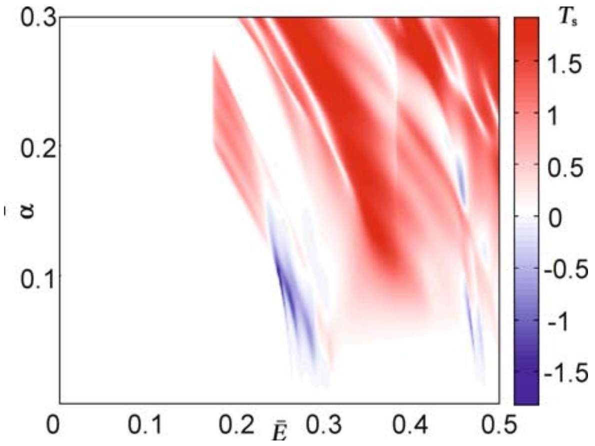
Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 12

Panel a The square lattice discretization of a quantum wire (width $W = 15a$) with a single constriction of length $L_{PC} = 10a$, see also Eq. (27). Panel b Periodic array of $N = 5$ electrostatic barriers with period length L and barrier height U_B. Panel c Charge T_C, spin T_S and spin resolved transmission probabilities $T_{\sigma,\sigma'}$ for the system depicted in panel a) and specified in the text at fixed SO interaction strength $\bar{\alpha} = [(m^* a)/\hbar^2]\,\alpha_C = 0.1$ with respect to the Fermi energy $\bar{E} = [(2m^* a^2)/\hbar^2]\,E$. The nth transversal mode in the wire opens at $\bar{E}_n = (\pi^2 n^2)/(W/a)^2$



Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 13

Spin transmission probability T_S at fixed injection energy $\bar{E} = 0.25$ within the second transversal mode for three different SO interaction strengths $\bar{\alpha} = 0.1$ (*black dots*), $\bar{\alpha} = 0.075$ (*red squares*) and $\bar{\alpha} = 0.05$ (*green diamonds*) with respect to the length of the constriction L_{PC}



Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 14

Spin transmission probability T_S plotted as a function of the Fermi energy $\bar{E}$ and SO interaction strength $\bar{\alpha}$ for a quantum wire with $N = 5$ electrostatic barriers of length $L = 10a$ and height $\bar{U}_{Barr} = [(2m^* a^2)/\hbar^2]\,U_{Barr} = 0.2$

adiabatic constrictions or barriers, resulting in a higher degree of spin polarization. For $\bar{\alpha} = [(m^* a)/\hbar^2]\,\alpha_C = 0.1$ the spin transmission even approaches the highest possible value $T_S = 2$. One drawback of the presented system is its restriction to unidirectional spin polarization. In agreement with the model of [80], Fig. 12 and 13 give evidence that $T_S \geq 0$ for the parameter range considered. This limitation to output current with fixed spin polarization direction restricts the usability of the spin filter to special purposes. A possible way to circumvent this constraint is the use of a periodic array of electrostatic barriers [82], which we now briefly investigate. Figure 14 shows the spin transmission of a straight hard-wall quantum wire ($C(x) = 0$ in Eq. (27)) subject to $N = 5$ electrostatic barriers,

$$U_B(x, y) = U_B(x) = \begin{cases} \frac{U_{Barr}}{2}\left(1 - \cos\left(\frac{2\pi\left(x + \frac{L}{2}\right)}{L}\right)\right) \\ \qquad\qquad \text{for } -N\frac{L}{2} < x < N\frac{L}{2} \\ 0 \quad \text{otherwise}\,, \end{cases}$$

(as shown in Fig. 12b). The spin transmission is plotted as a function of the Fermi energy and the SO interaction strength. Again, one observes $T_S = 0$ for energies below $\bar{E}_2$. Furthermore, different regions in parameter space exhibit opposite sign of T_S, enabling to change the sign of the output polarization, e. g., by tuning α_c via gate voltages [25]. This additional functionality is due to resonant tunneling, which is absent for a quantum wire with only a single constriction or barrier.

Pure Spin Current Generation

In the preceding sections we focused on mesoscopic geometries that exhibit functionalities such as spin filtering or spin switching when applying an external bias between the contacts in the system. In the case of a static dc bias in a two terminal geometry those spin currents arise due to different currents of spin-up and spin-down electrons flowing into the direction of the contact with the lower chemical potential. However, over the last few years a growing number of device proposals has been put forward, that exhibit the interesting feature of pure spin current generation, i. e. spin currents in the absence of net charge transport. This intriguing case appears, when the direction of motion of spin-up electrons is opposite to the direction of motion of spin-down electrons and both currents equal in absolute magnitude.

Among the devices sharing the prospect of creating pure mesoscopic spin currents are systems with more than two terminals realized in 2DEGs exhibiting Rashba [2,3] and/or the Dresselhaus [94] SO coupling. Here a charge current is induced in this multiterminal structure by the application of bias voltages between the different contacts of the system. However, if the voltage of one of the leads is adjusted to make it work as a voltage probe, no charge current passes this lead but a pure spin current can appear owing to the SO coupling present in the system. The basic working principle behind these devices is the so-called mesoscopic spin Hall effect [95], a version of the intrinsic spin Hall effect [27], where the typical system size does not exceed the phase coherence length of the electrons. The SO interaction leads to different transport dynamics for different spin species, which can be used to extract the desired pure spin currents by a clever design of the multiterminal geometry [21,96,97].

Complementary to the generation of pure spin current in multiterminal geometries, there are other types of devices not relying on the application of a net dc-bias. In spin pumping, the cyclic variation of two or more system parameters, such as e. g. gate voltages, induces spin-polarized currents at zero bias, where the induced charge current can be tuned to disappear, leaving pure spin currents. Several realizations of spin pumps in mesoscopic systems have been proposed, relying on SO interaction [98,99] or the Zeeman coupling of electrons to external magnetic fields [100]. The latter proposal has been experimentally confirmed [101] by detecting spin-polarized currents making use of a transverse electron focusing technique [73] mentioned in the previous section.

Complementary to pumps, ratchets only require a single driving parameter to achieve directed transport, and the current direction can be switched upon tuning external parameters such as temperature. In addition to the requirement of a broken spatial symmetry the ratchet has to be operated out of thermal equilibrium. The concept of particle ratchets, which has been addressed in numerous works [102], has recently been extended to systems called spin ratchets. To be specific, the mesoscopic spin ratchets proposed so far [82,85,103], are based on a quantum wire realized in a 2DEG. Between the two contacts attached to the quantum wire an ac bias voltage $U_R(t)$ is applied (rocking ratchet) with zero net (time-averaged) bias. Furthermore, in the central region of the quantum wire the spin degeneracy is lifted due to either SO interaction [82] or the Zeeman coupling to an external magnetic field [85,103]. Upon appropriate choice of the system geometry and tuning of the external driving the charge transported in the forward ($U_R > 0$) and backward bias ($U_R < 0$) situation can be made equal allowing for spin currents in the absence of net charge transport.

In the following we outline the model for the spin ratchets introduced in [82,85,103]. There, driving with a period t_0 is considered. It is implied, that this period is much larger than characteristic time scales related to the electron transport through the quantum wire. Therefore, the system is assumed to be in a steady state at every instance of time, and the Landauer–Büttiker approach to transport is used for the computation of the ratchet currents. To be specific, we consider an unbiased square wave driving $U_R(t) = U_0 \operatorname{sign}[\sin(2\pi t/t_0)]$, where $U_R(t)$ is restricted to the values $\pm U_0$. The net current is then given by the average of the steady-state currents in the two rocking situations (labeled $+U_0$ and $-U_0$ respectively) for both charge and spin,

$$\langle I_{C/S}(U_0)\rangle = \frac{I_{C/S}(+U_0) + I_{C/S}(-U_0)}{2} . \tag{28}$$

Since the spin ratchet effect requires nonlinear transport [103], i. e. finite bias voltages, the Hamiltonian (24) introduced in the previous section has to be extended to additionally include the effective electrostatic potential in the conductor due to the applied bias. Therefore, we add the term $H_R = eU_R g(x, y; U_R)$ to the Hamiltonian (24) yielding the full Hamiltonian at finite bias:

$$H = H_0 + H_R\,. \tag{29}$$

Furthermore at finite bias a generalized version of the expressions for charge and spin current valid at $U_R \neq 0$ has to be used. For coherent Landauer transport those currents can be obtained from an integration of the transmission probabilities over the Fermi window [1]. Finally, the averaged charge $\langle I_C\rangle$ and spin $\langle I_S\rangle$ currents can be written as [85]

$$\langle I_{C/S}(U_0)\rangle = \frac{G_{C/S}}{2e}\int_{E_C}^{\infty} dE\,\Delta f(E, U_0)\Delta T_{C/S}(E, U_0)\,.$$

Here E_C is the energy of the conduction band edge and $\Delta f(E, U_0) = [f(E, E_F + eU_0/2) - f(E, E_F - eU_0/2)]$ is the difference between the Fermi functions of the leads at bias voltage U_0, defining the Fermi window. The averaged charge/spin transmission is just the difference between the steady state transmissions in the two rocking situations:

$$\Delta T_{C/S}(E, U_0) = T_{C/S}(E, +U_0) - T_{C/S}(E, -U_0)\,. \tag{30}$$

Considering the Hamiltonian (29) we now show under what conditions the net charge transported after one full rocking period is zero, i. e., $\langle I_C(U_0)\rangle = 0$. If the electrostatic potentials $V(x, y)$, $U_B(x, y)$ and the Rashba SO strength $\alpha(x)$ are invariant under inversion of the x-coordinate,

$$\begin{aligned} V(x, y) &= V(-x, y)\,,\\ U_B(x, y) &= U_B(-x, y)\,,\\ \alpha(x) &= \alpha(-x)\,, \end{aligned} \tag{31}$$

it is appropriate to assume that the electrostatic potential distribution due to the finite applied voltage $g(x, y; U_R)$ also possesses this symmetry. Then the total Hamiltonian (29) is invariant under the action of the symmetry operation $\hat{\mathcal{P}} = -i\hat{C}\hat{R}_U\hat{R}_x\sigma_z$ where R_U switches the sign of the bias voltage ($\pm U_0 \leftrightarrow \mp U_0$), yielding the relation

$$T_{\sigma,\sigma'}(E, \pm U_0) = T_{\sigma',\sigma}(E, \mp U_0)$$

between the spin-resolved transmission probabilities in the two rocking situations [85]. Inserting this relation into Eq. (30), we observe that the expression for the net charge transmission ΔT_C is zero, resulting in vanishing net charge current. Furthermore it can be used to simplify the expression for the net spin current:

$$\begin{aligned}\langle I_S(U_0)\rangle = &\frac{G_S}{e}\int_{E_C}^{\infty} dE\,\Delta f(E; U_0)\\ &\times [T_{+,-}(E, +U_0) - T_{-,+}(E, +U_0)]\,.\end{aligned}$$

At $U_0 = 0$ the Hamiltonian (29) reduces to Eq. (24), which is invariant under the operation of Eq. (26), yielding $T_{+,-}(E, 0) = T_{-,+}(E, 0)$. This absence of net spin current $\langle I_S(U_0 = 0)\rangle = 0$ in the linear response regime is in agreement with the theoretical prediction [85]. However, for finite rocking voltages $U_0 \neq 0$ the additional potential introduced via H_R breaks this symmetry and therefore enables different spin flip transmissions and thus a resulting net spin current.

We now turn our attention to the quantum wire shown in Fig. 12a. For this system, which exhibits the symmetries of Eq. (31), we perform numerical calculations at finite bias U_0, in order to confirm its operability as a spin ratchet. In general, the function $g(x, y; U_R)$ has to be obtained by self-consistently solving the Schrödinger and Poisson equation of the system. However, in the present treatment we make use of a simple model for $g(x, y; U_R)$ assuming a linear voltage drop in the region where the point contact is formed in the quantum wire:

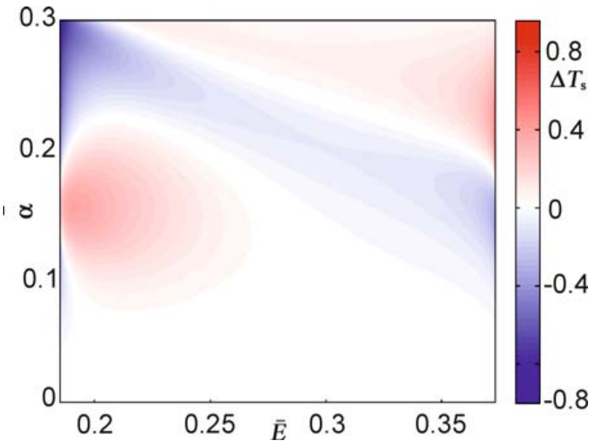
$$g(x, y; U_R) = g(x) = \begin{cases} \frac{1}{2} & \text{for } x < -\frac{L_{PC}}{2}\,,\\ -\frac{x}{L_{PC}} & \text{for } -\frac{L_{PC}}{2} < x < \frac{L_{PC}}{2}\,,\\ -\frac{1}{2} & \text{for } x > \frac{L_{PC}}{2}\,. \end{cases}$$

It is well known that a constriction in a quantum wire acts as an effective potential barrier constituting a region where the voltage applied across the wire is likely to drop. Since the bias voltages we consider are small compared to the energy shift introduced by the constriction, this assumption of a linear voltage drop should be an appropriate approximation for the actual distribution of the electrostatic potential in this wire [104]. Self-consistent calculations have confirmed that this approximation is valid [105].

In Fig. 15 we plot the net spin transmission ΔT_S as a function of $\bar{\alpha}$ and the injection energy in the range, where both leads support two transversal modes. We observe that $|\Delta T_S|$ reaches values of up to 0.9 in the parameter range shown. Furthermore, for a given value of injection energy, the sign of ΔT_S can be switched by changing α_C. Since the strength of the Rashba SO interaction α_C can be tuned via gate voltages [25] the presented system offers also the possibility for experimentally steering and switching the spin current direction.

Future Directions

In the present work we outlined general theoretical and computational concepts of coherent spin-dependent transport at low temperatures and focussed, with regard to numerical examples and possible experimental realiza-



Spin-Polarized Quantum Transport in Mesoscopic Conductors, Figure 15

Net ratchet spin transmission probability $\Delta T_S(U_0) = 2\left(T_{+,-}(+U_0) - T_{-,+}(+U_0)\right)$ for a stripe with a junction (see text) presented as a function of injection energy $\bar{E}$ and SO interaction strength $\tilde{\alpha}$ at finite applied voltage $eU_0 = 0.02\,\hbar^2/(2m^* a^2)$. Note the sign change in the spin transmission upon tuning the SO coupling

tions, onto ballistic two-dimensional nanostructures based on non-magnetic high-mobility semiconductors.

In order to experimentally achieve high spin polarizations and reasonable spin currents, if possible at room temperature, broad efforts are made to investigate and design novel materials for spintronics. Here, prominent and promising examples, both with respect to fundamental physics and possible applications, are magnetic semiconductors such as GaMnAs [106] or semimagnetic materials with huge g-factors, for instance HgTe [107]. Charge transport in these materials is based on holes. However, relatively few theoretical papers deal with phase coherence effects for hole (spin) transport, though the rich band structure and the interplay between heavy and light hole (or electron- and hole-like) degree of freedoms promise interesting additional features.

The theoretical methods for quantum transport, presented here in the context of mesoscopic systems, are also applied and extended to treat transport in a further prospective field, namely through single-molecule junctions [108], for instance (break) junctions with a molecule bridging the gap between two leads or scanning tunneling microscope measurements of tunnel current through molecules at surfaces. In *Molecular Spintronics* [44,109] spin effects in transport through molecules are addressed. This subfield of spin electronics is still in its infancy. On the computational side these systems pose considerable problems since an adequate approach requires an appropriate description of the electronic and possibly vibrational properties of the molecule including the coupling to and effects of the leads. Whether (spin) DFT calculations for such an embedded molecule, combined with Landauer-type transport calculations, are appropriate, remains to be an issue, in particular if charging or non-equilibrium effects are involved.

As a further future direction we expect that spin transport in graphene, monolayers of graphite, may evolve as another future research line. After its experimental discovery in 2004 [110], graphene has gained much experimental and huge theoretical attention owing to its many exotic properties such as the massless charge carriers, internal spin-like degree of freedoms and unconventional transport characteristics. Also first experiments on graphene-based nanoconductors, e. g., measurements of the Aharonov–Bohm effect in graphene rings [111], are on their way. Graphene is also viewed as a prospective candidate for spin-electronics, since the spin decoherence and spin relaxation times in graphene are expected to be long [112,113]. Recent promising experiments already succeeded in injecting spins from ferromagnetic metallic contacts into graphene, although the conductance mismatch between graphene and the ferromagnetic leads is expected to suppress the efficiency. Recent theoretical proposals predict efficient spin injection into bulk graphene from graphene ribbons employing the occurrence of current-carrying spin-polarized edge states in the ribbons [114].

Acknowledgments

Parts of the results presented are based on previous work together with D. Bercioux, D. Frustaglia, and A. Pfund. We further thank I. Adagideli, M. Grifoni and D. Weiss for useful discussions. Stability and Feedback Stabilization

EDUARDO D. SONTAG

New Brunswick, USA

Article Outline

Glossary

Stability A globally asymptotically stable equilibrium is a state with the property that all solutions converge to this state, with no large excursions.

Stabilization A system is stabilizable (with respect to a given state) if it is possible to find a feedback law that renders that state a globally asymptotically stable equilibrium.

Lyapunov and control-Lyapunov functions A control-Lyapunov functions is a scalar function which decreases along trajectories, if appropriate control actions are taken. For systems with no controls, one has a Lyapunov function.

Definition of the Subject

The problem of stabilization of equilibria is one of the central issues in control. In addition to its intrinsic interest, it represents a first step towards the solution of more complicated problems, such as the stabilization of periodic orbits or general invariant sets, or the attainment of other control objectives, such as tracking, disturbance rejection, or output feedback, all of which may be interpreted as requiring the stabilization of some quantity (typically, some sort of "error" signal). A very special case, when there are no inputs, is that of stability.

Introduction

This article discusses the problem of stabilization of an equilibrium, which we take without loss of generality to be the origin, for a finite-dimensional system $\dot{x} = f(x, u)$. The objective is to find a *feedback law* $u = k(x)$ which renders the origin of the "closed-loop" system $\dot{x} = f(x, k(x))$ globally asymptotically stable. The problem of stabilization of equilibria is one of the central issues in control. In addition to its intrinsic interest, it represents a first step towards the solution of more complicated problems, such as the stabilization of periodic orbits or general invariant sets, or the attainment of other control objectives, such as tracking, disturbance rejection, or output feedback, all of which may be interpreted as requiring the stabilization of some quantity (typically, some sort of "error" signal). A very special case (when there are no inputs u) is that of stability.

After setting up the basic definitions, we consider *linear* systems. Linear systems are widely used as models for physical processes, and they also play a major role in the general theory of local stabilization. We briefly review pole assignment and linear-quadratic optimization as approaches to obtaining feedback stabilizers.

In general, there is a close connection between the existence of continuous stabilizing feedbacks and smooth *control-Lyapunov functions*, (cfl's), which constitute an extension of the classical concept of Lyapunov functions from dynamical system theory. We discuss the role of clf's in design methods and "universal" formulas for feedback controls.

For nonlinear systems, it has been known since the late 1970s that, in general, there are topological obstructions to the existence of even continuous stabilizers. We review these obstructions, using tools from degree theory.

Finally, we turn to discontinuous stabilization and the associated issue of defining precisely a "solution" for a differential equation with discontinuous right-hand side. We introduce techniques from nonsmooth analysis and differential games, in order to deal with discontinuous controllers. In particular, we discuss the effect of measurement errors on the performance of such controllers.

Preliminaries

In this article, we restrict attention to continuous-time deterministic systems whose states evolve in finite-dimensional Euclidean spaces $\mathbb{R}^n$. (This excludes many other equally important objects of study in control theory: systems which evolve on infinite dimensional spaces and are described by PDE's, systems evolving on manifolds which serve to model state constraints, discrete-time systems described by difference equations, and stochastic systems, among others.) In order to streamline the presentation, we suppose throughout that controls take values in $\mathcal{U} = \mathbb{R}^m$ (constraints in controls would lead to proper subsets $\mathcal{U}$). A *control* (other names: *input*, *forcing function*) is any measurable locally essentially bounded map $u(\cdot)\colon [0, \infty) \to \mathcal{U} = \mathbb{R}^m$. In general, we use the notation $|x|$ for Euclidean norms, and use $\|u\|$ to indicate the essential supremum of a function $u(\cdot)$. For basic terminology and facts about control systems, see [25].

Given a map $f\colon \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$ which is locally Lipschitz and satisfies $f(0, 0) = 0$, we consider the associated forced system of ordinary differential equations

$$\dot{x}(t) = f(x(t), u(t)) \,. \tag{1}$$

The maximal solution $x(\cdot)$ of (1) which corresponds to a given initial state $x(0) = x^0$ and to a given control u is defined on some maximal interval $[0, t_{\max}(x^0, u))$, and is denoted by $x(t, x^0, u)$. In the special case when f does not depend on u, we have an unforced system, or system with no inputs

$$\dot{x}(t) = f(x(t)) \,. \tag{2}$$

Unforced systems are associated to a controlled system (1) in two different ways. The first is when one substitutes a feedback law $u = k(x)$ in (1) to obtain a "closed-loop" system $\dot{x} = f(x, k(x))$. The second is when one considers instead the autonomous system $\dot{x} = f(x, 0)$ which models the behavior of (1) in the absence of any controls. All definitions stated for unforced systems are implicitly applied also to systems with inputs (1) by setting $u \equiv 0$; for instance, we define the global asymptotic stability (GAS) property for (2), but we say that (1) is GAS if $\dot{x} = f(x, 0)$ is. For systems with no inputs (2) we write just $x(t, x^0)$ instead of $x(t, x^0, u)$.

Stability and Asymptotic Controllability Stability is one of the most important objectives in control theory, because a great variety of problems can be recast in stability terms. This includes questions of driving a system to a desired configuration (e. g., an inverted pendulum on a cart, to its upwards position), or the problem of tracking a reference signal (such as a pilot's command to an aircraft). We focus in this talk on global asymptotic stabilization.

Recall that the class of $\mathcal{K}_\infty$ functions consists of all $\alpha\colon \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ which are continuous, strictly increasing, unbounded, and satisfy $\alpha(0) = 0$. The class of $\mathcal{KL}$ functions consists of those $\beta\colon \mathbb{R}_{\geq 0} \times \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ with the properties that

(1) $\beta(\cdot, t) \in \mathcal{K}_\infty$ for all t, and
(2) $\beta(r, t)$ decreases to zero as $t \to \infty$.

We will also use $\mathcal{N}$ to denote the set of all nondecreasing functions $\sigma\colon \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$. Expressed in terms of such comparison functions, the property of *global asymptotic stability (GAS)* of the origin for a system with no inputs (2) becomes:

$$(\exists \beta \in \mathcal{KL}) \quad |x(t, x^0)| \leq \beta\left(|x^0|, t\right) \quad \forall x^0\,, \forall t \geq 0\,.$$

This definition is equivalent to a more classical "ε-δ" definition usually provided in textbooks, which defines GAS as the combination of stability and global attractivity. For one implication, simply observe that

$$|x(t, x^0)| \leq \beta\left(|x^0|, 0\right)$$

provides the stability (or "small overshoot") property, while

$$|x(t, x^0)| \leq \beta\left(|x^0|, t\right) \underset{t \to \infty}{\longrightarrow} 0$$

gives attractivity. The converse implication is an easy exercise.

More generally, we define what it means for the system with inputs (1) to be (open loop, globally) *asymptotically controllable (AC)* (to the origin). The definition amounts to requiring that for each initial state x^0 there exists some control $u = u_{x^0}(\cdot)$ defined on $[0, \infty)$, such that the corresponding solution $x(t, x^0, u)$ is defined for all $t \geq 0$, and converges to zero as $t \to \infty$, with "small" overshoot. Moreover, we wish to rule out the possibility that $u(t)$ becomes unbounded for x near zero. The precise formulation is as follows.

$$(\exists \beta \in \mathcal{KL})(\exists \sigma \in \mathcal{N}) \quad \forall x^0 \in \mathbb{R}^n \exists u(\cdot)\,,\ \|u\| \leq \sigma\left(\left|x^0\right|\right),$$

$$|x(t, x^0, u)| \leq \beta\left(|x^0|, t\right) \quad \forall\, t \geq 0\,.$$

In particular, (global) asymptotic stability amounts to the existence of $\beta \in \mathcal{KL}$ such that $|x(t, x^0, u)| \leq \beta\left(|x^0|, t\right)$ holds for all $t \geq 0$. A very special case is that of *exponential* stability, in which an estimate of the type $|x(t, x^0, u)| \leq M\mathrm{e}^{-\lambda t}|x^0|$ holds. For linear systems (see below), asymptotic stability and exponential stability coincide. It is a puzzling fact that for general systems, one can find continuous coordinate changes that make asymptotically stable systems exponentially stable [8,13] (a fact of little practical utility, since finding such coordinate changes is as hard as establishing stability to being with).

Feedback Stabilization A map $k\colon \mathbb{R}^n \to \mathcal{U}$ is a *feedback stabilizer* for the system with inputs (1) if k is locally bounded (that is, k is bounded on each bounded subset of $\mathbb{R}$), $k(0) = 0$, and the closed-loop system

$$\dot{x} = f(x, k(x)) \tag{3}$$

is GAS, i. e. there is some $\beta \in \mathcal{KL}$ so that $|x(t)| \leq \beta\left(|x(0)|\,, t\right)$ for all solutions and all $t \geq 0$. (A technical difficulty with this definition lies the possible lack of solutions of (1) when k is not regular enough. We ignore this for now, but will most definitely return to this issue later.)

For example, if (1) is a model of an undamped spring/mass system, where u represents the net effect of external forces, one obvious way to asymptotically stabilize the system is to introduce damping. In control-theoretic terms, this means that we choose $u(t) = k(x(t))$ to be a negative linear function of the velocity. Physically, one may implement a feedback controller by means of an analog device. In the example of the spring/mass system, one could achieve this by adding friction or connecting a dashpot. Alternatively, in modern control technology, one uses a digital computer to measure the state x and compute the appropriate control action to be applied. (There are many implementation issues which arise in digital control and are ignored in our theoretical formulation "$u = k(x)$", among them the effect of delays in the actual computation of the control $u(t)$ to be applied at time t, and the effect of quantization due to the finite precision of measuring devices and the digital nature of the computer. These issues are addressed in the literature, although a comprehensive theoretical framework is still lacking.)

Observe that, obviously, if there exists a feedback stabilizer for (1), then (1) is also AC (we just use $u(t) := k(x(t, x^0))$ as u_{x^0}). Thus, it is very natural to ask whether the converse holds: *is every asymptotically controllable system also feedback stabilizable?*

Linear Systems

A *linear system* is a system (1) for which the map f is linear. In other words, there are two linear transformations $A\colon \mathbb{R}^n \to \mathbb{R}^n$ and $B\colon \mathbb{R}^m \to \mathbb{R}^n$ so that the equations take the form

$$\dot{x} = Ax + Bu\,. \tag{4}$$

Such a system is completely specified once that we are given A and B, which we identify by abuse of notation with their respective matrices $A \in \mathbb{R}^{n\times n}$ and $B \in \mathbb{R}^{n\times m}$ with respect to the canonical bases in $\mathbb{R}^n$ and $\mathbb{R}^m$. We also say "the system (A, B)" when referring to (4).

It is natural to look specifically for *linear* feedbacks $k\colon \mathbb{R}^n \to \mathbb{R}^m$ which stabilize a linear system (just as a linear term, inversely proportional to velocity, stabilizes an undamped harmonic oscillator). (In fact, this is no loss of generality, since it can be easily proved for linear systems [25] that if a feedback stabilizer $u = k(x)$ exists, then there also exists a linear feedback stabilizer.) We write $u = Fx$, when expressing $k(x) = Fx$ in matrix terms with respect to the canonical bases. Substituting this control law into (4) results in the equation $\dot{x} = (A + BF)x$. Thus, the mathematical problem reduces to:

given $A \in \mathbb{R}^{n\times n}$ and $B \in \mathbb{R}^{n\times m}$, find $F \in \mathbb{R}^{m\times n}$ such that $A + BF$ is Hurwitz.

(Recall that a Hurwitz matrix is one all whose eigenvalues have negative real parts, and that the origin of the system $\dot{x} = Hx$ is globally asymptotically stable if and only if H is a Hurwitz matrix.) The fundamental stabilization result for linear systems is as follows [25]:

Theorem 1 *A linear system is asymptotically controllable if and only if it admits a linear feedback stabilizer.*

A Remark on Linearization

If the dynamics map f in (1) is continuously differentiable, we may expand to first order $f(x, u) = Ax + Bu + o(x, u)$. Let us suppose that the linearized system (A, B) is AC, and pick a linear feedback stabilizer $u = Fx$, whose existence is guaranteed by Theorem 1. Then, the same feedback law $k(x) = Fx$, when fed back into the original system (1), results in $\dot{x} = f(x, Fx) = (A + BF)x + o(x)$. Thus, k locally stabilizes the origin for the nonlinear system. Of course, the assumption that the linearization is AC is not always satisfied. Systems in which inputs enter multiplicatively, such as those controlling reaction rates in chemical problems, lead to degenerate linearizations. In addition, even if the linearized system (A, B) is AC, in general a linear stabilizer $u = Fx$ will not work as a global stabilizer. For example, the system $\dot{x} = x + x^2 + u$ can be locally stabilized with $u := -2x$, but any linear feedback $u = -fx$ $(f > 1)$ results in an additional equilibrium away from the origin (at $x = f - 1$). Nonlinear feedback must be used (obviously, in this, example, $u = -2x - x^2$ works for global stabilization).

Returning to linear systems, let us note that Theorem 1 is of great interest because (1) there is a simple algebraic test to check the AC property, and (2) there are several practically useful algorithms for obtaining a stabilizing F, including pole placement and optimization, which we sketch next.

Pole Placement

The first technique for stabilization is purely algebraic. In order to simplify this exposition, we will suppose that the system (4) is not just AC but is in fact *controllable*, meaning that every state can be steered, in finite time, to every other state. (Any AC system (4) can be decomposed into two components, of which one is already GAS and the other one is controllable, cf. [25], so this represents no loss of generality.) Controllability is characterized by the property – generically satisfied for pairs (A, B) – that

$$\operatorname{rank}\left[B\middle|AB\middle|A^2B\middle|\dots\middle|A^{n-1}B\right] = n$$

(note that the composite matrix shown has n rows and nm columns).

Two pairs (A, B) and $(\widetilde{A}, \widetilde{B})$ are said to be *feedback equivalent* if there exist $T \in GL(n, \mathbb{R})$, $F_0 \in \mathbb{R}^{m\times n}$, and $V \in GL(m, \mathbb{R})$ so that

$$(A + BF_0)T = T\widetilde{A} \quad \text{and} \quad BV = T\widetilde{B}\,. \tag{5}$$

Feedback equivalence corresponds to changes of basis in the state and control-value spaces (invertible matrices T and V, respectively) and feedback transformations $u = F_0x + u'$, where u' is a new control. (An equivalent way to describe feedback equivalence is by the requirement that two pairs should be in the same orbit under the action of a "feedback group" which is obtained as a suitable semidirect product of $GL(n,\mathbb{R})$, $(\mathbb{R}^{m\times n},+)$, and $GL(m,\mathbb{R})$.) Controllability is preserved under feedback equivalence. Moreover, if (5) holds and if one finds a matrix $\widetilde{F}$ so that $\widetilde{A}+\widetilde{B}\widetilde{F}$ is Hurwitz, then

$$A+BF = T(\widetilde{A}+\widetilde{B}\widetilde{F})T^{-1}$$

is also Hurwitz, where $F := F_0 + V\widetilde{F}T^{-1}$. Thus, the task of finding a stabilizing feedback F can be reduced to the same problem for any pair $(\widetilde{A},\widetilde{B})$ which is feedback equivalent to the given pair (A,B).

One then proceeds to show that there always exists an equivalent pair $(\widetilde{A},\widetilde{B})$ which has a form simple enough that the existence of $\widetilde{F}$ is trivial to establish. In order to find such a pair, it is useful to study the classification of controllable pairs under feedback equivalence. This classification is closely related to Kronecker's theory of "matrix pencils" applied to polynomial matrices $[\lambda I - A, B] = \lambda[I,0] + [-A,B]$ modulo matrix equivalence, cf. [25]. The orbits under feedback equivalence are in one-to-one correspondence with the possible partitions of $n = \kappa_1 + \ldots + \kappa_r$ into the sum of r positive integers, $r \le m$, and in each orbit one can find a pair $(\widetilde{A},\widetilde{B})$ which is in "controller canonical form", for which F can be trivially found. For simplicity, let is just discuss here the very special case of single-input systems ($m = 1$). For this case, the action of the feedback group is transitive, and each controllable system is feedback equivalent to the following special system:

$$A := \begin{pmatrix} 0 & 1 & 0 & \ldots & 0 \\ 0 & 0 & 1 & \ldots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \ldots & 1 \\ 0 & 0 & 0 & \ldots & 0 \end{pmatrix} \quad B := \begin{pmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{pmatrix} .$$

For this system, a stabilizing feedback is trivial to obtain. Indeed, take the polynomial $p(\lambda) = (\lambda+1)^n = \lambda^n - \alpha_n\lambda^{n-1} - \ldots - \alpha_2\lambda - \alpha_1$. With $F = (\alpha_1,\alpha_2,\alpha_3,\ldots,\alpha_n)$,

$$A+BF := \begin{pmatrix} 0 & 1 & 0 & \ldots & 0 \\ 0 & 0 & 1 & \ldots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \ldots & 1 \\ \alpha_1 & \alpha_2 & \alpha_3 & \ldots & \alpha_n \end{pmatrix}$$

has characteristic polynomial $(\lambda+1)^n$, and hence is a Hurwitz matrix, as required for stabilization.

Observe that, instead of the particular $p(\lambda)$ which we used, we could have picked any polynomial all whose roots have negative real parts, and the same argument applies. The conclusion is that, not only can we make $A+BF$ Hurwitz, but we can assign to it any desired set of n eigenvalues (as long as they form a set closed under conjugation). This is the reason that the technique is called *eigenvalue placement* (or "pole placement" because the eigenvalues of A are the poles of the resolvent $(\lambda I - A)^{-1}$). See Chap. 5 in [25] for a detailed treatment of the pole placement problem.

Variational Approach

A second technique for stabilization is based on optimal control techniques. We first pick any two symmetric positive definite matrices $R \in \mathbb{R}^{m\times m}$ and $Q \in \mathbb{R}^{n\times n}$ (for instance the identity matrices of the respective sizes). Next, we consider the problem of minimizing, for each initial state x^0 at time $t = 0$, the infinite-horizon cost

$$\mathcal{J}_{x^0}(u) := \int_0^\infty \left\{u(t)'Ru(t) + x(t)'Qx(t)\right\} \mathrm{d}t$$

over all controls $u\colon [0,\infty) \to \mathbb{R}^m$ which make $\mathcal{J}_{x^0}(u) < \infty$, where $x(t) = x(t,x^0,u)$ and prime indicates transpose. The main result from linear-quadratic optimal control (cf. Sect. 8.4 in [25]) implies that, for AC systems, there is a unique solution u to this problem, which is given in the following form: there is a matrix $F \in \mathbb{R}^{m\times n}$ such that solving $\dot{x} = (A+BF)x$ with $x(0) = x^0$ gives that $u(t) := Fx(t)$ minimizes $\mathcal{J}_{x^0}(\cdot)$. Moreover, this F stabilizes the system (which is intuitively to be expected, since $\mathcal{J}_{x^0}(u) < \infty$ implies that solutions $x(t)$ must be in L^2), and F can be computed by the formula

$$F := -R^{-1}B'P\,, \tag{6}$$

where P is a symmetric and positive definite solution of the *Matrix Algebraic Riccati Equation*

$$PBR^{-1}B'P - PA - A'P - Q = 0\,. \tag{7}$$

A Sufficient Nonlinear Condition

Although of limited applicability, it is worth remarking that there is a partial extension to nonlinear systems of the stabilization method which was just described. For simplicity, we specialize our discussion to control-affine systems, i. e., those for which the input appears only in an affine form. This class is sufficient for the study of most forced mechanical systems. The Eq. (1) becomes:

$$\dot{x} = g_0(x) + \sum_{i=1}^m u_i g_i(x) = g_0(x) + G(x)u\,.$$

(See Sect. 8.5 in [25] for general f, and for proofs). We now pick two continuous functions $Q\colon \mathbb{R}^n \to \mathbb{R}_{\geq 0}$ and $R\colon \mathbb{R}^n \to \mathbb{R}^{n\times n}$, so that $R(x)$ is a symmetric positive definite matrix for each x.

In general, we say that a continuous function

$$V\colon \mathbb{R}^n \to \mathbb{R}_{\geq 0}$$

is *positive definite* if $V(x) = 0$ only if $x = 0$, and it is *proper* (or "weakly coercive") if for each $a \geq 0$ the set $\{x | V(x) \leq a\}$ is compact, or, equivalently, $V(x) \to \infty$ as $|x| \to \infty$ (radial unboundedness). Given any such V which is also differentiable, we denote the vector function whose components are the directional derivatives of V in the directions of the various control vector fields g_i, $i \geq 1$ by:

$$L_G V(x) := \nabla V(x) G(x) = \left(L_{g_1} V(x), \ldots, L_{g_m} V(x)\right) ,$$

and also write $L_{g_0} V(x) := \nabla V(x) g_0(x)$.

We consider the following PDE on such functions V:

$$\forall x \quad Q(x) + L_{g_0} V(x) - \frac{1}{4} L_G V(x) R(x)^{-1} \left(L_G V(x)\right)' = 0 . \tag{8}$$

This reduces to the Algebraic Riccati Eq. (7) in the special case of linear systems, quadratic $V(x) = x'Px$ and $Q(x) = x'Qx$, and constant matrices $R(x) \equiv R$. We also take the following generalization of the feedback law (6):

$$k(x) := -\frac{1}{2} R(x)^{-1} \left(L_G V(x)\right)' . \tag{9}$$

Finally, we assume that Q is a positive definite function. One then has [25]:

Theorem 2 *Suppose that V is a twice continuously differentiable, positive definite, and proper solution of the PDE (8). Then, k defined by (9) stabilizes the system.*

This theorem arises from the following optimization problem: for each state $x^0 \in \mathbb{R}^n$, minimize the cost

$$\mathcal{J}_{x^0}(u) := \int_0^\infty u(t)' R(x(t)) u(t) + Q(x(t)) \mathrm{d}t ,$$

where $x(t) = x(t, x^0, u)$, over all those controls $u\colon [0, \infty) \to \mathcal{U}$ for which the solution $x(t, x^0, u)$ of (1) is defined for all $t \geq 0$ and satisfies $\lim_{t\to\infty} x(t) = 0$. Under the above assumptions, and as for linear systems, one also concludes that for each state x^0 the solution of $\dot{x} = f(x, k(x))$ with initial state $x(0) = x^0$ exists for all $t \geq 0$, the control $u(t) = k(x(t))$ is optimal, and $V(x^0)$ is the optimal cost from initial state x^0. Moreover, the formula for k arises from the Hamilton–Jacobi–Bellman equation of optimal control theory, because

$$k(x) = \underset{u}{\operatorname{argmin}} \left\{\nabla V(x) \cdot f(x, u) + u' R(x) u + Q(x)\right\}$$

when $f(x, u) = g_0(x) + G(x)u$.

There are applications where this method has proven useful. Unfortunately, however, and in contrast to the linear case, in general there exists no positive definite, proper, and C^2 solution V of the above PDE. On the other hand, the formula (9) does appear, with variations, in other contexts, including generalizations of the idea of adding damping to systems, cf. Sect. 5.9 in [25], and, more generally, the use of auxiliary positive definite and proper functions V, in similar roles, will be central to the control-Lyapunov ideas discussed later.

Nonlinear Systems: Continuous Feedback

One of the central topics which we will address here concerns possibly discontinuous feedback laws k. Before turning to that subject, however, we study continuous feedback. When dealing with linear systems, linear feedback is natural, and indeed sufficient from a theoretical standpoint, as shown by the results just reviewed. However, for our general study, major technical questions arise in even deciding on just what degree of regularity should be imposed on the feedback maps k.

It turns out that the precise requirements away from 0, say asking whether k is merely continuous or smooth, are not very critical; it is often the case that one can "smooth out" a continuous feedback (or, even, make it real-analytic, via Grauert's Theorem) away from the origin. So, in order to avoid unnecessary complications in exposition due to nonuniqueness, let us call a feedback k *regular* if it is locally Lipschitz on $\mathbb{R}^n \setminus \{0\}$. For such k, solutions of initial value problems $\dot{x} = f(x, k(x))$, $x(0) = x^0$, are well defined (at least for small time intervals $[0, \varepsilon)$) and, provided k is a stabilizing feedback, are unique (cf. Exercise 5.9.9 in [25]).

On the other hand, behavior at the origin cannot be "smoothed out" and, at zero, the precise degree of smoothness plays a central role in the theory [12]. For instance, consider the system

$$\dot{x} = x + u^3 .$$

The continuous (and, in fact, smooth away from zero) feedback $u = k(x) := -\sqrt[3]{2x}$ globally stabilizes the system (the closed-loop system becomes $\dot{x} = -x$). However, there is no possible stabilizing feedback which is differentiable at the origin, since $u = k(x) = O(x)$ implies that

$$\dot{x} = x + O\left(x^3\right)$$

about $x = 0$, which means that the solution starting at any positive and small point moves to the right, instead of towards the origin. (A general result, assuming that A has no purely imaginary eigenvalues, cf. [25], Section 5.8, is that if – and only if – $\dot{x} = Ax + Bu + o(x, u)$ can be locally asymptotically stabilized using a feedback which is differentiable at the origin, the linearization $\dot{x} = Ax + Bu$ must be AC itself. In the example that we gave, this linearization is just $\dot{x} = x$, which is not AC.)

We now turn to the question of existence of regular feedback stabilizers. We first study a comparatively trivial case, namely systems with one state variable and one input. After that, we turn to multidimensional systems.

The Special Case $n = m = 1$

There are algebraic obstructions to the stabilization of $\dot{x} = f(x, u)$ if the input u appears nonlinearly in f. Ignoring the requirement that there be a $\sigma \in \mathcal{N}$ so that controls can be picked with $\|u\| \leq \sigma(|x^0|)$, asymptotic controllability is, for $n = m = 1$, equivalent to:

$$(\forall x \neq 0)(\exists u)\ xf(x, u) < 0 \tag{10}$$

(this is proved in [28]; it is fairly obvious, but some care must be taken to deal with the fact that one is allowing arbitrary measurable controls; the argument proceeds by first approximating such controls by piecewise constant ones). Let us introduce the following set:

$$\mathcal{O} := \{(x, u) | xf(x, u) < 0\} \ ,$$

and let $\pi\colon (x, u) \mapsto x$ be the projection into the first coordinate in $\mathbb{R}$. Then, (10) is equivalent to:

$$\pi\mathcal{O} = \mathbb{R} \setminus \{0\} \ .$$

(One can easily include the requirement "$\|u\| \leq \sigma(|x^0|)$" by asking that for each interval $[-K, K] \subset \mathbb{R}$ there must be some compact set $C_K \subset \mathbb{R}^2$ so that $[-K, K] \subseteq \pi(C_K)$. For simplicity, we ignore this technicality.) In these terms, a stabilizing feedback is nothing else than a locally bounded map $k\colon \mathbb{R} \to \mathbb{R}$ such that $k(0) = 0$ and so that k is a section of π on $\mathbb{R} \setminus \{0\}$:

$$(x, k(x)) \in \mathcal{O} \ \ \forall x \neq 0 \ .$$

For a regular feedback, we ask that k be locally Lipschitz on $\mathbb{R} \setminus \{0\}$.

Clearly, there is no reason for Lipschitz, or for that matter, just continuous, sections of π to exist. As an illustration, take the system

$$\dot{x} = x\left[(u - 1)^2 - (x - 1)\right]\left[(u + 1)^2 + (x - 2)\right] \ .$$

Let

$$\mathcal{O}_1 = \left\{(u + 1)^2 < (2 - x)\right\} \text{ and } \mathcal{O}_2 = \{(u-1)^2 < (x-1)\}$$

(these are the interiors of two disjoint parabolas). Here, $\mathcal{O}$ has three connected components, namely $\mathcal{O}_2$, $\mathcal{O}_1$ intersected with $x < 0$, and $\mathcal{O}_1$ intersected with $x < 0$. It is clear that, even though $\pi\mathcal{O} = \mathbb{R}$, there is no continuous curve (graph of $u = k(x)$) which is always in $\mathcal{O}$ and projects onto $\mathbb{R} \setminus \{0\}$. On the other hand, there exist many possible feedback stabilizers provided that we allow one discontinuity. It is also possible to provide examples, even with $f(x, u)$ smooth, for which an infinite number of switches are needed in any possible stabilizing feedback law. Finally, it may even be possible to stabilize semiglobally with a regular feedback, meaning that for each compact subset K of the state-space there is a regular, even smooth, feedback law $u = k_K(x)$ such that all states in K get driven asymptotically to the origin, but yet it may be impossible to find a single $u = k(x)$ which works globally. See [26] for details.

When feedback laws are required to be continuous at the origin, new obstructions arise. The case of systems with $n = m = 1$ is also a good way to introduce this subject. The first observation is that stabilization about the origin (even if just local) means that we must have, near zero:

$$f(x, k(x)) \begin{cases} > 0 & \text{if} \quad x < 0 \\ < 0 & \text{if} \quad x > 0 \\ = 0 & \text{if} \quad x = 0 \end{cases} .$$

In fact, all that we need is that $f(x_1, k(x_1)) < 0$ for some $x_1 > 0$ and $f(x_2, k(x_2)) > 0$ for some $x_2 < 0$. This guarantees, via the intermediate-value theorem that, if k is continuous, the projection

$$(-\varepsilon, \varepsilon) \to \mathbb{R} \ , \quad x \mapsto f(x, k(x))$$

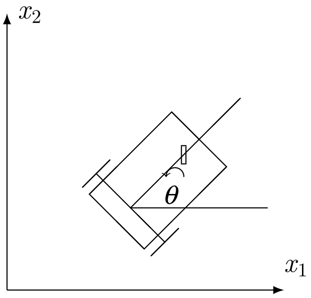
is onto a neighborhood of zero, for each $\varepsilon > 0$. It follows, in particular, that the image of

$$(-\varepsilon, \varepsilon) \times (-\varepsilon, \varepsilon) \to \mathbb{R} \ , \quad (x, u) \mapsto f(x, u)$$

also contains a neighborhood of zero, for any $\varepsilon > 0$ (that is, the map $(x, u) \mapsto f(x, u)$ is open at zero). This last property is intrinsic, being stated in terms of the original data $f(x, u)$ and not depending upon the feedback k. Brockett's condition, to be described next, is a far-reaching generalization of this argument; in its proof, degree theory replaces the use of the intermediate value theorem.

Obstructions and Necessary Degree Conditions

If there are "obstacles" in the state-space, or more precisely if the state-space is a proper subset of $\mathbb{R}^n$, discontinuities in feedback laws cannot in general be avoided,



Stability and Feedback Stabilization, Figure 1
Shopping cart

since the domain of attraction of an asymptotically stable vector field must be diffeomorphic to Euclidean space. But even if states evolve in Euclidean spaces, similar obstructions may arise. These are due not to the topology of the state space, but to "virtual obstacles" implicit in the form of the system equations. These obstacles occur when it is impossible to move instantaneously in certain directions, even if it is possible to move eventually in every direction, the phenomenon of "nonholonomy". As an illustration, let us consider a model for the "shopping cart" shown in Fig. 1 ("knife-edge" or "unicycle" are other names for this example). The state is given by the orientation θ, together with the coordinates x_1, x_2 of the midpoint between the back wheels. The front wheel is a castor, free to rotate. There is a non-slipping constraint on movement: the velocity $(\dot{x}_1, \dot{x}_2)'$ must be parallel to the vector $(\cos\theta, \sin\theta)'$. This leads to the following equations:

$$\begin{aligned}\dot{x}_1 &= u_1 \cos\theta\\ \dot{x}_2 &= u_1 \sin\theta\\ \dot{\theta} &= u_2\end{aligned}$$

where we may view u_1 as a "drive" command and u_2 as a steering control. (In practice, one would implement these controls by means of differential forces on the two back corners of the cart.) The feedback transformation $z_1 := \theta$, $z_2 := x_1 \cos\theta + x_2 \sin\theta$, $z_3 := x_1 \sin\theta - x_2 \cos\theta$, $v_1 := u_2$, and $v_2 := u_1 - u_2 z_3$ brings the system into the system with equations $\dot{z}_1 = v_1, \dot{z}_2 = v_2, \dot{z}_3 = z_2 v_1$ known as "Brockett's example" or "nonholonomic integrator" (yet another change can bring the third equation into the form $\dot{z}_3 = z_1 v_2 - z_2 v_1$). We view the system as having state space $\mathbb{R}^3$. Although a physically more accurate state space would be the manifold $\mathbb{R}^2 \times \mathbb{S}^1$, the necessary condition to be given is of a local nature, so the global structure is unimportant.

This system is (obviously) completely controllable (formally, controllability can be checked using the Lie algebra rank condition, as in e. g. [25], Exercise 4.3.16), and in particular is AC. However, we may expect that discontinuities are unavoidable due to the non-slip constraint, which does not allow moving from, for example the position $x_1 = 0$, $\theta = 0$, $x_2 = 1$ in a straight line towards the origin. Indeed, one then has [3]:

Theorem 3 *If there is a stabilizing feedback which is regular and continuous at zero, then the map $(x, u) \mapsto f(x, u)$ is open at zero.*

The test fails here, since no points of the form $(0, \varepsilon, *)$ belong to the image of the map

$$\begin{aligned}\mathbb{R}^5 \to \mathbb{R}^3 \colon (x_1, x_2, \theta, u_1, u_2)' &\mapsto f(x, u)\\ &= (u_1 \cos\theta, u_1 \sin\theta, u_2)'\end{aligned}$$

for $\theta \in (-\pi/2, \pi/2)$, unless $\varepsilon = 0$.

More generally, it is impossible to continuously stabilize any system without drift

$$\dot{x} = u_1 g_1(x) + \ldots + u_m g_m(x) = G(x)u$$

if $m < n$ and $\operatorname{rank}[g_1(0), \ldots, g_m(0)] = m$ (this includes all totally nonholonomic mechanical systems). Indeed, under these conditions, the map $(x, u) \mapsto G(x)u$ cannot contain a neighborhood of zero in its image, when restricted to a small enough neighborhood of zero. Indeed, let us first rearrange the rows of G:

$$G(x) \rightsquigarrow \begin{pmatrix} G_1(x) \\ G_2(x) \end{pmatrix}$$

so that $G_1(x)$ is of size $m \times m$ and is nonsingular for all states x that belong to some neighborhood N of the origin. Then,

$$\begin{pmatrix} 0 \\ a \end{pmatrix} \in \operatorname{Im}\left[N \times \mathbb{R}^m \to \mathbb{R}^n \colon (x, u) \mapsto G(x)u\right] \Rightarrow a = 0$$

(since $G_1(x)u = 0 \Rightarrow u = 0 \Rightarrow G_2(x)u = 0$ too).

If the condition $\operatorname{rank}[g_1(0), \ldots, g_m(0)] = m$ is violated, we cannot conclude a negative result. For instance, the system $\dot{x}_1 = x_1 u$, $\dot{x}_2 = x_2 u$ has $m = 1 < 2 = n$ but it can be stabilized by means of the feedback law $u = -(x_1^2 + x_2^2)$.

Observe that for linear systems, Brockett's condition says that

$$\operatorname{rank}[A, B] = n$$

which is the Hautus controllability condition (see e. g. [25], Lemma 3.3.7) at the zero mode.

Idea of the Proof One may prove Brockett's condition in several ways. A proof based on degree theory is probably easiest, and proceeds as follows (for details see for instance [25], Sect 5.9). The basic fact, due to Krasnosel'ski, is that if the system $\dot{x} = F(x) = f(x, k(x))$ has the origin as an asymptotically stable point and F is regular (since k is), then the degree (index) of F with respect to zero is $(-1)^n$, where n is the system dimension. In particular, the degree is also nonzero with respect to points p in a neighborhood of 0, which means that the equation $F(x) = p$ can be solved for small p, and hence $f(x, u) = p$ can be solved as well. The proof that the degree is $(-1)^n$ follows by exhibiting a homotopy, namely

$$F_t(x^0) = \frac{1}{t}\left[x\left(\frac{t}{1-t}, x^0\right) - x^0\right],$$

between $F_0 = F$ and $F_1(x) = -x$, and noting that the degree of the latter is obviously $(-1)^n$. An alternative proof uses Lyapunov functions. Asymptotic stability implies the existence of a smooth Lyapunov function V for $\dot{x} = F(x) = f(x, k(x))$, so, on the boundary ∂B of a sublevel set $B = \{x | V(x) \leq c\}$ we have that F points towards the interior of B. Thus, for p small, $F(x) - p$ still points to the interior, which means that B is invariant with respect to the perturbed vector field $\dot{x} = F(x) - p$. Provided that a fixed-point theorem applies to continuous maps $B \to B$, this implies that $F(x) - p$ must vanish somewhere in B, that is, the equation $F(x) = p$ can be solved. (Because, for each small $h > 0$, the time-h flow ϕ of $F - p$ has a fixed point $x_h \in B$, i. e. $\phi(h, x_h) = x_h$, so picking a convergent subsequence $x_h \to \bar{x}$ gives that $0 = (\phi(h, x_h) - x_h)/(h) \to F(\bar{x}) - p$.) A fixed point theorem can indeed be applied, because B is a retract of $\mathbb{R}^n$ (use the flow itself); note that this argument gives a weaker conclusion than the degree condition.

Control-Lyapunov Functions

The method of control-Lyapunov functions ("clf's") provides a powerful tool for studying stabilization problems, both as a basis of theoretical developments and as a method for actual feedback design.

Before discussing clf's, let us quickly review the classical concept of Lyapunov functions, through a simple example. Consider first a damped spring-mass system $\ddot{y} + \dot{y} + y = 0$, or, in state-space form with $x_1 = y$ and $x_2 = \dot{y}$, $\dot{x}_1 = x_2$, $\dot{x}_2 = -x_1 - x_2$. One way to verify global asymptotic stability of the equilibrium $x = 0$ is to pick the (Lyapunov) function $V(x_1, x_2) := \frac{3}{2}x_1^2 + x_1x_2 + x_2^2$, and observe that $\nabla V(x).f(x) = -|x|^2 < 0$ if $x \neq 0$, which means that

$$\frac{\mathrm{d}V(x(t))}{\mathrm{d}t} = -\left|x(t)^2\right| < 0$$

along all nonzero solutions, and thus the energy-like function V decreases along all trajectories, which, since V is a nondegenerate quadratic form, implies that $x(t)$ decreases, and in fact $x(t) \to 0$. Of course, in this case one could compute solutions explicitly, or simply note that the characteristic equation has all roots with negative real part, but Lyapunov functions are a general technique. (In fact, the classical converse theorems of Massera and Kurzweil [17,19] show that, whenever a system is GAS, there always exists a smooth Lyapunov function V.)

Now let us modify this example to deal with a control system, and consider a forced (but undamped) harmonic oscillator $\ddot{x} + x = u$, i. e. $\dot{x}_1 = x_2$, $\dot{x}_2 = -x_1 + u$. The damping feedback $u = -x_2$ stabilizes the system, but let us pretend that we do not know that. If we take the same V as before, now the derivatives along trajectories are, using "$\dot{V}(x, u)$" to denote $\nabla V(x).f(x, u)$ and omitting arguments t in $x(t)$ and $u(t)$:

$$\dot{V}(x, u) = -x_1^2 + x_1x_2 + x_2^2 - (x_1 + 2x_2)u\,.$$

This expression is affine in u. Thus, if x is a state such that $x_1 + 2x_2 \neq 0$, then we may pick a control value u (which depends on this current state x) such that $\dot{V} < 0$. On the other hand, if $x_1 + 2x_2 = 0$, then the expression reduces to $\dot{V} = -5x_2^2$ (for any u), which is negative unless x_2 (and hence also $x_1 = -2x_2$) vanishes.

In conclusion, for each $x \neq 0$ there is some u so that $\dot{V}(x, u) < 0$. This is, except for some technicalities to be discussed, the characterizing property of control-Lyapunov functions. For any given compact subset B in $\mathbb{R}^n$, we now pick some compact subset $\mathcal{U}_0 \subset \mathcal{U}$ so that

$$\forall x \in B, x \neq 0\,, \quad \exists u \in \mathcal{U}_0 \quad \text{such that} \quad \dot{V}(x, u) < 0\,. \tag{11}$$

In principle, then, we could then stabilize the system, for states in B, by using the steepest descent feedback law:

$$k(x) := \underset{u \in \mathcal{U}_0}{\operatorname{argmin}}\ \nabla V(x) \cdot f(x, u) \tag{12}$$

("argmin" means "pick any u at which the min is attained"; we restricted $\mathcal{U}$ to be assured that $\dot{V}(x, u)$ attains a minimum). Note that the stabilization problem becomes, in these terms, a set of static nonlinear programming problems: minimize a function of u, for each x. Global stabilization is also possible, by appropriately picking $\mathcal{U}_0$ as a function of the norm of x; later we discuss a precise formulation.

Control–Lyapunov functions, if understood non-technically as the basic paradigm "look for a function $V(x)$ with the properties that $V(x) \approx 0$ if and only if $x \approx 0$, and so that for each $x \neq 0$ it is possible to decrease $V(x)$ by some control action," constitute a very general approach to control (sometimes expressed in a dual fashion, as maximization of some measure of success). They appear in such disparate areas as A.I. game-playing programs (position evaluations), energy arguments for dissipative systems, program termination (Floyd/Dijkstra "variant"), and learning control ("critics" implemented by neural-networks). More relevantly to this paper, the idea underlies much of modern feedback control design, as illustrated for instance by the books [7,11,15,16,25].

Differentiable clf's: Precise Definition A *differentiable control-Lyapunov function* (clf) is a differentiable function $V\colon \mathbb{R}^n \to \mathbb{R}_{\geq 0}$ which is proper, positive definite, and *infinitesimally decreasing*, meaning that there exists a positive definite continuous function $W\colon \mathbb{R}^n \to \mathbb{R}_{\geq 0}$, and there is some $\sigma \in \mathcal{N}$, so that

$$\sup_{x\in\mathbb{R}^n} \min_{|u|\leq\sigma(|x|)} \nabla V(x)\cdot f(x,u) + W(x) \leq 0\,. \tag{13}$$

This is basically the same as condition (11), with $\mathcal{U}_0 =$ the ball of radius $\sigma(|x|)$ picked as a function of x. The main difference is that, instead of saying "$\nabla V(x)\cdot f(x,u) < 0$ for $x \neq 0$" we write $\nabla V(x)\cdot f(x,u) \leq -W(x)$, where W is negative when $x \neq 0$. The two definitions are equivalent, but the "Hamiltonian" version used here is the correct one for the generalizations to be given, to nonsmooth V.

The basic result is due to Artstein [2]:

Theorem 4 *A control-affine system $\dot{x} = g_0(x) + \sum u_i g_i(x)$ admits a differentiable clf if and only if it admits a regular stabilizing feedback.*

The proof of sufficiency is easy: if there is such a k, then the converse Lyapunov theorem, applied to the closed-loop system $F(x) = f(x,k(x))$, provides a smooth V such that

$$L_F V(x) = \nabla V(x) F(x) < 0 \quad \forall x \neq 0\,.$$

This gives that for all nonzero x there is some u (bounded on bounded sets, because k is locally bounded by definition of feedback) so that $\dot{V}(x,u) < 0$; and one can put this in the form (13).

The necessity is more interesting. The original proof in [2] proceeds by a nonconstructive argument involving partitions of unity, but it is also possible [24,25] to exhibit explicitly a feedback, written as a function:

$$k\left(\nabla V(x)\cdot g_0(x), \ldots, \nabla V(x)\cdot g_m(x)\right)$$

of the directional derivatives of V along the vector fields defining the system (*universal formulas* for stabilization). Taking for simplicity $m = 1$, one such formula is:

$$k(x) := -\frac{a(x) + \sqrt{a(x)^2 + b(x)^4}}{b(x)} \quad (0 \text{ if } b = 0)$$

where $a(x) := \nabla V(x)\cdot g_0(x)$ and $b(x) := \nabla V(x)\cdot g_1(x)$. The expression for k is analytic in a,b when $x \neq 0$, because the clf property means that $a(x) < 0$ whenever $b(x) = 0$ [24,25].

Thus, the question of existence of regular feedback, for control-affine systems, reduces to the search for differentiable clf's, and this gives rise to a vast literature dealing with the construction of such V's, see [7,15,16,25] and references therein. Many other theoretical issues are also answered by Artstein's theorem. For example, via Kurzweil's converse theorem one has that the existence of k merely continuous on $\mathbb{R}^n \setminus \{0\}$ suffices for the existence of smooth (infinitely differentiable) V, and from here one may in turn find a k which is smooth on $\mathbb{R}^n \setminus \{0\}$. In addition, one may easily characterize the existence of k continuous at zero as well as regular: this is equivalent to the *small control property*: for each $\varepsilon > 0$ there is some $\delta > 0$ so that $0 < |x| < \delta$ implies that $\min_{|u|\leq\varepsilon} \nabla V(x)\cdot f(x,u) < 0$ (if this property holds, the universal formula automatically provides such a k). We should note that Artstein provided a result valid for general, not necessarily control-affine systems $\dot{x} = f(x,u)$; however, the obtained "feedback" has values in sets of relaxed controls, and is not a feedback law in the classical sense. Later, we discuss a different generalization.

Differentiable clf's will in general not exist, because of obstructions to regular feedback stabilization. This leads us naturally into the twin subjects of discontinuous feedbacks and non-differentiable clf's.

Discontinuous Feedback

The previous results and examples show that, in order to develop a satisfactory general theory of stabilization, one in which one proves the implication "asymptotic controllability implies feedback stabilizability," we must allow discontinuous feedback laws $u = k(x)$. But then, a major technical difficulty arises: solutions of the initial-value problem $\dot{x} = f(x,k(x))$, $x(0) = x^0$, interpreted in the classical sense of differentiable functions or even as (absolutely) continuous solutions of the integral equation $x(t) = x^0 + \int_0^t f(x(s), k(x(s)))\mathrm{d}s$, do not exist in general. The only general theorems apply to systems $\dot{x} = F(x)$ with continuous F. For example, there is no solution to $\dot{x} = -\operatorname{sign} x$, $x(0) = 0$, where $\operatorname{sign} x = -1$ for $x < 0$ and $\operatorname{sign} x = 1$ for $x \geq 0$. So one cannot even pose the stabilization problem in a mathematically consistent sense.

There is, of course, an extensive literature addressing the question of discontinuous feedback laws for control systems and, more generally, differential equations with discontinuous right-hand sides. One of the best-known candidates for the concept of solution of (3) is that of a *Filippov solution* [6,9], which is defined as the solution of a certain differential inclusion with a multivalued right-hand side which is built from $f(x, k(x))$. Unfortunately, there is no hope of obtaining the implication "asymptotic controllability implies feedback stabilizability" if one interprets solutions of (3) as Filippov solutions. This is a consequence of results in [5,22], which established that the existence of a discontinuous stabilizing feedback in the Filippov sense implies the Brockett necessary conditions, and, moreover, for systems affine in controls it also implies the existence of regular feedback (which we know is in general impossible).

A different concept of solution originates with the theory of discontinuous positional control developed by Krasovskii and Subbotin in the context of differential games in [14], and it is the basis of the new approach to discontinuous stabilization proposed in [4], to which we now turn.

Limits of High-Frequency Sampling

By a *sampling schedule* or *partition* $\pi = \{t_i\}_{i \geq 0}$ of $0, +\infty$ we mean an infinite sequence

$$0 = t_0 < t_1 < t_2 < \ldots$$

with $\lim_{i\to\infty} t_i = \infty$. We call

$$\mathbf{d}(\pi) := \sup_{i \geq 0}(t_{i+1} - t_i)$$

the *diameter* of π. Suppose that k is a given feedback law for system (1). For each π, the *π-trajectory starting from x^0* of system (3) is defined recursively on the intervals $[t_i, t_{i+1})$, $i = 0, 1, \ldots$, as follows. On each interval $t_i, t_{i+1})$, the initial state is measured, the control value $u_i = k(x(t_i))$ is computed, and the constant control $u \equiv u_i$ is applied until time t_{i+1}; the process is then iterated. That is, we start with $x(t_0) = x^0$ and solve recursively

$$\dot{x}(t) = f(x(t), k(x(t_i)))\,, t \in t_i, t_{i+1})\,, \quad i = 0, 1, 2, \ldots$$

using as initial value $x(t_i)$ the endpoint of the solution on the preceding interval. The ensuing π-trajectory, which we denote as $x_\pi(\cdot, x^0)$, is defined on some maximal nontrivial interval; it may fail to exist on the entire interval $[0, +\infty)$ due to a blow-up on one of the subintervals $t_i, t_{i+1})$. We say that it is *well defined* if $x_\pi(t, x^0)$ is defined on all of $[0, +\infty)$.

Definition The feedback $k \colon \mathbb{R}^n \to \mathcal{U}$ *stabilizes* the system (1) if there exists a function $\beta \in \mathcal{KL}$ so that the following property holds: For each

$$0 < \varepsilon < K$$

there exists a $\delta = \delta(\varepsilon, K) > 0$ such that, for every sampling schedule π with $\mathbf{d}(\pi) < \delta$, and for each initial state x^0 with $|x^0| \leq K$, the corresponding π-trajectory of (3) is well-defined and satisfies

$$\left|x_\pi(t, x^0)\right| \leq \max\left\{\beta\left(K, t\right), \varepsilon\right\} \quad \forall t \geq 0\,. \tag{14}$$

In particular, we have

$$\left|x_\pi(t, x^0)\right| \leq \max\left\{\beta\left(\left|x^0\right|, t\right), \varepsilon\right\} \quad \forall t \geq 0 \tag{15}$$

whenever $0 < \varepsilon < |x^0|$ and $\mathbf{d}(\pi) < \delta(\varepsilon, |x^0|)$ (just take $K := |x^0|$).

Observe that the role of δ is to specify a lower bound on intersampling times. Roughly, one is requiring that

$$t_{i+1} \leq t_i + \theta\left(|x(t_i)|\right)$$

for each i, where θ is an appropriate positive function.

Our definition of stabilization is physically meaningful, and is very natural in the context of sampled-data (computer control) systems. It says in essence that a feedback k stabilizes the system if it drives all states asymptotically to the origin and with small overshoot when using *any fast enough sampling schedule*. A high enough sampling frequency is generally required when close to the origin, in order to guarantee small displacements, and also at infinity, so as to preclude large excursions or even blow-ups in finite time. This is the reason for making δ depend on ε and K.

This concept of stabilization can be reinterpreted in various ways. One is as follows. Pick any initial state x^0, and consider any sequence of sampling schedules π_ℓ whose diameters $\mathbf{d}(\pi_\ell)$ converge to zero as $\ell \to \infty$ (for instance, constant sampling rates with $t_i = i/\ell$, $i = 0, 1, 2, \ldots$). Note that the functions $x_\ell := x_{\pi_\ell}(\cdot, x^0)$ remain in a bounded set, namely the ball of radius $\beta(|x^0|, 0)$ (at least for ℓ large enough, for instance, any ℓ so that $\mathbf{d}(\pi_\ell)\delta(|x^0|/2, |x^0|)$). Because $f(x, k(x))$ is bounded on this ball, these functions are equicontinuous, and (Arzela–Ascoli's Theorem) we may take a subsequence, which we denote again as $\{x_\ell\}$, so that $x_\ell \to x$ as $\ell \to \infty$ (uniformly on compact time intervals) for some absolutely continuous (even Lipschitz) function $x\colon [0,\infty) \to \mathbb{R}^n$. *We may think of any limit function $x(\cdot)$ that arises in this fashion as a generalized solution of the closed-loop Eq.* (3). That is, generalized solutions are the limits of trajectories arising from arbitrarily high-frequency sampling when using the feedback law $u = k(x)$. Generalized solutions, for a given initial state x^0, may not be unique – just as may happen with continuous but non-Lipschitz feedback – but there is always existence, and, moreover, for any generalized solution, $|x(t)| \leq \beta(|x^0|\,, t)$ for all $t \geq 0$. This is precisely the defining estimate for the GAS property. Moreover, if k happens to be regular, then the unique solution of $\dot{x} = f(x, k(x))$ in the classical sense is also the unique generalized solution, so we have a reasonable extension of the concept of solution. (This type of interpretation is somewhat analogous, at least in spirit, to the way in which "relaxed" controls are interpreted in optimal trajectory calculations, namely through high-frequency switching of approximating regular controls.) The definition of stabilization was given in [4] in a slightly different form; see [26] for a discussion of the equivalence.

Stabilizing Feedbacks Exist

The main result is [4]:

Theorem 5 *The system (1) admits a stabilizing feedback if and only if it is asymptotically controllable.*

Necessity is clear. The sufficiency statement is proved by construction of k, and is based on the following ingredients:

- Existence of a nonsmooth control-Lyapunov function V.
- Regularization on shells of V.
- Pointwise minimization of a Hamiltonian for the regularized V.

In order to sketch this construction, we start by quickly reviewing a basic concept from nonsmooth analysis.

Proximal Subgradients Let V be any continuous function $\mathbb{R}^n \to \mathbb{R}$ (or even, just lower semicontinuous and with extended real values). A *proximal subgradient* of V at the point $x \in \mathbb{R}^n$ is any vector $\zeta \in \mathbb{R}^n$ such that, for some $\sigma > 0$ and some neighborhood $\mathcal{O}$ of x,

$$V(y) \geq V(x) + \zeta \cdot (y - x) - \sigma^2 \left|y - x^2\right| \quad \forall y \in \mathcal{O}\,.$$

In other words, proximal subgradients are the possible gradients of supporting quadratics at the point x. The set of all proximal subgradients at x is denoted $\partial_p V(x)$.

Nonsmooth Control–Lyapunov Functions A continuous (but not necessarily differentiable) $V\colon \mathbb{R}^n \to \mathbb{R}_{\geq 0}$ is a *control-Lyapunov function* (clf) if it is proper, positive definite, and infinitesimally decreasing in the following generalized sense: there exist a positive definite continuous $W\colon \mathbb{R}^n \to \mathbb{R}_{\geq 0}$ and a $\sigma \in \mathcal{N}$ so that

$$\sup_{x \in \mathbb{R}^n} \max_{\zeta \in \partial_p V(x)} \min_{|u| \leq \sigma(|x|)} \zeta \cdot f(x, u) + W(x) \leq 0\,. \quad (16)$$

This is the obvious generalization of the differentiable case in (13); we are still asking that one should be able to make $\nabla V(x) \cdot f(x, u) < 0$ by an appropriate choice of $u = u_x$, for each $x \neq 0$, except that now we replace $\nabla V(x)$ by the proximal subgradient set $\partial_{\mathrm{p}} V(x)$. An equivalent property is to ask that V be a viscosity supersolution of the corresponding Hamilton–Jacobi–Bellman equation.

For nonsmooth clf's, the main basic result is [23,26]:

Theorem 6 *The system (1) is asymptotically controllable if and only if it admits a continuous clf.*

The proof is based on first constructing an appropriate W, and then letting V be the optimal cost (Bellman function) for the problem min $\int_0^\infty W(x(s))\mathrm{d}s$. However, some care has to be taken to insure that V is continuous, and the cost has to be adjusted in order to deal with possibly unbounded minimizers. An important and very useful refinement of this result is the fact that a locally Lipschitz clf can also be shown to exist [21].

Regularization Once V is known to exist, the next step in the construction of a stabilizing feedback is to obtain Lipschitz approximations of V. For this purpose, one considers the Iosida–Moreau inf-convolution of V with a quadratic function:

$$V_\alpha(x) := \inf_{y \in \mathbb{R}^n} \left[V(y) + \frac{1}{2\alpha^2} |y - x|^2 \right]$$

where the number $\alpha > 0$ is picked constant on appropriate regions. One has that $V_\alpha(x) \nearrow V(x)$, uniformly on compacts. Since V_α is locally Lipschitz, Rademacher's Theorem insures that V_α is differentiable almost everywhere. The feedback k is then made equal to a pointwise minimizer k_α of the Hamiltonian, at the points of differentiability (compare with (12) for the case of differentiable V):

$$k_\alpha(x) := \operatorname*{argmin}_{u \in \mathcal{U}_0} \nabla V_\alpha(x) \cdot f(x, u)\,,$$

where α and the compact $\mathcal{U}_0 = \mathcal{U}_0(\alpha)$ are chosen constant on certain compacts and this choice is made in between level curves. The critical fact is that V_α is itself a clf for the original system, at least when restricted to the region where it is needed. More precisely, on each shell of the form

$$C = \{x \in \mathbb{R}^n | r \leq |x| \leq R\} ,$$

there are positive numbers m and α_0 and a compact subset $\mathcal{U}_0$ such that, for each $0 < \alpha \leq \alpha_0$, each $x \in C$, and every $\zeta \in \partial_{\mathrm{p}} V_\alpha(x)$,

$$\min_{u \in \mathcal{U}_0} \zeta \cdot f(x, u) + m \leq 0 .$$

See [26]. (Actually, this description is oversimplified, and the proof is a bit more delicate. One must define, on appropriate compact sets

$$k(x) := \operatorname*{argmin}_{u \in \mathcal{U}_0} \zeta_\alpha(x) \cdot f(x, u) ,$$

where $\zeta_\alpha(x)$ is carefully chosen. At points x of nondifferentiability, $\zeta_\alpha(x)$ is not a proximal subgradient of V_α, since $\partial_{\mathrm{p}} V_\alpha(x)$ may well be empty. One uses, instead, the fact that $\zeta_\alpha(x)$ happens to be in $\partial_{\mathrm{p}} V(x')$ for some $x' \approx x$. See [4] for details.)

Sensitivity to Small Measurement Errors

We have seen that every asymptotically controllable system admits a feedback stabilizer k, generally discontinuous, which renders the closed-loop system $\dot{x} = f(x, k(x))$ GAS. On the other hand, one of the main motivations for the use of feedback is in order to deal with uncertainty, and one possible source of uncertainty are measurement errors in state estimation. The use of discontinuous feedback means that undesirable behavior – chattering – may arise. In fact, one of the main reasons for the focus on continuous feedback is precisely in order to avoid such behaviors. Thus, we turn now to an analysis of the effect of measurement errors. Suppose first that k is a continuous function of x. Then, if the error e is small, using the control $u' = k(x + e)$ instead of $u = k(x)$ results in behavior which remains close to the intended one, since $k(x + e) \approx k(x)$; moreover, if $e \ll x$ then stability is preserved. This property of robustness to small errors when k is continuous can be rigorously established by means of a Lyapunov proof, based on the observation that, if V is a Lyapunov function for the closed-loop system, then continuity of $f(x, k(x + e))$ on e means that

$$\nabla V(x) \cdot f(x, k(x + e)) \approx \nabla V(x) \cdot f(x, k(x)) < 0 .$$

Unfortunately, when k is not continuous, this argument breaks down. However, it can be modified so as to avoid invoking continuity of k. Assuming that V is continuously differentiable, one can argue that

$$\nabla V(x) \cdot f(x, k(x+e)) \approx \nabla V(x+e) \cdot f(x, k(x+e)) < 0$$

(using the Lyapunov property at the point $x + e$ instead of at x). This observation leads to a theorem, formulated below, which says that a discontinuous feedback stabilizer, robust with respect to small observation errors, can be found provided that there is a C^1 clf. In general, as there are no C^1, but only continuous, clf's, one may not be able to find any feedback law that is robust in this sense.

There are many well-known techniques for avoiding chattering, and a very common one is the introduction of deadzones where no action is taken. The feedback constructed in [4], with no modifications needed, can always be used in a manner robust with respect to small observation errors, using such an approach. Roughly speaking, the general idea is as follows. Suppose that the true current state, let us say at time $t = t_i$, is x, but that the controller uses $u = k(\tilde{x})$, where $\tilde{x} = x + e$, and e is small. Call x' the state that results at the next sampling time, $t = t_{i+1}$. By continuity of solutions on initial conditions, $|x' - \tilde{x}'|$ is also small, where $\tilde{x}'$ is the state that would have resulted from applying the control u if the true state had been $\tilde{x}$. By continuity, it follows that $V_\alpha(x) \approx V_\alpha(\tilde{x})$ and also $V_\alpha(x') \approx V_\alpha(\tilde{x}')$. On the other hand, the construction in [4] provides that $V_\alpha(\tilde{x}') < V_\alpha(\tilde{x}) - \mathrm{d}(t_{i+1} - t_i)$, where d is some positive constant (this is valid while we are far from the origin). Hence, if e is sufficiently small compared to the intersample time $t_{i+1} - t_i$, it will necessarily be the case that $V_\alpha(x')$ must also be smaller than $V_\alpha(x)$. This discussion may be formalized in several ways; see [26] for a precise statement.

If we insist upon fast sampling, a necessary condition arises, as was proved in the recent paper [18] (which, in turn, represented an extension of the work by Hermes [10] for classical solutions under observation error). We next discuss the main result from that paper. We consider systems

$$\dot{x}(t) = f(x(t), k(x(t) + \mathrm{e}(t)) + \mathrm{d}(t)) \qquad (17)$$

in which there are observation errors as well as, now, possible actuator errors $d(\cdot)$. Actuator errors $d(\cdot)\colon [0, \infty) \to \mathcal{U}$ are Lebesgue measurable and locally essentially bounded, and observation errors $\mathrm{e}(\cdot)\colon [0, \infty) \to \mathbb{R}^n$ are locally bounded. We define solutions of (17), for each sampling schedule π, in the usual manner, i. e., solving recursively on the intervals $t_i, t_{i+1})$, $i = 0, 1, \ldots$, the differential equation

$$\dot{x}(t) = f\big(x(t), k(x(t_i) + \mathrm{e}(t_i)) + \mathrm{d}(t)\big) \qquad (18)$$

with $x(0) = x^0$. We write $x(t) = x_\pi(t, x^0, \mathrm{d}, \mathrm{e})$ for the solution, and say it is *well-defined* if it is defined for all $t \geq 0$.

Definition The feedback $k\colon \mathbb{R}^n \to \mathcal{U}$ *stabilizes* the system (17) if there exists a function $\beta \in \mathcal{KL}$ so that the following property holds: For each

$$0 < \varepsilon < K$$

there exist $\delta = \delta(\varepsilon, K) > 0$ and $\eta = \eta(\varepsilon, K)$ such that, for every sampling schedule π with $\mathbf{d}(\pi) < \delta$, each initial state x^0 with $|x^0| \leq K$, and each e, d such that $|\mathrm{e}(t)| \leq \eta$ for all $t \geq 0$ and $|\mathrm{d}(t)| \leq \eta$ for almost all $t \geq 0$, the corresponding π-trajectory of (17) is well-defined and satisfies

$$\left|x_\pi(t, x^0, \mathrm{d}, \mathrm{e})\right| \leq \max\left\{\beta\left(K, t\right), \varepsilon\right\} \quad \forall t \geq 0\,. \qquad (19)$$

In particular, taking $K := |x^0|$, one has that

$$\left|x_\pi(t, x^0, d, e)\right| \leq \max\left\{\beta\left(\left|x^0\right|, t\right), \varepsilon\right\} \quad \forall t \geq 0$$

whenever $0 < \varepsilon < |x^0|$, $\mathbf{d}(\pi) < \delta(\varepsilon, |x^0|)$, and for all t, $|\mathrm{e}(t)| \leq \eta(\varepsilon, |x^0|)$, and $|\mathrm{d}(t)| \leq \eta(\varepsilon, |x^0|)$.

The main result in [18] is as follows.

Theorem 7 *There is a feedback which stabilizes the system (17) if and only if there is a C^1 clf for the unperturbed system (1).*

It is interesting to note that, as a corollary of Artstein's Theorem, for control-affine systems $\dot{x} = g_0(x) + \sum u_i\, g_i(x)$ we may conclude that if there is a discontinuous feedback stabilizer that is robust with respect to small noise, then there is also a regular one, and even one that is smooth on $\mathbb{R}^n \setminus \{0\}$. For non control-affine systems, however, there may exist a discontinuous feedback stabilizer that is robust with respect to small noise, yet there is no regular feedback.

Briefly, the sufficiency part of Theorem 7 proceeds by taking a pointwise minimization of the Hamiltonian, for a given C^1 clf, i. e. $k(x)$ is defined as any u with $|u| \leq \sigma(|x|)$ which minimizes $\nabla V(x) \cdot f(x, u)$. The necessity part is based on the following technical fact: if the perturbed system can be stabilized, then the differential inclusion

$$\dot{x} \in F(x) := \bigcap_{\varepsilon > 0} \overline{\mathrm{co}}\, f(x, k(x + \varepsilon B))$$

(where B denotes the unit ball in $\mathbb{R}^n$) is strongly asymptotically stable. One may then apply converse Lyapunov theorems for upper semicontinuous compact convex differential inclusions to deduce the existence of V.

We now summarize exactly which implications hold, writing "robust" to mean stabilization of the system subject to observation and actuator noise:

$$\begin{tikzcd}
C^1 V \arrow[r, Leftrightarrow] \arrow[d, Rightarrow] & \exists \text{ robust } k \arrow[d, Rightarrow] & \\
C^0 V \arrow[r, Leftrightarrow] & \exists k \arrow[r, Leftrightarrow] & \mathrm{AC}\,.
\end{tikzcd}$$

Future Directions

There are several alternative approaches to feedback stabilization, notably the very appealing approach to discontinuous stabilization throgh *patchy feedbacks* [1], as well as other related "hybrid" approaches [20]. It is also extremely important to understand the effect of "large" disturbances on the behavior of feedback systems. This study leads one to the very active area of input to state stability (ISS) and related notions (output to state stability as a model of detectability, input to output stability for the study of regulation problems, and so forth), see [27].

Article Outline

Glossary

Ordinary differential equation An equation for an unknown vector of functions of a single variable that involves derivatives of the unknown functions. The order of a differential equation is the highest order of the derivatives that appear. The most important class of differential equations are first-order systems of ordinary differential equations that can be written in the form $\dot{u} = f(u, t)$, where f is a given smooth function $f\colon U \times J \to \mathbb{R}^n$, U is an open subset of $\mathbb{R}^n$, and J is an open subset of $\mathbb{R}$. The unknown functions are the components of u, and the vector of their first-order derivatives with respect to the independent variable t is denoted by $\dot{u}$. A solution of this differential equation is a function $u\colon K \to \mathbb{R}^n$, where K is an open subset of J such that $\frac{\mathrm{d}u}{\mathrm{d}t}(t) = f(u(t), t)$ for all $t \in K$.

Dynamical system A set and a law of evolution for its elements. The first-order differential equation $\dot{u} = f(u, t)$, where $f\colon U \times J \to \mathbb{R}^n$, is the law of evolution for the set $U \times J$; it defines a continuous (time) dynamical system: Given $(v, s) \in U \times J$, the solution $t \mapsto \psi(t, s, v)$ such that $\phi(s, s, v) = v$ determines the evolution of the state v: the state v at time s evolves to the state $\psi(t, s, v)$ at time t. Similarly, a continuous function $f\colon X \to X$ on a metric space X defines a discrete dynamical system. The state $x \in X$ evolves to $f^k(x)$ (which denotes the value of f composed with itself k times and evaluated at x) after k time-steps. The images of $t \mapsto \phi(t, s, v)$ and $k \mapsto f^k(x)$ are called the orbits of the corresponding states v and x.

Stability theory The mathematical analysis of the behavior of the distances between an orbit (or set of orbits) of a dynamical system and all other nearby orbits.

Definition of the Subject

An orbit or set of orbits of a dynamical system is stable if all solutions starting nearby remain nearby for all future times. This concept is of fundamental importance in applied mathematics: the stable solutions of mathematical models of physical processes correspond to motions that are observed in nature.

Introduction

Stability theory began with a basic question about the natural world: Is the solar system stable? Will the present configuration of the planets and the sun remain forever; or, might some planets collide, radically change their orbits, or escape from the solar system?

With the advent of Isaac Newton's second law of motion and the law of universal gravitation, the motions of the planets in the solar system were understood to correspond to the solutions of the Newtonian system of ordinary differential equations that modeled the positions and velocities of the planets and the sun according to their mutual gravitational attractions. Short-term approximate predictions (up to a few years in the future) verified this theory; but, due to the complexity of the differential equations of motion, the problem of long-term prediction was not solved; it still occupies a central place in mathematical research.

Does the Newtonian model predict the stability of the solar system?

During the 18th Century, Pierre Simon Laplace [52, 53] asserted a proof of the stability of the solar system. He considered the changes in the semi-major axes and eccentricities of the elliptical motions of the planets around the sun. Using (reasonable) approximations of the Newtonian equations of motion, he showed that for his approximate model these orbital elements do not change over long periods of time due to the disturbances caused by the gravitational attractions of the other bodies in the solar system. If true for the full Newtonian equations of motion, these assertions would imply the stability of the Newtonian solar system. In fact, no proof of the stability of the solar system is known (see [69]). Laplace's results merely provide evidence in favor of stability of the solar system; on the other hand, this work was a primary stimulus for the later development of a general theory of stability.

One of the first rigorous results in stability theory was stated by Joseph-Louis Lagrange [49] and proved by Lejeune Dirichlet [23,24]; it states that an isolated minimum of the potential energy of a conservative mechanical system is the position of a stable equilibrium point.

Joseph Liouville [56,57,58,59] discussed the problem of the stability of rotating fluid bodies. The further development of this theory was suggested to Aleksandr Mikhailovich Lyapunov as a thesis topic by his advisor Pafnuty Chebyshev. This led to the fundamental and foundational work of Lyapunov on stability theory [63].

Henri Poincaré's introduction of the qualitative theory of differential equations [71] influenced Lyapunov's treatment of stability theory and laid much of the foundation for the modern theory of nonlinear dynamical systems. In addition, Poincaré's work on celestial mechanics [72,73,74,75,76] discusses stability theory.

Mathematical Formulation of the Stability Concept and Basic Results

Consider the first-order ordinary differential equation

$$\dot{u} = f(u, t) , \tag{1}$$

where the dependent variable u is an n-dimensional real vector, $\dot{u}$ denotes the derivative of u with respect to the independent variable t, and f (a mapping, from the cross product of an open subset U of n-dimensional space $\mathbb{R}^n$ and an open subset J of the real line $\mathbb{R}$, into $\mathbb{R}^n$) is at least class C^1. The existence and uniqueness theorem for differential equations (see, for example, [19]) states that if $(v, s) \in U \times J$, then there is a unique solution $t \mapsto \psi(t, s, v)$ of the differential equation such that $\psi(s, s, v) = v$. Moreover, the function ψ is as smooth as the function f.

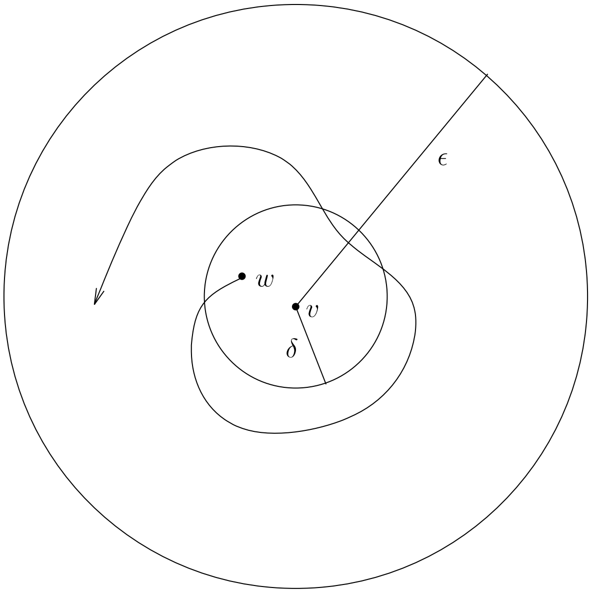
Definition 1 For $v \in \mathbb{R}^n$, the notation $|v|$ denotes the length of v.

A solution $t \mapsto \psi(t, s, v)$ of the differential Eq. (1) is called stable if it is defined for all time $t \geq s$ and for every positive number ϵ there is a positive number δ such that $|\phi(t, s, w) - \phi(t, s, v)| < \epsilon$ whenever $t \geq s$ and $|w - v| < \delta$ (see Fig. 1).

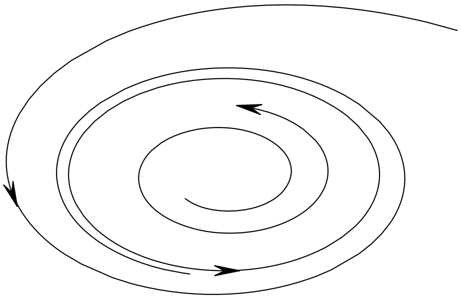
A stable solution $t \mapsto \psi(t, s, v)$ is called orbitally asymptotically stable if there is a choice of δ such that the distance between the point $\psi(t, s, w)$ and the set $\{\psi(t, s, v) \colon t \geq s\}$—called the forward orbit of the solution—converges to zero as $t \to \infty$.

A stable solution $t \mapsto \psi(t, s, v)$ is called asymptotically stable if there is a choice of δ such that the distance $|\phi(t, s, w) - \phi(t, s, v)|$ converges to zero as $t \to \infty$ whenever $|w - v| < \delta$ (see Fig. 2).

A solution is called unstable if it is not stable.



Stability Theory of Ordinary Differential Equations, Figure 1
The figure depicts a stable rest point *v*. The orbit starting at *w*, an arbitrary point whose distance from *v* is less than δ, remains within distance ϵ for all positive time



Stability Theory of Ordinary Differential Equations, Figure 2
The figure depicts an orbitally asymptotically stable elliptical periodic orbit together with two additional orbits that approach the periodic orbit, one from the outside and one from the inside of the region bounded by the periodic orbit

While the definitions just given are widely accepted, the words “asymptotic stability” are often used to mean orbital asymptotic stability. For most situations orbital asymptotic stability is the desired concept. It is clear from the definitions that the concept of asymptotic stability is much stronger than the concept of orbital asymptotic stability for stable solutions whose orbits consist of more than one point. The position of the evolving state along an asymptotically stable orbit is approached by an open set of evolving states. On the other hand, for a solution to be orbitally asymptotically stable only the distances between the elements of this open set of evolving states and the point set consisting of the forward orbit of the stable solution is required to approach zero. There is no requirement that the open set of evolving states all converge to the evolving state on the stable orbit in unison as time increases without bound. An important concept introduced by Poincaré, the return map, is useful in the study of orbital asymptotic stability; it will be discussed below.

To illustrate the concept of stability, let us consider the (dimensionless) harmonic oscillator

$$\ddot{x} + x = 0 \,. \tag{2}$$

This second-order differential equation is recast as the first-order system

$$\dot{x} = y \,, \quad \dot{y} = -x \tag{3}$$

by introducing the velocity $y := \dot{x}$ as a new variable. It is a classical mechanical system with kinetic energy $\frac{1}{2}\dot{x}^2$ and potential energy $\frac{1}{2}x^2$. According to the principle of Lagrange, the equilibrium solution $(x, y) = (0, 0)$ (which corresponds to an isolated minimum of the potential energy) is stable. This result is easily verified by inspection of the general solution of system (3) that is given by

$$\phi(t, \xi, \eta) = \begin{pmatrix} \cos t & \sin t \\ -\sin t & \cos t \end{pmatrix} \begin{pmatrix} \xi \\ \eta \end{pmatrix} , \tag{4}$$

where (ξ, η) is an arbitrary point in $\mathbb{R}^2$. All non-equilibrium solutions are periodic. In fact, the orbit of the solution starting at (ξ, η) is a circle with radius $\sqrt{\xi^2 + \eta^2}$. Given an open subset containing the origin, the disk bounded by one of these circles defines an open subset. Every orbit with initial value inside this disk remains inside the disk (and hence the given open set) for all $t \geq 0$. On the other hand, the origin is not orbitally asymptotically stable; indeed, the periodic solutions do not approach the origin in positive time.

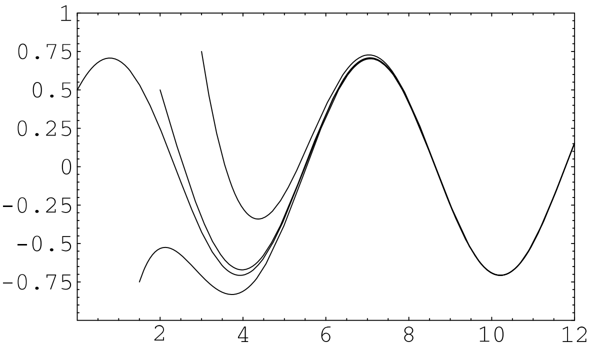
The origin is also an equilibrium of the damped harmonic oscillator

$$\ddot{x} + \epsilon\dot{x} + x = 0 \,, \tag{5}$$

where $\epsilon > 0$. Again, inspection of the general solution shows that the origin is asymptotically stable and therefore orbitally asymptotically stable. In effect, all terms in the formula for the general solution contain the factor $\mathrm{e}^{-\epsilon t/2}$, which converges to zero as $t \to \infty$.

For a nonautonomous example (that is, a differential Eq. (1) such that the partial derivative of f with respect to t is not zero), consider the first-order scalar differential equation

$$\dot{x} = -x + \sin t \tag{6}$$



Stability Theory of Ordinary Differential Equations, Figure 3
A graph of the asymptotically stable solution (7) of the scalar first-order differential Eq. (6) is depicted together with the graphs of three additional solutions given by $t \mapsto \phi(t,s,v)$ for (s,v) equal to $(1.5,-0.75)$, $(3.0,0.75)$, and $(2.0,0.5)$

whose solutions are given by

$$\phi(t,s,v) = \left(v - \frac{1}{2}(\sin s + \cos s)\right) e^{s-t} + \frac{1}{2}(\sin t + \cos t)\,.$$

The solution starting at the state 1/2 at time zero,

$$\phi\left(t, 0, \frac{1}{2}\right) = \frac{1}{2}(\sin t + \cos t)\,, \tag{7}$$

is asymptotically stable. This result is true due to the presence of the exponential factor in the general solution; it decreases to zero for each fixed s as $t \to \infty$ (cf. Fig. 3).

The origin is an unstable equilibrium for the scalar first-order differential equation $\dot{x} = x^2$, whose solutions are given by

$$\phi(t,s,v) = \frac{v}{1-(t-s)v}\,.$$

Indeed, for every $\delta > 0$ (no matter how small) there is a some $v \in \mathbb{R}$ such that $|v| < \delta$ and $v > 0$. The corresponding solution converges to infinity as $t \to (1+sv)/v$.

Because explicit solutions of differential equations are rare, the main subject of stability theory is the determination of criteria for stability that do not require knowledge of the general solution of the differential equation.

While the theory of stability is mature with many branches of development, the main results (originally obtained by Poincaré and Lyapunov) follow from two fundamental ideas: linearization and Lyapunov functions.

The Principle of Linearized Stability

A linear first-order differential equation is a differential equation of the form

$$\dot{u} = A(t)u\,, \tag{8}$$

where $A(t)$ denotes an $n \times n$ matrix-valued function of the independent variable t.

Most of the analysis of autonomous linear differential equations can be reduced to linear algebra. Indeed, a function of the form $e^{\lambda t}v$, where λ is a complex number and $v \neq 0$ is a complex vector with n components, is a complex solution of the differential equation

$$\dot{u} = Au\,, \tag{9}$$

if and only if $Av = \lambda v$; that is, λ is an eigenvalue of the matrix A and v is a corresponding eigenvector. The real and imaginary parts of a complex solution are automatically real solutions of the real differential Eq. (9). Also, linear combinations of solutions of linear equations are again solutions. Thus, in case there is a basis of eigenvectors, all solutions of the linear system can be expressed as linear combinations (superpositions) of the special exponential solutions. The general solution, for an arbitrary system matrix A, can always be obtained from linear combinations of solutions of the form $p(t)e^{\lambda t}v$, where $p(t)$ is a polynomial of degree at most $n-1$ and $Av = \lambda v$. In fact, there is always a linear change of variables $w = Bu$, given by some invertible matrix B, such that the new system

$$\dot{w} = Jw\,,$$

where the transformed system matrix $J := BAB^{-1}$ is in Jordan canonical form (see, for example, [78]). This block diagonal system can be solved by linear combinations of solutions of the form $p(t)e^{\lambda t}v$, and the solution of the original system (9) is obtained by the inverse change of variables. Alternatively, it is not difficult to prove that the general solution of the system (9) is given by

$$\phi(t,s,v) = e^{(t-s)A}v\,, \tag{10}$$

where

$$e^{tA} := I + \sum_{k=1}^{\infty}(tA)^k \tag{11}$$

and v is an arbitrary point in $\mathbb{R}^n$.

Solutions of the form $t \mapsto p(t)e^{\lambda t}v$ converge to zero as $t \to \infty$ whenever the real part of the eigenvalue λ is less than zero. This observation leads to a basic result:

Theorem 2 *If all eigenvalues of the matrix A have negative real parts, then the zero solution of the autonomous system (9) is asymptotically stable.*

To examine the stability of a solution ψ of the (perhaps nonlinear) differential Eq. (1), consider a second solution γ, define the deviation $\delta = \gamma - \psi$, and note that

$$\dot{\delta} = f(\gamma,t) - f(\psi,t) = f(\delta+\psi,t) - f(\psi,t)$$

Definition 3 The linearized equation along the solution ψ of the differential Eq. (1) is

$$\dot{w} = f_u(\psi(t), t)w\,, \tag{12}$$

where the subscript denotes the partial derivative with respect to u.

The linearized equation may be viewed as an approximation of the differential equation for the deviation δ because the linearized equation is also obtained by Taylor expanding the function

$$\delta \mapsto f(\delta + \psi, t) - f(\psi, t)$$

to first-order at $\delta = 0$ and ignoring the remainder term. The principle of linearized stability states that the original solution ψ is stable whenever the zero solution of the linearized equation is stable.

The principle of linearized stability is not a theorem; rather, it serves as the underlying idea for the theory of stability by linearization. A basic result of this theory is the following theorem (see [63]).

Theorem 4 *Let*

$$\dot{u} = Au + B(t)u + g(u, t)\,, \quad u(t_0) = u_0\,, \quad u \in \mathbb{R}^n$$

be a smooth initial value problem with solution $t \mapsto \psi(t)$. If

(1) A is a constant matrix and all its eigenvalues have negative real parts,
(2) B is an $n \times n$ matrix valued function, continuously dependent on t, such that the matrix norm $\|B(t)\|$ converges to zero as $t \to \infty$,
(3) g is smooth and there are constants $a > 0$ and $k > 0$ such that $|g(v, t)| \leq k|v|^2$ for all $t \geq 0$ and $|v| > a$,

then there are constants $C > 1$, $\beta > 0$, and $\lambda > 0$ such that

$$|\psi(t)| \leq C|u_0|e^{-\lambda(t-t_0)}\,, \quad t \geq t_0$$

whenever $|u_0| \leq \beta/C$. In particular, the zero solution is asymptotically stable.

Theorem 4 is used for the stability analysis of rest points of autonomous first-order differential equations. If $f\colon \mathbb{R}^n \to \mathbb{R}^n$ and $f(\xi) = 0$, for some $\xi \in \mathbb{R}^n$, then the constant function $\phi(t, \xi) = \xi$ is a solution of the autonomous differential equation

$$\dot{u} = f(u)\,. \tag{13}$$

In this case, ξ is called a rest point for the differential equation. By Taylor expansion at the rest point—this time keeping the remainder term, the differential equation is recast in the form

$$\dot{\gamma} = Df(\xi)\gamma + R(\xi, \gamma)\,,$$

where Df denotes the derivative of f and $\gamma := \phi - \xi$ for an arbitrary solution ϕ. If f is class C^2, we have that

$$|R(\xi, v)| \leq k|v|^2\,.$$

Thus, under the hypothesis that all eigenvalues of the constant system matrix $Df(\xi)$ have negative real parts, Theorem 4 implies that the rest point ξ is asymptotically stable. The hypothesis that f is class C^2 can be relaxed (see, for example, [19]):

Theorem 5 *If $f\colon \mathbb{R}^n \to \mathbb{R}^n$ is class C^1, $\xi \in \mathbb{R}^n$, $f(\xi) = 0$, and all eigenvalues of the matrix $Df(\xi)$ have negative real parts, then the rest point ξ is asymptotically stable. If the matrix $Df(\xi)$ has an eigenvalue with positive real part, then the rest point ξ is unstable.*

The damped harmonic oscillator (5) is equivalent to the first-order system of (linear) differential equations

$$\dot{u} = Au\,, \tag{14}$$

where the system matrix is

$$A := \begin{pmatrix} 0 & 1 \\ -1 & -\epsilon \end{pmatrix}. \tag{15}$$

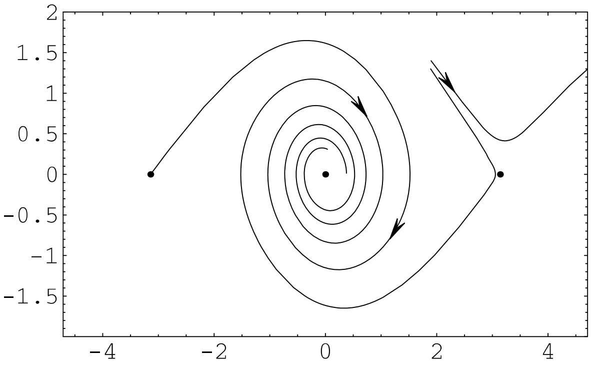
If $\epsilon > 0$, the system matrix has eigenvalues $\frac{1}{2}(-\epsilon \pm \sqrt{\epsilon^2 - 4})$ whose real parts are always negative. Thus, the rest point at the origin is asymptotically stable in agreement with physical intuition.

The power of the linearization method is demonstrated by its applications to systems whose general solutions are not known explicitly; for example, the nonlinear oscillator

$$\ddot{x} + \epsilon x + x + g(x) = 0\,, \tag{16}$$

where g is an arbitrary (smooth) function such that $g(0) = Dg(0) = 0$. In this case, the origin is a rest point of the equivalent first-order system and the system matrix of the linearized system at the origin is again the matrix (15); therefore, by Theorem 5, the origin is asymptotically stable. This result applies to the rest point $(\theta, \dot{\theta}) = (0, 0)$ of the damped pendulum

$$\ddot{\theta} + \epsilon\dot{\theta} + \sin\theta = 0\,. \tag{17}$$



Stability Theory of Ordinary Differential Equations, Figure 4
The figure depicts portions of six orbits in the phase portrait of the damped pendulum (17) with $\epsilon = 0.2$: the rest points at $(\theta, \dot\theta)$ equal to $(-\pi, 0)$, $(0, 0)$, and $(\pi, 0)$; and, the orbits starting at $(-\pi, 0.001)$, $(\pi - 1.25, 1.3)$, and $(\pi - 1.243, 1.4)$. The last two orbits pass close to the (saddle type) unstable rest point at $(\pi, 0)$

The differential Eq. (17) also has a rest point at $(\theta, \dot\theta) = (\pi, 0)$ where the system matrix of the linearized differential equation is

$$\begin{pmatrix} 0 & 1 \\ 1 & -\epsilon \end{pmatrix} . \tag{18}$$

If $\epsilon > 0$, this matrix has an eigenvalue with positive real part; therefore, this rest point—which corresponds to the upward vertical equilibrium of the physical pendulum—is unstable (cf. Fig. 4).

Definition 6 An $n \times n$ matrix is called infinitesimally hyperbolic if all of its eigenvalues have non-zero real parts. A rest point of an autonomous system is called hyperbolic if the system matrix of the linearized equation at this rest point is infinitesimally hyperbolic. The rest point is called nondegenerate if the system matrix is invertible.

An important result on the principle of linearized stability for rest points is the Grobman–Hartman theorem (see [30,31,34,35] and [19,22]):

Theorem 7 *If v is a hyperbolic rest point for the autonomous differential equation $\dot u = f(u)$, then there is an open set V containing v and a homeomorphism H with domain V such that the orbits of this differential equation in V are mapped by H to orbits of the linearized system $\dot w = Df(v)w$.*

In other words, the qualitative behavior of an autonomous differential equation in a sufficiently small neighborhood of a hyperbolic rest point is the same as the behavior of its linearization at this rest point.

The related problem of the existence of a change of variables (a diffeomorphism) taking a given system to its linearization in a neighborhood of a rest point is more difficult to resolve. Fundamental work in this area is due to Poincaré [74], Carl Siegel [88], Henri Dulac [25], Shlomo Sternberg [90,91] and A.D. Brjuno [16] (see also [9,89]). The non-existence of certain relationships (resonances) among the eigenvalues of the system matrix of the linearization plays an important role in the theory.

Definition 8 The vector of eigenvalues $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_n)$ of the $n \times n$-matrix A is called resonant if there is an n-vector of nonnegative integers $M = (m_1, m_2, \dots, m_n)$ such that $\sum_{k=1}^{n} |m_k| \geq 2$ and at least one of the eigenvalues λ_k is given by

$$\lambda_k = \langle M, \lambda \rangle ,$$

where the angle brackets denote the usual inner product. The eigenvalues are nonresonant if no such relationship occurs.

The first theorem of the subject was proved by Poincaré:

Theorem 9 *If the eigenvalues of the linearization of a vector field given by a formal power series are nonresonant, then there is a change of variables in the form of a formal power series that transforms the vector field to its linearization.*

In case the linearization is resonant, there is a formal change of variables that removes all of the terms in the formal series that defines the vector field except those that are resonant (that is, the corresponding monomials are given by products of variables whose powers form vectors with the properties of M in the definition of resonance).

Definition 10 The vector of eigenvalues $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_n)$ of the $n \times n$-matrix A belongs to the Poincaré domain if the convex hull of its components in the complex plane does not contain the origin; otherwise, the vector belongs to the Siegel domain. The vector λ is called type (C, ν) for $C > 0$ and $\nu > 0$, if the inequality

$$|\lambda_k - \langle M, \lambda \rangle| \geq \frac{C}{(\sum_k |m_k|)^\nu}$$

is satisfied for each component λ_k of λ and all vectors M as in Definition 8.

Theorem 11 *If the eigenvalues of the linearization of an analytic vector field are nonresonant and in the Poincaré domain, then there is an analytic change of coordinates that transforms the vector field to its linearization. If the eigenvalues of the linearization of an analytic vector field are of* *type (C, ν), then there is an analytic change of coordinates that transforms the vector field to its linearization.*

For modern proofs of Poincaré's and Siegel's theorems see [71] or [87]. Sternberg proved Siegel's result for vector fields in the Siegel domain for sufficiently smooth vector fields (see [90,91]).

To successfully apply linearized stability for rest points of autonomous systems, the fundamental problem is to determine the real parts of the eigenvalues of a square matrix; especially, it is important to determine conditions that ensure all eigenvalues have negative real parts. The most important result in this direction is the Routh-Hurwitz criterion (see [40,84]):

Theorem 12 *Suppose that the characteristic polynomial of the real matrix A is written in the form*

$$\lambda^n + a_1\lambda^{n-1} + \cdots + a_{n-1}\lambda + a_n \, ,$$

let $a_m = 0$ for $m > n$, and define the determinants Δ_k for $k = 1, 2, \ldots, n$ by

$$\Delta_k := \det \begin{pmatrix} a_1 & 1 & 0 & 0 & 0 & 0 & \cdots & 0 \\ a_3 & a_2 & a_1 & 1 & 0 & 0 & \cdots & 0 \\ a_5 & a_4 & a_3 & a_2 & a_1 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ a_{2k-1} & a_{2k-2} & a_{2k-3} & a_{2k-4} & a_{2k-5} & a_{2k-6} & \cdots & a_k \end{pmatrix} .$$

If $\Delta_k > 0$ for $k = 1, 2, \ldots n$, then all roots of the characteristic polynomial have negative real parts.

The principle of linearized stability is not valid in general. In particular, the stability of the linearized equation at a rest point of an autonomous differential equation does not always determine the stability of the rest point. For example, consider the scalar differential equation $\dot{u} = -u^m$, where $m > 1$ is a positive integer. The origin $u = 0$ is a rest point for this differential equation and the corresponding linearized system is $\dot{w} = 0$. The origin (and every other point on the real line) is a stable rest point of this linear differential equation. On the other hand, by solving the original equation, it is easy to see that the origin is asymptotically stable in case m is odd and unstable in case m is even. Thus, the stability of the linearization does not determine the stability of the rest point.

There is no theorem known that can be used to determine the stability of a general nonautonomous first-order linear differential Eq. (8). In particular, there is no obvious relation between the (time-dependent) eigenvalues of a time-dependent matrix and the stability of the zero solution of the corresponding first-order linear differential equation. Consider, as an example, the π-periodic system $\dot{u} = A(t)u$, where

$$A(t) = \begin{pmatrix} -1 + \frac{3}{2}\cos^2 t & 1 - \frac{3}{2}\sin t \cos t \\ -1 - \frac{3}{2}\sin t \cos t & -1 + \frac{3}{2}\sin^2 t \end{pmatrix} , \quad (19)$$

which was constructed by Lawrence Marcus and Hidehiko Yamabe [66]. The real parts of the eigenvalues of $A(t)$ (given by $\frac{1}{4}(-1 \pm \sqrt{7}\, i)$) are negative; but,

$$u(t) = e^{t/2} \begin{pmatrix} -\cos t \\ \sin t \end{pmatrix}$$

is a solution that grows without bound.

While a general theory of linearized stability for non-constant solutions of differential equations remains an area of research, much is known in case the non-constant solution is periodic.

Suppose that $t \mapsto \psi(t)$ is a periodic solution with period T of the differential Eq. (1) defined on $\mathbb{R}^n$. Linearization leads to the differential equation

$$\dot{\gamma} = f_u(\psi(t), t)\gamma \, , \quad (20)$$

where the matrix (valued function) $A(t) := f_u(\psi(t), t)$ is periodic with period T. Thus, the theory of linearized stability for periodic solutions starts with the stability theory for the periodic linear differential Eq. (8). The most basic results in this setting are due to Gaston Floquet [27]. To state them, let us first recall that a linear differential equation admits matrix solutions; that is, matrices whose columns are vector solutions. A fundamental matrix solution is an $n \times n$-matrix solution with linearly independent columns; or, equivalently, a matrix solution whose values are all invertible as $n \times n$-matrices.

Floquet's main results are stated in the following theorem (see [19] and recall the definition of the matrix exponential in display (11)).

Theorem 13 *If $\Phi(t)$ is a fundamental matrix solution of the T-periodic system (8), then*

$$\Phi(t + T) = \Phi(t)\Phi^{-1}(0)\Phi(T)$$

for all $t \in \mathbb{R}$. In addition, there is a matrix B (which may be complex) such that

$$e^{TB} = \Phi^{-1}(0)\Phi(T)$$

and a T-periodic matrix function $t \mapsto P(t)$ (which may be complex valued) such that $\Phi(t) = P(t)e^{tB}$ for all $t \in \mathbb{R}$. Also, there is a real matrix R and a real $2T$-periodic matrix function $t \to Q(t)$ such that $\Phi(t) = Q(t)e^{tR}$ for all $t \in \mathbb{R}$.

The stability of the zero solution of the periodic linear differential equation is intimately connected with the eigenvalues of the matrix R in Floquet's theorem. Indeed, the time-dependent (real) change of variables $u = Q(t)v$ transforms the T-periodic differential Eq. (8) to the autonomous linear system

$$\dot{v} = Rv \, .$$

Definition 14 The representation $\Phi(t) = P(t)\mathrm{e}^{tB}$ of the fundamental matrix solution Φ in Floquet's theorem is called a Floquet normal form. The eigenvalues of the matrix e^{tB} are called the characteristic (or Floquet) multipliers of the corresponding linear system. A complex number μ is called a characteristic (or Floquet) exponent if there is a characteristic multiplier ρ such that $\mathrm{e}^{\mu T} = \rho$.

Theorem 15

(1) *The characteristic multipliers and the characteristic exponents do not depend on the choice of the fundamental matrix solution of the T-periodic differential Eq. (8).*
(2) *If the characteristic multipliers of the periodic system (8) all have modulus less than one; equivalently, if all characteristic exponents have negative real parts, then the zero solution is asymptotically stable.*
(3) *If the characteristic multipliers of the periodic system (8) all have modulus less than or equal to one; equivalently, if all characteristic exponents have nonpositive real parts, and if the algebraic multiplicity equals the geometric multiplicity of each characteristic multiplier with modulus one; equivalently, if the algebraic multiplicity equals the geometric multiplicity of each characteristic exponent with real part zero, then the zero solution is stable.*
(4) *If at least one characteristic multiplier of the periodic system (8) has modulus greater than one; equivalently, if a characteristic exponent has positive real part, then the zero solution is unstable.*

While Theorem 15 gives a complete description of the stability of the zero solution, no general method is known to determine the characteristic multipliers (cf. [98]). The power of the theorem is an immediate corollary: A finite set of numbers (namely, the characteristic multipliers) determine the stability of the zero solution, at least in the case where none of them have modulus one. The characteristic multipliers can be approximated by numerical integration. And, in special cases, their moduli can be determined by mathematical analysis.

One of the most important applications for Floquet theory and the method of linearization, is the analysis of Hill's equation

$$\ddot{x} + a(t)x = 0 \, , \tag{21}$$

or, equivalently, the first-order linear system

$$\dot{x} = y \, , \quad \dot{y} = -a(t)x \, , \tag{22}$$

where x is a scalar and a is a T-periodic function (see [19, 64]). This equation arose from George Hill's study of lunar motion. It is ubiquitous in stability theory.

The stability of the zero solution of Hill's system (22) can be reduced to the identification of a single number; namely, the magnitude of the trace of the principal fundamental matrix solution $\Phi(t)$ at $t = T$ (that is, the fundamental matrix solution $\Phi(t)$ such that $\Phi(0) = I$, where I is the $n \times n$ identity matrix).

Theorem 16 *Suppose that $\Phi(t)$ is the principal fundamental matrix solution of system (22). If $|\operatorname{trace} \Phi(T)| < 2$, then the zero solution is stable. If $|\operatorname{trace} \Phi(T)| > 2$, then the zero solution is unstable.*

This result, of course, requires knowledge of the solutions of the system. On the other hand, a beautiful theorem of Lyapunov [55] gives a stability criterion using only properties of the function a:

Theorem 17 *If $a \colon \mathbb{R} \to \mathbb{R}$ is a positive T-periodic function such that*

$$T \int_0^T a(t)\,dt \le 4 \, ,$$

then all solutions of the Hill's equation $\ddot{x} + a(t)x = 0$ are bounded. In particular, the trivial solution is stable.

The principle of linearized stability for periodic solutions of nonlinear systems motivates a theory similar to the stability theory for rest points. There is, however, one essential difference that will be explained for a T-periodic solution γ of the autonomous first-order differential equation

$$\dot{u} = f(u). \tag{23}$$

The linearized equation at γ is $\dot{w} = Df(\gamma(t))w$. Let $\phi(t) = f(\gamma(t))$ and note that

$$\dot{\phi}(t) = Df(\gamma(t))f(\gamma(t)) = Df(\gamma(t))\phi(t) \, ;$$

that is, $t \mapsto f(\gamma(t))$ is a solution of the linearized equation. This solution is given by

$$f(\gamma(t)) = \Phi(t)f(\gamma(0)) \, ,$$

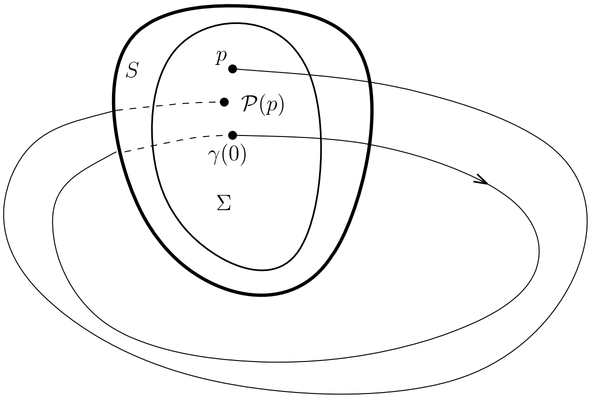
where $\Phi(t)$ is the principal fundamental matrix solution of the linearized equation. If follows that $\Phi(T)f(\gamma(0)) =$

$f(\gamma(0))$; therefore, the number 1 is a characteristic multiplier. It corresponds to motion in the direction of the periodic solution and does not contribute to the stability or instability of the periodic solution. This characteristic multiplier must be treated separately in the stability theory.

Theorem 18 *If the number 1 occurs with algebraic multiplicity one in the set of characteristic multipliers of the linearized differential equation at a periodic solution and all other characteristic multipliers have modulus less than one, then the periodic solution is orbitally asymptotically stable. If at least one characteristic multiplier has modulus larger than one, then the periodic solution is unstable.*

Poincaré introduced a geometric approach to stability for periodic solutions. His idea is simple and useful: Consider a periodic solution γ and some point, say $\gamma(0)$, on the orbit of this solution in $\mathbb{R}^n$. Construct a hypersurface S in $\mathbb{R}^n$ that contains $\gamma(0)$ and is transverse to the orbit of γ at this point. By the implicit function theorem, there is an open neighborhood Σ of $\gamma(0)$ in S such that the solution of the differential equation starting at every point in Σ returns to S. This defines a local diffeomorphism $\mathcal{P}\colon \Sigma \to S$, called the Poincaré (or return) map, which assigns p to its point of first return on S (cf. Fig. 5).

The eigenvalues of the derivative of $\mathcal{P}$ at $\gamma(0)$ are exactly the characteristic multipliers associated with γ. Thus, if all eigenvalues of this derivative have modulus less than one, then γ is orbitally asymptotically stable. The derivative of the Poincaré map can be computed using the linearized equations of the corresponding differential equation along its the periodic orbit. While explicit formulas for the desired derivative are only available for special cases, the Poincaré map provides an indispensable tool for organizing the study of stability for periodic orbits in general.



Stability Theory of Ordinary Differential Equations, Figure 5
A schematic diagram of a Poincaré map $\mathcal{P}$ defined on a Poincaré section Σ near a periodic orbit containing the point $\gamma(0)$

It should be clear that the discrete dynamical system defined by $\mathcal{P}$ codes all the information about the qualitative behavior of the solutions of the differential equation that start near the orbit of γ. The existence of the Poincaré map is thus the main connection between discrete and continuous dynamical systems.

Often, but not always, the dynamical properties of diffeomorphisms (or maps) are simpler to analyze than the corresponding properties of differential equations. Thus, theorems are often proved first for maps and later for differential equations. For instance, the Grobman–Hartman theorem was first proved for diffeomorphisms. This result can be applied to the Poincaré map of a periodic orbit to prove the existence of a homeomorphism that maps nearby orbits to the orbits of a corresponding linearization.

For the special case of periodic solutions of autonomous first-order differential equations on the plane, there is exactly one important Floquet multiplier; it is identified in the following fundamental result.

Theorem 19 *If γ is a periodic solution with period T of the differential Eq. (23) defined on $\mathbb{R}^2$, then the number*

$$\mu = \int_0^T \operatorname{div} f(\gamma(t))\,dt$$

(where div *denotes the divergence) is (up to a positive scalar multiple) a characteristic exponent of γ. If μ is negative, then γ is orbitally asymptotically stable. If μ is positive, then γ is unstable.*

The system of differential equations

$$\dot{x} = x - y - (x^2 + y^2)x\,, \quad \dot{y} = x + y - (x^2 + y^2)y$$

has the periodic solution $t \to (\cos t, \sin t)$ (depicted with a non-unit aspect ratio in Fig. 2). Also, the divergence of the vector field is $2 - 4(x^2 + y^2)$; it has value -2 along the corresponding periodic orbit $\Gamma = \{(x, y)\colon x^2 + y^2 = 1\}$. By Theorem 19, Γ is orbitally asymptotically stable. This is an example of a limit cycle; that is, an isolated periodic orbit. By changing to polar coordinates (r, θ), the transformed system

$$\dot{r} = r(1 - r^2)\,, \quad \dot{\theta} = 1$$

decouples, and its flow is given by

$$\phi_t(r, \theta) = \left(\left(\frac{r^2 e^{2t}}{1 - r^2 + r^2 e^{2t}} \right)^{\frac{1}{2}}, \theta + t \right). \tag{24}$$

The positive x-axis is a Poincaré section with corresponding Poincaré map P given by

$$P(x) = \left(\frac{x^2 e^{4\pi}}{1 - x^2 + x^2 e^{4\pi}} \right)^{\frac{1}{2}} .$$

The periodic orbit Γ intersects the Poincaré section at $x = 1$ where we have $P(1) = 1$ and $P'(1) = e^{-4\pi} < 1$.

A periodic solution of an autonomous system cannot be asymptotically stable. This fact depends on a special property of the solutions of autonomous systems: if the differential Eq. (1) is autonomous, then the function ψ giving the solutions, $t \mapsto \psi(t, s, v)$, is a function of $t - s$. Hence, by replacing $t - s$ by t, each solution can be expressed in the form $t \mapsto \phi(t, v)$ where $\phi(0, v) = v$ and $\phi(t, \phi(s, v)) = \phi(t + s, v)$ whenever both sides are defined. The family of functions $v \mapsto \phi(t, v)$, parametrized by t is called the flow of the differential Eq. (1).

Suppose that $t \mapsto \phi(t, v)$ is an asymptotically stable periodic solution with period T. Let $\delta > 0$ be as in Definition 1. If $|w - v| < \delta$, then $\lim_{t\to\infty} |\phi(t, w) - \phi(t, v)| = 0$. For all sufficiently small s, we have that $|\phi(s, w) - v| < \delta$. Hence, $\lim_{t\to\infty} |\phi(t, \phi(s, w)) - \phi(t, v)| = 0$. By the triangle law,

$$\begin{aligned} &|\phi(t + s, v) - \phi(t, v)| \\ &\le |\phi(t + s, v) - \phi(t + s, w)| + |\phi(t + s, w) - \phi(t, v)| \\ &\le |\phi(s, \phi(t, v)) - \phi(s, \phi(t, w)| + |\phi(t + s, w) - \phi(t, v)|. \end{aligned}$$

Since $\xi \mapsto \phi(s, \xi)$ is smooth and a periodic orbit is compact, the law of the mean implies that there is a constant $C > 0$ such that

$$\begin{aligned} &|\phi(t + s, v) - \phi(t, v)| \\ &\quad \le C|\phi(t, v) - \phi(t, w)| + |\phi(t + s, w) - \phi(t, v)| . \end{aligned}$$

Both summands on the right-hand side of the last inequality converge to zero as $t \to \infty$. Hence, we have that

$$\lim_{k\to\infty} |\phi(kT + s, v) - \phi(kT, v)| = 0 ,$$

where k denotes an integer variable. It follows that $\phi(s, v) = v$ for all s in some open set. The point v must be a rest point on a periodic orbit, in contradiction to the uniqueness of solutions.

While a periodic solution of an autonomous system cannot be asymptotically stable, we can ask that an orbitally asymptotically stable periodic orbit satisfy a stronger type of stability.

Definition 20 Let ϕ denote the flow of the autonomous differential Eq. (23) and suppose that Γ is a periodic orbit corresponding to the solution $t \mapsto \phi(t, p)$. We say that $q \in \mathbb{R}^n$ has asymptotic phase p with respect to Γ if the solution $t \mapsto \phi(t, q)$ is such that

$$\lim_{t\to\infty} |\phi(t, q) - \phi(t, p)| = 0 .$$

We say that Γ is isochronous if there exists an open neighborhood of its orbit such that every point in this neighborhood has asymptotic phase with respect to the period solution.

Theorem 21 *If all eigenvalues of the derivative of a Poincaré map at the periodic solution $t \mapsto \phi(t, p)$ of (23) lie strictly inside the unit circle in the complex plane (equivalently, the corresponding periodic orbit is hyperbolic), then every point q in some open neighborhood of this periodic orbit has asymptotic phase.*

A theory of asymptotic phase that includes orbitally stable periodic orbits such that some eigenvalues of the derivative of an associated Poincaré map have modulus one was recently completed (see [21,26]).

Lyapunov Functions

In case the linearized differential equation along a solution is stable but not orbitally asymptotically stable, the principle of linearized stability usually cannot be justified. One of the great contributions of Lyapunov is the introduction of a method that can be used to determine the stability of such solutions.

The fundamental ideas of Lyapunov are most clear for the stability analysis of rest points of autonomous systems (see [63]); but, the theory goes far beyond this case (see [51]).

Definition 22 Let u_0 be a rest point of the autonomous differential Eq. (23). A continuous function $L\colon U \to \mathbb{R}$, where $U \subseteq \mathbb{R}^n$ is an open set with $u_0 \in U$, is called a Lyapunov function at u_0 if

(1) $L(u_0) = 0$,
(2) $L(x) > 0$ for $x \in U \setminus \{u_0\}$,
(3) the function L is continuously differentiable on the set $U \setminus \{u_0\}$, and, on this set, $\dot{L}(x) := \operatorname{grad} L(x)\cdot f(x) \le 0$.

The function L is called a strict Lyapunov function if, in addition,

(4) $\dot{L}(x) < 0$ for $x \in U \setminus \{u_0\}$.

Property (3) states that L does not increase along solutions.

Theorem 23 *If there is a Lyapunov function defined on an open neighborhood of a rest point of an autonomous first-order differential equation, then the rest point is stable. If, in* *addition, the Lyapunov function is a strict Lyapunov function, then the rest point is asymptotically stable.*

Lyapunov's theorem was motivated by Lagrange's principle: a rest point of a mechanical system corresponding to an isolated minimum of the potential energy is stable. To obtain this result, recall that the equation of motion of a (conservative) mechanical system for the motion of a particle is

$$m\ddot{x} = -\operatorname{grad} G(x)$$

where m is the mass of the particle and $x \in \mathbb{R}^n$ is its position. The kinetic energy of the particle is defined to be $K = \frac{m}{2}\langle \dot{x}, \dot{x}\rangle$ (where the angle brackets denote the usual inner product) and the potential energy is G, a quantity defined up to an additive constant.

Consider the corresponding equivalent first-order system

$$\dot{x} = y\,, \quad \dot{y} = -\frac{1}{m}\operatorname{grad} G(x)\,,$$

and suppose that x_0 be an isolated minimum of G. The state $(x, y) = (x_0, 0)$ is a rest point of the mechanical system. By inspection, the total energy

$$L(x, y) := \frac{m}{2}\langle y, y\rangle + G(x) - G(x_0)$$

(with an appropriate translation of the potential energy) is a Lyapunov function at the rest point. Thus, the rest point is stable.

The proof of the first part of Lyapunov's theorem is simple: Choose an open ball B with center at the rest point and radius sufficiently small so that its closure is in the domain of the Lyapunov function L. The continuous positive function L on the closed and bounded spherical boundary of B has a non-zero minimum value b. Because the continuous function L vanishes at the rest point, there is a second ball A that is concentric with B, has strictly smaller radius, and is such that the maximum value of L on all of A is smaller than b. A solution of the differential equation starting in A cannot reach the boundary of B because L does not increase along solutions. Thus, the rest point is stable.

Lyapunov's method extends to nonautonomous systems with an appropriate modification of the notion of a Lyapunov function. Suppose that the first-order differential Eq. (1) has a rest point in the sense that for some $T \in \mathbb{R}$, $f(u_0, t) = 0$ for all $t \geq T$. A Lyapunov function is a class C^1 function defined in a neighborhood of u_0 for all $t \geq T$ such that $L(u_0, t) = 0$ for $t \geq T$, there is a continuous nonnegative function M defined on the same neighborhood of u_0 such that $L(u, t) \geq M(u)$ for all $t \geq T$ and $\dot{L} = L_t + L_u \cdot \dot{u} \leq 0$ for all $t \geq T$. If such a Lyapunov function exists, then the rest point is stable. If, in addition, there is a positive function N with the same domain as M such that $\dot{L}(u, t) \leq -N(u)$ for all $t \geq T$, then the rest point is asymptotically stable.

Lyapunov's direct method can be used to prove the principle of linearized stability for rest points of autonomous systems. To see how this might be done, consider the differential equation

$$\dot{u} = Au + g(u)\,, \quad u \in \mathbb{R}^n\,,$$

where A is a real $n \times n$ matrix and $g\colon \mathbb{R}^n \to \mathbb{R}^n$ is a smooth function. Suppose that every eigenvalue of A has negative real part, and that for some $a > 0$, there is a constant $k > 0$ such that, using the usual norm on $\mathbb{R}^n$,

$$|g(x)| \leq k|x|^2$$

whenever $|x| < a$. Let $\langle\cdot,\cdot\rangle$ denote the usual inner product on $\mathbb{R}^n$, and let A^* denote the transpose of the real matrix A. Suppose that there is a real symmetric positive definite $n \times n$ matrix that also satisfies Lyapunov's equation

$$A^*B + BA = -I$$

and define $L\colon \mathbb{R}^n \to \mathbb{R}$ by

$$L(x) = \langle x, Bx\rangle\,.$$

Using Schwarz's inequality, it can be proved that the restriction of L to a sufficiently small neighborhood of the origin is a strict Lyapunov function. The proof is completed by showing that there is a symmetric positive-definite solution of Lyapunov's equation. In fact,

$$B := \int_0^\infty \mathrm{e}^{tA^*}\mathrm{e}^{tA}\,\mathrm{d}t$$

is a symmetric positive definite $n \times n$ matrix that satisfies Lyapunov's equation. Alternatively, it is possible to prove the existence of a solution to Lyapunov's equation using purely algebraic methods (see, for example, [97]).

The instability of solutions can also be detected by Lyapunov's methods. A simple result in this direction is the content of the following theorem.

Theorem 24 *Suppose that L is a smooth function defined on an open neighborhood U of the rest point u_0 of the autonomous differential Eq. (23) such that $L(u_0) = 0$ and $\dot{V}(u) > 0$ on $U \setminus \{u_0\}$. If L has a positive value somewhere in each open set containing u_0, then u_0 is unstable.*

One indication of the subtlety of the determination of stability is the insolvability of the center-focus problem [41].

Consider a planar system of first-order differential equations in the form

$$\dot{x} = y + P(x, y)\,, \quad \dot{y} = -x + Q(x, y)\,,$$

where P and Q are analytic at the origin with leading-order terms at least quadratic in x and y. Is the origin a focus (that is, asymptotically stable or asymptotically unstable) or a center (that is, all orbits in some neighborhood of the origin are periodic)? There is no algorithm that can be used to solve this problem for all such systems in a finite number of steps. On the other hand, the center-focus problem is solved, by using Lyapunov's stability theorem, if a certain sequence of numbers called Lyapunov quantities (which can be computed iteratively and algebraically) has a non-zero element. One problem is that the algorithm for computing the Lyapunov quantities may not terminate in a finite number of steps (see, for example, [19,89]).

The center-focus problem is solved for some special cases. The most important theorem in this area of research is due to Nikolai Bautin (see [14] and [99,100] for a modern proof); he found (among other results) a complete solution of the center-focus problem for quadratic systems (that is, where P and Q are homogeneous quadratic polynomials). While the center-focus problem for quadratics had been solved by Dulac [25] and others [28,43,44,45] before his paper appeared; Bautin introduced a method, which involves the use of polynomial ideals, that has had far reaching consequences.

Stability in Conservative Systems and the KAM Theorem

Stability theory for conservative systems leads to many delicate problems, some of which—for example Lagrange's problem—can be resolved by the method of Lyapunov functions. While the total energy, the total angular momentum, or other first integrals all have the property that their derivatives vanish along trajectories, these integrals do not always serve as Lyapunov functions because they often fail to be positive definite in punctured neighborhoods of rest points or periodic orbits. Thus, other methods are required.

As in the quest to determine the stability of the solar system, a basic problem in mechanics is to determine the stability of periodic motions (or rest points) of conservative differential equations with respect to small perturbations. While no general solution is known, great progress has been made culminating in the Kolmogorov–Arnold–Moser (KAM) theorem (see [5,46,47,68,87,89,92]).

A mechanical system with N degrees-of-freedom (that is, the positions are determined by N-coordinates) is called completely integrable if it has N independent first integrals whose Poisson brackets are in involution (see p. 271 in [8]). In this case, the system can be transformed to a first-order system of differential equations in the simple form

$$\dot{I} = 0, \quad \dot{\theta} = \Omega(I)\,, \tag{25}$$

where I is an N-dimensional variable (of actions), θ is an N-dimensional variable (of angles), and Ω is a smooth function. The new coordinates are called action-angle variables (see, for generalizations, [39,42]). This system is in Hamiltonian form ($\dot{I} = \partial H/\partial\theta$, $\dot{\theta} = -\partial H/\partial I$) with Hamiltonian $H(I, \theta) := -\omega(I)$, where ω is an anti-derivative of Ω; and, of course, the Hamiltonian is constant along solutions of the system.

The corresponding perturbed system is taken to have the form

$$\dot{I} = \epsilon \frac{\partial F}{\partial \theta}(I, \theta), \quad \dot{\theta} = \Omega(I) - \epsilon \frac{\partial F}{\partial I}(I, \theta) \tag{26}$$

(or, more generally, a similar form with additional terms that are higher-order in ϵ), where F is a smooth function that is 2π-periodic in θ. This system is in Hamiltonian form with Hamiltonian

$$\mathcal{H}(I, \theta, \epsilon) := -\omega(I) + \epsilon F(I, \theta)\,.$$

The unperturbed integrable system can be solved explicitly as

$$I(t) = I_0\,, \quad \theta(t) = \Omega(I_0)t + \theta_0;$$

hence, by inspection, all orbits are periodic or quasi-periodic (when the angular variables are defined modulo 2π) according to whether or not the vector of frequencies $\Omega(I_0)$ satisfies a resonance relation, that is, $\langle M, \Omega(I_0)\rangle = 0$ for some N-vector M with integer components.

Every orbit of the unperturbed system with one degree-of-freedom is periodic; but, for example for two degrees-of-freedom, orbits are periodic with period T only if there are integers m_1 and m_2 such that

$$T\Omega_1(I_0) = 2\pi m_1, \quad T\Omega_2(I_0) = 2\pi m_2$$

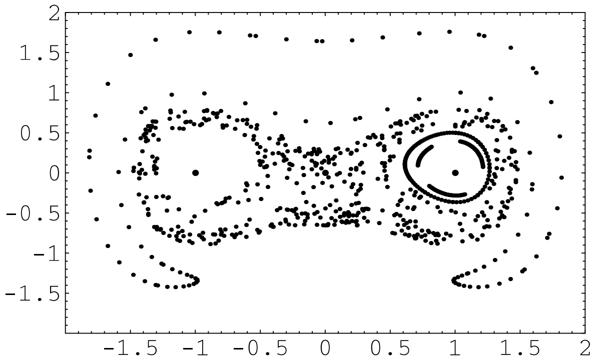
or $m_1\Omega_2(I_0) - m_2\Omega_1(I_0) = 0$.

Geometrically, a choice of actions fixes an energy level and the angles correspond to an N-dimensional invariant torus. The flow on this torus is either periodic or quasi-periodic according to the existence of a corresponding resonance relation. For this reason, the tori with periodic flows are called resonant; the others are called nonresonant. The KAM theorem states that most of the nonresonant tori in the unperturbed system (25) survive after small perturbations as invariant tori of the perturbed system (26).

Theorem 25 *If (in the Hamiltonian system (26)) $\mathcal{H}$ is sufficiently smooth, $D\Omega(I)$ is invertible, and ϵ is sufficiently small, then almost all (in the sense of Lebesgue measure) nonresonant unperturbed invariant tori persist.*

There are similar theorems for time-dependent perturbations of integrable systems and for area-preserving maps (see [8]).

For a mechanical system with N degrees-of-freedom, the perturbed invariant tori are N-dimensional manifolds embedded in the $2N$-dimensional phase space. After restriction to a regular energy surface (that is, a level set of $\mathcal{H}$ corresponding to one of its regular values), these N-dimensional tori are embedded in a $(2N-1)$-dimensional manifold. For $N \le 2$, the invariant tori that exist by the KAM theorem separate the energy hypersurface into two components, one inside and one outside of each invariant torus. A motion starting in a bounded region whose boundary is one of these invariant tori cannot escape to the corresponding unbounded component. Since the invariant tori are dense, such motions are stable (cf. Fig. 6). More generally, each perturbed invariant torus is stable as an invariant set. This result can be used, for example, to prove the stability of certain periodic orbits in the restricted three-body problem (see [54]). On the other hand, for $N > 2$, the invariant tori no longer separate energy surfaces into bounded and unbounded components. Thus, it is possible for orbits to migrate outside nearby tori in a conjectured process called Arnold diffusion (see [6]). The validity of Arnold diffusion for the general Hamiltonian system (26) is an area of current research (see, for a review, [60]).



Stability Theory of Ordinary Differential Equations, Figure 6
The figure depicts portions of seven orbits of the (stroboscopic) Poincaré map $\xi \in \mathbb{R}^2 \mapsto \phi(2\pi, \xi)$ for the forced oscillator $\dot{x} = y, \dot{y} = x - x^3 + 0.05 \sin t$: three fixed points at (x, y) equal to $(-1, 0)$, $(0, 0)$, and $(1, 0)$; an orbit starting at $(x, y) = (1.0, 0.4)$ at time $t = 0$, which is close to a $(3 : 1)$ resonance; an orbit starting at $(1.0, 0.5)$, which is on an invariant torus that surrounds the resonant orbit; an orbit starting at $(1.0, 0.6)$, which appears to be "chaotic"; and an orbit starting at $(1, 1)$, which is on a large invariant torus. The $(3 : 1)$ resonant orbit is stable

Averaging and the Stability of Perturbed Periodic Orbits

As we have seen, systems of the form

$$\dot{I} = \epsilon P(I, \theta)\,, \qquad \dot{\theta} = \Omega(I) + \epsilon Q(I, \theta)\,, \tag{27}$$

where P and Q are 2π-periodic, often arise in mechanics. Here, the properties of system (27) are considered for general perturbations, which are not necessarily conservative.

Note that, in case ϵ is small, the vector of actions (components of I) in the differential Eq. (27) evolves slowly relative to the evolution of the vector of angles θ. The averaging principle states that the evolution of the actions for such a system is well-approximated by the corresponding averaged equation given by

$$\dot{\mathcal{I}} = \epsilon \bar{P}(\mathcal{I})\,, \tag{28}$$

where

$$\bar{P}(\mathcal{I}) := \frac{1}{(2\pi)^N} \int_{\mathbb{T}^N} P(\mathcal{I}, \theta)\, \mathrm{d}\theta$$

and $\mathbb{T}^N$ denotes the N-dimensional torus of angles.

Exactly what is meant by "well-approximated" is clarified by the averaging theorem, which requires a severe restriction: the vector of angles is one-dimensional (cf. [61,86]).

Theorem 26 *If θ is a scalar variable and Ω is bounded away from zero, then there is a near-identity change of variables of the form $\mathcal{I} = I + \epsilon k(I, \theta)$ that is 2π-periodic in θ which transforms system (27) into the form*

$$\dot{\mathcal{I}} = \epsilon \bar{P}(\mathcal{I}) + \epsilon^2 P_1(\mathcal{I}, \theta, \epsilon)\,, \qquad \dot{\theta} = \Omega(\mathcal{I}) + \epsilon Q_1(\mathcal{I}, \theta, \epsilon)\,.$$

where P_1 and P_2 are 2π-periodic in θ. Moreover, if the evolution of I starting at I_0 is given by $I(t)$ and the evolution (according to the differential Eq. (28)) of the averaged action $\mathcal{I}$ starting at I_0 is given by $\mathcal{I}(t)$, then there are constants $C > 0$ and $T(I_0) > 0$ such that

$$|\mathcal{I}(t) - I(t)| \le C\epsilon$$

on the time interval $0 \le \epsilon t < T(I_0)$.

The existence and stability of perturbed period solutions is the content of the following theorem.

Theorem 27 *Consider the system*

$$\dot{I} = \epsilon F(I,\theta) + \epsilon^2 F_2(I,\theta,\epsilon)\,, \qquad \dot{\theta} = \Omega(I) + \epsilon G(I,\theta,\epsilon)\,, \tag{29}$$

where $I \in \mathbb{R}^M$, θ is a scalar, F, F_2, and G are 2π-periodic functions of θ, and there is some number c such that $\Omega(I) \geq c > 0$. If the averaged system has a nondegenerate rest point (see Definition 6) and ϵ is sufficiently small, then system (29) has a periodic orbit. If in addition $\epsilon > 0$ and the rest point is hyperbolic, then the periodic orbit has the same stability type as the hyperbolic rest point; that is, the dimensions of the corresponding stable and unstable manifolds are the same (see Definition 29).

For a typical application of Theorem 27, consider the system of differential equations

$$\begin{aligned} \dot{I} &= \epsilon(a + b\sin k\theta)\sin\psi + \epsilon^2 P(I,\psi,\theta),\\ \dot{\psi} &= \epsilon c I + \epsilon^2 Q(I,\psi,\theta),\\ \dot{\theta} &= 1, \end{aligned} \tag{30}$$

where a, b, and c are non-zero constants, k is a positive integer, and both P and Q are 2π-periodic in θ. The averaged system of differential equations

$$\dot{I} = \epsilon a \sin\psi\ , \quad \dot{\psi} = \epsilon c I$$

has hyperbolic rest points at $(I,\psi) = (0,0)$ and $(I,\psi) = (0,\pi)$. According to Theorem 27, if ϵ is sufficiently small, the system of differential Eq. (30) has corresponding hyperbolic periodic solutions. In case $ac > 0$, the solution of the perturbed system corresponding to $\psi = 0$ is stable, and the solution corresponding to $\psi = \pi$ is unstable (in fact, it is a hyperbolic saddle). If $ac < 0$, the stability types are switched.

Structural Stability

An important aspect of the global theory of dynamical systems is the stability of the orbit structure as a whole. The motivation for the corresponding theory comes from applied mathematics. Mathematical models always contain simplifying assumptions. Dominant features are modeled; supposed small disturbing forces are ignored. Thus, it is natural to ask if the qualitative structure of the set of solutions—the phase portrait—of a model would remain the same if small perturbations were included in the model. The corresponding mathematical theory is called structural stability.

The correct mathematical formulation of the definition of structural stability requires the introduction of a topology on the space of dynamical systems under consideration. The natural setting for the theory is the space of class C^1 vector fields on a smooth compact manifold.

There is a one-to-one correspondence between vector fields and differential equations: the right-hand side of a first-order autonomous differential equation defines a vector field on $\mathbb{R}^n$. The local representatives, with respect to coordinate charts, of a vector field on an n-dimensional manifold M are vector fields on $\mathbb{R}^n$. The set of all smooth vector fields $\mathfrak{X}(M)$ on M has the structure of a Banach space after the introduction of a Riemannian metric. Thus, two vector fields are close if the distance between them in this Banach space is small.

Definition 28 A vector field X on a smooth manifold M is called structurally stable, if there is some neighborhood U of X in $\mathfrak{X}(M)$ such that for each $Y \in U$ there is a homeomorphism of M that maps orbits of Y to orbits of X and preserves the orientation of orbits according to the direction of time. Such a homeomorphism is called a topological equivalence.

In other words, all perturbations of a structurally stable vector field have the same qualitative orbit structures.

At first impression, it might seem that the homeomorphism in the definition of structural stability should be a diffeomorphism. But, this requirement is too strong. To see why, consider a hyperbolic rest point u_0 of the first-order autonomous differential Eq. (23) in $\mathbb{R}^n$. Let $\dot{u} = g(u)$ be a differential equation on $\mathbb{R}^n$, and consider the perturbation of the differential Eq. (23) given by $\dot{u} = f(u) + \epsilon g(u)$. We have that $f(u_0) = 0$. Thus, $F(u,\epsilon) := f(u) + \epsilon g(u)$ is such that $F(u_0, 0) = 0$ and $DF(u_0, 0) = Df(u_0)$. Because of the hyperbolicity, the linear transformation $Df(u_0)$ is invertible. By an application of the implicit function theorem, there is a smooth function $\beta\colon J \to \mathbb{R}^n$, where J is an open interval in $\mathbb{R}$ containing the origin, such that $F(\beta(\epsilon),\epsilon)) = 0$ for all ϵ in J. In other words, every small perturbation of (the vector field) f has a rest point near u_0. Moreover, for sufficiently small ϵ (and in view of the continuity of eigenvalues with respect to the components of the corresponding matrix), the perturbed rest point $\beta(\epsilon)$ is hyperbolic with the same number of eigenvalues (counting multiplicities) with positive and negative real parts as the eigenvalues of $Df(u_0)$. But, of course, the perturbed eigenvalues are in general not the same as the eigenvalues of $Df(u_0)$. The hyperbolic rest point u_0 is structurally stable in the sense that the local phase portraits at the corresponding rest points of sufficiently small perturbations of f are qualitatively the same as the phase portrait of the differential Eq. (23). This fact can be proved using the Grobman–Hartman theorem together with an argument to show that the phase portraits of hyperbolic linear first-order systems are topologically equivalent if their system matrices have the same numbers of eigenvalues (counting multiplicities) with positive and negative real parts. Suppose there were a diffeomorphism h taking orbits to orbits. It would correspond to a change of variables $v = h(u)$ (a smooth conjugacy) taking the differential Eq. (23) to the differential equation $\dot{v} = F(v)$, where the parameter ϵ is suppressed for simplicity. By differentiation of the equation $v = h(u)$ with respect to the independent variable t, it follows that $F(h(u)) = Dh(u)f(u)$. By linearization at the rest point u_0, we have

$$DF(h(u_0))Dh(u_0) = Dh(u_0)Df(u_0)\,.$$

In particular the system matrix $Df(h(u_0))$ for the linearized system at the perturbed rest point is similar, via the invertible matrix $Dh(u_0)$, to the system matrix $Df(u_0)$ for the linearized system at the unperturbed rest point. Thus, the two rest points would have to have exactly the same eigenvalues, contrary to the general situation for which the eigenvalues of the perturbed linearization are different from the eigenvalues of the unperturbed linearization.

The notion of hyperbolicity is an essential hypothesis in structural stability theory; indeed, hyperbolic rest points are structurally stable. Likewise hyperbolic periodic orbits, defined to be those periodic orbits such that there is an associated hyperbolic Poincaré map are structurally stable. This notion can be extended to general invariant sets. The essential requirement is that all of the solutions of the linearized differential equations along the solutions in the invariant set, which are not initially in the direction of the invariant set, either grow or decay exponentially with uniform exponential growth rates over the entire invariant set.

The global theory of structural stability requires a global hypothesis to ensure that the rest points and period orbits are connected with orbits in general position.

Definition 29 Let A be an invariant set (a union of orbits) of an autonomous first-order differential equation, vector field, or discrete dynamical system. The stable manifold of A, denoted $W^s(A)$ is the set of all solutions that converge to A as $t \to \infty$. The unstable manifold $W^u(A)$ is the set of all solutions that converge to A as $t \to -\infty$.

The stable manifold theorem asserts that the stable and unstable manifolds for rest points and periodic orbits of smooth vector fields are indeed (immersed) smooth manifolds (see, for example, [37,38]).

Two immersed manifolds are called transversal if they do not intersect; or, if the sum of their tangent spaces at each point of their intersection is the tangent space of the ambient manifold.

While periodicity is the most familiar form of recurrence for dynamical systems, a more subtle notion of recurrence is required for structural stability theorems.

Definition 30 The point u is called a nonwandering point for an autonomous differential equation if, for each neighborhood U of u and each time $t_0 > 0$, there is some time $t > t_0$ such that at least one solution starting in U at time zero returns to U at time t. Likewise for a discrete dynamical system defined by a diffeomorphism h, the point u is nonwandering if for each neighborhood U of u there is some integer $k > 0$ such that $h^k(U) \cap U$ is not empty. The set of all nonwandering points is called the nonwandering set.

For vector fields on compact orientable two-dimensional manifolds, the classical structural stability theorem is due to M. Peixoto [70] and is a generalization of earlier work for vector fields in the plane by L. Pointryagin and A. Andronov [2,3].

Theorem 31 *A class C^1 vector field on a compact orientable two-dimensional manifold M is structurally stable if and only if*

(1) all rest points are hyperbolic,
(2) all periodic solutions are hyperbolic,
(3) stable and unstable manifolds of all pairs of saddle points (rest points whose linearizations have one positive and one negative eigenvalue) are disjoint,
(4) the nonwandering set consists of only rest points and periodic solutions.

Moreover, the structurally stable vector fields form an open and dense set in $\mathfrak{X}(M)$.

The notion of transversality in Peixoto's theorem is embodied in the property (3). The generalization of this property is an essential ingredient of the theory.

Definition 32 A dynamical system satisfies the strong transversality property if for every pair of points $\{u, v\}$ in its nonwandering set, the corresponding invariant manifolds $W^s(u)$ and $W^u(y)$ intersect transversally (at all their points of intersection).

Definition 33 A dynamical system satisfies Axiom A if its nonwandering set is hyperbolic and the periodic orbits are dense in this set.

The most important result of the theory is the structural stability theorem:

Theorem 34 *A class C^1 diffeomorphism is structurally stable if and only if it satisfies Axiom A and the strong transversality property.*

Joel Robbin [77] proved that a C^2 diffeomorphism is C^1 structurally stable if it satisfies Axiom A and the strong transversality property. This result was improved by Clark Robinson [81] by relaxing the C^2 requirement to C^1; he also proved the analogous result for differential equations [79,80]. Ricardo Mañé [65] proved the converse.

A simple example of a structurally stable diffeomorphism is the north-pole south-pole map of the Riemann sphere; it is given by $z \mapsto 2z$ for the complex variable z. There are two hyperbolic rest points, an unstable fixed point at $z = 0$ and a stable fixed point at $z = \infty$. All other points are attracted to ∞ under forward iteration and to zero under backward (inverse) iteration.

A more exotic example is provided by the hyperbolic toral automorphisms. To define these maps, note that a 2×2-integer matrix with determinant one determines a diffeomorphism of the plane that preserves the integer lattice. Thus, it projects to a map of the torus formed by the quotient space $\mathbb{R}^2/\mathbb{Z}^2$. In case the matrix is hyperbolic, the corresponding diffeomorphism on the torus has a dense set of periodic orbits and thus its nonwandering set is the entire torus. It can be proved that the linear hyperbolic structure of the transformation of the plane (that is, one stable and one unstable eigenspace) projects to a uniform hyperbolic structure on the entire torus; and, moreover, the strong transversality condition is satisfied. Thus, small perturbations of such a map have the same properties. This example was generalized by Dmitri Anosov and others to include a class of diffeomorphisms and vector fields in the continuous case now called Anosov dynamical systems. The most important example of a continuous flow with this property is the geodesic flow in the unit tangent bundle of a compact Riemannian manifold with negative sectional curvatures (see [4]).

Attractors

A natural outgrowth of the theory of stability for rest points and periodic solutions is its generalization to invariant sets. The fundamental objects of study are the attractors. Unfortunately, the definition of this concept is not universally accepted; different authors use different definitions. The following definition is perhaps the most popular:

Definition 35 A closed invariant set A for a dynamical system is called an attracting set if it is contained in an open neighborhood U of the ambient space such that the intersection of the sequence of all forward motions of U under the action of the dynamical system is equal to A. An attracting set is called an attractor if, in addition, there is no closed invariant attracting subset of A.

The existence of attractors is part of the stability theory of dynamical systems; the structure of attractors is the subject of another rich theory. For most of the history of differential equations the only known attractors (the classical attractors) were rest points, periodic orbits, and tori, which are all manifolds. The existence of attractors with fractal dimensions, called strange attractors, was noticed and proved only recently [62,82,85,95].

For differential equations in $\mathbb{R}^n$, the existence of an attractor for autonomous systems is usually proved by demonstrating the existence of an $(n-1)$-dimensional sphere (or other separating hypersurface) such that the vector field corresponding to the differential equation points into the bounded region of space bounded by the sphere (more precisely, the inner product of the vector field and the inner normal is positive at all points on the sphere).

As an example, consider the Lorenz equations on $\mathbb{R}^3$

$$\begin{aligned} \dot{x} &= \sigma(y-x), \\ \dot{y} &= rx - y - xz, \\ \dot{z} &= xy - bz, \end{aligned}$$

where σ, r, and b are positive constants. The origin is a rest point for the Lorenz system and, if $r < 1$, then

$$L(x,y,z) := \frac{1}{\sigma}x^2 + y^2 + z^2$$

is a Lyapunov function. In this case, the origin is globally asymptotically stable. More generally (that is, with no restriction on the size of r), there is a constant $c > 0$ such that the vector field points into the bounded region of space bounded by the ellipsoid $rx^2 + \sigma y^2 + \sigma(z - 2r)^2 = c$. Thus, the Lorenz equations have an attractor. For some parameter values, for example $\sigma = 10$, $b = 8/3$, and $r = 28$, the attractor is a fractal, called the Lorenz attractor (see [29,62,93,95]).

For the special case of two-dimensional first-order autonomous systems, the existence and nature of attractors can be more precisely specified. The main result is the Poincaré-Bendixson theorem (see [15] and, for a proof, [1]):

Theorem 36 *An attractor of the class C^1 differential Eq. (23) on the plane that contains no rest points is a periodic orbit.*

Corollary 37 *If the differential Eq. (23) on the plane is analytic and has a positively invariant annulus containing no rest points, then the annulus contains an orbitally asymptotically stable periodic solution (a stable limit cycle).*

As an example, consider the model of a damped pendulum with torque given by the first-order planar system

$$\dot{\theta} = \nu \,, \quad \dot{\nu} = -\sin\theta + \mu - \lambda\nu \,, \tag{31}$$

where λ and μ are positive constants. By viewing the variable θ as an angular variable modulo 2π, the phase space is the cylinder rather than the plane. Nonetheless, the Poincaré-Bendixson theory is valid on the cylinder because a bounded region of the cylinder can be flattened by a change of variables to a region of the plane. If $|\mu| > 1$, then the system of differential Eq. (31) has a globally attracting periodic orbit. Three main observations can be used to construct a proof: there are no rest points, the quantity $-\sin\theta + \mu - \lambda\nu$ is negative for sufficiently large values of $\nu > 0$, and it is positive for negative values of ν with sufficiently large absolute values. These facts imply the existence of an invariant annulus containing no rest points. The remainder of the proof uses Theorem 19 and the analyticity of solutions (see p. 98 in [19]).

Generalizations and Future Directions

The concepts of stability theory have been successfully generalized to infinite-dimensional dynamical systems (which arise from the analysis of partial differential equations) defined on Banach spaces and to abstract dynamical systems on metric spaces [13,32,33,36,83,94]. Research in this direction has produced some results on stability and the existence of attractors.

No general theorem akin to Lyapunov's Theorem 4 is known for infinite-dimensional dynamical systems. A main difficulty is that, for an unbounded operator A, the non-zero elements in the spectrum of e^A may not all be given by the exponentials of elements in the spectrum of A (see, for a discussion, Chap. 2 in [20]). Thus, to determine the stability of a rest point by linearization, this spectral mapping property must be checked separately for most cases of interest.

Part of the motivation for the determination of attractors in infinite-dimensional dynamical systems is the possibility of reducing the long-term dynamical properties to the analysis of a finite-dimensional dynamical system on the attractor. The fundamental organizing concept in this direction is the "inertial manifold".

Definition 38 An inertial manifold is a finite-dimensional Lipschitz manifold that is invariant under forward motions of the dynamical system and attracts all solutions of the dynamical system at an exponential rate.

Inertial manifolds have been proved to exist for many dynamical systems defined by evolution-type partial differential equations, for example, reaction-diffusion equations with appropriate boundary conditions. Much current research is devoted to determining conditions that imply the existence of inertial manifolds (or their generalizations) for the equations of fluid dynamics.

The conceptual framework and basic abstract theory of stability is mature and well-understood for finite-dimensional dynamical systems. This theory is currently being extended to an abstract theory for infinite-dimensional dynamical systems. The most important direction for further development is the application of this theory to specific differential equations (including partial differential equations) that arise as mathematical models in applied mathematics. Even the problem that originally motivated stability theory (that is, the stability of periodic and quasi-periodic motions of the N-body problem of classical mechanics) remains open to future research.

Article Outline

Glossary

Player A participant in a game.

Action set The set of actions that a player may choose.

Action profile A list of actions, one for each player.

Payoff The utility a player obtains from a given action profile.

Definition of the Subject

Game theory concerns the interaction of decision makers. This interaction is modeled by means of games. There are various approaches to constructing games. One approach is to focus on the possible outcomes of the decision-makers' interaction by abstracting from the actions or decisions that may lead to these outcomes. The main tool used to implement this approach is the *cooperative game*. Another approach is to focus on the actions that the decision-makers can take, the main tool being the *non-cooperative game*. Within this approach, strategic interactions are modeled in two ways. One is by means of *dynamic*, or extensive form games, and the other is by means of *static*, or strategic games. Dynamic games stress the sequentiality of the various decisions that agents can make. An essential component of a dynamic game is the description of who moves first, who moves second, etc. Static games, on the other hand, abstract from the sequentiality of the possible moves, and model interactions as simultaneous decisions, where the decisions may well be complicated plans of actions that dictate different moves for different situations that may arise. All extensive form games can be modeled as static games, and all strategic form games can be modeled as extensive form games. But some situations may be more conveniently modeled as one or the other kind of game.

This chapter reviews the main ideas and results related to static games, as well as some interesting relationships that connect equilibrium concepts with the idea of rationality. The objective is to introduce the reader to the area of static games and to stimulate his interest for further knowledge of game theory in general. For a comprehensive exposition of some results not covered in this chapter, the reader is referred to the many excellent textbooks available on game theory. Binmore [6], Fudenberg and Tirole [9], Osborne [20], Osborne and Rubinstein [21] constitute only a partial list.

Although the definition of a static game is a very simple one, static games are a very flexible model which allows us to analyze many different situations. In particular, one can use them to analyze strategic interactions that involve either common interests or diametrically opposed interests. Similarly, one can also use static games to model situations where players have either symmetric or asymmetric information. The range of applications of static games is very wide and covers many disciplines, such as economics, political science, biology, philosophy, and computer science among others.

Introduction

In this section we introduce some examples that will be used later to motivate different concepts. We also introduce the definition of a static game.

The prisoner's dilemma involves a donor who is interested in donating some amount of money to two universities. The donor decides that the amount each university will receive depends on the content of the messages the presidents of the respective universities will send to him. Each university will send simultaneously one of two messages. One possible message is "Give him 2" and the other is "Give me 1". The donor will do exactly as told. For instance, if University I sends the message "Give me 1" and University II sends "Give him 2", the donor will donate \$3 to University I and \$0 to University II. This game can be described by means of the following matrix, where the entries represent the payoffs for University I and University II, respectively, that result from the corresponding action choices.

		University II	
		Give him 2	*Give me 1*
University I	*Give him 2*	2, 2	0, 3
	Give me 1	3, 0	1, 1

The battle of the sexes consists of two friends, She and He, who want to go out together, but have no means of communication. They have to decide, each one separately but both simultaneously, whether to go to a boxing match or to a ballet show. For both of them, the worst possible outcome would be to choose different events and not meet. But if they meet, he would rather meet her at the boxing match, while she would rather meet him at the ballet. The battle of the sexes can be described by the following matrix.

		She	
		Box	Ballet
He	Box	2, 1	0, 0
	Ballet	0, 0	1, 2

Again, the entries of this matrix represent the payoffs that he and she get, as a result of their corresponding choices.

Chicken models two drivers who approach each other on a narrow street. If none of them slows down they'll have an accident and their corresponding payoffs will be 0. But if at least one of them slows down, the accident is prevented. The problem is that both of them would like the other to slow down. If only one driver slows down, this driver gets a payoff of 2 and the other driver gets a payoff of 7. If both drivers slow down, then both drivers get a payoff of 6. This situation can be described by the following matrix.

		Driver 2	
		Slow Down	Speed up
Driver 1	Slow Down	6, 6	2, 7
	Speed up	7, 2	0, 0

Matching Pennies involves two friends, each of whom places a coin on a table. If both coins are placed heads up or tails up, then friend 1 gets one dollar from friend 2. If one coin is placed heads up and the other tails up, then friend 1 pays one dollar to friend 2. Matching pennies can be described by the following matrix, where the entries are the amounts of money that the friends get from each other.

		Friend 2	
		Heads	Tails
Friend 1	Heads	$1, -1$	$-1, 1$
	Tails	$-1, 1$	$1, -1$

The above examples of strategic interactions can be modeled as static games. A static game is a formalization of a strategic situation according to which players choose their actions separately and simultaneously, and as a result obtain certain payoffs. The interaction that a static game models need not require that players take their actions simultaneously. But the interaction is modeled by defining actions in such a way that lets us think of the players as acting simultaneously.

All of the above examples involve a set of players, and for each player there is a set of available actions and a function that associates a payoff level to each of the profiles of actions that may result from the players' choices. These are the three essential components of a static game, as formalized in the following definition.

Definition 1 A static game is a triple $\langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$ where N is a finite set of players, and for each player $i \in N$, A_i is i's set of actions, and $u_i : \times_{k \in N} A_k \rightarrow \mathbb{R}$ is player i's utility function.

In the prisoner's dilemma the set of players is $N = \{\text{University I, University II}\}$; the sets of actions are $A_{\text{I}} = A_{\text{II}} = \{\textit{Give me 1}, \textit{Give him 2}\}$; the utility function of University I is $u_{\text{I}}(\textit{Give me 1}, \textit{Give me 1}) = 1$, $u_{\text{I}}(\textit{Give me 1}, \textit{Give him 2}) = 3$, $u_{\text{I}}(\textit{Give him 2}, \textit{Give me 1}) = 0$, $u_{\text{I}}(\textit{Give him 2}, \textit{Give him 2}) = 2$; and the utility function of University II is $u_{\text{II}}(\textit{Give me 1}, \textit{Give me 1}) = 1$, $u_{\text{II}}(\textit{Give me 1}, \textit{Give him 2}) = 0$, $u_{\text{II}}(\textit{Give him 2}, \textit{Give me 1}) = 3$, $u_{\text{I}}(\textit{Give him 1}, \textit{Give him 1}) = 1$.

In this chapter we sometimes refer to static games simply as games. For any game $\langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$, the set of action profiles $\times_{k \in N} A_k$ is denoted by A, and a typical action profile is denoted by $a = (a_i)_{i \in N} \in A$. If A is a finite set, then we say that the game is finite. Player i's utility function represents his preferences over the set of action profiles. For instance, for any two action profiles a and a' in A, $u_i(a) \geq u_i\left(a'\right)$ means that player i prefers action profile a to action profile a'. Clearly, although player i has preferences over action profiles, he can only affect his own component, a_i, of the profile.

Nash Equilibrium

One objective of game theory is to select, for each game, a set of action profiles that are interesting in some way. These action profiles may be interpreted as predictions of the theory, or prescriptions for the players to follow, or simply as equilibrium outcomes in the sense that if they occur, the players do not wish that they had acted differently. These action profiles are formally given by solution concepts, which are functions that associate each strategic game with the selected set of action profiles. The central solution concept in game theory is known as *Nash equilibrium*. The hypothesis behind this solution concept is that each player chooses his actions so as to maximize his utility, given the profile of actions chosen by the other players. To give a formal definition of the Nash equilibrium concept, we first introduce some useful notation. For each player $i \in N$, let $A_{-i} = \times_{k \in N \setminus \{i\}} A_k$ be the set of the other players' profiles of actions. Then we can write $A = A_i \times A_{-i}$, and each action profile can be written as $a = (a_i, a_{-i}) \in A_i \times A_{-i}$, thereby distinguishing player i's action from the other players' profile of actions.

Definition 2 The action profile $a^* = (a_i^*)_{i \in N} \in A$ in a game $\langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$ is a *Nash equilibrium* if for each player, $i \in N$, and every action $a_i \in A_i$ of player i, a^* is at least as good for player i as the action profile (a_i, a_{-i}^*). That is, if

$$u_i(a^*) \geq u_i(a_i, a_{-i}^*) \quad \text{for all } a_i \in A_i \quad \text{and for all } i \in N\,.$$

It is a *strict Nash equilibrium* if the above inequality is strict for all alternative actions $a_i \in A_i \setminus \{a_i^*\}$.

Analysis of Some Finite Games

Prisoner's Dilemma Recall that the prisoner's dilemma can be described by the following matrix.

		University II	
		Give him 2	*Give me 1*
University I	*Give him2*	2, 2	0, 3
	Give me1	3, 0	1, 1

The action profile (*Give me 1, Give me 1*) is a Nash equilibrium. Indeed,

$$u_{\mathrm{I}}(\textit{Give me 1, Give me 1}) = 1 \\ \geq u_{\mathrm{I}}(\textit{Give him } 2,\ \textit{Give me } 1) = 0$$

and

$$u_{\mathrm{II}}(\textit{Give me } 1,\ \textit{Give me } 1) = 1 \\ \geq u_{\mathrm{II}}(\textit{Give me } 1,\ \textit{Give him } 2) = 0\,.$$

On the other hand, the action profile (*Give him 2, Give him 2*) is not a Nash equilibrium, since University I prefers action "*Give me 1*" if University II chooses action "*Give him 2*":

$$2 = u_{\mathrm{I}}(\textit{Give him } 2,\ \textit{Give him } 2) \\ < u_{\mathrm{I}}(\textit{Give me } 1,\ \textit{Give him } 2) = 3\,.$$

Battle of the Sexes Recall that the battle of the sexes can be described by the following matrix.

		She	
		Box	Ballet
He	Box	2, 1	0, 0
	Ballet	0, 0	1, 2

One can check that (*Box, Box*) is a Nash equilibrium and (*Ballet, Ballet*) is a Nash equilibrium as well. It can also be checked that these are the only two action profiles that constitute a Nash equilibrium.

Matching Pennies The reader can check that Matching Pennies has no Nash equilibrium.

Before we analyze the next example, we introduce a technical tool that allows us to reformulate the definition of Nash equilibrium more conveniently. More importantly, this alternative definition is the key to the standard proof of the existence of Nash equilibrium.

Definition 3 Let $G = \langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$ be a strategic game and let $i \in N$ be a player. Consider a list of actions $a_{-i} = (a, \ldots, a_{i-1}, a_{i+1}, \ldots, a_n) \in \times_{k \in N \setminus \{i\}} A_k$ of all the players other than i. The set of player i's best responses to a_{-i} is

$$\mathcal{B}_i(a_{-i}) = \{a_i \in A_i \colon u_i(a_i, a_{-i}) \geq u_i(b_i, a_{-i}) \\ \text{for all } b_i \in A_i\}\,.$$

The correspondence $\mathcal{B}_i \colon \times_{j \neq i} A_j \twoheadrightarrow A_i$ that assigns to each $(n-1)$-tuple of actions in A_{-i} the set of best responses to it is called the *best response correspondence* of player i.

The definition of a Nash equilibrium may be stated in terms of the players' best response correspondences, as stated in the following proposition.

Proposition 1 *The action profile $a^* \in A$ is a Nash equilibrium if and only if every player's action is a best response to the other players' actions. That is, if*

$$a_i^* \in \mathcal{B}_i(a_{-i}^*) \quad \textit{for all } i \in N\,.$$

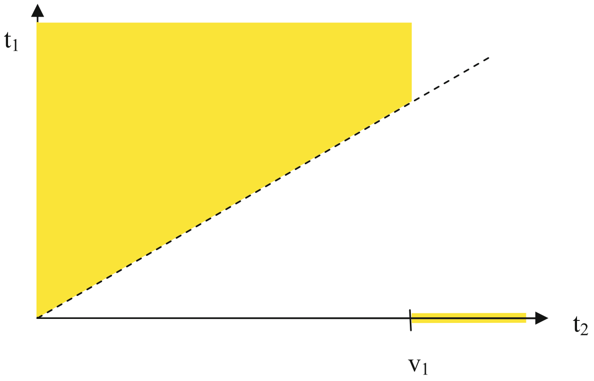
Until now, all the examples involved games where the action sets contained two actions. The next example is a game where the players' action sets are infinite. We will use the player's best response correspondences to find all its Nash equilibria.

The War of Attrition Two animals, 1 and 2, are fighting over a prey. Each animal chooses a time at which it intends to give up. Once one animal has given up, the other obtains the prey; if both animals give up at the same time then they split the prey equally. For each $i = 1, 2$, animal i's willingness to fight for the prey is given by $v_i > 0$. The value v_i is the maximum amount of time that animal i is willing to spend to obtain the prey. Since fighting is costly, each animal prefers as short a fight as possible. If animal i obtains the prey after a fight of length t, his utility will be $v_i - t$. We can model the situation as the game $G = \langle\{1,2\},(A_1,A_2),(u_1,u_2)\rangle$ where

- $A_1 = [0,\infty] = A_2$ (an element $t \in A_i$ represents a time at which player i plans to give up)
- $$u_1(t_1,t_2) = \begin{cases} -t_1 & \text{if } t_1 < t_2 \\ \frac{1}{2}v_1 - t_2 & \text{if } t_1 = t_2 \\ v_1 - t_2 & \text{if } t_1 > t_2 \end{cases}$$
- $$u_2(t_1,t_2) = \begin{cases} -t_2 & \text{if } t_2 < t_1 \\ \frac{1}{2}v_2 - t_1 & \text{if } t_1 = t_2 \\ v_2 - t_1 & \text{if } t_2 > t_1\,. \end{cases}$$

We are interested in the best response correspondences. First, we calculate player 1's best response correspondence, $\mathcal{B}_1(t_2)$. There are three cases to consider.

Case 1: $t_2 < v_1$ In this case, $v_1 - t_2 > \frac{1}{2}v_1 - t_2$ and $v_1 - t_2 > -t_1$. Consequently, given that player 2's action is t_2, player 1's utility function has a maximum value of $v_1 - t_2$, which is attained at any $t_1 > t_2$. Therefore, $\mathcal{B}_1(t_2) = (t_2,\infty)$.



Static Games, Figure 1
Player 1's best response correspondence

Case 2: $t_2 = v_1$ In this case, $0 = v_1 - t_2 > \frac{1}{2}v_1 - t_2$. Therefore, player's 1 utility function $u_1(\cdot,t_2)$ has a maximum value of 0, which is attained at $t_1 = 0$ and at $t_1 > t_2$. Therefore, $\mathcal{B}_1(t_2) = \{0\} \cup (t_2,\infty)$.

Case 3: $t_2 > v_1$ In this case $\frac{1}{2}v_1 - t_2 < v_1 - t_2 < 0$. As a result, player 1's utility function $u_1(\cdot,t_2)$ has a maximum value of 0, which is attained at $t_1 = 0$. Therefore, $\mathcal{B}_1(t_2) = \{0\}$.

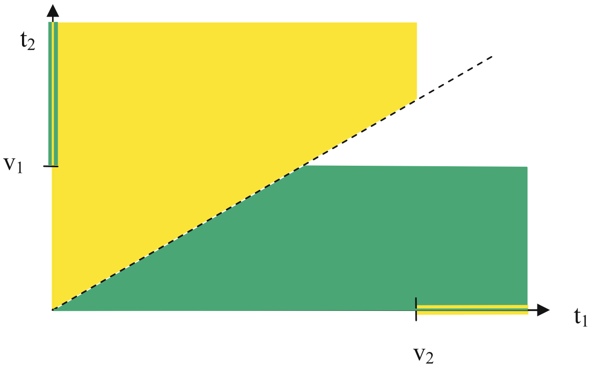
Summarizing, player 1's best response correspondence is:

$$\mathcal{B}_1(t_2) = \begin{cases} (t_2,\infty) & \text{if } t_2 < v_1 \\ \{0\} \cup (t_2,\infty) & \text{if } t_2 = v_1 \\ \{0\} & \text{if } t_2 > v_1 \end{cases}$$

which is depicted in Fig. 1.
Similarly, player 2's best response correspondence is:

$$\mathcal{B}_2(t_1) = \begin{cases} (t_1,\infty) & \text{if } t_1 < v_2 \\ \{0\} \cup (t_1,\infty) & \text{if } t_1 = v_2 \\ \{0\} & \text{if } t_1 > v_2\,. \end{cases}$$

Combining the two best response correspondences we get that (t_1^*, t_2^*) is a Nash equilibrium if and only if either $t_1^* = 0$ and $t_2^* \geq v_1$ or $t_2^* = 0$ and $t_1^* \geq v_2$. Figure 2 depicts the set of all the Nash equilibria as the intersection of the two best response correspondences. Two things are worth noting. First, it is not necessarily the case that the player who values the prey most wins the war. That is, there are Nash equilibria of the war of attrition where the player with the highest willingness to fight for the prey gives in first, and as a result the object goes to the other player. Second, in none of the Nash equilibria is there a physical fight. All Nash



Static Games, Figure 2
The equilibria

equilibria involve one player giving in immediately to the other. This second feature seems rather unrealistic, since fights in "war of attrition"-like situations are commonly observed. If one wants to obtain a fight of positive length in the war of attrition one needs to either drop the Nash equilibrium concept and adopt an alternative one, or model the war of attrition differently. We will adopt this second course of action later.

Existence

As the matching pennies example shows, not all games have a Nash equilibrium. The following theorem, which dates back to Nash [18] and Glicksberg [11], states sufficient conditions on a game for it to have a Nash equilibrium. An earlier version of this theorem for the smaller but prominent class of zero-sum games can be found in von Neumann [23] (translated in von Neumann [24]). The standard proofs use Kakutani's fixed point theorem. We present here an alternative proof, due to Geanakoplos [10], which uses Brouwer's fixed point theorem instead.

Theorem 1 *The game $\langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$ has a Nash equilibrium if for all $i \in N$*

- *the set A_i of actions of player i is a nonempty compact convex subset of an Euclidean space,*
- *the utility function u_i is continuous,*
- *the utility function u_i is concave in A_i.*

Proof (Geanakoplos) Define the correspondence $\varphi_i \colon A \twoheadrightarrow A_i$ by

$$\varphi_i(\bar{a}) = \arg\max_{a_i \in A_i} \{U_i(a_i, \bar{a}_{-i}) - \|a_i - \bar{a}_i\|^2\} ,$$

where, $\|\cdot\|$ denotes a norm in the relevant Euclidean space. Note first that φ_i is a nonempty valued correspondence because the maximand is a continuous function and A_i is compact. Second, note that the function $\|a_i - \bar{a}_i\|$ is convex:

$$\begin{aligned} &\|(\lambda a_i + (1-\lambda)b_i) - \bar{a}_i\| \\ &\quad = \|(\lambda a_i - \lambda \bar{a}_i) + ((1-\lambda)b_i - (1-\lambda)\bar{a}_i)\| \\ &\quad \leq \|(\lambda a_i - \lambda \bar{a}_i)\| + \|((1-\lambda)b_i - (1-\lambda)\bar{a}_i)\| \\ &\quad \leq |\lambda| \|a_i - \bar{a}_i\| + |1-\lambda| \|b_i - \bar{a}_i\| . \end{aligned}$$

Since the quadratic function is strictly convex, then the maximand is a strictly concave function. Therefore, the correspondence φ_i is in fact a function. Furthermore, since the maximand is continuous in the parameter $\bar{a}$, φ_i is also continuous. To see this, let $\bar{a}_n \to \bar{a}$ be a convergent sequence of action profiles and let $a_{i\,n} = \varphi_i(\bar{a}_n)$. This means that $U(a_{i\,n}, (\bar{a}_n)_{-i}) \geq U(b_i, (\bar{a}_n)_{-i})$ for all $b_i \in A_i$. Since A_i is a compact set, $a_{i\,n}$ has a convergent subsequence. Denoting by a_i the limit of this subsequence and applying limits to the above inequality, we obtain that

$$U(a_i, \bar{a}_{-i}) \geq U(b_i, \bar{a}_{-a}) \quad \text{for all } b_i \in A_i ,$$

namely $a_i = \varphi_i(\bar{a})$. Since this is true for every convergent subsequence of $a_{i\,n}$, we have that $\varphi_i(\bar{a}_n) = a_{i\,n} \to a_i = \varphi_i(\bar{a})$, which means that φ is continuous.

Now define $\varphi \colon A \to A$ by $\varphi = (\varphi_1, \ldots, \varphi_N)$. Clearly, φ is a continuous function mapping a compact set to itself. Therefore, by Brouwer's fixed point theorem, it has a fixed point: $\varphi(\bar{a}) = \bar{a}$. We now show that $\bar{a}$ is a Nash equilibrium of the game. Assume not. Then, there is some $i \in N$ with $a_i \in A_i$ such that $U_i(a_i, \bar{a}_{-i}) - U_i(\bar{a}) = E > 0$. Then, by concavity of U_i, for all $0 < \epsilon < 1$,

$$\begin{aligned} &U_i(\epsilon a_i + (1-\epsilon)\bar{a}_i, \bar{a}_{-i}) - U_i(\bar{a}) \\ &\quad \geq \epsilon U_i(a_i, \bar{a}_{-i}) + (1-\epsilon)U_i(\bar{a}) - U_i(\bar{a}) \\ &\quad \geq \epsilon E > 0 , \end{aligned}$$

while $\|\epsilon a_i + (1-\epsilon)\bar{a}_i - \bar{a}_i\|^2 = \epsilon^2 \|a_i - \bar{a}_i\|^2 < \epsilon E$, for small enough ϵ. Therefore, for such small ϵ, the action $\epsilon a_i + (1-\epsilon)\bar{a}_i$ satisfies

$$U_i(\epsilon a_i + (1-\epsilon)\bar{a}_i, \bar{a}_{-i}) - \|\epsilon a_i + (1-\epsilon)\bar{a}_i - \bar{a}_i\|^2 > U_i(\bar{a})$$

which contradicts the fact that $\varphi_i(\bar{a}) = \bar{a}_i$. □

Mixed Strategies

So far, we have formally defined a game, and have introduced the solution concept of Nash equilibrium which is arguably the central solution concept of game theory. However, there seem to be two problems with this concept. One is that although Nash equilibria exist in a wide class of games, there are many simple games that do not have a Nash equilibrium. The most troubling example is Matching Pennies. If game theory cannot provide a prediction for this simple game then one must wonder if there is any value to the theory. The second problem is that the concept of Nash equilibrium predicts a very unrealistic outcome in the war of attrition. One would expect that game theory would not only provide nonempty predictions, but also ones that look reasonable and help explain what we see around us.

One way to approach these problems is not to abandon the theory or the concept of Nash equilibrium altogether, but to modify the way we model the problematic situations. The idea behind mixed strategies is to first modify the game by extending the set of actions available to the players, and then to apply the concept of Nash equilibrium to this extended game. In this way one may obtain additional Nash equilibria, some of which may provide reasonable predictions to the game.

Let $G = \langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$ be a finite game. For any A_i, a probability distribution on A_i is a function

$$x_i \colon A_i \to \mathbb{R}_+$$

such that

$$\sum_{a_i \in A_i} x_i(a_i) = 1 \,.$$

The set of all probability distributions on A_i is denoted by $\Delta(A_i)$. A *mixed strategy on* A_i is a random choice over elements of A_i, namely an element of $\Delta(A_i)$. If x_i is a mixed strategy on A_i, $x_i(a_i)$ denotes the probability that action $a_i \in A_i$ is selected when x_i is adopted. Since elements of $\Delta(A_i)$ can have an alternative interpretation, such as beliefs about the choice of player i, we denote the set of mixed strategies by X_i to distinguish it from the more abstract set of probability distributions on A_i. Also, we denote the set of mixed strategy profiles as $X = \times_{i \in N} X_i$. Denoting for each player $i \in N$, $X_{-i} = \times_{k \in N \setminus \{i\}} X_k$, a typical mixed strategy profile can be written as $(x_k)_{k \in N} = (x_i, x_{-i}) \in X_i \times X_{-i}$. The *mixed extension* of the strategic game G is the strategic game $\langle N, (X_i)_{i \in N}, (U_i)_{i \in N} \rangle$ where the set of actions of player i is the set of mixed strategies, X_i, and the payoff function $U_i \colon \times_{i \in N} X_i \to \mathbb{R}$ of player i is defined by

$$U_i((x_k)_{k \in N}) = \sum_{a = (a_k)_{k \in N} \in A} u_i(a) \Pi_{k \in N} x_k(a_k) \,.$$

Remark 1 Since each mixed strategy of player i, x_i, can be identified with a vector $x_i = (x_i(a_i))_{a_i \in A_i} \in \mathbb{R}^{|A_i|}$, the function U_i is multinomial in the coordinates of its variables, and, as a result, it is continuous as a function of the players' mixed strategies.

Definition 4 An *equilibrium in mixed strategies* of the game $\langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$ is a Nash equilibrium of the mixed extension of the game. In other words, it is a list of mixed strategies $\left(x_k^*\right)_{k \in N} \in X$ such that for all players $i \in N$ and for all his mixed strategies x_i,

$$U_i\left(\left(x_k^*\right)_{k \in N}\right) \geq U_i\left(\left(x_i, x_{-i}^*\right)\right) \,.$$

Alternatively, $\left(x_k^*\right)_{k \in N} \in X$ is a mixed strategy equilibrium if

$$x_i^* \in \mathcal{B}_i\left(x_{-i}^*\right) \quad \text{for all } i \in N \,.$$

Note that for every finite game $G = \langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$, its mixed extension is a strategic game that satisfies the conditions of Theorem 1. As a result, every finite game has a mixed strategy equilibrium.

Example 1 Consider again Matching Pennies. Its mixed extension is the game $\langle N, (X_i)_{i \in N}, (U_i)_{i \in N} \rangle$ where the set of players is $N = \{1, 2\}$, the sets of mixed strategies are $X_1 = \{(p_H, p_T) \geq (0, 0) \colon p_H + p_T = 1\}$, and $X_2 = \{(q_H, q_T) \geq (0, 0) \colon q_H + q_T = 1\}$, and the utility functions are given by $U_1((p_H, p_T), (q_H, q_T)) = p_H q_H + p_T q_T - p_H q_T - p_T q_H$ and $U_2((p_H, p_T), (q_H, q_T)) = p_H q_T + p_T q_H - p_H q_H - p_T q_T$. It can be checked that the only Nash equilibrium of this mixed extension is $((1/2, 1/2), (1/2, 1/2))$. Indeed, since $U_1((p_H, p_T), (1/2, 1/2))$ is identically 0, it attains its maximum at, among other strategies, $(1/2, 1/2)$. The same is true for $U_2((1/2, 1/2), (q_H, q_T))$. To see that there is no other equilibrium, note that for (q_H, q_T) with $q_H > q_T$, player 1's best response is $(1, 0)$. But player 2's best response to $(1, 0)$, is $(0, 1)$. Since $0 \leq 1$, (q_H, q_T) with $q_H > q_T$ cannot be part of an equilibrium. Similarly, for any (q_H, q_T) with $q_H < q_T$, player 1's best response is $(0, 1)$. But player 2's best response to $(0, 1)$ is $(1, 0)$. Since $1 \geq 0$, (q_H, q_T) with $q_H < q_T$ cannot be part of an equilibrium.

We next present a characterization of the mixed strategy equilibria of a game that will sometimes allow us to compute them in an easy way. Further, this characterization serves as the basis of an interesting interpretation of the mixed strategy equilibrium concept that we will discuss later. For this purpose, we identify the action $a_i \in A_i$ of player i with the mixed strategy of player i that assigns probability 1 to action a_i, and 0 to all other actions. Therefore, given a player i, one of his actions $a_i \in A_i$, and a profile $x = (x_k)_{k \in N}$ of the players' mixed strategies, (a_i, x_{-i}) denotes the mixed strategy profile obtained from x by replacing i's mixed strategy x_i by the mixed strategy of player i that assigns probability 1 to action a_i. With this notation we can state the following identity:

$$U_i((x_k)_{k \in N}) = \sum_{a_i \in A_i} x_i(a_i) U_i((a_i, x_{-i})) . \qquad (1)$$

Indeed,

$$\begin{aligned} U_i((x_k)_{k \in N}) &= \sum_{a=(a_k)_{k \in N} \in A} u_i(a) \Pi_{k \in N} x_k(a_k) \\ &= \sum_{a_i \in A_i} \sum_{a_{-i} \in A_{-i}} u_i(a) \Pi_{k \in N} x_k(a_k) \\ &= \sum_{a_i \in A_i} x_i(a_i) \sum_{a_{-i} \in A_{-i}} u_i(a) \Pi_{k \in N \setminus \{i\}} x_k(a_k) \\ &= \sum_{a_i \in A_i} x_i(a_i) U_i((a_i, x_{-i})) . \end{aligned}$$

Identity (1) is useful to prove the following characterization of the mixed strategy Nash equilibria.

Lemma 1 *The strategy profile $x^* = (x_k^*)_{k \in N}$ is an equilibrium of the mixed extension of $\langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$ if and only if for all players $i \in N$ and for all $a_i \in A_i$,*

$$\text{If } x_i^*(a_i) > 0 \quad \text{then } U_i((a_i, x_{-i}^*)) = U_i(x^*) \qquad (2)$$

$$\text{If } x_i^*(a_i) = 0 \quad \text{then } U_i((a_i, x_{-i}^*)) \leq U_i(x^*) . \qquad (3)$$

Proof Assume that $x^* = (x_k^*)_{k \in N}$ satisfies conditions (2) and (3). Let $i \in N$, and let x_i be a mixed strategy of player i. Then, by (1)

$$\begin{aligned} U_i(x_i, x_{-i}^*) &= \sum_{a_i \in A_i} x_i(a_i) U_i((a_i, x_{-i}^*)) \\ &\leq \sum_{a_i \in A_i} x_i(a_i) U_i(x^*) = U_i(x^*) \end{aligned}$$

and therefore x^* is an equilibrium.

Assume now that $x^* = (x_k^*)_{k \in N}$ is an equilibrium. Let $i \in N$. Then

$$U_i(x^*) \geq U_i((a_i, x_{-i}^*)) \quad \forall a_i \in A_i \qquad (4)$$

and, in particular, condition (3) holds for all $a_i \in A_i$ such that $x_i(a_i) = 0$. Also, using (1) we can write

$$\sum_{a_i \in A_i} x_i^*(a_i) U_i(x^*) = \sum_{a_i \in A_i} x_i^*(a_i) U_i\left(a_i, x_{-i}^*\right) . \qquad (5)$$

If there is $a_i \in A_i$ such that $x_i^*(a_i) > 0$ and $U_i(x^*) > U_i\left(a_i, x_{-i}^*\right)$ then, using (4),

$$\sum_{a_i \in A_i} x_i^*(a_i) U_i(x^*) > \sum_{a_i \in A_i} x_i^*(a_i) U_i((a_i, x_{-i}^*))$$

in contradiction to (5). □

Corollary 1 *The strategy profile $x^* = (x_k^*)_{k \in N}$ is an equilibrium of the mixed extension of $\langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$ if and only if for all players $i \in N$ and for all $a_i \in A_i$,*

$$x_i^*(a_i) > 0 \quad \textit{implies } a_i \in \mathcal{B}_i(x_{-i}^*) .$$

According to the standard interpretation, a player's mixed strategy in a game G is an action, but in a different game, namely in the mixed extension of G. According to this interpretation, a mixed strategy is a deliberate choice of a player to use a random device. A mixed strategy equilibrium then is a profile of *independent* random devices, each of which is a best response to the others. Corollary 1 provides an alternative interpretation of a mixed strategy equilibrium. According to this interpretation, a player's mixed strategy represents the uncertainty in the minds of the other players concerning the player's action. In other words, a player's mixed strategy is interpreted not as a deliberate choice of the player but the belief, shared by all the other players, about the player's choice. That is, if $(x_k)_{k \in N}$ is a profile of mixed strategies, then x_i is the conjecture, shared by all the players other than i, about i's ultimate choice of action. Consequently, x_{-i} are the conjectures entertained by player i about his opponents' actions. According to this interpretation, Corollary 1 says that a mixed strategy equilibrium $(x_k^*)_{k \in N}$ is a profile of beliefs about each player's actions (entertained by the other players) according to which each player chooses an action that is a best response to his own beliefs.

The War of Attrition (cont.)

We have seen in Sect. "Analysis of Some Finite Games" that all the Nash equilibria of the war of attrition predict no real fight for the prey. We will now see that there is a mixed strategy equilibrium of the war of attrition that predicts a positive-length fight with probability one.

The players' action sets in the war of attrition are intervals of real numbers. A mixed strategy for player i in that game can be represented by a cumulative distribution function $F_i\colon [0, \infty] \to [0, 1]$. For each $t \in (0, \infty]$, $F_i(t)$ is the probability that player i gives up at or before t. We will look for a Nash equilibrium (F_1, F_2) that consists of two strictly increasing, differentiable cumulative distribution functions. The density of F_i is denoted by f_i. We will try to find an equilibrium at which each player is indifferent between all pure actions.

Consider player i. Given that his opponent is using mixed strategy F_j, $j \neq i$, if he chooses to give in at time t, then he will face a lottery according to which,

- With probability $1 - F_j(t)$, player i does not obtain the prey and gets a payoff of $-t$,
- With probability $F_j(t)$, player i obtains the prey at time t_j, where t_j is a random variable whose cumulative distribution function is $F_j(t_j)/F_j(t)$ (the distribution player j's surrender time, conditional on his having given in before t).

Therefore, the corresponding expected utility of choosing time t is

$$U_i(t, F_j) = (1 - F_j(t))(-t) + F_j(t)\int_0^t (v_i - t_j)\,\mathrm{d}\frac{F_j(t_j)}{F_j(t)}$$
$$= (1 - F_j(t))(-t) + \int_0^t (v_i - t_j)\mathrm{d}F_j(t_j)\,.$$

Since in the equilibrium we are looking for, player i is indifferent among all his actions, the above expression is independent of t. Namely, $U_i(t, F_j) \equiv c$. As a result, the derivative of the above utility with respect to t equals 0. Formally,

$$\frac{\partial U_i(t, F_j)}{\partial t} = tf_j(t) - (1 - F_j(t)) + (v_i - t)f_j(t)$$
$$= (1 - F_j(t)) + v_i f_j(t) = 0.$$

This is a differential equation whose general solution is

$$F_j(t) = 1 - K\mathrm{e}^{-\frac{t}{v_i}}\,.$$

If we want it to satisfy $F_j(0) = 0$, we obtain that $K = 1$. As a result, the distribution function is given by

$$F_j(t) = 1 - \mathrm{e}^{-\frac{t}{v_i}}\,.$$

Consequently, the equilibrium we are looking for is

$$(F_1(t), F_2(t)) = \left(1 - \mathrm{e}^{-\frac{t}{v_2}}, 1 - \mathrm{e}^{-\frac{t}{v_1}}\right)\,.$$

According to this equilibrium, for any t, the probability that there is a fight that lasts at least t is $(1 - F_1(t))(1 - F_2(t)) > 0$. Consequently, there is a fight with probability one. The introduction of mixed strategies allowed the concept of Nash equilibrium to be consistent with fights that last a positive length of time. However, the mixed strategy equilibrium has the following unfortunate property. If $v_1 < v_2$, then for all $t > 0$, $F_1(t) < F_2(t)$. In other words, it is more likely that the player with the highest willingness to fight for the prey gives up earlier than any given t, than that the player with the lowest willingness to fight gives in earlier than the same t. Therefore, in equilibrium it is more likely that the player with the lower willingness to fight wins the war than the other way around. In particular, the probability that player 1 gets the object is given by

$$\int_0^\infty F_2(t)\mathrm{d}F_1(t)$$

which can be checked to be equal to $\frac{v_2}{v_1+v_2} > 1/2$. In order to obtain the more intuitive result that the higher the willingness to fight for the prey, the higher is the probability to obtain it, we will need to model the war of attrition in yet a different way. We'll return to this when we introduce asymmetric information to the games.

Equilibrium in Beliefs

The mixed extension of the game $\langle N, (A_i)_{i\in N}, (u_i)_{i\in N}\rangle$ is constructed in two steps. First, we enlarge the set of actions available to each player by allowing him to choose any mixed strategy on his original action set. Second, since the action choices are now probability distributions over actions, we extend the players' original preferences to preferences over profiles of mixed strategies. We do so by evaluating each mixed strategy profile according to the expected value of the original utilities with respect to the probability distribution over action profiles induced by the mixed strategy.

The first step seems uncontroversial since it is certainly possible for players to use random devices. But the second step is somewhat problematic because, by evaluating mixed strategies according to the expected utility of the resulting lotteries, one is implicitly imposing on the players a certain kind of risk preferences. One may wonder what the implications would be if instead of extending the preferences by assuming that players are expected utility maximizers, we assume that players have more general preferences over profiles of mixed strategies. In particular, we would like to know if there is a suitable generalization of Corollary 1.

Let $G = \langle N, (A_i)_{i\in N}, (u_i)_{i\in N}\rangle$ be a finite game. We define the mixed extension of G as the strategic game $\langle N, (X_i)_{i\in N}, (U_i)_{i\in N}\rangle$ where, as in Sect. "Mixed Strategies", X_i is the set of probability distributions over the actions in A_i, for $i \in N$, but unlike there, the utility function $U_i\colon X \to \mathbb{R}^N$ is not necessarily a multilinear function of the probabilities, but a general continuous function of the mixed strategies. The only requirement on U_i is that for all profiles of degenerate mixed strategies $(a_k)_{k\in N}$, we have $U_i\left((a_k)_{k\in N}\right) = u_i\left((a_k)_{k\in N}\right)$. As before, a mixed strategy Nash equilibrium of $\langle N, (A_i)_{i\in N}, (u_i)_{i\in N}\rangle$ is a Nash equilibrium of its mixed extension $\langle N, (X_i)_{i\in N}, (U_i)_{i\in N}\rangle$. In other words, it is a list of mixed strategies $\left(x_k^*\right)_{k\in N}$ such that for all players $i \in N$ and for all of his mixed strategies x_i,

$$U_i(\left(x_k^*\right)_{k\in N}) \geq U_i(\left(x_i, x_{-i}^*\right)) .$$

Alternatively, $\left(x_k^*\right)_{k\in N}$ is a mixed strategy equilibrium if

$$x_i^* \in \mathcal{B}_i(x_{-i}^*) \quad \text{for all } i \in N .$$

Observation 1 It is important to note that two different actions of a player may be best responses to a given mixed strategy profile of the other players, and yet no probability mixture of the two actions will be a best response to the given mixed strategy profile. This will typically be the case when the function U_i is strictly convex in X_i, since strictly convex functions attain their maximum at boundary points.

Theorem 1 shows that Nash equilibria exist when the extended utility function U_i is concave in X_i. However, Observation 1 indicates that a Nash equilibrium may fail to exist when U_i is strictly convex in X_i. Indeed, take a game $G = \langle N, (A_i)_{i\in N}, (u_i)_{i\in N}\rangle$ with no pure strategy Nash equilibrium, like Matching Pennies, and consider its mixed extension $\Gamma = \langle N, (X_i)_{i\in N}, (U_i)_{i\in N}\rangle$ where for all players, their extended utility function is strictly convex. Then, for any player $i \in N$ and for any profile of mixed strategies x_{-i} of the other players, the set of i's best responses $\mathcal{B}_i(x_{-i})$ consists of only degenerate mixed strategies. Since G has no pure strategy Nash equilibrium, we conclude that Γ does not have a Nash equilibrium.

Observation 2 It is also important to note that, unlike in the standard expected utility case, a player's mixed strategy x_i^* may very well be a best response to some profile x_{-i}^* of the other players' mixed strategies and at the same time may assign positive probability to an action that (when regarded as a degenerate mixed strategy) is not a best response to x_{-i}^*. Formally, it may very well be the case that

$$U_i(\left(x_k^*\right)_{k\in N}) \geq U_i(\left(x_i, x_{-i}^*\right)) \quad \text{for all } x_i \in X_i$$

and yet

$$U_i(\left(a_i, x_{-i}^*\right)) < U_i(\left(x_k^*\right)_{k\in N}) \quad \text{for some } a_i \text{ such } \quad x_i^*(a_i) > 0 .$$

This will typically occur when the function U_i is strictly concave in X_i.

The definition of mixed strategy equilibrium requires from each strategy in the equilibrium profile that it be a best response to the other strategies. Corollary 1 stated that when preferences have the expected utility form, each mixed strategy in a mixed strategy equilibrium is also a probability mixture over best responses to the other strategies in the profile. This result allowed us to interpret a mixed strategy Nash equilibrium as a profile of beliefs, rather than as a profile of probability mixtures. As explained in Observation 2, however, when preferences over mixed strategies are not expected utility preferences, a mixture over best responses is not necessarily a best response. Therefore, Corollary 1 does not extend to the mixed extension where preferences are not of the expected utility form.

In this setup, however, one can still interpret a player's mixed strategy as a belief entertained by the other players about the actions chosen by that player. And a profile of such beliefs will be in equilibrium if the probability distribution over the player's actions that represents i's beliefs is obtained as a mixture of best responses of this player to his beliefs about the other players' actions. With this idea in mind, Crawford [8] defined the notion of an equilibrium in beliefs. Before we formally present his definition we need to introduce some notation.

Since when the extended utility functions U_i are concave in i's own strategy a best response to a given profile of the other players' strategies may be a non-degenerate mixed strategy, a mixture of best responses will typically be a mixture over non-degenerate mixed strategies. This mixture induces a probability distribution over actions in a natural way by reducing the compound mixture to a simple mixture. This induced probability distribution can be interpreted as a belief over the actions ultimately chosen. For example, in Matching Pennies, if player 1 believes that there is a probability of 1/2 that player 2 will choose the mixed strategy $(1/3, 2/3)$ and a probability of 1/2 that player 2 will choose the mixed strategy $(2/3, 1/3)$, then player 1 believes that player 2 will choose each one of his two actions with equal probability. More generally, if player i assigns probability p_k to the event that player j will choose mixed strategy $x^k \in X_j$, for $k = 1, \ldots, K$, then player i's beliefs about player j's actions are given by $\sum_{k=1}^K p_k x^k \in X_j$. That is, for each action $a_j \in A_j$ of player j, player i believes that player j will choose a_j with probability $\sum_{k=1}^K p_k x^k(a_j)$. For each set $T \subset X_i$ of mixed strategies, let $D[T] \subset X_i$ denote the set of probability distributions over i's actions that are induced by mixtures over elements of T. With this notation in hand, we can define the concept of equilibrium in beliefs.

Definition 5 Let $G = \langle N, (A_i)_{i\in N}, (u_i)_{i\in N}\rangle$ be a game. For each $i \in N$, let $\mathcal{B}_i \colon X \to X_i$ be the best response correspondence in the mixed extension of G. The profile of beliefs $(x^*_k)_{k\in N} \in \times_{k\in N}\Delta(A_k)$ is an *equilibrium in beliefs* if

$$x^*_i \in D\left[\mathcal{B}_i(x^*_{-i})\right] \quad \text{for all } i \in N\,.$$

An equilibrium in beliefs is a profile of beliefs $\left(x^*_k\right)_{k\in N}$. For each $i \in N$, x^*_i is the common belief of the players other than i about player i's choice of actions. In order for this profile of beliefs to be in equilibrium, we require that for each player $i \in N$ all the other players believe that i chooses a mixed strategy that is a best response to his beliefs, which are given by $\left(x^*_k\right)_{k\in N\setminus\{i\}}$, about the other players' choices of actions. In other words, x^*_i must be a convex combination of best responses of i to $\left(x^*_k\right)_{k\in N\setminus\{i\}}$.

Example 2 Consider again the mixed extension of Matching Pennies $\langle N, (X_i)_{i\in N}, (U_i)_{i\in N}\rangle$ where the set of players is $N = \{1,2\}$, the sets of mixed strategies are $X_1 = \{(p_H, p_T) \geq (0,0)\colon p_H + p_T = 1\}$ and $X_2 = \{(q_H, q_T) \geq (0,0)\colon q_H + q_T = 1\}$, and the utility functions are now given by $U_1((p_H,p_T),(q_H,q_T)) = (p_Hq_H)^2 + (p_Tq_T)^2 - p_Hq_T - p_Tq_H$ and $U_2((p_H,p_T),(q_H,q_T)) = (p_Hq_T)^2 + (p_Tq_H)^2 - p_Hq_H - p_Tq_T$. Since the utility functions are strictly convex in the players's own mixed strategies, the best response to any strategy of the opponent is a pure strategy. In particular, one can verify that

$$\mathcal{B}_1(q_H,q_T) = \begin{cases} (1,0) & \text{if } q_H > q_T \\ \{(1,0)\,,(0,1)\} & \text{if } q_H = q_T \\ (0,1) & \text{if } q_H < q_T \end{cases}$$

and

$$\mathcal{B}_2(p_H,p_T) = \begin{cases} (0,1) & \text{if } p_H > p_T \\ \{(1,0)\,,(0,1)\} & \text{if } p_H = p_T \\ (1,0) & \text{if } p_H < p_T\,. \end{cases}$$

It can also be verified that $((p^*_H,p^*_T),(q^*_H,q^*_T)) = ((1/2,1/2),(1/2,1/2))$ is an equilibrium in beliefs. Indeed, for both $i = 1,2$, $(1/2,1/2) \in X_i$ is a convex combination of $(1,0)$ and $(0,1)$, which are both in $\mathcal{B}_j\,(1/2,1/2)$, $j \neq i$. In this equilibrium,

1. Player 1 believes that player 2 will choose $(1,0)$ with probability 1/2, and $(0,1)$ with probability 1/2.
2. Therefore player 1 believes that player 2 will ultimately choose H and T, each with probability 1/2.
3. Given these beliefs, player 1's only best replies are $(1,0)$ and $(0,1)$, and
4. Player 2 believes that player 1 will choose each one with probability 1/2. As a result,
5. Player 2 believes that player 1 will ultimately choose H and T each with probability 1/2.
6. Given these beliefs, player 2's only best replies are $(1,0)$ and $(0,1)$, and
1. Player 1 believes that player 2 will choose $(1,0)$ with probability 1/2, and $(0,1)$ with probability 1/2.

The following result is a direct implication of the definition of an equilibrium in beliefs.

Proposition 2 (Crawford [8]) *Let $G = \langle N, (A_i)_{i\in N}, (u_i)_{i\in N}\rangle$ be a strategic game, and $\Gamma = \langle N, (X_i)_{i\in N}, (U_i)_{i\in N}\rangle$ be the mixed extension of G, where U_i is continuous but not necessarily multilinear.*

1. *Every mixed strategy Nash equilibrium of G is an equilibrium in beliefs.*
2. *If for all $i \in N$, U_i is quasiconcave in X_i, then every equilibrium in beliefs is a mixed strategy Nash equilibrium of G.*

Proof

1. Since $\mathcal{B}_i(x^*_{-i}) \subset D\left[\mathcal{B}_i(x^*_{-i})\right]$ for all $i \in N$, every Nash equilibrium is an equilibrium in beliefs.
2. When the utility function U_i is quasiconcave in i's mixed strategy, the set of best responses $\mathcal{B}_i(x^*_{-i})$ is a convex set. Therefore, $D\left[\mathcal{B}_i(x^*_{-i})\right] = \mathcal{B}_i(x^*_{-i})$, and any equilibrium in beliefs is a Nash equilibrium. □

Crawford [8] shows that although some games have no Nash equilibrium, every game has an equilibrium in beliefs.

Correlated Equilibrium

In the mixed extension of a game, players do not choose their actions directly, but rather choose probability distributions over their action sets according to which the actions are ultimately selected. The important feature about these probability distributions is that they represent independent random variables. The realization of one player's random variable does not give any information about the realization of the other players' random variables. There is nothing in the bare notion of equilibrium, however, that requires players' behavior to be independent. The basic feature of an equilibrium is that each player is best responding to the behavior of others, and that each player is free to choose any action in his action set. But one thing is that players can, if they so wish, change their behavior without the consent of others, and another different thing is to expect players' choices to be independent. Therefore, one could ask what would happen if the random devices players use to ultimately choose their actions were correlated. In that case, knowledge of the realization of one's random device would provide some partial information about the realization of the other players' random devices, and therefore of their choices. In equilibrium, a player should take this information into account. To illustrate this point, consider the game of Chicken.

		Driver 2	
		Slow Down	Speed up
Driver 1	Slow Down	$6, 6$	$2, 7$
	Speed up	$7, 2$	$0, 0$

This game has two pure-action Nash equilibria, and one equilibrium in mixed strategies. According to the mixed strategy Nash equilibrium, each player chooses Slow Down with probability 2/3 and Speed Up with probability 1/3. This mixed strategy equilibrium can be implemented by the following random device. Consider two random variables S_1 and S_2, whose joint distribution is given by the following table:

Driver 1 chooses his action as a function of the realization of S_1 and Driver 2 chooses his action as a function of the realization of S_2. (Neither player is informed of the realization of the other player's random variable.) In particular, Driver 1 chooses Slow Down if $S_1 = 1$ and Speed Up otherwise. Similarly, Driver 2 chooses Slow Down if $S_2 = 1$, and Speed Up otherwise. Note that according to this pattern of behavior, each player chooses to slow down with probability 2/3. But more importantly, since S_1 and S_2 are independent random variables, knowledge of the realization of one random variable does not give any information about the realization of the other one. Therefore, after Driver 1 learns the realization of S_1, he still believes that Driver 2 will choose Slow Down with probability 2/3 and consequently any choice is optimal, in particular the one described above. Similarly, after Driver 2 learns the realization of S_2, he still believes that Driver 1 will choose to slow down with probability 2/3, and his planned behavior continues to be optimal.

Static Games, Table 1
A random device

		S_2	
		1	2
S_1	1	4/9	2/9
	2	2/9	1/9

But what would happen if the joint distribution of S_1 and S_2, was not as presented in Table 1, but rather as follows?

		S_2	
		1	2
S_1	1	1/3	1/3
	2	1/3	0

To answer this question, assume that both players still choose their actions according to the previous pattern of behavior: Driver 1 chooses Slow Down if $S_1 = 1$, and Speed Up otherwise. The same holds for Driver 2. As a result, it is still true that each player chooses Slow Down with probability 2/3 and Speed Up with probability 1/3. However, since this time the conditioning random variables S_1 and S_2 are not independent, knowledge of the realization of S_1 affects the beliefs of Driver 1 about the probability with which Driver 2 chooses his actions. In particular, if $S_1 = 1$, Driver 1 updates his beliefs and assigns probability 1/2 to Driver 2 choosing either action, and consequently, Driver 1's only optimal action is Slow Down, which is precisely the choice dictated by the above pattern of behavior. Similarly, if $S_1 = 2$, Driver 1 should update his beliefs and assign probability one that Driver 2 will choose Slow Down. Consequently, Driver 1's best reply is to follow the above pattern of behavior and choose Speed Up. One can see that, given that the players know that the random variables S_1 and S_2 are correlated and they use this information accordingly, there is no incentive for either of them to deviate from the proposed pattern of behavior. Therefore, we can say that this pattern of behavior is an equilibrium. This notion of a correlated equilibrium was introduced in Aumann [2]. Before we give a formal definition we introduce the concept of a correlated strategy profile, which will play a central role not only in this section, but in the next one as well.

Definition 6 Let $G = \langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$ be a game. A *correlated strategy profile in* G consists of

- A finite probability space (Ω, π)
- For each player $i \in N$, a partition $\mathcal{P}_i$ of Ω into events of positive probability
- For each player $i \in N$, a function $\sigma_i : \Omega \to A_i$ which is measurable with respect to $\mathcal{P}_i$.

A correlated strategy profile is a description of what players do and know while playing the game G. The collection $\langle(\Omega, \pi), (\mathcal{P}_i)_{i \in N}\rangle$ represents the random devices used by the players to ultimately choose their actions. The underlying probability space that governs the players' random devices is (Ω, π). Ω is the set of states, and for each state ω, $\pi(\omega)$ is the probability that ω occurs. For each $i \in N$, the partition $\mathcal{P}_i$ represents player *i*'s information. Each element of the partition represents a different realization of the random device used by *i* to choose his action. Two states that belong to the same element of the partition $\mathcal{P}_i$ cannot be distinguished by *i*, while two states that belong to different partition cells can be distinguished by him. For each player $i, \sigma_i : \Omega \to A_i$ is the random variable that describes players *i*'s choice of action, $\sigma_i(\omega)$ being the action chosen by him at state ω. The measurability of σ_i with respect to $\mathcal{P}_i$ formalizes the requirement that the actions chosen by player *i* depend only on his information about the state of the world. Therefore, for any two states that belong to the same element of his partition, the actions chosen by *i* at those states must be the same. That is, for any $\omega, \omega' \in P \in \mathcal{P}_i$ we have $\sigma_i(\omega) = \sigma_i(\omega')$.

For example, the correlated strategy profile described earlier for the game of chicken can be formalized as $\langle(\Omega, \pi), (\mathcal{P}_i)_{i \in N}, (\sigma_i)_{i \in N}\rangle$, where $N = \{\text{I}, \text{II}\}$, and

- $\Omega = \{(1,1), (1,2), (2,1))\}$
- $\pi(\omega) = 1/3$ for all $\omega \in \Omega$
- $\mathcal{P}_{\text{I}} = \{\{(1,1), (1,2)\}, \{(2,1)\}\}$ and $\mathcal{P}_{\text{II}} = \{\{(1,1), (2,1)\}\}, \{(1,2)\}$
- $\sigma_{\text{I}}(\omega) = \begin{cases} \text{Slow Down} & \text{if } \omega \in \{(1,1),(1,2)\} \\ \text{Speed up} & \text{if } \omega \in \{(2,1)\} \end{cases}$
- $\sigma_{\text{II}}(\omega) = \begin{cases} \text{Slow Down} & \text{if } \omega \in \{(1,1),(2,1)\} \\ \text{Speed up} & \text{if } \omega \in \{(1,2)\}\,. \end{cases}$

According to this correlated strategy profile, there are three equally likely states, and the players can distinguish only one component of the state, namely the realization of their random variable. The players' actions are described by the functions σ_I and σ_{II} which depend only on the respective player's information.

In what follows we denote by $\sigma : \Omega \to A$ the function that associates with each $\omega \in \Omega$ the action profile induced by the strategies σ_k, for $k \in N$. That is, $\sigma = (\sigma_k)_{k \in N}$. Also, for any $i \in N$, $\sigma_{-i} = (\sigma_k)_{k \in N \setminus \{i\}}$ so that $\sigma = (\sigma_{-i}, \sigma_i)$. We are interested in correlated strategy profiles in which no player benefits by altering his behavior. These special profiles are introduced in the following definition.

Definition 7 Let $G = \langle N, (A_i)_{i \in N}, (u_i)_{i \in N}\rangle$ be a strategic game. A *correlated equilibrium of* G is a correlated strategy $\langle(\Omega, \pi), (\mathcal{P}_i)_{i \in N}, (\sigma_i)_{i \in N}\rangle$ such that for every $i \in N$ and every function $\tau_i : \Omega \to A_i$ that is measurable with respect to $\mathcal{P}_i$,

$$\sum_{\omega \in \Omega} \pi(\omega) u_i(\sigma_{-i}(\omega), \sigma_i(\omega)) \geq \sum_{\omega \in \Omega} \pi(\omega) u_i(\sigma_{-i}(\omega), \tau_i(\omega))\,. \quad (6)$$

The value $v_i = \sum_{\omega \in \Omega} \pi(\omega) u_i(\sigma_{-i}(\omega), \sigma_i(\omega))$ is player *i*'s correlated equilibrium payoff.

In a correlated strategy profile each player plans to condition his choice of action on the realization of a random variable, and the players' random variables may be correlated. A correlated strategy profile is a correlated equilibrium if no player can find an alternative way to condition his choice on the same random device, so that his expected utility is increased. Note that the player presumably chooses his strategy (his way to condition his actions on the outcomes of the random device) before he learns the realization of the device. Nonetheless, he evaluates the outcomes generated by the players' strategies by taking into account the precise correlation of the random devices on which outcomes players are conditioning their behavior.

Although strictly speaking mixed strategy Nash equilibria are not correlated equilibria, they do induce a correlated equilibrium distribution over action profiles. In order to state this claim, we need the following definition.

Definition 8 Let $\langle(\Omega, \pi), (\mathcal{P}_i, \sigma_i)_{i \in N}\rangle$ be a correlated strategy profile for G. Its induced probability distribution over action profiles is given by the function $p : A \to [0,1]$ defined by

$$p(a) = \pi(\{\omega \in \Omega : \sigma(\omega) = a\}) = \sum_{\{\omega \in \Omega : \sigma(\omega) = a\}} \pi(\omega) \quad \text{for all } a \in A\,.$$

Proposition 3 *Let* $G = \langle N, (A_i)_{i \in N}, (u_i)_{i \in N}\rangle$ *be a strategic game, and let* $x = (x_1, \cdots, x_n)$ *be a mixed strategy Nash equilibrium of G. Then, there is a correlated equilibrium* $\langle(\Omega, \pi), (\mathcal{P}_i)_{i \in N}, (\sigma_i)_{i \in N}\rangle$ *whose induced probability distribution over action profiles is the same as x's distribution.*

Proof Let $\langle(\Omega, \pi), (\mathcal{P}_i)_{i \in N}, (\sigma_i)_{i \in N}\rangle$ be defined as follows:

- $\Omega = A$
- $\pi(a) = \prod_{i \in N} x_i(a_i)$
- $\mathcal{P}_i(a) = \{b \in A : b_i = a_i\}$
- $\sigma_i(a) = a_i$.

We claim that $\langle(\Omega, \pi), (\mathcal{P}_i)_{i \in N}, (\sigma_i)_{i \in N}\rangle$ is a correlated equilibrium whose probability distribution is the same as x's distribution. Let $i \in N$. Since x is a mixed strategy Nash equilibrium, we know by Lemma 1 that for all $a_i \in A_i$

$$\begin{aligned} &\text{if } x_i(a_i) > 0 \quad \text{then } U_i(x) = U_i(a_i, x_{-i}) \\ &\text{if } x_i(a_i) = 0 \quad \text{then } U_i(x) \geq U_i(a_i, x_{-i}) \,. \end{aligned}$$

Consequently, for all $a_i \in A_i$

$$x_i(a_i) U_i(a_i, x_{-i}) \geq x_i(a_i) U_i(b_i, x_{-i}) \quad \text{for all } b_i \in A_i \,. \tag{7}$$

Now let $\tau_i \colon A \to A_i$ be a function that is measurable with respect to $\mathcal{P}_i$. Let $a_{-i} \in A_{-i}$ be a fixed profile of actions for players other than i. Letting $b_i = \tau_i(a_i, a_{-i})$, Eq. (7) implies that

$$x_i(a_i) U_i(a_i, x_{-i}) \geq x_i(a_i) U_i(\tau_i(a_i, a_{-i}), x_{-i}) \quad \text{for all } a_i \in A_i \,.$$

Adding over all $a_i \in A_i$,

$$\sum_{a_i \in A_i} x_i(a_i) U_i(a_i, x_{-i}) \geq \sum_{a_i \in A_i} x_i(a_i) U_i(\tau_i(a_i, a_{-i}), x_{-i}) \,.$$

Taking into account the definition of $U_i(a_i, x_{-i})$ and $U_i(\tau_i(a), x_{-i})$, and using the measurability of τ_i with respect to $\mathcal{P}_i$, we get

$$\begin{aligned} &\sum_{a_i \in A_i} x_i(a_i) \sum_{a_{-i} \in A_{-i}} \left(\prod_{j \in N \setminus \{i\}} x_j(a_j) \right) u_i(a_i, a_{-i}) \\ &\quad \geq \sum_{a_i \in A_i} x_i(a_i) \sum_{a_{-i} \in A_{-i}} \left(\prod_{j \in N \setminus \{i\}} x_j(a_j) \right) u_i(\tau_i(a), a_{-i}) \\ &\sum_{a \in A} \left(\prod_{j \in N} x_j(a_j) \right) u_i(a_i, a_{-i}) \\ &\quad \geq \sum_{a \in A} \left(\prod_{j \in N} x_j(a_j) \right) u_i(\tau_i(a), a_{-i}) \\ &\sum_{a \in A} \pi(a) u_i(a_i, a_{-i}) \geq \sum_{a \in A} \pi(a) u_i(\tau_i(a), a_{-i}) \\ &\sum_{a \in A} \pi(a) u_i(\sigma_i(a), \sigma_{-i}(a)) \geq \sum_{a \in A} \pi(a) u_i(\tau_{-i}(a), \sigma_{-i}(a)). \end{aligned}$$

This shows that $\langle(\Omega, \pi), (\mathcal{P}_i)_{i \in N}, (\sigma_i)_{i \in N}\rangle$ is a correlated equilibrium of G. Its induced probability distribution over action profiles is

$$\begin{aligned} p(a) &= \pi(\{b \in A \colon \sigma(b) = a\}) \\ &= \pi(\{b \in A \colon b = a\}) \\ &= \pi(a) \\ &= \prod_{i \in N} x_i(a_i) \,. \end{aligned}$$

□

Although a correlated strategy profile consists of a randomizing device used by the players, it turns out that the only feature of the device that determines whether or not the correlated strategy profile constitutes a correlated equilibrium is its induced probability distribution over the action profiles. This is shown by the next proposition.

Proposition 4 *Let $G = \langle N, (A_i)_{i \in N}, (u_i)_{i \in N}\rangle$ be a finite strategic game. Every correlated equilibrium probability distribution over action profiles can be obtained in a correlated equilibrium of G in which*

- $\Omega = A$
- $\mathcal{P}_i(a) = \{b \in A \colon b_i = a_i\}$.

Proof Let $\left\langle(\Omega', \pi'), (\mathcal{P}'_i, \sigma'_i)_{i \in N}\right\rangle$ be a correlated equilibrium of G. Consider the correlated strategy profile $\langle(\Omega, \pi), (\mathcal{P}_i, \sigma_i)_{i \in N}\rangle$ defined by

- $\Omega = A$
- $\pi(a) = \pi'(\{\omega \in \Omega \colon \sigma'(\omega) = a\})$ for each $a \in A$
- $\mathcal{P}_i(a) = \{b \in A \colon b_i = a_i\}$ for each $i \in N$ and for each $a \in A$
- $\sigma_i(a) = a_i$ for each $i \in N$.

It is clear that this correlated strategy profile induces the required distribution over action profiles. Indeed,

$$\begin{aligned} p(a) &= \pi(\{\omega \in \Omega \colon \sigma(\omega) = a\}) \\ &= \pi(\{a' \in A \colon a' = a\}) \\ &= \pi(a) \\ &= \pi'(\{\omega \in \Omega' \colon \sigma'(\omega) = a\}) \,. \end{aligned}$$

It remains to show that this profile is a correlated equilibrium. Take a function $\tau_i \colon A \to A_i$ that is measurable with respect to $\mathcal{P}_i$. Define $\tau'_i \colon \Omega' \to A_i$ by $\tau'_i(\omega) = \tau_i(\sigma'(\omega)) = \tau_i(\sigma'_{-i}(\omega), \sigma'_i(\omega))$. The function τ'_i is measurable with respect to $\mathcal{P}'_i$. Indeed, if $\omega' \in \mathcal{P}'_i(\omega)$, then $\sigma'_i(\omega') = \sigma'_i(\omega)$ by measurability of σ'_i with respect to $\mathcal{P}'_i$. Therefore, by definition of $\mathcal{P}_i$, $\mathcal{P}_i(\sigma'(\omega')) = \mathcal{P}_i(\sigma'(\omega))$, and both $\sigma'_i(\omega')$ and $\sigma'_i(\omega)$ belong to the same element of

$\mathcal{P}_i$. Since τ_i is measurable with respect to $\mathcal{P}_i$, we conclude that $\tau'_i(\omega') = \tau_i(\sigma'_i(\omega')) = \tau_i(\sigma'_i(\omega)) = \tau'_i(\omega)$.

Also,

$$\begin{aligned}\sum_{\omega\in\Omega} &\pi(\omega)u_i(\sigma_{-i}(\omega),\tau_i(\omega))\\ &= \sum_{a\in A}\pi(a)u_i(a_{-i},\tau_i(a))\\ &= \sum_{a\in A}\sum_{\{\omega\in\Omega' : \sigma'(\omega)=a\}}\pi'(\omega)u_i(\sigma'_{-i}(\omega),\tau_i(\sigma'(\omega)))\\ &= \sum_{a\in A}\sum_{\{\omega\in\Omega' : \sigma'(\omega)=a\}}\pi'(\omega)u_i(\sigma'_{-i}(\omega),\tau'_i(\omega))\\ &= \sum_{\omega\in\Omega'}\pi'(\omega)u_i(\sigma'_{-i}(\omega),\tau'_i(\omega))\,.\end{aligned}$$

In particular, for $\tau_i = \sigma_i$,

$$\sum_{\omega\in\Omega}\pi(\omega)u_i(\sigma_{-i}(\omega),\sigma_i(\omega)) = \sum_{\omega\in\Omega'}\pi'(\omega)u_i(\sigma'_{-i}(\omega),\sigma'_i(\omega))\,.$$

Since $\langle(\Omega',\pi'),(\mathcal{P}'_i,\sigma'_i)_{i\in N}\rangle$ is a correlated equilibrium,

$$\sum_{\omega\in\Omega'}\pi'(\omega)u_i(\sigma'_{-i}(\omega),\sigma'_i(\omega)) \geq \sum_{\omega\in\Omega'}\pi'(\omega)u_i(\sigma'_{-i}(\omega),\tau'_i(\omega))$$

and therefore

$$\sum_{\omega\in\Omega}\pi(\omega)u_i(\sigma_{-i}(\omega),\sigma_i(\omega)) \geq \sum_{\omega\in\Omega}\pi(\omega)u_i(\sigma_{-i}(\omega),\tau_i(\omega))\,.$$

□

Rationality, Correlated Equilibrium and Equilibrium in Beliefs

As mentioned earlier, Nash equilibrium and correlated equilibrium are two examples of what is known as solution concepts. Solution concepts assign to each game a pattern of behavior for the players in the game. The interpretation of these patterns of behavior is not always explicit, but it is fair to say that they are usually interpreted either as descriptions of what rational people do, or as prescriptions of what rational people should do. There is a growing literature that tries to connect various game theoretic solution concepts to the idea of rationality. Rationality is generally understood as the characteristic of a player who chooses an action that maximizes his preferences, given his information about the environment in which he acts. Part of the information a player has is represented by his beliefs about the behavior of other players, their beliefs about the behavior of other players, and so on. So when one speaks of the rationality of players, one needs to take into account their *epistemic state*. There is a formal framework which is appropriate for discussing the actions, knowledge, beliefs and rationality of players. Namely, the framework of a correlated strategy profile. As defined in Sect. "Correlated Equilibrium", a correlated strategy profile in a game G consists of

- A finite probability space (Ω,π)
- For each player $i \in N$ a partition $\mathcal{P}_i$ of Ω into events of positive probability
- For each player $i \in N$ a function $\sigma_i : \Omega \to A_i$ which is measurable with respect to $\mathcal{P}_i$.

For the present discussion we interpret a correlated strategy profile $\langle(\Omega,\pi),(\mathcal{P}_i)_{i\in N},(\sigma_i)_{i\in N}\rangle$ as a description of the players' behavior and beliefs, as observed by an outside observer. The set Ω is the set of possible states of the world and π is the prior probability on Ω shared by all the players. For each player $i \in N$, $\mathcal{P}_i$ is a partition of Ω that represents i's information. At state $\omega \in \Omega$, player i is informed not of the state that actually occurred, but of the element $\mathcal{P}_i(\omega)$ of his partition that contains ω. Player i then uses this information and his prior π to update his beliefs about the true state of the world. Finally, the function σ_i represents the actions taken by player i at each state. In particular, $\sigma_i(\omega)$ is the action chosen by i at state ω. Although a correlated equilibrium can be interpreted as a correlated strategy profile *prescribed* by a given solution concept (that of a correlated equilibrium), here we want to interpret a correlated strategy profile as a description of what players actually do and believe. Although players cannot freely choose their beliefs (in the same way as they cannot choose their preferences), they can choose their actions. Furthermore, they have no obligation to behave according to the specified correlated strategy profile. However, ultimately players do behave in a certain way and that behavior is what is represented by the given correlated strategy profile.

Once we fix a correlated strategy profile we can address the rationality of the players. Formally,

Definition 9 Player $i \in N$ is *Bayes rational* at $\omega \in \Omega$ if his expected payoff at ω, $E(u_i(\sigma)|\mathcal{P}_i)(\omega)$, is at least as large as the amount $E(u_i(\sigma_{-i}, a_i)|\mathcal{P}_i)(\omega)$ that he would have got had he chosen action $a_i \in A_i$ instead of $\sigma_i(\omega)$.

In other words, player i is rational at a given state of the world if the action $\sigma_i(\omega)$ he chooses at that state maximizes his expected utility given his information, $\mathcal{P}_i(\omega)$, and, in particular, given his beliefs about the actions of the other players.

As before, for any finite set T, let $\Delta(T)$ be the set of all probability distributions on T. The beliefs of player i about the actions of the other players are represented by his conjectures. A conjecture of i is a probability distribution $\psi_i \in \Delta(A_{-i})$ over the elements of A_{-i}. For any $j \neq i$, the marginal of ψ_i on A_j is the conjecture of i about j induced by ψ_i. Given a correlated strategy profile $\langle(\Omega, \pi), (\mathcal{P}_i)_{i\in N}, (\sigma_i)_{i\in N}\rangle$, one can determine the conjectures that each player is entertaining at each state of the world about the actions of the other players. These conjectures are given by the following definition.

Definition 10 Given a correlated strategy profile $\langle(\Omega, \pi), (\mathcal{P}_i, \sigma_i)_{i\in N}\rangle$, the conjectures of $i \in N$ about the other players' actions are given by the function $\phi_i \colon \Omega \to \Delta(A_{-i})$ defined by

$$\phi_i(\omega)(a_{-i}) = \frac{\pi\left[\{\omega' \in \mathcal{P}_i(\omega) \colon \sigma_{-i}(\omega') = a_{-i}\}\right]}{\pi\left[\mathcal{P}_i(\omega)\right]} .$$

For each ω, $\phi_i(\omega) \in \Delta(A_{-i})$ is the conjecture of i at ω. For $j \neq i$, the marginal of $\phi_i(\omega)$ on A_j is the conjecture of i at ω about j's actions.

Given a correlated strategy profile, we can speak about what each player knows. The object of knowledge are called *events*, which are the subsets of the set of states of the world Ω. We say that player i *knows* event $E \subset \Omega$ at state ω, if $P_i(\omega) \subset E$. That is, i knows E at ω if whatever state he deems possible at ω is in E.

The next result, proved by Aumann and Brandenburger [5], shows a remarkable relationship between the rationality of players and the concept of equilibrium in beliefs.

Theorem 2 *Fix a two-person game,* $G = \langle N, (A_i)_{i\in N}, (u_i)_{i\in N}\rangle$, *and let* $\langle(\Omega, \pi), (\mathcal{P}_i)_{i\in N}, (\sigma_i)_{i\in N}\rangle$ *be a correlated strategy profile for G. Let* $\psi_1 \in \Delta(A_1)$ *and* $\psi_2 \in \Delta(A_2)$ *be two conjectures, one about player 1's actions and the other about player 2's actions. Assume that at some state* $\omega \in \Omega$ *each player knows that the other is rational and that their conjectures at* ω *are* $(\phi_1(\omega), \phi_2(\omega)) = (\psi_2, \psi_1)$. *Then,* (ψ_1, ψ_2) *is an equilibrium in beliefs.*

Proof The fact that player i knows at ω that j's conjecture is ψ_i means that

$$\mathcal{P}_i(\omega) \subset \{\omega' \in \Omega \colon \phi_j(\omega')(a_i) = \psi_i(a_i) \quad \text{for all } a_i \in A_i\} .$$

Therefore

$$\phi_j(\omega)(a_i) = \psi_i(a_i) \quad \text{for all } a_i \in A_i . \tag{8}$$

Given Proposition 2 and Corollary 1, we need to show that if $\psi_i(a_i^*) > 0$, a_i^* is a best response to ψ_j, for $i, j = 1, 2$, $i \neq j$. For this purpose, assume that $\psi_i(a_i^*) > 0$ for some $a_i^* \in A_i$. Then, by definition of ϕ_j and (8), $\phi_j(\omega)(a_i^*) = \pi\left[\{\omega' \in \mathcal{P}_j(\omega) \colon \sigma_i(\omega') = a_i^*\}\right] > 0$. Consequently, there is $\omega' \in \mathcal{P}_j(\omega)$ such that $\sigma_i(\omega') = a_i^*$. Since player j knows at ω that player i is rational,

$$\omega' \in \mathcal{P}_j(\omega) \subset \left\{\omega'' \in \Omega \colon E\left[u_i(\sigma)|\mathcal{P}_i\right](\omega'') \geq E\left[u_i(\sigma_{-i}, a_i)|\mathcal{P}_i\right](\omega'') \quad \text{for all } a_i \in A_i\right\} .$$

Therefore,

$$E\left[u_i(\sigma)|\mathcal{P}_i\right](\omega') \geq E\left[u_i(\sigma_{-i}, a_i)|\mathcal{P}_i\right](\omega') \quad \text{for all } a_i \in A_i$$

and since $\sigma_i \colon \Omega \to A_i$ is measurable with respect to $\mathcal{P}_i$, $\sigma_i(\omega') = a_i^*$ is the action that player i chooses at all states in $\mathcal{P}_i(\omega')$. Then we can write

$$E\left[u_i(\sigma_{-i}, a_i^*)|\mathcal{P}_i\right](\omega') \geq E\left[u_i(\sigma_{-i}, a_i)|\mathcal{P}_i\right](\omega') \quad \text{for all } a_i \in A_i .$$

That is, for all $a_i \in A_i$

$$\sum_{\omega'' \in \mathcal{P}_i(\omega')} \frac{\pi(\omega'')}{\pi(\mathcal{P}_i(\omega'))} u_i(\sigma_{-i}(\omega''), a_i^*) \geq \sum_{\omega'' \in \mathcal{P}_i(\omega')} \frac{\pi(\omega'')}{\pi(\mathcal{P}_i(\omega'))} u_i(\sigma_{-i}(\omega''), a_i)$$

$$\sum_{a_j \in A_j} \sum_{\substack{\omega'' \in \mathcal{P}_i(\omega') \\ \sigma_j(\omega'') = a_j}} \frac{\pi(\omega'')}{\pi(\mathcal{P}_i(\omega'))} u_i(a_j, a_i^*) \geq \sum_{a_j \in A_j} \sum_{\substack{\omega'' \in \mathcal{P}_i(\omega') \\ \sigma_j(\omega'') = a_j}} \frac{\pi(\omega'')}{\pi(\mathcal{P}_i(\omega'))} u_i(a_j, a_i)$$

$$\sum_{a_j \in A_j} \frac{\pi\left[\{\omega'' \in \mathcal{P}_i(\omega') \colon \sigma_j(\omega'') = a_j\}\right]}{\pi(\mathcal{P}_i(\omega'))} u_i(a_j, a_i^*)$$
$$\geq \sum_{a_j \in A_j} \frac{\pi\left[\{\omega'' \in \mathcal{P}_i(\omega') \colon \sigma_j(\omega'') = a_j\}\right]}{\pi(\mathcal{P}_i(\omega'))} u_i(a_j, a_i)$$
$$\sum_{a_j \in A_j} \phi_i(\omega')(a_j) u_i(a_j, a_i^*)$$
$$\geq \sum_{a_j \in A_j} \phi_i(\omega')(a_j) u_i(a_j, a_i)\,. \tag{9}$$

Since $\omega' \in \mathcal{P}_j(\omega)$ and player j knows at ω that i's conjecture is ψ_j, then

$$\omega' \in \mathcal{P}_j(\omega) \subset \left\{\omega'' \in \Omega \colon \phi_i(\omega'')(a_j) = \psi_j(a_j) \text{ for all } a_j \in A_j\right\}.$$

Therefore $\phi_i(\omega')(a_j) = \psi_j(a_j)$ for all $a_j \in A_j$, or $\phi_i(\omega') = \psi_j$. That is, i's conjecture at ω' about j's actions is ψ_j. Consequently, substituting in (9),

$$\sum_{a_j \in A_j} \psi_j(a_j) u_i(a_j, a_i^*) \geq \sum_{a_j \in A_j} \psi_j(a_j) u_i(a_j, a_i) \quad \forall a_i \in A_i\,.$$

That is, a_i^* is a best response to player i's beliefs about j's actions. □

The only assumptions required by Theorem 2 is that players know they are rational, and that they know each other's conjectures. In a correlated strategy profile for a two-player game, there is only one player entertaining a conjecture about the actions of player 1, namely, player 2. Similarly, player 1 is the only one who entertains a conjecture about the actions of player 2. In an n-person game, with $n > 2$, for each player, there is more than one player entertaining a conjecture about his actions. Therefore, since an equilibrium in beliefs consists of a profile of beliefs, each of which is shared by $n-1$ players, a generalization of Theorem 2 would require the players' beliefs about player i's actions, for $i \in N$, to be identical. In order to obtain these common beliefs it is not sufficient to assume that players know each other's conjectures. One need to strengthen this assumption. Also, in an equilibrium in beliefs, the common belief about player i's actions assigns positive probability only to best responses to i's conjectures about the choices of the other players. Furthermore, i's conjectures about the other players' choices is the product of his beliefs about each of the other players. In other words, an equilibrium in beliefs implicitly assumes that players believe that the other players' choices are independent. Aumann and Brandenburger [5] show that one way to obtain common conjectures and, simultaneously, that players believe that the other players act independently, is to assume that players' conjectures are commonly known. This surprising and deep result is stated in the next theorem.

Theorem 3 *Let $G = \langle N, (A_i)_{i \in N}, (u_i)_{i \in N}\rangle$ be a strategic game, and let $\langle(\Omega, \pi), (\mathcal{P}_i)_{i \in N}, (\sigma_i)_{i \in N}\rangle$ be a correlated strategy profile for G. Also let $(\psi_i)_{i \in N} \in \times_{i \in N} \Delta(A_{-i})$ be a profile of conjectures, one for each player. Assume that at some state $\omega \in \Omega$ each player knows that the others are rational. Further, assume that at ω their conjectures are commonly known to be $(\psi_i)_{i \in N}$. Then, for each j, all the conjectures ψ_i of players i other than j, induce the same belief $\varphi_j \in \Delta(A_j)$ about j's actions, and the resulting profile of beliefs, $(\varphi_i)_{i \in N}$, is an equilibrium in beliefs.*

Rationality and Correlated Equilibrium

The previous result shows a surprising relationship between the players' rationality and the concept of equilibrium in beliefs. If at some state of the world players know that everybody is rational, and if their conjectures are commonly known at that state, then their beliefs about each player's actions are in equilibrium. It is not that their actions constitute an equilibrium, but that their beliefs do. The question that naturally arises is: are there any epistemic conditions on the players that would induce them to play according to equilibrium? To answer this we turn to Aumann [3], where it is stated that if players are rational at every state, then their behavior constitutes a correlated equilibrium. Therefore, in order to obtain an equilibrium behavior, a sufficient condition is not that players be rational, or that they know that they are rational at some particular state, but that their rationality be common knowledge. And if it is common knowledge that all players are rational, then their behavior is not necessarily a Nash equilibrium, but a correlated equilibrium.

Theorem 4 *Let G be a strategic game, and let $\langle(\Omega, \pi), (\mathcal{P}_i)_{i \in N}, (\sigma_i)_{i \in N}\rangle$ be a correlated strategy profile for G. If each player is rational at each state of the world, then $\langle(\Omega, \pi), (\mathcal{P}_i)_{i \in N}, (\sigma_i)_{i \in N}\rangle$ is a correlated equilibrium.*

Proof Let $\tau_i \colon \Omega \to A_i$ be a function that is measurable with respect to $\mathcal{P}_i$. Since i is Bayes rational at ω

$$E(u_i(\sigma)|\mathcal{P}_i)(\omega) \geq E(u_i(\sigma_{-i}, a_i)|\mathcal{P}_i)(\omega) \quad \forall a_i \in A_i\,.$$

That is,

$$\sum_{\omega' \in \mathcal{P}_i(\omega)} \frac{\pi(\omega')}{\pi(\mathcal{P}_i(\omega))} u_i(\sigma_{-i}(\omega'), \sigma_i(\omega')) \geq \sum_{\omega' \in \mathcal{P}_i(\omega)} \frac{\pi(\omega')}{\pi(\mathcal{P}_i(\omega))} u_i(\sigma_{-i}(\omega'), a_i) \quad \forall a_i \in A_i \,.$$

In particular, for $a_i = \tau(\omega) = \tau(\omega')$ for all $\omega' \in \mathcal{P}_i(\omega)$,

$$\sum_{\omega' \in \mathcal{P}_i(\omega)} \frac{\pi(\omega')}{\pi(\mathcal{P}_i(\omega))} u_i(\sigma_{-i}(\omega'), \sigma_i(\omega')) \geq \sum_{\omega' \in \mathcal{P}_i(\omega)} \frac{\pi(\omega')}{\pi(\mathcal{P}_i(\omega))} u_i(\sigma_{-i}(\omega'), \tau(\omega')) \,.$$

Multiplying both sides by $\pi(\omega)$ and adding over all the elements of $\mathcal{P}_i$ we get

$$\sum_{\omega \in \Omega} \pi(\omega) u_i(\sigma_{-i}(\omega), \sigma_i(\omega)) \geq \sum_{\omega \in \Omega} \pi(\omega) u_i(\sigma_{-i}(\omega), \tau(\omega)) \,.$$

□

Bayesian Games

Thus far, we have considered static games, which are objects of the form $\langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$. Although these games have many applications, they are not readily suitable for the analysis of situations involving asymmetric information. Indeed, an implicit assumption behind the definition of a static game is that all players have the same information about the relevant aspects of the situation. In particular, all players have the same information about the sets of actions and preferences of all players. A static game seems suitable to model strategic interactions like the prisoner's dilemma, rock scissors paper, and even chess. At the time they choose their actions, all the players have exactly the same information. There might be what is called strategic uncertainty, namely, uncertainty about what the players will do, but there is no uncertainty about the rules of the game and about the preferences of the players. But how would one translate a game of cards like bridge or poker into a static game? In a game of cards, at the time of choosing his actions, each player knows the cards he holds in his hand, but does not know the cards of his opponents. He only has a belief about the cards held by his opponents. In order to make a sound choice, a player will try to predict the actions of his opponents, but for this it is crucial to use his beliefs about the cards they hold. For the same reason, his opponents should use their beliefs about their own opponents' cards in order to make a sound choice. Thus, the beliefs about the cards held by each player should be part of a description of a game with asymmetric information. Further, in order to predict his opponents' actions, a player also needs to assess his opponents' beliefs about his own cards. This seems to induce an intractable infinite regress of beliefs, and beliefs about beliefs. Harsanyi [12] provided the basic structure to describe and analyze strategic situations where players are asymmetrically informed. This structure is called a Bayesian game.

Definition 11 A *Bayesian Game* is a system $\langle N, (\Omega, \mu), (A_i, \mathcal{P}_i, u_i)_{i \in N} \rangle$ where

- N is the set of players
- Ω is the set of states of nature
- μ is the players' common prior belief (a probability measure over the set of states)
- A_i is player i's set of actions
- $\mathcal{P}_i$ is player i's information partition (a partition of Ω into sets of positive measure). Each element of the partition is referred to as a player's type.
- $u_i\colon \times_{i \in N} A_i \times \Omega$ is player i's Bernoulli utility function (a function over pairs (a, ω) where $a \in A$ and $\omega \in \Omega$, the expected value of which represents the player's preferences among lotteries over the set of such pairs).

The interpretation of a Bayesian game is as follows. The basic uncertainty is represented by the probability space (Ω, μ) of all states of nature and the prior probability over them. Each state represents a realization of all the parametric uncertainty of the model. For instance, in a game of cards, each state represents each of the possible card deals. The information of player $i \in N$ is represented by his information partition $\mathcal{P}_i$. While states in the same element of the partition cannot be distinguished by the player, he can distinguish between states that belong to different partition cells. In a game of cards, for instance, each partition cell represents a particular set of cards dealt to the player. The probability measure μ represents the players' prior belief about the state of nature. This prior belief will be used along with the information obtained by each player to form beliefs about the other players' information. The set of actions of player i is A_i. Note that there is no loss of generality in assuming that this set does not depend on the state of nature. One can always add unavailable actions and assign them intolerable disutility. Finally, u_i is the payoff function that associates to each state of nature and action profile a utility level. Note that since the state of the world is unknown to the player at the time of making his choice, a player faces a lottery for any given action profile. The assumption is that the player evaluates this lottery according to the expected value of u_i with respect to that lottery.

Let $\langle N, (\Omega, \mu), (A_i, \mathcal{P}_i, u_i)_{i \in N}\rangle$ be a Bayesian game. A strategy for player $i \in N$ is a function $\sigma_i \colon \Omega \to A_i$ that is measurable with respect to $\mathcal{P}_i$. We denote the set of strategies for player i by $\mathcal{B}_i$. That is, $\mathcal{B}_i = \{\sigma_i \colon \Omega \to A_i \colon \sigma_i \text{ is measurable w.r.t. } \mathcal{P}_i\}$. The interpretation of a strategy in a Bayesian game is the usual one. For each state of nature $\omega \in \Omega, \sigma_i(\omega)$ is the action chosen by player i at ω. The measurability requirement imposes that player i's actions depend only on his information. If player i cannot distinguish between two states of nature, then he must choose the same action at both states. Player i evaluates a profile $\sigma \colon \Omega \to A$ of strategies according to the expected value of u_i with respect to μ.

In order to define an equilibrium notion for Bayesian games we follow the same idea used for the definition of a mixed strategy equilibrium. Namely, we translate the Bayesian game into a standard game, and then define an equilibrium of the Bayesian game as the Nash equilibirum of the induced game.

Definition 12 A *Bayesian equilibrium* of a Bayesian game $\langle N, (\Omega, \mu), (A_i, \mathcal{P}_i, u_i)_{i \in N}\rangle$ is a Nash equilibrium of the strategic game: $\langle N, (\mathcal{B}_i)_{i \in N}, (U_i)_{i \in N}\rangle$ where for each profile $\sigma \colon \Omega \to A$ of strategies, $U_i(\sigma) = E_\mu[u_i(\sigma(\omega), \omega)]$ is i's expected utility with respect to μ.

A Bayesian equilibrium of a Bayesian game is a Nash equilibrium of a properly defined static game. As such, conditions for its existence can be derived from Theorem 1. However, in many situations one is interested in particular kinds of equilibria. Specifically, in the analysis of auctions or of the war of attrition, one is often interested in efficient outcomes. In a single object auction, efficient outcomes are characterized by the fact that in equilibrium the object is allocated to the buyer who values it most. According to many standard auction rules, the object goes to the highest bidder. Therefore, in such auctions, to guarantee an efficient outcome, one would need a monotone equilibrium, namely, one in which bidders bids are higher the higher their valuations for the object are. Athey [1] shows conditions under which a Bayesian equilibrium exists where strategies are non-decreasing. The crucial conditions are that the players' types can be represented by a one-dimensional variable, and that, fixing a nondecreasing strategy for each of a player's opponents, this player's expected payoffs satisfies a single-crossing property. This single-crossing property roughly says that if a high action is preferred to a low action for a given type t, then the same must be true for all types higher than t. McAdams [16] extended Athey's result to the case where types and actions are multidimensional and partially ordered.

The Asymmetric Information Version of the War of Attrition

We have seen that, when applied to the war of attrition, as modeled by a standard strategic game or by its mixed extension, the notion of Nash equilibrium does not yield a satisfactory prediction.[1] In the former case all the equilibria involve no fight, and in the latter case the equilibrium dictates a more aggressive behavior to the player who values the contested object less. In what follows, we analyze the war of attrition as a Bayesian game. That is, we assume that the players are ex-ante symmetric but they have private information about their value for the contested object.

A Bayesian game that represents the war of attrition is given by $\langle N, \Omega, (A_i, \mu_i, \mathcal{P}_i, u_i)_{i \in N}\rangle$ where

- $N = \{1, 2\}$
- $\Omega = [0, \infty)^2 = \{(v_1, v_2) \colon 0 \le v_i < \infty, i = 1, 2\}$
- $A_i = [0, \infty)$ for $i = 1, 2$
- $\mathcal{P}_i(\hat{v}_1, \hat{v}_2) = \{(v_1, v_2) \in \Omega \colon v_i = \hat{v}_i\}$ for $i = 1, 2$
- $\mu((v_1, v_2) \le (\hat{v}_1, \hat{v}_2)) = F(\hat{v}_1) \times F(\hat{v}_2)$
- $u_i((a_1, a_2), (v_1, v_2)) = \begin{cases} -a_i & \text{if } a_i \le a_j \\ v_i - a_j & \text{if } a_i > a_j \, . \end{cases}$

Here the set of types of player i, for $i = 1, 2$, is represented by the player's willingness to fight, v_i. The players' willingness to fight are drawn independently from the same distribution F. A state of the world is, therefore, a realization (v_1, v_2) of the players' types, and at that state, each player is informed only of his type. Finally, the utility of a player is his valuation for the prey, if he obtains it, net of the time spent fighting for it. We are interested in a symmetric equilibrium in which both players use a symmetric, strictly increasing strategy $\beta \colon [0, \infty) \to [0, \infty)$, where $\beta(v)$ is the time at which a player with willingness to fight v is dictated by the equilibrium to give up. Such an equilibrium would imply that types who value the prey more, are willing to fight more. Further, the probability of observing a fight in equilibrium would not be 0 (in fact, it would be 1.)

It turns out that a symmetric equilibrium strategy is given by

$$\beta(v) = \int_0^v \frac{x f(x)}{1 - F(x)} \mathrm{d}x ,$$

[1] The war of attrition was analyzed in Maynard Smith [14]. For an analysis of the asymmetric information version of the war of attrition, see Krishna and Morgan [13].

where f denotes the derivative of F. To see this, assume that player j behaves according to β and that player i chooses to give up at t. Letting z be the type such $\beta(z) = t$, the expected utility of player i from choosing t is

$$U(v_i, z) = \int_0^z (v_i - \beta(y)) f(y) \mathrm{d}y - \beta(z)(1 - F(z)) \,.$$

Taking derivatives with respect to z, and using the fact that $\beta'(z) = z f(z)/[1 - F(z)]$ we obtain

$$\begin{aligned}\frac{\partial U}{\partial z}(v_i, z) &= v_i f(z) - \beta'(z)(1 - F(z)) \\ &= (v_i - z) f(z),\end{aligned}$$

which is positive for $z < v_i$, and negative for $z > v_i$. As a result, the expected utility of player i with willingness to pay v_i is maximized at $z = v_i$, which implies that the optimal choice is $\beta(v_i)$.

Thus, modeling the war of attrition as an asymmetric game has allowed us to find an equilibrium in which players with higher willingness to fight fight more, and there is a non-negligible probability of observing a fight.

Evolutionary Stable Strategies

The notion of the Nash equilibrium concept involves players choosing actions that maximize their payoffs given the choices of the other players. The usual interpretation of a Nash equilibrium is as a pattern of behavior that rational players *should* adopt. However, Nash equilibria are sometimes interpreted more descriptively as patterns of behavior that rational players *do* adopt. Certainly, rationality of players is neither a necessary condition nor a sufficient one for players to play a Nash equilibrium. The relationship between rationality and the various solution concepts is not apparent and has been the focus of an extensive literature (see, for example, [3,4,5,7]). Nonetheless, the notion of a Nash equilibrium evokes the idea of players consciously making choices with the deliberate objective of maximizing their payoffs. It is therefore quite remarkable that a concept almost identical to that of Nash equilibrium has emerged from the biology literature. This concept describes a population equilibrium where unconscious organisms are programmed to choose actions with no deliberate aim. In this equilibrium, members of the population meet at random over and over again to interact. At each interaction, these players act in a pre-programmed way and the result of their actions is a gain in biological fitness. Fitness is a concept related to the reproductive value or survival capacity of an organism. In a temporary equilibrium, the fitness gains are such that the proportions of individuals that choose each one of the possible actions remain constant. However, this temporary equilibrium may be disturbed by the appearance of a mutation, which is a new kind of behavior. This mutation may upset the temporary equilibrium if its fitness gains are such that the new behavior spreads over the population. Alternatively, if the fitness gains of the original population outweigh those of the mutation, then the new behavior will fail to propagate and will eventually disappear. In a population equilibrium, the interaction of any mutant with the whole population awards the mutant insufficient fitness gains, and as a result the mutants disappear. The notion of a population equilibrium is formalized by means of the concept of an evolutionary stable strategy, introduced by Maynard Smith and Price [15].

In what follows we restrict our attention to symmetric two-player games. So let $G = \langle \{1,2\}, \{A_1, A_2\}, \{u_1, u_2\} \rangle$ be a game such that $A_1 = A_2 = \overline{A}$, and such that for all $a, b \in \overline{A}, u_1(a,b) = u_2(b,a)$. An evolutionary stable strategy is an action in $\overline{A}$ such that if all members of the population were to choose that action, no sufficiently small proportion of mutants choosing an alternative action would succeed in invading the population. Alternatively, an evolutionary stable strategy is an action in $\overline{A}$ such that if all the members of the population were to choose that action, the population would reject all sufficiently small mutations involving a different action.

More specifically, suppose that all members of the population are programmed to choose $a \in \overline{A}$, and then a proportion ε of the population mutates and adopts action $b \in \overline{A}$. In that case, the probability that a given member of the population meets a mutant is ε, while the probability of meeting a member that plays a is $1 - \varepsilon$. Therefore, the mutation will not propagate and will vanish if the expected payoff of a mutant is less than the expected payoff of a member of the majority. Otherwise it will propagate. This leads to the following definition.

Definition 13 An action $a \in \overline{A}$ is an evolutionary stable strategy of G if there is an $\bar{\varepsilon} \in (0,1)$ such that for all $\varepsilon \in (0, \bar{\varepsilon})$, and for all $b \in \overline{A}$

$$(1-\varepsilon)u_1(a,a) + \varepsilon u_1(a,b) > (1-\varepsilon)u_1(b,a) + \varepsilon u_1(b,b) \,. \tag{10}$$

The following result shows that the concept of an evolutionary stable strategy is very close to the notion of a Nash equilibrium.

Proposition 5 *If $a \in \overline{A}$ is an evolutionary stable strategy of G, then (a,a) is a Nash equilibrium. And if (a,a) is* *a strict Nash equilibrium then a is an evolutionary stable strategy.*

Proof If $u_1(a,a) > u_1(b,a)$ for all $b \in \overline{A} \setminus \{b\}$, then inequality (10) holds for all sufficiently small $\varepsilon > 0$. If $u_1(b,a) > u_1(a,a)$ for some $b \in \overline{A}$, the reverse inequality holds for all sufficiently small ε. □

Future Directions

Static games have been shown to be a useful framework for analyzing and understanding many situations that involve strategic interaction. At present, a large body of literature is available that develops various solution concepts, some of which are refinements of Nash equilibrium and some of which are coarsenings of it. Nonetheless, several areas for future research remain. One is the application of the theory to particular games to better understand the situations they model, for example auctions. In many markets trade is conducted by auctions of one kind or another, including markets for small domestic products as well as some centralized electricity markets where generators and distributors buy and sell electric power on a daily basis. Also, auctions are used to allocate large amounts of valuable spectrum among telecommunication companies. It would be interesting to calculate the equilibria of many real life auctions. Simultaneously, future research should also focus on the design of auctions whose equilibria have certain desirable properties.

Another future direction would be to empirically and experimentally test the theory. The various equilibrium concepts predict certain kinds of behavior in certain games. Our confidence in the predictive and explanatory power of the theory depends on its performance in the field and in the laboratory. Moreover, the experimental and empirical results should provide valuable feedback for further development of the theory. Although some valuable experimental and empirical tests have already been performed (see [17,19,22,25] to name a few), the empirical aspect of game theory in general, and of static games in particular, remains underdeveloped.

Statistical Applications of Wavelets

Sofia Olhede
Department of Statistical Science,
University College London, London, UK

Article Outline

Glossary

Locally stationary process A stochastic process that when sampled in time, its sampled points have joint characteristics in a short time window that only depend on the difference between the sampled time points, and not the global time point of the samples within the time window.

Multiresolution analysis The analysis of a phenomenon of interest over different temporal or spatial scales and locations.

Shrinkage A method of estimation where the initial estimator is decreased by multiplication with a factor of magnitude less than or equal to one. If the object being estimated is small, then a reduced variance will arise, that sets off the increased bias in estimation.

Sparsity Sparsity in a vector corresponds to the support of the vector being limited. The sparsity can either be strict, i. e. the vector is perfectly supported in a small subset of all its entries, or the magnitudes of the entries decay sufficiently rapidly, if ordered in magnitude.

Stationary process A stochastic process that when sampled in time, its sampled points have joint characteristics that only depend on the difference between the sampled time points, and not the global time point of the samples.

Thresholding A method of estimation where the initial estimator is set to zero if it does not exceed a given threshold. Thresholding is a special case of shrinkage.

Wavelet and scaling functions The functions that the wavelet and scaling filters converge to in increasing scale, when using discrete wavelet filters. These are not for any finite scale equivalent to the wavelet and scaling filters.

Wavelet and scaling filters The high and low pass digital filters that are used to calculate the discrete wavelet transform of a given sequence or vector. These are a pair of quadrature mirror filters that satisfy the perfect reconstruction property.

Definition of the Subject

A wavelet is a function essentially supported over a small time-window, that is oscillatory, with a local period that ranges over a limited sets of values. A wavelet function can be considered jointly local in time and frequency. Wavelets have become an integral part of statistical analysis of structured phenomena. Their utility for inference is based on several of their important properties, namely compression, separation of multiscale features, and differencing of a given set of moments. The statistical analysis of processes using wavelets presents a more faceted view of the phenomenon of interest than traditional methods. The utility of this in many areas is unquestionable, and statistical applications of wavelets include areas as disparate as climatology, econometrics, finance, geophysics, mathematics, as well as signal and image processing.

Introduction

The field of wavelets in statistics can roughly be divided into two areas, namely the usage of continuous wavelets, and the usage of discrete wavelets. Continuous wavelets are defined at a continuum of locations, whilst discrete wavelet filters are sequences defined only at a countable number of locations and scales. These sequences are not strictly speaking wavelet functions, but converge in increasing scale to such functions. Unfortunately in the literature both functions and filters are referred to as 'wavelets'.

Continuous wavelets are applied to the characterization of random processes, but are not usually used for actual signal estimation, as the transform does not possess an exact discretely implementable inverse. Continuous wavelets do not necessarily satisfy the constraint of compactness in time, and this permits more freedom in their design. A third class of wavelets that often receive separate treatment are complex-valued discrete wavelet filters. These can be thought of as bridging the gap between continuous and discrete representations. Complex wavelets are often chosen to be redundant, and have interpretable magnitude and phase, see for example the review of these in [48].

The statistical representation of structured phenomena using decompositions was first introduced by [47] who analyzed time series using Fourier decompositions. This analysis method corresponds to decomposing a sample into cosines and sines to determine the power associated with each frequency or mode. The interpretation of the observed weight attached to each frequency depends on the model posited for the observed data. If the process is assumed to be *stationary*, then the observed weight can be shown to converge in expectation to the true weight, namely the Fourier transform of the autocovariance of the time series. By calculating the full set of weights across frequencies, we may obtain a picture of the frequency content of the process. Even for processes that are not *stationary*, decomposing the set of observations into sinusoids allows us to visualize the frequency content of the signal. As long as the process is *harmonizable*, see [36], such decompositions are suitable.

Unfortunately whilst the decomposition of a time-varying process into sines and cosines is interpretable in a global sense, and can be shown to possess some suitable properties, it is not as easily interpreted as might be the case. Many processes are generated by mechanisms that fundamentally alter over time. It is therefore suitable to use decomposition functions that unlike sines are limited in time, but still correspond to oscillatory functions. A popular choice of such functions is wavelets.

A wavelet is a time-limited oscillation, or a "little wave". The first family was constructed by Alfred Haar in 1910, see [26]. The subject lay dormant for many years, until the mid 1980s when their usage in geophysics revitalized interest in the set of decompositions, by Morlet, and one of the groundbreaking new articles corresponds to [24]. A great theoretical leap forward was the construction of discrete wavelet filters, see [10]. Most of the statistical usage of wavelets has focused around the usage of discrete wavelets.

The development of statistical methods can really be grouped into three main strands of development: i) the usage of compression for non-parametric signal estimation, following work by [15,16,17], ii) the characterization of stochastic difference stationary processes, see [38,51], and iii) the inference of locally stationary wavelet processes, see [40]. Theoretical results have also been achieved in terms of the characterization of stochastic processes, see [3,4,8,34], but these results as of yet have had limited practical implications.

After initial usage of the wavelet transform for signal estimation it became obvious that despite the wavelet transform's orthogonalizing effects, relationships between coefficients must be used, to derive better representations, see [58] The development of data driven decompositions, and usage of the 'lifting algorithm', [12], followed in the second strand of developments. Further steps forward included the construction of two dimensional decompositions for image estimation, where notable contributions include the ridgelet, curvelet and bandelet transforms, see [9,33,52]. Outstanding problems remain in the statistical usage of these transforms, and investigations have mainly been limited to modeling the observed phenomena as deterministic and immersed in some form of noise.

Decomposition View of Random Processes

Wavelets are used to analyze observations whose generating mechanism can be characterized in terms of the location the observation is made at. This could be time, space or some other suitable indexing. We shall denote the location of any observation by $t \in \mathbb{R}^d$, where d denotes the dimension of the indexing, this could be $d = 1$, like a time series, or $d = 2$, like an image. If $\{x(t)\}$ is a random process then its structure can be determined from its moments. The first order structure of $x(t)$ is given by its mean, defined by

$$\mu_x(t) = \mathrm{E}\{x(t)\}\,, \quad t \in \mathbb{R}^d\,, \tag{1}$$

and the second order structure of $x(t)$ is given by its covariance, namely

$$\gamma_x(t_1, t_2) = \operatorname{cov}\{x(t_1), x(t_2)\}\,, \quad t_1,\ \ t_2 \in \mathbb{R}^d\,. \tag{2}$$

$\mathrm{E}\{\cdot\}$ denotes the expectation operator, and $\operatorname{cov}\{\cdot,\cdot\}$ the covariance operator. If the process is assumed to be a Gaussian process, i. e. if any sample of n observations from $\{x(t)\}$ is multivariate Gaussian, then $\{\mu_x(t)\}$ in combination with $\{\gamma_x(t_1, t_2)\}$ fully characterize the generation of the process $\{x(t)\}$.

Often we only take n observations from the process $\{x(t)\}$ and still want to fully characterize the generating mechanism, so that we can test hypotheses of interest regarding $\{x(t)\}$ or just estimate some parameters of interest. To be able to do this we must make some further assumptions about $x(t)$, and these could correspond to fully parametric or non-parametric assumptions on $\{\mu_x(t)\}$ or $\{\gamma_x(t_1, t_2)\}$. Typical examples might be $\mu_x(t) = a_x + b_x t$, which is a parametric specification of the mean, or $\mu_x(t)$ possessing a certain degree of smoothness. If the latter approach is taken then it is convenient to represent $\mu_x(t)$ in terms of some functions where the assumed smoothness can be easily incorporated into the modeling. Furthermore the covariance structure can be assumed to simplify if we choose a suitable representation. If $x(t)$ is represented in terms of linear combinations of known basis functions, such as wavelets, then Gaussian processes will be transformed into Gaussian processes with a different mean and covariance function. For certain classes of auto-covariance functions the analysis is much simplified by considering the transformed rather than the original Gaussian process.

Wavelets

A wavelet function, is a complex-valued square integrable function satisfying the admissibility condition, see [27]. We denote a generic wavelet by $\psi(t)$. The Continuous

Wavelet Transform (CWT) of a signal $x(t)$ with respect to a wavelet $\psi(t)$ is defined as a filtration of $x(t)$:

$$w^{(x)}(t,s) = \int_{-\infty}^{\infty} x(t')\psi_{t,s}(t')\,\mathrm{d}t' \,,$$
$$\psi_{t,s}(t') = s^{\frac{-1}{2}}\psi\left(\frac{t'-t}{s}\right) . \tag{3}$$

The choice of normalization, here $s^{-1/2}$ varies across application fields. Sometimes 1/2 is replaced by 1 if more convenient for analysis, see [54]. The former is referred to as the *energy normalization*, and the latter as the *compression normalization*. The former normalization conserves the variance of the transformed process.

If $\{x(t)\}$ is a stochastic process satisfying some regularity conditions, see [34], then $\left\{w^{(x)}(t,s)\right\}$ is a doubly indexed stochastic process with mean

$$\mathrm{E}\left\{w^{(x)}(t,s)\right\} = \int_{-\infty}^{\infty} \mu_x(t')\psi_{t,s}(t')\,\mathrm{d}t' \,,$$
$$\psi_{t,s}(t') = s^{\frac{-1}{2}}\psi\left(\frac{t'-t}{s}\right) \tag{4}$$

$$\equiv w^{(\mu_x)}(t,s) \,. \tag{5}$$

The form of this expression simplifies if $x(t)$ takes the simpler form of a time-varying oscillation, see [13], or a singularity [28,55], or is a sufficiently regular function, see [56]. Under such circumstances very few of $\left\{w^{(\mu_x)}(t,s)\right\}$ are non-zero and inferences can be made about the model from the few non-zero coefficients. In the special case of time-varying oscillations the theory of *wavelet ridge analysis* has been developed to characterize the local oscillations. Applications of such methods include mechanical vibratory signals, see [31,59], seismic signals [44,45], as well as ocean eddy time series, see [6,35].

The usage of continuous wavelets does not extend greatly beyond the aforementioned methods of signal inference. The characterization of various stochastic processes have been investigated using continuous wavelets, i. e. [3,8,25,32,34], but this has been put to little practical usage. Some interesting developments for the prediction of continuous signals using wavelets have been developed in [1,2].

The main focus of wavelet usage in statistics has instead evolved around the usage of the Discrete Wavelet Transform (DWT). The DWT is defined as a reversed convolution between a discretely sampled signal and the wavelet filter. We denote the jth level wavelet filter $\left\{h_{j,l}\right\}$, and the scaling filter $\left\{g_{j,l}\right\}$. For a complete review of the properties of these objects see [11,37,46]. These are constructed from the $j=1$ level filters $\{h_l\}$ and $\{g_l\}$, that satisfy the quadrature mirror relationship of $g_l = (-1)^{l+1}h_{L-1-l}$ where L is the length of the two filters. Given a sampled process $x_n = x(n\Delta t)$ the wavelet coefficients are defined by:

$$w_{j,l}^{(x)} = \sum_n h_{j,l}x_n \,, \quad h_{j,l} = \sum_{k=0}^{L-1} h_k g_{j-1,l-2^{j-1}k} \,, \tag{6}$$

where the wavelet filters given $\left\{g_{j-1,l}\right\}$ can now be determined iteratively. To complement the wavelet coefficients of x_n, additionally the scaling coefficients are computed, of

$$v_{j,l}^{(x)} = \sum_n g_{j,l}x_n \,, \quad g_{j,l} = \sum_{k=0}^{L-1} g_k g_{j-1,l-2^{j-1}k} \,, \tag{7}$$

this completing the iterative specification of the wavelet and scaling filters. If we collect the wavelet and scaling coefficients in a vector $\mathbf{W}^{(x)} = [w_{1,0}^{(x)}, \ldots, w_{1,N/2-1}^{(x)}, w_{2,0}^{(x)}, \ldots, v_{J/2,0}^{(x)}]$, then the DWT can be represented as:

$$\mathbf{W}^{(x)} = \mathcal{W}\mathbf{X} \,, \tag{8}$$

where $\mathcal{W}$ is composed of $\left\{h_{j,l}\right\}$ and $\left\{g_{J,l}\right\}$, see [46]. Equation (8) is not the method to compute the DWT, popularly the transform is implemented using Mallat's pyramid algorithm, see [37], but it enables the easy determination of the stochastic properties of the wavelet transform. The CWT and the DWT are not two disparate objects: if we possess a sequence of coefficients $\left\{v_{0,l}^{(x)}\right\}$ such that

$$x(t) = \sum_{n=-\infty}^{\infty} v_{0,l}^{(x)}\phi_{0,k}(t) \tag{9}$$

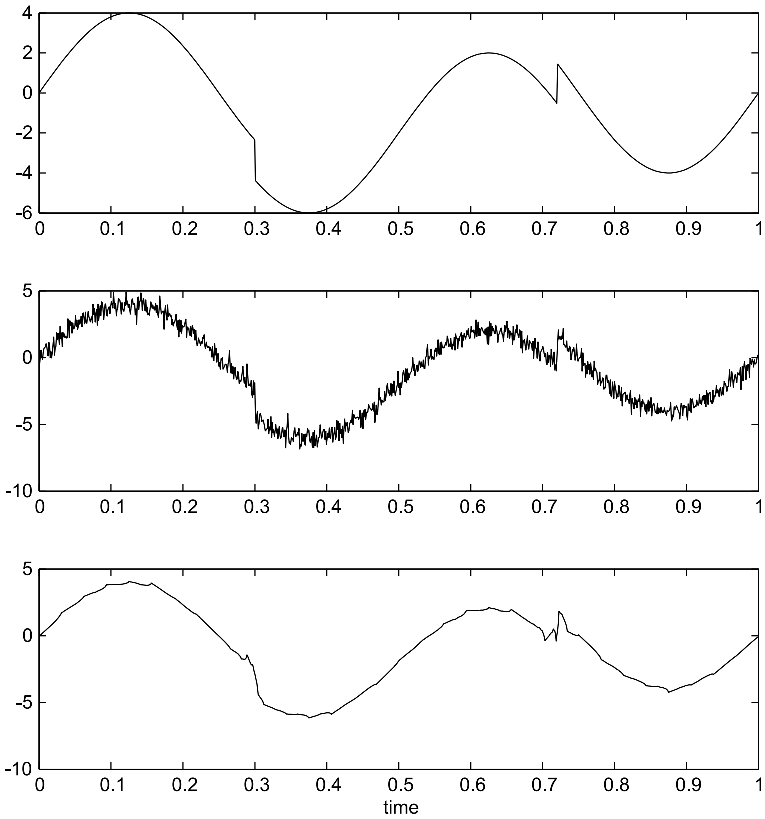
then $w_{j,l}^{(x)}$ can be calculated from $v_{0,l}^{(x)}$, as can $v_{j,l}^{(x)}$, and correspond to the CWT as well as scaling coefficients of the continuous rather than the sampled process. In practise x_n is equated to $v_{0,n}^{(x)}$, even if this is formally inappropriate.

Signal Estimation or Denoising

The most popular statistical application of wavelets is denoising, or function estimation. This proceeds from a model of the observed signal of:

$$x_n = \mu(n\Delta t) + \epsilon_n, \quad n = 0,\ldots,N-1 \,, \tag{10}$$

where Δt is referred to as the sampling period of the signal, and the sample size is N. To fully specify the generation of the observations $\{\epsilon_n\}$ must be modeled, and a popular model is to assume this sequence as zero-mean, uncorrelated (white) and Gaussian, with some constant vari-



Statistical Applications of Wavelets, Figure 1

The clean Heavisine signal (*top*), the noisy Heavisine signal (*middle*) and the denoised Heavisine signal (*bottom*). The plots show the typical features of a wavelet estimator, namely the adaptation to local smoothness, where the sinusoidal parts of the signal are smoothed, and the discontinuities, are kept without over smoothing

ance σ^2, that needs to be determined to implement estimation. To see a typical realization of such a signal, see Fig. 1. This signal, 'Heavisine' is famous as one of the four typical signals that were introduced by [16]. Heavisine has been immersed in noise, see Fig. 1. This signal is not trivial to smooth as it possesses varying degrees of smoothness across the realization, compare for example the discontinuities with the smooth portions of the signal.

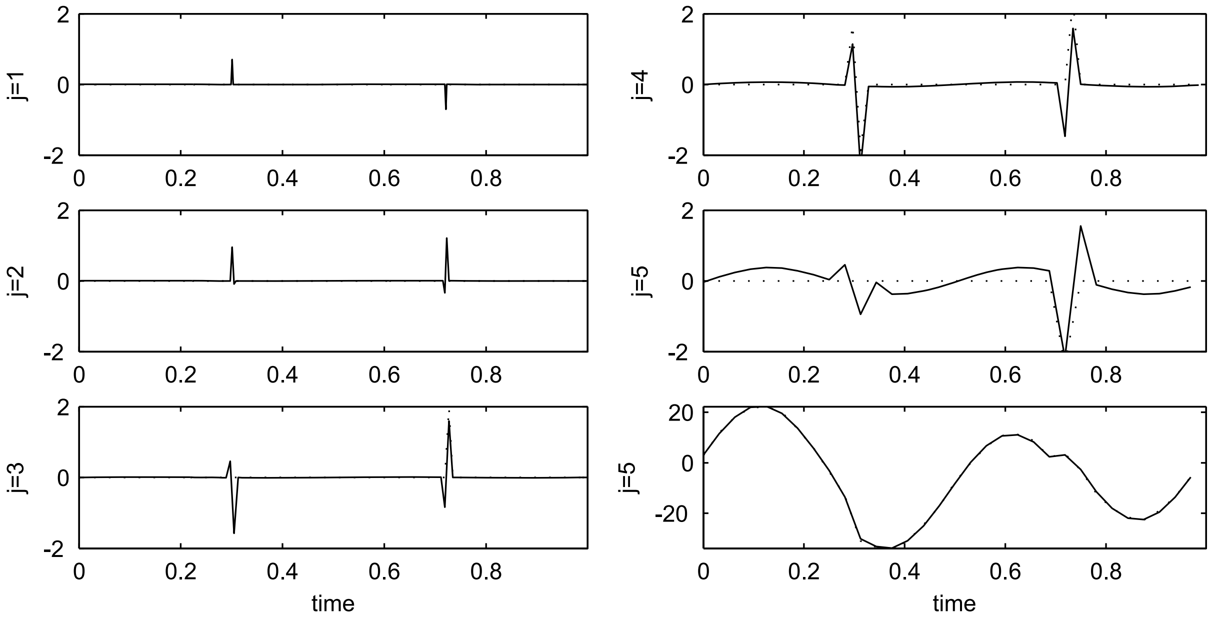
One important inference problem in this setting is to estimate $\{\mu(n\Delta t)\}$ with low expected square deviation, i. e. to chose an estimator $\widehat{\mu}(n\Delta t)$ such that

$$\mathrm{MSE}(\widehat{\mu}, \mu) = \sum_{n=0}^{N-1} \mathrm{E}\left\{\left(\mu(n\Delta t) - \widehat{\mu}(n\Delta t)\right)^2\right\} , \qquad (11)$$

is as small as possible. Common methods of estimating $\mu(n\Delta t)$ include using many different adaptive linear estimation methods, such as kernel smoothers, smoothing splines, truncated Fourier methods etc. Smoothing using the DWT was introduced by [15,16], and has enjoyed an incredible success. The simplest form of wavelet estimation is based on the compression of the DWT of $x(t)$ alone, combined with the uniformity of the white process across time.

The wavelet coefficients of $\mu(\cdot)$ are given as $\left\{w_{j,l}^{(\mu)}\right\}$, and together with the scaling coefficients, $\left\{v_{j,l}^{(\mu)}\right\}$, these are sufficient to reconstruct $\mu(n\Delta t)$ via calculating the Inverse DFT (IDFT) or:

$$\begin{pmatrix} \mu(0\Delta t) \\ \dots \\ \mu((N-1)\Delta t) \end{pmatrix} = \mathcal{W}^{-1} \begin{pmatrix} w_{1,0}^{(\mu)} \\ \dots \\ w_{1,\frac{N}{2}-1}^{(\mu)} \\ w_{2,0}^{(\mu)} \\ \dots \\ w_{2,\frac{N}{4}-1}^{(\mu)} \\ \dots \\ v_{J,0} \end{pmatrix} . \qquad (12)$$



Statistical Applications of Wavelets, Figure 2

The wavelet coefficients of the Heavisine signal, used in the original paper by Donoho and Johnstone [15]. We show the first five level wavelet coefficients, and the scaling coefficients of the signal in *solid line*. Added to the picture are the thresholded wavelet and scaling coefficients of a noisy realization in *dotted line*

Thus a good estimator of $\left\{w_{j,l}^{(\mu)}\right\}$ can easily be converted into a good estimator of $\mu(n\Delta t)$, using Eq. (12). To see the motivation behind the most commonly adopted choice of estimation for the wavelet coefficients, observe the wavelet coefficients of the Heavisine signal, that we plotted in Fig. 1, plotted in Fig. 3. Most of the wavelet coefficients are quite small. If a given signal $\mu(\cdot)$ is sufficiently regular then it can be shown that $\left\{w_{j,l}^{(\mu)}\right\}$ must decrease in magnitude. For this reason one may argue that most of this set are zero, and the transform exhibits compression or sparsity, see [56]. We are therefore trying to estimate a sequence of variables of which most are zero, and only a few are large. It is *not* optimal to equate the estimator to the sample DWT, but instead shrinkage estimation is suitable. Consider the generic setting of an estimator for w denoted by $\widehat{w}$ which is unbiased, but potentially has large variance. A shrinkage estimator of this quantity is given by $\widehat{w}^{(s)} = c\widehat{w}$ for some $0 \leq c \leq 1$. Clearly this estimator has smaller variance as compared to $\widehat{w}$ (or possibly equal variance), but introduces some bias into the estimation. The mean square error is in fact given by:

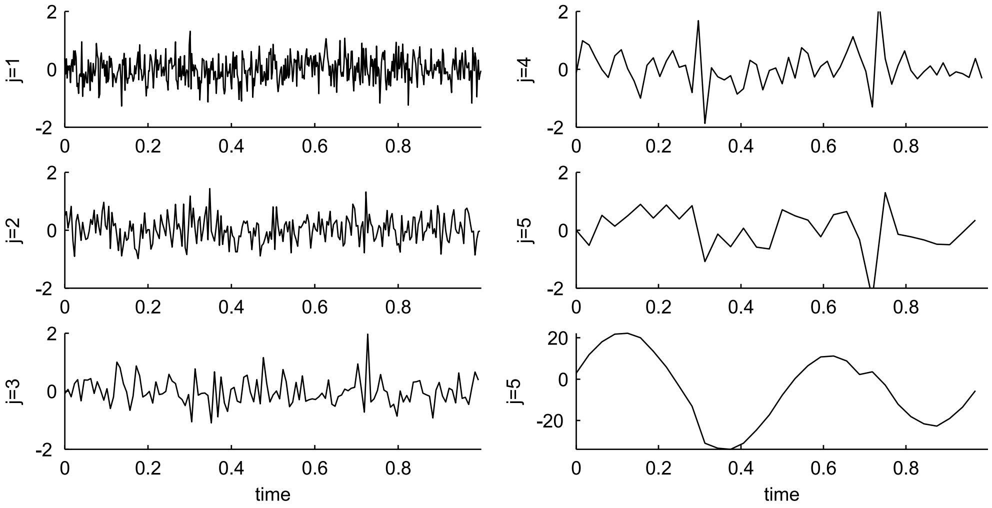
$$\mathrm{MSE}(\widehat{w}, w) = c^2\sigma^2 + (1-c)^2 w^2\,. \tag{13}$$

Thus if the quantity we are trying to estimate is small compared to the variance of the empirical estimator $\widehat{w}$ then by choosing $|c|$ smaller than one, we reduce the mean square error in estimation. Thus for $|w|$ taking a range of values it would be better to use the shrinkage estimator. This may seem non-intuitive, but corresponds to a whole set of theory derived due to [53]. If there was an oracle that could for a given shrinkage rule inform the estimator how coefficients should be shrunk, then good estimators would be obtained. Fortunately it is not necessary to have an oracle, for large sample sizes, to expect to get an estimator with equivalent performance to using an oracle. Looking at Fig. 2 and Fig. 3 we certainly see that replacing most of the empirical wavelet coefficients by zero, should greatly improve the estimation of these coefficients.

Two special shrinkage functions are commonly used, namely the *soft* and *hard* threshold functions. The soft threshold estimator modifies the empirical estimator $\widehat{w}$ by

$$\widehat{w}_{\lambda}^{(st)} = \begin{cases} \widehat{w} - \lambda & \text{if} \quad \widehat{w} \geq \lambda \\ 0 & \text{if} \quad |\widehat{w}| < \lambda \\ \widehat{w} + \lambda & \text{if} \quad \widehat{w} \leq -\lambda \end{cases} \tag{14}$$

i. e. if the observed empirical estimate is sufficiently large a set amount is removed from its magnitude, whilst if it is not sufficiently large, the estimator is set to zero. Also



Statistical Applications of Wavelets, Figure 3

The noisy wavelet coefficients of the Heavisine signal, used in the original paper by Donoho and Johnstone. The decomposition has been stopped at level five, and then the scaling coefficients have been calculated to complete the representation

popular is the hard threshold estimator, defined by:

$$\widehat{w}_{\lambda}^{(ht)} = \begin{cases} \widehat{w} & \text{if} \quad \widehat{w} \geq \lambda \\ 0 & \text{if} \quad |\widehat{w}| < \lambda \\ \widehat{w} & \text{if} \quad \widehat{w} \leq -\lambda \end{cases} . \tag{15}$$

Most wavelet coefficients of sufficiently regular functions (i. e. functions in a suitable Besov space) will be very small, or even zero. One would greatly reduce the mean square error of the estimated mean function if one estimated those by zero, rather than their observed value. Thus we define the "oracle risk" in estimation as the mean square error which arises from using the best keep or kill procedure on the empirical wavelet coefficients, denoted by R_N:

$$R_N = \sum_{n=0}^{N-1} \min\left(w_n^2, \sigma^2\right) \tag{16}$$

If instead the estimator $\widehat{w}_{\sigma\lambda_N}^{(ht)}$ for $\lambda_N = \sigma\sqrt{2\log(N)}$ (the *universal threshold*) is used, then Donoho and Johnstone showed that the mean square error of this procedure is close to the oracle risk, see [56]. Alternative methods chose a value of λ that is permitted to vary with the value of j. σ is estimated using a robust scale estimator on the first level wavelet coefficients, such as the median absolute deviation estimator.

If there is only noise present, then using the universal threshold with a hard thresholding procedure will ensure that noise only signals are estimated as zero, see [56]. [18] give a more flexible definition of a universal thresholding procedure in terms of the probability of keeping the largest noise coefficient.

The simplest wavelet estimation method, suitable for regularly spaced, uncorrelated and Gaussian data has subsequently been extended to deal with irregularly spaced data, that is contaminated with correlated noise, and is immersed in non-Gaussian perturbations. A whole class of methods arise from transforming non-Gaussian observations, using say the Anscombe transform. Of particular note is the Haar–Fisz transform, introduced by [21]. The wavelet Haar–Fisz transform is defined by:

$$f_j^k = \begin{cases} 0 & \text{if} \quad v_{jk} = 0 \\ \frac{w_{jk}}{\sqrt{v_{jk}}} & \text{if} \quad v_{jk} \neq 0 \end{cases} , \tag{17}$$

and the distribution of this variable is substantially more Gaussian than the original wavelet coefficients. Fryzlewicz and Nason have established the properties of using this transform in signal estimation in a series of papers, see [21,22,23]. The denoising of correlated data was treated by [30].

Many different extensions also exist to the basic procedure for white Gaussian random variables: usually the DWT coefficients exhibit some form of structured behavior, and either clustering across time (l) or persistence across scale (j) is observed in the magnitude of the coefficients. Various methods have been proposed to use these observed characteristics, such as treating whole blocks of coefficients together, see [7], using Bayesian methods where the dependence of the coefficients is modeled in the prior and other methods, such as wavelet footprints due to [19], and 'Analytic' denoising proposed by Olhede and Walden and later extended to two dimensions, see [43] and [42]. To observe the clustered structure of wavelet coefficients, see Fig. 2. The discontinuity in the considered signal causes wavelet coefficients to be non-zero near the discontinuities in time across all scales, and across scales at the given time location of the discontinuity. To represent the discontinuities perfectly, and avoid wavelet Gibb's effects, all of these coefficients should be kept, thus estimating a single discontinuity without artifacts. Similar statements can be made for other features than perfect discontinuities, and the above mentioned methods all address this problem in a chosen manner.

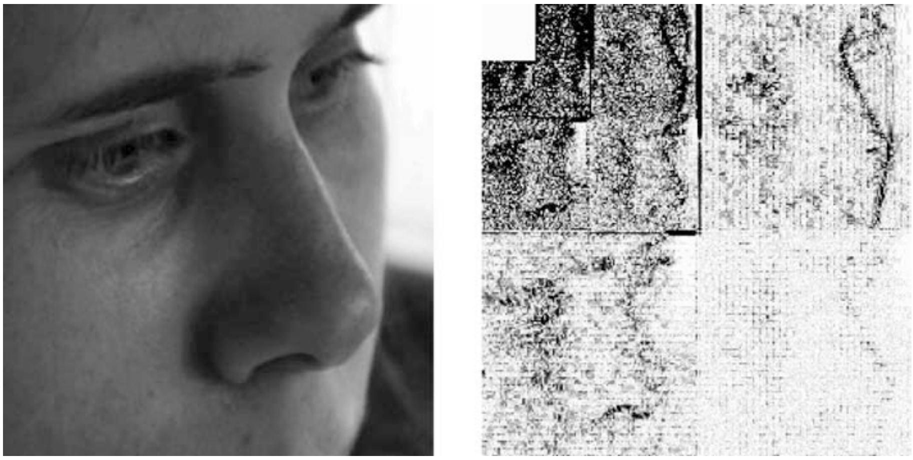
A key characteristic of observed coefficients is the sparsity level, i. e. how many of the coefficients that are approximately zero in expectation. Choosing the threshold λ should be done in light of the sparsity of the data. Optimally such sparsity is learned from the data. [29] proposed the EBAYES procedure whereby at each scale the sparsity of the data is estimated and a threshold chosen using marginal likelihood.

2-D Extensions of Wavelets

The development of statistical estimation methods for 1-D signals observed in noise is a mature field. Greater challenges lie in higher dimensional objects such as spatial, or spatiotemporal signals. In the early days when methods for extended into 2-D, the two spatial directions were treated as if the observed phenomena were two different phenomena. This caused a number of unpalatable effects in the reconstruction of the estimated images, such as edge effects and blocking, as well as using too many coefficients to reproduce simple phenomena. To see an example of this, observe Fig. 4. The woman is mainly a smooth picture, and should only correspond to a limited set of coefficients in a compressed representation. Using separable wavelets to represent the picture, because the curve of the woman's nose is misaligned with the decomposition, causes too many coefficients to be used. This lack of compression, leads to poor performance in the estimation.

The solution to these problems came by the development of non-separable decompositions, this leading to fewer non-zero coefficients in the decompositions, or by statistical processing of the separable decompositions, using the combined magnitude of the many coefficients to improve estimation. The main methods of note are ridgelets and curvelets proposed by [9,52], the dualtree complex wavelet transform, proposed by Kingsbury (see [48]), and bandelets (see [33]). The implementation of several of these transforms is slightly more complicated than the 1-D wavelet transform, but all correspond to linear operations on the observed signal. This means that the statistical properties of the transform coefficients can be determined by direct (if sometimes numerical) calculations. Again, thresholding and inverse transformation forms the basis for most estimation procedures, much in the same manner as the 1-D estimation procedures.

Open areas of research in this general setting, is the development of higher dimensional processing, and suitable transformations for discrete analysis on the sphere.



Statistical Applications of Wavelets, Figure 4

A picture of a woman (*left*), and the absolute value of the separable 2-D wavelet coefficients of the picture (*right*). Observe that the nose of the woman takes too many coefficients to record, despite the curve of the nose corresponding to a smooth curve. This illustrates the lack of compression of the 2-D separable wavelet transform

Covariance Estimation Using Wavelets

Wavelets have been used to estimate properties of zero-mean stochastic processes, characterized by their dependence structure alone. One of the fundamental aspects is noting classes of stochastic processes for which the transform provides a simplification of the description of the signal. One set of developments has defined a set of locally stationary processes using wavelet filters as the building block, so called Locally Stationary Wavelet Processes, see [41]. The estimation of the fundamental representation of this process, which is very much like a time varying spectrum, was addressed by Nason and his coauthors, and has subsequently been improved upon by Fryzlewicz and Nason, see [23]. The model has been used to classify sleep states of babies, and has been used in modeling financial times series, see [5,20]. This corresponds to the most natural modification of existing theory for locally stationary time series from local Fourier to wavelet bases.

The usage of wavelets for estimating time series that when differenced are stationary has also seen substantial investigation. By using wavelets the number of differencing steps needs often not be determined, which is a clear advantage. Likelihood theory has been extended from the Fourier domain to the wavelet domain for such time series, see [39], and various procedures for estimating the decay of long memory processes have been adapted for wavelet coefficients, see [38]. Characterization of sets of time series that are jointly stationary when differenced, has also been developed, see [49,50,51,57]. A fundamental method of analysis is to characterize the covariances of the process associated with different time-scales, this yielding a multiresolution analysis of the stochastic process, both considering the auto-covariance of a single process, and cross-covariances between several processes.

Future Directions

The usage of the wavelet transform in 1-D is a mature field. Current developments are mainly in the application and adaption of existing methods to novel applications. The development of higher dimensional transforms has also slowed down considerably. The modern thrust and drive is instead found in using several concepts which the development of analysis methods from the wavelet transform were founded upon. The key two notions for these developments are sparsity and incoherence. For many signals of interest, their wavelet coefficient representation was compressed. This means the sparsity could be used to substantially improve the estimation procedure. The area of 'compressed sensing' is based on using the compression of a signal in a known decomposition, to improve the estimation of the signal, see [14]. Surprisingly the limitations of Nyquist sampling has been circumvented, and near miraculous reconstruction performance obtained. As the data deluge that faces modern signal processing will increase, this stands as a very interesting area of future development.

Statistical and Non-linear Physics, Introduction to

M. Cristina Marchetti
Physics Department, Syracuse University, Syracuse, USA

The field of Statistical and Nonlinear Physics combines the venerable subject of statistical mechanics with the newer area of nonlinear science to create a highly interdisciplinary and exciting area of research. It has its roots in equilibrium statistical physics, but it has evolved to encompass and emphasize nonequilibrium and dynamical phenomena. It is a field in rapid evolution, with a constantly changing focus. It overlaps naturally with many other disciplines, including fluid dynamics, computational physics, biological physics, condensed matter physics and polymer physics.

Statistical physics aims to describe the large-scale collective behavior of systems composed of a large number of interacting units or degrees of freedom. Starting with a microscopic model, one performs various types of "coarse-graining" to describe phenomena that occur on length and time scales large compared to microscopic ones, such as the size of the particles or the characteristic interaction times. At this large scale the system exhibits collective or emergent behavior that is far richer than that of the individual units. One of the hallmarks of collective behavior is phase transitions. An everyday example is the change from liquid to solid that occurs upon tuning a parameter such as temperature or pressure. Another familiar example arises in the study of the properties of magnetic materials and is highlighted in the article ▶ Complex Systems and Emergent Phenomena, which is a good starting point for the reader of this section.

When going from the deterministic Hamiltonian description of a system of many interacting units to the large scale coarse-grained description of the same system in terms of a continuum or hydrodynamic theory, an element of randomness is naturally introduced into the problem as one looses the invariance under time reversal that was present in the Hamiltonian description. At the same time randomness on the other hand is an intrinsic property of the dynamics of individual nonlinear systems that are known to often exhibit sensitive dependence to initial conditions and chaotic behavior. There is in fact a deep connection between the randomness of chaotic systems and the irreversible transport properties of extended systems (see ▶ Chaotic Dynamics in Nonequilibrium Statistical Mechanics). This connection highlights the unity of the two areas of statistical and nonlinear science.

Rather than presenting an exhaustive review of the field of statistical and nonlinear physics, the articles in this section focus on nonequilibrium phenomena that are the subject of current research. Even then, only a fraction of the problems and physical systems that are studied using the tools and ideas of statistical and nonlinear physics are described here. Many of the others can be found in articles throughout the rest of the Encyclopedia.

The topics highlighted in this section of the Encyclopedia may at a first glance seem disparate, but are unified by the ideas that are used to study them. Principal among those are the notions of scaling and universality. The concept of universality, which has been around for some time, has its roots in the study of phase transitions and critical phenomena. Near a phase transition, the system is universal in that its behavior at large scales does not depend on the microscopic physics. The systems and physical problems described in this section of the Encyclopedia may be different in the details, but generally involve the onset of collective or emergent behavior with "universal" properties.

The ideas of scaling universality have had a crucial impact in the study of long-standing problems in nonlinear physics, such as pattern formation and turbulence (see ▶ Non-linear Fluid Flow, Pattern Formation, Mixing and Turbulence). The same tools and ideas have more recently been applied to the study of the complex dynamics of neuronal systems (see ▶ Neuronal Dynamics), lasers (see ▶ Noise and Stability in Modelocked Soliton Lasers), and even the physics of economics (see ▶ Econophysics, Statistical Mechanics Approach to). Rich chaotic behavior has also been discovered in quantum systems (see ▶ Quantum Chaos).

Recently, a new field has emerged that uses many of the ideas of statistical mechanics to explore problems in "soft" condensed matter physics. Soft materials are literally materials that yield easily to mechanical deformations, They encompass an extremely wide range of systems, from complex fluids such as colloidal suspensions, liquid crystals and polymers (see ▶ Polymer Physics) to soft elastic gels (see ▶ Anisotropic Networks, Elastomers and Gels), and granular matter in both its fluidized (see ▶ Granular Flows) and its jammed (see ▶ Jamming of Granular Matter) states. The jamming or structural arrest of granular matter when the density reaches a critical value bears striking similarities with the glass transition. Jammed granular matter and glassy systems share many of the intriguing dynamical properties discussed in ▶ Glasses and Aging, A Statistical Mechanics Perspective on. Jamming also provides an example of the nonequilibrium phase transitions that are ubiquitous in the systems studied by modern statistical physics. Nonequilibrium phase transitions do occur in "pure" systems, i. e., ones without any extrinsic disorder, as a result of the dynamical constraints arising from interactions, but are even more common in systems with quenched disorder, induced for instance by impurities and materials defects (see ▶ Disordered Elastic Media for a general perspective on such systems). Notable examples include the depinning transition that occurs in driven extended systems such as vortex lattices in type-II superconductors under the action of a uniform external driving force (see ▶ Collective Transport and Depinning) and the slip-stick motion that characterizes the physics of friction and tectonic motion (see ▶ Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of). Living matter, such as the cytoskeleton of eukaryotic cell or even the whole cell, has also been described as a novel form of nonequilibrium soft matter (see ▶ Cytoskeleton and Cell Motility).

The complexity of the systems that are studied by statistical physicists has naturally led to the development of sophisticated numerical methods. Principal among those is the technique of Monte Carlo simulations (see ▶ Monte Carlo Simulations in Statistical Physics). More recently physicists have also begun to adapt ideas and algorithms from computer science (see ▶ Optimization Problems and Algorithms from Computer Science).

Novel experimental techniques have recently allowed us to begin to study the properties of soft and living matter on length and time scales that require a qualitative new way of thinking and a modification of the familiar tools from statistical physics (see ▶ Fluctuation Theorems, Brownian Motors and Thermodynamics of Small Systems). These range from optical techniques for study of the properties of individual biomolecules (see ▶ Protein Mechanics at the Single-Molecule Level) to microfluidics devices for the study of the rheological and mechanical properties of complex materials and cells on novel time and length scales (see ▶ Microfluidics).

Yet another class of problems that has caught the attention of statistical physicists lately is the study of networks (see ▶ Networks: Structure and Dynamics). Examples of networks are as disparate as the world-wide web, human societies, languages and their structure, and power grids. An especially important class of networks occurs in biology. It consists of the cell signaling networks that control many of the functions of living cells (see ▶ Cell Biology: Networks, Regulation and Pathways).

Finally, complex emergent behavior is also ubiquitous in quantum matter, where the interactions and fluctuations are controlled by quantum mechanics, as described in the article ▶ Ultracold Atomic Gases: Novel States of Matter.

Statistics with Imprecise Data

Article Outline

Glossary

Fuzzy estimators Estimators of "parameters" of probability distributions, or other characteristics, of random variables/fuzzy random variables (such as e. g. the expected value/the fuzzy expected value) when statistical data are imprecise and are described by means of fuzzy sets.

Fuzzy random variable Random element whose observed values are described by fuzzy sets.

Fuzzy set Generalization of a classical notion of a set. In contrast to the case of a classical set, each element x of a fuzzy set may belong to it to a degree described by the so-called membership function $\mu(x)$. Thus, the fuzzy set may be defined as a set of ordered pairs $(x, \mu(x))$, where x belongs to a set $\mathbb{X}$ called the universe of discourse or referential. Alternatively, the fuzzy set can be identified with its membership function (in the same way that a classical set can be identified with its indicator function).

Fuzzy statistical tests Statistical tests used for the verification of hypotheses about the values of "parameters" of probability distributions, or other characteristics, of random variables/fuzzy random variables when statistical data are imprecise and are described by fuzzy sets.

Fuzzy statistics Generalization of traditional statistics that allows to handle imprecise data described in terms of fuzzy sets.

Imprecise data Data that cannot be described by either real numbers or vectors with real-valued components.

Random sets Random elements whose observed values are sets (e. g. intervals, subsets of a plane).

Definition of the Subject

Traditional statistics deals usually with precisely defined data. The source of these data may be of different nature. Usually the data are collected from observations of random experiments, i. e. experiments whose performance leads to an outcome which cannot be predicted in advance with one hundred percent sureness. When the knowledge about the nature of these random events is available we can use the methods of mathematical statistics and draw conclusions about the source of available data. Uncertainty being intrinsic to random outcomes/events is properly described by using the formalism of the mathematical theory of probability, and generally it is attributed to *future* observations of these outcomes/events.

Traditionally, statistical experimental data are described by real numbers or by vectors whose components are real numbers. These numbers are either observed directly as results of measurements (e. g. height and weight of a person) or correspond to observed counts of certain categories representing labeled events (e. g. a gender of that person). However, in real life applications the results of measurements are never precise. The precision of every measurement is limited by the precision of a measuring device. In the majority of practical applications this lack of precision may be neglected, and for statistical analysis of available data we can use traditional methods of statistics. If the measurement error cannot be neglected statistical analysis of interval data is recommended by specialists in metrology. However, when statistical data are presented by human beings we need more sophisticated methods for the description of their lack of precision. Therefore, there is a practical need to generalize traditional statistical methods in order to make them applicable for handling imprecise data, e. g. the data described by statements expressed by using a plain language (the so-called "linguistic data").

Introduction

There is a common agreement that uncertainty characterized by randomness shall be described by considering the theory of probability. Thus, mathematical statistics is a proper tool for dealing with data generated by random experiments and described by precisely defined numbers. However, there also exist other types of uncertainty which are related to vagueness, imprecision, existence of only partial information about experimental outcomes/events of interest, etc. In contrast to randomness, uncertainties of such types are attributed rather to *current* perceptions/observations. It has to be noted that the mathematical modeling of all these types of uncertainty which are different from simple randomness is still the subject of controversies. A good overview of the related problems can be found in the paper by P. Walley [36]. In this article we confine ourselves to the case when randomness is observed together with vagueness understood as the lack of precision.

Specialists in measurement theory recognize different types of uncertainty. For instance, in the ISO/IEC Guide [18] it is recommended to distinguish between uncertainty related to pure randomness and uncertainty of other nature, such as a lack of precision. However, the lack of precision of statistical data is usually omitted in the statistical analysis of measurements. Consider, for example, the analysis of results of measurements coming from a digital meter. The results of measurements coming from such a meter are always rounded in order to have their representation by a certain number of digits. When we observe a displayed result of a measurement we never know what is the actual value of the measured quantity. What is more important, and often overlooked by statisticians, we may not increase our knowledge about that value by averaging the results of repeated measurements, as it is frequently recommended by statisticians. Consider, for example, a series of measurements showing exactly the same result. Having such results we are in principle not able to distinguish between two fundamentally different cases when the measured quantity is constant and its value belongs to the range of rounding or when it is varying from measurement to measurement with values belonging to that range.

The situation described in the previous paragraph is relatively simple as the range of possible actual values corresponding to the observed result of a measurement is usually precisely defined. There exist, however, situations when either this range is not precisely known or values in the range are not equally compatible with the available data/information/events. We face such cases when results of measurements or classifications are evaluated by humans (e. g., by evaluating indications of an analog meter or classifying individuals in accordance with their height, and so on). The result of a measurement is even more imprecise when it has been obtained without the usage of any meter (e. g., when we visually evaluate the distance between two points); in such situations statistical data may consist of imprecise statements like "around 5 meters", "more or less between 5 and 10 seconds", etc. The classification of a person in accordance with his/her height leads often to imprecise assessments, like "very short", "rather tall", etc. A similar situation occurs when we deal with retrospective data recalled by human beings; for example, in reliability analysis of field lifetime data we may face situations when failure times are reported imprecisely using statements like 'the failure occurred about one month ago', etc. In all these cases statistical data consist of *imprecise perceptions* of actual real values.

In the previous paragraphs we considered situations when actual values of measured quantities exist, but they are imprecisely perceived. There exist, however, situations when we have to analyze statistical data that represent imprecisely defined concepts. Take for example the color of human hair described using categories such as "blond" or "dark blond"; it is obvious that the border between these two categories is vague; one can try to establish a precise border between these two categories in terms of the results of precise measurements of the spectrum of reflected light, but such attempts seem to be practically senseless. We face a similar situation in classifying a client of a bank office in accordance with his/her degree of aversion to investment which leads to imprecise assessments, like "very low", "moderate", etc. In both these cases we could try to collect precise statistical data, e. g., by either asking a respondent to a questionnaire to indicate exactly one choice or coding it numerically. However, it seems to be more prudent, natural and informative to expect imprecise answers to questions pertained to vague notions. If we do so, we may face imprecise statistical data for further analysis. In all these cases statistical data consist of *imprecise actual values* themselves.

There also exists another source of imprecision while dealing with statistical data. For example, in reliability lifetime tests we perform tests in more severe "over-stress" conditions, and then we try to recalculate test results to conditions which are considered "normal". For this recalculation we can utilize some partial knowledge about possible values of stress-dependent recalculation coefficients. In such a case we have originally precise lifetime data, but after recalculation these data become imprecise.

In all considered cases the lack of precision can be appropriately described by using fuzzy sets introduced by Lotfi A Zadeh. In the second section of the article we recall some basic definitions related to fuzzy sets. We will present the fuzzy sets methodology as a useful tool for the description of imprecise data. When fuzzy lack of precision is mixed with randomness, either in the sense that available fuzzy data are supposed to come from the perception of real- or vectorial-valued data generated by a random mechanism, or in the sense of they being directly generated by a random mechanism, a convenient tool to use is that of the notion of a fuzzy random variable. This notion is introduced in the third section of this article. The interpretation of the fuzzy random variable depends upon the type of observed fuzzy data and events. In the paper we distinguish between the two types of data which have been described in this section. We start with the description of statistical methods which are useful for the analysis of fuzzy perceptions of existing precise values. Then, we present statistical methods which are useful in the analysis of intrinsically fuzzy-valued data.

Mathematical Modeling of Imprecise Data

There exist competitive methods for the description of vagueness. For example, some statisticians claim that the theory of subjective probability is sufficient for the description of all types of uncertainty. However, many other researchers have shown examples of situations when the application of the classical theory of probability is not sufficient for modeling these situations. Therefore, other formalisms have been proposed for the description of vagueness/imprecision. One of those formalisms, namely the theory of *fuzzy sets* proposed by Lotfi A. Zadeh [37], has been slowly but widely accepted as a good methodology for the description of imprecise data, both from practical and theoretical (see, e. g., the paper by Terán [33]) points of view.

The basic concept of the theory of fuzzy sets is the universe of discourse or referential $\mathbb{X}$ which may be understood as the set of all possible (feasible) elements that are relevant for the description of a certain concept (quantity). Mathematically speaking a ***fuzzy subset*** A of a set $\mathbb{X} \neq \emptyset$ (or a fuzzy set, for short) is a map $A : \mathbb{X} \to [0, 1]$, where $A(x)$ can be interpreted as the degree of compatibility of x with the ill-defined property characterizing A, or degree of truth of the assertion "x is A", or degree of membership of x to A. Equivalent, but more intuitive for some purposes, a fuzzy set A of $\mathbb{X}$ can be defined as a set of ordered pairs $\{(x, \mu_A)\}$, where $x \in \mathbb{X}$ and $\mu_A : \mathbb{X} \to [0, 1]$ is the so-called *membership function* of A. In other words, a fuzzy set can be identified with its membership function, in the same way that a classical set can be identified with its indicator function. In what follows, we will consider indistinctly A or μ_A to denote and refer to a fuzzy subset.

Unfortunately, there is no one generally accepted methodology for the construction of membership functions. The majority of researchers assume that the membership function $\mu_A(x)$ is a purely subjective function provided by a person who describes his/her perception of a certain phenomenon or quantity. Some authors provide practical methods for the construction of the membership function when it is interpreted in terms of the theory of possibility as the possibility distribution (see [8] for more information). Some other authors, e.g Bandemer and Näther [1] or Viertl [35], present methods which may be used for the construction of membership functions in a more objective way from measurements of physical quantities. Anyway, our purpose is not entering a discussion here about this point.

In the analysis of imprecise data we are usually interested in the description of interesting phenomena by numbers. For this purpose we can use the concept of a fuzzy number defined as follows (see [5]):

Definition 1 The fuzzy subset A of the space of real numbers $\mathbb{R}$, with the membership function $\mu_A : \mathbb{R} \to [0, 1]$, is a **fuzzy number** if and only if

(a) A is normal, i. e. there exists at least an element $x_0 \in \mathbb{R}$ such that $\mu_A(x_0) = 1$;
(b) A is fuzzy convex, i. e., $\mu_A(\lambda x_1 + (1-\lambda)x_2) \geq \mu_A(x_1) \wedge \mu_A(x_2)$, for all $x_1, x_2 \in \mathbb{R}$, and $\lambda \in [0,1]$;
(c) μ_A is upper semicontinuous;
(d) the support set, $\operatorname{supp} A = \{x \in \mathbb{R} : \mu_A(x) > 0\}$, is bounded (that is, its closure $\operatorname{cl}(\operatorname{supp} A)$ is compact).

It is easily seen that if A is a fuzzy number then its membership function can be expressed as follows:

$$\mu_A(x) = \begin{cases} 0 & \text{for } x < a_1 \\ r_{l_A}(x) & \text{for } a_1 \leq x < a_2 \\ 1 & \text{for } a_2 \leq x \leq a_3 \\ r_{u_A}(x) & \text{for } a_3 < x \leq a_4 \\ 0 & \text{for } x > a_4 \,, \end{cases} \tag{1}$$

where $a_1, a_2, a_3, a_4 \in \mathbb{R}$, $a_1 \leq a_2 \leq a_3 \leq a_4$, $r_{l_A} : [a_1, a_2] \to [0,1]$ is a nondecreasing upper semicontinuous function, and $r_{u_A} : [a_3, a_4] \to [0,1]$ is a nonincreasing upper semicontinuous function. Functions r_{l_A} and r_{u_A} are called sometimes the left and the right "arms" (or "sides") of the fuzzy number, respectively.

A useful notion for dealing with a fuzzy number is the so-called α-level set, also known as the *α-cut*. For $\alpha \in (0,1]$ the *α-level set* of the fuzzy number A is the ordinary (non-fuzzy) set defined as

$$A_\alpha = \{x \in \mathbb{R} : \mu_A(x) \geq \alpha\} \tag{2}$$

and the 0-level set is usually intended to be given by $A_0 = \operatorname{cl}(\operatorname{supp} A)$. The family $\{A_\alpha : \alpha \in [0,1]\}$ is a set representation of the fuzzy number A. According to the resolution identity proposed by Zadeh, we can represent the membership function as:

$$\mu_A(x) = \sup\{\alpha \cdot \mathbf{1}_{A_\alpha}(x) : \alpha \in (0,1]\}\,, \tag{3}$$

where $\mathbf{1}_{A_\alpha}(x)$ denotes the indicator function of A_α.

On the basis of the notion of α-level, a fuzzy number A can be viewed as a fuzzy subset of $\mathbb{R}$ such that its α-level sets are nonempty compact and convex sets of $\mathbb{R}$, that is, nonempty compact intervals. Hence, for each $\alpha \in [0,1]$ we have that $A_\alpha = [A_L(\alpha), A_U(\alpha)]$, where

$$\begin{aligned} A_L(\alpha) &= \inf\{x \in \mathbb{R} : \mu_A(x) \geq \alpha\}\,, \\ A_U(\alpha) &= \sup\{x \in \mathbb{R} : \mu_A(x) \geq \alpha\}\,. \end{aligned} \tag{4}$$

If the sides of the fuzzy number A are strictly monotonic functions, then from Eq. (1) one can see easily that $A_L(\alpha)$ and $A_U(\alpha)$ are inverse functions of r_{l_A} and r_{u_A}, respectively.

In statistical analysis of random data we use functions (and, in particular, operations) of the observed random samples. These functions, called statistics, can be also defined for fuzzy random data. Their membership functions can be derived by using Zadeh's *extension principle*. This principle has the following formulation [38]:

Let $\mathbb{X}$ be a Cartesian product of universes $\mathbb{X} = \mathbb{X}_1 \times \ldots \times \mathbb{X}_r$, and $A_1, \ldots, A_r$ be r fuzzy subsets of $\mathbb{X}_1, \ldots, \mathbb{X}_r$, respectively. Let f be a mapping from $\mathbb{X} = \mathbb{X}_1 \times \ldots \times \mathbb{X}_r$ to a universe $\mathbb{Y}$ such that $y = f(x_1, \ldots, x_r)$. The extension principle allows us to induce from the r fuzzy sets A_i a fuzzy set B on $\mathbb{Y}$ through f, $B = f(A_1, \ldots, A_r)$ such that

$$\mu_B(y) = \begin{cases} \sup_{x_1,\ldots,x_r | y = f(x_1,\ldots,x_r)} \\ \quad \min\{\mu_{A_1}(x_1), \ldots, \mu_{A_r}(x_r)\} & \text{if } f^{-1}(y) \neq \emptyset \\ 0 & \text{if } f^{-1}(y) = \emptyset \end{cases} \tag{5}$$

In case of A_i, $i = 1, \ldots, n$ being fuzzy numbers, and f being either an injective or a continuous function, then for each $\alpha \in [0,1]$ the α-level of $B = f(A_1, \ldots, A_r)$ can be shown to be equal to $B_\alpha = \big(f(A_1, \ldots, A_r)\big)_\alpha$ with

$$\begin{aligned} &\big(f(A_1, \ldots, A_r)\big)_L(\alpha) \\ &\quad = \min_{(x_1,\ldots,x_r) \in (A_1)_\alpha \times \ldots \times (A_r)_\alpha} f(x_1, \ldots, x_r)\,, \\ &\big(f(A_1, \ldots, A_r)\big)_U(\alpha) \\ &\quad = \max_{(x_1,\ldots,x_r) \in (A_1)_\alpha \times \ldots \times (A_r)_\alpha} f(x_1, \ldots, x_r)\,. \end{aligned} \tag{6}$$

Thus, the application of the extension principle for the calculation of the membership function of $y = f(x_1, \ldots, x_r)$ is equivalent to the application of the interval arithmetics on α-level sets of the arguments of this function (see [29] as a basis for the proof). For instance, if A and B are fuzzy numbers, then,

$$\begin{aligned} (A+B)_L(\alpha) &= A_L(\alpha) + B_L(\alpha), \\ (A+B)_U(\alpha) &= A_U(\alpha) + B_U(\alpha)\,, \\ (\lambda \cdot A)_L(\alpha) &= \begin{cases} \lambda \cdot A_L(\alpha) & \text{if } \lambda \geq 0 \\ \lambda \cdot A_U(\alpha) & \text{if } \lambda < 0 \end{cases} \\ (\lambda \cdot A)_U(\alpha) &= \begin{cases} \lambda \cdot A_U(\alpha) & \text{if } \lambda \geq 0 \\ \lambda \cdot A_L(\alpha) & \text{if } \lambda < 0 \end{cases} \end{aligned}$$

for any $\lambda \in \mathbb{R}$, and $\alpha \in [0,1]$.

Fuzzy Random Variables

Uncertainty, understood as randomness, is well described in Probability Theory. The concept of a random variable, which is basic in this theory, is well-known and its definition does not need to be recalled in this article.

However, when we observe random experimental data which are imprecise, a useful tool to model either the imprecise perception of values coming from real-valued random variables or the random mechanisms generating directly these imprecisa data is the one associated with the so-called concept of fuzzy random variables. Actually, we can consider two different approaches to the concept of fuzzy random variable; the motivation for these approaches and the situations they apply to are different, but the formalization of the second notion and the associated statistical methodology can be applied to the first one.

Historically, the first widely accepted definition of the fuzzy random variable was proposed by Kwakernaak [21,22]. Kruse [19] proposed an interpretation of this notion, and according to this interpretation a fuzzy random variable $\mathcal{Z}$ may be considered as a fuzzy perception of an unknown true real-valued random variable Z_0 associated with a random experiment, and referred to as 'the original' of $\mathcal{Z}$. Below, we recall the version of this definition elaborated by Kruse and Meyer [20].

Definition 2 (Kruse and Meyer [20]) Let $(\Omega, \mathcal{A}, P)$ be a probability space, where Ω is the set of all possible outcomes of a random experiment, $\mathcal{A}$ is a σ-field of subsets of Ω (the set of all possible events of interest), and P is a probability measure associated with $(\Omega, \mathcal{A})$.

A mapping $\mathcal{X} : \Omega \to \mathcal{F}_c(\mathbb{R})$, where $\mathcal{F}_c(\mathbb{R})$ is the space of all fuzzy numbers, is called a **fuzzy random variable** if it satisfies the following properties:

i) $\{\mathcal{X}_\alpha(\omega) : \alpha \in [0,1]\}$, where $\mathcal{X}_\alpha(\omega) = (\mathcal{X}(\omega))_\alpha$ is a set representation of $\mathcal{X}(\omega)$ for all $\omega \in \Omega$;
ii) for each $\alpha \in [0,1]$ both $\mathcal{X}_\alpha^L : \Omega \to \mathbb{R}$ and $\mathcal{X}_\alpha^U : \Omega \to \mathbb{R}$, with $\mathcal{X}_\alpha^L(\omega) = \inf \mathcal{X}_\alpha(\omega)$ and $\mathcal{X}_\alpha^U(\omega) = \sup \mathcal{X}_\alpha(\omega)$, are usual real-valued random variables associated with $(\Omega, \mathcal{A}, P)$.

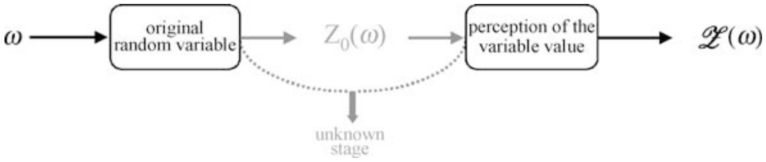
Values of a fuzzy random variable in Definition 2 have been conceived to model fuzzy perceptions of existing real-valued values (the values of the original, see Fig. 1). For instance, when we qualify the price of a given item in a specific store, we can perceive/label it as being 'cheap', but there is an existing price (although assumed to be unknown for the person receiving and processing data information).

Puri and Ralescu [31] introduced the concept of the also called fuzzy random variable as a generalization of the concept of random set or set-valued random element (and hence, as a generalization also of the concept of random variable). According to this definition a fuzzy random variable $\mathcal{Z}$ may be considered as a random element associating with each experimental outcome a value which is intrinsically fuzzy. Below, we recall Puri and Ralescu's definition

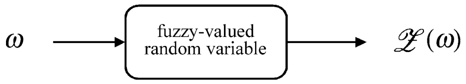
Definition 3 (Puri and Ralescu [31]) Given a probability space $(\Omega, \mathcal{A}, P)$, a mapping $\mathcal{X} : \Omega \to \mathcal{F}_c(\mathbb{R})$ is said to be a *fuzzy random variable* (also referred to as *random fuzzy set*) if for each $\alpha \in [0,1]$ the set-valued mapping $X_\alpha : \Omega \to \mathcal{K}_c(\mathbb{R})$, where $\mathcal{K}_c(\mathbb{R})$ is the class of the nonempty compact intervals and $X_\alpha(\omega) = (X(\omega))_\alpha$ for all $\omega \in \Omega$, is a compact convex random sets (that is, a Borel-measurable mapping with respect to the Borel σ-field generated by the topology associated with the Haussdorf metric on $\mathcal{K}_c(\mathbb{R})$).

Remark 1 The notion of fuzzy random variable has been in fact introduced in a more general way by considering as the codomain the space of fuzzy sets of the p-dimensional Euclidean space, or even more general Banach spaces, whose α-levels are nonempty compact subsets of this space. In case one constrains to $p = 1$ and fuzzy sets being convex, then one gets the last definition.

Remark 2 Although motivation to introduce fuzzy random variables was different in the approaches by Kwakernaak/Kruse and Meyer and by Puri and Ralescu, one can prove that the notion in Definition 3 implies the one in Definition 2. As a consequence, probabilistic ideas and results for the notion in Definition 3 (or for the more general one in Remark 1) apply to the notion in Definition 2, and the same happens for statistical developments. However, many probabilistic conclusions, and most of the statistical procedures for Definition 2 are based on the assumption



Statistics with Imprecise Data, Figure 1
Fuzzy random variables in Kwakernaak/Kruse and Meyer's sense



Statistics with Imprecise Data, Figure 2
Fuzzy random variables in Puri and Ralescu's sense

of having an unknown but existing original, and considering Zadeh's extension principle, so that these conclusions and procedures are not usually applicable to deal with data coming from fuzzy random variables in Definition 3.

Remark 3 The concept of fuzzy random variable in Definition 3 can be alternatively formalized as a Borel-measurable mapping with respect to the Borel σ-field generated by the topology associated with some metrics on the space $\mathcal{F}_c(\mathbb{R})$, among them an operational one we will later refer to. Borel-measurability allows us to guarantee that notions like those of the induced distribution by a fuzzy random variable, independence of fuzzy random variables, identically distributed fuzzy random variables, and so on, can be immediately formalized in the probabilistic setting.

Values of a fuzzy random variable in Definition 3 have been conceived to model existing fuzzy values (see Fig. 2). For instance, when we classify a client of a bank in accordance with the degree of aversion to investment as having a 'rather high' degree, there is no underlying real-valued degree, but the classification itself is essentially imprecise.

Statistical Analysis of Fuzzy Data Corresponding to Fuzzy Perceptions of Existing Real–Valued Data

Fuzzy Estimation

When imprecise statistical data correspond to fuzzy perceptions of unobserved/unknown precise (i. e. crisp) statistical data we can treat them as observed values of fuzzy random variables in the sense of Kwakernaak/Kruse and Meyer. In such a case we can analyze imprecise data in terms of probability distributions of their unobserved originals in a similar way as precise statistical data are analyzed using methods of traditional mathematical statistics. The only difference stems from the fact that having imprecise input information in the form of fuzzy data we cannot precisely evaluate the characteristics of the underlying probability distribution. Therefore, instead of finding precise values of the estimators of the 'parameters' describing the underlying probability distribution (the one of the original), it seems more coherent finding their imprecise fuzzy perceptions.

Assume that we observe a fuzzy random sample $\mathcal{X}_1,\dots,\mathcal{X}_n$ which is viewed as a fuzzy perception of an unobserved random sample $X_1,\dots,X_n$. Let $F(x;\theta)$ be the cumulative probability function of the original random variable X characterized by a crisp parameter $\theta\in\Theta$. Suppose now that an estimator of θ which is given by a statistic $\hat{\theta}=\phi(X_1,\dots,X_n)$ is considered. By using Zadeh's extension principle we can consider as a *fuzzy estimator* of θ based on $\mathcal{X}_1,\dots,\mathcal{X}_n$ the one associating with each fuzzy sample information $(\tilde{x}_1,\dots,\tilde{x}_n)$ the *fuzzy estimate* $\phi(\tilde{x}_1,\dots,\tilde{x}_n)$ given by

$$\mu_{\phi(\tilde{x}_1,\dots,\tilde{x}_n)}(t) = \begin{cases} \sup_{(x_1,\dots,x_n)\,|\,t=\phi(x_1,\dots,x_n)} \min\{\mu_{\tilde{x}_1}(x_1),\dots,\mu_{\tilde{x}_n}(x_n)\} \\ \qquad \text{if } t\in\mathrm{Im}(\phi(X_1,\dots,X_n) \\ 0 \quad \text{otherwise} \end{cases} \tag{7}$$

Alternatively, $\phi(\widetilde{x}_1,\dots,\widetilde{x}_n)$ can be viewed as a fuzzy estimate of the induced fuzzy parameter $\vartheta=\theta(\mathcal{X})$ with $\theta(\mathcal{X})(t)=\sup_{X\in\mathcal{E}(\Omega,\mathcal{A},P)\,|\,\theta(X)=t}\inf_{\omega\in\Omega}\mu_{\mathcal{X}(\omega)}X(\omega)$ and $\mathcal{E}(\Omega,\mathcal{A},P)$ being the class of all possible originals of $\mathcal{X}$. In many practical cases, when $\phi(x_1,\dots,x_n)$ has a simple form, the calculation of (7) is straightforward. For example, when $\phi(x_1,\dots,x_n)=$ sample mean $=(x_1+\ldots+x_n)/n$ the α-levels of the estimate of its expected value θ are expressed as

$$(\phi(\tilde{x}_1,\dots,\tilde{x}_n))_\alpha=\left[\frac{1}{n}\sum_{i=1}^{n}(\tilde{x}_i)_L(\alpha),\ \frac{1}{n}\sum_{i=1}^{n}(\tilde{x}_i)_U(\alpha)\right] \tag{8}$$

Analogously, whenever the estimator of θ is given by a continuous function or an injective function, the α-levels becomes also rather simple. In other cases, the limits of the α-levels should often be found by solving nonlinear mathematical programming problems defined by (7).
